DISCUSSION

Male weevils fed on the storage root cores to a lesser degree than females and did not show any feeding preferences between cultivars. This is in contrast to feeding on sweet potato leaves, where males and females were found to feed to an equal extent (Nottingham, et al., 1988). Females have to encounter the roots prior to oviposition, whereas males might obtain sufficient nutrients from the vines.

The relative levels of preference found for the four cultivars corresponded closely with results obtained in field plots (Mullen et al., 1985). Feeding and oviposition preference appeared to be closely related in choice bioassays. Barlow and Rolston (1981), in bioassays, showed that the ratio of oviposition to

feeding punctures did not differ significantly among a range of cultivars. However, Regal had relatively high levels of feeding in no-choice bioassays, while being least preferred for oviposition. The differences in preference, which persisted in no-choice bioassays, may have a chemical basis, particularly for oviposition where differences were more clearly defined. Feeding and oviposition may be mediated by different host-plant chemicals. Centennial, the most preferred cultivar for oviposition, was found to have differences in its surface chemistry compared to the other three cultivars. The component in peak 5 (Figure 1), present in significant levels only in Centennial, was tentatively identified as a pentacyclic triterpene (molecular weight 468) and is currently being characterized (Son et al., 1987). This could potentially be an oviposition stimulant. Alternatively, Centennial has less of a component in peak 4 (molecular weight 498) (Figure 1), which could be inhibiting oviposition in the other cultivars.

The presence of an oviposition-stimulating substance in the root periderm has been demonstrated; Nottingham et al. (1987) showed that factors involved in cultivar preference and oviposition stimulation reside in the root periderm, while Wilson et al. (1988) reduced the oviposition-stimulating activity of roots (Centennial cultivar) by washing them in an ultrasonic bath of methylene chloride. When the methylene chloride root extract was applied back onto washed roots, oviposition behavior was restored, showing that behavioral activity

resided in the extract. Surface components of Centennial cultivar are currently being fractionated for further characterization, and behavioral activity of components will be determined in a root-core bioassay (Nottingham et al., 1987), concentrating initially on the identified triterpenol acetate.

(Received August 25, 1986; accepted March 25, 1988)

Abstract—Decomposing onions at certain microbial successional stages produce potent volatile attractants and ovipositional stimulants of the onion fly, *Delia antiqua* (Diptera: Anthomyiidae). A reproducible source of these compounds was obtained by culturing *Erwinia carotovora* var. *carotovora* (EC) on sterile onion tissue. In laboratory choice tests, EC-inoculated onion was more attractive than *Klebsiella pneumoniae* (KP) cultured on onion, EC cultured on potato (a nonhost of onion fly), or the chemical synthetic baits dipropyl disulfide and an aqueous solution of 2-phenylethanol and pentanoic acid. Onion flies were mildly attracted to potato after inoculation with EC, but females did not accept EC-inoculated potato for oviposition. This work emphasizes that sources of semiochemicals may need to be defined micro-biologically as well as physically and chemically.

Key Words—Onion fly, *Delia antiqua*, Diptera, Anthomyiidae, *Erwinia carotovora* var. *carotovora*, *Klebsiella pneumoniae*, food attractant, ovipositional stimulant, dipropyl disulfide, 2-phenylethanol, pentanoic acid.

INTRODUCTION

Onion fly, *Delia antiqua* (Meigen) (Diptera: Anthomyiidae), is a major pest of commercial onions in the temperate northern hemisphere. Decomposing onions produce more potent onion fly attractants and ovipositional stimulants than do

¹ Diptera: Anthomyiidae.

² Paper No. 12106 of the Michigan State University Agricultural Experiment Station.

³ Current address: Building E402, DuPont Experiment Station, Wilmington, Delaware 19898.

healthy or freshly cut onions (Dindonis and Miller, 1981a; Ishikawa et al., 1981), but only at certain successional stages of microbial and physical damage (Vernon et al., 1981; Miller et al., 1984). Using gas-liquid chromatography (GLC), Vernon et al. (1981) demonstrated that changes in onion fly attractancy were associated with qualitative and quantitative changes in the headspace chemical profile of onion as decomposition progressed.

Many factors influence volatile metabolite production in decomposing plant material. A complex interaction of environmental factors such as temperature, oxygen concentration, characteristics of the host plant, and presence of competing microorganisms and their metabolites may influence which organisms and volatile metabolites predominate. Under controlled growth conditions, microorganisms give reproducible headspace profiles that are often unique to a given genus, and, sometimes, species (Larsson et al., 1984). Indeed, using GLC for the qualitative and quantitative determination of volatile compounds has become an accepted technique in identifying anaerobic bacteria (Zechman and Labows, 1984) and some groups of aerobic bacteria (e.g., Lee et al, 1979). Bacteria infecting urine, meat, and other substrates are analyzed by direct headspace analysis of the sample or by subculturing the bacteria onto media that are selective or enriched in precursors to targeted metabolites (Larsson et al., 1984). Pure cultures may produce a distinctive series of volatile organics or a distinctive odor such as the grapelike 2-aminoacetophenone, a diagnostic marker for *Pseudomonas aeruginosa* (Cox and Parker, 1979).

The variable attractancy of decomposing onion has hindered work aimed at identifying potent onion fly attractants and ovipositional stimulants. This paper describes how a reproducible source of these compounds has been obtained by culturing bacterial isolates associated with onion decomposition on sterilized onion tissue.

METHODS AND MATERIALS

Insects. Parental *D. antiqua* stock was collected from commercial onion fields in Eaton Rapids, Michigan. Insects used were 5 to 7 generations removed from the field. Adults were fed water and a dry artificial diet (Ticheler, 1971) and housed as described by Schneider et al. (1983), except onion foliage in ovipositional dishes was replaced by green surrogate stems (Harris and Miller, 1983). Larvae were reared in sand-filled boxes provisioned with an excess of bisected onion bulbs.

All behavioral bioassays were conducted at $35 \pm 5\%$ relative humidity, $23 \pm 1^\circ\text{C}$, and in a 16 : 8 light-dark regime; alternating cool 55-W and warm 85-W white fluorescent bulbs were placed 10 cm above the cages. Three days before assaying, flies from the laboratory culture were placed in cylindrical,

metal-screened cages (42 cm diam. \times 46 cm). Between assays, flies were given food, water, and access to ovipositional dishes of freshly cut onion covered with moist sand. In the center of each dish we placed a 4-mm-diam. \times 9-cm-long surrogate onion stem. Before each assay, the water dish was placed in the center of the cage, but food and ovipositional dishes were removed.

Bacterial Cultures. *Erwinia carotovora* var. *carotovora* (EC) causes soft rot on a wide range of vegetables. Onion maggots moving through infested soil may spread the bacterium (Agrios, 1978). EC was isolated from damaged stored onions (Spartan Banner hybrid) potted in moist muck soil taken from a commercial onion field in East Lansing, Michigan. Damage was inflicted by 20 second-instar *D. antiqua* larvae taken from our laboratory culture and added to each potted bulb. After five days of larval feeding, 10 g of the decomposing onion tissue was homogenized with a sterile mortar and pestle in 25 ml sterile buffer (0.2 M KH_2PO_4 and 0.2 M K_2HPO_4 , pH 7.0). For the isolation of soft-rot bacteria, dilutions of the homogenate were made in buffer and plated on a selective medium containing crystal violet and sodium polypectate (CVP) (Cuppels and Kelman, 1974). Plates were incubated overnight at $25 \pm 2^\circ\text{C}$.

Colonies of *Erwinia* spp. formed deep, cuplike depressions in the selective medium. They could be distinguished from pectolytic *Pseudomonas* spp., which form shallow, wider depressions (Cuppels and Kelman, 1974). A bacterial isolate of *Erwinia* sp. was obtained and designated as strain EC6. Isolate EC6 was identified using current taxonomic keys and texts (Lelliott, 1974; Kelman and Dickey, 1980).

Klebsiella pneumoniae (KP) had been stored at -65°C in 4% (v/v) DMSO in nutrient broth (0.3% beef extract and 0.5% peptone; Difco). The original strain, JM1, was isolated and identified as a predominant microorganism from decomposing onions that were five times more attractive in the field than fresh cut onions (Miller et al., 1984).

For use in experiments, colonies of both EC and KP were grown on Bacto nutrient agar (Difco) at $25 \pm 2^\circ\text{C}$. Stock cultures were maintained on nutrient agar in the refrigerator at $4-6^\circ\text{C}$.

Preparation of Axenic Onion and Potato. Axenic plant tissues were prepared from Russet Burbank potatoes and an undetermined cultivar of yellow onions from commercial storage. The outer, papery scales and upper and lower 2 cm of bulb were removed; potatoes were peeled. Plant tissues were soaked in 75% ethanol for 20 min and flame sterilized 1–2 min. The flamed outer 0.5 cm of potato and the flamed outer two onion scales were removed with sterilized instruments and discarded.

Two sizes of potato and onion tissue were cut. Squares of tissue measuring $3.5 \times 3.5 \times 0.5$ cm and $2 \times 2 \times 0.5$ cm were placed individually in polystyrene Petri dishes (diameters of 5.5 cm and 3.5 cm, respectively). Onion squares were cut only from the 2 to 3 outer scales. After sterile distilled water was

added to cover the dish bottom, tissues were incubated at $25 \pm 2^\circ\text{C}$. Because the concentration of sulfur- and nitrogen-containing compounds in onion are known to differ in the outer and inner scales (Freeman, 1975), only tissue taken from the same onion scale (or the same potato) was used within the same cage for bioassays.

Experiment 1: Attractancy of Axenic Onion. Approximately 100–125 flies of mixed sexes and ages were placed in each cylindrical cage. Wire screen baskets were hung in the tube traps of Weston and Miller (1985); all parts were autoclaved. Between 4 and 15 hr into photophase, treatments were enclosed individually in the wire baskets and assayed in choice tests by spacing traps equally along the periphery of cylindrical cages. After the bioassay, flies in each trap were sexed and counted.

In each of four cages, traps were baited with either a $3.5 \times 3.5 \times 0.5$ -cm axenic onion square cut immediately before assaying, cut axenic onion held for one, two, and three days before assaying, or a petri dish filled with sterilized, distilled water. At the time of cutting, two parallel grooves ca. 1 cm apart and 2.5 cm deep were cut into each square. Onion tissues were assayed in their original water-filled polystyrene petri dishes with the covers removed.

Experiment 2: Time course of Attractancy of Bacteria Cultured on Onion. To determine the minimal time needed to incubate soft rot bacteria on onion to obtain significant differences in onion fly attractancy, traps were baited with axenic onion inoculated with a bacterial isolate and incubated one, two, or three days before assaying. These treatments were compared to freshly cut axenic onion and a water control. To inoculate onion with bacteria, two parallel grooves ca. 1 cm apart and 2.5 mm deep were cut into each square. A loopful of 24-hr inoculum was placed in each groove. Tissues were incubated at $25 \pm 2^\circ\text{C}$. Experiments using EC and using KP were replicated seven times as described in experiment 1.

Experiment 3: Relative Attractancy of EC- and KP- inoculated Onion. To determine the relative attractancy of the two isolates cultured on onion, traps were baited with onion inoculated with EC, KP, or EC plus KP and incubated for three days at $25 \pm 2^\circ\text{C}$ before assaying along with freshly cut axenic onion. Onion was inoculated as described in experiment 2 with EC or KP inoculum placed in both grooves of a square or with EC inoculum in one groove and KP inoculum in the other. Eight replications were conducted as described in experiment 1.

Experiment 4: Attractancy of EC-Inoculated Host and Nonhost Plant. The volatile onion fly attractants produced by EC-inoculated onion may have been due to EC, regardless of the nutritive medium used, or to the interaction of EC with onion, the primary host plant of the onion fly. To determine the importance of the host plant in the production of attractants, EC was cultured on axenic onion and axenic potato, a nonhost plant of onion fly, as described in experi-

ment 2. Traps were baited with EC-inoculated onion, inoculated potato, axenic onion, axenic potato, and water control. Axenic onion was freshly cut; other treatments were incubated three days before assaying. This experiment was replicated seven times as described in experiment 1.

Experiment 5: Attractancy of EC-Inoculated Onion vs. Chemical Synthetics. The attractancy of onion inoculated with EC and incubated three days before assaying was compared to synthetic chemical attractants. One chemical attractant was a solution of 100 μ l 2-phenylethanol (2-PhEt) and 25 μ l pentanoic acid mixed in 50 ml distilled water. These chemicals were reported by Ishikawa et al. (1984) as *D. antiqua* attractants extracted from decomposing onions. This formulation was reported to give an optimal release rate for onion fly attractancy in the field (Ishikawa et al., 1984). Ten-milliliter glass beakers containing 10 ml of this aqueous solution were placed in traps immediately before testing.

A second chemical attractant was *n*-dipropyl disulfide (Pr_2S_2), a predominant volatile secondary metabolite from fresh onions (Block, 1985). For an optimal release rate (ca. 100 μ g/hr), 100 μ l Pr_2S_2 (purity 99%) was placed into size 3 BEEM (Ted Pella Co., Box 510, Tustin, California 92680) polyethylene enclosures (Dindonis and Miller, 1981b). One capsule per trap was used. To attain a stable release rate, filled capsules were held for 6 hr prior to assaying. The experiment was replicated four times as described in experiment 1.

Experiment 6: Oviposition on EC-Inoculated Host and Nonhost Plant. Ovipositional dishes (35 ml) were filled with sterilized sand moistened with sterilized, distilled water. A 4-mm-diam \times 9-cm-long surrogate onion stem stood vertically in the center of each dish. By spacing ovipositional dishes equally along the cage periphery, five different test materials were assayed simultaneously in cages containing six to eight gravid *D. antiqua* females. Treatments were assayed 8–14 hr into photophase, thus spanning the peak diurnal ovipositional period of *D. antiqua* (Havukkala and Miller, 1987).

In one ovipositional experiment, the 2.0 \times 2.0 \times 0.5-cm squares of plant tissue, along with associated water, were placed ca. 0.5 cm beneath the sand surface immediately before assaying. No plant material was placed in the cup designated as a water control. In a second experiment, to determine whether volatiles alone from test materials stimulated oviposition, Petri dishes containing the 3.5 \times 3.5 \times 0.5-cm squares of tissue and water were placed in sterilized glass quart canning jars. A GLC septum was inserted into each of two holes drilled into the jar lid. Teflon tubing (1 mm ID) was inserted into each septum. One tube passed through the screened cage wall and was threaded through a septum inserted into a hole in the side of the ovipositional cup. The tubing opened ca. 5 mm from the surrogate stem and ca. 1.25 cm below the sand surface. The second tube led from the jar lid to a small plastic manifold and then to the filter of a compressed air tank. Air carrying volatiles from the jars to the ovipositional cups flowed at 10 ml/min.

In both ovipositional experiments, the treatments used were onion and potato inoculated with EC and incubated for three days before assaying, axenic potato held three days before assaying, freshly cut axenic onion, and a water control. Preparation of treatments followed the procedure outlined in experiments 1 and 2. Both experiments were replicated four times.

RESULTS

Identification of Isolate EC6. Bacterial cells of EC6 were motile, straight rods occurring primarily singly, but sometimes in pairs or short chains. This isolate was gramnegative, facultatively anaerobic, oxidase negative, phosphatase negative, reduced nitrate, did not produce reducing substances from sucrose, and utilized Simmon's sodium citrate. Growth occurred at 36°C and in 5% NaCl. No special growth factors were required. Colonies on yeast extract-dextrose-CaCO₂ agar (YDC) were creamy white with no diffusible pink or blue pigments; colonies on nutrient agar were translucent white with no yellow pigments. Inoculation on sterile potato disks caused soft rot. Based on these results and the characteristic growth on CVP medium, EC6 was identified as a strain of *Erwinia carotovora* var. *carotovora*.

Experiment 1: Attractancy of Axenic Onion. Sterilized onion tissues incubated one day or more before the assay lost activity (Figure 1); therefore, sterilized onions used as controls in the remaining bioassays were cut immediately before assaying.

FIG. 1. Onion fly attractancy as influenced by time sterilized onion tissue was held before assaying. Orthogonal contrasts after ANOVA: freshly cut onion vs. onion incubated 1, 2, and 3 days ($P < 0.05$); freshly cut onion vs. water control ($P < 0.05$); and water control vs. onion incubated 1, 2, and 3 days ($P > 0.20$).

Experiment 2: Time Course of Attractancy of Bacteria Cultured on Onion. Attractancy of EC-inoculated onion increased with incubation times from one to three days (Figure 2A). Onion inoculated and incubated two or three days caught significantly more flies than either noninoculated onion or the water control. A similar pattern of increasing attractancy with incubation times from one to three days was seen for KP-inoculated onion tissue (Figure 2B). A three-day incubation period was judged sufficient to obtain significant differences in attractancy between bacterially inoculated onion and sterile onion.

Experiment 3: Relative Attractancy of EC- and KP-Inoculated Onion. Traps baited with onion inoculated with EC caught significantly more flies than those baited with KP-inoculated onion (Figure 3). Onion tissue inoculated with both bacteria did not catch significantly more flies than onion inoculated with

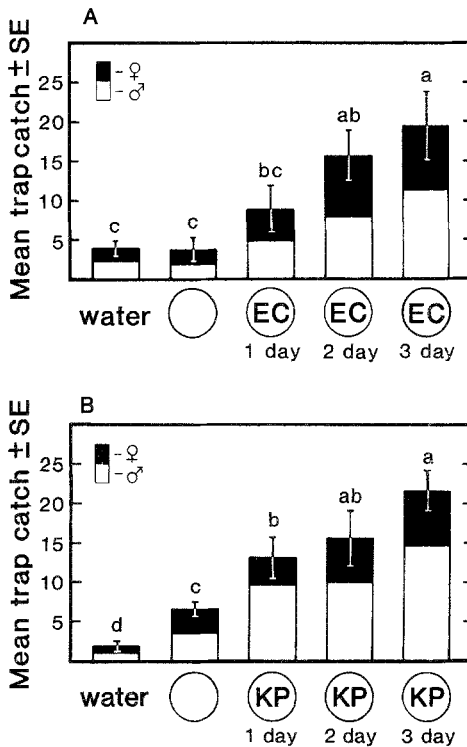

FIG. 2. Influence of incubation time on onion fly attractancy of onion inoculated with bacterial isolates. Sterilized onion tissue (○) inoculated with EC (A) or with KP (B) and incubated 1, 2, or 3, days before the bioassay. Treatments marked by different letters are significantly different (Tukey's HSD all-pairwise comparisons after ANOVA; $P < 0.05$ for A; $P < 0.10$ for B).

FIG. 3. Relative onion fly attractancy of EC and/or KP inoculated on sterilized onion tissue (○) and incubated 3 days before the bioassay. Treatments marked by different letters are significantly different (Tukey's HSD all-pairwise comparisons after ANOVA; $P < 0.05$).

either bacterial isolate alone ($P > 0.20$). Regardless of the bacterial isolate used, all inoculated onion baits caught significantly more flies than traps baited with noninoculated onion. The remaining experiments focused on the bacterial isolate EC.

Experiment 4: Attractancy of EC-Inoculated Host and Nonhost Plant. A higher mean trap catch was attained when onion rather than potato was inoculated with EC (Figure 4). Traps baited with EC-inoculated potato did catch significantly more flies than those baited with noninoculated potato.

Experiment 5: Attractancy of EC-Inoculated Onion vs. Chemical Synthetics. Traps baited with EC-inoculated onion caught significantly more flies than any other bait used (Figure 5). The mean fly catches obtained with traps baited with either chemical attractant or with noninoculated onion were all low and did not differ significantly from each other ($P > 0.20$). All baits tested caught significantly more flies than the water control, except Pr_2S_2 ($P > 0.20$).

Experiment 6: Oviposition on EC-Inoculated Host and Nonhost Plant. When test materials were placed directly in the ovipositional dishes, EC-inoculated onion received significantly more eggs than any other treatment (Table 1, experiment A). Freshly cut, sterilized onion received fewer eggs than EC-inoculated onion but more eggs than all other treatments. No other significant differences were found ($P > 0.20$).

FIG. 4. Production of onion fly attractants by the interaction of EC on onion fly host and nonhost tissue. Sterilized onion tissue (○) and potato tissue (□) inoculated with EC and incubated 3 days before the bioassay. Statistically significant interaction between plant tissue used and presence or absence of EC [two-way ANOVA of data transformed to $(X \pm 0.5)^{1/2}$; $p < 0.01$]. Orthogonal contrasts: potato vs. EC-inoculated potato ($P < 0.01$); onion vs. EC-inoculated onion ($P < 0.01$); EC-inoculated potato vs. EC-inoculated onion ($P < 0.01$); potato vs. onion ($P > 0.20$).

When volatiles from these treatments were pumped into the dishes, EC-inoculated onion received significantly more eggs than any other treatment group (Table 1 experiment B). No other differences were found among the remaining treatments ($P > 0.20$), all of which received very few eggs.

FIG. 5. Comparison of chemical synthetics and EC-inoculated onion as onion fly attractants. Symbols and statistics as in Figure 3.

TABLE 1. MEAN NUMBER OF EGGS LAID^a BY *D. antiqua* IN RESPONSE TO EC CULTURED ON HOST AND NONHOST PLANT TISSUE

Treatment	Experiment ^b	
	A	B
Ec-inoculated onion	73.5 ^a ± 23.87	47.5 ^a ± 10.54
Noninoculated onion	12.5 ^b ± 2.96	1.0 ^b ± 0.56
EC-inoculated potato	1.0 ^c ± 1.00	1.0 ^b ± 0.41
Noninoculated potato	0.0 ^c	0.0 ^b
Water control	0.0 ^c	0.0 ^b

^aMeans ± SE followed by the same letter within a column are not significantly different [one-way ANOVA of data transformed to $(X + 0.5)^{1/2}$ followed by Tukey's all-pairwise comparisons (Gill, 1978); $P < 0.05$].

^bTreatments presented in ovipositional dishes (experiment A) or as volatiles pumped into ovipositional dishes (experiment B).

DISCUSSION

The unstable sulfenic acids released from cut onion degrade to form various sulfur-containing volatiles that, in large part, give onion its characteristic odor and taste (Block, 1985). A number of these volatiles, (e.g., dipropyl disulfide) are known to attract and/or stimulate oviposition by the onion fly (Matsumoto and Thorsteinson, 1968; Vernon et al., 1978). As the volatiles from damaged onion cells are exhausted, the attractancy of freshly cut sterilized onion would be expected to decrease; hence, freshly cut sterilized onion was chosen as an appropriate control for assays testing the effects of culturing bacteria on sterilized onion tissue.

The interaction of EC and of KP with onion tissue increased *D. antiqua* trap catches (Figure 2) and oviposition (Table 1). Behavioral activity in response to EC- or KP-inoculated onion increased with time (Figure 2), probably due to a rise in volatile release. As the bacterial population increases, a concomitant increase in amounts of pectolytic and cellulolytic enzymes would be expected (Starr and Chatterjee, 1972). Qualitative changes in volatiles also would be expected as the chemical composition of the host changes and bacteria exhaust available nutrients.

Human olfaction detects little difference between sterilized and EC-inoculated potato tissue. Indeed, many vegetables infected with *E. carotovora* var. *carotovora* alone do not release the unpleasant odors commonly associated with decomposing plants. Saprophytic bacteria that colonize plant tissue after pathogenic infection generally are responsible for the foul odor. Two notable exceptions are crucifers and alliums, both of which release unpleasant sulfurous odors when inoculated with the soft-rot pathogen (Agrios, 1978). EC-inoculated potato

may release simple volatile metabolites not particularly odoriferous but nevertheless mildly attractive to onion fly, e.g., short-chain alcohols and hydrocarbons (Stotzky and Schenck, 1976).

The aqueous solution of 2-PhEt and pentanoic acid reported by Ishikawa et al. (1984) to be a potent attractant of *D. antiqua* was much less attractive than EC-inoculated onion tissue (Figure 5), suggesting that attractants associated with decomposing onions remain to be identified. Indeed, the low fly catches obtained with 2-PhEt/pentanoic acid as well as with Pr₂S₂ demonstrate that currently known synthetic attractants do not closely simulate fresh or maximally attractive decomposing onion. Perhaps decomposing onions used as positive controls in the studies emphasizing the potency of 2-PhEt/pentanoic acid as attractants for *D. antiqua* were inadequate (Ishikawa et al., 1984).

Even though they were significantly attracted, female onion flies did not accept EC-inoculated potato as an ovipositional site (Table 1). For *D. antiqua*, oviposition is a specific behavioral response restricted to stimuli from *Allium cepa* and its closest relatives. On the other hand, attractancy can include both host-finding and food-finding. Thus, onion flies may be attracted to and feed on decomposing nonhost plants (Miller et al., 1984) but may not accept them for oviposition.

The most notable points made here are: (1) that a source of consistent highly active *D. antiqua* attractants has been found (this advance should greatly facilitate chemical identification of these attractants), and (2) sources of behavior-modifying stimuli may need to be defined microbiologically as well as physically and chemically.

(Received January 21, 1988; accepted March 29, 1988)

Abstract—Ferulic acid, a frequently cited allelopathic agent, inhibited photosynthesis, leaf expansion, and root elongation of cucumber seedlings grown in aerated nutrient cultures in a growth chamber. Other effects were a reduction in the proportion of radioactivity fixed by photosynthesis translocated to roots, a stimulation in secondary root initiation, and an increase in root–shoot ratios. Inhibition of leaf expansion and root elongation induced by multiple ferulic acid treatments was rapidly lost once ferulic acid was removed from the root environment. The changes in general root morphology, i.e., average root length and root number, associated with ferulic acid treatments, were partially reversed or not affected when ferulic acid was removed from the root environment.

Key Words—Allelopathy, ferulic acid, leaf expansion, root elongation, carbon allocation, *Cucumis sativus*, cucumber.

INTRODUCTION

Ferulic acid, a frequently cited allelopathic compound (Rice, 1984), has been shown to inhibit germination, radicle elongation, leaf area expansion, and dry matter accumulation of shoots and roots (Patterson, 1981; Einhellig et al., 1985; Waters and Blum, 1987; Blum et al., 1987). Effects of ferulic acid are rapidly

¹Paper No. 11411 of the Journal Series of the North Carolina Agricultural Research Service, Raleigh, North Carolina 27695-7601. The use of trade names in this publication does not imply endorsement by the North Carolina Agricultural Research Service of the products named, nor criticism of similar ones not mentioned.

lost, however, once it is removed from the root environment (Blum et al., 1985a; Balke, 1985; Waters and Blum, 1987). Exposure of plant roots to ferulic acid reduces plant water utilization (Blum and Dalton, 1985; Blum et al., 1985a), modifies turgor and osmotic pressure, closes stomates (Einhellig et al., 1985), and reduces rates of photosynthesis (Patterson, 1981) and ion uptake (Balke, 1985).

Shoots and roots are in many ways complementary in function because both supply required resources to the whole plant. This makes the two organs dependent on each other and suggests that their growth rates are under mutual control (Brouwer, 1983). The underlying physiological mechanisms, however, are poorly understood. Information in the literature on the effects of ferulic acid on shoots of a variety of species is extensive (Rice, 1984), while information on the effects of ferulic acid on roots is limited. The objective of this study was to determine the effects of ferulic acid on roots and root-shoot relationships. Cucumber (*Cucumis sativus*) was chosen as the model species because of its sensitivity to ferulic acid, its rapid growth rates, and its predictable behavior (Blum and Dalton, 1985; Blum et al., 1985a,b). The present report represents an effort to refine methodology that will aid in the understanding of allelopathic interactions.

METHODS AND MATERIALS

General Aspects. Cucumber seeds (*Cucumis sativus* cv. Early Green Cluster; Wyatt Quarles Seed Company, Raleigh, North Carolina) were germinated in the dark at 25°C in trays containing vermiculite and a modified nutrient solution (see below). After 72 hr in the dark, the seedlings were exposed to light [photosynthetic photon flux density (PPFD) 642 $\mu\text{mol m}^2/\text{sec}$] for 10 hr and then transferred to glass jars containing 430 ml nutrient solution. Seedlings were suspended in the nutrient solution by a foam collar through a hole in the cap of the jars. Light was excluded from the jar with foil. Nutrient solutions containing seedling roots were aerated continuously 48 hr after transplanting.

Plants were grown in a growth chamber of the Southeastern Plant Environmental Laboratory (North Carolina State University Phytotron) with 25°C day/night temperature, a 10-hr photoperiod (PPFD of 642 $\mu\text{mol m}^2/\text{sec}$ provided by incandescent and cool white fluorescent bulbs at an input wattage ratio of 3:10, respectively), and a relative humidity > 80%. Phytotron nutrient solution (Downs and Thomas, 1983) without sodium fluorescein and supplemented with 606 mg KNO_3 and 84 mg K_2HOP_4 per liter was used throughout the study. Deionized water was added twice a day to each jar to compensate for evapotranspiration. Nutrient solutions with or without ferulic acid (Sigma Chemical

Company, St. Louis, Missouri) were changed every other day. The initial pH of all solutions was 5.5.

Leaf length and width were recorded just before solution changes and/or at final harvest. Shoot and root weights were measured at various intervals and/or at final harvest. Roots sampled to determine root number and length were stored in a 70% EtOH solution.

Leaf Areas. Leaf length, width, and area were determined (Li-Cor model 3000 Leaf Area Meter, Lambda Instruments Co.) at various ages ranging from 9 to 20 days from seed. These data were used to develop the following model:

$$\text{Leaf area} = -4.77 + 0.00916 (LW); r^2 = 0.97; N = 95$$

where leaf area is in square cm and LW equals leaf length \times width in mm. This model was used to determine leaf area for all experiments. The areas of the cotyledons were not included in the estimates of total leaf area per plant.

Effects of Ferulic Acid on Leaf Areas and Roots. Seedlings were treated with 0, 0.125, 0.25, or 0.5 mM ferulic acid (six seedlings per concentration) in fresh nutrient solution every other day starting with day 7. Leaf measurements were made and plants were harvested 15 days from seed. Root systems were separated from the shoot and placed into bottles containing 70% EtOH. To obtain root measurements: (1) roots were floated in a pan of tap water, (2) the primary root was identified, (3) all secondary roots were cut from the primary root, and (4) root length of both the primary and the secondary roots was determined. The number of secondary roots was also recorded. In addition, the number of tertiary roots was counted on 10 randomly selected secondary root sections of > 10 cm length.

Dimension Analysis. Seedlings were treated with 0, 0.125, 0.25, or 0.5 mM ferulic acid (12 seedlings per concentration) in fresh nutrient solution every other day starting on day 8 from seed. Root and shoot dry weight, leaf area, root number, and root length were determined when seedlings were 16 days old. Leaf areas were determined for all seedlings, but dry weights and root measurements were made on different sets of seedlings (six seedlings per concentration per set).

Effects of Ferulic Acid on Carbon Allocation to Roots. Seedlings were treated with 0, 0.25, or 0.5 mM ferulic acid in fresh nutrient solution every other day starting on day 8. Immediately after solutions were changed on day 14, seedlings were placed into Plexiglas chambers (18 cm high, 19.5 cm diameter) for exposure to $^{14}\text{CO}_2$. Six seedlings (one per chamber) were exposed to $^{14}\text{CO}_2$ each exposure. Exposures were conducted between 1200 and 1600 hr on two consecutive days, and two sets of seedlings were exposed each day. Temperature in the exposure chambers ranged from 25 to 30°C and PPFD was approximately 513 $\mu\text{mol cm}^2/\text{sec}$. $^{14}\text{CO}_2$ was generated by the action of 1 N

HCl on [^{14}C]Na $_2$ CO $_3$ in aqueous solution (4 μCi of ^{14}C in 20 μl of 1 N NaOH) to generate a radioactivity of 2.97×10^7 dpm/liter of chamber atmosphere. After 15 min, residual $^{14}\text{CO}_2$ was captured in 3 N NaOH by means of a circulating pump. Thirty minutes later, seedlings were removed from the chambers. Half the plants were harvested immediately, and the other half were harvested 24 hr later. On harvest, plants were cut into sections (leaves, stem, and roots), weighed, and respective sections were placed into separate scintillation vials. Sections were oven-dried (40°C) and chopped, and the dry weight in each vial was calculated using the appropriate fresh-dry weight ratios determined from sections of unlabeled seedlings. To bleach the tissue, a 30% hydrogen peroxide solution (0.5 ml/50 mg tissue) was added to each vial, and vials were placed under a light bank until the samples were dry. EtOH (2 ml, 95%) was added to each vial, and the capped vials were incubated at 40–50°C overnight (Shann and Blum, 1987a). Scintiverse LC (Fisher Scientific Co., Springfield, New Jersey) cocktail was added, and the radioactivity was determined by liquid scintillation spectrophotometry (Beckman LS 7000). The counting efficiency of radioactivity was 70%. Background radiation of unlabeled tissue averaged 30 cpm. The experimental design was: three ferulic acid concentrations, two harvests per exposure, and four exposures, totaling 24 seedlings.

Recovery after Ferulic Acid Treatments. Seedlings were treated with 0 or 0.5 mM ferulic acid in fresh nutrient solution starting on day 7 and given two (days 7 and 9), three (days 7, 9, 11), or four (days 7, 9, 11, 13) ferulic acid treatments. Solutions in jars were changed every other day. Four seedlings were harvested every other day for the control and the four-times-treated seedlings. For the remaining treatments, seedlings were harvested every other day starting 48 hr after the last ferulic acid treatment. Mean absolute rates of leaf expansion were determined by the following equation:

$$AGR = \text{leaf area at time}_x - \text{leaf area at time}_{x-1}$$

where AGR is in square cm per two days. Mean relative rates of leaf expansion were determined as follows:

$$RGR = \log(\text{leaf area at time}_x) - \log(\text{leaf area at time}_{x-1})$$

where RGR is in square cm per square cm per two days. For additional details about growth analysis equations see Evans (1972).

Data Analyses. Log-transformed and untransformed data were analyzed using Statistical Analysis System (SAS Institute Inc., Cary, North Carolina) programs for analysis of variance and regressions. Logarithmic transformations were used to stabilize the variance of the radioactivity data because the error is inversely proportional to the magnitude of the mean count. Linear, quadratic, and cubic equations were fitted to data. Least significant differences (LSD 0.05)

were calculated as a measure of experimental precision. Inferences are based on the appropriate analysis of variance or regression analysis ($\alpha \leq 0.05$).

RESULTS

Effects of Ferulic Acid on Leaf Areas and Roots. As ferulic acid treatment concentrations were increased, concurrent decreases were obtained for leaf area [area (cm²) = 288.20 - 178.57 (conc.); $r^2 = 0.38$; where conc. is in mM], root length of primary and secondary roots [length (cm) = 678.14 - 563.02 (conc.); $r^2 = 0.74$], average root length of primary and secondary roots [average length (cm) = 37.39 - 37.71 (conc.); $r^2 = 0.83$], and the number of tertiary roots [number = 243.21 - 220.70 (conc.); $r^2 = 0.67$]. All such relationships were linear, and higher-order terms were not significant. The number of primary and secondary roots and the frequency (number/cm) of tertiary roots were not modified by multiple ferulic acid treatments. One reason for the low r^2 values of some of these models can be seen in Table 1 where, for example, leaf area was only reduced substantially by the 0.5 mM ferulic acid treatment.

Dimension Analysis. Leaf area, shoot and root weight, and total and average length of primary and secondary roots at final harvest were suppressed by multiple treatments of ferulic acid (Tables 2 and 3). The root-shoot ratio and the number of roots (primary and secondary) increased with increasing ferulic acid treatment concentrations.

Models developed with leaf area as the independent variable and dry weight, total and average root length, or root number as dependent variables demonstrated that most variables were directly related to leaf area (Table 4).

TABLE 3. PARTIAL REGRESSION COEFFICIENTS AND r^2 VALUES FOR LEAF AREA, DRY WEIGHT, ROOT-SHOOT RATIO, ROOT LENGTH, NUMBER OF ROOTS, AND AVERAGE ROOT LENGTH OF CUCUMBER SEEDLINGS GIVEN MULTIPLE FERULIC ACID TREATMENTS^a

Variable	Intercept	Linear	Quadratic	r^2
Leaf area (cm ²)	262.13	115.08	-667.09	0.67
Shoot weight (g)	0.96	-0.07	-1.48	0.84
Root weight (g)	0.18	-0.11		0.44
Root/shoot ratio	0.18	0.084		0.47
Root length (cm) ^b	473.60	263.69	-1065.38	0.48
Number of roots ^b	19.37	47.47		0.87
Average root length (cm) ^b	24.19	-33.56		0.84

^aIndependent variable = concentration; 0, 0.125, 0.25, and 0.5 mM.

^bValues based on primary and secondary roots.

Log transformation of variables (i.e., dependent and/or independent) did not improve the r^2 values of models based on nontransformed data. Root dry weight could be estimated from shoot dry weight by a linear model (Table 4).

Effects of Ferulic Acid on Carbon Allocation to Roots. Growth of seedlings exposed to ¹⁴CO₂ was suppressed by ferulic acid treatments (Table 5). Seedling photosynthesis (based on total seedling radioactivity immediately after the ¹⁴CO₂ exposure) was inhibited by multiple ferulic acid treatments (log radioactivity (cpm) = 11.46 - 0.98 (conc.); r^2 = 0.31; where conc. is in mM; also see Table 6). Radioactivity of seedlings was 101,838, 71,381 or 63,371 cpm for the 0, 0.25, or 0.5 mM ferulic acid treatments, respectively. This amounted to a 30 or 38% reduction in radioactivity for the 0.25 or 0.5 mM treatments, respectively.

TABLE 4. PARTIAL REGRESSION COEFFICIENTS AND r^2 VALUES FOR DRY WEIGHT, ROOT LENGTH, NUMBER OF ROOTS, AND AVERAGE ROOT LENGTH^a

* Immediately after $^{14}\text{CO}_2$ exposure.

** Column means followed by the same letter are not significantly different.

*** 24 hr after $^{14}\text{CO}_2$ exposure.

Twenty-four hours after the $^{14}\text{CO}_2$ exposure, radioactivity of shoots was 84,428, 62,627 or 46,527 cpm and of roots was 10,325, 6156, or 3725 cpm for the 0, 0.25, or 0.5 mM ferulic acid treatments, respectively. Models for shoot, root, and seedling log cpm were as follows: (1) shoot log cpm = $11.32 - 1.19 (\text{conc.})$; $r^2 = 0.60$ where conc. is in mM; (2) root log cpm = $9.2 - 2.04 (\text{conc.})$; $r^2 = 0.70$; and (3) seedling log cpm = $11.44 - 1.27 (\text{conc.})$; $r^2 = 0.63$. The radioactivity of roots expressed as a percentage of total seedling radioactivity [$\% \text{ root cpm} = 0.1079 - 0.070 (\text{conc.})$; $r^2 = 0.50$] was reduced by 18 or 32% for the 0.25 or 0.5 mM ferulic acid treatments, respectively (Table 6).

Recovery after Ferulic Acid Treatments. Significant differences for leaf area and root length due to ferulic acid treatments were lost almost immediately after seedlings were removed from ferulic acid solutions (Table 7). For average root length, a partial recovery occurred after roots were removed from ferulic acid, while the effects of ferulic acid treatments on root number persisted after seedlings were removed from ferulic acid solutions. Recovery of absolute rates of leaf expansion occurred within 48 hr after seedlings were removed from ferulic acid solutions (Table 8). Relative rates of leaf expansion were stimulated 48 hr after the seedlings were removed from ferulic acid solutions.

DISCUSSION

Consistent measurable effects of ferulic acid on shoots and roots of cucumber seedlings occurred at ≥ 0.25 mM. One of the documented effects of ferulic acid is the inhibition of leaf expansion (Blum and Dalton, 1985; Blum et al. 1985a,b; Waters and Blum, 1987). Effects of ferulic acid on root elongation, however, have not been well documented. The previously reported inhibition of radicle growth (Blum et al., 1984), the inhibition of root elongation reported here, and the subsequent recovery of both following removal from ferulic acid solutions suggest that cell elongation (i.e., cell expansion) in roots is also impacted by ferulic acid. Cell division may also be affected by ferulic acid, but this has not been determined. Roots of seedlings treated with ferulic acid (≥ 0.25 mM) appeared to be much thinner, tan in color, and frequently with enlarged or deformed root tips. Control roots were creamy white in color.

Ferulic acid also directly or indirectly stimulated the initiation of secondary roots in two of three experiments. In one experiment the average number of roots increased, but this increase was not significant. Thus, ferulic acid-treated root systems were not only shorter and more delicate but also more branched. The nature of this difference is illustrated by average root length, which was

reduced by 67%, and root number, which more than doubled (Table 2) for the 0.5 mM ferulic acid treatments when compared to controls. If such changes in root morphology occurred in soil environments, acquisition of nutrients and water could be substantially impacted.

The suppression of seedling growth may be attributable to inhibition of photosynthesis and changes in source-sink relationships. Proportionally more of the radioactivity fixed by the photosynthetic process was retained by the shoots than was translocated to the roots. This is consistent with the observation that when growth is limited by shoot uptake of CO₂, shoot growth is relatively favored (Brouwer, 1983). The increasing root-shoot dry weight ratio observed in this study, however, does not support this hypothesis. The increase in the root-shoot ratio may be a result of differential lignification in shoots and roots of seedlings treated with ferulic acid (Shann and Blum, 1987b).

Transpiration and water utilization by cucumber seedlings was reduced by ferulic acid treatments (Blum and Dalton, 1985; Blum et al., 1985). In these studies it was noted that the reduction in water utilization was not due to the osmotic potential of the ferulic acid-nutrient solutions, because similar responses could not be generated by polyethylene glycol at equivalent milliosmoles. Changes in seedling turgor and osmotic pressure, closure of stomates, and reductions in mineral absorption have been noted for several other species when these were treated with ferulic acid (Einhellig et al., 1985; Balke, 1985). The rapid recovery of growth for both cucumber leaves and roots, once roots were removed from ferulic acid solutions, supports the hypothesis that root water uptake (not due to water potential of the solution) is a primary limiting factor and that effects on energy fixation may be secondary.

Finally, allelopathic constituents associated with organic matter in the soil are most likely unevenly distributed in soil, so that only a portion of a root system is impacted by such substances at any given time (Patrick et al., 1964).

Since the recovery of root growth was so rapid once ferulic acid was removed from the root environment, it is possible that the portion of the root system not in contact with allelopathic agents may grow normally and compensate for root inhibition experienced by roots in contact with allelopathic agents. The proportion of a root system required for contact with an allelopathic agent before growth inhibition of shoots can be detected remains undetermined.

(Received August 17, 1987; accepted April 4, 1988)

Abstract—Previous experiments demonstrated an oviposition-deterrent effect of larval frass in the Egyptian cotton leaf worm, *Spodoptera littoralis* (Boisd.). In this study, females were shown to perceive the oviposition-deterrent substance(s) with their antennae. During dark, airtight, and cold (−10°C) storage, the deterrent was persistent for at least 395 days. On the other hand, larval frass retained its activity for only two days when applied to cotton leaves. The deterrent activity of frass was independent of larval density. Frass of larvae reared at high densities deterred oviposition as well as frass of larvae feeding separately or in small groups. For significant oviposition deterrence, the minimum amount of frass was in the range of 5–10 mg frass per cotton leaf. An acetone extract of larval frass was highly deterrent, in contrast to extracts prepared with water, ethanol, chloroform, or pentane.

Key Words—*Spodoptera littoralis*, Lepidoptera, Noctuidae, Egyptian cotton leaf worm, oviposition behavior, oviposition deterrence, larval frass.

INTRODUCTION

Host plants visited for oviposition by a phytophagous insect should offer sufficient food for the progeny. Since laying eggs on infested host plants might result in a lack of space and food for the hatching larvae, females may regulate ovi-

²Present address: Lehrstuhl für Tierökologie II, Universität Bayreuth, Postfach 10 12 51, 8580 Bayreuth, F.R. Germany.

position on a host plant according to the infestation density to obtain optimal developmental conditions for the hatching larvae. It has been shown for a wide array of phytophagous insect species that chemical messengers of either insect or plant origin inform females about the infestation of a host plant and thus regulate oviposition (Prokopy, 1981; Prokopy et al., 1984).

In several species of Lepidoptera, feeding larvae and larval frass respectively indicate occupancy of the host plant and deter egg deposition (e.g., Ditttrick et al., 1983; Mitchell and Heath, 1985; Renwick and Radke, 1980, 1981; Rothschild and Schoonhoven, 1977; Williams et al., 1986). Recently we found that oviposition is also deterred by larval frass in the Mediterranean noctuid moth *Spodoptera littoralis* (Boisd.) (Hilker, 1985).

To date, nothing was known about biological and chemical properties of this oviposition deterrent in *S. littoralis*. We hypothesized that only larvae at high densities excrete oviposition-detering substances to which females respond by avoiding egg deposition. Several studies of *S. littoralis* indicate a change of metabolism when larval density increases (e.g., Hodjat, 1970; Rivnay and Meisner, 1965; Zaher and Moussa, 1961). Metabolic changes might cause a change of frass compounds. These changed substances in the frass of larvae feeding at high densities might signal to gravid females when a site is unsuitable for oviposition. We therefore investigated whether the activity of larval frass is dependent on larval density. We have also studied the perception of the oviposition deterrent, its stability during cold storage, the persistence of the detering activity of larval frass on the host plant, and the solubility of the deterrent, and we have determined the minimum amount of frass that is necessary for significant oviposition deterrence. The results of these studies are reported here.

METHODS AND MATERIALS

For oviposition bioassays, moths of *S. littoralis* were obtained from a laboratory culture reared on semiartificial diet (Patana, 1969; Shorey and Hale, 1965). Only 3- to 4-day-old moths were used. Frass was collected daily from larvae of the fifth and sixth instar, feeding on cotton plant leaves. Only these late-instar larvae produced so much frass that sufficient material was available after a short time of collection. A determination of the fresh weight of frass production per day revealed that larvae feeding on cotton leaves excreted about 20–50 mg frass during the fifth instar and about 50–350 mg frass during the sixth instar, whereas third- and fourth-instar larvae produced only about 2–5 mg frass per day. Unless mentioned otherwise, the tested frass was 1–10 weeks old. After collection, frass was stored in dark, airtight conditions at -10°C . Cotton plants, *Gossypium barbadense* Mill., were grown in a greenhouse.

Bioassays were conducted in screened cages ($50 \times 50 \times 70$ cm) situated in a chamber with constant temperature ($27 \pm 1^\circ\text{C}$) and a 14 hr : 10 hr light-dark cycle according to conditions in Egyptian summer. Each bioassay began with the onset of the light period and lasted 24 hr. Three females and five males were placed in each cage. For oviposition, moths were offered two treated and two control cotton leaves. Each leaf was deposited in a 100 ml vial filled with water and situated in a corner of the cage.

With the exception of the bioassay testing the solubility of the deterrent, leaves were treated with a water suspension of frass. This suspension was prepared in a Potter homogenizer and applied to the undersurface of a leaf with a brush. Eggs are usually laid only on the undersurface of a cotton leaf. A test leaf was treated with 1 ml suspension and a control leaf with 1 ml water. Unless cited otherwise, the concentration of the suspension was 100 mg/ml H_2O . Six different experiments were conducted.

Experiment I. In order to determine the stability of the oviposition deterrent during storage, we tested larval frass stored in 15 ml vials at -10°C for either 6 or 395 days in airtight, dark conditions.

Experiment II. This experiment was conducted to determine the persistence of frass activity on the host plant. We bioassayed test and control leaves for 24 hr either immediately after treatment (persistence day 1), or during the second day after treatment (persistence day 2), or during the third day (persistence day 3). Prior to testing persistence day 2 and persistence day 3, leaves were kept in vials filled with water at room conditions.

Experiment III. In order to investigate the perception of the oviposition deterrent, antennae of female moths were removed. One hour before the antennae were ablated, the test females were put into a cold (-2°C) room. One hour later, the antennae of the motionless females could easily be cut at the base with small scissors. About 15 min after the moths had been taken out of the cold room, they showed normal activity. For control, females with intact antennae were used. The control females were also chilled at -2°C for 1 hr prior to testing.

Experiment IV. In order to determine the amount of frass that is necessary for significant oviposition deterrence, we tested suspensions in the following concentrations: 5 mg frass/ml H_2O , 10 mg frass/ml H_2O , and 100 mg frass/ml H_2O .

Experiment V. In order to analyze a possible influence of larval density on the activity of frass, we tested frass produced by larvae of the fifth and sixth instar kept at different densities. The following densities were calculated from the number of larvae per square cm area, where they could move: 0.002 larvae/cm² (one single larva per 500 cm²); 0.01 larvae/cm² (a small group of five larvae per 500 cm², moderate density); 0.07 larvae/cm² (35 larvae per 500 cm², overcrowded). All larvae were fed with cotton leaves in surplus.

Experiment VI. In order to get information on the solubility of the oviposition deterrent, we tried to extract it with different solvents. Extracts were prepared as follows: 1.1 g frass was added to 80 ml *n*-pentane, stirred for 12 hr at room temperature, and then filtered to obtain an *n*-pentane extract. The vacuum-dried residue was added to 80 ml chloroform, stirred for 12 hr, and newly filtered to obtain a chloroform extract. The extraction was continued in this way with acetone, ethanol, and water. The undersurface of each test leaf was treated with 1 ml of the various extracts using a soft brush. Each control leaf was treated with 1 ml of the respective solvent.

At the end of a bioassay, the number of egg masses on each leaf was counted. The number of replicates for the experiments was 23 with the exception of 20 in experiment VI. Statistical significance was tested by using the Wilcoxon test for paired differences.

RESULTS

The results of this study are compiled in Table 1.

Experiment I. Both larval frass stored for 6 days and for 395 days significantly deterred oviposition. Thus the oviposition deterrent was very stable when held in dark, airtight, and cold (-10°C) storage.

Experiment II. Larval frass distributed on cotton leaves deterred oviposition for two days. On the third day, cotton leaves treated with larval frass completely lost their oviposition-detering activity.

Experiment III. The oviposition deterrent was perceived with the antennae. Females without antennae were unable to differentiate between control leaves and leaves treated with larval frass. This was in obvious contrast to females with antennae.

Experiment IV. Frass at 5 mg per leaf did not significantly reduce oviposition, but a small effect was seen with 10 mg frass per leaf. On leaves treated with 10 mg frass, significantly fewer egg masses were deposited than on control leaves. The strongest oviposition deterrence was caused by 100 mg frass per leaf. The threshold value for statistical significance in oviposition deterrence was in the range of 5–10 mg frass per leaf.

Experiment V. The oviposition-detering effect of larval frass was independent of larval density. Frass of larvae feeding singly deterred oviposition as well as frass of larvae reared in moderate or high density.

Experiment VI. The oviposition deterrent was extractable from larval frass with acetone. The number of egg masses on cotton leaves treated with an acetone extract of frass was significantly lower than the number of egg masses on

^bOne single test listed several times for comparison. In this test we used larval frass stored under dark, airtight, and cold conditions for six days. Frass was obtained from larvae provided with cotton leaves and reared in small groups (0.01 larvae/cm²). Frass, 100 mg, was applied to each test leaf and bioassayed during the first day after application.

control leaves. All other tested extracts did not cause a significantly provable oviposition deterrence.

DISCUSSION

The results of this study provided information on the oviposition deterrent in *S. littoralis* and the first hints of its chemical nature. Moreover, useful clues resulted for further studies of the chemistry of the deterrent.

The investigation of the stability of the deterrent during cold storage demonstrated that there is no necessity of using fresh frass in order to show its oviposition-deterrent activity. During cold, dark, airtight storage the oviposition-deterrent was stable for longer than one year. Therefore, in chemical studies of old frass, stored at the above described conditions, it can be certain that active oviposition-deterrent substances are still present.

In contrast to the high stability of the oviposition deterrent during cold storage, its persistence was rather short when frass was applied to cotton leaves. Activity was lost after two days. Oviposition deterrents in other phytophagous insects showed a longer period of biological activity. The oviposition deterrents in larval frass of the corn borer, *Ostrinia nubilalis* Hb. (Dittrick et al., 1983), and the cabbage looper, *Trichoplusia ni* (Hb.) (Renwick and Radke, 1980), remained active for at least three days. The period during which the oviposition-deterrent pheromone of *Rhagoletis cerasi* L. retained its activity was at least 12 days (Katsoyannos, 1975). The oviposition-deterrent pheromone produced by females of *Pieris brassicae* L. was still active after it had been dried for seven weeks at room conditions in a desiccator (Schoonhoven et al., 1981).

In *S. littoralis* the development of all individuals of a population is not completely simultaneous. Therefore, it is possible that emergence of females coincides with the occurrence of feeding larvae. There should be no necessity for a long-lived oviposition deterrent, because feeding larvae continuously excrete fresh frass and, thereby, further oviposition-deterrent substances. The loss of activity of larval frass may be due to either evaporation or damage by oxygen or light.

Perception of the oviposition deterrent by the antennae does not provide evidence for olfactory perception. Gravid females often could be observed touching the leaves with their antennae. Therefore, perception by chemotactile sensilla should be considered. Helal and Abdel Gawaad (1984) investigated the antennae of *S. littoralis* males and females by means of scanning electron microscopy and found seven different types of sensilla. Electrophysiological

experiments are necessary in order to determine the sensilla responding to the oviposition deterrent in *S. littoralis*.

To our knowledge there is no other study that addresses sensory perception of oviposition deterrents when the deterrent is in larval frass. The oviposition-detering pheromone deposited by females of *Rhagoletis pomonella* Walsh is principally perceived by sensilla located on the tarsi (Crnjar et al., 1978; Prokopy and Spatcher, 1977). In addition to tarsal and probably abdominal contact chemoreceptors, in females of *Pieris brassicae* L. also olfactory sensilla located on the antennae show electrophysiological responses to the inherent oviposition-detering pheromone of the eggs (Behan and Schoonhoven, 1978; Klijnstra and Roessingh, 1986).

Females of *S. littoralis* need to perceive a minimum amount of larval frass before decreasing egg deposition. The threshold value for the quantity of frass causing a significant deterrence of egg laying was in the range of 5–10 mg frass per cotton leaf. Two days after moulting, a sixth-instar larva feeding on cotton leaves produces about 100 mg frass per day. About 10% of this daily frass production of a late-instar larva on a cotton leaf obviously indicated such a high feeding activity that a gravid female “decides” her offspring will not be sufficiently provided for at this site and therefore seeks another, more suitable, oviposition site. The result of this laboratory bioassay needs to be checked in the field in order to get information on ecological consequences of oviposition deterrence in *S. littoralis*. Field observations by Campion et al. (1977) revealed that *S. littoralis* emigrated from areas with high population densities. Possibly *S. littoralis* females respond to oviposition deterrents by emigration, in order to look for a place where the offspring will find suitable developmental conditions.

We previously hypothesized that frass activity is dependent on larval density. This hypothesis is based on the following background. Several studies demonstrated that an increase of larval density is correlated with numerous changes, e.g., larval color changes, activity of larvae increases, and fat and water content of the resulting pupae are different (e.g., Hodjat 1970; Rivnay and Meisner, 1965; Zaher and Moussa, 1961). These results indicate metabolic changes at higher larval density. Such metabolic changes may be correlated with changes of frass compounds. Possibly gravid females only avoid egg deposition in response to such changed frass compounds. These changed frass compounds would then indicate high larval density and, thus, unsuitable oviposition sites. Examination of this hypothesis revealed that the oviposition-detering activity of frass was independent of larval density. The oviposition-detering substances were obviously not subjected to metabolic changes when larval density increased.

The acetone solubility of the oviposition deterrent in frass of *S. littoralis* larvae indicates a moderate polar character of the deterring substances. The oviposition deterrent in larval frass of the European corn borer, *Ostrinia nubilalis* Hb., showed a similar solubility: methanol and acetone extracts of frass proved effective in reducing oviposition by 90% (Dittrick et al., 1983). A water extract of frass showed no activity in *S. littoralis*.

In contrast, the oviposition deterrent in larval frass of *Spodoptera exigua* L. and *Spodoptera eridania* (Cramer) could be extracted both with water and organic solvents like ethanol and dichloromethane (Mitchell and Heath, 1985). Oviposition in *Spodoptera frugiperda* (J.E. Smith) was also deterred by aqueous extracts of larval frass (Williams et al., 1986). The results of our study suggest that the oviposition-detering substances of *S. littoralis* will be chemically different from deterrents of other *Spodoptera* species. To date, the only identified oviposition deterrent is that released by females of *Rhagoletis cerasi* L.: Hurter et al. (1987) characterized this pheromone as *N*[15(β -glucopyranosyl)oxy-8-hydroxypalmitoyl]taurine.

Oviposition by *S. exigua*, *S. eridania*, and *S. frugiperda* was also deterred by extracts of damaged host-plant material (Mitchell and Heath, 1985; Williams et al., 1986). Furthermore, deposition of eggs by the noctuid moth *Trichoplusia ni* (Hb.) was reduced not only by larval frass, but also by damaged leaves of the host plants (Renwick and Radke, 1981). These results indicate that oviposition-detering substances in the larval frass of these species are undigested, allelochemical substances of the host plants. In *S. littoralis*, a suspension of macerated cotton leaves in water (100 mg/ml) did not deter oviposition (Hilker, 1985). This result does not prove that the oviposition deterrent in *S. littoralis* is a pheromone produced by the larvae themselves. In a suspension of macerated cotton leaves, oviposition-attracting substances might compete with oviposition-detering compounds that are possibly set free by damaging the leaves. In larval frass, the oviposition-attracting substances might be digested so far that undigested oviposition-detering plant substances would display their activity.

In our current work we hope to determine whether the oviposition deterrent in the larval frass of *S. littoralis* is a pheromone or an allelochemical plant substance.

Acknowledgments—This study was supported by a grant of the "Bundesministerium für Forschung und Technologie" (project No. 0385216). We express appreciation to Prof. Dr. S. Bom-bosch, Prof. Dr. Ch. Podufal (both University of Goettingen, F.R. Germany), and Prof. Dr. H. Schildknecht (University of Heidelberg, F.R. Germany) for interesting discussions. Thanks are further due to Prof. Ph.D. M.N. Stitt (University of Bayreuth, F.R. Germany) and Dr. U. Noldt for revision of the manuscript.

STRUCTURAL CORRELATION BETWEEN CUTICULAR
HYDROCARBONS AND FEMALE CONTACT SEX
PHEROMONE OF GERMAN COCKROACH
Blattella germanica (L.)

(Received January 19, 1988; accepted April 4, 1988)

Abstract—The structural relationships between the cuticular hydrocarbons and the contact sex pheromone of the female German cockroach, *Blattella germanica*, were investigated. Cuticular hexane extracts were separated into hydrocarbon and ketone fractions by TLC or silicic acid column chromatography. The ketone fraction (which contains the major contact sex pheromone component) was analyzed by GC-MS before and after reduction to hydrocarbon. In addition to 3,11-dimethyl-2-nonacosanone, 3,11-dimethyl-2-heptacosanone was also identified. Females have the 3,11- and 3,9-dimethyl C₂₇ and C₂₉ alkanes, but only the 3,11- isomer of the dimethylketones. In addition to the hydrocarbon components previously reported, a number of new components were characterized. Although the ratios of cuticular hydrocarbons differ among nymphs, adult males, and adult females, they have qualitatively identical hydrocarbon profiles, suggesting that the production of the contact sex pheromone results from the sex-specific oxidation of 3,11-dimethylalkanes to pheromone components by the female.

Key Words—Contact sex pheromone, cuticular hydrocarbons, 3,11-dimethyl-2-nonacosanone, 3,11-dimethyl-2-heptacosanone, German cockroach, *Blattella germanica*, Orthoptera, Blattellidae.

INTRODUCTION

The cuticular lipids of insects play a major role in protecting against desiccation and, in some cases, are involved in inter- and intraspecies chemical communication (Howard and Blomquist, 1982; Blomquist et al., 1987). Many components that function in chemical communication serve as short-range or contact pheromones because of their relatively high molecular weights and low vapor pressures.

The contact sex pheromone of the German cockroach, *Blattella germanica*, is present in cuticular extracts of adult females. This pheromone elicits in males a wing-raising courtship behavior that precedes copulation (Roth and Willis, 1952). The major component of the pheromone is 3,11-dimethyl-2-nonacosanone, with lesser amounts of 29-hydroxy-3,11-dimethyl-2-nonacosanone and 29-oxo-3,11-dimethyl-2-nonacosanone also reported (Nishida and Fukami, 1983). All three compounds independently stimulate males, resulting in a complete courtship response.

The major cuticular hydrocarbons of the German cockroach have been identified as homologous series of straight chain and methyl branched heptacosanes and nonacosanes (Augustynowicz et al., 1987). Since isomers of dimethylheptacosane and dimethylnonacosane were present in the cuticular hydrocarbons, we examined the methyl ketone pheromone fraction to determine if similar isomers and homologs were also present in this fraction. We report that in addition to 3,11-dimethyl-2-nonacosanone, 3,11-dimethyl-2-heptacosanone is also present. In addition to the hydrocarbon components previously reported (Augustynowicz et al., 1987), we report the structure of a number of other hydrocarbons on the surface of the German cockroach.

METHODS AND MATERIALS

Insects. Cockroaches were reared in 2-liter glass jars and fed Purina dog chow and water ad libitum. They were kept at 27°C with a 12:12 light-dark cycle. Males and females were separated on the day of adult emergence and 15-day-old insects were utilized.

Separation of Hydrocarbons and Pheromone. Insects were extracted by immersion in hexane for 10 min followed by two 1-ml hexane washes or were extracted by two 5-min hexane washes. The hexane extracts were combined and the solvent removed under a stream of nitrogen. Internal standards, hexacosane and 14-heptacosanone, were included during extraction to allow quantitation of hydrocarbons and ketones, respectively. Hydrocarbons and pheromone were separated by thin-layer chromatography (TLC) on silica gel type H, developed in hexane-diethyl ether (90:10 v/v) and the bands corresponding to hydrocarbons and the methyl ketone fraction scraped into test tubes

and extracted with diethyl ether. Alternatively, hexane extracts from individual insects were separated on Biosil A mini-columns (Howard et al., 1978).

Gas Chromatography and Gas Chromatography-Mass Spectrometry. Hydrocarbons and the ketone fraction were analyzed by gas chromatography (GC) with a flame ionization detector on both packed and capillary columns. Separations on packed columns utilized a 1.8-m \times 3.2-mm-ID glass column packed with Dexsil 300 on Supelcoport, temperature programmed from 200°C to 310°C at 5°C/min. Separations on capillary columns utilized a 60-m \times 0.32-mm-ID DB-1 column or a 15-m \times 0.53-mm-ID SPB-1 column temperature programmed from 80°C to 270°C at 20°C/min and then to 320°C at 3°C/min. Splitless injection was used on both capillary columns.

Gas chromatography-mass spectrometry (GC-MS) was performed on a Finnigan 4123 using an INCOS data system. Material was separated on a 30-m \times 0.72-mm capillary column temperature programmed from 200°C to 260°C at 2°C/min. A Finnigan 8200 high-resolution magnetic MS using a SS300 data system was also used. Material was separated on a 60-m \times 0.32-mm DB-1 capillary column with on-column injection.

Reduction of Methyl Ketone. The methyl ketone pheromone components were reduced by a modified Wolff-Kishner reaction (Huang-Minlon, 1946). The methyl ketone fraction (approx. 0.8–1.2 mg) was dissolved in 2 ml of diethylene glycol (DEG) to which 840 μ g NaOH in aqueous solution, 1.2 μ l hydrazine hydrate, and 1.0 mg 2-nonadecanone were added. The C-19 methyl ketone was added because preliminary studies indicated that the amount of pheromone was below the critical mass of the reaction conditions. The system was refluxed with a water-cooled condenser for 2 hr to allow formation of the hydrazone intermediate. The water was disconnected from the condenser and the reaction mixture gradually warmed to approximately 200°C, a temperature sufficient to evaporate the water and reflux DEG. After formation of crystalline material in the condenser, indicative of the presence of hydrocarbon, water was reconnected to the condenser, and the reaction refluxed for 4 hr more to decompose the hydrazone to hydrocarbon. The reaction mixture was then extracted three times with hexane and the reduced pheromone components purified on a 6-cm \times 0.5-mm Biosil A column by eluting with hexane. The hexane fraction was analyzed by GLC and found to contain the reduction products of the principal pheromone components. These were analyzed by GC-MS.

RESULTS

A chromatogram of the cuticular hydrocarbons from adult females separated by capillary GC is presented in Figure 1. The 15 principal hydrocarbon components have been identified previously by Augustynowicz et al. (1987) and are homologous series of heptacosanes and nonacosanes. We have now

FIG. 1. A capillary column GC trace of the cuticular hydrocarbons from 15-day-old virgin German cockroach females. Peaks are numbered according to the components identified in Table 1.

identified a number of minor components, additional isomers of the major components, and the unknown dimethylalkanes not determined previously (Augustynowicz et al., 1987).

The previously unidentified dimethylheptacosane (peak 4, Figure 1) has the methyl groups in the 11,15- positions with diagnostic ion fragments at m/z 168/169, 196/197, 239, and 267. The fragments containing a single methyl branch have an odd-to-even ratio of about 1 and the fragments that contain a second methyl branch have a higher ratio of odd-to-even mass units. In each spectrum referred to here, if the odd-to-even ratio were near 1, both fragments are listed, whereas if the odd-numbered fragments clearly dominate, only one mass number is listed. The previously unidentified dimethylnonacosane (peak 21, Figure 1) is a mixture of 5,9- and 5,11- isomers with diagnostic ion fragments at m/z 84/85, 155, 308/309, 183, 280/281, and 379. In addition to 13,17-dimethylnonacosane, this GC peak (peak 18, Figure 1) also has an isomer with methyl groups in the 11,15- positions (m/z 168/169, 224/225, 239, and 295). We have also identified additional isomers in the dimethylheptacosane series. In addition to 5,11-dimethylheptacosane, the 5,9- isomer is also present [m/z 351 ($M-57$)⁺, 155, 280/281] (peak 6, Figure 1) and in addition to 3,11-dimethylheptacosane, the 3,9- isomer is also present [m/z 379 ($M-29$)⁺, 155, 280/

281] (peak 8, Figure 1). In addition to the 11-, 13-, and 15-methylnonacosane the 9- isomer is also present (m/z 140/141 and 308/309) (peak 15, Figure 1).

Minor components not identified in the paper by Augustynowicz et al. (1987) consist of 2-methyloctacosane [m/z 365 ($M-43$)⁺] (peak 10, Figure 1) and 4-methyloctacosane [m/z 365 ($M-43$)⁺, 337/336 ($M-71/72$)⁺] (peak 11, Figure 1). Both 2- and 4-methylalkanes give strong ion fragments at m/z ($M-43$)⁺, whereas 4-methylalkanes also show ion fragments at ($M-71$)⁺ and ($M-72$)⁺ (Blomquist et al., 1987). Other minor components present are 4,8- and 4,10-dimethyltriacontane [m/z 407 ($M-43$)⁺, 141, 169, 308/309 and 336/337], 11-, 13-, and 15-methylhentriacontane (m/z 168/169, 206/207, 224/225, 252/253, 280/281 and 308/309), 13,17- and 11,15-dimethylhentriacontane (m/z 168/169, 196/197, 224/225, 239, 267, 252/253, 295 and 323), 5,9- and 5,11-dimethylhentriacontane [m/z 407 ($M-57$)⁺, 84/85, 155, 183, 308/309 and 336/337], and 10- and 12-methyldotriacontane (m/z 154/155, 182/183, 308/309 and 336/337).

The percent composition of the hydrocarbon fraction from males, females, and nymphs is presented in Table 1. No qualitative differences were observed between the different life stages or sexes, and the 3,*x*-dimethylalkanes were present in all groups. However, consistent quantitative differences were observed between 15-day-old adult males and virgin females (Table 1). The most prominent components extracted from cuticles of females were isomers of 3,*x*-dimethylnonacosane ($18.6 \pm 0.7\%$, $32.4 \pm 1.4 \mu\text{g}$), while isomers of internally branched monomethylnonacosanes (9-, 11-, 13-, and 15-) were the most abundant components of males ($22.7 \pm 0.6\%$, $41.0 \pm 2.2 \mu\text{g}$). Last nymphal instar males also have more 9-, 11-, 13-, and 15-methylnonacosanes than last instar females.

A chromatogram of the methylketone fraction after isolation by TLC and analysis by packed column GC is presented in Figure 2. The major components are 3,*x*-dimethyl-2-nonacosanone (79.2%) and 3,*x*-dimethyl-2-heptacosanone (8.1%). Since the cuticular hydrocarbons had isomers of dimethylnonacosane in the 3,11-, 3,9-, and 3,7- positions and dimethylheptacosane in the 3,11- and 3,9- positions, we determined whether these same positional isomers are present in the methyl ketone pheromone fraction. Mass spectra of dimethyl-2-nonacosanone and dimethyl-2-heptacosanone are shown in Figure 3 with the M⁺ ion fragments at m/z 450 and 422, respectively. The ion fragments at m/z 127, 141, 155, 169, and 197 are indicative of a 2-keto group with an adjacent methyl branch in the hydrocarbon chain. The position of the methyl groups could not be determined from these data.

The methyl branch positions of dimethyl-2-nonacosanone and dimethyl-2-heptacosanone were determined by reducing the ketone to the hydrocarbon followed by GC-MS analysis. The mass spectra are presented in Figure 4. The

TABLE 1. PERCENT COMPOSITIONS OF CUTICULAR HYDROCARBONS FROM LAST INSTAR NYMPHS AND ADULT MALE AND FEMALE *Blattella germanica*

	Percent composition			
	Adult		Last instar	
	Male	Female	Male	Female

ion fragments at 183, 252/253, and 379 in Figure 4A indicate that only the 3,11- positional isomer of dimethylheptacosane is present. The same is true for the 31-carbon component with the ion fragments at 183, 280/281, and 407, indicating that only the 3,11- isomer is present (Figure 4B). These data indicate

that the principal dimethylketone component is 3,11-dimethyl-2-nonacosanone with lesser amounts of 3,11-dimethyl-2-heptacosanone also present.

DISCUSSION

The principal cuticular hydrocarbons of the German cockroach are composed of homologous series of straight chain, mono-, and dimethyl heptacosanes and nonacosanes (Augustynowicz et al., 1987). Also present as minor components are homologous series of hentriacontane except that components with the 3,*x*- branching patterns are absent.

In female German cockroaches, the 3,*x*-dimethylalkanes comprise the major type of hydrocarbon. Hydrocarbons with 3,*x*-dimethyl branching patterns were first reported in the fire ants, *Solenopsis invicta* and *S. richteri* (Nelson et al., 1980), where they were present in trace amounts. This type of hydrocarbon has also been reported in the housefly, *Musca domestica* (Nelson et al., 1981) and more recently in several other species (Blomquist et al., 1987). However, in all the previous species examined that contain 3,*x*-dimethylalkanes, they are present in trace amounts. The relatively large amounts of the 3,*x*-dimethylalkanes in the female German cockroach may reflect their use as the biosynthetic precursor to the dimethylketone contact pheromone components.

The 3,*x*-dimethylheptacosanes and nonacosanes both contain 3,11- and 3,9-dimethyl isomers with the nonacosane series also containing the 3,7- isomer. The methylketone component of the pheromone has been identified as only one isomer, the 3,11-dimethyl-2-nonacosanone (Nishida et al., 1974). Since the cuticular hydrocarbons contain at least two positional isomers of 3,*x*-dimethylnonacosane and dimethylheptacosane, we performed experiments to determine if female cockroaches also had the same homologs and positional isomers of methyl ketones as they have for the hydrocarbons. Unlike the hydrocarbons, the C₃₁ methyl ketone component of the pheromone contains only the 3,11-isomer, as was also shown by Nishida et al. (1974). We have found, however, that the heptacosanone homolog is also present, but again, only as the 3,11-isomer.

The structural similarities between the cuticular hydrocarbons and the contact pheromone suggests a similar biosynthetic origin. Malonyl-CoA serves as the two-carbon donor for chain elongation during hydrocarbon synthesis. In insects methyl branches in cuticular hydrocarbons arise from the substitution of methylmalonyl-CoA for malonyl-CoA at specific biosynthetic steps during this elongation (Blomquist et al., 1987). Various substrates have been shown to serve as precursors to methylmalonyl-CoA. In the housefly, *Musca domestica*, studies with [1-¹³C] propionate showed that 3,*x*-dimethylalkanes were formed by the insertion of propionates, as methylmalonyl-CoA derivatives, during the early stages of chain elongation (Dillwith et al., 1982). The source of the propionyl-CoA and methylmalonyl-CoA used in branched alkane biosynthesis has been shown to be the amino acids valine and isoleucine in the housefly and American cockroach (Dillwith et al., 1982; Halarnkar et al., 1985). In termites, succinate is converted to the methylmalonyl unit that forms the methyl branch group (Chu et al., 1980; Blomquist et al., 1980).

Two possible explanations exist to account for the presence of the carbonyl group at the 2-position of the pheromone component. The female cockroach could oxidize the preformed hydrocarbon at this position or fail to reduce the carbonyl group that is present at this position during the condensation reaction by which the hydrocarbon is synthesized. The epoxides in the sex pheromone of the housefly (Blomquist et al., 1984) and the gypsy moth (Prestwich, 1987; Kasang, 1974) arise from the insertion of an oxygen into a preformed alkene. Similarly, the carbonyl group in the (*Z*)-14-tricosene-10-one pheromone component of the female housefly arises from the insertion of an oxygen into a preformed chain. A cytochrome P-450 polysubstrate mixed function oxidase hydroxylates the carbon chain, and the secondary alcohol is then apparently oxidized to the ketone (Ahmad et al., 1987).

Assuming that the methyl ketone pheromone components arise from a preformed hydrocarbon, the enzyme(s) involved in synthesis of the pheromone would require a high degree of specificity for a 3,11-dimethylalkane branching

pattern but apparently are not as specific as to chain length. Only the 3,11-isomers were found in the methyl ketone fraction, but both heptacosanone and nonacosanone homologs were present. The absence of 3,11-dimethylhentria-cosane in the hydrocarbon profile and absence of the corresponding methyl ketone also suggests specificity of the enzyme for a 3,11- isomer. Indeed, the ratio of 3,11-dimethylheptacosanone to its hydrocarbon analog (4.4) is similar to the ratio of 3,11-dimethyl-2-nonacosanone to its hydrocarbon analog (4.3), suggesting equal efficiency in conversion of both hydrocarbons to their respective methyl ketones.

It appears that only adult females have the enzymes necessary to synthesize the methyl ketone pheromone. Both 3,11-dimethyl C₂₇ and C₂₉ hydrocarbons are present in males, but apparently the enzyme system is not. We report different hydrocarbon composition profiles from that previously reported (Augustynowicz et al., 1987). Augustynowicz et al. (1987) found that the 11-, 13-, and 15-methylnonacosane isomers were most abundant (16.5%), followed by 3- (14.7%) and 5-methylnonacosane (10.4%). The 3,7-, 3,9-, and 3,11-dimethylnonacosane isomers made up 11.3% of the cuticular hydrocarbons. We report that in adult females the 3,7-, 3,9-, and 3,11-dimethylnonacosane isomers make up the largest group by percent composition (18.6%) followed by the 9-, 11-, 13-, and 15-methylnonacosane isomers (14.5%). In adult males the most abundant hydrocarbons were the 9-, 11-, 13-, and 15-methylnonacosanes (22.7%), whereas the 3,*x*-dimethylnonacosane isomers make up only 14.0% of the hydrocarbon fraction (Table 1). These differences between our results and those of Augustynowicz et al. (1987) are clearly due to the combining of male and female cockroaches in their analysis.

Acknowledgments—We thank Thomas Hartman and Roy Pancirov, Center for Advanced Food Technology at Rutgers University, and Roger Scholl (UNR) for use of the GC-MS facilities, and Ritsuo Nishida and Albert Burgstahler for generous gifts of synthetic 3,11-dimethyl-2-nonacosanone. (Received February 22, 1988; accepted April 4, 1988)

Abstract—Three years of field data in northeastern Nebraska demonstrate that a grain sorghum crop reduces weediness in the following crop year. Weed growth was consistently lower in sorghum areas the year after strip-cropping fields with sequences of four-row bands of grain sorghum, soybeans, and corn. Percentage weed cover was significantly lower early in the year, and midsummer weed biomass was well below that found after corn and soybeans. Weed biomass in June and July following corn was two to four times that of grain sorghum strips. Inhibitory effects of grain sorghum were primarily on broadleaf weeds, often showing no action on grass weeds. No obvious differences were noted in the weed species present after the three crops. Allelopathy provides a logical explanation for the sorghum-mediated weed inhibition found in this study. The data have implications for weed management strategies in agriculture.

Key Words—Allelopathy, grain sorghum, *Sorghum bicolor*, weed inhibition, weed management.

INTRODUCTION

Cultivated *Sorghum* species have a history of use in weed management. Overland (1966) noted that they were among those crops used as "smother crops," with the implication that they competitively suppressed weed populations growing during the same time period. Recently, Putnam et al. (1983) showed that grain sorghum [*Sorghum bicolor* (L.) Moench] and sudangrass [*Sorghum sudanense* (Piper) Stapf.] were useful cover crops for controlling weeds in orchards.

Residues from frost-killed sorghum planted in the intertree space in apple and cherry orchards inhibited weed growth. A sorghum \times sudangrass hybrid used in these studies reduced the weed biomass to less than 40% of that found without a cover crop. In annual cropping systems, planting without tillage into a desiccated cover crop of sorghum or sudangrass almost totally eliminated certain weed problems (Putnam and DeFrank, 1983). At least part of these effects were attributed to allelopathy.

Sorghum species contain a variety of water-soluble substances that can inhibit seed germination and seedling growth. Guenzi and McCalla (1966a) isolated substantial quantities of ferulic, *p*-coumaric, vanillic, syringic, and *p*-hydroxybenzoic acids from decomposing *S. bicolor* residues. Subsequent work indicated phytotoxicity from these compounds could persist in field conditions for at least 28 weeks (Guenzi and McCalla, 1966b; Guenzi et al., 1967). Lehle and Putnam (1983) found inhibitory activity from several chemical fractions separated after aqueous extraction of herbage from *S. bicolor* cv. Bird-a-boo, and these fractions included more than phenolic acids. Phytotoxicity from germinating seeds, root exudates, and aqueous extracts of foliage has also been reported from other *S. bicolor* cultivars (Hussain and Gadoon, 1981; Panasiuk et al., 1986). Extracts from various organs of *S. vulgare* Pers., a forage crop, and Johnson grass, [*S. halepense* (L.) Pers.], a troublesome weed, contain allelopathic chemicals (Alsaadawi et al., 1986; Abdul-Wahab and Rice, 1967). The latter produces dhurrin and taxiphyllin, two cyanogenic compounds which yield HCN and *p*-hydroxybenzaldehyde upon hydrolysis (Nicollier et al., 1983). Apparently a variety of compounds may contribute to any suspected cases of *Sorghum* allelopathy.

Agricultural weed control alternatives to the present commercial herbicide-dominated programs are now being given wide consideration (Einhellig and Leather, 1988). As noted, there is compelling evidence that planting into a sorghum cover crop residue may provide weed control. Weed suppression has also been obtained when fall-seeded alfalfa immediately follows a summer *Sorghum* forage (Forney et al., 1985). What is less well established is the year-to-year carryover weed-control capability of a sorghum crop. Hence, these investigations were undertaken to determine the impact of *S. bicolor* on the weed population in a subsequent year. Their initiation was stimulated from observations in a working farm situation.

METHODS AND MATERIALS

Field Site. The study sites were located on a farm in northeastern Nebraska, known locally as the Gary Young farm (South Half of 3129, One West, Cedar County, Nebraska). Soils of this area are Peoria loess and are deep, well-drained, and eroded (Milliron, 1985). The history of the fields was well docu-

mented, and there was no record of herbicide or commercial fertilizer application. In the study years, crops were planted using a no-till approach, and no herbicide, pesticide, or fertilizer were employed. Data from the first year (1985) were from a field with Nora silty clay loam with 6–11% slope. The other two years' data were collected from two fields with Moody silty clay loam soil, 2–6% slope. Both soil types are closely related and are described as being suited for dry land corn, soybeans, oats, and alfalfa. Our soil analysis showed 29% clay with a pH of 7.1 for the first year field, and 27% clay, pH 6.9, for the latter years. These analyses are in agreement with the county soil survey (Milliron, 1985).

The data collection plan for the first year was to analyze weed conditions the year after fields had been strip cropped with alternating, four-row bands of grain sorghum [*Sorghum bicolor* (L.) Moench] and soybeans [*Glycine max* (L.) Merr.]. In the next two years, corn (*Zea mays* L.) was added as a third crop in the strip-cropping sequences. Crops were planted on a 38-in.-row spacing, and the cultivars of the crops planted were different each year. Early weed cover the following year was obtained from sampling the entire field. Biomass sampling of weeds later in the season was obtained from within adjacent 12-m lengths of the former strip crops, which were left unplanted during the sampling year.

Data Collection. The point-contact method was used to quantify weed cover in May of the year after the crops (Crockett, 1964). Sampling was conducted using a point frame with 10 contact points spaced 10 cm apart. Each previous crop area was systematically sampled with 50 point frames, making a total of 500 points. Care was taken to avoid sampling the edges of the strip plots. Points hitting aerial cover of grass and broadleaf weeds were recorded. The data were analyzed by considering each point frame as a sample. Differences between the treatments in grass weeds, broadleaf weeds, and total weed cover were ascertained using analysis of variance (ANOVA) with Duncan's multiple-range test.

Later in the growing season (June and July), systematic sampling of above-ground weed biomass involved clear-clipping five 0.5-m² quadrats in each of the undisturbed prior-year crop areas. Weeds were separated into grass weeds and broadleaf weeds, and dry weights were obtained after 48 hr at 105°C. Statistical comparisons of the grass, broadleaf, and total weed biomass components between crop areas were made using ANOVA as previously described.

RESULTS

Data from all three years of this study demonstrated that the nature of the crop species in one year influenced weed growth in the subsequent year. Weed reduction in areas where grain sorghum had been the previous year was often

apparent from visual inspection. During the first year of data collection, 1985, the weed population was monitored in a field which had been cropped in 1984 with alternating bands of grain sorghum and soybeans. When the field was viewed in early May 1985, strips where the soybeans had been the previous year were quite green, compared to a more barren appearance in the grain sorghum strips.

Point-frame sampling data obtained on May 7 established that grain sorghum strips had about one fourth the weed cover found in the soybean rows (Figure 1). Both grass and broadleaf weeds were significantly less where sorghum had grown the year before. By May 28, the aerial weed cover in the sorghum strips was 80% of that found after soybeans, a differential that was not statistically different. However, ANOVA showed that the broadleaf component of this weed cover was still significantly lower in grain sorghum. Visual observations at this time also suggested that the weed biomass was much less in sorghum strips.

Weed biomass in quadrats sampled on June 18 averaged 27 g for prior sorghum areas, compared to 48 g in soybeans (Figure 1). The biomass of broadleaf weeds in soybean areas was two and one-half times that of sorghum,

FIG. 1. Effects of the prior year (1984) crop on weed abundance in 1985. S = grain sorghum; SB = soybeans. Bars within each sampling date having different letters are significantly different, $P < 0.05$, ANOVA with Duncan's multiple-range test.

whereas grass weeds were significantly higher in the sorghum. Sampling in July still showed grain sorghum strips had less weed biomass, but there was much more variability among quadrats, and the difference in total biomass between the treatments was not significant. *Setaria* spp. appeared to make up a greater component of the weeds found in sorghum strips. Other species noted in both areas included *Polygonum pensylvanicum* L., *Kochia scoparia* (L.) Schrad., *Lactuca serriola* L., *Solanum rostratum* Dun., *Ambrosia trifida* L., *Amaranthus retroflexus* L., *Convolvulus arvensis* L. and *Physalis subglabrata* Mackenz. & Bush.

Fields in the second and third year had corn added to the strip cropping so that comparisons might be made with a crop where there would be no question about effects from residual nitrogen fertility. At each of the sampling dates in both 1986 and 1987, the weed growth was significantly lower in strips of the prior year sorghum than either soybeans or corn (Figures 2 and 3).

FIG. 2. Effects of the prior year (1985) crop on weed abundance in 1986. S = grain sorghum; SB = soybeans; CO = corn. Bars within each sampling date having different letters are significantly different, $P < 0.05$, ANOVA with Duncan's multiple-range test.

FIG. 3. Effects of the prior year (1986) crop on weed abundance in 1987. S = grain sorghum; SB = soybeans; CO = corn. Bars within each sampling date having different letters are significantly different, $P < 0.05$, ANOVA with Duncan's multiple-range test.

Weed cover from all weeds in grain sorghum areas early in the 1986 season was approximately one third of that found after soybeans, and one half that following corn (Figure 2). This was also the pattern seen for the differences in broadleaf weeds among the three treatments, whereas grasses were not significantly different between sorghum and corn. At the second sample, weed cover in grain sorghum was 40 and 45%, respectively, of that in the prior year soybean and corn. These differences reflected the significant reduction in broadleaf weed cover following grain sorghum. In contrast, grass weed cover in corn was slightly less than in the other two prior crops. Data from both June and July showed a significant reduction in weed biomass after grain sorghum (Figure 2). The total biomass in grain sorghum plots on June 20 was approximately one third of that found after corn, and on July 24 these same areas were 54% of corn plots. Essentially all of these differences were in the broadleaf component of the biomass. No marked differences in the species composition among the three treatments were observed.

In the third year, treatment effects on weed abundance early in the season could not be as readily seen as they had been in the other two years. However, data obtained on May 7 showed aerial weed cover was significantly lower in the prior year grain sorghum areas than either of the other two crops (Figure

3). Favorable temperatures resulted in very rapid early weed growth in 1987, so a second assessment of cover was not obtained. In June, it was easy to see the contrast between grain sorghum and the other two treatments. Although grain sorghum plots had less weed growth, the distribution of species appeared similar across the three areas, and these were similar to previous years. Grain sorghum quadrats on June 25 averaged less than one third the weed biomass found in plots of the prior year corn or soybean (Figure 3). All of the biomass difference was from a suppression of broadleaf weeds. The July corn quadrats had more than four times the biomass of the grain sorghum quadrats, and at this sampling corn areas supported more weed biomass than the soybean areas.

DISCUSSION

The data show weed abundance in the year following grain sorghum was markedly suppressed in comparison to the weed conditions after either corn or soybeans. These results were obtained in the absence of tillage. The impact of grain sorghum was not an absence of weeds, but one of delayed emergence and growth inhibition. Total biomass accumulation late in the season was well below that which occurred in the nonsorghum areas. The reproducibility of these results is evidenced by the fact that they occurred in three different fields and with variations in moisture (Table 1) and other climatic conditions over the three year study.

Edaphic factors do not provide a logical explanation for the reduction in

TABLE 1. MONTHLY PRECIPITATION (cm) BETWEEN CROP PLANTINGS AND SUBSEQUENT YEAR SAMPLING PERIOD

July	3.8	3.1	11.5
14-Month total	94.3	80.7	103.3

weeds the year after grain sorghum, since the test areas were side-by-side strips having the same soil type and receiving a comparable quantity of moisture. It is possible that weed germination in soybean areas could have been stimulated by nitrates that might be higher in these areas (Roberts and Smith, 1977; Vincent and Roberts, 1977). This might account for the greater weed cover in soybeans than corn plots in 1986. It cannot explain the fact that weed cover in the corn was still more than twice that found following grain sorghum. If there was any bias of the physical conditions between the corn and grain sorghum areas, it was that the former had a more extensive surface cover of crop residue than occurred with grain sorghum, and this might be expected to slightly delay soil warming in the corn plots. In spite of this, early emergence and subsequent growth of weeds was greater where corn had been.

Allelopathic conditions from grain sorghum as the donor plant must be considered as a major factor in the weed inhibition. We suspect that no one compound mediates this allelopathy, but that it is the result of the collective action of several compounds (Einhellig et al., 1982; Lehle and Putnam, 1983; Einhellig, 1987). The focus of this research was not on isolation and identification of the allelochemicals, but it is likely they included cyanogenic glycosides and a variety of phenolic acids and aldehydes that have been previously reported (Guenzi and McCalla, 1966a; Martin et al., 1938).

The extent of any sorghum-mediated allelopathy will be influenced by environmental conditions, both with regard to production of allelochemicals and seasonal carryover. The level of accumulation of many phenolic and coumarin allelochemicals in a plant is influenced by plant age, light intensity, and numerous stress conditions (Woodhead, 1981; Lehle and Putnam, 1982). Rainfall could be important to the persistence of allelochemicals into the next crop year. However, the data over the three years showed similar effects in all years even though the second year was drier than the others. It is possible that the heavy rainfall in March of the third year may have reduced the degree of difference in weed cover among the plots in May of 1987.

Recognition that under no-till conditions *S. bicolor* can suppress weeds in the year following the crop has potential applications in agriculture. Any such application strategies should be tested with intended tillage operations, crop cultivars, rotation sequences, and climatic and soil conditions of the region. It has also been shown that some allelochemical inhibitions can work in conjunction with commercial herbicides (Einhellig, 1987). Hence, grain sorghum might be used in a crop rotation sequence either with or in the absence of other weed control measures. In any case, the planned use of a grain sorghum crop as a provision for weed management could reduce reliance on herbicides.

Acknowledgments—The authors wish to express their thanks and gratitude to farm owner Gary Young for his cooperation in providing the field requirements for this project. We also thank

Sondra Goodman, Small Farm Resources Project, Center for Rural Affairs, Hartington, Nebraska, for her assistance in the first year of the project.

(Received December 16, 1987; accepted April 11, 1988)

Abstract—We tested the hypothesis that the monoterpenoid levels in the ingesta from various digestive organs of sage grouse are less than that expected from the big sagebrush leaves ingested. Results supported the hypothesis. Dramatic reductions occurred between the gizzard and duodenum. Monoterpenoid levels in the ceca were nil; thus adverse effects of monoterpenoids on ceca microbes would also be nil.

Key Words—volatile oils, essential oils, digestion, *Centrocerus urophasianus*, big sagebrush, *Artemisia tridentata*, sage grouse.

INTRODUCTION

Monoterpenoids (volatile or essential oils) have bacteriostatic and bactericidal activity (Nicholas, 1973; Nagy and Regelin, 1977). Before the discovery of antibiotics, microbiologists had studied these compounds to determine their usefulness as prophylactic agents. Because of the antimicrobial nature of monoterpenoids, researchers in the sixties and seventies became concerned about the possible adverse effects terpenoid-producing plants such as big sagebrush (*Artemisia tridentata*) might have on ruminant and cecal microorganisms' cellulolytic digestive abilities (Nagy et al., 1964; Oh et al., 1967, 1968; Dietz and

¹The use of trade or firm names in this paper is for reader information and does not imply endorsement by the U.S. Department of Agriculture of any product or service.

Nagy, 1976; Wallmo et al., 1977). These concerns ignored two important points. The first was the large amount of big sagebrush consumed by wintering wildlife species such as mule deer (*Odocoileus hemionus hemionus*), pronghorn antelope (*Antilocapra americana*), pygmy rabbit (*Brachylagus idahoensis*), and sage grouse (*Centrocercus urophasianus*) without any apparent harmful effects (Leach, 1956; Severson et al., 1968; Kufeld, 1973; Tueller, 1979; Green and Flinders, 1980; Remington and Braun, 1985). The second was the volatile nature of monoterpenoids.

Detrimental effects on wintering wildlife species as a result of heavy big sagebrush consumption has yet to be demonstrated outside the laboratory. Due to the high volatility of monoterpenoids, their levels in ingesta of wintering pygmy rabbits and mule deer were 23% and 20%, respectively, of expected levels (White et al., 1982b; Cluff et al., 1982). This would greatly reduce the harmful effects of the monoterpenoids on cellulolytic digestion by rumen or cecal microbes. One probable reason for the reduction is thorough mastication of the big sagebrush tissues by these animals. This would aid in the volatilization and loss of monoterpenoids from the digestive tract (Welch and Pederson, 1981; White et al., 1982b). But what about nonmasticating animals such as sage grouse, whose winter diets are nearly 100% big sagebrush leaves (Remington and Braun, 1985)? Have sage grouse evolved other types of mechanisms that reduce the levels of monoterpenoids in their ingesta, or have they evolved cecal microbes that are tolerant of monoterpenoids? The first step in finding answers to these questions is to demonstrate whether or not a reduction of monoterpenoids occurs in the ingesta. The purpose of this study is to test the hypothesis that the monoterpenoid levels in the ingesta from various digestive organs of sage grouse are less than expected from the big sagebrush leaves ingested.

METHODS AND MATERIALS

We used a two-phased procedure to test our hypothesis: (1) determine the monoterpenoid concentration of sage grouse ingesta from the various organs of the digestive tract, and (2) establish a baseline concentration of monoterpenoids in whole leaves of fed-on big sagebrush plants. For the first phase, we collected five wintering sage grouse from a flock feeding on a Wyoming big sagebrush (*A. t. ssp. wyomingensis*) flat about 15.6 km west of Loa, Utah (section 30, R2E, T27S). The birds were shot between 1200 and 1400 hours during mid-February 1984. We chose those times because the birds should by then be between their morning and evening feedings—when, we believe, the crop would be emptied and the gizzard full. After a bird was killed, it was frozen with dry

ice and placed in a cooler filled with snow for transporting to a laboratory freezer.

To obtain ingesta samples, the birds were thawed for about 8 hr. Breast muscles and sternum next to the keel along with other tissues were cut to allow removal of the windpipe, heart, lungs, liver, and the digestive tract. The digestive tract was isolated from the other organs and quickly washed in cold tap water. The mesentery was cut to allow for the separation of the various digestive organs. Ingesta were removed from the gizzard, duodenum, small and large intestine, and cecum. With the exception of the gizzard, ingesta from the other organs were pooled into one sample for each organ. At the time of pooling, we were concerned there would not be enough dry matter from individual bird organs to allow for extraction and monoterpene analyses. This proved to be true; however, enough dry matter was in the ingesta of the gizzards to allow separate bird analyses.

Ingesta were placed in beakers (250 ml) and thoroughly mixed. About 20% of the ingesta from each sample was removed for dry matter determination. The weights of the remaining ingesta were determined and placed in 250-ml Erlenmeyer flasks. Then 150 ml of absolute ether was added to the flasks to extract the monoterpenoids. The flasks were rotated in a shaker at 215 rpm for 2 hr. Separatory funnels were used to separate water from the ether extractions. Next, the extracts were concentrated to 20–30 ml by reduced pressure. One milliliter of a carvone standard (31.25 g/250 ml) was added. Absolute ether was then added to bring the volume of each sample to 50 ml. We stored extracts in airtight polyethylene bottles at -35°C until chromatographic analyses.

Chromatographic analyses were achieved with a 5830A Hewlett-Packard flame ionization, reporting gas chromatograph. Monoterpenoids were separated by use of a 120-cm \times 3-mm stainless-steel column packed with 10% Carbowax 20 M on 80–100 chromosorb WHP. Temperature programming (Table 1) was used to separate individual monoterpenoids. We identified monoterpenoids through retention times of standards. Dry matter content of each sample was determined, and the concentration of individual monoterpenoids was expressed as a percent of dry matter.

For the second phase, establishment of baseline monoterpene concentrations in the food, we collected vegetative samples in the same area where we had collected the sage grouse. The birds had been occupying this area for four to five weeks prior to sample collecting and had fed on most of the big sagebrush plants. Whole leaves were needed for establishing the baseline values. Because of the small size of the big sagebrush plants and heavy use by the sage grouse, there were not enough whole leaves per plant to allow individual plant monoterpene analyses. Instead, from 250 fed-on Wyoming big sagebrush plants, a single vegetative current year's stem with leaves was removed. The

TABLE 1. GAS CHROMATOGRAPHIC PARAMETER SETTINGS USED TO SEPARATE AND QUANTIFY INDIVIDUAL MONOTERPENOIDS^a

Parameter	Setting
Initial oven temperature	70°C
Initial time	1.0 min
Initial temperature rate	5.0°C/min
Programmed temperature rate changes	
At 2.5 min	1.0°C/min

Flame ionization detector temperature	250°C
Maximum oven temperature	225°C

^a Area rejection mode was used to reject the solvent (absolute ether) peak.

collecting of vegetative samples occurred seven days after collecting the birds. All 250 stems were pooled in a plastic bag, frozen with dry ice, and transported to laboratory freezers in a cooler filled with snow.

We separated frozen whole leaves from stems with a pair of small surgical scissors. Detached leaves were frozen by placing them inside a 1-liter, stainless-steel, wide-mouth vacuum bottle filled with 500 ml of liquid nitrogen. After removal from the stems, the leaves were poured out of the vacuum bottle into a strainer. After the liquid nitrogen evaporated, the leaves were placed in a plastic bag, sealed, and stored in a freezer until needed for grinding.

Grinding of whole leaves was accomplished by placing the leaves inside the mortar of a steel, motorized mortar and pestle. The mortar and pestle were precooled twice with liquid nitrogen. Liquid nitrogen was then poured over the leaves and the leaves ground to a fine powder. After grinding, the leaf material was placed in a polyethylene bottle fitted with an airtight cap and stored in a laboratory freezer until needed for monoterpene analysis.

A Soxhlet extraction apparatus with absolute ether was used to extract the monoterpenoids. Ten grams of leaf tissue were placed in a cellulose Soxhlet extraction thimble. A fiberglass plug was placed on top of the sample to prevent spillage during the extraction process. Monoterpenoids were exhaustively extracted from the leaf tissues over a 6-hr period. Next, the volume of the extract was reduced to about 20–30 ml by reduced pressure. An internal standard of carvone was added as described, then the extract brought to 50 ml

volume and stored in a freezer until needed for chromatographic analyses. Analyses for leaf monoterpenoids were the same as previously described.

Unfortunately, due to the pooling of ingesta and leaf samples, statistical analyses could not be performed on this data set. Nevertheless, meaningful general comparisons between baseline monoterpenoid levels of leaves and levels in ingesta can be made.

RESULTS

Results of the monoterpenoid analyses are given in Table 2. From a qualitative and, in general terms, from a quantitative point of view the monoterpenoid profile of the leaves matches the monoterpenoid profile of ingesta from the gizzards. This supports the assumption that the plants sampled were the same as those on which the birds were feeding.

Of the 81 digestive tract observations of individual and total monoterpenoid concentrations, 32 observations showed no detectable amounts of monoterpenoids, 39 observations were lower than the baseline concentration of leaves, 2 were the same, and 8 above the baseline (Table 2). Loss of monoterpenoids occurs early in the digestive process. Reduction of total monoterpenoids of ingesta from the gizzards was 36% of the total monoterpenoids found in the leaves. Ingesta from the duodena and ceca contained no detectable amounts of monoterpenoids. Small and large intestine ingesta contained only 1 and 8%, respectively, of the monoterpenoids of leaves.

DISCUSSION

The data presented in Table 2 show that dramatic reductions in the level of monoterpenoids occur. The reduction starts early in the digestive process in the gizzard where big sagebrush leaves are ground into small fragments.⁴ Ceca monoterpenoid levels were below detectable levels, perhaps even entirely absent from the ingesta. At any rate, the probable impacts of big sagebrush monoterpenoids on ceca microbes' cellulolytic digestive abilities are nil. These observations and conclusions are supported by four reports: Welch and Pederson (1981), Cluff et al. (1982), White (1982b), and Foley et al. (1987).

During *in vitro* digestion trials, Welch and Pederson (1981) observed loss of monoterpenoids. They added specific amounts of α -pinene (one of the most

⁴Remington and Braun (1985) described the gizzard of sage grouse as a nongrinding gizzard. The gizzard receives nearly whole (90% or more) leaves from the crop and grinds the leaves into fragments. What they probably meant to say was that the gizzard of sage grouse is a nongrit grinding gizzard and not capable of breaking down hard foods such as seeds.

^aData expressed on a dry matter basis. No statistical test could be performed on this data set. Duodenum, small and large intestine, and ceca samples were pooled from five sage grouse. Food sample was pooled from single branches taken from 250 fed-on plants (whole leaves only).

^bUnknown monoterpene; number represents retention time in minutes.

volatile monoterpenoids) and camphor (one of the least volatile) to three digestive tubes containing only buffer. After the first incubation period, they measured the monoterpenoid levels in the three tubes. They found that all of the α -pinene added to the flasks was lost through the one-way valves into the atmosphere. Camphor loss was 17.3%. Before extracting the two monoterpenoids from the flasks, the two researchers noted a white condensate ring around the neck of the three flasks. This condensate ring was about 70 mm above the surface of the digestion solution (in this case buffer) and was identified as camphor. They concluded that, first, the force that drove the two monoterpenoids from the solution was the heat of the water bath—in other words, normal body temperature is sufficient to volatilize monoterpenoids; and second, monoterpenoids in the rumen of mule deer could be reduced through mastication, rumination, eructation, and possibly by absorption and excretion. Cluff et al. (1982) reported an 80% reduction between the monoterpenoid levels in the rumen ingesta of wintering mule deer and the levels expected from the ingested forage. White et al. (1982b) reported similar reduction for stomach ingesta from wintering pygmy rabbits; they also reported large monoterpenoid losses during mastication. Foley et al. (1987) reported similar results for the greater glider (*Petauroides volans*) and brushtail possum (*Trichosurus vulpecula*) but discounted losses due to mastication.

Sage grouse consume big sagebrush leaves whole, and thus the only probable pathway for reducing monoterpenoids from the digestive tract of a non-masticating, nonruminating, and probably noneructating animal is through absorption, probably at the gizzard and either elimination or assimilation (Cook et al., 1952; Alexander and Chowdhury, 1958). Igimi et al. (1974) found that radioactive limonene, a monoterpene, rapidly disappeared from the stomach of rats. Also, Narjisse (1981) was unable to detect monoterpenoids in the rumen ingesta of goats 3 hr after direct infusion. Rapid absorption of monoterpenoids across the mucosa of the stomach and gizzard of both ruminants and hindgut fermenters is highly possible.

Another way that sage grouse could reduce the amount of monoterpenoids in the ingesta is through diet selection, that is, selecting big sagebrush plants that have lower concentrations of monoterpenoids. Remington and Braun (1985) suggest that wintering sage grouse preferred Wyoming big sagebrush (*Artemisia tridentata* ssp. *wyomingensis*) over mountain big sagebrush (*A. t.* ssp. *vaseyana*).⁵ Wyoming big sagebrush contained lower concentrations of mono-

⁵We do not fully accept the interpretation of the data presented in the Remington and Braun (1985) report concerning the preferential use of Wyoming big sagebrush over mountain big sagebrush by wintering sage grouse. Data in their Table 1 suggest two to one that the use of Wyoming and mountain big sagebrush is a function of occurrence and not palatability differences between the two kinds of big sagebrush. We believe their random sample method is biased because portions of mountain big sagebrush grow at the bottom of draws where sage grouse seldom feed. Consequently, part of their perceived preferential use could be due to feeding habit differences and not to palatability differences.

terpenoids than mountain big sagebrush. They did not detect differences in monoterpenoid concentrations among browsed, unbrowsed, and random plants within the two types of big sagebrush. Welch et al. (1983) reported that monoterpenoid content of various accessions of sagebrush taxa was not significantly related to wintering mule deer preference. Also, White et al. (1982a) reported no significant correlation between monoterpenoid content and dietary preference of pygmy rabbits for big sagebrush. The case for sage grouse selecting for big sagebrush plants lower in monoterpenoids is shaky, but still viable enough to need more investigation.

Beck and Braun (1978) reported that sage grouse gain weight during the winter months. This winter weight gain is probably due to the interaction of four factors: (1) the relatively high digestibility of winter tissues of big sagebrush (Welch, 1983); (2) the reduction to near zero of monoterpenoid within the cecum (this study); (3) the relatively large volume of the sage grouse cecum in comparison to other birds (Leopold, 1953); and (4) a probably high turnover rate of foodstuff (a guess).

In summary, data presented support our hypothesis that the monoterpenoid levels in the ingesta from various digestive organs of sage grouse are less than expected from the big sagebrush leaves ingested.

(Received January 6, 1988; accepted April 11, 1988)

Abstract—In order to assess the possible function of pulsed release of wind-borne pheromones, calculations were performed to predict the concentration pattern downwind of the source. Two patterns of pulsed releases (sinusoidal and instantaneous) were compared to a constant release pattern. In all three cases, the average rate of release was the same. Assuming the receiving animal needs only a momentary exposure to concentrations above threshold to respond, it is clear that sinusoidal release has a greater distance of detection than constant release and that instantaneous release is even better. The relative magnitude of the increase in range of detection depends on the ratio of average release rate to threshold concentration. Pulsed releases have a greater advantage when the threshold is high and the range of attraction is inherently short. Under these conditions, sinusoidal release can double the range of attraction and instantaneous release can increase it 10-fold. In contrast, with a low threshold and consequent long range of attraction, the pulsed patterns are lost and the increase in range is insignificant. Several testable predictions are derived from the hypothesis that the primary function of pulsed release is to extend the range and time over which a given quantity of pheromone can act.

Key Words—Pheromone, plume, pulsed release, moth.

INTRODUCTION

There has long been speculation about whether animals transmit information via temporal patterning of chemical release (Bossert, 1968). It has been shown that certain simple organisms such as slime molds and nematodes can make use of a temporal pattern of a diffusing stimulus (Robertson and Drage, 1975; Dusenbery, 1988). It has also been demonstrated that the females of certain

moth species release sex attractants in a pulsed manner (Conner et al., 1980) and that males respond better to fluctuating than to constant concentrations (Baker et al., 1985). Although many possible functions for this behavior have been suggested, there are few reports of tests of specific functions. Among these few are a report that pulsing increases the rate of release, although this function may be limited to species that have an unusually high concentration of pheromone (Schal and Cardé, 1985), and a report that there was not improved orientation to the plume from a pulsed source (Cardé et al., 1984).

A straightforward hypothesis of the function of pulsed releases of pheromone is that they extend the range of attraction possible with a given average rate of release. This hypothesis is based on the assumption that a male moth needs only momentary exposure to pheromone concentrations above threshold to know there is a female upwind. Consequently, the greatest range of attraction is the greatest range at which the concentration is above threshold, even if only for a brief time (Aylor et al., 1976).

METHODS AND MATERIALS

The specific questions addressed here are: how much can the range of attraction be increased by pulsed release, and is the increase biologically significant? Precise answers cannot be obtained because of the effects of atmospheric turbulence. However, if uniform flow without turbulence is assumed, some relatively simple calculations can give an indication of what is possible. Specifically, the results should give a good indication of the relative advantage of pulsed release, since concentrations in a turbulent flow should all be proportional to the concentration at the source.

The calculations are based on the following parameters: The diffusion constant is 2×10^{-5} m²/sec, which is appropriate for molecular diffusion of a small molecule in air; the wind speed is 0.5 m/sec; and the pulse frequency is 1 Hz, which is close to what is commonly found in moths (Conner, 1985). Three patterns of pheromone release are compared—all with the same average rate of release:

1. Constant release at a fixed rate. Calculations were based on equation 3 of Roberts (1923).
2. Pulsed release according to a sinusoidal pattern that goes to zero momentarily, i.e., 100% modulation. Calculations were based on Bossert's equation 10 (1968) with an extra factor of 2 in the denominator so as not to assume reflection from the ground. (A square wave pattern would give rise to similar results.)
3. Release in instantaneous pulses much shorter than the time between pulses. Calculations are based on equation 2 of Roberts (1923) for a single

pulse. The distribution for a sequence of pulses was determined by adding the contributions of neighboring pulses. This procedure is mathematically rigorous (Crank, 1975, p. 11). The equation assumes an infinitely short pulse but will apply reasonably well to any pulse that is much shorter than the time between pulses after enough time has elapsed for the pulse to start spreading by diffusion (about 0.001 sec for a source size of 0.3 mm).

The pattern of concentration distributions at various distances along the axis of the plume for the three different types of sources is shown in Figure 1. Within a few meters of the source, instantaneous release produces much higher concentrations than the other two types of release. The sinusoidal release produces maxima that are, at most, twice the concentration of constant release. A

FIG. 1. Patterns of pheromone distribution. Intensity (sec/m^3) is concentration divided by the average rate of release. The solid line is for instantaneous release. The dashed line is for sinusoidal release. The dotted line is for constant release.

few hundred meters downwind, diffusion has smoothed out both types of pulsed releases so that the peaks are only fractionally higher than constant release. At this range, pulsing of the source makes relatively little difference.

The effect of pulsing on the detection distance is addressed directly in Table 1. The effect varies greatly depending on the ratio of threshold concentration to average rate of release. If the threshold is high so that the range of detection is inherently short, then pulsing can have a major effect. Sinusoidal release can double the range, and instantaneous release can increase the range an order of magnitude. If the threshold is very low, so that the range of detection is inherently long, then pulsing has very little effect on the range.

The actual ranges calculated should not be taken too seriously. In the natural environment, turbulence will tear the plume apart. The juxtaposition of pure air with air containing pheromone will increase the concentration gradients and speed up the diffusion process. However, it is now known that the use of "eddy diffusion constants" (based on average concentrations over several minutes) is a very poor approximation for biological receptors (that average over less than a second) because under natural conditions, concentrations downwind of a source fluctuate orders of magnitude in fractions of a second (Jones, 1977; Storebø et al., 1983; Murlis, 1986). However, the peak concentrations observed at any location should be proportional to the peak concentrations at the source. In view of this, the best interpretation of the above calculations is probably to consider them as setting an upper limit on what can occur in nature.

RESULTS AND DISCUSSION

The above calculations suggest that under certain circumstances pulsed releases can have a dramatic impact on the range of detection. If the primary function of pulsed releases is as hypothesized, a variety of predictions follow:

TABLE 1. MAXIMUM RANGE OF DETECTION

Threshold (sec/m^3) ^a	Range (m) for release patterns		
	Constant	Sinusoidal	Instantaneous
10,000	0.4	0.8	4.3
1,000	4.0	7.8	19.9
100	40	66	92
10	398	425	445

^aThreshold is measured in terms of the ratio of concentration to the average rate of release.

1. Pulsed releases should occur in species that have a relatively short range of communication based on amount released by the female and the sensitivity of male.

2. It should be possible for males to detect a pulsed source further away than a constant source with the same average rate of release. The data of Cardé et al. (1984) suggest pulsed sources with one third the average rate of release of a constant source were just as effective.

3. Males may respond under conditions where average concentrations are below threshold. This has been observed (Elkinton et al., 1984).

4. There is no reason to expect a pulsed plume to be easier to follow than a constant one. It has been proposed that a pulsed source might be easier to locate than a constant one, but tests have failed to demonstrate this (Cardé et al., 1984; W.E. Conner, personal communication).

5. The optimal pulse rate is probably of the order of magnitude of 1 Hz. The faster the rate, the faster diffusion evens out the pulses and the shorter the range over which pulsing is an advantage. Also, there is no point in pulsing faster than the adaptation time of the male's receptors, which is probably about 0.1 Hz. On the other hand, the slower the rate, the harder it will probably be for males to follow the plume. The optimum is probably close to the time scale of natural fluctuations due to turbulence in the atmosphere. This is in the range 0.1–1 sec (Murlis, 1986), which is also the range of pulse rates that are commonly observed (Conner et al., 1985).

6. There would be no purpose served by temperature compensation of the pulse rate. Therefore, one would predict that it would vary with temperature, as do most physiological processes ($Q_{10} \approx 2$). This has been observed (Conner et al., 1985).

7. It is not clear whether pulse rate should be expected to be adjusted for wind speed. Assuming the source is fixed in position, in different winds, pulse rate might be adjusted to maintain constant spacing between pulses (to maintain a fixed range at which the pulse pattern damps out or to maintain a maximal distance between peaks at which male orientation is successful). To do this, the pulse rate should be proportional to wind speed. This is approximately observed for *U. ornatrix* (Conner et al., 1985). Other species do not show a change in pulse rate with wind speed. However, those that call at dusk (when wind speed is relatively high) seem to pulse at a rate nearly twice that of those that call at dawn (when wind speed is generally lowest).

8. It is advantageous to release pheromone in short pulses in contrast to sinusoidal or square-wave patterns. To the extent this is physiologically practical, this pattern should be observed, although there is no advantage to pulses shorter than the adaptation time of the male receptors. Extreme cases of pulsed release might give males problems in locating the female at close range. How-

ever, at close range, constant release of a very low level (say 1%) would solve the problem. Thus, one might predict that the optimal pattern of release is short pulses superimposed on a low level of constant release.

9. There should be a limiting relationship between threshold, rate of release, rate of diffusion, rate of pulsing, and wind velocity, such that the effect of pulsing is still present at the range of maximum detection.

Clearly it is possible to test the hypothesis that the primary function of pulsed release is to extend the range and time over which a given quantity of pheromone can act. There are already some observations that favor it over alternatives, but more experimental work is required.

Acknowledgments—I wish to thank W.E. Conner for generously sharing his unpublished data on this topic and T. Eisner for providing support during a sabbatical year at Cornell.

MEASURING PLANT PROTEIN WITH THE BRADFORD ASSAY

1. Evaluation and Standard Method

Abstract—The suitability of the Bradford protein assay for measuring plant protein was evaluated and a standard method developed. The assay involves extraction of dried, fresh, or frozen plant material in 0.1 NaOH for 30 min. Replicate 100- μ l aliquots of centrifuged supernatant are assayed with 5 ml Bio-Rad Bradford dye reagent (Coomassie brilliant blue G-250) diluted 1:4 and containing 3 mg/ml soluble polyvinylpyrrolidone. Absorbance at 595 nm is recorded after 15 min against a NaOH blank. Samples are calibrated against a ribulose 1,5-diphosphate carboxylase-oxygenase standard in NaOH. Procedures for plant preparation, extraction stability, the effects of phenol removal and quinone formation, and assay recovery are evaluated. Assay absorbance stability and techniques for increasing absorbance stability are reported. Changes in protein quality are briefly discussed.

Key Words—Soluble protein, Coomassie brilliant blue G-250, binding, leaves, extraction, spectrophotometry, protein assay.

INTRODUCTION

Foliar nitrogen concentration is an important variable in many ecological relationships (Mattson, 1980; Scriber and Slansky, 1981; Gnaiger and Bitterlich, 1984; Slansky and Scriber, 1985). Protein, particularly ribulose 1,5-

³Present address: University of Washington School of Medicine, WAMI Program, Health Sciences Center, Seattle, Washington 98195.

diphosphate carboxylase–oxygenase (RUDP), is often the dominant form of foliar N (Ellis, 1977). Other forms include inorganic N, free amino acids and polypeptides, nucleic acids, and secondary metabolites such as alkaloids, betalains, cyanide, and glucosinolates.

A number of methods are available for estimating protein concentrations. Some of these methods, such as Kjeldahl (Maynard and Loosli, 1969) or elemental analysis, are not protein-specific. Other methods have greater specificity for protein but were developed for animal tissues and physiological fluids where protein concentrations are high and concentrations of interfering components are low. In plants, protein N is in low concentrations (1–4%), and phenolics are ubiquitous. These compounds interfere with many of the assays that are based on reduction (i.e., copper reduction, Lowry et al., 1951; bicinchoninic acid, Smith et al., 1985; silver binding, Krystal et al., 1985; ultraviolet, Warburg and Christian, 1941/1942; biuret, Riegler, 1914). Other methods that use protein precipitation (i.e., TCA, Harborne, 1973; Bensadoun and Weinstein, 1976; amido black, Martin et al., 1985) or hydrolysis (ninhydrin, Marks et al., 1985; OPA, Peterson, 1983) involve multiple steps that are time consuming and have a number of other limitations.

An ideal method for estimating plant protein in ecological studies should be specific and sensitive to protein, insensitive to interference, cheap, rapid, simple, and compatible with field sampling. The Bradford protein assay (Bradford, 1976) seems to fulfill many of these requirements and is widely used for animal proteins (Bio-Rad Laboratories, 1985). The method is gaining popularity for ecological studies with plants (Hare, 1983; Faeth, 1985; Denno et al., 1986; Trumble et al., 1987). The assay depends upon the binding of Coomassie brilliant blue G-250 dye to protein to produce a complex absorbing at 595 nm. The dye exists in three forms; cationic, neutral, and anionic. Only the anion binds to protein. Anion is not freely present at the dye reagent pH but is generated in the presence of protein. The dye has specific binding requirements for macromolecules with specific reactive functional groups—primarily arginine and basic and aromatic amino acid residues. The dye will not react with free amino acids, low-molecular-weight polypeptides (less than about 6–10 peptides), or many other nitrogen-containing or proteinlike molecules (Compton and Jones, 1985). Protein must be solubilized for the assay. Here we evaluate the use of the assay for plant protein and present a standard method. In particular, we address methods of preparation of plant material, extraction of protein from plant tissues, and assay stability.

METHODS AND MATERIALS

Standard Method

1. Fresh or frozen plant material should be finely chopped and ground with mortar and pestle or blended in a centrifuge tube using a tissue homogenizer.

A ratio of between 10 and 100 mg fresh weight (FW) per milliliter 0.1 N NaOH (pH 12.8) should be used, depending on the approximate protein and water content [i.e., 1–50 mg dry weight (DW) equivalents/ml]. Use 25% of the NaOH volume initially for grinding and the remaining volume to wash material into a centrifuge tube. Frozen material may be ground in liquid nitrogen, the liquid N₂ allowed to evaporate, and the 0.1 N NaOH then added. Dried material should be ground in a Wiley mill or similar device (<60 mesh), then combined in a centrifuge tube with 0.1 N NaOH at a ratio of between 1 and 50 mg DW/ml, again depending on approximate protein content. Final samples should contain sufficient protein to be within the linear range of the assay (approximately 0.1–1.8 mg RUDP equivalents/ml).

2. Samples are agitated for 3 sec on a vortex mixer and left to extract for 30 min at room temp.

3. Samples are remixed (3 sec), centrifuged for 5 min at high speed (>5000g) on a bench centrifuge, and the supernatant solution is decanted and remixed (3 sec).

4. Aliquots (100 μ l) of three replicates per sample (CV is usually circa 10% with three replicates), or 100 μ l 0.1 N NaOH (blank) are each mixed (3 sec) in a test tube with 5 ml of 1:4 diluted Bradford dye reagent (Bio-Rad Laboratories) that has been filtered, stored, and diluted according to the Bio-Rad Laboratories Manual (Bio-Rad Laboratories, 1985), but has been modified by addition of 3 mg/ml soluble polyvinylpyrrolidone (PVP) (Sigma pharmaceutical grade; MW ~ 40,000).

5. After 15 min, an appropriate volume of each replicate is transferred to cuvettes (glass, quartz, or disposable polystyrene) or tubes. The absorbance at 595 nm is recorded against the dye reagent/NaOH blank using a single- or dual-beam spectrophotometer.

6. Samples are calibrated against a standard of RUDP (Sigma) in 0.1 N NaOH with three replicates of at least four sample concentrations that are within the linear range of the assay and that also span the anticipated range of sample protein concentrations.

7. If agglutination of dye-protein complex occurs before 15 min, rerun the assay using a one half or one fourth dilution of the original extract.

8. If agglutination before 15 min still occurs and/or if grinding and extraction of fresh samples proves difficult because of resins or oils, then consider acetone washing. Wash plant material with three aliquots of 100% acetone (1 ml/60 mg FW or DW equivalents). Centrifuge and discard supernatant, then extract with 0.1 N NaOH as above. Protein recovery should be determined by adding RUDP to some samples.

Methodology Used in Evaluation

With the following exceptions, methods were described in the standard methodology or in the results.

Plant Species. Field-collected or greenhouse-grown leaves or algal material of the following species were used to represent a diversity of plant taxa and foliar chemistry: *Cladophora* sp. (Bryopsidophyceae); *Matteuccia pennsylvanica* (L.) Todaro (Polypodiaceae); *Phragmites communis* Trin. (Poaceae); *Phaseolis vulgaris* L. var. NY State Light Red Kidney (Fabaceae); *Comptonia peregrina* (L.) Coult. (Myricaceae); *Tsuga canadensis* (L.) Carr. (Pinaceae); *Citrus sinensis* (L.) Osbeck var. Valencia (Rutaceae); *Platanus occidentalis* L. (Platanaceae); *Quercus alba* L. (Fagaceae).

Preparation of Plant Material. Fresh material was weighed and processed immediately after collection. The FW to DW conversion was determined from independent samples for samples processed fresh or frozen. Plant samples for flash-freezing were collected, weighed, and immediately placed into liquid nitrogen or Dry Ice-acetone. Samples were stored in these solutions or used immediately. Some flash-frozen samples were lyophilized on a LabConco FD-3 or FD-5 at $<25\ \mu\text{m}$, $< -50^\circ\text{C}$, and then reweighed. Air-dried samples were first weighed fresh and then dried to constant weight at 24°C .

Comparison of Plant Preparation Methods. Single leaves of *P. occidentalis*, *C. peregrina*, *C. sinensis*, or *M. pennsylvanica* were split in half longitudinally along the mid-rib and the paired leaf halves compared. *P. communis* leaves were split in half horizontally across the mid-rib and the two halves compared. In addition, for all species, leaves were collected and mixed either by selecting for uniform size, age, and position on the plant or by randomizing by these variables. Random subsamples were taken from the mixture after preparation.

Extraction of Plant Material. Between 20 and 300 mg DW or 400 and 800 mg FW was extracted with 10 ml of either phosphate buffer (0.1 M KH_2PO_4 , pH 7.0, or 0.2 M $\text{K}_2\text{HPO}_4/\text{KH}_2\text{PO}_4$ adjusted to pH 6, 7, 8, 9, or 10) or 0.1 N NaOH, pH 12.8.

RESULTS

Preparation of Plant Material. We compared protein yields and reproducibility of analyses between fresh material and flash-frozen, freeze-dried, and air-dried tissues, for nine species of plants. Species varied considerably in the yields obtained by the same preparation method, and different preparation methods gave very different yields with the same species (Table 1). Contrary to our expectations, fresh material did not always give the greatest protein yield; air-drying did not uniformly produce lower yields; flash-freezing did not consistently result in similar yields to fresh material. We noted that species that were difficult to grind—in particular, resinous *Tsuga canadensis* and tough *Platanus occidentalis*—gave greater yields when the preparation involved freezing or air-

TABLE 1. EFFECT OF PREPARATION METHOD FOR PLANT MATERIAL ON ESTIMATION OF PROTEIN CONTENT

Species	Range of protein content of fresh material, %FW (range of CV %) RUDP equivalents	Mean protein content as % of that in fresh material (CV%)		
		Flash-frozen	Freeze-dried	Air-dried
<i>Tsuga canadensis</i> ^a	0.5-1.0 (3.3-13.8)	183a (3.2) ^b	—	301a (5.9)
<i>Platanus occidentalis</i> ^a	0.06-1.4 (6.0-15.7)	480a (4.8)	—	582a (9.0) ^c
<i>Comptonia peregrina</i> ^a	1.9-4.7 (2.4-10.5)	89b (4.3)	69c (36.0)	83b (5.3)
<i>Cirsium sinensis</i> ^a	1.8-2.6 (19.8-20.5)	94 (21.1)	109 (18.7)	59a (34.1)
<i>Phragmites communis</i> ^a	1.8-2.4 (22.9-40.4)	123b (19.7)	14a (96.2) ^c	55a (44.4)
<i>Quercus alba</i>	0.7 (4.3)	—	—	46a (12.3)
<i>Matteuccia pennsylvanica</i>	0.5 (4.6)	—	—	68b (10.9)
<i>Phaseolus vulgaris</i>	1.8 (4.8)	—	—	97 (4.9)
<i>Cladophora</i> sp.	0.3 (23.0)	—	—	86 (5.1)

^aSamples at various times of the season (NY and CA) were used for 5 species. The remaining species were sampled in August.

^bMeans significantly different from fresh material, paired *t* tests; a, $P < 0.001$; b, $P < 0.005$, > 0.001 ; c, $P < 0.05$, > 0.01 .

^cCoefficient of variation significantly different from CV or fresh material; *F*-test; $P < 0.05$, > 0.01 . All other means and CV values are not significantly different from fresh; *t* tests or *F* tests; $P > 0.05$. Sample sizes were a minimum of three in each case, excepting *P. communis* ($N = 4$ or 24), and *C. peregrina*, freeze-dried or air-dried ($N = 6$).

drying. Both these processes make the leaves more friable and facilitate grinding and subsequent extraction.

Variation in protein yield between replicate samples was influenced by both processing method and plant species. The greatest range in the coefficient of variation (CV) occurred with fresh material across plant species (2.4–40%), and with *Phragmites communis* between preparation methods (19.7–96.2%) (Table 1). However, variation between replicates for a given processing method was significantly greater than that found for fresh material in only two of the 17 cases. We concluded that these preparation methods did not consistently change the amount of variation between replicate samples, compared to that of fresh material.

Extraction of Protein. We compared dye responses to extracts of three species of plants extracted with phosphate buffer (pH 7.0) or 0.1 N NaOH (pH 12.8). Alkaline extraction gave significantly greater yields of protein than neutral buffer extracts, up to 35 times greater (Table 2). We also evaluated a range of pH values from 6 to 10 using phosphate buffer and pH 12.8 (0.1 N NaOH) with *C. sinensis*. Leaves were split in half vertically—one half being extracted at a low pH, the other half being the pH 12.8 control. Protein extracted, as a percentage of that removed at pH 12.8, was significantly less at all lower pH values (paired *t* tests; $P < 0.05$; $N = 4$), and increased at pH values above 8 (mean % ± 1 SD: pH 6 = 63 ± 4 ; pH 7 = 65 ± 4 ; pH 8 = 63 ± 8 ; pH 9 = 80 ± 3 ; pH 10 = 81 ± 1 ; pH 12.8 = 100 ± 2).

Extraction Time and Mixing. We evaluated the effect of the duration of alkaline extraction on protein yield with two species. There was no significant difference in protein yield for *Comptonia peregrina* extracted for 30 min to 24 hr (times = 0.5, 1, 2, 3, 4, 5, 24 hr; $N = 3$; paired *t* tests; controls = 0.5 hr;

TABLE 2. EFFECTS OF pH ON EXTRACTION OF PROTEIN

Species	Mean protein content (± 1 SD) ^a	
	pH 7	pH 12
<i>Tsuga canadensis</i>		
Fresh	0.36 (.11)	9.88 ^b (1.36)
Air-dried	1.43 (.28)	29.79 ^b (1.75)
<i>Platanus occidentalis</i>		
Fresh	0.53 (.35)	13.60 ^b (.82)
Air-dried	2.30 (1.52)	79.17 ^b (7.15)
<i>Comptonia peregrina</i>		
Fresh	1.41 (.03)	9.29 ^b (.20)

^aProtein content as mg/g FW or DW RUDP equivalents, depending on preparation method.

^bMeans significantly greater than mean for pH 7; *t* tests; $P < 0.0001$; $N = 3$ in all cases.

$P > 0.05$). Similarly, there was no significant difference in yield for *Citrus sinensis* extracted for 1–60 min (times = 1, 15, 30, 60 min; $N = 4$; paired t tests; controls = 1 min; $P > 0.05$). Since extraction is rapid when samples are finely ground, mixing of samples during extraction did not increase yield. Protein yields from alkaline extracts of *C. peregrina* mixed continuously for 30 min were not greater than yields for extracts that were initially mixed for 10 sec only (one-tailed t test, $P > 0.05$).

Stability of Extracts. We determined the stability of dye response to alkaline solutions that were extracted, centrifuged, and the supernatant refrigerated for periods between 0 and 30 days. We used bovine serum albumin (BSA) (Bio-Rad Laboratories) and RUDP standards and extracts of *Comptonia peregrina*. There was no significant difference in dye response in any case (RUDP: 0, 9, 30 days; $N = 3, 10, 5$, respectively; paired t tests; controls, RUDP at 0 days, fresh standard; $P > 0.05$. BSA and *C. peregrina*: 0, 14, 73 days; $N = 3$; paired t tests; controls 0 hr; $P > 0.05$).

Pretreatment of Plant Material with Acetone. This has been commonly used to remove phenolics and pigments (Loomis and Battaile, 1966; Eze and Dumbroff, 1982). We evaluated the effects of washing fresh plant material with 80% and 100% acetone prior to alkaline extraction, using five species of plants and pure RUDP. Acetone washing reduced protein yield in eight of nine experiments, including RUDP, with significant reductions in six cases. Yield was never increased (Table 3). We analyzed the acetone wash for the presence of protein, but could not detect significant amounts, even with pure RUDP. The decrease in yield was therefore probably due to a change in the solubility properties of proteins following acetone washing.

Addition of Phenol-Complexing Agents at Extraction. Soluble PVP or insoluble polyvinylpyrrolidone (PVPP) are often added to plant extracts to bind phenolics and prevent deactivation of enzymes at the lower pH of most extractions (Loomis et al., 1979). We evaluated the effect of adding these compounds to high pH NaOH-plant tissue mixtures at the time of extraction, using RUDP and *C. peregrina*. Addition of PVPP (Sigma, 10 mg/ml as a slurry) to RUDP standard in NaOH significantly reduced recovery (mean % recovery \pm 1 SD: RUDP = 98.6 ± 4.0 ; RUDP + PVPP = 77.2 ± 5.3 ; paired t test; $N = 3$; $P < 0.005$). Similarly, addition of PVP to alkaline extracts of *C. peregrina* reduced protein yield significantly in two separate experiments (mean protein content, mg/g DW RUDP equivalents \pm 1 SD: experiment 1 *C. peregrina* = 0.63 ± 0.03 ; *C. peregrina* + PVP = 0.54 ± 0.001 . Experiment 2 *C. peregrina* = 0.60 ± 0.01 ; *C. peregrina* + PVP = $0.52 \pm .005$; paired t tests; $N = 3$; $P < 0.005$).

Quinone Formation in Extracts. Extraction of plant material at pH 12.8 can result in the formation of brown-colored extracts. If phenols are present, these become oxidized to brown quinones. These quinones can then oxidize

proteins (Loomis, 1969), forming melanoproteins (Pierpont, 1969a,b; Wehr and Loomis, 1971). We investigated whether or not quinone formation and presence affected the dye response to alkaline extracts. Addition of hydroquinone (HQ, 1.4 mg/ml) to phenol-free pure RUDP in alkaline extracts (pH 12.8) (1.4 and 0.7 mg/ml) produced the characteristic brown color but did not significantly affect dye response compared to alkaline RUDP controls in two separate experiments (mean blank corrected absorbance ± 1 SD: RUDP, 1.4 mg/ml = 0.87 ± 0.02 ; RUDP + HQ = 0.83 ± 0.02 ; RUDP, 0.7 mg/ml = 0.41 ± 0.03 ; RUDP + HQ = 0.39 ± 0.06 ; $N = 3$; paired t tests; $P > 0.05$). Similarly, addition of hydroquinone (1.4 mg/ml) to alkaline extracts of *C. peregrina* (10 mg DW/ml) (that were presumably naturally low in phenolics because they were not brown in color) then produced the characteristic brown color, but did not significantly affect dye response compared to controls (mean blank corrected absorbance ± 1 SD: *C. peregrina* = 0.82 ± 0.03 ; *C. peregrina* + HQ = 0.83 ± 0.03 ; paired t test; $P > 0.05$).

Recovery of Protein in Extracts. We determined the recovery of RUDP standards in the alkaline extraction procedure with pure RUDP standard and

RUDP standard added to plant extracts. We also carried out repeated extraction of the residue left after the first extraction had been centrifuged in order to determine what percent of the total extractable protein was removed in the first extraction. Pure RUDP was recovered 98.6 and 100% in two separate experiments (not significantly different from expected; χ^2 ; $N = 3$ in each experiment; $P > 0.05$). Addition of RUDP to air-dried *C. peregrina* resulted in an average recovery of 98.6% (three experiments; $N =$ three replicates per experiment; χ^2 not significantly different from expected; $P > 0.05$). Between 66 and 100% of the total protein extracted in three sequential extractions was removed in the first extraction, depending upon species and preparation method (Table 4). All but one value exceeded 75%, and two sequential extractions invariably removed over 95% of all the protein that could be extracted in three sequential extractions.

Assay Absorbance Stability. The dye anion-protein complex is not formed instantaneously, and so absorbance values initially fluctuate (Bio-Rad Laboratories, 1985). We examined stability of absorbance values for RUDP and BSA standards over time. Absorbance values stabilized after about 5 min (< 10% variation in three repeated measures within a 1-min period) and remained stable for up to about 30 min. Sometime thereafter, agglutination and precipitation of

the complex takes place. We noted that this agglutination occurred more rapidly (< 15 min) with some plant samples, presumably because some plant constituents promote agglutination at the assay pH. For example, when we added tannic acid (5% DW) to alkaline extracts of RUDP standard (1.4 mg/ml), dye reponse to protein was not affected (paired *t* test; $P > 0.05$), but the time before agglutination occurred was reduced to less than 15 min.

We evaluated the effects of sample dilution as a means of increasing the time before agglutination occurred. Table 5 shows that agglutination was slowed substantially by diluting samples to one half and one fourth strength before assay. We also examined the use of soluble PVP in the dye reagent. If rapid agglutination was due to phenolics, PVP should bind these compounds at the reagent pH of 0.77 (cf. Loomis and Battaile, 1966) and slow down the rate of agglutination. Table 5 shows that agglutination is slowed by the presence of 3 mg/ml soluble PVP (MW \approx 40,000) in the dye reagent. Soluble PVP in the reagent did not significantly change absorbance values compared to PVP-free controls ($N = 5$; paired *t* test; $P > 0.05$).

^aExtracts were of 40 mg/ml air-dried *Comptonia peregrina*. PVP was added at 3 mg/ml dye reagent. Missing absorbance values are due to the difficulty of measuring accurate values during agglutination.

^bAgglutination is scored none (0), slight (+), and extensive (++)

DISCUSSION

Our data show no simple, clear-cut differences in the effects of plant preparation methods. Flash-freezing usually gave higher yields than fresh material. This was most likely due to the ease of grinding frozen material relative to fresh plants. In fact, the effect of preparation method on the production of finely ground tissue may be more important than the effects of preparation method on leaf biochemistry. This may be because the NaOH extraction is very efficient at preventing or reversing complexing of protein and in solubilizing protein when material is finely ground. Air-drying seems to be an acceptable method in many cases, especially given the logistical advantages. Air-drying may be particularly appropriate when protein concentrations are low, since a large amount of plant material can be ground and extracted in the same NaOH volume, compared to fresh or frozen material. Freeze-drying is time-consuming, requires special equipment, and does not produce consistently better results than other simpler methods. Since there is so much variation between plant species in the response to preparation method, initial comparison of a chosen method against fresh material would be appropriate.

Extraction with 0.1 N NaOH appears to be an efficient, rapid process that avoids or reverses protein-phenol complexation. Extracts are stable, and quinone formation does not appear to affect dye-protein binding. We presume that extraction under alkaline conditions prevents the hydrogen bonding of polyphenolics to protein and the formation of insoluble complexes that occurs under neutral or acidic conditions (Loomis, 1969). Since the Bradford assay does not require that the solubilized protein be enzymically active, extraction at cytosolic pH—with all these attendant problems—can be avoided. Mattoo et al. (1987) have argued that the Bradford assay is unsuitable for plant tissues rich in phenols and phenolases, because free phenols, quinones, and polyquinones complex with protein and perhaps because these compounds also react with the dye-protein complex. However, their studies were carried out in unbuffered aqueous and saline solutions and not under the strong alkaline conditions we used. They also did not use PVP in the dye reagent. Using our techniques there is no evidence that phenolic-derived quinones cause any of these problems.

The alkaline extraction is also probably effective at solubilizing membrane-bound proteins, as well as cytosolic protein (Loomis, 1969), and is effective at leaching protein into solution away from cellular debris. This is evidenced by the rapidity of extraction and the lack of any effects of mixing extracts. This efficiency of extraction may partially compensate for any problems in grinding of plant material. For this reason, the standard method recommends a 30-min extraction, even though some plant species yield protein with less time.

It seems clear that acetone washing of plant material prior to extraction

reduces the yield of protein. Removal of phenolics by washing (Loomis and Battaile, 1966) may be unnecessary given the alkaline extraction procedure, and so there is little justification for the use of routine acetone washing. However, there are two potential benefits of acetone washing that should be considered for certain species. First, we observed that highly resinous species, such as *Tsuga canadensis*, became easier to grind after acetone washing had removed the resin. Acetone-washed samples were also easier to centrifuge because leaf particles were no longer caught in a resin-NaOH emulsion. Second, prior acetone washing reduced the rate of agglutination of the dye-protein complex for this same species. Thus if agglutination persists despite sample dilution and the use of PVP in the dye reagent, or if samples are resinous or oily, acetone washing—with appropriate corrections for changes in recovery—could be considered.

The addition of phenolic-binding agents, PVP or PVPP, to neutral or acidic extracts is common practice (Loomis et al., 1979). In our experiments, however, these compounds reduced protein recovery. At pH 12.8 PVP or PVPP will not hydrogen bond to phenols because the latter are ionized, but PVP or PVPP might cross-link protein and reduce its solubility, and this may explain the reduced yields we observed.

Rapid agglutination of dye-protein complexes only occurred with some species, and it would appear that sample dilution and the use of soluble PVP in the dye reagent can slow down agglutination sufficiently that the assay absorbance can be reliably determined after 15 min.

We believe the most appropriate protein standard is RUDP, since it is the most abundant plant protein, and large portions of the molecule are structurally very similar between species (Ellis, 1977). Therefore, variation in RUDP structure should not contribute greatly to variation in dye response between plant samples. Since the Bradford assay, like most other protein assays, measures relative protein concentration, differences in the composition of different proteins ("quality") between samples can result in differences in dye response (Bio-Rad Laboratories, 1985). Differences in protein "quality" between samples can be evaluated by using a TCA precipitation technique we have used. A ratio of 2:1 v/v of 5% (w/v) TCA to extract supernatant solution is used, and the samples centrifuged for 10 min at $\approx 12,000g$. The supernatant is discarded and the pellet dried and weighed. The pellet is then resuspended in the original volume of 0.1 N NaOH, and the assay carried out. Absorbance per unit dry weight of protein can then be compared between samples. Differences in this value can be used as an indicator of changes in protein "quality." We have observed 100% recovery of RUDP standard using this technique.

In summary, we consider that the use of alkaline extracts of finely ground plant material, followed by assay with PVP-modified Bradford reagent, is a simple, reliable, protein-specific assay for plant protein. The use of the alkaline

extraction procedure avoids many of the problems associated with extraction at lower pH.

(Received November 5, 1987; accepted April 15, 1988)

Abstract—A series of quassinoids was tested for antifeedant activity against the aphid *Myzus persicae* (Hemiptera, Aphididae). Isobrucein B, brucein B and C, glaucarubinone, and quassin decreased feeding at concentrations down to 0.05% and isobrucein A was effective at 0.01%. Only quassin showed no phytotoxic effects and is therefore the most promising compound for further development.

Key Words—Antifeedant, *Myzus persicae*, Hemiptera, Aphididae, quassinoid, Simaroubaceae.

INTRODUCTION

Quassinoids (Bhatnagar et al., 1987; Polonsky, 1973, 1985) have been isolated from a number of plants belonging to the family Simaroubaceae. These compounds have many interesting biological properties, for example, antineoplastic activity (Cassady and Suffness, 1980), antimalarial properties (Trager and Polonsky, 1981), antimicrobial activity (Giesbrecht et al., 1978), and amebicidal action (Casinovi et al., 1981). Quassinoids were also shown to have insecticidal, antifeedant, and growth inhibitory effects against the tobacco budworm, *Heliothis virescens* (F.), and the fall armyworm, *Spodoptera frugiperda* (J.E. Smith) (Klocke et al., 1985), and decreased feeding by the Mexican bean beetle, *Epilachna varivestis* Muls., and the Southern armyworm, *Spodoptera eridania*

(Cram.) (Leskinen et al., 1984). All these species are chewing insects. The aim of the present work was to investigate the activity of quassinoids as antifeedants against aphids, which are important plant pests having a piercing and sucking method of feeding.

METHODS AND MATERIALS

The quassinoids were extracted from plants by methods already described (see references in Polonsky, 1973, 1985). Quassinoid analog **2** (Scheme 1) was a semisynthetic product (Bhatnagar et al., 1987). The compounds, established as pure by nuclear magnetic resonance spectroscopy (Polonsky et al., 1975), thus obtained were dissolved in ethanol for testing against aphids. Aphids select their food plants by first making a series of short-duration probes into the surface of the plant. Only if the results of these initial investigations are satisfactory, do they go on to make a deeper penetration which, typically, terminates in the phloem. Antifeedant activity was assessed, therefore, by painting the

SCHEME 1.

upper (adaxial) leaf surfaces of Chinese cabbage, *Brassica campestris* var. *Chinensis* (L.) Makino, with test solutions and exposing the surfaces to aphids. The test chemical was applied to one side of each leaf lamina and the lamina on the other side of the midrib was treated with solvent only, to act as a control. Aphids were confined on the leaf surface under glass Petri-dish lids placed centrally so that the insects had a choice between equal areas of treated and control surfaces. Tests were done in dim light with leaves oriented randomly to eliminate possible effects of differential lighting. The aphids used in the tests were apterous viviparae of *Myzus persicae* (Sulz.) (Hemiptera, Aphididae), collected from cultures maintained on Chinese cabbage at 20°C and 16 hr day length. There were 20 aphids in each Petri dish and 10 replicated treatments per test. Numbers of aphids settled on treated or control areas were counted at 24 hr; wandering aphids and those on the midrib were not counted. Results were analyzed by analysis of variance. All compounds were first tested at a concentration of 0.1% a.i., painted on the leaf surface at ca. 0.01 ml/cm² (250 ppm w/w of leaf). Compounds active at this concentration were then tested at successively lower doses (0.05, 0.01, 0.005%) until antifeedant activity ceased. Leaves were kept for several days after each test and examined for signs of leaf damage, and the nature of any phytotoxic symptoms was noted.

RESULTS

The six compounds listed in Table 1 were inactive as aphid antifeedants at 0.1% a.i. All except simarolide (4) caused leaf damage, the symptoms varying in severity from small dry patches on the leaf to extensive erosion of the leaf surface.

Quassin (12)	0.1	5.5	9.2	0.05	-
	0.05	4.8	9.2	0.01	-
	0.01	7.6	10.7	NS	-

^aFor explanation of symbols, see Table 1.

Of the more active compounds (Table 2 and Scheme 2), isobrucein A (7) exhibited antifeedant activity down to 0.01%, a dose that caused only slight leaf damage. Isobrucein B (8) and brucein B (9) and C (10) appeared less active, although with the latter two compounds at 0.1%, only a few aphids settled on either side of the midrib. Glaucarubinone (Scheme 1, 11) showed antifeedant activity accompanied by some leaf damage, whereas quassin (12) showed similar antifeedant activity with no visible effects on the plant.

DISCUSSION

Although tests using leaf surfaces are useful in evaluating antifeedants for possible agricultural use, they do not distinguish between the direct action of antifeedants against insects and indirect effects involving changes in the leaf. However, there is evidence that the effects are separate; for example, sergeolide (1) and ailanthinone (3) caused considerable leaf damage but did not deter aphids

SCHEME 2.

from settling, whereas quassin (**12**) was effective as an antifeedant but was not detectably phytotoxic.

There was no obvious correlation between chemical structure of compounds and antifeedant activity against aphids. Some compounds that were structurally similar, for example 15β -heptylchaparrinone (**2**) and ailanthinone (**3**), had a similar lack of activity, whereas other structurally very similar compounds, such as the isobruceins (**7,8**) and bruceins (**6,9,10**), had somewhat different antifeedant activities. Thus, in the isobrucein series, although a decrease in the size of the carbon chain of the acyloxy groups on carbon-15 involved a loss of activity (i.e., **7** to **8**), a similar change in substituents at carbon-15 in the brucein series (i.e., **6** to **9**) conferred activity. The increase in

hydrophilicity in the carbon-15 substituent between bruceins A (6) and C (10) also appeared to confer activity, and this was true on going from ailanthinone (3) to glaucarubinone (11). Isobrucein A (7), the compound most active against aphids, is also known to be active against chewing insects (Klocke et al., 1985). However, this correlation was not apparent for the other quassinoids tested here; for example, simalikalactone D (5) is relatively inactive against aphids but is known to be biologically active against the Mexican bean beetle and the Southern armyworm (Leskinen et al., 1984).

Phytotoxicity was displayed by many of the compounds tested and is a serious limitation to their use against phytophagous insects. In this respect quassin (12), being relatively active as an aphid antifeedant and not phytotoxic at the doses tested, is the most promising compound for further development.

(Received September 21, 1987; accepted April 18, 1988)

Abstract—Over 200 beetle- and food-produced volatiles were collected from cultures of the saw-toothed grain beetle *Oryzaephilus surinamensis* (L.) on oats. It proved possible to develop the electroantennogram recording technique for these beetles, despite their small size, allowing volatiles causing antennal responses to be identified by coupled GC-EAG and subsequent GC-MS techniques. Three beetle-produced macrolide lactones were identified as (Z,Z)-3,6-dodecadien-11-olide, (Z,Z)-3,6-dodecadienolide, and (Z,Z)-5,8-tetradecadien-13-olide in an average ratio of 4.4:1:2. These have been reported as components of the aggregation pheromone from a different population of this species, although the ratio of the components produced was different. Three food volatiles with EAG activity were also identified: 1-octen-3-ol, 3-octanone, and nonanal. A mixture of the six identified volatiles produced similar levels of attraction, in a behavioral assay, to the entire mixture of collected volatiles.

Key Words—Aggregation pheromone, *Oryzaephilus surinamensis*, saw-toothed grain beetle, macrolide lactones, electroantennogram, GC-EAG.

INTRODUCTION

Oryzaephilus surinamensis (L.) is a pest of stored products on a worldwide scale and the most widespread pest of stored grain in the United Kingdom (Free-

man, 1976). Under present tolerance limits, consignments of grain can be rejected or downgraded following the discovery of a single live insect (Pinniger et al., 1984), so there is clearly a need for a system to detect and monitor levels of this species, especially at low densities. Traps containing sources of either food volatiles (Levinson and Levinson, 1979) or pheromones (Burkholder and Ma, 1985) have been proposed for stored-product insects in general, and a number of previous studies have attempted to identify suitable attractant materials for *O. surinamensis* (Freedman et al., 1982; Mikolajczak et al., 1983, 1984; A.M. Pierce et al., 1981; O'Donnell et al., 1983; Stubbs et al., 1985).

Observation of the behavior of saw-toothed grain beetles suggests the existence of a pheromone that promotes aggregation, since beetles often clump together in culture jars, either on the surface of the food or on the glass walls (P.R. White, personal observation). A chemical basis for this is suggested since, if beetle aggregations are removed from the glass walls, they often reform in exactly the same spot. Pierce et al. (1981) showed that both sexes of *O. surinamensis* aggregated in response to volatiles collected from adult beetles and also from frass, and, more recently, they have identified three compounds produced by male beetles, which together elicit responses in both sexes (A.M. Pierce, et al., 1984, 1985; H.D. Pierce, Jr., et al., 1984; Oehlschlager et al., 1987).

These previous investigations of both pheromones and food attractants have involved successive fractionation of the collected volatiles and subsequent behavioral testing. This method, however, suffers several drawbacks. To determine the response to every component in a complex mixture involves considerable effort. Furthermore, the presence of a repellent material in a fraction may mask the effect of an attractant. In contrast, this study aimed to collect both beetle- and food-produced volatiles and determine which were biologically active by coupled gas chromatography-electroantennography (GC-EAG) (Moorhouse et al., 1969) with subsequent behavioral assays of EAG-active components.

Although it has been widely used as a screening technique in Lepidoptera (Roelofs, 1984), the EAG has not previously been applied to silvanid or cucujid beetles. Electrophysiological recordings from *O. surinamensis* have been limited to preliminary studies of antennal contact chemoreceptors, although the olfactory receptors of the antenna have been the subject of a structural study (White and Luke, 1986). The aims of this study, therefore, were: (1) to determine whether it was possible to investigate the antennal response to volatiles by the electroantennogram method; (2) to collect all the volatiles produced by a culture of *O. surinamensis* on oats; (3) to investigate the antennal response to all the volatiles collected by the coupled GC-EAG technique and subsequently identify those materials causing EAG activity; and (4) to determine the behavioral response of *O. surinamensis* to the EAG-active volatiles, and thus

assess the relative potential of oat- and beetle-produced volatiles for use in detection traps.

METHODS AND MATERIALS

Insect Material. Insects for both the aerations and the assays were from a reference insecticide-susceptible strain, cultured on a 5:5:1 mixture, by weight, of rolled oats, whole-wheat flour, and brewers' yeast, at an average density of 4000 adults/kg of food, at 25°C and 70% relative humidity. Insects for behavioral assays were used when three to five weeks post-eclosion, and insects for electrophysiological recordings were four to five weeks after eclosion. In both cases, insects were removed from culture and deprived of food in clean glass tubes for 24 hr prior to testing.

Collection and Analysis of Volatiles. Volatiles were collected in a series of aerations conducted in a similar manner to that described by H.D. Pierce, Jr., et al. (1984). In each case, the all-glass apparatus was cleaned before use by heating at 510°C for at least 4 hr. Humidified, purified air was drawn at 2 liters/min through an aeration chamber, a trap containing Porapak Q, and a flowmeter. For the collection of beetle volatiles, each aeration started with about 10,000 *O. surinamensis* adults (estimated by weight) at about five weeks after adult eclosion, and 150 g of rolled oats. The aeration chamber was wrapped in foil to exclude light, and the temperature of the culture was continuously monitored by an internal thermocouple. To avoid collecting volatiles from larvae hatching in the aeration vessel, the food was renewed each week. Adults were removed using an aspirator and their number reestimated by weighing. After mixing with the appropriate proportion of fresh oats (0.015 g/adult), they were returned to the aeration chamber.

In the initial insect experiment the aeration chamber was 40 cm high × 6 cm diameter, and the majority of the insects congregated in one mass on top of the food. All subsequent aerations used shallower, wider chambers (20 cm high × 13 cm diameter) because in these there was a more even distribution of insects within the food and much larger amounts of volatiles were collected.

The Porapak Q (Millipore UK Ltd., Harrow, HA1 2YH, U.K.) was conditioned before use by rinsing with dichloromethane for 5 hr followed by Soxhlet extraction with HPLC-grade pentane for 48 hr. Each trap was 70 mm high × 20 mm diameter and contained about 14 g of the Porapak. (Tests had shown this was enough to prevent volatiles from an identical aeration bleeding out of the trap.) After collecting volatiles for periods of between two and five weeks, depending on the experiment, the Porapak trap was exchanged for a new one. The removed Porapak was extracted with 250 ml HPLC-grade pentane in a Soxhlet apparatus for 48 hr. (Tests had shown this to be sufficient to remove all these volatiles.) The extract was then concentrated to 1 ml on a rotary evap-

orator (16 mm Hg/20°C). Detailed results are presented here for the successive extracts (B1 to B5) from one typical aeration of beetles on oats, and for the single extract (F) from a control of 166 g of food (oats) alone.

Aeration extracts were analyzed on a Varian 3700 gas-liquid chromatograph fitted with a 25-m \times 0.22-mm-ID BP1 nonpolar bonded-phase capillary column (Scientific Glass Engineering UK Ltd., Milton Keynes, MK11 3LA). The carrier gas was helium at a linear flow rate of about 24 cm/sec. Injections were made in the splitless mode with the injector at 200°C. The oven program was 40°C for 1 min, then at 10°/min to 220°C, and the detector (FID) temperature was 240°C. The amplifier output was recorded on a model SP4270 computing integrator (Spectra Physics Ltd., St. Albans, AL1, 5UF).

Electroantennogram (EAG) Recordings. EAG responses were recorded as described in White and Birch (1987) with minor modifications. Intact individuals were used, mounted on a cork stage using double-sided adhesive tape. The recording electrode was inserted into the terminal (11th) antennal segment. Due to the toughness of the cuticle, small holes had to be punched with a finely etched tungsten needle prior to electrode insertion. The indifferent electrode was inserted into a hole punched in the second antennal segment.

To determine whether adult beetles produced any EAG-active volatiles, the EAG responses to combined beetle and food volatiles (extract B2) and food volatiles alone (extract F) were compared. A standard stimulus of 5 μ l of each extract was presented to 20 individuals (10 males, 10 females) in random order [5 μ l of extract F was equivalent to 280 gram hours (gh) of oats; 5 μ l of extract B2 was equivalent to 260 gh of oats plus 16,000 beetle hours (bh) of aeration]. Prior to each test, a solvent blank (5 μ l of pentane) was presented and the response subtracted from the following EAG response. Results were analyzed using a two-way analysis of variance (Sokal and Rohlf, 1969) to identify differences between the responses of individuals to the two extracts and between the responses of males and females.

Coupled Gas Chromatography-Electroantennography (GC-EAG). For each of the extracts the components causing EAG responses were located using a coupled GC-EAG technique (White and Birch, 1987), with oven conditions and programs as described above. Each extract was presented to a minimum of six individuals, using both sexes, and any GC peaks producing consistent responses in different EAG traces were subsequently identified by coupled GC-MS.

Gas Chromatography-Mass Spectrometry (GC-MS). GC-MS analysis was conducted on a Hewlett Packard 5790 gas chromatograph fitted with a 25-m \times 0.22-mm-ID CP-Sil 5 CB nonpolar bonded-phase capillary column (Chrompack UK Ltd., London E14 9TN), coupled to a Jeol DX300 mass spectrometer operating in electron impact mode at 70 eV. The carrier gas was helium at 8 psi head pressure, sample introduction was by splitless injection at 220°C and the oven program was 40°C for 1 min, then at 10°/min to 220°C.

Authentic Chemicals. Synthetic samples of (*R,S*)-(*Z,Z*)-3,6-dodecadien-11-olide (II), (*Z,Z*)-3,6-dodecadienolide (III), and (*R,S*)-(*Z,Z*)-5,8-tetradecadien-13-olide (IV) (Roman numeral notation as used by A.M. Pierce et al., 1984) were kindly supplied by Dr. A.M. Pierce, Simon Fraser University, Burnaby, British Columbia, Canada. They were quantified by GC using methyl laurate as external standard (chosen because of its similar polarity, GC retention time, and effective carbon number). Their purity was assessed as: *R,S*-II, 82% volatile material; III, 89%; and *R,S*-IV, 86%. Solutions of each lactone were tested using the GC-EAG technique. Only the lactones caused an EAG response (Figure 1), confirming that any impurities present would not affect the EAG results.

(*R,S*)-1-Octen-3-ol, 3-octanone, and nonanal (Aldrich Chemical Co. Ltd., The Old Brickyard, New Rd., Gillingham, Dorset, SP8 4JL, U.K.) were found to be pure by GC. In addition, two samples of enantiomerically enriched 1-octen-3-ol, 93%*R*:7%*S* and 17%*R*:83%*S*, were kindly supplied by Dr. D.R. Hall, Overseas Development of Natural Resources Institute, 56-62 Gray's Inn Road, London, U.K.

Behavioral Assays. The level of attraction to aeration extracts and synthetic materials was measured using a two-choice pitfall test (White and Birch, 1987; White, 1987), with 20 insects of mixed sex per test. Tests were run during mornings, and insects were tested once only and then discarded.

Behavioral responses were investigated to aeration extract B2 (beetle plus food volatiles), to individual components (synthetic) identified from extracts by GC-EAG, and to a synthetic mixture of these components in the amounts found in extract B2. Each extract, component, or mixture was tested at five dosages (using 5 μ l per test) with six replicates of each, in a totally randomized design. In a separate series of experiments, the response to 5 μ l of another extract of

FIG. 1. Coupled GC-EAG trace for synthetic pheromone component III, showing lack of EAG response to impurities.

beetles on oats (A1) was compared to the response to a mixture of the three lactones alone, at the same dosages.

Results were expressed as the percent attraction to both test and control stimuli (number of insects found in each pitfall divided by the total number tested, $\times 100$), and differences between test and control were tested for significance using a χ^2 test.

RESULTS

GC Analysis of Aeration Extracts. GC analysis of the aeration extracts demonstrated over 200 volatile components produced by cultures of *O. surinamensis* adults on oats (Figure 2), and the parallel aerations of oats alone collected a similar number of volatiles (Figure 3). The aeration of oats produced between six and ten times the total GC area count (per microliter per day) of a parallel aeration containing neither oats nor beetles, while aerations from beetles on oats produced even more. The major source of the volatiles was therefore the oats or beetles, rather than the Porapak or the incoming air. Careful comparison of the reporting integrator outputs for the various extracts showed that, although the ratios of volatiles varied between extracts, only three volatiles, with relatively long retention times, were collected exclusively from cultures containing beetles (peaks C, D, and E in Figure 2) and were thus beetle-produced. The average temperature within the aeration medium was 24.6°C.

EAG Response to Aeration Extracts. Analysis of the results showed that the EAG response of individuals to a standard dose of extract B2 (beetle plus oat volatiles) was significantly greater than the response to F (oat volatiles alone) ($F = 55.5$, $P < 0.001$, Table 1). Adult beetles were therefore shown to produce EAG-active volatiles. There was no difference, however, between the responses of the sexes ($F = 0.1$ NS).

Identification of EAG-Active Volatiles. GC-EAG traces of the response to various aeration extracts of beetle plus oat volatiles each showed three major EAG responses and two minor responses (Figure 2). Similar response traces were obtained for both sexes. The three major responses corresponded to the volatiles that only appeared in beetle aerations (peaks C, D, and E), while the materials causing the minor responses (peaks A and B) were also collected from aerations of oats alone.

Analysis by GC-MS enabled the materials with EAG activity to be identified as follows:

Peak A: 1-Octen-3-ol:3-octanone (1:2) (quantified by examination of MS data), R_t (min) 6:04, m/e 110(4%) ($M-18$)⁺, 99(6), 85(10), 72(19), 57(100), and 41(17), identical to authentic 1-octen-3-ol and R_t 6:06, m/e 128(12%) M^+ , 99(46), 85(11), 72(53), 57(100), and 43(70), identical to authentic 3-octanone.

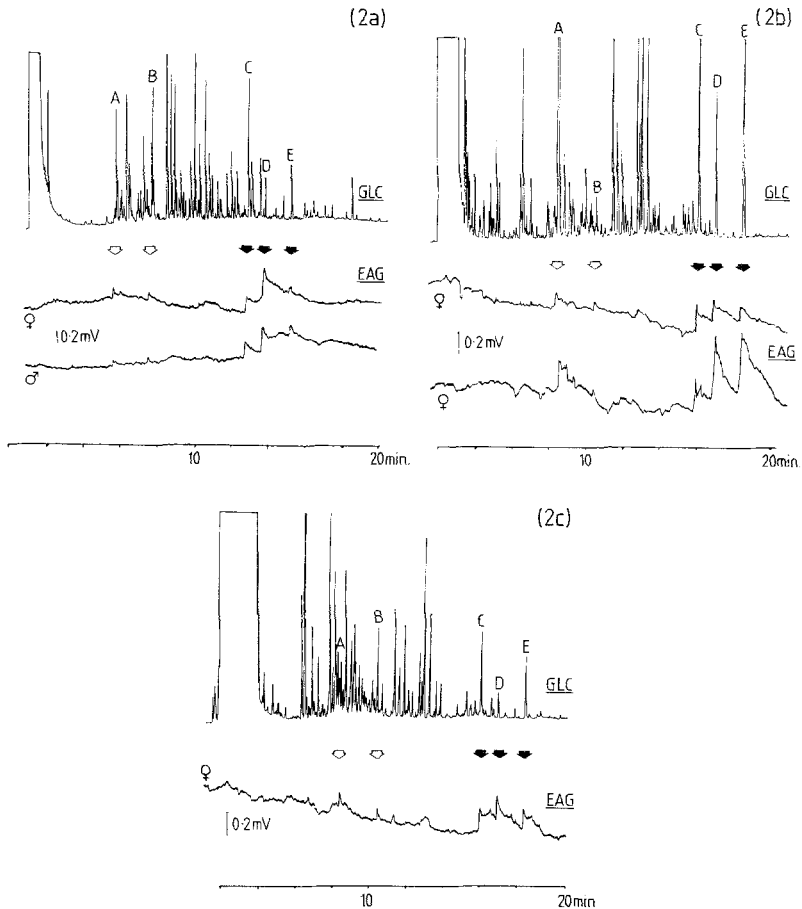

FIG. 2. Coupled GC-EAG traces for three aeration extracts from beetles on oats. Each trace shows three responses to beetle-produced volatiles (closed arrows) and two EAG responses to food-produced volatiles (open arrows.)

Peak B: Nonanal, R_t 11:09, m/e 124(8%) ($M-18$)⁺, 114(14), 98(60), 82(50), 70(60), and 57(100), identical to authentic nonanal.

Peak C: (*Z,Z*)-3,6-Dodecadien-11-olide (lactone II), R_t 13:08, m/e 194(13%) M^+ , 176(4), 134(14), 121(17), 93(35), and 79(100), identical to authentic lactone II.

Peak D: (*Z,Z*)-3,6-Dodecadienolide (lactone III), R_t 14:02, m/e 194(32%) M^+ , 166(11), 134(10), 121(11), 93(47), and 79(100), identical to authentic lactone III.

FIG. 3. Coupled GC-EAG traces for aeration extract F (oats only) showing no consistent EAG responses.

TABLE 1. EAG RESPONSES OF MALE AND FEMALE *O. surinamensis* TO 5 μ l OF AERATION EXTRACTS F (OAT VOLATILES) AND B2 (OAT PLUS BEETLE VOLATILES) ($N = 10$)

Extract	Amount	Response (μ V)	
		Males	Females
F	280 gh	88 \pm 28	75 \pm 20
B2	16,000 bh + 260 gh	392 \pm 78	368 \pm 46

Peak E: (*Z,Z*)-5,8-Tetradecadien-13-olide (lactone IV), R_t 15:27, *m/e* 222(19%) M^+ , 180(27), 140(24), 121(22), 93(52), and 79(100), identical to authentic lactone IV.

When the authentic chemicals were tested individually, both (*R,S*)-1-octen-3-ol and 3-octanone were found to have some EAG activity and were presumed to have contributed to the EAG activity of peak A in the aeration extracts. The EAG activity in each case was small, however, and when the two samples of enantiomerically enriched 1-octen-3-ol were tested, it was not possible to tell whether the EAG response was due to one or both of the enantiomers. Similarly, authentic nonanal was found to have a low EAG activity (Table 2).

GC-EAG traces of oat volatiles (F) failed to identify any EAG-active peaks,

probably because the EAG response to the whole extract was low (Table 1) and due to a summation of several small responses that could not be individually distinguished from background noise in the EAG recording (Figure 3).

Quantitation of EAG-Active Volatiles. Quantitation of the EAG-active volatiles in the aeration extracts was undertaken by GC comparison with methyl laurate in the case of the lactones, and with authentic material in the other cases. The concentrations of these components in extract B2, for example, were: lactone II, 142 ng/ μ l; lactone III, 44 ng/ μ l; lactone IV, 103 ng/ μ l; 1-octen-3-ol, 12 ng/ μ l; 3-octanone, 24 ng/ μ l; and nonanal, 71 ng/ μ l.

With regard to the beetle-produced volatiles, the chromatograms of various extracts (see, for example, Figure 2) showed that the amounts of lactones II, III, and IV varied between extracts, suggesting differing production rates between aeration cultures. Even within one culture the production rate seems to vary quite widely over time (Table 3). The ratio of lactones produced also varied both between and within individual cultures from 2:1:1 to 8:1:2. The mean ratio of lactones II, III, and IV in eight extracts was 4.4:1:2, respectively.

TABLE 2. EAG RESPONSE OF *O. surinamensis* TO 1 μ g OF AUTHENTIC CHEMICALS

Material	EAG response	N
(<i>R,S</i>)-1-Octen-3-ol	45 \pm 13 μ V	6
3-Octanone	80 \pm 26 μ V	6
Nonanal	90 \pm 26 μ V	6
(<i>R,S</i>)-Lactone II	168 \pm 21 μ V	20
Lactone III	232 \pm 25 μ V	20
(<i>R,S</i>)-Lactone IV	178 \pm 26 μ V	20

TABLE 3. PRODUCTION OF LACTONES IN CONSECUTIVE EXTRACTS FROM ONE AERATION

Extract	Average age after adult eclosion (weeks)	Average production rates (pg/bh)			Ratio II:III:IV
		II	III	IV	
B1	5-9	13.0	1.7	2.5	7.6:1:5
B2	9-12	44.4	13.8	32.1	3.2:1:2.3
B3	12-14	8.7	1.7	3.8	5.1:1:2.2
B4	14-17	40.6	12.1	28.6	3.4:1:2.4
B5	17-19	78.8	33.8	48.4	2.3:1:1.4

Behavioral Assays. The pitfall assay demonstrated that the aeration extract B2 was strongly attractive to adult beetles (Figure 4g), with a threshold equivalent to approximately 16 beetle-hours. When tested individually, the identified non-beetle-produced volatiles caused little evidence of attraction (Figure 4a-c). Neither 1-octen-3-ol nor 3-octanone were attractive at any of the doses tested, and at 100 ng 1-octen-3-ol acted as a repellent. Similarly, nonanal showed evidence of repellency at this dosage, yet was attractive at the highest dosage.

The three beetle-produced lactones all demonstrated attractancy, although to differing extents. Lactone III was only attractive at the highest dose (1000 ng), while the other two materials also produced significant responses at lower doses (Fig. 4d-f)

When the six identified components were combined to give the concentrations found in the aeration extract B2 (using twice the amounts of the chiral lactones II and IV, since only racemic material was available), the mixture produced high levels of attraction (Figure 4h), similar to that of the complete aeration extract. In the separate experiment, the attraction of beetles to 5 μ l of aeration extract A1 (beetles on oats) was $70.9\% \pm 3.5\%$ (control response subtracted from test response). The response to the mixture of the lactones alone at the same dosages (II, 13.9 ng; III, 4.0 ng; IV, 6.5 ng) was $61.4\% \pm 4.3\%$. These responses were not significantly different (χ^2 test).

DISCUSSION

Despite their small size, it proved possible to record EAG responses from the antennae of *O. surinamensis*. Furthermore, by use of the coupled GC-EAG technique, it was possible to screen all the aeration volatiles for EAG activity in a relatively short period. Examination of collected volatiles by coupled GC-EAG identified the same three active beetle-produced components previously reported by A.M. Pierce et al. (1984, 1985), who used a totally different method. This confirms the earlier findings and suggests that both our strain and the Pierce strain use the same compounds for intraspecific communication. H.D. Pierce, Jr., et al. (1984) and A.M. Pierce et al. (1987) also reported the production of small amounts of a fourth lactone, (*Z*)-5-tetradecen-13-olide, by males of their strain, but did not consider this to act as a pheromone component. Despite careful analysis of the aeration extracts, no evidence of this other material could be detected in the present study. Other differences in the pheromone components could also occur, however, since two of the components are chiral compounds (lactones II and IV), and separate strains of one species have previously been found to utilize different blends of optical isomers (e.g., *Ips pini*; Birch, 1984). The Pierce strain of *O. surinamensis* produces and responds to only the *R* enantiomers of lactones II and IV (Oehlschlager et al., 1987; A.M.

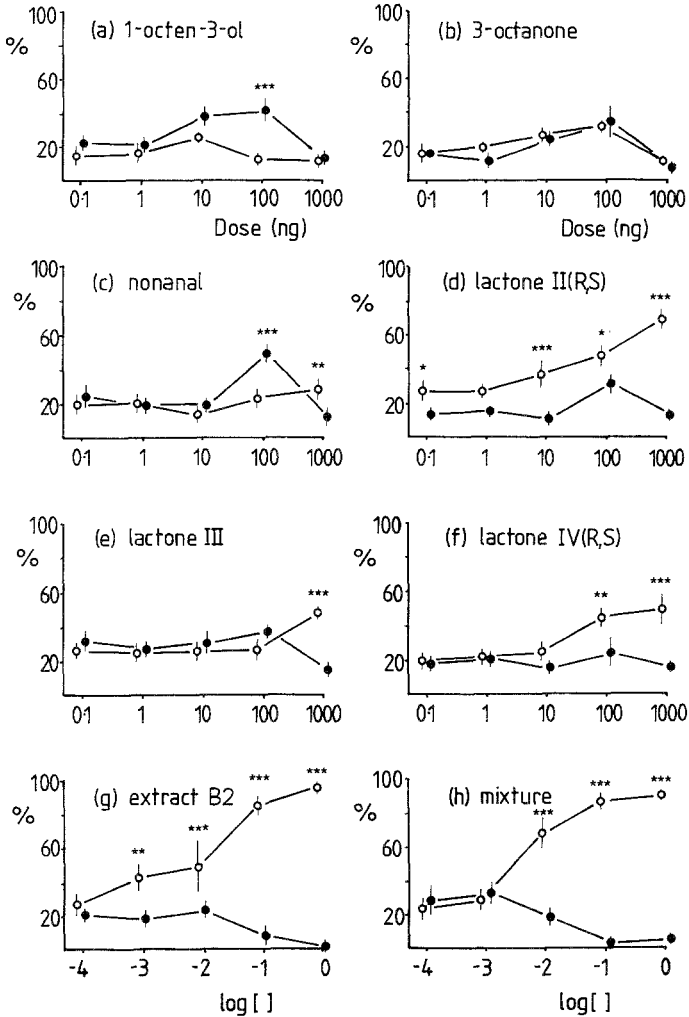

FIG. 4. The behavioral response of *O. surinamensis*, in the two-choice pitfall bioassay, to: individual authentic chemicals (a-f), aeration extract B2 (g), and to a synthetic mixture of the authentic chemicals in the concentrations found in extract B2 (h). Points on graphs give means \pm SE ($N = 6$) of percent attraction to test (open circles) and control (closed circles) tubes. Significance of difference between test and control: * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$. (χ -square test).

Pierce et al., 1987). So far it has not been possible to identify the chirality of the lactones produced in this study or to test the response to chiral compounds, but this will be attempted as suitable material becomes available.

A.M. Pierce et al. (1984) reported that the production rate of the lactones remained reasonably constant when the adult age exceeded five weeks post-eclosion, whether the aeration cultures had 20 or 100 beetles/g of oats. In the present study, however, with about 67 beetles/g oats, the production rates varied widely. Since both the availability of food and the density of beetles were kept approximately constant, and there is no evidence to suspect artifacts in either the collection or analytical procedures, these fluctuations may reflect synchronicity in pheromone production or release. Casual observations of the beetles while the aerations were in progress did suggest that some synchrony in behavior does occur. It would be wrong to read too much into this, since the present experiment was not intended to be a study of production rates, but it is interesting to speculate why beetles at these relatively high densities should produce any aggregation pheromone at all.

The two strains of *O. surinamensis* studied did differ, however, in the ratio of the macrolide lactones produced. The Pierce strain produced a ratio of 1:1:3 (II:III:IV) (A.M. Pierce et al., 1984), while that measured above had a mean ratio of 4:1:2, demonstrating a different major component in the two strains. Such strain or population differences have been reported previously in several species (e.g., the turnip moth *Agrotis segetum*; Lofsted et al, 1986). Since glyceride acids in the diet appear essential for production of the macrolide lactones (H.D. Pierce, Jr., et al., 1984), such differences in production ratios could reflect different availabilities of precursors for each lactone between the diets used in each study. In their proposed biosynthetic routes, however, H.D. Pierce, Jr., et al. (1984) suggest that all three lactones in *O. surinamensis* are produced from a common precursor, linoleic acid. If this is so, diet differences would not explain the observed differences in production ratios between the two strains. Furthermore, the present study also demonstrated variability in the produced ratio within a strain, which was fed the same diet throughout. Assuming that the collection efficiency was constant, this variability could have been due to either, or a combination of, two causes. Either individuals could alter the ratio that they produce, for example, with age, or different beetles may produce slightly different blends and the relative numbers of such individuals could alter over time. To distinguish between these possibilities requires collection of volatiles from individual beetles, rather than from large, high-density cultures, and such techniques are under development.

The other three EAG-active compounds identified from the aeration extracts appeared to originate from the oats. 1-Octen-3-ol and 3-octanone are known to be formed when grain is contaminated by mold (Kaminski et al., 1973). 1-Octen-3-ol is known to be an attractant for tsetse flies (Hall et al., 1984), and 3-octanone has been reported to be a component of the alarm pheromone of the

ant *Crematogaster peringueyi* (Fletcher, 1970), but there have been no previous reports of the effects of either of these chemicals on the behavior of stored-product insects. Nonanal has previously been identified in oat volatiles and tested against *O. surinamensis* in a pitfall assay, but no significant attraction was observed, even at the highest dose tested (100 μg) (Mikolajczak et al., 1984). Using an insect activity detector assay, O'Donnell et al. (1983) recorded attraction to *O. surinamensis* with nonanal at 0.02 μl (16.5 μg) and 0.1 μl (83 μg), but not at 1.0 μl (830 μg). In the present study, only the highest dose of nonanal (1 μg) appeared to attract the beetles. At the lower concentrations it was found to repel the insects, as did 1-octen-3-ol, while 3-octanone appeared to produce no observable effect on beetle behavior.

Since the three beetle-produced lactones alone could account for most of the attraction observed to complete aeration extracts of beetles on oats, they appear to have the greatest potential, of the EAG-active volatiles identified here, to augment trap catch in the field. Their use, however, may be limited by their stability, availability, and present high cost. Consequently, they will only be worthwhile as attractants if their effectiveness can be maximized, which in turn requires understanding of the mode of action of such materials in the natural chemical communication system of these insects. To improve this understanding was the objective of the following paper (White and Chambers, 1989).

Acknowledgments—This work was carried out as part of the joint Oxford University/ADAS Slough Laboratory project on The Responses of Stored-Product Insects to Food Odours and Pheromones. P.R.W. was funded by an open contract from the MAFF Chief Scientist. We should like to thank Dr. A.M. Pierce and Dr. D.R. Hall for gifts of chemicals, Miss K.M. Amos and Mr. T.J. Binns for technical assistance, and Mr. D.B. Pinniger for helpful discussions.

SAW-TOOTHED GRAIN BEETLE *Oryzaephilus surinamensis* (L.) (COLEOPTERA: SILVANIDAE)
Antennal and Behavioral Responses to Individual Components and Blends of Aggregation Pheromone

(Received September 21, 1987; accepted April 15, 1988)

Abstract—The antennal and behavioral responses of the saw-toothed grain beetle, *Oryzaephilus surinamensis*, to the three components of its male-produced aggregation pheromone were investigated. EAG recordings showed no differences between the responses of the two sexes to the synthetic pheromone components. In contrast, laboratory behavioral assays demonstrated marked differences between the sexes. More females than males were consistently attracted to mixtures of the synthetic components, and this bias appeared to be caused by one component in the blend. Altering the blend ratio resulted in changes in the ratio of the sexes attracted. Thus, if, as suggested by preliminary work, males vary the blend produced, this should alter the relative response of the sexes to the aggregation pheromone.

Key Words—Saw-toothed grain beetle, *Oryzaephilus surinamensis*, Coleoptera, Silvanidae, aggregation pheromone, electroantennogram, behavioral bioassay, blend ratio.

INTRODUCTION

The saw-toothed grain beetle, *Oryzaephilus surinamensis*, is an important and widespread pest of stored grain on a global scale, yet in large bulks of grain it is difficult to detect, especially at low density. Traps baited with pheromones have been proposed as a means to improve the detection and monitoring of stored-product insects in general (Burkholder and Ma, 1985), but to achieve this, the mode of action of such pheromones must be elucidated to ensure that these often expensive chemicals are used to best advantage and that the chances of detecting insects at low population densities are optimized.

Chemical communication in *O. surinamensis* utilizes beetle-produced volatiles that constitute a multicomponent aggregation pheromone (A.M. Pierce et al., 1984). This classification, although accurate, belies the complex mode of action of such chemicals.

Aggregation pheromones have been defined as "substances produced by members of either or both sexes, that induce members of both sexes to aggregate" (Borden, 1985). Several functions have been ascribed to such aggregations. In the aposematically colored beetle *Lycus loripes*, pheromone-mediated aggregations provide mutual protection against predation (Eisner and Kafatos, 1962), while among bark beetles that attack and kill previously healthy trees, large aggregations are necessary to overcome the defenses of the host tree (Birch, 1984). It has also been suggested that aggregation pheromones have been evolved as indicators to conspecific individuals of a suitable food source or habitat (Shorey, 1973; Borden, 1977), although it is difficult to explain the advantage to the emitter of attracting potential competitors to a food source, unless group feeding or conditioning of the habitat occurs.

Since in many examples only one sex produces the aggregation pheromone, it is likely that such pheromones have at least a partial sexual function related to mate location or courtship. In such cases, although both sexes respond, the pheromone might be expected to attract primarily the nonproducing sex and thus act in part as a sex pheromone. In the bark beetle *Dendroctonus brevicomis*, for example, colonizing females release *exo-brevicommin*, which preferentially attracts males, while males release *frontalin*, which attracts mainly females (Vité and Pitman, 1969). Similarly, field tests with several species of *Ips* have demonstrated that more females than males are attracted to the male-produced aggregation pheromone (Wood, 1972; Birch and Light, 1977; Lanier and Burkholder, 1974; Lanier and Wood, 1975). Among stored-product insects, female rust-red flour beetles (*Tribolium castaneum*) aggregate more than males in response to the male-produced chemical (Levinson and Mori, 1983).

Such sexual differences in the behavioral response to aggregation pheromones have often been reflected at the sensory level by sexual differences in the EAG responses recorded. In the above case of *T. castaneum*, for example, the EAG response of the females to the aggregation pheromone was found to be greater than that of males (Levinson and Mori, 1983). In other cases, however, such as *Dendroctonus frontalis*, no differences in antennal sensitivity to pheromone were found, despite observed differences in the behavioral response (Payne, 1970, 1971, 1975). In yet other examples, such as the boll weevil, *Anthonomus grandis*, sexual differences in antennal sensitivity have been found to some components of multicomponent pheromones but not to others (Dickens, 1984).

A.M. Pierce and co-workers (1984) reported that the aggregation pheromone of *O. surinamensis* was male-produced, and that both sexes were attracted.

Until recently, however (White et al., 1989), no recordings have been made of the EAG responses to the pheromone components. The initial aim of this study, therefore, was to investigate both the antennal and behavioral responses of the saw-toothed grain beetle to synthetic pheromone components and to identify sexual differences at either the sensory or behavioral levels.

The pheromone produced by the saw-toothed grain beetle consists of three components (A.M. Pierce et al., 1984; White et al., 1989), and such multicomponent systems are typical of beetles (Tumlinson, 1985) and insects in general (Silverstein and Young, 1976). Such systems may operate in two ways: either each component causes a separate behavioral response (and thus would constitute separate pheromones), or all components are required as a specific blend before a response can be elicited (i.e., a multicomponent pheromone). Most work on pheromone blends has been conducted on sex pheromones of moths. Several studies have suggested that different components affect separate behaviors in the approach of males to the calling females (Baker et al., 1976; Bradshaw et al., 1983). Other work, however, has shown that all of the components are needed, even the minor ones, for maximum sensitivity to the pheromone during each separate behavior and that the blend acts as an integral unit (Linn et al., 1984, 1986; Baker and Cardé, 1979).

In many such blends, the ratio of components confers species specificity on the pheromone, since many closely related species use the same components (Roelofs and Brown, 1982). In *O. surinamensis*, however, the ratio of components produced appears to be variable, both within and between populations (White et al., 1989). Consequently, this study also attempted to investigate the role of individual components and mixtures in the attraction of conspecifics and to determine the effect of changes in the blend ratio on the level of response.

METHODS AND MATERIALS

Insect Material

Insects were obtained from a reference insecticide-susceptible strain (cultured in the laboratory since before 1958), and cultured on a 5:5:1 mixture of rolled oats, whole-wheat flour, and brewers' yeast at 25°C in a reversed 8 hr:16 hr light-dark lighting regime (lights on 1800 hr, lights off 1000 hr). Insects for both electrophysiological and behavioral assays were used four to five weeks after adult eclosion and were removed from culture and kept in clean glass tubes (5 × 2.5 cm) without food for 24 hr before use.

Olfactory Stimuli

Synthetic samples of the three macrolide lactones identified from *O. surinamensis* (A.M. Pierce et al., 1984; H.D. Pierce et al., 1984) were supplied

by Dr. A.M. Pierce, Simon Fraser University, Burnaby, British Columbia, Canada. They were quantified by capillary GLC, using methyl laurate as external standard, and the purity determined as (*R,S*)-(*Z,Z*)-3,6-dodecadien-11-olide (lactone II) 82%, (*Z,Z*)-3,6-dodecadienolide (lactone III) 89%, and (*R,S*)-(*Z,Z*)-5,8-tetradecadien-13-olide (lactone IV) 86% (White et al., 1989).

Logarithmic dilution series were made up for each component in hexane (Gold label, spectrophotometric grade, Aldrich Chem. Co.), for use in both EAG and behavioral assays, and stored at -70°C when not in use. A food odor, "carob distillate," was used in EAG tests as a standard stimulus, to control for possible variability between preparations and within the life of a single preparation. Carob distillate was collected as an aqueous vacuum distillate obtained by heating pods of the carob tree *Ceratonia siliqua* (Leguminosae) (Stubbs et al., 1985). Previous recordings had shown that there was no significant difference between male and female EAG responses to this food odor (White, 1987).

Electroantennogram (EAG) Responses

The responses of male and female antennae to the three synthetic pheromone components were investigated using the EAG technique (White et al., 1989). Each individual was presented with nine doses of each pheromone component, each in 10 μl of solvent, in ascending order of concentration, interspersed with blank (10 μl of solvent only) and standard (10 μl of carob distillate) cartridges. The order of presentation of the pheromone components at each concentration was randomized. A total of 20 individuals (10 of each sex), all four to five weeks after adult eclosion, were tested. The results were normalized as a percentage of the standard response to carob distillate, and then analyzed using a split-plot analysis of variance (ANOVA) to determine sexual differences and differences between the responses to the individual pheromone components (Sokal and Rohlf, 1969). An analysis was also performed on the raw (i.e., unnormalized) data for comparison, but both analyses gave similar results.

Behavioral Assays

The responses of insects to synthetic pheromone components and mixtures were measured using the two-choice pitfall bioassay method previously described (White et al., 1989). Each test used 20 insects and was run for 1 hr at 25°C in darkness. At the end of this time, the number of insects in the test and control pitfalls and those not responding were counted. For comparison between tests, an index of attraction was used, calculated as percent attraction = $100(T - C)/N$ where T is the number of insects in test pitfall, C the number of insects in control pitfall, and N the total number of insects tested (Tamaki et al., 1971; Nara et al., 1981). Percentage attraction could thus vary from +100%

(all insects in the test pitfall) through 0% (equal numbers in test and control tubes) to -100% (all insects in the control pitfall).

Sexual Differences in Attraction to Aggregation Pheromone. Sexual differences were determined by testing the attraction of males and females, separately, to a mixture of synthetic pheromone components in the approximate ratio produced by beetles of this strain (White et al., 1989).

Large numbers of insects were cultured, removed on emergence as adults, their sex determined (Halstead, 1963), and kept in single-sex cultures at equal densities for four weeks before use. The percent attraction to the synthetic pheromone components II, III, and IV in the ratio of 8:1:4 (using racemic mixtures of II and IV) was determined over a range of five dosages on a logarithmic scale, with 10 replicates of each sex at each dose. The experiment was conducted as a fully randomized design and the results tested by a two-way analysis of variance to determine any sexual differences in the responses (Sokal and Rohlf, 1969).

Although the above experiment would identify sexual differences in attraction to the aggregation pheromone, it did not allow for differences in culture conditions prior to testing. As males produce the pheromone, females would not have been exposed to pheromone prior to the tests, in contrast to the males, and this could be responsible for any observed differences in their responses. To examine this possibility, therefore, a second experiment was conducted in which insects were removed from culture at emergence, sexed, and both single and mixed-sex cultures set up. These were tested as before after four weeks, but at just one dose of the synthetic pheromone mixture (1.0 μg). After testing, the insects in the mixed-sex assays were sexed to determine the percent response of each sex in each test. Thus, for the mixed-sex insects, the culture and test conditions were identical for both sexes, and so could not affect the behavioral response. Results were analyzed using a two-way analysis of variance (Sokal and Rohlf, 1969) to identify any effects of sex and culture type on the attraction to the pheromone mixture.

Attraction to Individual and Multiple Pheromone Components. For both this and the subsequent experiment, insects were raised as mixed-sex cultures, used when four to five weeks old, and sexed on the day prior to use. Using the two-choice pitfall assay, each sex was tested for its response to individual pheromone components, binary mixtures, and a mixture of all three components, with five replicates of each test mixture for each sex. To maintain the relevant ratio, the amounts of each component used were 0.8 μg (*R,S*)-II, 0.1 μg III, and 0.4 μg (*R,S*)-IV. The experiment was conducted in a randomized design, and analyzed using a factorial analysis of variance (Sokal and Rohlf, 1969) to determine the effect of the presence or absence of each separate pheromone component and the effect of the sex of the responding insects on the level of attraction observed.

Effect of Blend Ratio on Attraction to Aggregation Pheromone. To test the effect of blend ratio, each sex was tested separately against a variety of blends. The blends used were 8:1:4 [which corresponds to the average produced ratio of 4:1:2 assuming that both II and IV are produced enantiomerically pure (Oehlschlager et al., 1987)] and the five other permutations of this combination, plus ratios of 1:1:1 and 2:1:6. The same total amount of material was used in each test (1.3 μg), using racemic mixtures of lactones II and IV. [Recently, it has been reported that *O. surinamensis* produces and responds to only the *R* enantiomer of lactones II and IV (Oehlschlager et al., 1987; A.M. Pierce et al., 1987). If the strain used in this study also produces and responds to only one enantiomer of II and one of IV, this would have led to slightly different total amounts of active components in each of the blends tested. However, such differences would have been small on a log scale and would not have affected the male/female response ratio to any individual blend.]

The experiment was run as a randomized design with five replicates of each blend tested against each sex. Results were analyzed using ANOVA to identify significant effects of sex or blend ratio.

RESULTS

Antennal (EAG) Responses

Analysis of the results for all three lactones showed no significant differences between the responses of the sexes, using either the normalized ($F = 2.6$, NS) or raw EAG data ($F = 1.8$, NS) (Figure 1). There were significant differences, however, between the responses to the separate pheromone components ($F = 3.4$, $P < 0.05$ for normalized data; $F = 10.4$, $P < 0.001$ for raw data). The mean response to lactone III was higher than that to lactones II or IV, although when the higher doses were analyzed separately, there were no significant differences between the maximum EAG responses to the three pheromone components ($F = 0.7$, NS). (Mean response \pm SE to maximum dose (100 μg): lactone II = $267 \pm 42 \mu\text{V}$; lactone III = $247 \pm 29 \mu\text{V}$; lactone IV = $290 \pm 32 \mu\text{V}$; mean response to 10 μl of carob distillate = $480 \pm 33 \mu\text{V}$, $N = 20$).

Behavioral Responses

Sexual Differences in Attraction to Aggregation Pheromone. Analysis of the pitfall assay results (Figure 2) showed a highly significant difference between the sexes in their response to the synthetic pheromone mixture ($F = 23.9$, $P < 0.001$), with females showing the greater response at all doses above the threshold level of ca. 1 ng. The subsequent experiment on the effect of sex and culture type on the response also showed that more females than males were

FIG. 1. EAG response of males (○) and females (●) to individual synthetic pheromone components R,S II, III and R,S IV (means \pm SE, n = 10).

FIG. 2. Attraction of males (○) and females (●) to 5 doses of a mixture of the synthetic pheromone components R,S II, III and R,S IV, in the ratio 8:1:4, using the 2-choice pitfall bioassay. (20 insects/test, means \pm SE, $n = 10$).

attracted to the pheromone ($F = 46.5$, $P < 0.001$) (Table 1). Culture and test type were not significant as a main effect ($F = 1.4$, $P = 0.25$), but there was a significant interaction between sex and culture type ($F = 6.6$, $P = 0.01$). Inspection of Table 1 shows that fewer males were attracted in the single-sex tests than in the multiple-sex tests, while in females there was a slight bias in the opposite direction, accounting for the significant interaction.

Attraction to Individual and Multiple Pheromone Components. Statistical analysis of the results (Table 2) demonstrated that the presence of each of the three pheromone components had a highly significant effect on the level of attraction produced ($P < 0.001$). Inspection of the results (Figure 3A) showed that lactones II and III caused limited attraction either singly or together. When used alone, lactone IV produced no significant effect, but caused a marked

increase in the attraction of both sexes when added to lactone III, [accounting for the significant interaction between lactones III and IV ($F = 9.2$, $P < 0.01$)] and an increase in the attraction of females, but not of males, when added to lactone II (accounting for the significant interaction observed between sex and lactones II and IV). The sex of the responding insects had a highly significant effect on the behavioral response to the components and mixtures ($F = 16.4$, $P < 0.001$), with more females than males responding overall. Inspection of the results (Figure 3A) and the highly significant interaction observed between sex and lactone II (Table 2) showed, however, that significant differences between the sexes were only found in response to mixtures containing component II. The results therefore suggest that although this material had a large effect on the attraction of females, it had much less effect on male beetles.

Effect of Blend Ratio on Attraction to Aggregation Pheromone. The analysis of variance showed that both blend ratio and sex of the test insects were highly significant as main effects on the level of attraction (blend: $F = 4.4$, $P < 0.001$; sex: $F = 25.0$, $P < 0.001$) (Figure 3B), again with more females than males responding overall to the pheromone.

The results have been replotted in Figure 4 to show the effect of the pheromone blend on the attraction of males and females. Two trends are shown. First, the level of attraction of both sexes appeared to be positively correlated with the amount of component IV in the blend (i.e., vertical axis of Figure 4).

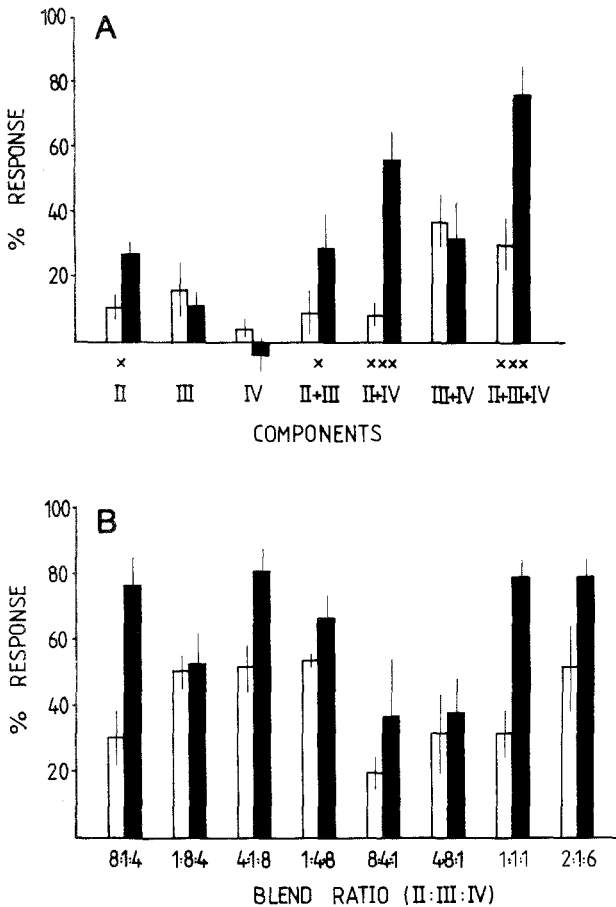

FIG. 3. (A) Attraction of males (open blocks) and females (closed blocks) to various combinations of the synthetic pheromone components (*R,S*)-II (0.8 μ g), III (0.1 μ g), and (*R,S*)-IV (0.4 μ g). (means \pm SE, $N = 5$). (B) Attraction of males (open blocks) and females (closed blocks) to various blend ratios of the synthetic pheromone components (*R,S*)-II, III, and (*R,S*)-IV, the total dose being 1.3 μ g in each case.

Secondly, the ratio of the male to female response (M/F) increased from left to right in Figure 4; i.e., as the amount of component II decreased and component III increased.

DISCUSSION

Although the sex producing an aggregation pheromone is often less sensitive, at the antennal level, to one or more of the components than its partner

FIG. 4. Attraction of males (open blocks) and females (closed blocks) to various blend ratios of the synthetic pheromone components as shown in Figure 3B. The position of the base of the blocks corresponds to the blend ratio of the three components. Each corner represents 100% of the component indicated, falling to 0% along the opposite side of the triangle.

(Dickens, 1986), this does not appear to apply to *O. surinamensis*, since no sexual differences were found in either sensitivity or maximum EAG response to any of the synthetic samples of the three male-produced lactones.

The magnitude of the maximum EAG response has been suggested as a measure of the relative number of acceptor sites on the antenna for any given stimulus (Payne, 1975; Dickens and Payne, 1977). This assumes, however, that all acceptor sites contribute equally to the EAG potential recorded, regardless of their type or position. Sites for different components may differ in their transducing amplification. Also, even if transduction at each acceptor site produces an equal local change in membrane permeability, distal sites on the olfactory dendrites might be expected to make a smaller contribution to the EAG response recorded in the antennal hemolymph than more proximal sites. The above correlation, therefore, also assumes a uniform distribution of different acceptor site types on the dendritic branches of the olfactory cells. Given such assumptions, however, the results in this study imply that the numbers of acceptor sites on the antennae of male and female *O. surinamensis* for any one pheromone component were approximately equal. Similarly, since for any individual the maximum EAG amplitude produced by each component was roughly equal, acceptor

site populations for each component appeared to be of equal size. The apparent greater sensitivity of antennae to lactone III may be due to the optical impurity in the samples of lactones II and IV used, rather than differences in the acceptor populations.

The lack of sexual differences in the antennal response is in agreement with an earlier structural study, which found that there was no sexual dimorphism in either the numbers or distribution of antennal olfactory sensilla (White and Luke, 1986). Similarly, the small amplitude of the EAG responses to any of the pheromone components probably reflects the low numbers of olfactory sensilla (less than 200 per antenna) found in the same study.

Even the maximum EAG responses to the pheromone components were low, however, compared to the response to the carob distillate standard, suggesting that the antenna of *O. surinamensis* bears more acceptor sites for food volatiles than for the aggregation pheromone components. Such a situation is uncommon, since in most insect species studied the EAG responses to pheromone components have been found to be considerably larger. In the Douglas-fir beetle *Dendroctonus pseudotsugae*, for example, male and female antennae are 10–1000 times more sensitive to the aggregation pheromone components than to plant odors (Dickens, 1986). Some cases similar to *O. surinamensis* have been reported, however: male boll weevils (*Anthonomus grandis*), for example, are as sensitive to cotton volatiles as to any pheromone components (Dickens, 1984). The results in this study do, therefore, suggest the relative importance of food volatiles to adult saw-toothed grain beetles, and these may be involved in the location of suitable food sources, e.g., grain stores. In contrast to the antennal responses, however, there was a marked difference in the behavioral responses between the sexes to the synthetic pheromone components and mixtures. This would suggest sexual differences in the central integration of olfactory inputs and generation of motor output rather than differences in the sensory input from antennal receptors.

Although, as its name implies, the aggregation pheromone of *O. surinamensis* attracts both sexes, overall more females than males responded to the synthetic components and mixtures in all four experiments, suggesting that the male-produced blend does act in part as a sex pheromone. A.M. Pierce et al. (1984) also found a slightly greater response by females but attributed no significance to this difference. Millar and coworkers (1985a,b), however, found sexual differences in the responses of two related grain beetles, *Cryptolestes pusillus* and *C. turcicus*. In the latter species females showed the greater response, while in the former males responded at lower concentrations and had higher overall responses to the male-produced aggregation pheromone. This is inconsistent with the above hypothesis of a partial sex pheromone function in these grain beetles and merits further investigation. Another interesting result has been reported from *Oryzaephilus mercator*, the merchant grain beetle. Males

of this species produce a two-component aggregation pheromone (A.M. Pierce et al., 1984). While both components caused responses in both sexes, the results presented suggest that males were more sensitive to one component and that females were more sensitive to the other (A.M. Pierce et al., 1985). Thus, the ratio of the sexes responding to any mixture might be dependent on the blend ratio.

In *O. surinamensis* the female response to the naturally produced ratio was greater than that of males, whether the insects were raised in single- or mixed-sex cultures. Culture type did have an effect, however, since fewer males from single-sex cultures were attracted than from mixed-sex cultures, yet the reverse was true for females. The effect was apparently stronger for males. Culture type could affect insects in several ways, including mated state (virgins in single-sex cultures, mated insects in mixed-sex cultures) and differences in preexposure to the pheromone, which would only be present in male and mixed-sex cultures. The lower response of males from single-insect cultures than from mixed-sex cultures could be explained by greater preexposure to the pheromone in the former, but further work would be necessary to confirm this. The results do show, however, the importance of standardizing culturing methods and the mated state of insects used for assaying aggregation pheromones as well as sex pheromones.

Overall, although more females than males were attracted in all four experiments, the ratio of male to female responses varied with the components and mixtures tested. No mixtures, however, attracted significantly more males than females. The highly significant interaction found between the sex of the responding insects and the pheromone component II suggested that the greater response of females was largely due to the presence of this component. Addition of this material to a mixture increased the numbers of females responding, but had little effect on males. The tests with different blend ratios also supported this, since the ratio of males to females responding to a blend appeared to fall as the amount of component II in the blend increased. This contrasts with the antennal responses, however, since, at the peripheral sensory level, both sexes were found to be equally responsive to lactone II.

Since no detailed observations were made of the behavior of individual insects in this study, no conclusions can be drawn as to whether each component of the pheromone has a specific and separate effect on behavior or whether the response is to the entire blend. The results do show, however, that all three components are necessary to attract individuals most effectively, at least in females. If these materials are to be used in the field to improve detection of this species, all three materials would appear necessary to increase trap catch significantly. To optimize the effect of the pheromone, however, blend ratio must be considered, since alterations in the blend ratio had a clear effect on the level of attraction of both males and females.

Previous work on the importance of blend ratio has concentrated on the sex pheromones of moths. Such studies have suggested that the blend ratio of the sex pheromone confers species specificity on the signal (Baker et al., 1981; Linn and Roelofs, 1983) and that this is important in closely related sympatric species that utilize the same pheromone components. In *O. surinamensis*, however, blend ratio was not that critical, since several markedly different ratios produced equally high levels of attraction and, furthermore, the naturally produced ratio did not produce the greatest mean attraction in either sex. This contrasts with the above studies of moths, where departures from the natural ratio often resulted in sharp decreases in the male response. It should be noted, however, that the present tests were conducted with relatively high doses and that blend ratio may be more critical at concentrations around the threshold level for detection.

The blend ratio of the aggregation pheromone does not, therefore, appear critical for species specificity in these beetles. Specificity could be conferred by the chemical identity of the three components, since no other species is known to use this mixture, although *O. mercator* does use the same enantiomer of lactone II as a pheromone component (Oehlschlager et al., 1987). The actual blend ratio may be important in conveying extra information about the emitter, such as reproductive state, since both males and females appear to mate repeatedly, and this could explain the differential responses of males and females to changes in blend ratio. Such added complexity in aggregation pheromone communication systems might be expected since, not only are both sexes responding, but also insects that utilize aggregation pheromones are generally long-lived as adults (Burkholder, 1982) and may need to alter the "meaning" (Slater, 1983) of the signal over time. In the boll weevil *Anthonomus grandis*, for example, the aggregation pheromone attracts both sexes, but at one time of the year acts as a sex pheromone and attracts mainly females (Mitchell et al., 1972). In this case, however, the change appears to be in the responsiveness of the insects rather than in the blend ratio.

Collection of volatiles suggested that the blend ratio of the aggregation pheromone produced by *O. surinamensis* cultures varied both between and within populations, but it was not possible to distinguish whether this was due to individual males altering the blend they released or whether each male produced a fixed blend, and changes were caused by fluctuations in the numbers of males producing a given ratio (White et al., 1989). If males could alter the ratio they emit, theoretically they could affect the ratio of males to females likely to be attracted, perhaps drawing in females when sexually mature or both sexes if habitat conditioning (e.g., by raising humidity) was required. Further research awaits the development of techniques to collect and analyze the pheromone blend produced by individual beetles.

The present study has highlighted the complexity of the chemical com-

munication system in the saw-toothed grain beetle. If this system is to be successfully manipulated to improve detection and monitoring of this economically important yet elusive pest, a full understanding of the factors affecting both the production of and the response to the pheromone is essential.

Acknowledgments—This work was carried out as part of the Oxford University/ADAS Slough Laboratory project on The Responses of Stored-Product Insects to Food Odours and Pheromones. P.R.W. was funded by an open contract from the MAFF Chief Scientist. We should like to thank Dr. A.M. Pierce, Simon Fraser University, British Columbia, for supplying synthetic samples of the pheromone, and Mr. D.B. Pinniger, Slough Laboratory, for much useful advice and discussion.

PYGIDIAL SECRETIONS OF *Pasimachus subsulcatus*
(COLEOPTERA: CARABIDAE) DETER PREDATION BY
Eumeces inexpectatus (SQUAMATA: SCINCIDAE)

BRIAN W. WITZ and HENRY R. MUSHINSKY

*Department of Biology
University of South Florida
Tampa, Florida 33620*

Abstract—The carabid beetle *Pasimachus subsulcatus* is an abundant ground-dwelling insect in west central Florida that exudes a powerful mucous membrane irritant when disturbed. This secretion can be sprayed over 10 cm from the abdominal tip. The southeastern five-lined skink, *Eumeces inexpectatus*, is an abundant insectivorous lizard sympatric with *Pasimachus*. We assessed the availability of *Pasimachus* to *Eumeces* and found it to be within the foraging microenvironment of the lizard. Analysis of *Eumeces* gut contents and field feeding trials indicate that *Pasimachus* are not ingested by the lizard, yet arthropods of comparable size and exoskeletal thickness are ingested. The movement response of *Eumeces* to isolated *Pasimachus* secretion constituents, conducted in a modified Y-maze laboratory experiment, was used to assess the repellent capabilities of the secretion. *Eumeces* are consistently repelled by *Pasimachus* secretion constituents, indicating that the beetle is protected chemically from the lizard.

Key Words—Defensive mechanism, avoidance response, *Eumeces inexpectatus*, *Pasimachus subsulcatus*, Coleoptera, Carabidae, lizard ecology, lizard predation.

INTRODUCTION

Noxious substances are among the myriad defensive mechanisms exhibited by insects. These substances are produced either internally (Smolanoff et al., 1975; Eisner and Dean, 1976; Eisner et al., 1976, 1978, 1981; Jefson et al., 1983; Carrel and Eisner, 1984) or obtained from the environment and incorporated into the defensive repertoire (Morrow et al., 1976). The mechanics of discharge

and the chemical constituency of certain arthropod defensive secretions have been studied extensively (Eisner et al., 1963a,b; Eisner and Meinwald, 1966). Arthropod secretions are effective deterrents to ants (Smolanoff et al., 1975; Eisner et al., 1976; Jones et al., 1976; Jefson et al., 1983), spiders (Eisner and Dean, 1976; Carrel and Eisner, 1984), and certain vertebrate predators (Eisner et al., 1978, 1981). Many species of carabid beetles possess defensive pygidial glands (Forsyth, 1972; Blum, 1982). Secretions of these glands contain formic acid, methacrylic acid, *p*-benzoquinone, toluquinone, *m*-cresol, and salicylaldehyde; all are noxious to vertebrate predators (Eisner, 1966). Information regarding the effectiveness of arthropod secretions against insectivorous reptiles, specifically lizards, is limited (Eisner et al., 1961; Vogel and Brockhusen-Holzer, 1984).

The carabid beetle *Pasimachus subsulcatus* is abundant throughout the year in the sandhills of west central Florida (McCoy, 1987). Both *P. subsulcatus* and the larger sympatric congener *P. strenuus* exude a highly volatile mucous membrane irritant from the pygidial gland when disturbed by a predator. The secretion is expelled either by a slow oozing over the surface of the abdomen or by an expulsion in a highly directional spray.

The southeastern five-lined skink, *Eumeces inexpectatus*, is an abundant, ground-dwelling lizard throughout the southeastern United States and is sympatric with *Pasimachus* in the sandhills of west central Florida. It occurs in both xeric and mesic habitats in central Florida. Skinks (family Scincidae) are grouped with the families Lacertidae, Teiidae, Cordylidae, Helodermatidae, Varanidae, in the Autarchoglossa (Camp, 1923; Bissinger and Simon, 1979). Autarchoglossans have a highly protrusible, elongated bifurcating tongue, a well-developed Jacobson's organ, and use chemoreception extensively for environmental assessment (e.g., prey selection and/or avoidance, search behavior, conspecific recognition, etc.), although vision may be equally important (Nicolletto, 1985; Cooper, 1981).

The congeneric five-lined skink, *Eumeces fasciatus*, ingests coleopterans; however, certain sympatric carabid beetles that were within the size range of ingested prey were absent from their scats and stomachs (Fitch, 1954). Forsyth (1972) surmised that the noxious qualities of certain carabid beetles protect them from predation.

How reptiles detect prey and avoid nonprey is poorly understood. Burghardt (1966) considered increased tongue-flick frequency by reptiles an indication of response to preferred prey; however, the specific motivation for tongue flicking may vary (see Simon, 1983). Experimental designs that focus on measuring predator movement in relation to potential prey may provide more conclusive evidence for understanding lizard predator-prey relationships than those that measure tongue flicking.

In this study, we quantify the movement responses of *Eumeces inexpectatus*

tatus to isolated secretions of *Pasimachus subsulcatus* to determine the effectiveness of the secretion and its constituents as a skink predator deterrent. Specifically, we test the following hypotheses: (1) *Pasimachus subsulcatus* is an available prey for *Eumeces inexpectatus*. (2) *Eumeces inexpectatus* refuse to ingest *P. subsulcatus* and other arthropods of similar size and habits under controlled field conditions. (3) Museum specimens of *Eumeces* contain no *Pasimachus subsulcatus* in their digestive tract and no other arthropods of comparable size and habits. (4) *Pasimachus* secretion and individual secretion constituents have no effect on the movement behavior of *E. inexpectatus*.

METHODS AND MATERIALS

Study Area. Field work was conducted in the sandhill portion of the University of South Florida Ecological Research Area. For a complete description of the habitat see Mushinsky (1985).

Availability of Prey. The daily activity cycles of *Pasimachus subsulcatus* and *Eumeces inexpectatus* are asynchronous. *Pasimachus subsulcatus* is nocturnal and active throughout the year, while *E. inexpectatus* is diurnal and active primarily only in the warmer months from April through October. *Eumeces* forage in leaf litter (Fitch, 1954; Vitt and Cooper, 1986). It was important to determine whether or not the beetle occurred in the litter during the day and, therefore, was available to the lizards.

Leaf litter core samples (area of core base = 78.54 cm) were taken randomly from the study area ($N = 150$). Litter depth was determined by measuring the distance from the soil-litter interface to the top of the litter layer. Samples were stored separately, returned to the laboratory, and weighed. They were dried at 70°C for 24 hr, and the dry weight was recorded. Density of each sample was calculated using the formula $D = m/v$, where m is the dry weight (mg) and v is the volume (cm³). The following variables were then estimated: (1) percent contribution to leaf litter of dominant tree species, ranked from most to least frequently monotypic leaf litter type, using the first 50 samples; (2) range of litter depth for each common monotypic leaf litter type; and (3) range of litter density for each common monotypic leaf litter type.

Manipulations were performed in the field to estimate the location of *Pasimachus subsulcatus* during its daytime inactivity period. Five 40-liter glass aquaria were buried in randomly selected locations, with the upper 5 cm above ground. The aquaria were filled to ground level with local soil. In May and June 1986, the months of peak activity for *Eumeces* in west central Florida, individual *P. subsulcatus* were placed in each aquarium with each common litter type (*Quercus geminata*/*Q. virginiana* combined, *Q. laevis*, and *Pinus palustris*). *Quercus geminata* and *Q. virginiana*, and *Quercus laurifolia* and *Q.*

incana (least common species) were combined because these couplets of oaks frequently hybridize and because they share similar leaf morphologies. Low, medium, and high densities of each common litter species were determined by using the minimum, median, and maximum values obtained from field samples. Litter samples were resaturated with water to the moisture level measured prior to the manipulation. Aquaria were covered with wire screens to prevent the beetles from escaping and to reduce predation. After 24 hr, the litter was removed carefully and the position of the beetle was recorded. Each beetle was checked for presence or absence of secretion by squeezing the abdomen and pulling an appendage, thereby simulating a predator attack. Pearson product moment correlations (Sokal and Rohlf, 1981) were calculated for beetle location with both litter depth and litter density.

Feeding Trials. Field feeding trials were conducted to determine if *Pasimachus subsulcatus* are ingested by *Eumeces*. A 1-m² quadrat was selected randomly and enclosed with tin drift fence material to form a test pen. All plant material was removed from the quadrat to facilitate unobstructed observation. Lizards were offered centipedes, millipedes, spiders, orthopterans, and several species of coleopterans including *Pasimachus*. Each individual prey was placed separately in the test pen with a lizard and observed for 1 hr or until the prey was ingested.

Analysis of Gut Contents. The 35 *Eumeces inexpectatus* in the University of South Florida herpetological collection were dissected to check for presence or absence of *Pasimachus subsulcatus* and to determine if prey of similar size and habits were ingested. Museum specimens were collected from a variety of locations in west central Florida. All partially digested coleopterans were identified by elytral fragments. Prey in stomachs and intestines were identified to order. Gut contents were dried at 70°C for 24 hr before weighing.

Response to Isolated Pygidial Secretions. *Eumeces* were housed individually in 2-liter plastic containers and maintained at 28°C on a 12:12 hr light-dark cycle. Lizards were fed *Tenebrio molitor* larvae to satiety weekly and tested one day prior to the scheduled experimental feeding to ensure a similar degree of hunger. The antipredator effectiveness of *Pasimachus subsulcatus* pygidial secretions was evaluated by measuring the movement response of *Eumeces* to commercially synthesized secretion constituents obtained from Eastman Kodak Corporation (Table 1). *Pasimachus subsulcatus* pygidial gland reservoirs were removed from freezer-killed animals and placed in separate ampules. Thomas Eisner and Brad Davidson of Cornell University, Ithaca, New York, kindly identified the secretion constituents. Two individual purified constituents and a mixture of three purified constituents (Table 2) combined in their natural proportions (Table 1) were presented to *Eumeces* in a rectangular Plexiglas test chamber (19 × 21 × 5 cm). The test chamber was partitioned equally into three compartments. Doorways (4 cm²) were cut in the center of the par-

** $P < 0.01$.

titions to allow the lizards access to each compartment (Figure 1). The test room was dark except for lamps illuminating the four sides of the test chamber (Vitt and Cooper, 1986). This technique allowed us to observe the lizard without disturbing it. A lizard was placed in the center chamber and denied access to the other chambers by blocking the doorways with Plexiglas doors for 1 min. Removal of the doors allowed the lizard to move freely between chambers for 10 min. Lizards came to rest in one of the chambers after approximately 10

FIG. 1. Test chamber used in isolated secretion experiments. X indicates location of doorways.

min. Fifteen trials per lizard were conducted without stimuli on 10 lizards to determine if the distribution differed significantly from random (0.33 probability of being located in any chamber). Lizards were treated as replicates with multiple trials per lizard. Values were pooled if individual lizard's responses did not differ significantly from the expected random distribution.

Lizards then were tested by placing a paper toweling strip (4×1 cm) across the floor at the entrance to the left and right chambers. A trial consisted of wetting one strip with 0.5 ml of a beetle secretion constituent (experiment) while the other strip was saturated with 0.5 ml of distilled water (control). Experimental and control strips were assigned randomly to the chambers. A lizard was placed in the center chamber and tested in the same manner as the trials without stimuli. After 10 min, the lizard's location was recorded and the trial terminated. A total of 283 trials were conducted, 106 for secretion A (isobutyric acid), 96 for secretion B (methacrylic acid), and 81 for secretion C (tiglic, methacrylic, and isobutyric acids combined). Since the trials for each lizard differed significantly from the expected random distribution, the results for all lizards were combined. The pooled results of each stimulus were tested with a *G*-test goodness-of-fit analysis adjusted for chi-square approximation with Williams' correction formula (Sokal and Rohlf, 1981) to determine if the observed distribution of lizard locations was different from expected.

RESULTS

Litter Measurements and Availability of Prey. Quercus geminata/Q. virginiana ranked first in relative abundance of litter types; *Quercus laevis* was

second, *Pinus palustris* third, and *Q. laurifolia/Q. incana* fourth (Table 3). Low, medium, and high litter depths and densities are listed in Table 4.

In 29 of 40 litter density manipulations (73%), beetles were found at or above the soil-litter interface. Nine beetles (23%) were found in the soil (two beetles died during the experiment). Given a choice, most beetles rest in or just below the litter during their inactive period. Six of the 29 beetles were located at the soil-litter interface while the remaining 23 were above it. Beetles burrowed in the soil most frequently at low litter densities. Seven of the nine beetles that had burrowed into the soil were located only 0.5 cm below the interface. No beetle burrowed more than 3.0 cm into the soil. Beetle location did not correlate with litter depth ($r = 0.34$, $P > 0.05$). Beetle burrowing depths in all manipulated litter types and densities are listed in Table 5.

Eight of nine beetles that burrowed into the soil failed to produce pygidial secretion upon simulation of a predator attack. We assumed that the gland had been depleted prior to the experiment. Only two of 23 beetles located in the litter lacked the secretion, as did one of the six beetles located at the interface. Perhaps beetles that lack secretion tend to burrow into the soil to avoid predators.

Analysis of Gut Contents. Of 68 prey found in the guts of 28 lizards, 58

^bAquaria could not accommodate the high density of *Pinus*.

(85%) were arthropods (Table 6). Seven lizards (20%) contained nothing in the gut. Although coleopterans constituted nearly 15% of the prey, no adult *Pasi-machus subsulcatus* were found; however, three coleopteran larvae were found that could not be identified. Ten items (15%) were not identified. Two intact tenebrionids were found in one lizard. The size of beetles found in the gut was similar to that of *P. subsulcatus*. None of the elytra matched those of *P. subsulcatus*.

Feeding Trials. *Eumeces* readily ingested large lycosid spiders (20 mm maximum body length), adult and larval tenebrionid beetles (two species),

TABLE 6. GUT CONTENTS OF PRESERVED *Eumeces inexpectatus*

Prey type	Percent of lizards with prey type	Percent of total prey
Araneae	33	22.1

orthopterans, and large centipedes (10 cm in length). *Pasimachus subsulcatus* is well within the size range of these prey. Lycosid spiders placed anywhere in the test pen with *Eumeces* immediately adopted a sustained defense posture, which consisted of rearing up on the posterior legs with the chelicerae poised for attack. The approach of *Eumeces* was met with a series of lunges by the spiders. *Eumeces* subsequently seized the spiders, smashed them against the substrate, and proceeded to dismember and ingest them. *Eumeces* grasped centipedes in their jaws and smashed them against the substrate for up to 1 min. Defensive reactions of the centipedes consisted of multiple bitings and exaggerated writhing movements. Millipedes were attacked but not ingested. No *Pasimachus* were ingested or attacked. Only one lizard tongue-flicked *Pasimachus*. One beetle actually hid under the body of *Eumeces* during the trial without evoking a response from the lizard. Although movement of most prey resulted in an immediate orientation or movement response from *Eumeces*, movement by *Pasimachus* was typically ignored.

Response to Isolated Pygidial Secretions. In trials without stimuli, lizard locations were not significantly different from the expected random distribution (Table 2). Of 283 trials ($N = 11$ lizards), the chamber labeled with the pygidial secretions was occupied in seven (2%) trials. Of the remaining 276 trials, the center chamber was occupied 166 (59%) times and the chamber labeled with the control was occupied 110 (39%) times. The distribution of lizard locations differed significantly from the expected random distribution for all secretions tested (Table 2).

DISCUSSION

Both the vomeronasal and the nasal olfactory systems are important for prey detection by lizards (Simon, 1983). Each system is innervated separately and may be effective at different distances from a stimulus. Our qualitative observations of *Eumeces inexpectatus* support the assertion that tongue-flick rate increases upon presentation of novel yet undesirable prey as well as upon introduction into an unfamiliar aquarium (see De Fazio et al., 1977). Because the specific motivation for tongue flicking may vary (Burghardt, 1973; Cooper and Vitt, 1986a,b, 1987), conclusions from experiments measuring lizard movement in relation to a potential prey may be less ambiguous than those derived from counting tongue flicks.

Although *Pasimachus subsulcatus* is active at night, it is likely that the beetle rests during the day within the foraging microenvironment of the diurnally active *Eumeces inexpectatus*. Examination of *Eumeces* gut contents indicated that the skinks are capable of ingesting prey comparable in habits to *Pasimachus*. Lycosid spiders are nocturnal and rest in litter during the day (per-

sonal observation), yet were found frequently in the guts of *Eumeces*. In fact, most of the prey found in *Eumeces* were nocturnally active and were inactive and hidden during the lizards' foraging period. *Pasimachus subsulcatus* have a thick exoskeleton and may require longer handling times than soft-bodied arthropods of comparable size. Elytral fragments found in the guts of preserved lizards comparable in thickness to those of *Pasimachus* indicate that *Eumeces* are capable of ingesting these hard-bodied arthropods.

Feeding trials confirm that *Eumeces* prey upon relatively large arthropods. Centipedes more than half the length of *Eumeces* were ingested easily. Tenebrionid beetles similar in size, color, and exoskeletal thickness to *Pasimachus* were ingested by *Eumeces*. Large lycosid spiders were killed and ingested within 1 min of a *Eumeces* attack. Orthopteran tibial spines also did not inhibit predation by the lizards. However, millipedes were not ingested. Eisner et al. (1963a) and Smolanoff et al. (1975) have shown that certain millipedes are protected chemically from predation. We conclude that *Pasimachus* is available and within the size and structure range of prey taken by *Eumeces*. The absence of a positive response by *Eumeces* to *Pasimachus* in all feeding trials indicates that lizards either have learned or are programmed genetically to avoid *Pasimachus subsulcatus*.

Investigations regarding chemosensory-mediated prey selection in lizards have been limited to within-clutch analyses of tongue-flick response to nonnoxious prey (Loop and Scovile, 1972; Burghardt, 1973). The chemosensory response of a population of *Eumeces inexpectatus* ($N = 11$) from west central Florida convincingly demonstrates that this lizard typically does not occupy chambers labeled with *Pasimachus subsulcatus* secretion. Lizards walked about the test chamber frequently, and virtually every forward movement was accompanied by a series of tongue flicks. Tongue flicks were directed primarily at the substrate but also at the air immediately ahead of the lizard. Lizards approaching a chamber labeled with a beetle secretion typically halted, reversed direction, and rubbed the snout on the chamber floor for several seconds. After tongue-flicking the *Pasimachus* secretion, lizards often ran to the far chamber. One lizard entered the chamber labeled with a beetle secretion four times. Lizards that entered secretion-labeled chambers did not tongue flick the secretion upon entering the chamber. Once in the secretion-labeled chamber, lizards remained there if they contacted the secretion while attempting to leave. Perhaps these lizards did not detect the secretion upon entering the chamber but may have sensed it while attempting to exit.

Vomer nasal contact with *Pasimachus subsulcatus* pygidial secretion is sufficient to halt the forward progress of *Eumeces inexpectatus*. Eisner (1970) has determined that the elytral sculpturing of certain beetles impedes evaporation of residual pygidial spray. Residual secretion may remain on the elytra for several hours and subsequently still be an effective predator deterrent. Perhaps

predators need only sample these residual molecules, without actually being sprayed, to exhibit an avoidance response. Because *Eumeces inexpectatus* relies heavily on chemoreception to detect their diurnally inactive prey, it may be more economical energetically to use the same sensory mechanisms to avoid concealed noxious prey.

Acknowledgments—We thank Earl D. McCoy for his suggestions and for statistical consultations. Glen E. Woolfenden's guidance in structuring this manuscript and in keeping the natural history of the organisms always in mind was invaluable. Thanks to Karen E. Petersen for reading drafts and for the use of her personal computer. We also thank the members of the biology department on the second floor of the Life Sciences building at the University of South Florida for tolerating the foul smells emanating from our laboratory. Finally, without the help of Thomas Eisner and Brad Davidson in analyzing the secretion, this project could not have been undertaken.

(Received December 21, 1987; accepted April 25, 1988)

Abstract—(*Z*)-11-Octadecenyl acetate (Z11-18:Ac) and (*Z*)-11-eicosenyl acetate (Z11-20:Ac) were identified as the aggregation pheromones of *Drosophila ananassae*, and Z11-20:Ac was identified as the aggregation pheromone of *Drosophila bipectinata*. Z11-18:Ac and Z11-20:Ac were not attractive alone; however, in combination with fermenting food odors, the acetates attracted flies of both sexes in a wind-tunnel olfactometer. The pheromones were present in the ejaculatory bulb of sexually mature male flies and transferred to the female during mating. Male *D. bipectinata* released little if any Z11-20:Ac to the food; however, recently mated females released Z11-20:Ac to the surrounding surfaces in just a few hours after mating. *D. ananassae* males, on the other hand, appeared to release more Z11-18:Ac and Z11-20:Ac to the surroundings than mated females. Although *D. bipectinata* males had no Z11-18:Ac, flies were as attracted to Z11-18:Ac as to an equal quantity of Z11-20:Ac. *D. ananassae* were attracted to Z11-18:Ac but not to Z11-16:Ac or Z11-20:Ac. However, Z11-20:Ac in combination with Z11-18:Ac was significantly more attractive than Z11-18:Ac alone.

Key Words—*Drosophila ananassae*, *Drosophila bipectinata*, Diptera, Drosophilidae, aggregation pheromone, (*Z*)-11-octadecenyl acetate, (*Z*)-11-eicosenyl acetate, *cis*-vaccenyl acetate.

INTRODUCTION

In all *Drosophila* species studied to date, aggregation pheromones exist that are produced exclusively by the sexually mature males, attractive to both sexes,

and most active in combination with food odors (Bartelt and Jackson, 1984; Bartelt et al., 1985a,b, 1986, 1988; Moats et al., 1987; Schaner et al., 1987, 1989) In the *virilis* species group, the aggregation pheromones are a blend of hydrocarbons and esters of tiglic and hexanoic acids (Bartelt and Jackson, 1984; Bartelt et al., 1985a, 1986, 1988). The hydrocarbons are transferred by the male to the food media (unpublished). In *D. hydei*, a member of the *repleta* group, the aggregation pheromone is a mixture of ketones along with the esters of tiglic acid (Moats et al., 1987). The esters of tiglic acid are a component of the pheromone blend common to both groups, yet each required compounds with different chemical functional groups in combination with the esters for optimal aggregation response. In the *melanogaster* subgroup of the *melanogaster* group, *D. melanogaster* and *D. simulans* sexually mature males produce (*Z*)-11-octadecenyl acetate (*Z*11-18:Ac) (Bartelt et al., 1985b; Schaner et al., 1987); however, in the *ananassae* subgroup, *D. malerkotliana* males produce (*Z*)-11-eicosenyl acetate (Schaner et al., 1989). In both subgroups the pheromone is stored in the ejaculatory bulb, transferred to the females during mating, emitted by the female to the food within a few hours after mating, and functions as the aggregation pheromone.

We report here the identification, transfer, and bioassay characteristics of the aggregation pheromones in *D. ananassae* and *D. bipectinata*, also of the *ananassae* subgroup.

METHODS AND MATERIALS

Flies. *D. ananassae* (strain 14024-0371) and *D. bipectinata* (strain 14024-0381) were obtained from the National Drosophila Species Resource Center at Bowling Green, Ohio. Flies were reared on Instant Drosophila Medium Formula 4-24 (Carolina Biological Supply Co., Burlington, North Carolina) in 1-liter jars or in 3.5×10 -cm vials under a light-dark cycle of 16:8 hr and 22-24°C.

The method of extraction, chromatography, identification, bioassay, and pheromone transfer have been reported previously (Bartelt and Jackson, 1984; Bartelt et al., 1985b; Schaner et al., 1987, 1989). Briefly, flies were separated by sex at 0-6 hr old and extracted at 6-7 days of age by soaking the flies in hexane at room temperature for 24 hr. Hexane extracts were fractionated on open columns of silicic acid eluted with: hexane; 10% ether in hexane; 50% ether in hexane; and 10% methanol in methylene chloride.

Bioassays were conducted in a wind-tunnel olfactometer containing ca. 1000 (0- to 2-day-old) flies that had been without food or water for approximately 2 hr. An extract, fraction, synthetic compound, or control solvent was applied to a filter paper inserted around the lip of a glass vial. Each bioassay

test consisted of placing two differently treated vials to be compared into the olfactometer for 3 min. The bioassay data were transformed to the $\log(X + 1)$ scale before analysis to stabilize variance, and analysis was done by the method of Yates (1940).

Production, Transfer, and Dispersal of Pheromone. The methods have previously been described (Schaner et al., 1989). Briefly, ejaculatory bulbs were removed from adult male flies at various ages, extracted with hexane, and analyzed by gas chromatography (GC). The transfer of pheromone during mating was quantitated by removing the reproductive tract of females and the ejaculatory bulb and ducts of males immediately after mating, crushing the organs with the head of a dissecting pin, extracting with hexane, and analyzing by GC relative to an internal standard.

RESULTS AND DISCUSSION

Identification of Pheromone Components. Crude hexane extracts of either male or female flies were not active in aggregation assays (2.6 and 2.1 mean catch, respectively, for *D. ananassae* and *D. bipectinata* male extracts alone). Other *Drosophila* frequently require food or food odors in combination with the pheromone to demonstrate or enhance aggregation activity (Bartelt et al., 1985b, 1986, 1988; Schaner et al., 1989). Both *D. bipectinata* and *D. ananassae* crude hexane extract of males were synergistic with fermenting food (Table 1, A). For convenience, solvents such as acetone (Bartelt et al., 1985b; Schaner et al., 1989) and 0.1% acetic acid were tested to mimic the coattraction observed with fermenting food (Table 1, B). Both acetone and acetic acid were effective coattractants. Acetic acid in combination with the crude extracts attracted more flies, so it was used throughout this investigation.

The crude hexane extracts of mature male flies along with acetic acid were clearly active in bioassay for both species (Table 2), whereas the extracts from female flies were inactive. After chromatography of the extracts of male flies, the most active fraction in both species was the 10% ether-hexane fraction, which contains the acetate esters (Bartelt et al., 1985b; Schaner et al., 1987, 1989). Gas chromatography and gas chromatography-mass spectrometry (GC-MS) of the 10% ether-hexane fraction revealed that in *D. ananassae* the fraction was 29% (Z)-11-octadecenyl acetate (Z11-18:Ac) and although no (Z)-11-eicosenyl acetate (Z11-20:Ac) was detected in this fraction, a small amount of Z11-20:Ac was later discovered in the ejaculatory bulb. In *D. bipectinata* the fraction was 50% Z11-20:Ac with no detectable Z11-18:Ac. The position of the unsaturation was determined by GC-MS of the dimethyl disulfide derivative (Nichols et al., 1986).

In bioassay, the 10% ether-hexane fraction accounted for more than all of

50% ether fraction	44*** (1.4, 6.5, 12.9)	-51 (3.5, 0.8, 8.8)
10% MEOH/CH ₂ Cl ₂ fxn.	9** (1.2, 2.9, 19.5)	-23 (2.7, 1.0, 10.1)
Crude extract of females	7 (1.9, 2.9, 16.6)	-16 (2.6, 1.5, 9.6)

^aRelative response = [(fraction - control)/(male crude extract - control)] × 100.

^b** and *** denote significance of *t* tests vs. controls at the 0.01 and 0.001 level, respectively.

^cThe numbers in parenthesis are mean catch of flies to 0.1% acetic acid control, fraction + 0.1% acetic acid, male crude extract + 0.1% acetic acid.

the activity of the male crude extract (Tables 2 and 3). This suggests that the active compounds were in the 10% ether-hexane fraction, but the crude extract may have had compounds that diminish the aggregation activity. Synthetic Z11-18:Ac and Z11-20:Ac accounted for all the aggregation activity of the male 10% ether-hexane fraction for *D. ananassae* and *D. bipectinata*, respectively.

Since the crude hexane extracts of males were synergistic with fermented food, synthetic Z11-18:Ac and Z11-20:Ac were bioassayed with *D. ananassae* and *D. bipectinata*, respectively, to determine whether they also were synergistic with the aggregation activity of food. The synthetic acetate esters were synergistic with fermenting food (Table 1, C).

Aggregation Activity Specificity. The specificity of the flies' response to a certain chain length Z11-acetate was tested, and *D. ananassae* showed high specificity for Z11-18:Ac and no attraction toward Z11-20:Ac (Table 1, D). Because males possess both Z11-18:Ac and Z11-20:Ac, the two were combined to test for synergism. Z11-18:Ac and Z11-20:Ac together were significantly more attractive than Z11-18:Ac alone (Table 1, E). *D. bipectinata* responded equally to either Z11-18:Ac or Z11-20:Ac even though males produce only Z11-20:Ac. Neither species was attracted to Z11-16:Ac. In previous studies (Schaner et al., 1989), *D. melanogaster* and *D. simulans* were

attracted only to Z11-18:Ac, but *D. malerkotliana* responded to both Z11-18:Ac and Z11-20:Ac. *D. melanogaster* preferred Z11-16:Ac slightly over controls, but neither of the other species were attracted to Z11-16:Ac. Of the five species so far tested against these three acetate esters, there was a range of specificity that does not follow taxonomic lines, but varies within each species group. A more complete rationale for the specificity variation awaits further studies of other species.

Dose Response. For *D. ananassae*, when a dose of Z11-18:Ac was increased from 1.2 ng to 12 ng, there was a dramatic increase in the aggregation activity (Figure 1). Activity increased only slightly when the dose increased to 1200 ng. The dose of 12 ng of Z11-18:Ac was the lowest dosage to result in a maximum dose plateau so far observed for this type of aggregation pheromone. For *D. bipectinata* (Figure 1), the same trend was observed. There was also a dramatic increase in response when the dose of Z11-20:Ac was increased from 20 ng to 200 ng. From 200 ng to 2000 ng, and from 2000 ng to 20,000 ng, the response of the flies increased slightly, but not significantly.

Location, Production, Transfer, and Dispersal of Aggregation Pheromones. As previously observed in *D. melanogaster*, *D. simulans*, and *D. malerkotliana* (Brieger and Butterworth, 1970; Schaner et al., 1987, 1989), the ejaculatory bulb of *D. ananassae* and *D. bipectinata* mature male flies was the site of storage of the aggregation pheromone. Analysis of *D. ananassae* ejaculatory bulb contents (Figure 2) showed an increase in Z11-18:Ac with age from 0 ng/fly at day 1 up to a plateau of ca. 52 ng/fly on day 7. The ejaculatory bulbs of male *D. ananassae* also contained Z11-20:Ac, which increased after day 1 to a plateau of about 15-17 ng/fly. *D. ananassae* was the only species

FIG. 1. Dose-response curves relative to the amount of pheromone that was hexane extractable from content of one mature male fly (100%). Solid line was the response for *D. ananassae* to Z11-18:Ac. Dashed line was the response for *D. bipectinata* to Z11-20:Ac.

found to possess both the aggregation pheromone common to the *melanogaster* subgroup (Z11-18:Ac) and that of the *ananassae* subgroup (Z11-20:Ac).

D. bipectinata male flies produce ca. 30 ng of Z11-20:Ac at 1 day of age (Figure 2) and ca. 300 ng/fly by 4 days of age, where they reach a plateau. Z11-18:Ac was not detected in ejaculatory bulb extracts of *D. bipectinata*, even though they responded to Z11-18:Ac in aggregation assays (Table 1, D). The amount of Z11-20:Ac produced in the ejaculatory bulb and the bioassay response towards both Z11-18:Ac and Z11-20:Ac was the same as that observed for *D. malerkotliana* (Schaner et al., 1989).

As was observed in *D. melanogaster* (Brieger and Butterworth, 1970; Butterworth, 1969; Jallon et al., 1981; Bartelt et al., 1985b), *D. simulans* (Schaner et al., 1987), and *D. malerkotliana* (Schaner et al., 1989), a portion of the aggregation pheromone in the ejaculatory bulb of *D. ananassae* and *D. bipectinata* was transferred to the female fly during mating (Table 4). *D. bipectinata* male flies transferred about two thirds of their Z11-20:Ac to the female during mating and nearly half of the Z11-20:Ac was released by the female flies to the vial within 6 hr. Neither mated nor virgin males of *D. bipectinata* released

FIG. 2. Pheromone content in the ejaculatory bulb of male flies as they age. Dashed line for Z11-20:Ac in *D. bipectinata*. Solid line for Z11-18:Ac and dotted line for Z11-20:Ac in *D. ananassae*. The bars indicate standard deviation.

Z11-20:Ac to their surroundings in 6 hr. *D. ananassae* male flies, on the other hand, transferred both Z11-18:Ac (ca. 14 ng/fly) and Z11-20:Ac (ca. 5 ng/fly) to the female reproductive tract. Within 6 hr after mating, female flies released only a trace of both compounds to the vial and had retained most of the transferred compounds in their reproductive tracts. Both mated and virgin *D. ananassae* males release Z11-18:Ac to their surroundings in 6 hr (Table 4). This was the first time that the release by males, either mated or virgin, was greater than the release by mated female flies. By 12 hr after mating, the mated females had released approximately half of the Z11-18:Ac that was transferred. The release by mated males during 12 hr after mating was ca. 35 ng of Z11-18:Ac and ca. 2 ng of Z11-20:Ac per fly, which was about seven times more than was released by the mated females. Virgin males also released similar amounts. This suggests that there was not only release, but also synthesis of at least Z11-18:Ac. Unlike the *Drosophila* species observed so far, *D. ananassae* males were the primary releasers of the aggregation pheromone rather than mated females, as observed here for *D. bipectinata* and previously for *D. melanogaster* (Bartelt et al., 1985b), *D. simulans* (Schaner et al., 1987), and *D. malerkotliana* (Schaner et al., 1989).

In nature, mating, feeding, and oviposition all occur at the same location, and flies are attracted to these locations by odors (Spieth, 1974). We believe this attraction is caused not only by food odors but often by a combination of

food odors and fly-derived compounds. *D. ananassae* and *D. bipectinata* males produce an aggregation pheromone that is synergistic with food odors. In the case of *D. bipectinata*, males cannot release the pheromone, but a recently mated female is capable of emitting levels of Z11-20:Ac that are attractive with a food source in our olfactometer. On the other hand, a *D. ananassae* male or recently mated female can release levels of Z11-18:Ac that are also attractive with a food source. These results suggest that in nature, flies are not only attracted to feeding sites by food odors, but they may demonstrate an even stronger attraction to food sources that are already occupied by others of the same species.

In summary, aggregation pheromones in *D. ananassae* and *D. bipectinata* have been identified and characterized, and attraction towards them has been demonstrated. The pheromones are (Z)-11-octadecenyl acetate and (Z)-11-eicosenyl acetate in *D. ananassae* and (Z)-11-eicosenyl acetate in *D. bipectinata*. In both species the pheromones are produced exclusively by sexually mature male flies, stored in the ejaculatory bulb, transferred to the female during mating, synergistic with food odors, and attracted flies of both sexes in a wind-tunnel olfactometer.

The *ananassae* species group is divided into two species complexes based on the structure of the male genitalia (reviewed by Lemeunier et al., 1986). *D. malerkotliana* and *D. bipectinata* of the *bipectinata* complex both produce Z11-20:Ac, which is released by mated female flies, and they respond to either Z11-18:Ac or Z11-20:Ac. *D. ananassae* in the *ananassae* complex produces both Z11-18:Ac and Z11-20:Ac, which is released by mature male flies, and they respond to Z11-18:Ac and a combination of Z11-18:Ac with Z11-20:Ac, but not to Z11-20:Ac alone. Whether the production and response specificity is present in other members of the *ananassae* and *bipectinata* complexes remains to be determined.

(Received September 7, 1987; accepted April 26, 1988)

Abstract—1,5,7-Trioxaspiro[5.5]undecane, an analog of the major sex pheromone (olean) of the olive fruit fly, was synthesized via two different routes and tested for biological activity under laboratory and field conditions. In laboratory tests, its activity was comparable to that of olean, especially when a stabilizer or a high concentration was used. In field tests, its activity reached the level of olean only when a stabilizer and an open-type dispenser, which allows high rates of evaporation, were used. The residual activity of the analog dispensers did not exceed two weeks both under laboratory and field conditions compared to over four months for olean.

Key Words—Olive fruit fly, *Dacus oleae*, Diptera, Tephritidae, pheromones, attractants, sex attractants, pheromone analog, 1,5,7-trioxaspiro[5.5]undecane.

INTRODUCTION

The olive fruit fly, *Dacus oleae* (Gmelin), is a major pest of olives in the Mediterranean region. Present control practices involve the use of wide-spectrum insecticides with serious ecological and toxicological consequences. Scientists in all interested countries are working on the development of alternative control methods. The finding of a four-component female pheromone blend for this pest (Baker et al., 1980; Mazomenos and Haniotakis, 1981, 1985) has stimu-

FIG. 1. Chemical structures of 1,7-dioxaspiro[5.5]undecane, the major pheromone of *Dacus oleae* (1), and its analog, 1,5,7-trioxaspiro[5.5]undecane (2).

lated research towards its use for the development of such methods (Haniotakis et al., 1986b, 1987; Montiel and Mata, 1984). The spiroacetal, 1,7-dioxaspiro[5.5]undecane (olean), (1 in Figure 1) is the major component of the blend, which acts as a potent, long-range male attractant and which is released as a racemate (Haniotakis et al., 1986a). The same compound was also found in male flies (Mazomenos and Pomonis, 1983; Haniotakis et al., 1986a), which is as attractive to males as olean isolated from females. No female attraction has been observed, however, to olean of either male or female origin. EAG studies of the racemic mixture of synthetic olean showed similar response of male and female antennae (Van der Pers et al., 1984). Olean isolated from males appears to be also racemate but verification of first results is still required. Further studies showed that (*R*)-1 (Figure 1) is the long-range attractant for males while (*S*)-1 (Figure 1) is an arrestant and aphrodisiac for females (Haniotakis et al., 1986a). We synthesized analogs of olean to find cheaply available attractants (or repellents) and for basic studies on insect olfaction. The synthesis of 1,5,7-trioxaspiro[5.5]undecane, which in this paper will be called analog for convenience, via two different routes, and its biological activity under laboratory and field conditions are reported here.

METHODS AND MATERIALS

Synthesis of 1,5,7-Trioxaspiro[5.5]undecane (Analog). According to the literature, spirocyclic orthoesters are commonly synthesized from the corresponding lactones either by *p*-toluene sulfonic acid-catalyzed condensation with a diol in refluxing benzene (LeMahieu and Kierstead, 1970; Saucy et al., 1977) or by epoxide treatment in the presence of Lewis acid (Bodenbenner, 1959; Inoue and Kataoka, 1965; Imakure, 1971).

The above methods were proven unsatisfactory in the case of the condensation of the simple 1,5-pentanolide (δ -valerolactone) with propane-1,3-diol.

The synthesis of 1,5,7-trioxaspiro[5.5]undecane was realized by two high-yield reaction schemes:

A. Starting from 5-hydroxypentanitrile (Laronze et al., 1980) (Figure 2) a Pinner reaction (Roger and Neilson, 1961) gave the 2-iminotetrahydropyran hydrochloride (**3**). A mixture of **3** with a slight excess of propane-1,3-diol in anhydrous ether was refluxed for 4 hr and, after a simple work-up, pure 1,5,7-trioxaspiro[5.5]undecane (**2**) was obtained, in 80% overall yield.

B. Starting from 1,5-pentanolide (Figure 3), pure 2,2-diethoxytetrahydropyran (**4**) was easily obtained according to the literature (Deslongchamps et al., 1975). A mixture of 8.7 g (0.05 mol) of 2,2-diethoxytetrahydropyran, 3.8 g (0.05 mol) of propane-1,3-diol and 0.01 g *p*-toluenesulfonic acid was gently heated in a distillation apparatus equipped with a small Vigreux column so that ethanol distilled slowly (80–90°C). When ethanol ceased to distill, 0.1 g of anhydrous sodium carbonate was added and the mixture was distilled under medium vacuum. One main fraction of 1,5,7-trioxaspiro[5.5]undecane (**2**) was obtained at 70–74°C and 8–10 mm Hg (7 g, 88% yield).

The biological tests were made with samples of material obtained after two distillations with the following physical and spectral data: Boiling point, 70°C at 8 mm Hg; purity by GC, more than 95% in a Perkin Elmer 8420 capillary gas chromatograph, fitted with a flame ionization detector and a 30-m SE-30 capillary column. Helium was used as carrier gas and the instrument was programmed at 2°C/min from 100 to 230°C. IR (cm⁻¹) 1200, 1140, 1070, 1030 (film on Perkin Elmer 397 spectrometer). [¹H]NMR(δ): 1.18–1.36 (m, 8H); 3.38–4.01 (m, 6H) (CDCl₃ on 80 MHz, Varian FT-80A Spectrometer). MS (*m/z*): 158(M, 4%), 128(55, 7), 113(12, 5%), 101(37, 5%), 100(100%),

83(8%), 72(7, 5%), 56(14, 5%), 55(26, 4%), 43(19, 4%), 42(35, 8%), 41(34, 3%). A Hewlett Packard 5970 mass spectrometer was interfaced with a Hewlett Packard 5980 gas chromatograph. The MS were obtained at 70 eV. The separations were accomplished in a 15-m capillary SE-30 column by using helium as carrier gas.)

Laboratory Bioassays. The biological activity of the analog on males was compared to that of racemic olean in an olfactometer, which is described in detail by Haniotakis (1974). It consisted of a wooden $1.38 \times 0.96 \times 0.38$ -m box with a clean Plexiglas top, divided into two sections by a partition along its long axis so that two materials can be tested simultaneously. A regulated air stream inside each section carried the chemical stimulus dispensed from a 1-ml low-density polyethylene vial loaded with 10 or 35 mg of the compounds to be tested. Responding insects entered a glass cage upwind for each of the materials compared, where they were counted. The response of 100 males was tested once per day during the last 4 hr of the photophase, a period that coincides with mating and male response to pheromones (Haniotakis, 1974). The analog was tested with and without stabilizer. The use of a stabilizer was decided upon after the anticipated instability of the analog molecule was verified with TLC (diethylether). When used, the stabilizer was added at a ratio of 33% and was of the following composition (%): (1) benzophenone 23.8; (2) BHT 28.8; (3) quinoline 32.8; (4) triethylamine 14.6. These substances were selected for their antioxidant and UV-absorption properties. Controls were empty vials when no stabilizer was added to the analog or vials containing the same amount of stabilizer which was added to the analog. To reduce high variation of *D. oleae* response to pheromones, which is usually observed in laboratory bioassays, tests were grouped for statistical analysis according to pairs of dispensers compared and insect batch used. For each test, analog and olean dispensers as well as insects used were of the same or very close age. Insect age varied from 4 to 18 days and dispenser age from 0 to 19 days. Lab-cultured flies were used for the tests. One-day-old flies (unmated) were immobilized by chilling at $2-4^{\circ}\text{C}$ for 1-2 hr and separated according to sex. They were kept in 270 cm^3 screen cages under artificial light (3000 lux intensity) and 10:14 hr dark-light regime. Temperature was maintained at $25 \pm 2^{\circ}\text{C}$ and relative humidity at $65 \pm 5\%$.

Field Tests. The biological activity of the analog at the concentration of 25 mg was compared to that of an equal concentration of racemic olean in six sets of field tests, in each of which a different formulation of the analog was used. The formulations tested were: (1) closed white low-density polyethylene vial without stabilizer, (2) closed white low-density polyethylene vial with stabilizer, (3) closed white high-density polyethylene vial with stabilizer, (4) rubber stopper without stabilizer, (5) rubber stopper with stabilizer, and (6) open, black low-density polyethylene vial with stabilizer and activated charcoal. For olean, only closed white low-density polyethylene vials without stabilizer were used. All polyethylene vials were of 1 ml volume. Controls were not used in

field experiments because it was known from previous experiments that unbaited sticky traps of the type used here capture no olive flies. Plywood sticky rectangles measuring 15 × 20 cm were used as traps. When used, stabilizer was of the same composition and at the same ratio as that used in lab tests. Olean and analog dispensers were of the same age except in a few cases (indicated) in which more than one analog formulation was tested at the same time, and the olean dispensers were no more than 30 days old. Olean dispensers of the type used here have an active life of about four months (Mazomenos et al., 1983). One trap was placed in every other olive tree, i.e., at distances that did not exclude trap competition. Traps were checked and cleaned once per week.

RESULTS

Laboratory Bioassays. The biological activity of the analog obtained by either method of synthesis is the same. Table 1 shows the response of *D. oleae* male flies to olean, analog, and to controls.

^cMale captures not significantly different, Student's *t* test, *P* = 0.05. Means not followed by letter are not significantly different.

be pointed out that in the group of tests in which the analog was used at the concentration of 35 mg (No. 5), the difference was much greater (highly significant) than that in the groups with the concentration of 10 mg (Nos. 1 and 2).

In the four groups of tests in which the analog was compared with olean (Nos. 3, 4, 6, and 7), male response was not significantly different in any except one (No. 4) in which no stabilizer was used and dispenser age was between 11 and 19 days. The addition of stabilizer and the use of a higher concentration increased the activity and prolonged the active life of the analog dispenser (No. 7).

Field Tests. Table 2 shows the numbers of *D. oleae* flies captured on olean and analog traps. Traps baited with analog contained in closed white low-density polyethylene vials without stabilizer captured very few flies whose accidental arrival to the trap cannot be excluded. Addition of stabilizer to the above vials increased the number of male flies caught during the first two weeks, which, however, was significantly lower than that caught on traps baited with olean. Use of high density polyethylene vials with stabilizer reduced trap performance, measured by the ratio of males caught on olean and analog traps. Use of rubber stoppers without stabilizer, a dispenser that allows high evaporation rates, increased trap performance but not to the level of olean traps and only during the first week. Use of rubber stoppers with stabilizer increased trap performance to the level of olean but did not prolong its active life. Use of open black vials with stabilizer and activated charcoal increased trap performance to the level of olean and extended its active life to two weeks.

DISCUSSION

Laboratory and field tests clearly showed that the analog of the major pheromone of *D. oleae* is biologically active and that its activity, expressed in male response in lab tests and numbers of males caught on traps in field tests, can be comparable to that of olean; however, stabilizer, open-type dispensers, or high concentration must be used for the analog. The limited residual activity of analog dispensers, not exceeding two weeks at best, indicates that the stabilizer used does not adequately protect the analog molecule from decomposition. The higher activity of the open-type dispensers, which allow high evaporation rates, and of the dispensers with high concentrations of analog, indicate a lower level of unit activity for the analog. More work is required for effective protection of the analog molecule from decomposition and for accurate regulation of its release rates for improvement of its field performance. If this is achieved, the analog can replace olean in steadily expanding practical applications, contributing to substantial cost reduction.

Acknowledgments—The authors gratefully acknowledge the assistance of the analytical department of Vioryl S.A., Athens, Greece, for the chromatographic determination of the purity of the synthetic compounds and, in particular, Miss Vasso Homatidou, for her help in obtaining the mass spectra.

POSSIBLE INDUCTION BY ESTROUS COWS OF PHEROMONE PRODUCTION IN PENMATES

PETR HRADECKÝ

*Department of Veterinary Anatomy
Texas A&M University
College Station, Texas 77843*

(Received September 3, 1987; accepted April 27, 1988)

Abstract—The primary attractive odors of estrous cows apparently induced production of secondary attractive odors in penmates. Presence of both odors was reflected by the bull's olfactory behavior. The inducing effect was strongest on the day of estrus and the day before. The information content of the primary and secondary odors was different since a sexually experienced bull was able to distinguish olfactorily between estrous and nonestrous cows. The secondary odors attracted at least transient bull's interest, resulting in sniffing, urine tasting, and flehmen reactions, but not mounting attempts. The induced production of attractive odors and lack of precise smell discrimination in penmates may lead to erroneous detection of estrus in cows and heifers that show false estrous signs without corresponding changes in their reproductive organs. Similar factors may be involved in triggering mounting among feedlot steers (buller steer syndrome).

Key Words—Bovine reproduction, estrus detection, estrous behavior, mounting behavior, estrous odor, flehmen, buller syndrome, reproductive pheromones, pheromone emission, smell sensitivity.

INTRODUCTION

The efficiency of artificial insemination (AI) in cattle is decreased by difficulties with accurate estrus detection because of inadequate observation of animals and/or overestimation of estrous signs. In the first case low personnel to animal ratios and demands for high work productivity do not allow sufficient time for undistracted observation of cow behavior. Occasional observation while performing other chores often fails to detect estrus, especially in postpartum cows

shortly after the resumption of ovarian activity when they frequently show silent heat or vague estrous signs. The estrus detection rate is low, and AI and conception are delayed.

In the second case many detected cows are not in true estrus because their estrous signs are not sufficiently scrutinized and compared with properly kept records. The detection rate is falsely high but the subsequent conception rate is low. In addition, inseminating cows in each reported "heat" increases the cost of AI and animal handling and the danger of uterine infections.

There are abnormal conditions when estrus in cattle occurs in shorter than the normal three-week intervals. Insufficient luteal function in postpartum beef cows shortens their estrous cycles (Odde et al., 1980) and cows with cystic ovarian syndrome may show behavioral signs of estrus quite erratically (Youngquist, 1986). However, there seem to be also physiological mechanisms causing some heifers and cows to show signs of heat without concurrent estrous changes in their internal reproductive organs.

There are indications that females in proestrus and estrus or under hormonal treatment may induce behavioral changes in nonestrous penmates that may reach an intensity sufficiently high to be erroneously reported as heat. This phenomenon has been observed in cattle (Kedrov, 1952; Glód, 1961; Lojda, 1966, 1968), primates (Ruiz de Elvira et al., 1982, 1983), and probably exists in carnivores (Hradecký, 1985). Reports also suggest associated induced metabolic changes, such as production of estrus-related compounds in cagemate foxes (Bailey et al., 1980) and urinary pH changes in closely spaced penmate cows (Hradecký, unpublished data). These inductive changes are likely mediated by airborne odorous signals (pheromones) among animals. While pheromonal effects on reproduction have been extensively studied in laboratory animals (Aron, 1979; Bronson, 1979; Milligan, 1980), similar studies in domestic animals remain in the initial phases (Izard, 1983; Vandenbergh and Izard, 1983).

This paper presents data on likely pheromonal influences of the estrous cows on nonestrous penmates in close proximity that were reflected by increased, although transient, olfactory interest of a teaser bull in the penmates during heat checking. These inductive influences were studied in a small group of animals to allow separation of the mutual influences. Multiple interactions in a larger group would be inseparable at this stage of study due to the lack of more precise measurable parameters.

METHODS AND MATERIALS

Three Holstein cows used for a study of bull-cow interactions (Hradecký et al., 1983) were kept together with a mature Hereford steer in a 250-m² dirt pen. During the nine-month study, the cows were tested daily for signs of heat by a teaser bull in an isolated area. The estrous cows were released from the

pen and tested after the bull had checked the nonestrous cows. The steer was present during the heat checking. Each daily observation lasted about 20 min until the bull lost interest in the cows. Evaluation of the bull's interest and flehmen reactions toward the estrous cows has been reported earlier (Hradecký et al., 1983). For this report the flehmen reactions toward the nonestrous cows and the steer were evaluated.

The bull's flehmen reactions toward each nonestrous cow were tallied separately for the days when some other cow was in heat or one day before heat (days 0 and -1; "induction days") and for the "clear" days when no other cow was in days -1 and 0 of estrus. All data collected from day -3 to +1 around the cow's own estrus were excluded. During this period cows emit estrus-related odors (Hradecký et al., 1983) and the effects of their own heat and induction on cow olfactory attractivity might be confounded.

The data were evaluated with the nonparametric χ^2 test (Daniel, 1978) with the null hypothesis of no difference between the averages for the induction and clear days in each of the three cows.

RESULTS

Interactions between the bull and the steer were dependent on the estrous cycle stages of penmate cows. During the heat checking, the bull was usually indifferent toward the steer but turned aggressive when the steer tried to approach an estrous cow and mount her. However, on repeated occasions the bull was attracted to the steer, which in turn did not show the usual fear and evasion. The bull typically nuzzled the steer's prepuce, stimulated him to urinate, tasted his urine (Figure 1), and showed repeated flehmen reactions (Figure 2). These peculiar periods of the bull's olfactory interest were observed only when a penmate cow was coming into heat but had not yet attracted the bull's full attention, or before an estrous cow was released into the bull's proximity. A few times the bull's interest in the steer was observed one to two days after heat in a penmate cow.

Interactions between the bull and the nonestrous cows showed that on days when some other cow was approaching heat or was in heat (induction days) the remaining two nonestrous penmate cows were also more attractive for the bull than on the clear days when no cow was in heat or close to it. During the induction days, the bull showed increased olfactory interest in the nonestrous cows by sniffing, urine tasting, and flehmen reactions but with no mounting attempts. Table 1 summarizes the data for both the induction and clear days in terms of the bull's flehmen reactions observed (total and average per daily observation) toward each of the three cows and compares them to similar data for the two (-1 and 0) estrous days (Hradecký et al., 1983).

The average frequencies of the bull's flehmen reactions toward each nones-

FIG. 1. The teaser bull (right) nuzzles the steer's prepuce, stimulates him to urinate, and tastes his urine.

TABLE 1. NUMBERS OF INDUCTION, CLEAR, AND ESTROUS DAYS AND NUMBERS OF FLEHMEN REACTIONS (f = TOTAL, \bar{X} = AVERAGE) OBSERVED FOR EACH COW DURING 9-MONTH STUDY

Day	Cow No.		
	884	885	886
Clear	$N = 163$	$N = 179$	$N = 164$
	$f = 90$	$f = 154$	$f = 92$
	$\bar{X} = 0.55$	$\bar{X} = 0.86$	$\bar{X} = 0.56$
Induction	$N = 33$	$N = 37$	$N = 38$
	$f = 26$	$f = 34$	$f = 36$
	$\bar{X} = 0.79$	$\bar{X} = 0.92$	$\bar{X} = 0.95$
Estrous	$N = 22$	$N = 25$	$N = 23$
	$f = 66$	$f = 64$	$f = 61$
	$\bar{X} = 3.00$	$\bar{X} = 2.56$	$\bar{X} = 2.65$

trous cow on induction and clear days were significantly different ($P < 0.005$) from the overall expected average 0.70 of reactions per observation period. The flehmen frequencies were consistently higher on the induction days than on clear days. There were no significant differences in the ability of individual estrous cows to induce the increased attractivity of nonestrous penmates or in the susceptibility of individual nonestrous penmates to the inducing effects of estrous cows. Also, no differences in the induction susceptibility between the first and the second half of the estrous cycle were noted. However, these differences may become evident in studies with larger cow groups and more precise methods of measurement.

DISCUSSION

Numerous reports have confirmed the existence of airborne chemical signals involved in cattle social communication and reproduction, although there is so far no consistent information about the chemical nature of the odorous compounds involved. Cows in heat emanate estrus-related odors (pheromones) that have been indirectly confirmed by the observations and experiments with bulls (Hart et al., 1946; Donovan, 1967; Sambraus, 1969a,b; Sambraus and Waring, 1975; Paleologou, 1977a,b; Hradecký et al., 1983), trained dogs (Akhlebininskii and Ishutov, 1974; Kiddy et al., 1978, 1984; Kiddy and Mitchell, 1981; Hawk et al., 1984), and rats (Ladewig and Hart, 1981). The odorous compounds are apparently produced in an unknown source in the body of the estrous cow and are distributed throughout her body by the bloodstream. Then they occur in many body fluids and effluents such as urine, vaginal secretions,

milk, skin secretions, saliva, and breath. The sexual behavior of animals indicates that especially the increased secretion of urogenital fluids during estrus provides a rich source of these odorous compounds (Nishimura et al., 1983, 1984; Klemm et al., 1987). The odor emanation increases with the hyperemia of sexual organs in estrous cows, which is enhanced by close proximity of a bull (Hradecký et al., 1983).

The estrus-related odors have immediate (signaling) effects on animal behavior. The bull is attracted to estrous cows and shows his interest by sniffing, nuzzling, urine tasting, flehmen, and mounting (Hradecký et al., 1983). The paramount significance of odors in this behavior can be derived from the observations that even a sexually experienced bull can be confused and mount restrained nonestrous cows or dummies smeared with estrous vaginal secretions and urine (Hart et al., 1946; Donovan, 1967; Paleologou, 1977a,b). The chemical composition of the attractive odors apparently rapidly changes during estrus since the bull can precisely discriminate the olfactory information and gradually increase his attention towards estrous cows but reserves mounting for the standing heat (receptivity) only. The nonestrous penmates also respond to the estrous odors by mounting the estrous cows, and they too can be easily confused by the estrous odors transferred to nonestrous animals (Nishimura et al., 1983, 1984). The behavioral responses of penmates are apparently less discriminatory than those of the bull. This may explain the lower efficiency of estrus detection based on the observation of cow and heifer behavior in comparison with the heat checking using a sexually experienced bull.

Reproductive pheromones also have delayed (priming) effects on reproductive functions and metabolism. However, in large farm animals these effects have not been fully recognized since they are hidden in the generally defined complex of social and environmental influences on animal reproduction. Relevant experimental data are scarce because of difficulties with experimental design, such as definition of pheromone sources, exposure (temperature, ventilation, time and space relationships), long reproductive periods, and high costs involved. Nevertheless, reports do indicate involvement of the odorous cues in the regulation of reproductive functions in large farm animals. The sows exposed to synthetic boar pheromone androstenone improved their reproductive performance (Hillyer, 1976). Ram pheromones induced and synchronized estrus in sheep (Schinckel, 1954; Knight and Lynch, 1980; Martin et al., 1986) and goats (Shelton, 1980; Chemineau, 1983, 1987) early in the breeding season and increased their ovulation rates.

The presence of bulls in beef cow herds accelerated resumption of estrous cycles in postpartum cows (Zalesky et al., 1984; Kinder and Zalesky, 1985; Alberio et al., 1987). Unknown compounds from estrous cow urine and vaginal secretions improved synchronization of the estrus induced with prostaglandins in heifers (Izard, 1983; Izard and Vandenbergh, 1982; Vandenbergh and Izard,

1983). Estrous cows induced in nonestrous penmate cows urinary pH changes that were comparable with those in estrous cows and that might be related to pheromone production and release (Hradecký, unpublished data). Postpartum cows synchronized with progestagens apparently induced nearly synchronous estrus in nontreated control penmates, which may be another example of pheromonal influences in cows (Weston and Ulberg, 1976). Estrous cows and heifers also induced behavioral signs of estrus in herdmates without corresponding changes in reproductive organs and made estrus detection more difficult (Kedrov, 1952; Głód, 1961; Lojda, 1966, 1968).

Previous studies have linked the bull's flehmen response (Hradecký et al., 1983) and the emanation of attractive odors in cows (Akhlebininskii and Ishutov, 1974; Kiddy et al., 1978, 1984; Kiddy and Mitchell, 1981; Ladewig and Hart, 1981; Hawk et al., 1984) to the occurrence of estrus. The coincident increase in the olfactory attractivity of both estrous and nonestrous cows for the bull reported in this paper strongly suggests an involvement of olfactory cues and chemical communication (Hradecký et al., 1983). The observed attractivity of nonestrous penmates was clearly associated with the occurrence of estrus in another penmate cow and was reflected by the bull's increased attention and number of flehmen reactions.

The apparent ability of estrous cows to increase the attractivity of penmates is likely based on the same odorous cues that mediate chemical communication between cows and bulls. The unambiguous olfactory response of the bull to the estrous cows and much weaker but distinct and simultaneous olfactory response to both the penmate steer and the penmate nonestrous cows indicate the direction of supposed inductive effects from the estrous cows toward the penmates. The estrous cows produce and emit primary estrus-related attractive odors that may induce simultaneous emanation of secondary attractive odors in penmates. These secondary odors might be slightly different from the primary estrous odors and convey information different from that of the primary odors because the bull's attention was increased only moderately in comparison with his responses to primary odors, and the bull was not stimulated to mount.

The suggested odorous communication and induction effects among cows may correspond to analogous mutual influences in female groups of other species such as rats (McClintock, 1983, 1984), carnivores (Hradecký, 1985), red deer (Iason and Guinness, 1985), monkeys (Ruiz de Elvira et al., 1982, 1983), and humans (McClintock, 1971; Preti et al., 1986), although none of these reports has brought unambiguous direct evidence about the nature of the signals and sensory channels involved.

The steer was probably very susceptible to the induction effects of estrous penmates and easily responded by the emission of attractive odors. This emission seemed to last at least as long as the emission of primary odors in the estrous cows, as judged by the bull's behavior. The easy induction of attractive

odor emission and limited olfactory discrimination ability in steers may be involved in the etiology of buller steer syndrome in feedlots where about 2–3% of steers are persistently ridden by their penmates (Pierson et al., 1976; Brower and Kiracofe, 1978; Ulbrich, 1981). The buller steers may emit attractive odors and elicit mounting by the penmates. In extreme cases the buller steers might also induce odor production in other susceptible penmate steers and trigger mass mounting with likely adverse economic impact. These features also make the steer a valuable experimental model for future studies of pheromonal influences among cattle.

Chemical communication and pheromonal effects are as yet on the periphery of current knowledge in mammalian reproductive biology. Contemporary research trends in animal reproduction do not emphasize the pheromonal effects, but their existence does not contradict current knowledge. The exploration of chemical communication may offer alternative explanations for reproductive phenomena not yet adequately understood.

(Received January 19, 1988; accepted May 5, 1988)

Abstract—In feeding experiments with insects reared in the laboratory, the presence of the dihydropyrrrolizines hydroxydanaidal and danaidal in the male scent organs (coremata) of the arctiids, *Estigmene acrea* (Drury), *Phragmatobia fuliginosa* (L.), and *Pyrrharctia isabella* (J.E. Smith), was shown to depend on the presence of a source of pyrrolizidine alkaloids (PAs) in the larval diet. *Phragmatobia* males given an artificial diet supplemented with the powdered roots of the PA-containing plant *Symphytum officinale* L. (comfrey) produced more hydroxydanaidal than danaidal, whereas males given an artificial diet supplemented with dried whole plants of another PA-containing species, *Senecio vulgaris* L., produced more danaidal than hydroxydanaidal. *Pyrrharctia* males produced hydroxydanaidal with little if any danaidal, whether the source of PAs was comfrey or *S. vulgaris*. A behavioral bioassay showed that the coremata of PA-denied *Pyrrharctia* male progeny of PA-denied parents were pheromonally inactive, whereas those of PA-denied male progeny of PA-supplied parents (male and/or female) were often active. This indicates that a small amount of pheromone is made from PAs transferred from the female to her eggs and that males effect copulatory transfers of PAs that are, in turn, passed to the eggs by the mated female. Field observations of *Phragmatobia* and *Pyrrharctia* larvae feeding on sources of PAs were reported. The PA monocrotaline was shown to be a feeding stimulant for *Pyrrharctia* larvae.

Key Words—Diet, scent, coremata, *Estigmene acrea*, *Phragmatobia fuliginosa*, *Pyrrharctia isabella*, Lepidoptera, Arctiidae, hydroxydanaidal, danaidal, pheromone.

INTRODUCTION

The plant secondary compounds known as pyrrolizidine alkaloids (PAs) are extremely widespread, currently known to occur in ca. 300 plant species in at least 11 families (Bull et al., 1968; Smith and Culvenor, 1981). Insects in four orders engage in "pharmacophagous" feeding on plants containing PAs (Boppré, 1986, and references cited), i.e., they ingest PAs for purposes other than primary metabolism or host-plant recognition (Boppré, 1984). This specialized feeding habit is widespread in two taxonomically distinct groups of Lepidoptera: the danaine and ithomiine butterflies (Nymphalidae) and the arctiid moths. Both groups include species in which adults obtain PAs by feeding through the proboscis on exudates of PA-containing plants (Pliske, 1975; Boppré, 1986, and references cited; Dussourd, 1986). The alkaloids are subsequently used as precursors for male scent secretions (Edgar et al., 1973; Schneider et al., 1975; Krasnoff and Dussourd, 1989, and references cited). There are also species in both groups in which PAs, subsequently used as pheromone precursors, are obtained from the larval host plant (Conner et al., 1981; Edgar, 1982; Boppré and Schneider, 1985, and references cited).

Previously we identified two dihydropyrrolizine pheromones, danaidal (Figure 1A) and hydroxydanaidal (Figure 1D), from the male scent organs (coremata) of two arctiids, *Phragmatobia fuliginosa* (L.) (hereinafter referred to as *Phragmatobia*) and *Pyrrharctia isabella* (J.E. Smith) (hereinafter referred to as *Pyrrharctia*) (Krasnoff et al., 1987), and showed that male pheromone titer varies widely in these species with most males having either ca. 1 μg of pheromone or less than 10 ng. Here we present evidence that the corematatal dihydropyrrolizines of these species as well as of another, *Estigmene acrea* (Drury) (hereinafter referred to as *Estigmene*), are also derived from PAs ingested by the larvae. We show that the pattern of variation in dihydropyrrolizine titer observed in *Phragmatobia* and *Pyrrharctia* is determined by differential feeding of larvae on PA-containing plants. For *Phragmatobia*, we show that the ratio of danaidal to hydroxydanaidal in the coremata varies with the species of PA-containing plant ingested by a larva. For *Pyrrharctia*, we present evidence that the pheromone precursors can be obtained from the parents in the absence of any larval access to PAs. We also report the association of *Phragmatobia* and *Pyrrharctia* larvae with sources of PAs in the field and present experimental evidence that PAs are feeding stimulants for *Pyrrharctia* larvae.

METHODS AND MATERIALS

Insects. Laboratory cultures were started with eggs obtained from females collected in the field at light traps in Ontario, Schuyler, Seneca, and Tompkins counties, New York State, during the summers of 1982, 1983, 1984, and 1985.

FIG. 1. Dihydropyrrolizidines (A,D); macrocyclic pyrrolizidine alkaloids (B,C); noncyclic diester and monoester pyrrolizidine alkaloids (E,F).

Larvae were reared in the laboratory on either natural plant material (*Arctium minus* (Hill) Bernh., *Taraxacum officinale* Weber, *Plantago lanceolata* L., *P. major* L., *P. rugellii* Dcne., *Polygonum cuspidatum* Sieb. & Zucc.), cultivated *Vicia faba* L. (fava bean), or an artificial pinto bean diet (Shorey and Hale, 1965). Larvae were held in a growth chamber at $25 \pm 2^\circ\text{C}$ under a 16:8 light-dark photoperiod. Records were kept of the diets of the parents of each brood in the second and subsequent generations removed from the field.

In addition, mature larvae were collected in the field during the fall and winter of 1983 and 1984 in Ontario, Steuben, and Tompkins counties, New York State. These larvae were maintained through winter diapause without food, according to the methods of Goettel and Philogène (1978). The following spring, the larvae pupated and adult moths were subsequently obtained.

Feeding Experiments. To investigate the effect of larval diet on male pheromone gland content, broods of larvae were divided into two groups. One (hereinafter referred to as PA-supplied) was offered a source of PA-laden food and the other (hereinafter referred to as PA-denied) was not. Larvae were supplied with PAs in one of several ways: (1) In addition to their primary food plant(s) or the artificial diet, larvae were given access to fresh material from a plant species either known to contain PAs (*Eupatorium maculatum* L., *Senecio vulgaris* L., *Symphytum officinale* L.) or presumed to contain PAs due to close taxonomic affiliation with a known PA-containing plant (*E. perfoliatum* L.) (Smith and Culvenor, 1981, and references cited). Control larvae were maintained on their original diet. (2) The dried roots of *Symphytum officinale* (comfrey), reported to contain PAs at ca. 0.1% by weight (Furuya and Araki, 1968; Furuya and Hikichi, 1971), were extracted in ethanol (100 g roots per 150 ml solvent) for 48 hr. The extract then was filtered and reduced in volume in a rotary evaporator and mixed thoroughly with a measured volume of pinto-bean diet so that a 1-gram-equivalent of roots was contained in 1.0 ml diet. Last-instar larvae feeding on the pinto bean diet were confined individually in 1-oz plastic cups with a 1.0-ml portion of treated diet. Controls were given a 1.0-ml portion of diet mixed with ethanol. Once the treated diet was consumed, larvae were returned to untreated diet and allowed to complete larval development. (3) A crude base fraction was obtained from the dried roots of comfrey using a modification of the methods of Furuya and Araki (1968) and Furuya and Hikichi (1971). These authors reported that the PA content of the crude base is 30–50%. Last-instar larvae feeding on fresh material from plants devoid of PAs were confined individually in 1-oz plastic cups with a leaf disk of the food plant treated with a known quantity of a 10% ethanol solution of the crude comfrey base. Controls were given a leaf disk treated with an appropriate amount of ethanol. After the disk had been completely consumed, larvae were returned to their previous food plant. (4) The dried roots of comfrey and oven-dried whole uprooted plants of *Senecio vulgaris* were ground to powders (20 mesh) that could be mixed into the pinto bean diet at a ratio of 15 g of powdered plant material to 500 ml of freshly prepared diet. These will hereinafter be referred to as comfrey powder and *Senecio* powder, respectively. At a known time after hatching, larvae feeding on the pinto bean diet were transferred to either the comfrey powder diet or the *Senecio* powder diet and allowed to feed until pupation. Controls were maintained on untreated pinto bean diet.

Corematal Chemistry. Extractions of coremata and subsequent mass spectral and gas chromatographic (GLC) analyses of corematal volatiles were carried out as described in Krasnoff et al. (1987).

Bioassay of Corematal Activity of PA-Denied Males. To determine whether males can use inherited PA precursors to make corematal pheromones, we adapted the experimental design used by Dussourd (1986) to demonstrate paren-

tal contribution of alkaloids to progeny in the arctiid *Utetheisa ornatrix* (L.). Comparisons were made of the stimulative capability of the coremata of PA-denied *Pyrharcitia* male progeny of (1) two PA-denied parents, (2) a PA-denied mother and a PA-supplied father, (3) a PA-supplied mother and a PA-denied father, and (4) two PA-supplied parents. A bioassay sensitive to picogram quantities of hydroxydanaidal (Krasnoff et al., 1987) was used. Male coremata were manually everted by gently squeezing the abdomen and were held ca. 2 mm from the antennae of a calling female for 5 sec. If the coremata elicited wing-fluttering and clicking in the female, a positive response was recorded (Figure 2). Each male was tested on one to four females, but each female was used only once with each male.

Larval Feeding on Pure Alkaloid. *Pyrharcitia* larvae (3 weeks old, third

FIG. 2. Presentation of manually extruded *Pyrharcitia isabella* male coremata to a conspecific female: (a) immediately preceding onset of the wing-fluttering and clicking response; (b) during the response.

to fourth instar) were placed individually in waxed cartons (6 cm high \times 9 cm diameter). Two 24-mm Whatman No. 542 filter paper disks were positioned on insect pins ca. 2 mm above the bottom opposite each other along the edge of the carton. One disk was treated with 1 mg of the PA monocrotaline (Aldrich Chemical Co., Inc.) dissolved in 50 μ l of chloroform. The other disk was treated with 50 μ l of chloroform alone. After 24 hr each disk was assessed for evidence of feeding, and the disk that had been fed upon the most was determined. The test was replicated with 25 larvae.

RESULTS

Coremata Chemistry. Hydroxydanaidal was identified from *Estigmene*, *Phragmatobia*, and *Pyrrharctia*, and danaidal was identified from *Phragmatobia* by comparisons of GC retention times on polar and nonpolar capillary columns and by mass spectra of peaks in coremata extracts, with retention times and spectra from authentic samples of synthetic material.

Feeding Experiments. Due to mortality in rearing, sufficient numbers of insects were not obtained using the same protocols for all three species studied. Therefore data were presented for experiments in which sufficient sample sizes (ca. 10 insects in both treated and control groups) were obtained. In these experiments PA-supplied males of all three species produced two to four orders of magnitude more dihydropyrrolizines than their PA-denied counterparts (Table 1).

TABLE 1. EFFECT OF LARVAL DIET ON TOTAL DIHYDROPYRROLIZINE (HYDROXYDANAIDAL + DANAIDAL) CONTENT (ng \pm STANDARD ERROR) EXTRACTED FROM COREMATA

Species	PA-supplied	PA-denied	<i>P</i> ^a
<i>Estigmene acrea</i> ^b	18352 \pm 3770 (<i>N</i> = 9)	1 \pm 0.2 (<i>N</i> = 10)	<0.0001
<i>Phragmatobia fuliginosa</i> ^c	732 \pm 65 (<i>N</i> = 11)	5 \pm 1.2 (<i>N</i> = 10)	<0.001
<i>Pyrrharctia isabella</i> ^d	2717 \pm 377 (<i>N</i> = 10)	1 \pm 0.2 (<i>N</i> = 11)	<0.0001

^a *t* test performed on totals transformed to log₁₀.

^b PA-supplied were transferred from untreated pinto-bean diet to comfrey powder diet at three weeks after hatching (ca. eight days before spinning the pupal cocoon). Controls were maintained on untreated pinto-bean diet.

^c PA-supplied were given a 1-g equivalent of crude ethanolic comfrey root extract in 1 ml of fresh pinto-bean diet during the last instar. PA-denied were given 1 ml of diet mixed with ethanol during the last instar.

^d PA-supplied were given 1 mg of crude base from comfrey in 10 μ l ethanol on a 1.5-cm disk of a leaf of *Polygonum cuspidatum*. PA-denied were given a leaf disk treated with 10 μ l of ethanol. Larvae were 26 days old when the leaf disks were consumed.

Phragmatobia males reared on nonalkaloid plants but given a choice of PA plants in the last larval stage produced detectable amounts of dihydropyrrolizines. Those given *Eupatorium maculatum* had 63 ± 10 ng ($N = 6$, range: 34–88 ng), those given *Eupatorium perfoliatum* ($N = 2$) had 241 and 251 ng, and those given *Senecio vulgaris* had 292 ± 138 ng ($N = 3$, range: 62–541 ng). These *Phragmatobia* males produced pheromone profiles specific to the plants fed upon. Those given either of the *Eupatorium* species produced hydroxydanaidal, whereas those given *Senecio* produced more danaidal than hydroxydanaidal (Figure 3). *Phragmatobia* males reared on the *Senecio* powder diet produced significantly more danaidal than hydroxydanaidal ($P < 0.0001$, two-sided paired t -test), whereas males reared on the comfrey powder diet produced more hydroxydanaidal than danaidal ($P < 0.0001$, two-sided paired t -test) (Figure 4A).

In contrast, *Pyrrharctia* males did not show this effect. Both *Senecio*-powder-supplied males and comfrey-powder-supplied males produced more hydroxydanaidal than danaidal ($P < 0.001$, two-sided paired t -tests) (Figure 4B).

Inheritance of Pheromone Precursors. None of the PA-denied *Pyrrharctia* male progeny of PA-denied parents had pheromonally active coremata, whereas many of the PA-denied progeny of either one or two PA-supplied parents had active coremata (Table 2).

Larval Feeding on Pure Alkaloid. *Pyrrharctia* larvae showed a significant preference for the monocrotaline-treated filter paper over the filter paper treated with chloroform alone. Of the 25 *Pyrrharctia* larvae tested, 15 fed on the alkaloid-treated disk only, two fed on both, and eight fed on neither. Both of the larvae that fed on both disks fed more extensively on the monocrotaline-treated disk. The proportion feeding on monocrotaline (17/25) was significantly higher than the proportion that fed on the control (2/25) based on lack of overlap of the 99% confidence intervals of the proportions (Snedecor and Cochran, 1967, p. 210).

Association of Phragmatobia and Pyrrharctia Larvae with PAs in the Field. During October and November 1983, 1984, 1985, and 1986, last-instar *Phragmatobia* (ca. 5/year) and *Pyrrharctia* larvae (ca. 30/year) were collected on comfrey plants in a patch (ca. 500 m²) in Ontario County, New York State. A single *Pyrrharctia* larva was observed actually feeding on comfrey (Figure 5a). Also, during the winter and early spring, larvae were collected on comfrey under the matted-down litter of the previous year's foliage. Intensive searches of *Arctium minus* plants, which were interspersed among the comfrey plants in the study patch and produce a mat of foliage similar in mass and extent to comfrey, failed to yield any larvae. A last-instar *Phragmatobia* larva was observed feeding on the corpse of a *Halysidota tessellaris* J.E. Smith moth (Figure 5b). *H. tessellaris* is known to feed on PA-containing plants as an adult and may sequester PAs (Dussourd, 1986; Krasnoff and Dussourd, 1989).

FIG. 3. Chromatograms of corematal pheromones of *Phragmatobia fuliginosa* males given access to the foliage of (A) *Senecio vulgaris* and (B) *Eupatorium maculatum*. Compound I is danaidal, compound II is hydroxydanaidal, compound III is a degradation product of II (see Krasnoff et al, 1987), and 16:HC is hexadecane, the internal standard. The peak marked by the question mark was unidentified. Estimates for male (A) were 252 ng for I and 21 ng for II. Estimates for male (B) were 31 ng I + III and 111 ng II.

FIG. 4. Comparison of the effects of comfrey powder and *Senecio* powder diet additives on the relative amounts of hydroxydanidal (HODAL) and danaidal (DAL) in the coremata of (A) *Phragmatobia fuliginosa* males and (B) *Pyrrharctia isabella* males. Variation indicated is standard error of the mean.

TABLE 2. EFFECT OF PARENTAL FEEDING HISTORY ON COREMATAL ACTIVITY OF PA-DENIED *Pyrrharctia isabella* MALE OFFSPRING

Parental feeding history ^a		Males (N)	Response % ^b	100% ^c	0% ^d
Mother	Father				
PA-denied	PA-denied	15	0.0 (33) a	0.0	100.0
PA-denied	PA-supplied	27	81.8 (66) b	74.1	7.4
PA-supplied	PA-denied	2	100.0 (4) b	100.0	0.0
PA-supplied	PA-supplied	47	63.8 (116) b	34.0	19.2

^aPA-denied moths were reared on untreated pinto-bean diet. PA-supplied parents were reared on pinto-bean for 21 days after hatching and were then shifted to pinto-bean diet treated with comfrey powder.

^bThe manually everted coremata of each male were presented to one to four females, but each female was used only once with each male. Shown is the percentage of positive responses with the total number of trials pooled for all males of the designated type shown in parentheses. Percentages not followed by the same letter are significantly different at the 0.01 level according to Ryan's test of proportions (Ryan, 1960).

^cShown is the percentage of males that elicited a positive response from all females tested.

^dShown is the percentage of males that elicited no positive responses from all females tested.

Caterpillars collected from comfrey produced both male and female moths. The two *Phragmatobia* males taken as larvae from comfrey had 430 and 322 ng of total dihydropyrrrolizines. The *Pyrrharctia* males ($N = 5$) had 3430 ± 702 ng of pheromone ($N = 5$, range: 2009–5848 ng). A sample of *Pyrrharctia* larvae collected randomly (crossing roads) produced 14 males having 0–4132 ng (four males in the < 10 ng range, one each with 10–30, 30–100, 100–300, 300–1000 ng, four with 1000–3000 ng, and two with 3000–10,000 ng).

DISCUSSION

Besides adding *Phragmatobia*, *Pyrrharctia*, and *Estigmene* to the list of arctiids that derive dihydropyrrrolizine male scent secretions from PA precursors (Conner et al, 1981; Schneider et al, 1982; Boppré and Schneider, 1985), our findings are the first to demonstrate a qualitative effect of PA precursor plants on male pheromone chemistry in the Arctiidae. Culvenor and Edgar (1972) found qualitative variation in the relative amounts of hydroxydanaidal and danaidal in the coremata of *Utetheisa lotrix* (Cram.) in the field in Australia. These authors suggested that this variation might depend on the availability of different PA-containing plants (and consequently different PA precursors) in the different areas in which the two "types" of moths were collected. Our findings for *Phragmatobia* indirectly support this hypothesis. Males with more hydroxydan-

FIG. 5. (a) *Pyrrharctia isabella* larva feeding on a damaged leaf stem of a comfrey plant (October 1984). (b) A *Phragmatobia fuliginosa* larva feeding on the corpse of a *Halysidota tessellaris* moth. The larva continued to feed during and after transfer to the laboratory from the walk-in light trap in which it was discovered (photograph by John Truini).

aidal than dananidal, which is the pheromone ratio produced by feeding on *Eupatorium maculatum*, *E. perfoliatum*, or comfrey powder diet, are rare in the field (Krasnoff et al, 1987). One of the two wild *Phragmatobia* males taken from comfrey as a larva had more hydroxydananidal than dananidal, suggesting that it had indeed fed on the plant. The other had dananidal alone, suggesting that it had previously fed on some other PA plant, such as *Senecio vulgaris*, which results in more dananidal than hydroxydananidal—the pheromone ratio most commonly encountered in males from the field. It is apparent that *Phragmatobia* larvae “prefer” some PA-containing plants to others, at least in our study area. Further analyses of these and other related species may show that coremetal dihydropyrrolizine profiles can be used to determine both inter-specific and intraspecific patterns of variability in host-plant usage, much as

cardenolide profiles have been used to fingerprint monarch butterflies to particular milkweed species (Brower, 1984, and references cited).

Pyrrharctia males present an intriguing contrast to *Phragmatobia* males. The finding that *Pyrrharctia* males make the same blend of hydroxydanaidal and danaidal with both *Senecio vulgaris* and comfrey clearly demonstrates that the two species metabolize the same alkaloids in different ways. *Pyrrharctia* males almost always have more hydroxydanaidal than danaidal in nature but occasionally a field-collected male will have more danaidal than hydroxydanaidal (Krasnoff et al., 1987). This indicates that there is a PA-containing plant(s) in the field, rarely fed on by *Pyrrharctia* larvae, with alkaloids that produce more danaidal. Alternatively, there is a rare genetic variant of *Pyrrharctia* that metabolizes PAs in a different way.

In looking for a plausible structural relationship between the PA precursors and the two dihydropyrrolizines, we noticed that the primary alkaloid components of *Senecio vulgaris*, which are senecionine (Figure 1B), senecephylline (Figure 1C), integerrimine (Aplin et al., 1968), and retrorsine (Bull et al., 1968), are all macrocyclic diesters. In contrast, symphytine (Figure 1E) and echimidine, the principal alkaloids of comfrey (Furuya and Araki, 1968), and echinatine (Figure 1F) and lycopsamine, the principal alkaloids of *Eupatorium maculatum* (Tsuda and Marion, 1963; Resch, Goldstein, and Meinwald, unpublished data) and possibly of *Eupatorium perfoliatum*, are either monoesters or nonmacrocyclic diesters. *Phragmatobia* males made mostly danaidal from plants containing the macrocyclic PAs and made mostly hydroxydanaidal from plants containing the noncyclic PAs. It is clearly necessary to use pure alkaloids to investigate further the effect of precursor structure on pheromone composition.

Male pheromone titer in *Phragmatobia* and *Pyrrharctia* from the field is bimodally distributed, with many males having less than 10 ng of pheromone, but many also having 1 μ g or more (Krasnoff et al., 1987). The dihydropyrrolizine titers of the PA-supplied *Phragmatobia* and *Pyrrharctia* males in this study are on a par with those of field-collected males near the higher mode for their species, whereas the titers of PA-denied males resemble those of the field-collected males near the lower mode for their species (Krasnoff et al., 1987). For *Pyrrharctia*, males originally having microgram quantities of pheromone still have microgram quantities after exposure of the coremata (Krasnoff, 1987). Thus, for this species, the distribution of pheromone titer seen in nature is not due to differential use of the coremata but rather to differential feeding on PA-containing plants. We believe this conclusion can also be applied to *Phragmatobia*, which, in the manner of *Pyrrharctia*, everts the coremata in short intermittent bursts while searching for and courting a female (Nielsen, 1982; Krasnoff, 1987). Further support for this conclusion comes from the finding that a sample of males collected randomly as caterpillars (crossing roads) included individuals with 10 ng of pheromone or less as well as individuals

with 1 μg or more, whereas all those collected from a PA-containing plant (comfrey) were in the higher end of the distribution. Since these males were either unmated or had mated once in the laboratory before they were analyzed and had a maximum corematal eversion time of ca. 30 sec, their pheromone titer could not have been affected appreciably by corematal exposure.

In *Estigmene* as well as in the Asian arctiids *Cretonotos gangis* L. and *C. transiens* (Walker), the coremata are everted in a static courtship display that may last as long as 1.5 hr (Willis and Birch, 1982; Wunderer et al., 1986). In *Cretonotos hydroxydanaidal* attracts both males and females to a mating aggregation (Wunderer et al., 1986). A similar aggregation forms in *Estigmene*, but whether its formation is pheromonally mediated by hydroxydanaidal has yet to be determined (Willis and Birch, 1982). Preliminary analyses of field-collected males indicate that a pattern of variation in pheromone titer similar to that found in *Phragmatobia* and *Pyrharctia* also occurs in *Estigmene* (range 0–150 μg hydroxydanaidal; Krasnoff, unpublished). A broad variation in male pheromone titer also was reported in arctiids of the genus *Cretonotos* (Boppré and Schneider, 1985). In view of the protracted corematal display in these species, it is possible that loss of corematal compounds by exposure during mating could account for more of the variation observed in nature than with *Phragmatobia* and *Pyrharctia*. However, in *Cretonotos* spp. differential feeding also dramatically affects the size of male coremata, and the observation of both small and large coremata in natural populations (Boppré and Schneider, 1985) indicates differential feeding on PAs in the field in those species as well. Because no such morphogenetic effect was observed with *Estigmene* (or with *Phragmatobia* or *Pyrharctia*), proof that quantitative variation in the dihydropyrrolizine titer of wild *Estigmene* males depends on differential intake of PA precursors and not on differential loss from exposure of the coremata will have to await analysis of adults reared from field-collected larvae.

Females of several arctiid species are capable of passing PAs into their eggs (Benn et al., 1979; Dussourd, 1986; Boppré and Schneider, 1985; Dussourd et al., 1988). *Ciseps fulvicollis* Hübner and *Utetheisa ornatrix* males transfer PAs to females during copulation, and the alkaloids are then passed on to the eggs by the females (Dussourd, 1986). By showing that the feeding history of the parents affects the corematal chemistry of the male progeny in *Pyrharctia*, our bioassays provide indirect evidence for both inheritance of PAs and nuptial transfer in this species. Furthermore, they show that the trace amounts of dihydropyrrolizines detected in the PA-denied male progeny of field-collected females could have been made from PAs inherited from either parent or both. The relevance of these inherited pheromones to male mating success is discussed elsewhere (Krasnoff, 1987).

It is important to note that the species under consideration in this study, as well as the related *Cretonotos* spp. (Boppré and Schneider, 1985), are essen-

tially polyphagous (Forbes, 1960; Tietz, 1952, 1972; Shapiro, 1968), but associate nonrandomly in some as yet unknown way with PA plants in nature. Our experiments with *Pyrrharctia* and observations of all three species indicate that larvae will ingest pure PAs, as was reported for *Cretonotos* larvae (Boppré, unpublished, cited in Boppré and Schneider, 1985). Boppré and Schneider (1985) state that *Cretonotos* larvae can "detect" PAs, but they do not mention a mechanism of oriented search. The *Pyrrharctia* larvae in our experiment can also be said to have detected PAs in that they chose to feed on PA-impregnated filter paper over blank filter paper. However, it remains unclear whether there is a mechanism of orientation such as the upwind walking to PAs reported for the grasshopper *Zonocerus elegans* (Thunb.) (Boppré et al., 1984) or the upwind flight to PA-derived volatiles seen in some ithomiine butterflies (Pliske et al., 1976) and arctiid moths (Krasnoff and Dussourd, 1989). In preliminary experiments *Estigmene* larvae failed to exhibit upwind-oriented movement toward a PA source in a tube olfactometer. It may be that larvae of these generalist arctiid species are preferentially arrested by PA plants during repeated sampling of many different types of plants (Rothschild et al., 1979) but, lacking a mechanism of direct search, many larvae simply never find a plant source of PAs. This view is consistent with our previously reported pheromone data, which show that fewer than half of the *Phragmatobia* and *Pyrrharctia* males in nature ever feed on a PA-containing plant (Krasnoff et al., 1987).

Phragmatobia and *Pyrrharctia*, which thrive in nature without ingesting PAs and mate successfully with or without the intercession of a PA-derived male pheromone (Krasnoff, 1987), stand in distinct contrast to a species such as *Utetheisa ornatrix*, which oviposits and feeds exclusively on PA plants and has a PA-derived male pheromone that is a critical element of a successful courtship (Conner et al., 1981). There is an interesting parallel to this contrast in the danaiine butterflies. Pliske (1975) found that male pheromone release behavior (hairpenciling) occurs often in monarch courtship but is not necessary for mating to occur as it is in other danaiines such as the queen butterfly (Pliske and Eisner, 1969). Pliske also noted that the PA-feeding behavior seen in other danaiine butterflies (see Introduction above) is only weakly expressed in the monarch and that little if any PA-derived pheromone is present in the hairpencils. In this light Pliske considered the role of the male pheromone in monarch courtship to be reduced evolutionarily as a concomitant of a reduced dependence on PAs. We suggest that a similar evolutionary reduction has occurred in the Arctiidae. Species such as *Phragmatobia* and *Pyrrharctia* may exhibit an intermediate condition in a transformation from an ancestral PA-host-plant specialization (as seen in *Utetheisa*) to the polyphagous feeding habit typical of the arctiid lineage (Arctiinae: Arctiini) to which these species belong (Ferguson, 1985). There are several genera in this group (e.g., *Apantesis*, *Arctia*) that can be said to have lost the male pheromone system entirely by virtue of the fact

that the coremata have been lost (Ferguson, 1985). We suggest that the seemingly weak dependence on PAs manifested by *Phragmatobia* and *Pyrreharctia* is the vestige of an ancestral character that may be more fully developed in other, as yet unknown species in the lineage. It is hoped that further studies of host ranges, mating systems, and PA-derived courtship pheromones in other arctiids, combined with phylogenetic studies of the major lineages in the group, will eventually permit strong inferences to be made about the direction of evolutionary change in host range in this group, specifically regarding the history of the relationship with plants containing PAs.

Acknowledgments—We thank J.A. Edgar, J. Meinwald, and G. Zarilli for gifts of dihydropyrolizines used as standards. We also thank M. Campbell and K. Poole for assistance in rearing insects, and B. Aldwinckle, R. Sticht, J. Ogradnick, and J. Truini for assistance in preparing figures.

ATTRACTION OF ADULT SWEET POTATO WEEVILS,
Cylas formicarius elegantulus (SUMMERS), (COLEOPTERA:
CURCULIONIDAE), TO SWEET POTATO LEAF AND
ROOT VOLATILES

(Received December 29, 1987; accepted May 9, 1988)

Abstract—A dual-choice olfactometer was developed to study the responses of sweet potato weevils, *Cylas formicarius elegantulus* (Summers), to volatiles from the sweet potato, *Ipomoea batatas* (L.) Lam. Both males and females were attracted by volatiles from sweet potato leaves and a methylene chloride leaf extract. Females, but not males, responded to volatiles from storage roots and a methylene chloride root extract. Leaves and storage roots from four sweet potato cultivars (Centennial, Jewel, Resisto, and Regal) were attractive to female weevils; however, the attractant response varied with cultivar. GC profiles from leaf and root extracts, and GC-MS analysis of leaf extract, for Jewel cultivar enabled the volatile peaks to be identified as sesquiterpenes.

Key Words—Sweet potato weevil, *Cylas formicarius elegantulus*, Coleoptera, Curculionidae, *Ipomoea batatas*, sweet potato volatiles, sesquiterpenes.

INTRODUCTION

The sweet potato weevil, *Cylas* spp., is a serious pest of sweet potato, *Ipomoea batatas* (L.) Lam., worldwide, both in the field and during postharvest storage

³Present address: AFRC Aphid Biology Link Group, Imperial College at Silwood Park, Ascot, Berks SL5 7PY, U.K.

(Edmond, 1971; Sutherland, 1986). The oligophagous weevil consumes all parts of its host plant, while eggs are laid singly, mainly in the basal stem and storage roots (Cockerham et al., 1954). Some cultivars of sweet potato are moderately resistant to the weevil (Rolston et al., 1979; Mullen et al., 1985). A chemical basis for such resistance is possible, which may be effective at any stage of the weevil's host-location, host-selection, or host-utilization behavior.

Plant volatiles that act as insect attractants are known to occur widely (Finch, 1980; Visser, 1986). In a recent review, Metcalf (1987) listed 300 insect species in five orders that have been shown to respond selectively to 64 identified plant odorants. Little is known about the volatiles of sweet potato, although volatiles have been identified from baked storage roots (Purcell et al., 1980; Tui et al., 1985).

In this study, using two relatively susceptible cultivars, Centennial and Jewel, and two moderately resistant cultivars, Resisto and Regal (Mullen et al., 1985), the objectives were: (1) to determine whether male and female *Cylas formicarius elegantulus* (Summers) respond to host-plant volatiles from foliage or storage roots; (2) to see if the response is similar with cultivars having different levels of resistance to the weevil in the field, and (3) to identify the volatile components of sweet potato odor.

METHODS AND MATERIALS

Insect Rearing. Sweet potato weevils (*Cylas formicarius elegantulus*) were reared in the laboratory on sweet potato storage roots in cages held at 28°C, 65% relative humidity and 16:8 light-dark. Adult weevils were transferred to fresh potatoes every seven days, with the old potatoes being incubated until the new generation emerged. Emerging weevils were collected weekly and held in cages until required for bioassays. Weevils in the age range 18–34 days with no previous exposure to sweet potato foliage were used.

Leaf Material. All material selected was young, healthy fully extended sweet potato leaves of similar size, picked from the third of the vine nearest the growing tip. Greenhouse-grown leaves (Jewel cultivar), used in the initial bioassays, were harvested at 9:00 AM and placed immediately in test tubes of water so that they remained turgid. Field-grown leaf material was collected between 8:00 and 9:00 AM from plants grown at the University of Georgia Horticulture Farm. One leaf was taken from each plant sampled, and leaves were bioassayed on the day they were picked. All field-grown leaf bioassays were done in late August 1987. Leaves of greenhouse-grown *Plectranthus tuberosus* Poir Chev. et. Perrot (Senewiratne and Appadurai, 1966), an unrelated tuber-forming crop plant with a similar growth form to sweet potato, of equivalent surface area were used as a control. Attractant activity of *P. tuberosus*

was tested against test tubes of water (5 ml) as a control. Leaf areas were measured with a LI-COR (LI 3000) area meter.

Leaf surface extract for Jewel cultivar was obtained by agitating 1000 leaves individually for 10 sec each, in 3000 ml of methylene chloride (B & J distilled in glass grade). After filtering through a bed of sodium sulfate on Whatman No. 1 filter paper, the extract was reduced to 50 ml in a flash evaporator at 40°C, placed in a glass vial, sealed with a Teflon-lined cap and kept at 0°C until required. Known volumes of extract, thoroughly mixed and warmed to room temperature, were pipetted onto 1 × 1-cm squares of Whatman No. 1 filter paper. Solvent was evaporated. The extract was bioassayed against the equivalent volume of solvent alone. Fifty microliters (one leaf equivalent), 10 μ l and 1 μ l were tested for attractant activity.

Root Material. Small roots from four sweet potato cultivars were dug in the field at 8:00–9:00 AM on the day they were to be bioassayed. Roots were transported in brown-paper bags. Small potatoes (about 55 g) were bioassayed against a water control (5 ml in a test tube).

Root surface extract for Jewel cultivar was obtained by submerging recently cured storage roots in a beaker containing 3000 ml of methylene chloride (B & J distilled in glass grade) for 9 min in an ultrasonic bath (Son et al., 1987); this time was found to be the most efficient for extraction in preliminary studies (Son, unpublished data). The total weight of the roots extracted was measured on a top-loading balance. The methylene chloride extract was filtered through a bed of sodium sulfate and reduced to 45 ml over a steam bath using two 300-mm Kuderna-Danish concentrator columns. The extract was sealed in a glass vial with a Teflon-lined cap and kept at 0°C until required. The extract, warmed to room temperature, was pipetted onto Whatman No. 1 filter paper and the solvent evaporated off; 0.8 ml of extract was 1 potato equivalent, and a dose-response was obtained using 10, 1, and 0.1 potato equivalents.

Bioassays. The airflow to the olfactometer chambers (Figure 1) was controlled by a low-flow-rate air delivery system that has been described by Todd et al. (1977). The system employed a low positive-pressure flow regulated by a barostat tower and a series of capillary flowmeters. Prior to entering the flowmetering system, the air was humidified by bubbling it through warm water (30°C). A regulated airflow (20 ± 0.5 ml/min) was fed through tygon tubing (G) to each side of six olfactometers. Airflow in each tube was measured with a bubble flowmeter, and tubes with the nearest equivalent flow were attached to the two sides of the same olfactometer. The olfactometers consisted of a main chamber (A) (600 ml) (Figure 1) with a fitted lid, two gauze-covered holes, through which air exited the system, and a central baffle to reduce turbulence. Two glass connecting tubes (E) linked the main chamber with two half-pint glass Mason jars (200 ml, 6 cm diam × 9.5 cm), the treatment (B) and control (C) chambers. In the initial bioassays with greenhouse-grown leaves (Jewel

FIG. 1. Dual-choice olfactometer. Arrows indicate direction of airflow (20 ml/min each side). A, main chamber; B and C, treatment and control chambers; D, wooden stand; E, glass connecting tubes; F, test tubes with gauze-covered holes; and G, air input lines.

cultivar), the leaves were placed in side chambers (B or C), and weevils moving into these jars were counted. When field-grown leaves and roots of the four cultivars were bioassayed, extra identical glass jars were connected on each side of the olfactometer, with tygon tubing, in which the material was presented. When leaf and root extracts were bioassayed, glass test tubes (10 ml, 1.4 cm diam. \times 7 cm) (F) with 1.2-cm-diameter gauze-covered holes were placed in the side chambers (Figure 1). The extracts, dried on filter paper, were placed in these test tubes. Between experiments, the equipment was dismantled and washed with detergent, and the glassware washed with acetone.

Experimental Procedure. Twenty-five male or female sweet potato weevils of known age were placed in the main chambers (A, Figure 1) of each of six olfactometers, with the side arms sealed by tape at the main chamber ends, and placed in experimental conditions (28°C and 65–75% relative humidity) 2 hr prior to treatments being introduced. All experiments were done in darkness, to ensure that the weevils were behaviorally active (Cockerham et al., 1954; Proshold, 1983). The chambers were carefully leveled, as an incline can affect weevil distribution (Mullen et al., 1980). To initiate olfactometer tests, weevils were given access to the side chambers by simultaneously removing the seals from the glass connecting tubes. All experiments were started at 2:00 PM and lasted for 2 hr, after which the numbers of weevils in the treatment and control chambers (B and C, Figure 1) were counted. An additional experiment was

done to see if the presence of weevils of the same sex and age ($n = 10$ weevils) in the side chamber attracted test weevils compared with a blank control.

Statistical Analysis. The numbers in the treatment and control chambers for each treatment replicate were analyzed using a paired Student's t test. An attraction index was also calculated for each replicate $[(T - C)/N \times 100]$, where T is the number of weevils in the treatment chamber, C is the number in the control chamber, and $N = 25$, the number of weevils originally in the main chamber] (Tipping et al., 1987). Paired t tests were done to compare attraction indices between treatments.

Chemical Analysis. The methylene chloride extracts of leaves and roots, as used in the olfactometer bioassays, were analyzed by gas chromatography. Volatiles were also collected from leaf material by a "purge-and-trap" technique (Easley et al., 1981). Fifty leaves (Jewel and Regal cultivars) picked from field plots (8:00–9:00 AM) were placed in a 1000-ml Wheaton purging unit, in a 60°C water bath. Volatile collection commenced at 9:30 AM by passing nitrogen (50 ml/min) through the leaf material and out through an initial water trap, then into pentane (B & J distilled in glass grade) in two 300-ml impingers, placed in series and cooled in beakers of ice. Collection was continued for 3 hr, after which pentane was reduced in volume to 5 ml with a Kuderna-Danish concentrator. Extract was stored at 0°C.

The methylene chloride and "purge-and-trap" extracts were analyzed for volatile components using a Hewlett-Packard 5790 gas chromatograph with 0.32-mm-ID \times 30-m OV-225 fused silica capillary column, using splitless injection and flame ionization. Temperature was initially at 30°C for 2 min then increased at 4°C/min to 200°C. GC-MS analysis was conducted on a Hewlett-Packard S985 modified for capillary GC-MS (Arrendale et al., 1984). *trans*-Caryophyllene and α -humulene were obtained from Fluka Chemical Corporation.

RESULTS

Both male and female weevils were attracted by volatiles given off from sweet potato leaves (Jewel cultivar) (Table 1, A), and the level of response was similar. No response was obtained when the non-host-plant control *P. tuberosus* was tested against a water control (Table 1, B) for either males or females. Female weevils were attracted by volatiles from leaves of four sweet potato cultivars (Table 2). However, the level of the attractant response was higher for Jewel and Resisto leaves than for Regal leaves.

Females and males were both attracted to 1 and 0.2 leaf equivalent concentrations of Jewel leaf extract, but not to a 0.02 leaf equivalent concentration (Table 3). The level of attraction (attraction indices) was similar for males and females.

Leaf equivalents	No. weevils/chamber		Attraction index
	Sweet potato	Control	
Female			
1	10.0 ± 1.5	3.3 ± 0.8**	26.8a
0.2	8.8 ± 1.3	1.0 ± 0.5**	31.2a
0.02	8.8 ± 2.0	5.8 ± 2.1	12.0b
Male			
1	12.8 ± 1.6	3.8 ± 1.1**	36.0a
0.2	13.2 ± 2.1	4.7 ± 1.2*	34.0a
0.02	2.3 ± 0.6	1.0 ± 0.4	5.2b

^aWeevils used were 21–34 days old. $N = 6$, \pm SE, 25 insects/replicate. Differences between numbers in two chambers of olfactometer, * $P < 0.10$, ** $P < 0.05$; treatments with different superscript letters have significantly different attraction indices, $P < 0.05$, paired t tests.

Female weevils were attracted by volatiles from storage roots of all four sweet potato cultivars (Table 4), with the attractant response to Jewel being significantly higher than to Resisto. Male weevils were not attracted by volatiles from storage roots of either Centennial or Jewel cultivar (Table 4).

Females were attracted by volatiles from three concentrations of Jewel root extract (Table 5), with the attractant response to 10 root equivalents being higher than that to 0.1 root equivalents. Males were not attracted to volatiles from Jewel root extract (Table 5).

No significant attraction was obtained to volatiles emitted from 10 weevils of the same sex in the treatment chamber (bioassayed against a blank control) for females (attraction index 4.8) or males (attraction index 2.8).

The methylene chloride leaf and root extracts from Jewel cultivar gave GC profiles with a number of peaks in the volatile range (Figure 2). The “purge-and-trap” volatile extracts from Jewel and Regal leaves showed the same volatile peaks; the Jewel leaf GC profile (Figure 2, top) had peaks that coincided with these in the methylene chloride leaf and root extracts; although the volatile components of the methylene chloride leaf extract may not have been trapped as efficiently due to its method of preparation. The “purge-and-trap” leaf volatile extract was subjected to GC-MS analysis, and all components eluting between peaks 1 and 7 (Figure 2) had molecular ions at m/e 204 and yielded spectra characteristic of sesquiterpenes. Peaks 1–5 (Figure 2) were tentatively

identified from their MS spectra using reference data (Stenhagen et al., 1974) as: peak 1, copaene; peak 2, *trans*-caryophyllene; peak 3, α -humulene; peak 4, γ -cadinene; and peak 5, γ -elemene. The identity of peaks 2 and 3 were also confirmed by comparison with mass spectral and GC retention times of authentic samples.

DISCUSSION

The results showed that sweet potato weevils respond behaviorally to host-plant volatiles. Both sexes were responsive to leaf volatiles, which is not surprising when it is considered that host plants act as feeding and mating sites for the weevils (Proshold, 1983). Females, but not males, were responsive to root volatiles. Previous data have shown that male and female weevils feed to an equal extent on leaves (Nottingham et al., 1988), but females feed to a greater extent than males on root cores (Nottingham et al., 1989); in culture conditions females are predominantly observed on the storage roots, with males being more frequently observed elsewhere around the cages. Therefore, both sexes may utilize host-plant foliage to a similar extent, but females may utilize the storage roots more than males, explaining the lower attractant response of males to root volatiles. Volatiles from the roots might contribute to the oviposition stimulation response of female weevils in the presence of storage root periderm (Nottingham et al., 1987).

Male and female weevils did not appear to be attracted to volatiles from weevils of the same sex. This was also found to be the case by Coffelt et al. (1978). This suggests that male-male or female-female aggregation pheromones might not occur in this species, although further work will need to be done to confirm this. Male weevils, however, are attracted to a female sex pheromone (Coffelt et al., 1978; Heath et al., 1986). Interactions between host-plant odor and pheromone may occur in the field, influencing host-selection behavior, e.g., for plants on which females are "calling." Males also appear to fly more freely than females (Deen, 1940) are caught more frequently in light traps than females (Cockerham et al., 1954), and fly to pheromone traps, particularly in the hours just before dusk (Proshold et al., 1986). A similar anemotactic behavior to that which males use to locate pheromone traps (Proshold et al., 1986) might also be used to locate the source of host-plant volatiles in conjunction with plant visual cues.

Jewel cultivar volatiles were more attractive to female weevils than Regal cultivar for the leaves, and Resisto cultivar for the roots. The highest attraction index occurred for Jewel cultivar for leaf and root volatiles. Differences in the relative levels of resistance of sweet potato cultivars to the weevil may have a chemical basis. For example, differences in the levels of feeding and oviposition on root cores of the same four cultivars as used in this study were observed (Nottingham et al., 1987), which corresponded with differences in the root surface chemistry of the cultivars (Nottingham et al., 1989). Differences in host-plant volatiles between cultivars might also contribute to the overall level of cultivar resistance. Volatile profiles of host plants are also likely to change with foliage age and host-plant condition and may affect weevil host-selection behavior accordingly (Finch, 1980).

The analysis of sweet potato volatiles showed that a number of similar sesquiterpenes were associated with the leaves and roots, although relative levels differed. All the major volatile peaks appeared to be sesquiterpenes, which therefore are likely to be involved in the attractant response of the sweet potato weevil. Sesquiterpenes are known attractants of other Coleoptera (Metcalf, 1987); for example, γ -cadinene is one of the attractants of the elm bark beetle, *Scolytus multistriatus* (Marsham) (Col.; Scolytidae) (Millar et al., 1986), while β -caryophyllene, along with β -bisabolol, are host-plant attractants of the boll weevil, *Anthonomus grandis* Boh. (Col.; Curculionidae) (Dickens, 1984).

Further work will aim to bioassay the sesquiterpenes identified, individually and in combinations, in order to identify the specific host-plant attractants of the sweet potato weevil.

Book Review

Special Issue on Pheromones (*Agriculture, Ecosystems and Environment*).
F.J. Ritter (ed.). 1988. U.S. \$59.00. Volume 21. 133 pages.

This special issue of *Agriculture, Ecosystems and Environment* is drawn together by guest editor F.J. Ritter from papers and posters presented in a symposium entitled "Pheromones and Other Behavior Modifying Chemicals" at the International Exhibition and Congress "Parasitis 1986" held late in 1988 in Switzerland. What makes this issue "special" beyond its bibliographic complexity? For JAEE, a strict focus upon agricultural chemical ecology is unusual. The content ranges from typical *Journal of Chemical Ecology* applied contributions of successfully implemented mass trapping and mating disruption programs to several disjointed collections of loosely related projects swept together under a general heading. Several countries whose research is less commonly seen in Europe and the United States are represented, such as Egypt and Peru, making some of the citation lists useful to those of us on different continents. What *is* special about this issue is the publisher's exorbitant asking price: \$59 (softcover)! Alternatively, the issue is received gratis by subscription to the *Journal of Agriculture, Ecosystems and Environment*.

None of the papers published in this issue represent either thorough reviews or conceptual advancements in applied chemical ecology. My advice to the reader is to buy the few stamps needed for mailing reprint requests for the one or two papers of interest.

OLFACTORY RESPONSES OF *Orius insidiosus* (Hemiptera: Anthocoridae) TO VOLATILES OF CORN SILKS

CRAIG D. REID and RICHARD L. LAMPMAN

*Illinois Natural History Survey and
University of Illinois at Urbana/Champaign
Urbana, Illinois 61820*

(Received March 4, 1988; accepted May 10, 1988)

Abstract—A synomone present in hexane extracts of corn silks was found to attract *Orius insidiosus* (Say). The attraction was a diurnal, innate behavior, independent of sex. A portion of the prey-searching behavior of *O. insidiosus* apparently relies on olfactory perception when corn is the prey's host.

Key Words—*Orius insidiosus*, Hemiptera, Anthocoridae, attraction, synomone, plant volatiles, corn silks.

INTRODUCTION

Orius insidiosus (Say), the minute pirate bug, is a polyphagous predator that feeds on several corn-related insects including the eggs of *Ostrinia nubilalis* (Hübner), the European corn borer (Bartholomai, 1954; Jarvis and Guthrie, 1987), and *Heliothis zea* (Boddie), the corn earworm (Barber, 1936). *O. insidiosus* may have the potential to assist in the control of some lepidopterous pests of corn.

One method for augmenting natural enemies is to manipulate their abundance and field distribution through the use of attractants and feeding stimulants (Nordlund et al., 1981). The volatiles of host plants, for example, often help predaceous insects locate habitat and prey (Greany and Hagen, 1981).

Several studies have found a variety of volatile compounds in corn leaves, husks, tassels, and whorls (Thompson et al., 1974; Buttery et al., 1978, 1980). Flath et al. (1978) identified 63 volatile components in corn silk. Cantelo and Jacobson (1979) identified nine volatiles from corn silks that attract the corn

borer and corn earworm. The present study was designed to investigate the possibility that corn silks might attract adult *O. insidiosus*.

METHODS AND MATERIALS

Preparation of Corn Silk Extracts. A Waring blender was used to homogenize 30 g fresh weight of corn silks in 200 ml of water, ethanol, methylene chloride, or hexane. The corn silk extracts were then filtered through a Buchner funnel lined with filter paper. Each extract was dried with anhydrous magnesium sulfate and refiltered to remove the hydrated salts. A rotary vacuum evaporator was used to reduce the volume of each extract to a volume of 25 ml (i.e., 1.2 g silk equivalent/ml of solvent). In one experiment, a 20-g silk equivalent/ml hexane extract was used and was derived from 20 g of silk as described above.

Bioassay Procedure. The responses of *O. insidiosus* adults to the extracts were tested in an olfactometer using the Y-tube principle (McIndoo, 1926). A 90-cm black rubber hose leading from an air pump was connected to the leg of a Y-shaped glass tube. From each arm of the Y-shaped tube, a 30-cm length of clear plastic hose was connected to a 50-ml side arm flask. A second 30-cm length of clear plastic hose connected each flask to one of the arms of a second Y-shaped glass tube. To prevent the adult *O. insidiosus* from moving past the arms of the olfactometer, a piece of drapery sheer was used to cover the arm ends of the second Y-shaped tube. The adults were introduced at the base of the Y of the second tube and given a maximum of 10 min to respond. If an adult moved into one of the olfactometer arms up to the drapery sheer insert, a positive response to the substance in the connecting side-arm flask was recorded. If, after 10 min, the adult remained at the lower end of the Y-shaped tube, "neither" was recorded as the response. After 10 min, the hoses of each side-arm flask were reversed on the olfactometer, the same adults reintroduced, and the observations repeated.

All tests were conducted at 25°C in a room under natural light from 1330 to 1430 hr. The *O. insidiosus* used in all but one experiment were from a laboratory colony raised on *Pseudoplusia includens* (Walker) eggs with snapbeans as an ovipositional substrate. In the fourth experiment adults were collected from a corn field.

The Test Series. A series of olfactometer tests were run to determine whether or not a kairomone existed in corn silks that was attractive to *O. insidiosus*.

The first test run was to investigate if *O. insidiosus* was attracted to any odor given off by corn silks. Five grams of fresh silk were placed in one side-arm flask and one of the following was placed in the other flask: 0.5 g of corn

pollen, 1 corn leaf crushed in 5 ml of water, or 0.5 ml of vanilla extract. Vanilla extract was used to determine if *O. insidiosus* merely responded to odors in general. This experiment used five adults and was replicated twice.

In the second, third, and fifth experiments, 1 ml of a 1.2-g silk equivalent/ml of solvent extract was placed on filter paper and allowed to dry for about 2.5 min to remove excess solvent. The filter paper was then placed in the side-arm flask. Each replicate used six adults in these three experiments.

The second set of experiments determined which of a series of silk extracts was more attractive to *O. insidiosus* than a water control. One milliliter of water was placed on filter paper. While still moist, the paper was placed in the other side-arm flask. This experiment was replicated 10 times, and six adults were used in each replicate.

The third experiment was conducted to determine if an attraction to an extract was the result of the extract components or of residual solvent in the extract. One milliliter of pure solvent was put on filter paper and allowed to dry. The paper was then placed into a side-arm flask. This experiment was replicated four times for each of the solvents, excluding water. Six adults were used in each replicate.

The fourth experiment compared the attractiveness of the hexane extract to that of fresh corn silks. Twenty grams of fresh corn silk were placed in one side-arm flask and 1 ml of a 20-g silk equivalent/ml hexane extract was placed in the other. The experiment used 10 adults and was replicated eight times. This experiment was also repeated using *O. insidiosus* collected in the field.

The final experiment compared the response of male and female *O. insidiosus* to the hexane extract; water was used as the control. Tests were conducted at 1330 hr and 2130 hr to check for diurnal rhythms of activity. This experiment was replicated six times over a three-day period. Six adults were used in each replicate.

Statistical Procedure. The second, third, and fourth experiments were statistically analyzed using the paired sign test (Steel and Torrie, 1980). The final experiment was analyzed using a 2×2 contingency table (Sokal and Rohlf, 1969). Insects that failed to choose either arm of the olfactometer were omitted from the analysis.

Extract Analysis. The hexane extract of the corn silks was injected onto a coupled Hewlett Packard 5995 GC-MS (electron impact, 70 eV) interfaced with a HP 59970A GC-MS computer system with an NBS mass spectral library containing spectra of over 38,000 compounds. The column was a fused silica capillary column (10 m \times 0.2 mm) with a cross-linked methyl silicone phase (Hewlett Packard, Rolling Meadows, Illinois), and helium was used as the carrier gas. The temperature program was 40°C to 250°C at 10°C per minute with a 2-min hold; injector transfer line, and ion sources were set at 230°C, 200°C, and 220°C, respectively. Authentic phenylacetaldehyde was purchased from

Aldrich Chemical Co. (Milwaukee, Wisconsin) and injected under the same conditions on the GC-MS.

RESULTS AND DISCUSSION

In the first test, 100% of 10 *O. insidiosus* adults were attracted to corn silks; none were attracted to the crushed corn leaf, the corn pollen, or the vanilla extract.

The corn silk extracts made with hexane and methylene chloride attracted significantly more *O. insidiosus* adults than did pure water (Table 1). Water alone attracted significantly more *O. insidiosus* than did corn silk extracts in ethanol or in water (Table 1). These data suggest a strong response either to the lipophilic components in corn silks or to the solvents hexane and methylene chloride. It is also possible that the ethanol and water extracts may contain a repellent.

Table 2 shows that the hexane extract attracted significantly higher numbers of *O. insidiosus* than did pure hexane solvent. Attraction to the ethanol and methylene chloride extracts were not significantly different from attraction to their respective solvents (Table 2). In an earlier test, methylene chloride extract attracted a significant number of adults (Table 1); the absence of significance in this experiment could be due to small sample size because over 40% of the adult *O. insidiosus* failed to respond to the methylene chloride extract or to pure methylene chloride. The response to the hexane extract is of particular interest; 95.8% of the adults were attracted, strongly suggesting that *O. insidiosus* responds to volatiles in the hexane extract of the corn silks.

Table 3 shows that naive laboratory-reared and field-collected *O. insidiosus* adults did not differ significantly in their attraction to corn silk. This result

TABLE 1. RESPONSE IN THE LABORATORY OF ADULT *O. insidiosus* TO VARIOUS CORN SILK EXTRACTS VS. WATER

^cSignificant at *P* < 0.05. Paired sign test (Steel & Torrie, 1980).

suggests that the attraction could be an innate behavior. Furthermore, their attraction to the hexane extract did not differ significantly from their attraction to fresh corn silk. This finding indicates that a component of the hexane extract is as effective in attracting adult *O. insidiosus* as the synomonal substances in corn silk.

Significantly higher numbers of adult *O. insidiosus* were attracted to the hexane extract at 1330 hr than at 2130 hr (Table 4). This finding suggests a diurnal rhythm in the response. In fact, no significant attraction occurred at 2130 hr, and most insects failed to enter either arm of the olfactometer. Of those that did, approximately equal numbers were attracted to water and to the hexane extract. The attraction of male *O. insidiosus* to the hexane extract at 1330 hr was not significantly different than that of females, a finding that indicates that attraction is independent of sex.

The preliminary analysis of the hexane extract of the corn silks indicated

compounds eluting after approximately 170°C were primarily waxes and long-chain hydrocarbons from the cuticular surface of the corn silks. Of the 16 compounds eluting before 170°C, eight compounds were tentatively identified by comparison to published mass spectra. These included four aliphatic aldehydes (hexanal, heptanal, nonanal, and undecanal), two alcohols (hexanol and 3-hexenol), one acid (heptanoic acid), and one aromatic aldehyde (phenylacetaldehyde). The aromatic compound was found to have the same retention time and mass spectrum as an authentic sample of phenylacetaldehyde. This compound has been previously isolated from corn silks and found to attract several corn-related pests (Cantelo and Jacobson, 1979). These compounds are presently being bioassayed with field populations of *O. insidiosus*.

This study provides evidence that a synomone attractive to adult *O. insidiosus* probably exists in corn silks. This behavior of *O. insidiosus* may be analogous to the ability of *Podisus maculiventris* (Say) to orient itself toward *Trichoplusia ni* (Hübner) larvae via a chemical stimulus either from the larvae or from a chemical released from injured soybean plants (Greany and Hagen, 1981).

Acknowledgments—This publication is a portion of a thesis submitted in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the Graduate College of the University of Illinois at Urbana-Champaign. We thank Drs. W.G. Ruesink, M. Kogan, and G.P. Waldbauer of the Illinois Natural History Survey for reviewing the manuscript. Special thanks go to Dr. R.L. Metcalf, also of the Survey, for sharing his laboratory facilities and equipment.

(Received December 22, 1987; accepted May 11, 1988)

Abstract—Predictions of the carbon–nutrient balance hypothesis were tested using a study of within-species phytochemical variation in the arroyo willow, *Salix lasiolepis*. The prediction that a balance between nutrients (total protein) and carbon-based secondary metabolites (total phenols) should exist was supported using water treatment and fertilizer experiments and wild willow clones. Leaf nitrogen content and net photosynthetic rates of plants potted in soil in which parental plants grew was low, indicating that wild plants exist under relatively low nutrient status–high carbon balance conditions. The hypothesis also correctly predicted positive relationships between shoot length and phenols in glasshouse plants, wild plants, and plants in the water treatment experiment and negative relationships between shoot length and phenols in the fertilizer treatment experiment. Total phenolic glycosides, fragilin, picein, salicortin, tremulacin, and tremuloidin all correlated positively with shoot length in glasshouse plants on a carbon-biased balance, and male willows had generally lower levels of phenolic glycosides than females. Salicortin and tremulacin showed the strongest positive relationships with shoot length.

Key Words—Carbon–nutrient balance, phenolic glycosides, phytochemical variation, salicortin, arroyo willow, *Salix lasiolepis*, shoot length, tremulacin.

INTRODUCTION

The carbon–nutrient balance hypothesis was proposed by Bryant et al. (1983). Much of the hypothesis relates to between-plant species variation in susceptibility to herbivores, but Bryant et al. (1983) also address specifically the anticipated phenotypic responses of plants to nutrient or carbon limitation. For plants with carbon-based secondary compounds like phenols, as in willows, they predict that a balance exists between nutrient concentrations and carbohydrate concentrations in tissues available to herbivores. Under conditions of low nutrients in the soil, but where photosynthesis is not otherwise limited, the carbohydrate-to-nutrient ratio will become higher than in a plant in an unstressed state. Higher carbohydrate concentrations provide a substrate supply for synthesis of carbon-based chemicals such as phenols, which increase in the plant. Lower nutrient concentrations, particularly nitrogen, result in less amino acid and protein synthesis than in the unstressed plant. Therefore, with stress from low nutrients, nutrient content of leaves and shoots declines while carbon-based chemicals increase. The opposite consequence occurs when plants grow in normal nutrient conditions but with a low carbon budget due to shading or low CO₂ concentrations. Nutrient concentrations are high relative to normal carbohydrate concentrations, so nutrient status increases while carbon-based chemicals decline. Because we have been interested in willow variation in relation to herbivore attack, we were interested in testing these predictions with the arroyo willow, *Salix lasiolepis*.

The C/N balance hypothesis also relates to growth rate of a plant. According to Bryant et al. (1983, p. 363) “the decline in growth with nutrient stress is generally greater than the decline in photosynthesis so that carbohydrates and carbon-based secondary metabolites such as phenols accumulate.” Conversely, under carbon stress due to shading, when photosynthesis and carbohydrate concentrations decline “growth rate is reduced more severely than is nutrient absorption, so that tissue nutrient concentrations accumulate above levels necessary to support growth. Under such circumstances one finds a reduction in carbon-based defense such as terpenes and phenolics . . . , because under such circumstances nutrients are cheap relative to carbon.”

We deduce from these arguments that C/N ratios must therefore relate to shoot length, for rapid growth will result in long shoots and slow growth will result in short shoots, both as estimates of mean growth per plant and for examining variation within plants. For example, slower growing shoots on a plant

are likely to be shaded, and therefore grow with a lower C/N ratio than rapidly growing longer shoots in full sunlight. Indeed, based on detailed experiments on C/N ratios in *Salix alaxensis*, Bryant (1987) suggested that shading by alder will increase palatability to snowshoe hares of willow stump sprouts, because carbon-based defenses are reduced in shade. Bryant et al. (1983) also recognized that an individual plant could change in its C/N balance in response to herbivore attack. In addition, in cloning species such as aspen, the same genet maintains a different C/N ratio in juvenile versus mature growth.

One assumption in the carbon-nutrient balance hypothesis, when related to herbivory, is that carbon-based secondary metabolites such as phenols act as defensive compounds against herbivores. A second assumption is that high nutrient status in plants is beneficial to herbivores because of high amino acid and protein concentrations. Some herbivores feed on plant tissues with high phenol concentrations (e.g., Coley, 1983), so the first assumption may not be correct for all herbivores. In general, the second assumption is correct more often than not (e.g., Scriber and Slansky, 1981; Scriber, 1984; Slansky and Scriber, 1985; Mattson and Scriber, 1987). We have addressed these assumptions elsewhere (Waring and Price, 1988), studying total phenolics and total protein in relation to *Salix lasiolepis* and a gall-forming sawfly, *Euura lasiolepis*, finding that neither assumption holds. Our findings do not undermine the basic C/N balance hypothesis, so we concentrate in this paper on the allocational patterns of the willow. However, patterns of chemical allocation in the plant may still affect choice of plants and shoots by *E. lasiolepis* when laying eggs and initiating gall formation, since females appear to use chemical cues on the willow plants. Thus, our ultimate goal remains to understand better the plant-herbivore relationship. We have shown that females attack longer shoots more often than shorter shoots (Craig et al., 1986; Price and Clancy, 1986a), so we were particularly interested in how the carbon-nutrient balance hypothesis related to this pattern.

Salix lasiolepis in northern Arizona grows as a shrub 2–3 m in height and spreads by layering to form clones of one genotype covering about 5–30 m². Clones can be distinguished by such characters as sex, shoot color, and flowering phenology. These clones usually remain distinct also in space because when clones grow toward each other and meet, branches are better supported and layering is prevented. The plant is restricted to such places as springs, artificial ponds, temporary streams, roadside ditches, and other locations that collect and hold water longer than usual in this area of the Colorado Plateau of limestone covered with volcanic lava and ash.

The timing of some sampling of willow coincided with attack by the shoot-galling sawfly, *E. lasiolepis*, which is described in Price and Craig (1984) and Price and Clancy (1986a). The sawfly lays eggs in young shoots and initiates galls, and attack is concentrated primarily in late May and June. The egg hatches

in late June and the larva feeds on gall tissue, spins a cocoon in the gall and overwinters, and emerges from the gall the following spring (Price and Craig, 1984).

In early analyses of phenol and protein concentrations in shoots and leaves of this willow we did not detect clear patterns of variation. We therefore undertook to test the carbon–nutrient balance hypothesis as a possible explanation of varying phytochemicals in relation to shoot length and herbivore attack. To do this we asked the following questions: 1. Does a carbon–nutrient balance occur in *S. lasiolepis*? 2. Which way is the balance tipped in field clones? 3. Do rapidly growing plant parts change in levels of phenols and proteins as types of stress on plants change? 4. Do all phenolic chemicals covary in relation to changes in plant stress?

METHODS AND MATERIALS

In 1982 we surveyed protein and phenol concentrations in young willow shoots. Nineteen willow clones were sampled from an area encompassed by a circle 1 km in diameter located just north of Flagstaff, Arizona, at 2132 m above sea level (35°14'N, 111°30'W). All willows were on the Schultz Creek and Rio de Flag drainages, in and adjacent to Museum of Northern Arizona property. The willow clones were designated according to their local position as follows: Museum of Northern Arizona (MNA, clones 1–7, due east of museum buildings); Northland Press (NP, clones 1–9, near Rt. 180 and 1 km south on Schultz Creek from the MNA site); Coyote Spring (CS, clones 1 and 2) at a small permanently running spring on museum property); and the former Biology Department building of the museum (BD, clone 1). MNA and NP clones on Schultz Creek are on a temporary watercourse, which runs only during spring snow melt, if at all. The BD clone receives much more than normal precipitation from the adjacent building roof. We have retained our original clonal designations to permit comparison with our other papers on this willow (e.g., Price and Clancy, 1986a,b).

For each clone, 10 shoots were sampled on June 9, when shoots were about half grown and while sawflies were attacking shoots (for 1982 phenology of shoot growth and sawfly attack, see Price and Clancy, 1986a). Each sample consisted of a shoot tip 25–30 mm long (including young leaves and associated stem), where sawflies attack and galls form, on shoots that were generally 50–90 mm long. Shoots on the outer perimeter of each clone were sampled, and in addition 10 shoots on NP8 were taken low in the clone where they were shaded. Each shoot sampled was measured for length of shoot. Sample shoots were enclosed in glassine envelopes and kept on ice until stored at –20°C within 1 hr of collection.

Total phenols were determined using the Folin-Denis procedure as described by Zucker (1982) for the samples taken before 1985. The Folin-Ciocalteu phenol reagent has since been found to be better, but the differences are small (Julkunen-Tiitto, 1985). After extraction of phenols, the samples of ground plant were also used to estimate percent total protein. Dried plant material was extracted in 1.0 ml 0.1 N NaOH in a closed tube for 3 hr, stirred for 5 min, and left overnight. Then the samples were stirred for 5 min and centrifuged for 3 min. One-tenth milliliter of supernatant was added to a test tube with 4.9 ml of Bio-Rad protein dye reagent prepared as specified. The optical density (OD) of the sample was measured at 595 nm. Bovine gamma globulin was used as a standard, and its assay was linear over a fivefold range of concentrations. Protein concentrations were expressed as percent protein in dry weight of sample.

In 1982 some potted plants were tested for rate of photosynthesis. For this, juvenile shoot cuttings were taken from wild clones in 1981, rooted in sand, and then transferred to 19-liter pots containing alluvial sandy silt from sites with the parental plants, along Schultz Creek. The clones used were MNA 1, 2, 3, 4; NP 8, 9; and BD 1, with one to three plants representing each clone for a total of 11 plants. In June 1982 these plants were transported to Palo Alto, California, and in September net photosynthesis was measured at light saturation utilizing a system described by Winner and Mooney (1980). Leaf nitrogen of the used leaves was also measured to test for the relationship between leaf nitrogen and net photosynthetic rate to see how these willows compared to other plants in other vegetation types (cf. Field and Mooney, 1986).

In 1982 another set of potted cuttings was started for water and fertilizer treatment experiments in Flagstaff in 1983. Methods were described in Price and Clancy (1986a), so they will be covered only briefly here. For the water experiment, three replicates each of the clones MNA 1, 2; and NP 8, 9 were assigned at random to three water treatments (total of 36 plants). High water (HW) treatment involved saturating each pot with spring water every day through the growing season. The medium water (MW) treatment involved the same treatment once every seventh day. The low water (LW) treatment had water applied in the same way but 22 days apart (May 28 and June 19), and then at 14-day intervals. No fertilizer or chemicals were applied to plants or foliage at any time during 1982 and 1983. For each plant the 10 most distal shoots were measured for length. Five undamaged, young, but fully expanded leaves were taken from two plants per clone per treatment (total of 120 samples) on August 17, 1983, and treated as above for total phenol and percent protein analyses. The positive effects of increased water on mean shoot length and sawfly attack have been reported (Price and Clancy, 1986a).

For the fertilizer experiment three or four replicates each of the clones MNA 1, 2, 3, 4 were assigned at random to three fertilizer treatments (total of

39 plants). All pots received the high water treatment as above. The no fertilizer treatment (HW/OF) had only water applied. The low fertilizer treatment (HW/LF) received fertilizer once per week, and the high fertilizer treatment (HW/HF) had fertilizer added twice per week, both for the period of maximum willow growth rate from May 28 to June 27, 1983. A fertilizer application consisted of 6.2 g Miracle Gro dissolved in 1 liter of water (15% N, 30% P, 15% K general fertilizer), with solution added to saturate the pot. Five leaves per plant on three plants per clone per treatment (180 samples total) were collected as in the water experiment for total phenol and percent protein analyses.

To study relationships between shoot length and individual phenol glycosides, five plants per clone on six clones were rooted in sand in the greenhouse in Flagstaff for three weeks in 1986. Three pairs of male and female clones were used as donors for cuttings, each pair growing within a few meters in the field: MNA 2 male, MNA 6 female; CS 2 male, CS 1 female; and NP 8 male, NP 9 female. They were transported as washed-root cuttings to Joensuu, Finland (62°30'N, 29°50'E) and, using potting soil (85% pure sand and 15% peat), grown in 3.6-liter pots in the glasshouse from May 19. On June 27, shoot samples were taken for phenol glycoside analysis. Up to 10 of the longest shoots per clone and up to 10 of the shortest shoots per clone were sampled, with at least five of each per clone. Shoot lengths were measured, and then tips 25–30 mm long were removed for analysis. Shoot tips were treated individually for GLC analysis. Briefly, samples were extracted in 80% acetone, filtrated, concentrated, and dissolved into methanol. The sample derivation and OV-1 capillary column analysis were processed as described in Julkunen-Tiitto (1985). From these analyses, individual phenol glycoside concentrations were calculated as milligrams per gram dry weight of plant. Lindroth and Pajutee (1987) have criticized the methods of Julkunen-Tiitto (1985), who used oven-dried samples for extraction. However, in response, Julkunen-Tiitto and Tahvanainen (1988) showed that there was a perfect correlation between individual phenol glycoside concentrations when extracted from fresh and oven-dried leaves ($N = 5$, $r^2 = 1.00$, $P < 0.01$). Therefore, we conclude that the methods used in the present paper, which were those employed by Julkunen-Tiitto and Tahvanainen (1988), are valid. Lindroth and Pajutee (1987) showed high and significant correlations between fresh and oven-dried samples in phenol glycoside concentrations in four of five species, with only *Populus tremuloides* samples showing radical differences. Thus these results and those of Julkunen-Tiitto and Tahvanainen (1989) show little discrepancy for willows.

Woody plants are heterogeneous in many characters. Watson and Casper (1984) speak of plants as assemblages of semiautonomous physiological units. Pitelka and Ashmun (1985) concluded that local vascular integration is more common than integration throughout the whole genet. Modular development and control in plants provides "relative autonomy among plant parts" (Waller,

1986, p. 298). Zucker (1982) recorded impressive differences in total phenol concentrations between leaves on the same poplar trees. Variation within plants to herbivore attack is well documented (Denno and McClure, 1983; Whitham et al., 1984; Gill, 1986). Therefore, modules such as shoots are likely to have individualistic properties, independent from all but the closest adjacent modules. For this reason we use individual shoots as samples in some analyses, because we have no evidence to show that they are not responding independently in the variables we have measured.

RESULTS

Carbon-Nutrient Balance. Tests among wild clones and experimental plants all shared a negative relationship between total phenols and total proteins, as predicted by the carbon-nutrient balance hypothesis (Table 1). In the fertilizer experiment nutrient status was increased, phenols were depressed, and the negative relationship was most clearly seen, accounting for 77% of the variance. Individual samples were tested to see if the balance operated within leaves and shoot tips, and in all cases a significant negative relationship was found. The only exception to this general pattern was the within-clone variation in NP 8 where the relationship was not significant and weakly positive.

Balance in the Field. A strong and positive relationship existed between leaf nitrogen and net photosynthesis, and the regression equation accounted for 83% of the variance (Figure 1). These nitrogen and photosynthesis levels were

FIG. 1. Relationship between leaf nitrogen (mg/g) and net photosynthesis (nmol CO₂/g/sec) in leaves of willow plants potted in soil in which the parental clones grow.

comparable to plants growing in low-nutrient habitats, such as chaparral and fynbos plants in South Africa (see Field and Mooney, 1986). These levels are among the lowest recorded in a wide range of vegetation types, clearly indicating low-nutrient status soils, as to be expected in alluvial sandy silt deposited by a mountain stream. The willows growing in these soils, mostly in full sun or slight shade for some of the day, will have low-nutrient status, and the balance will be shifted to a high-carbon-low-nutrient condition.

Balance Shift with Stress Changes. Plants growing with a high-carbon-low-nutrient balance should show increasing levels of carbon-based secondary metabolites as shoot length increases, according to the hypothesis and Bryant's (1987) empirical results. In every case tested, where plants were grown with a relatively positive carbon balance, there was a significant and positive relationship between phenols and shoot length (Table 2). This was true for phenol glycoside content of willows grown in the glasshouse in Finland in 1986, both in male and female plants, and for total phenols in water treatment experimental plants in 1983, and in wild plants in 1982. In general, female willows had phenol glycoside concentrations double that of males (intercept for females 20.34 mg/g dry wt, for males 9.49, with similar slopes, 0.21 and 0.26, respectively).

TABLE 2. RELATIONSHIPS BETWEEN SHOOT LENGTH (X) AND TOTAL PHENOL GLYCOSIDE (mg/g DRY WT) AND PHENOLS (OD 725/mg DRY WT) CONCENTRATIONS (Y) IN SHOOTS IN POTTED PLANTS GROWN IN THE GLASSHOUSE, FIELD, AND WILD CLONES

1982 Within wild clone (NP8)	$Y = 0.87 - 0.0044X$	20	0.44	<0.01

^aTotal phenol glycosides were measured in 1986.

^bTotal phenolics were measured in 1982 and 1983.

When we relieved the nutrient stress in the fertilizer experiment in 1983, nutrient status increased and phenols declined in relation to shoot length, as the hypothesis predicted, producing a negative relationship between shoot length and total phenol concentrations (Table 2). Within the wild clone NP 8 in 1982 the shoots low in the canopy were shaded but grew longer because they were on younger branches (cf. Craig et al., 1986), so they grew under carbon stress relative to the shorter shoots in full sunlight. So the longer shoots should have a lower concentration of phenols than shorter shoots, producing a negative relationship between shoot length and phenol concentration, as we found in this clone (Table 2).

Covariance of Phenol Glycosides. In plants grown in the glasshouse in Finland under very long daylight conditions at 62°N in June (daylight peaking at about 22 hr per day), there was a strong positive relationship between total phenolic glycosides and shoot length, accounting for 73% of the variance (Table 3). Five of the individual phenol glycosides, fragilin, picein, salicortin, tremulacin, and tremuloidin, showed the same pattern. Only salicin varied independently of shoot length, but generally constituted a small part of the total phenol glycoside content (Table 4). The chemical structures of all compounds are illustrated in Meier et al. (1985) and Lindroth et al. (1987). Salicortin and tremulacin were the major phenol glycosides present. They were the most strongly related in concentration to shoot length in terms of a strong slope in relation to shoot length, with 83% and 59% of the variance accounted for (Tables 3 and 4).

It is interesting to note that male plants had a carbon balance different from females (Table 4), at least in relation to phenol glycoside concentrations (see

TABLE 3. RELATIONSHIPS BETWEEN MEAN SHOOT LENGTH PER CLONE SAMPLE (mm) (X) AND PHENOLIC GLYCOSIDE CONTENT OF SHOOT TIPS (mg/g DRY WT) (Y) ON PLANTS GROWN IN THE GREENHOUSE (SAMPLE SIZE WAS 12 FOR EACH REGRESSION)

^aRelationships with large increases as shoot length increased.

also Table 2). In many of the pairwise comparisons of males and females that grow in proximity in the field, for both long shoot and short shoot comparisons, males had lower levels than females in total phenol glycosides, and the constituent glycosides (males were invariably lower than females in total phenol glycosides, salicortin and tremuloidin for both short and long shoots). Thieme (1965) and Palo (1984) noted such differences in the bark of some other willow species, with *Salix caprea* showing the largest sexual difference: females had almost two times the concentration of males. Such differences could contribute to the observed female-biased sex ratios in willows and preference for feeding on males by voles (e.g., Danell et al., 1985).

DISCUSSION

We have shown that predictions from the carbon-nutrient balance hypothesis, relating to the within-species variation of arroyo willow, fit the data to a remarkable degree. Every significant relationship we found was explained adequately by the hypothesis. We know of no alternative hypothesis that could account for so much of the variation seen in this willow species.

Although we always tested several willow genotypes, they all fitted the general patterns detected, suggesting that the environments in which the willows grow, and consequent shoot length, play a large part in phenotypic variation. For example, in the strongest relationships, such as in the glasshouse plants, shoot length accounted for 71–76% of the variance in total phenol glycoside content (Table 2), and we know that shoot length is strongly influenced by such nongenetic traits as plant age (Craig et al., 1986), and nutrient and

TABLE 4. PHENOLIC GLYCOSIDE CONTENT (mg/g DRY WT) OF LONG AND SHORT SHOOTS ON SIX WILLOW CLONES GROWN IN THE GLASSHOUSE (MEANS ARE FROM 3-6 SAMPLES PER SHOOT LENGTH CLASS PER CLONE)

Clone	Sex	Shoot length class	Mean shoot length (mm)	Phenolic glycoside

NP 9	Female	Long	161	45.1	1.1	1.4	1.4	22.9	16.2	2.1

water status of the environment (Price and Clancy, 1986a). This leaves very little variation to be accounted for by genotypically determined traits.

We must conclude that willows growing in natural conditions will be profoundly influenced by environmental variables, such as water supply, soil nutrients, and shading, in terms of their carbon-nutrient balance, and genotypic variation may be small. Several relationships between the factors measured, such as phenol-protein concentrations and shoot length-phenol correlations, changed between positive and negative slopes as water, nutrients, and shading varied.

The balance between nutrients and secondary metabolites, which are thought to play a defensive function, has been recorded in many other within-plant species systems. Leaf nitrogen was inversely related to tannin content (Jones, 1976; Phillips and Henshaw, 1979; Mattson, 1980). High protein concentrations reduced toxicity of phenolic compounds (Kirkham, 1954; Kiraly, 1976; Duffey et al., 1986), and proteins and phenolics were inversely correlated in *Salix lasiolepis* (Waring and Price, 1988). An inverse relationship between nitrogen content and glucosinolate levels in crucifers has also been described (Joseffson, 1970; Wolfson, 1980). Although Rhoades (1979) does not address the carbon and nutrient balance directly, emphasizing only responses to stress in plants in terms of "defensive" chemicals, three or four examples, out of seven in woody plants, are cited in which shading is correlated with decreases in tannins, which may be regarded as carbon-based defenses (his Table 2). Mattson (1980, p. 138) is emphatic that "Low plant N concentrations are invariably associated with . . . high allelochemic contents," citing three cases of increased N with decreased phenolics and five cases of decreased N with increased phenolics. A recent additional case is provided by Mihaliak et al. (1987).

What does the variation in phenols and proteins mean for the *S. lasiolepis* herbivore *E. lasiolepis*? We know that females attack independently of protein and total phenols in experiments (Waring and Price, 1988). However, in this isolated population of *S. lasiolepis*, it is probable that the large majority of plants are nutrient stressed, so that phenolic levels correlate with shoot length. Since females attack longer shoots more frequently (Craig et al., 1986, Price and Clancy, 1986a), they may be responding to total phenolic glycosides or individual phenolic glycosides (cf. Tables 3 and 4), in which case salicortin and tremulacin would provide the strongest indicators of shoot length. These compounds are actively defensive in *Populus tremuloides* against *Papilio glaucus glaucus* (Lindroth et al., 1988). Furthermore, female sawflies avoid previous oviposition wounds made by other females based on chemical cues, which could involve oxidation products of phenol glycosides (Craig et al., 1988). Therefore, levels of phenolics in shoots may relate to the levels of discrimination against

oviposition sites by subsequent female sawflies. These possibilities have yet to be tested.

Acknowledgments—Financial support was provided by National Science Foundation grants DEB-8021754, BSR-8314594, and BSR-870532 (P.W.P.) and by the Academy of Finland (R.J.-T. and J.T.). We appreciate Dr. William V. Zucker's guidance in phenol and protein analysis on the samples from Flagstaff. Grateful thanks are extended to reviewers of an earlier draft of this paper: J. Bryant, P. Coley, and W. Zucker.

ACQUIRED CHEMICAL DEFENSE IN THE LYCAENID BUTTERFLY, *Eumaeus atala*

M. DEANE BOWERS and ZOIA LARIN¹

Museum of Comparative Zoology
Harvard University
Cambridge, Massachusetts 02138

(Received August 25, 1986; accepted May 16, 1988)

Abstract—The lycaenid butterfly, *Eumaeus atala*, was found to contain cycasin, an azoxyglycoside, by thin-layer chromatography (TLC). Quantification of cycasin content in 10 individual freshly killed and frozen males and females, using capillary gas chromatography (GC), showed that cycasin contents of individual butterflies ranged from 0.21 to 0.51 mg (1.24–2.75% dry weight). A museum specimen of *E. atala* of unknown age had undetectable amounts of cycasin by GC. GC showed that larval frass contained about 0.10% cycasin, which was not detectable by TLC. Cycasin in the host plant was not detectable by TLC but was detected by GC and found to be 0.02% dry weight. There was no macrozamin, another azoxyglycoside characteristic of many cycads, in the butterfly or plant. Feeding trials with a colony of the ant, *Camponotus abdominalis floridanus*, showed that both cycasin and the adult of *E. atala* were deterrent to the ants.

Key Words—Cycasin, macrozamin, cycads, azoxyglycosides, *Eumaeus atala*, Lepidoptera, Lycaenidae, insect-plant interaction, chemical ecology, unpalatability, insect defense strategy, ants, *Camponotus abdominalis floridanus*.

INTRODUCTION

A variety of butterfly species in several families are known to be unpalatable to predators, including members of the Papilionidae, Pieridae, and Nymphalidae (e.g., Brower, 1984; Rothschild, 1985). In many of these species, unpalatable and/or toxic qualities are due to compounds sequestered from the larval

¹Current address: Room 336, The Imperial Cancer Research Fund, Lincoln's Inn Fields, London WC2A 3PX, U.K.

hostplant (e.g., Brower, 1984; Rothschild, 1985). Representatives of the Lycaenidae are conspicuously absent from this list and are not known to be unpalatable or toxic to potential predators, although Eliot (1973) suggests that members of the *Danis* section of the Polyommataini are unpalatable. Instead, lycaenids appear to use crypsis, false heads (Robbins, 1980, 1981), and associated ants (Eliot, 1973; Atsatt, 1981; Pierce, 1983) as defenses. The diversity of form and coloration among the lycaenids is striking (see Seitz, 1924; Howe, 1975), ranging from cryptic to brilliant warning coloration.

The genus *Eumaeus* Hübner is notable among lycaenids for the bright coloration of adults and larvae. In general, the adults are black with iridescent blue-green on the wings, and a bright red abdomen. The exception to this is *E. childrenae* Gray, which does not have a red abdomen. The gregarious larvae are bright red with yellow tubercles. Interestingly, the pupae are also warningly colored red-orange and are often found conspicuously clumped (DeVries, 1977) in contrast to other species of lepidopteran pupae, which are cryptic and solitary (Brower, 1984). The larvae of *Eumaeus* feed on cycads in the genera *Xamia* and *Cycas* (Cycadaceae). Cycads are known to contain a group of unusual nitrogenous compounds, azoxyglycosides, the aglycones of which are carcinogenic and mutagenic and are responsible for livestock poisoning in some areas of the world (Hooper, 1978). Two of the best characterized of these compounds are cycasin and macrozamin (Figure 1) (de Luca et al., 1980; Moretti et al., 1983). DeVries (1976, 1977) suggested that *Eumaeus minyas* Hübner was unpalatable, based on larval and adult coloration and larval host-plant alliances. Work by Teas (1967; Teas et al., 1966) showed that larvae of the warningly colored moth, *Seirarctia echo* Abbott and Smith (Arctiidae), accumulated cycasin after feeding on cycad leaves. Rothschild et al. (1986) found that one species of *Eumaeus*, *E. atala floridana* (Poey), contained cycasin. Here, we confirm this report and compare capillary gas chromatography (GC) and thin-layer chro-

FIG. 1. The structures of cycasin and macrozamin.

matography (TLC) as methods for detecting cycasin. Feeding experiments with ants and birds show that *E. atala* is unpalatable to representative vertebrate and invertebrate predators.

METHODS AND MATERIALS

Butterflies and Plants. *Eumaeus atala* was thought to be extinct in the mainland United States for about the past 35 years (Rawson, 1961; Lenczewski, 1980). Recently, several populations were discovered in the Miami area of Florida (Lenczewski, 1980), and it is now relatively common in many areas of southern Florida (Robbins, personal communication). Whether these populations resulted from small, scattered, mainland colonies that had remained undiscovered or from colonizers from Cuba or the Bahamas is unknown. *Eumaeus atala* had not been abundant in the Miami area since the 1920s, although a colony was known from Key Biscayne in 1961 (Rawson, 1961; Lenczewski, 1980). The host plant of *E. atala* in Florida is a cycad called coontie, *Xamia floridana* A. DC.

Eggs of *E. atala* were obtained in the course of a mark-release-recapture study in the Miami area (J. Weintraub, unpublished data). Larvae were reared in a growth chamber, first on *X. floridana* leaves brought from Florida and, when these leaves were eaten, leaves were obtained from greenhouse grown specimens of *X. floridana*. *E. atala* larvae were reared in plastic boxes under conditions of 14:10 light-dark, 30°C day:25°C night.

Butterflies were frozen upon emergence and kept in the freezer until prepared for GC or TLC. Butterflies were dried at 50°C for two days prior to analysis.

To determine whether azoxyglycosides could be detected in museum specimens, a specimen of *E. atala* of unknown age and lacking data, from the collection of the Museum of Comparative Zoology, Harvard University, was also analyzed.

Plant material for chemical analysis was obtained from greenhouse specimens of *X. floridana*.

Preparation of Butterfly and Plant Samples for Thin-layer Chromatography. Butterfly samples for TLC were prepared using a modification of the procedure of Yagi et al. (1980). They were first ground with 100 mg sand in a mortar. Then, samples were suspended in ice-cold 7:3 ethanol-water (10–15 ml), and debris was precipitated by centrifugation at 2000 rpm. The precipitate was washed three or four times with 2–5 ml ice-cold 7:3 ethanol-water, centrifuged at 2000 rpm after each washing, and the supernatants combined. These combined supernatants were evaporated to about 500 μ l under vacuum at 40°C. The whole butterfly sample was composed of two butterflies with a combined

weight of 60 mg. The butterflies were not sexed. The butterfly parts were obtained from three different butterflies; a total of 21.9 mg wings, 31.5 mg abdomen, and 33.9 mg head + thorax were analyzed.

Larval frass was collected during larval feeding on *X. floridana*, dried, and stored in the freezer prior to analysis. Larval frass (563 mg) was ground with 550 mg sand and extracted with cold ethanol as described for the butterflies.

Two methods were used to extract the plants. The first was that used for the butterflies. A second sample was prepared using leaves frozen in liquid nitrogen, which were then extracted as described above for insect samples.

Thin-layer Chromatography. Samples of 8 μ l of the total sample were spotted onto glass-backed silica gel TLC plates that were developed in a solvent system of *n*-butanol-acetic acid-water 4:1:1 (Matsumoto and Strong, 1963). Plates were sprayed with chromotropic acid reagent, composed of 1 g of 4,5-dihydroxy-2,7-naphthalene disulfonic acid disodium salt dissolved in 100 ml water and diluted to 500 ml with 12.5 M sulfuric acid (Matsumoto and Strong, 1963) and then heated at 110°C for 10–15 min.

Standards of purified cycasin and macrozamin were obtained from Dr. K. Tadera (Kagoshima University). Standard solutions were made up in 7:3 EtOH-H₂O, at 1 mg/ml for cycasin and 2 mg/ml for macrozamin.

The presence of cycasin in butterfly and plant samples was confirmed by the comigration of standards and butterfly and plant samples, spotted separately. Standards were also mixed with the samples and run on TLC. In addition, we confirmed the presence of cycasin in the samples by observing the disappearance of cycasin following incubation of another aliquot of the butterfly and plant solutions with β -glucosidase (Sigma). β -Glucosidase was used at a concentration of 1 mg/ml and was added to samples in 25 mM NaOAc (pH 5.0), and incubated at 30°C for 18 hr.

Preparation of Samples for Gas Chromatography. Gas chromatography was used to corroborate and quantify the presence or absence of cycasin in *E. atala* butterflies, larval frass, and *X. floridana* leaves. Ten *E. atala* butterflies, four females and six males, were crushed individually and extracted 3 \times in 5.0 ml 80% methanol in water (Rothschild et al., 1986). One female was analyzed whole, and the other nine butterflies were analyzed as abdomens separate from head, thorax, and wings. This technique was used to determine whether we would be able to assay the abdomens of specimens as an indication of the specimen's total cycasin content. In addition, the museum specimen was analyzed as abdomen separate from the wings + head + thorax. The samples were filtered and the filtrate evaporated to dryness. To this residue, 1.0 ml of catalpol (0.75 mg/ml water) was added as an internal standard, and the mixture evaporated to dryness. To this mixture, 1.0 ml MeOH was added and 100 μ l removed to a small glass sample tube and evaporated to dryness. The sample was sily-

lated by adding 0.10 ml of the silylation reagent TRI-SIL Z (Pierce Chemical Company) and the closed tube heated for 15 min at 70–80°C. After the solution was cooled, 1 μ l was injected onto the gas chromatograph. A solution of cycasin (0.50 mg/ml) and catalpol (0.75 mg/ml water) was silylated and used as a standard.

The dried frass sample (446 mg) was prepared for analysis using the same methods as for the butterflies. Plant material was extracted fresh (10.73 g wet weight), using the method of Rothschild et al. (1986).

The GC analyses were performed on a Hewlett Packard 5890 gas chromatograph equipped with a split-splitless injector, FID detector, and a 3393 Hewlett Packard integrator. The column was a DB-1 capillary (J&W Scientific), 30 m long and 0.32 mm ID, with a film thickness of 0.10 μ m. The injector was used in the split mode, split ratio of 13:1, and at a temperature of 275°C. Carrier gas was helium. The detector temperature was 325°C. Samples were run under the following program developed by Gardner (1987) for iridoid glycosides: initial column temperature 200°C for 1.00 min, which was then raised to 260°C at a rate of 20°/min and held for 6.00 min. The retention time (T_r) of cycasin was 4.05–4.07 min, of macrozamin 7.11 min, and of catalpol 7.95–8.00 min.

Feeding Experiments with Ants. To determine whether *E. atala* was unpalatable and whether cycasin was important in the chemical defense of *E. atala*, we used a colony of *Camponotus abdominalis floridanus* (Buckley) ants reared from a founding queen collected on Saddlebunch Key, Monroe County, Florida, in 1983, as potential predators. Although there are no published data on the natural diet of this species, they appear to be general predators and have been observed capturing scorpions and beetles in their natural habitat (N. Carlin, personal communication). This colony contained about 60–100 workers and soldiers and a queen, and was housed in a 20 \times 30-cm plastic box. The ants nested in glass test tubes and foraged in the clear area of the box. Ants were maintained on a diet of crickets and honey water.

Three experiments with the ants, using techniques similar to those of Pasteels et al. (1986), were used to determine whether cycasin was an effective chemical defense against such predators. Ants were starved for 48 hr prior to all the experiments, so that they would forage consistently during the testing.

In the first experiment, the ants were offered large drops of two solutions. The control solution was 25% sucrose, and the experimental solution was 25% sucrose + 1.0 mg cycasin/ml water. Ants were allowed to forage at these two drops for an hour. Additional solution was added when necessary. Every minute, the number of ants that visited and drank at the solution was tallied. An ant was considered to be drinking when it lowered its head and contacted the solution. With magnification, the ant's tongue could be observed in the solu-

tion. This experiment was repeated for a second hour the following day. In addition, in three separate trials, the length of time that the ants drank at each of these solutions was recorded.

A second experiment compared the behavior of the ants in response to a drop of a 25% sucrose solution versus a dried, ground *E. atala* butterfly in 25% sucrose solution (8.5 mg/ml). The number of ants drinking from the two drops was again monitored every minute over the course of an hour. This experiment was also repeated a second time, one week after the first trial.

A third experiment allowed ants to forage at two drops of water, the control containing ground up cricket, and the other containing ground up *E. atala* butterfly. The number of ants drinking at each drop was again counted every minute for an hour. This was repeated a second and a third time. The second trial was 22 days after the first and the third trial was 10 days later.

RESULTS

Chemical Analyses. TLC indicated that *E. atala* butterflies contained a compound with the same R_f as cycasin: in the standard the R_f was 0.32, and in the butterfly it was 0.31. Cycasin was present in the whole butterflies as well as in the wings, head + thorax, and the abdomen. The R_f of macrozamin was 0.19, and there was none detectable in the butterflies. There was no cycasin or macrozamin detectable by TLC in the larval frass. We were unable to detect cycasin in the leaves of *X. floridana* by TLC, as Teas (1967) had also found. Rothschild et al. (1986), however, did find cycasin in leaves of *X. floridana* using gas chromatography, which we did as well.

GC analyses showed that cycasin (R_t 4.05–4.07 min) occurred in relatively large amounts in both male and female *E. atala* butterflies (Table 1). For both males and females, the amounts in the abdomens were lower than those in the wings + head + thorax (Table 1). There was no detectable cycasin in the abdomen or wings + head + thorax of the museum specimen. No peak with the same R_t as macrozamin (7.11 min) was detectable in the butterflies by GC.

To determine whether the amount of cycasin in the abdomen was indicative of the amount in the whole butterfly, we attempted to correlate cycasin content of abdomen and the rest of the butterfly, using the data from the nine frozen individuals analyzed in parts. A plot of dry weight of the abdomen versus dry weight of the wings + head + thorax showed that these were highly correlated (Figure 2A). A similar plot of percent cycasin in abdomen versus percent cycasin in wings + head + thorax also showed a significant positive correlation (Figure 2B). Thus, analyzing only the abdomen indicated reliably whether the individual contained cycasin and could give a good indication of how much that individual contained.

TABLE 1. CYCASIN CONTENT OF MALE AND FEMALE *Eumaeus atala* BUTTERFLIES AS DETERMINED BY GAS CHROMATOGRAPHY

	N	Dry weight (mg, mean \pm SD)	Range	Cycasin content (mg, mean \pm SD)	Range	Cycasin (%, mean \pm SD)	Range
Males							
Abdomen	6	7.28 \pm 2.76	5.13-12.66	0.04 \pm 0.02	0.01-0.07	0.60 \pm 0.23	0.21-0.91
Wings + head + thorax	6	14.20 \pm 2.37	11.19-30.21	0.32 \pm 0.10	0.20-0.44	2.20 \pm 0.44	1.81-2.61
Total	6	21.48 \pm 4.97	16.32-30.21	0.36 \pm 0.12	0.21-0.51	1.66 \pm 0.33	1.24-2.06
Females							
Abdomen	3	5.51 \pm 0.69	5.04-6.31	0.06 \pm 0.03	0.03-0.08	1.08 \pm 0.57	0.43-1.50
Wings + head + thorax	3	10.78 \pm 0.95	9.80-11.70	0.30 \pm 0.09	0.22-0.40	2.75 \pm 0.60	2.19-3.38
Whole butterfly	1	21.59		0.41		1.90	
Total	4	17.68 \pm 2.67	16.04-21.59	0.37 \pm 0.09	0.24-0.46	2.11 \pm 0.54	1.50-2.75

FIG. 2. Dry weight (A) and cycasin content (B) of *E. atala* abdomen versus wings + head + thorax. open stars = females, solid squares = males. Correlations: (A) $r = 0.801$, $p = 0.01$; (B) $r = 0.710$, $p = 0.03$.

GC also showed that the frass sample contained about 0.1% dry weight of cycasin. Interestingly, the frass sample contained a peak with the same retention time (7.11 min) as macrozamin. Since no such peak occurred in the plant or butterflies analyzed, if this peak is indeed macrozamin, it suggests that the larvae may be converting something from the plant into macrozamin. Alternatively, some *X. floridana* plants may contain macrozamin. Larvae of *E. atala* were collected in Florida, and we were unable to analyze plant material from there.

According to GC analyses, the *X. floridana* frond contained about 0.02% dry weight cycasin.

Feeding Experiments with Ants. In both feeding trials of cycasin versus sucrose, the ant foragers initially fed at both solutions, but after 10–20 min, they stopped drinking at the cycasin solution and continued to drink at the sucrose solution (Figure 3). They did revisit the cycasin, but only briefly. A comparison of the total number of visits to the two solutions showed that significantly more ants visited the sucrose solution in both trials (trial 1, expected = 32.5, $\chi^2 = 11.22$, $P < 0.005$; trial 2, expected = 31, $\chi^2 = 18.65$, $P < 0.001$). The ants did not exhibit any apparent alteration in behavior or any toxic responses from drinking the cycasin solution. The decrease in visits to the cycasin solution while the visits to the sucrose solution remained relatively high suggests that the ants learned to avoid the cycasin solution. On the second trial on the following day, however, the ants went through the same process of initially drinking from both solutions and then avoiding the cycasin solution (Figure 2). Despite this behavior, the amount of time that the ants spent drinking at the two solutions was not significantly different (one-way ANOVA, $df = 1.65$; $F = 3.27$; $0.05 < P < 0.10$) (Figure 4).

FIG. 3. The response of foraging *C. abdominalis floridanus* ants to a choice of drops of solutions of 25% sucrose and 25% sucrose + 1.0 mg/ml cycasin. The number of ants drinking from the drops was recorded every minute, but the data were combined for 5-min intervals for presentation.

The ants showed a similar response to the *E. atala* in 25% sucrose. These experiments were performed later in the spring than the previous experiments (March for the first set and June for the second), and the colony had increased in size from about 60 to about 100. In this experiment, there were many more ants foraging at both drops initially; as many as 12 ants were drinking at the drops at the same time. The ants initially fed equally often from the control drop and the drop containing the ground up butterfly in the first trial, but in the second trial fewer ants initially visited the drop containing *E. atala* (Figure 5). The total number of ant visits was significantly higher to the sucrose solution in both trials (trial 1, expected = 99, $\chi^2 = 16.99$, $P < 0.005$; trial 2, expected = 81, $\chi^2 = 43.56$, $P < 0.001$).

The results from the trials with the cricket versus the ground *E. atala* butterfly in water showed that the ants avoided the water solution containing the *E. atala* butterfly (Table 2). The number of ant visits in this experiment was one quarter to one sixth that of the experiments using sucrose solutions, probably because sucrose is more attractive than protein.

FIG. 4. The lengths of time that *C. abdominalis floridanus* ants spent drinking at solutions of 25% sucrose and 25% sucrose + 1.0 mg/ml cycasin. Both drops were available to the ants at the same time.

DISCUSSION

The warning coloration of larvae, pupae, and adults of *E. atala*, and other *Eumaeus* species is striking. In addition, all life stages of *E. atala* and *E. minyas* (= *E. toxea*) (DeVries, 1976), and probably other *Eumaeus*, are gregarious. These characteristics, typical of unpalatable insects, suggested that *E. atala* and the other species of *Eumaeus* are unpalatable (DeVries, 1977). Our results showed that *E. atala* butterflies contain cycasin in amounts as high as 2.75% dry weight. Preliminary results of GC analyses of *E. toxea* and *E. goddardii* indicate that they contain cycasin as well (Bowers, Collinge, and Robbins, unpublished data). In addition, ants visited solutions of 25% sucrose or water containing *E. atala*, as well as a solution of 25% sucrose containing cycasin, significantly less than control solutions of 25% sucrose or water with ground cricket, suggesting that *E. atala* and cycasin itself are unpalatable to these ants.

Feeding trials with gray jays (*Perisoreus canadensis*, Corvidae) showed

FIG. 5. The response of foraging *C. abdominalis floridanus* ants to a choice of drops of solutions of 25% sucrose and a dried, ground *E. atala* butterfly in 25% sucrose (8.5 mg/ml). The number of ants drinking from the drops was recorded every minute, but the data were combined for 5-min intervals for presentation.

that *E. atala* were unpalatable to these vertebrate predators (Bowers and Farley, unpublished data). Four adult jays were each offered three to six *E. atala* as part of a larger series of feeding trials. *Galleria mellonella* (Pyralidae) moths (six per bird) were used as palatable controls. All birds attacked and tasted at least one of the *E. atala* offered, but only one bird ate one. All birds ate all six

TABLE 2. NUMBER OF *C. abdominalis floridanus* ANTS VISITING TWO DROPS OF WATER, ONE CONTAINING DRIED GROUND *E. atala* BUTTERFLY AND THE OTHER CONTAINING DRIED, GROUND CRICKET IN WATER (THREE TRIALS, 1 HR EACH)

Trial	Cricket	<i>E. atala</i>	X ²	P
1	12	3	5.40	<0.025
2	19	3	11.64	<0.005
3	22	0	22.00	<0.005

G. mellonella offered. Chi-square analysis showed a significant difference in the number of *E. atala* versus *G. mellonella* that were eaten and not eaten ($\chi^2 = 36.00, P < 0.001$).

There are several mimics of *Eumaeus*. One of the most interesting is a newly described species of *Castnia* in the moth family Castiniidae (Miller, 1986). Members of the Castniidae are often brightly colored, day-flying moths, many species of which are Batesian mimics (Miller, 1986). This new species was collected in an area in Brazil where a species of *Eumaeus* was also flying. The mimic has the iridescent wings typical of *Eumaeus*, as well as the red abdomen and red spots on the ventral hindwing next to the abdomen which is typical of most *Eumaeus* (Miller, personal communication). Another mimic is *Hades noctula* (Riodinidae). This species has the red spot on the underside of the forewing next to the thorax instead of on the hindwing next to the abdomen, but otherwise is very similar.

Using TLC, we were unable to detect cycasin in the leaves of *X. floridana*, or in the larval frass of *E. atala*. This is apparently due to the relatively low concentration of cycasin in these samples, because cycasin was detected in both samples by GC: 0.1% dry weight cycasin in frass and 0.02% dry weight in the *X. floridana* leaf. Thus *E. atala* larvae are selectively sequestering cycasin from the host plant, where it occurs in relatively low amounts, and eliminating a small amount in the frass.

The feeding trials with *C. abdominalis floridanus* showed that the ants were deterred by the presence of cycasin in a sucrose solution that was normally attractive, as well as by the butterfly in water. However, as far as we could determine, the cycasin was not toxic to the ants (although there might be long-term effects that we could not distinguish). Ants are extremely numerous and important predators of insects in the subtropics and tropics (Wilson, 1971), where *Eumaeus* species are found. Our results suggest that ants may learn to avoid *Eumaeus*, and the gregarious habit and sedentary behavior of *Eumaeus* species may aid in this. For example, foraging ants might learn to avoid cycads containing *Eumaeus* larvae and/or pupae.

The behavior of the ants in response to *E. atala* and cycasin was very interesting. Only a small portion of the colony foraged in any trial, probably not more than 15 (distinguished by their distended abdomens). After drinking, the foragers returned to the nest and appeared to feed other ants and larvae. In both experiments using a sucrose solution, the ants initially foraged equally at the two solutions (control versus that with *E. atala* or cycasin), but after 10 or 15 min ceased visiting the solutions with *E. atala* or cycasin. This suggests that the cycasin and *E. atala* were not initially deterrent or that the attraction of the sucrose was so strong that the ants were not initially responding to the deterrents. Another explanation may be that the ants did not begin avoiding the experimental solutions until some physiological effect had occurred, such as

poisoning, or until something had been communicated within the colony as these solutions were transferred to other ants or larvae. In addition, our results show that the ants did not retain the information to avoid the cycasin solution over 24 hr because a second trial the following day elicited almost identical behavior of the ants—they again visited the control and cycasin solutions equally at first and after a short time ceased visiting the cycasin solution (Figure 2).

The aposematic coloration and behavior of *Eumaeus* species suggest that this advertisement is directed at visually hunting vertebrate predators; and, indeed, adult *E. atala* were unpalatable to gray jays (Bowers and Farley, unpublished data). Nonetheless, invertebrate predators (ants) also avoided *E. atala* adults after initial exposure to them. Thus *E. atala*, and probably other species of *Eumaeus* as well, provide the first demonstration of host-plant acquired chemical defense and unpalatability in the Lycaenidae.

Acknowledgments—We thank S. Collinge, D. Gordon, S. Goodbourn, and R. Robbins for comments on the manuscript, and S. Goodbourn and S. Collinge for help in the laboratory. We are particularly grateful to Dr. K. Tadera for the generous gift of the samples of cycasin and macrozamin. We also thank J. Weintraub for the *E. atala* larvae and N. Carlin for providing the *C. abdominalis floridana* ant colony and for information on its natural history. This work was supported by NSF grants 83-07353 and R11 85-03816, and a Whitehall Foundation grant.

OLFACTORY ORIENTATION RESPONSES BY WALKING
FEMALE *Ips paraconfusus* BARK BEETLES
II. In an Anemotaxis Assay

R. PATRICK AKERS¹ and DAVID L. WOOD

Department of Entomological Sciences
University of California, Berkeley

(Received February 11, 1988; accepted May 16, 1988)

Abstract—Synthetic pheromone was released from a dispenser stretched across the width of a wind tunnel. Beetles in pheromone-free wind wandered in all directions and did not appear to orient to the wind. A dosage series showed that pheromone decreased the walking rate and deviations from the upwind direction, and it increased the turning rate. The tracks were composed of relatively straight or gently curving sections interspersed with more infrequent, larger course adjustments. Although pheromone clearly affected the average heading of beetles within a treatment, any given individual exposed to pheromone did not necessarily head directly upwind or maintain a fixed absolute angle with respect to the wind direction. The response appeared to be an inaccurate anemotaxis, rather than an anemomenotaxis.

Key Words—*Ips paraconfusus*, bark beetles, Coleoptera, Scolytidae, olfaction, orientation, anemotaxis, pheromones.

INTRODUCTION

The experiments described here were undertaken to develop an assay for quality discrimination by *Ips paraconfusus* among the three compounds that comprise its aggregation pheromone: *cis*-verbenol (cV), ipsenol (Ip), and ipsdienol (Id) (Silverstein et al., 1966; Wood et al., 1967). The key requirement for an assay was that the response be clearly modulated by the compounds of interest. Anemotaxis appeared to be a good candidate since the insects use the compounds

¹ Present address: Worcester Foundation for Experimental Biology, 222 Maple Ave., Shrewsbury, Massachusetts 01545.

for orientation in flight and since the upwind walking response has commonly been used to monitor attractancy (Wood and Bushing, 1963; Wood et al., 1966, 1967; Borden and Wood, 1966; Byers and Wood, 1981). Earlier assays generally employed a point source of odor, and the beetles might have been able to use differences in pheromone concentration between the pheromone plume and the surrounding uncontaminated air as one cue to guide themselves to the source (Kennedy, 1977b). Such chemotactic responses can be studied separately (Akers, 1985; Akers and Wood, 1989), and one of our goals was to have as many criteria as possible upon which to define odor discrimination. Therefore, an assay that permitted only anemotaxis and excluded chemotaxis was desirable. Chemotactic responses were avoided in the present assay by uniformly dispensing the pheromone across the width of a wind tunnel.

METHODS AND MATERIALS

Details concerning the compounds used as stimuli, the observation chamber, the recording procedures, the handling of the experimental animals, the experimental design and analysis of the experiments, and some of the analytical methods for orientation data have been described previously (Akers, 1985; Akers and Wood, 1989).

Compounds. Ipsenol, ipsdienol, and *cis*-verbenol were obtained from Booregard Industries, Ltd., Sarpsborg, Norway. Gas-liquid chromatography (GLC) showed the following purities: ipsenol 95%, ipsdienol 98%, and *cis*-verbenol >99%. None of the compounds had any contamination of the other compounds.

Observation and Recording Procedures. A beetle's movements were observed using a chamber, within which beetles oriented at random when no odor or wind was present. A beetle's movements were recorded by marking its position by hand at 1-sec intervals, with reference to an electronic metronome. If an animal stopped walking, recording of its position ceased until it began moving again. However, the beetles are highly thigmotactic, and most did not stop moving until they contacted the wall of the arena or the pheromone source, at which time tracking ceased. Tracks were later entered into a computer via a digitizing table.

Anemotaxis Assay. The design of the anemotaxis assay was based on the discussions of Kennedy (1977a,b, 1978) and was intended to eliminate possible chemotactic responses along the edge of an odor plume. Edges were avoided by dispensing the pheromone across the width of a wind tunnel.

The arena or working section of the wind tunnel was modified from the arena used in a previous chemotaxis assay (Akers, 1985; Akers and Wood, 1989). The top and bottom of the arena were each a pane of double-strength glass, 40.6 cm square. The top had a 1-cm hole in the center. Along the lengths

of two parallel edges of the plates ran aluminum rods, 1 cm square. This created an area $40.6 \times 38.6 \times 1$ cm, open on both ends. Heavy rubber bands along the open edges bound the arena together. One open end of the arena was slipped into the inlet manifold of the wind tunnel, completing the tunnel. The hole in the upper plate was sealed with a stopper except when access to the interior was needed.

A wind speed of about 0.9 m/sec was used in the assay because it is about midway in the range where *I. paraconfusus* is known to respond to pheromones in the field (Gara, 1963), and it is similar to wind speeds used in previous walking bioassays (0.76 m/sec in Wood and Bushing, 1963). Preliminary experiments showed no upwind responses to wind at 0.9 m/sec, in the absence of pheromone. Wind speed was measured at seven locations evenly spaced along the exit from the arena and was 0.94 ± 0.04 m/sec. The wind tunnel was isolated from the fan such that no vibration could be felt at the arena. Air temperature within the tunnel was $25 \pm 1^\circ\text{C}$.

The pheromone dispenser was a loop of six-strand, 100% cotton embroidery floss (J.P. Coats #1), 87 cm in circumference. This loop was attached at one point to a strong thread passing through the inlet manifold approximately 2 cm upwind of the arena. The stimulus could be presented at any moment by pulling the thread through the manifold. The dispenser then stretched across the entire width of the manifold approximately 0.4 cm above the floor of the arena. The stimulus was generally presented a few seconds after the beetles emerged into the wind stream.

Since a uniform stimulus across the arena was required, a uniform distribution of pheromone along the dispenser was necessary. The method described here was chosen because it gave a fairly uniform distribution, conserved pheromone compounds, and permitted an estimate of the dosage applied to the dispenser. The loop of floss was pressed into the bottom of a test tube. Enough test solution was applied to just thoroughly saturate the floss, with little or no excess. For the dispenser described, 0.7 ml was appropriate. The floss remained in the tube 3–4 min, then was stretched its full length. The solvent, pentane, evaporated in 1–2 min, and the dispenser was used immediately thereafter.

The distribution of the pheromone along the dispenser was determined by GLC. Linalool, 0.1 mg, was applied to each of four dispensers, using the method described above. Linalool was used to conserve pheromonal compounds and because its diffusion and evaporation properties are very similar to those of the pheromonal compounds (Table 1 in Akers and Wood, 1989). Five samples of floss, each 0.5 cm, were cut at 6-cm intervals along the length of each dispenser and were each extracted in 50 μl of pentane, to which an internal standard (decane) had been added, in order to check the measuring error. This would not include other sources of error such as variations in cutting the floss, or in the amount of pentane used to extract the samples. One microliter from

each sample was injected into the GLC. The coefficient of variation among the samples of a dispenser, as averaged over the four dispensers, was $22.3 \pm 6.8\%$ for the linalool and $16.7 \pm 4.2\%$ for the internal standard. These were not different at the 5% level in the *t* test. Should the observed means be the true population means, the variation from sample to sample along the floss would be about 15%.

The handling of each dispenser was relatively time-consuming. To test the effects of using a dispenser more than once, three dispensers were exposed in the wind tunnel for each of 0, 1, 3, and 5 min, and 0.1 mg of linalool was applied to each. After exposure, the dispensers were extracted individually in 2 ml of pentane for 20 min at room temperature, after which they were kept on Dry Ice. Two samples of $1 \mu\text{l}$ each were injected from each dispenser onto the GLC. About 60% of the pheromone evaporated in the first minute (Figure 1). Based on these results, a single dispenser was used only once in all behavioral experiments. Given the flow rate and dimensions of the arena, the average concentration in the air during the first minute of exposure was approx. 0.28 ng/ml.

A preliminary experiment showed that beetles did not exhibit any form of trail-following or otherwise interact with one another when more than one beetle was run within a single arena (Akers, 1985). In this experiment, the relationships between the tracks of two beetles that had run together within a single

arena were compared to the relationships between the tracks of a pair of beetles that had run in separate arenas. The average distance that the second beetle of a pair maintained with respect to the trail of the first beetle was measured, as were the walking and turning rates of the second beetle. There were no significant differences in these measurements between the beetles that had the opportunity to follow a trail and those that did not, in either the presence or absence of pheromone. Therefore, observations made on beetles tested within a single arena could still be considered as independent for statistical purposes, and testing more than one beetle in a single arena greatly reduced the time required per replicate. Ten beetles were usually run successively in each arena, with an interval of 2–3 min between them.

In order to minimize contamination between treatments, each treatment had its own arena. An arena was rinsed after each use in hot (approx. 70°C) water, flowing at a rate that provided an exchange of water approximately every 4 min. The rinse lasted about 40 min. The parts of an arena were then aired for three to five days before the next use.

Handling of Beetles. The beetles were collected from naturally infested ponderosa pine (Browne, 1972). Females were stored at 5°C in individual glass tubes, sealed with Teflon tape. They were removed from the cold 5–20 min before use, since their struggles within the storage tubes seemed to decrease their vigor after an hour or so. A beetle was brought out of the cold directly onto the observation platform of the observation chamber, where it recovered in 1–2 min, in the same light and temperature conditions under which it would be tested. A beetle was used only once.

When a beetle was to be released, the tape was removed from the storage tube and the beetle was slid gently but immediately into an L-shaped, glass release tube inserted through the hole in the arena. The direction of orientation of the outlet or the presence of wind did not have much effect on the consequent directions taken by the beetles (Figure 4 below). Nonetheless, the outlet of the tube was oriented approximately downwind, in an attempt to minimize random upwind movements. Since the pheromone components were at first thought to cause only attraction, the downwind release was intended to accentuate the difference between active and inactive treatments.

Experimental Design. A dosage series of a 1 : 1 : 1 blend of the three pheromonal compounds was used, as in earlier behavioral tests (Byers and Wood, 1981). Treatments were assigned in a randomized block design as a precaution against losing the supply of beetles during the experiment, but the effects of blocks were slight and are not reported. The treatments differed by powers of 10 and had a range of 10^{-7} –1 mg of each compound. The experimenter did not know the identity of the treatments, both during the experiment and during the manipulation of the data. Solutions were stored at –60°C or over Dry Ice until a few minutes before use.

Analysis of Orientation Data. The kinetic responses measured were the linear rate of motion and rate of turning. The estimate of the walking rate was the mean distance between each point on a beetle's track. Two related measures were used to summarize the turning rate. Both were based on the turn angle measured at each point on a track. The turn angle was defined as the angle between the direction from the previous to the current point on the track and the direction from the current to the next point. Zero degrees was defined as straight ahead from the current point on the track. For the "net turning rate," the "handedness" of a turn was taken into consideration, with left-hand turns defined as positive. In the "gross turning rate," the absolute value of each turn was used. The estimates of the rates were the mean turn angles over all the points on the track.

An insect's heading with respect to the wind was also measured at each point on its track. The heading was defined as the angle between the upwind direction and the direction from the present point to the next point on the track. The direction directly upwind was defined as 0°. Similar to the turning rate, a mean net heading and a mean gross heading were defined. In all, the data summaries included walking rate and its variation within a track, net turning rate, gross turning rate and its variation within a track, mean net heading, and mean gross heading and its variation within a track (Akers, 1985; Akers and Wood, 1989). The variations of net angle summaries were not examined because net angles are circular variables and the estimates of their variances have inherent statistical difficulties (Batschalet, 1981; Akers, 1985; Akers and Wood, 1989).

RESULTS

Increasing dosage decreased the walking rate (Figure 2A and Table 1), the mean gross heading (Figure 2G), and the magnitude of the mean net heading (Figure 2F); it increased the gross turning rate (Figure 2C) and its variability (Figure 2D). It also increased the variability of the mean gross heading (Figure 2H). Dosage did not affect the magnitude of the net turning rate or the variation of the walking rate. A beetle's track tended to have relatively linear or gently curving sections interspersed with sharper turns, even in the presence of pheromone (Figure 3). At the highest dosage, the tracks of some beetles became sinuous.

In a previous experiment on chemotaxis (Akers and Wood, 1989), a beetle had only a 2% chance of reaching the source by chance alone. Thus, when more than one or two beetles reached the source in a treatment, most of them were probably responding to the treatment. In the anemotaxis assay, no criterion could be found that satisfactorily distinguished responding from nonresponding beetles. First, in the absence of pheromone, the beetles apparently did not use

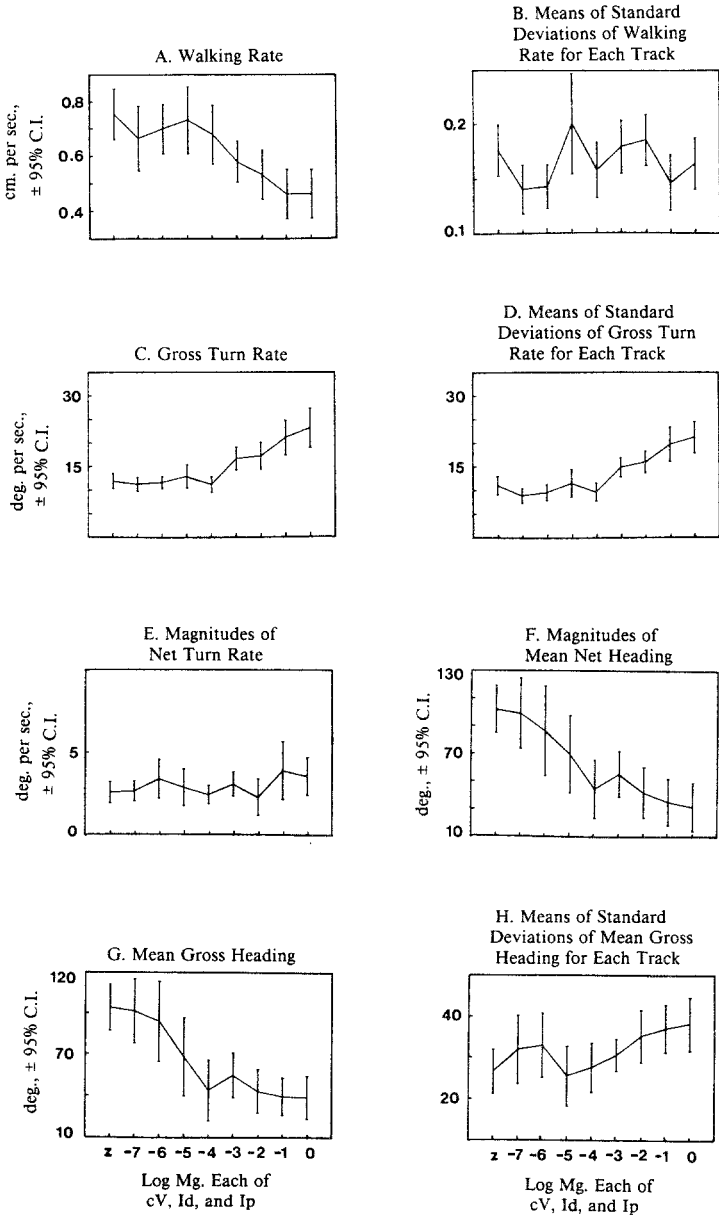

FIG. 2. The effects of dosage of a standard pheromone blend on measurements taken from the tracks of beetles in the anemotaxis assay. Ip = ipsenol, Id = ipsdienol, cV = *cis*-verbenol, z = zero dosage level. 95% C.I. = the 95% confidence interval of the mean.

TABLE 1. ANALYSES OF VARIANCE FOR EFFECTS OF PHEROMONE DOSAGES ON BEHAVIORAL MEASUREMENTS

Behavioral response	$F_{(obs)}$	P value ^a
Walking rate	5.44	<0.0001
Standard deviations of walking rates	1.48	0.168
Gross turning rate	12.20	<0.0001
Standard deviations of gross turning rates	12.99	<0.0001
Magnitudes of net turning rates	1.18	0.314
Mean gross headings	7.97	<0.0001
Standard deviations of mean gross headings	2.16	0.032
Magnitudes of net headings	7.31	<0.0001

^aThe P value is the probability of obtaining an F greater than the observed F , given that H_0 is true. H_0 : treatment means are not different from one another. N = a total of 218 beetles in nine treatments.

the wind for the purposes of orientation. They wandered in all directions after being released in a pheromone-free airstream, despite being released with a downwind orientation (Figure 4), similar to their random orientation in still air when no pheromone source was present (Akers, 1985; Akers and Wood, 1989). Further, even in high pheromone dosages, the angle any particular beetle maintained with respect to the wind was not necessarily directly upwind or even very nearly so (Figure 3).

Combined with the possibility that even an unstimulated beetle might head

FIG. 3. Four sample tracks selected randomly from each of the control and 0.1-mg treatments. Points on the trails are 1 sec apart. T_x = the starting point of trail x .

FIG. 4. A frequency histogram of the absolute mean net headings for the track of each of 40 beetles released into a clean wind stream in the anemotaxis assay. Beetles were originally released on a heading approximately downwind (180°).

upwind, the determination that any particular beetle had entered into odor-modulated anemotaxis became uncertain. For example, no criterion independent of heading, such as walking or turning rate, separated the beetles into two groups within which all or most of the beetles either did or did not orient strongly upwind. When criteria were developed based on heading, walking and turning rates were significantly different between the groups that had been provisionally identified as responding or not responding, but there were also significant differences among dosages within each group. Graphs of the data also showed similar trends within each group. For instance, gross turning rate tended to increase with dosage and walking rate decreased, even among the treatments in the group that had provisionally been classified as not responding to the pheromone. Furthermore, heading apparently decreased with dosage in this group. Results of this sort led us to believe that, while we could demonstrate strong effects on the responses of the population, we could not safely identify individual beetles as responding or not responding to the pheromone.

DISCUSSION

The results of this assay are very similar to those obtained in the chemotaxis assay (Akers and Wood, 1989), except that turning rate (Figure 2C) and its variability (Figure 2D) and mean gross heading (Figure 2G) and its variability (Figure 2H) were lower in the anemotaxis assay. These results reflect

the impression that the tracks were more linear in the anemotaxis assay (Figure 3) than in the taxis assay (Figure 7 in Akers and Wood, 1989). The tracks often seemed to be composed of relatively straight or very gently curving sections, interspersed with a few relatively large course adjustments. This is similar to observations on *Bombyx mori* and *Grapholita molesta* (Kramer, 1975; Willis and Baker, 1987). However, the beetles did not maintain fixed absolute headings with respect to the wind, while *B. mori* did so both in clean wind and in wind uniformly contaminated with pheromone. Neither did the beetles consistently head as directly upwind as the tracks of *G. molesta* illustrated in Willis and Baker (1987). However, since the latter work employed a point source of pheromone, perhaps a loss of the pheromone plume corrected any tendency of the moths to wander from a path straight upwind. Furthermore, the beetles were released facing downwind only about 22 cm below the pheromone source, whereas *G. molesta* was released about a meter from the pheromone source. Although the beetles usually took at least 30 sec to cover the distance to the source, perhaps their performance would have improved with more time.

When beetles were exposed to pheromone, the shape of their tracks often approximated those of control beetles, but their directional vectors had shifted upwind (Figure 3) (Bell and Tobin, 1982). In some cases, the beetles exposed to pheromone seemed to have a fairly high turning rate early in the track, while the later portions became more linear as the track approached the upwind direction (e.g., track T₁ in Figure 3). However, scattergrams and exploratory regressions of turning rate against time on the track or against percent of the total period of the track did not in general support the notion that turning rate slowed as the track was run. It seemed to be more a function of the individual beetle.

Wind was the only orienting cue available to the beetles in these experiments because the pheromone was released uniformly across the width of the windstream. The lower headings with respect to wind direction in the presence of pheromone (Figure 2F,G), and the linearity of the tracks (Figure 3) relative to the chemotaxis assay (Figure 7 in Akers and Wood, 1989), lead to the conclusion that the response is an odor-modulated orientation with respect to the wind direction (anemotaxis). The broad curves and course changes in the tracks indicate the beetles were not executing a compass orientation with respect to the wind (anemomenotaxis), as *B. mori* had.

The threshold dosage for the response appeared to be about 10^{-6} – 10^{-5} mg, while in the chemotaxis assay the threshold was no higher than 10^{-4} mg (Akers and Wood, 1989). A dose of 0.1 mg linalool produced an average pheromone concentration of 0.28 ng/ml in the air of the arena in the anemotaxis assay (see Methods and Materials), while a dose of 1.0 mg produced a concentration of 5.8 ng/ml at the release point of the beetles in the chemotaxis assay (Table 1 in Akers and Wood, 1989). Accordingly, the concentration in the air for a given dose of pheromone may have been similar in the two assays, making

these thresholds remarkably close. The threshold is lower in the anemotaxis assay, as might be expected since the odor does not have to provide directional cues. However, the low threshold in the taxis assay once again attests to the relative strength of that response in the beetles.

The results from the present anemotaxis assay are somewhat different from the results of earlier studies (Wood and Bushing, 1963; Borden and Wood, 1966; Byers and Wood, 1981) in which a point source of pheromone was released into a broad airstream. In those studies, the behavior of the beetles was not quantitatively described beyond noting whether they arrived at the source. However, descriptions and examples of the tracks indicate that they were fairly sinuous, so much so that the response was characterized as a chemoklinotaxis (Wood and Bushing, 1963; Borden and Wood, 1966). Although they were sinuous, the tracks did not appear to wander very far from a line connecting the release point of the beetles and the source of pheromone directly upwind of it, much like the tracks of *G. molesta* walking to a point source of pheromone (Willis and Baker, 1987). That is, the beetles seemed on average to head more directly upwind than in the present study. One potential explanation for the beetles' sinuous paths in the earlier studies might be that they execute an endogenously generated series of turns upon encountering pheromone-laden air. Some moths apparently initiate endogenously generated zigzagging when they encounter pheromone (Kennedy et al., 1980), although the control of turning by flying moths appears once again to be a matter of some controversy (Preiss and Kramer, 1986; David and Kennedy, 1987; Willis and Baker, 1987). In the present study the stimulus was presented a few seconds after the beetles emerged into the arena, and there was no sign of zigzagging or especially rapid turning early in the tracks (Figure 3). Apparently, then, the sinuous upwind responses observed in earlier studies were not purely anemotactic and were not zigzagging analogous to that of moths. Instead, some form of taxis may have been occurring along the border between clean and pheromone-laden air downwind from the point source. However, the behavior of the beetles upon emerging from pheromone-laden air needs to be studied before a cogent theory can be constructed as to the mechanism of orientation to a point source in wind. Perhaps a loss of pheromone stimulation initiated the sinuous movements seen in the earlier studies. Alternatively, some form of counterturning initiated by the loss of pheromone could be involved (Akers, 1985, 1989).

While this work was done with walking insects, the results have similarities to those obtained with flying beetles. Studies of anemotaxis with beetles flying in wind tunnels are scarce. One reason appears to be that beetles will not zigzag nicely within a wind tunnel, as will moths. Instead, they tend to take off each in their own particular direction and then fly in a fairly linear manner until they collide with the walls of the chamber. The addition of pheromone shifts the general direction of take-off towards the upwind direction, but the beetles

still do not zigzag and the direction of take-off seems to depend strongly on the individual (Choudhury and Kennedy, 1980), which is similar to our results.

Acknowledgments—We thank K.Q. Lindahl, Jr., for valuable discussions of experimental design and analysis, Andrew Liebhold for suggestions on the observation chamber, and J.K. Grace and M.W. Akers for helpful critiques of the manuscript. LOCATION OF VOLATILE ODOR SOURCES BY GHOST CRAB *Ocypode quadrata* (Fabricius)

CHRISTOPHER A. WELLINS, DAN RITTSCHOF, and
MATT WACHOWIAK

*Duke University Marine Laboratory
Beaufort, North Carolina 28516*

(Received March 14, 1988; accepted May 18, 1988)

Abstract—The ghost crab, *Ocypode quadrata*, was tested in the field for its ability to locate sources of volatile cues. The pure compound skatole, 3-methylindole, was a potent attractant. Crabs also located sources of complex odors such as dead fish, *Lutjanus campechanus*, dead mole crabs, *Emerita talpoida*; and peeled bananas. Ghost crabs possess concealed and reduced antennules that may not be the primary olfactory organs. Chemosensory hairs borne on the dactyls may be the primary detection system.

Key Words—*Ocypode quadrata*, ghost crab, olfaction, chemoreception, crustacea.

INTRODUCTION

Study of signaling functions of volatile compounds in complex mixtures for crustaceans is confounded in water by the presence of water-soluble nonvolatile cues. The study of responses of terrestrial crustaceans to airborne cues enables isolation of volatile from nonvolatile compounds in complex mixtures. Using this technique, Rittschof and Sutherland (1986) demonstrated that land hermit crabs *Coenobita rugosus* can use volatile chemicals to locate fruit, carrion, and feces.

We extended that study to another crustacean, namely the ecologically similar yet phylogenetically distant, semiterrestrial ghost crab, *Ocypode quadrata*. Ghost crabs live in burrows scattered from the intertidal to hundreds of meters inland. They emerge from their burrows shortly after dark to scavenge, predate, and reproduce. Ghost crabs eat live prey, including mole crabs (*Emerita talpoida*), coquina clams (*Donax variabilis*), and conspecifics (Wolcott,

1978). We have seen them scavenge horse manure, horseshoe crabs, sea gulls, cooked shrimp, peanuts, potato chips, candy wrappers, and beach wrack. Bearing in mind their adaptation to the terrestrial environment, we asked the question: can these crabs also use volatile cues to locate food?

METHODS AND MATERIALS

Study Area. Two 120 × 20-m areas of beach on Bird Shoal, immediately due East of the Beaufort Inlet, North Carolina, were field sites chosen because searches showed these areas were more densely populated with ghost crabs than were the adjacent stretches of shore. One area included approximately 60 m of the western shoreline, before the southernmost point, and 60 m of the southern shoreline. Dredge spoil dunes bordered this stretch of beach. Most of the dunes had dune grasses (*Spartina patens* and *Uniola paniculata*) growing on them. Burrows of crabs were located from the high intertidal to well within the dunes. The other site was 300 m east of the first, on the southern shore. This site had a few dunes to the west but for the most part was a flat sand isthmus between a low energy ocean beach and a tidal flat. Crab burrows were scattered throughout the isthmus area above the high tide line.

Odor Sources. Six odor sources, two each from the categories of animal, plant, and feces, were tested in the field. Five sources [red snapper (*Lutjanus campechanus*) and mole crabs; peanut butter and bananas; and horse manure] generated complex odors and were chosen because they mimic naturally occurring ghost crab food. Bananas, fish, and horse manure have previously been shown to be attractive to the land hermit crab (Rittschof and Sutherland, 1986). The pure compound, skatole, 3-methylindole, is a known component of feces (Stecher, 1960).

Field Assay. Rittschof and Sutherland's (1986) field assay was modified to test the ability of ghost crabs to locate substances using only olfaction. Bait was concealed in a cylindrical hole 10 cm in diameter × 15 cm deep. Each hole was covered with 1 cm mesh galvanized hardware cloth and marked with a surveyor's flag. Because of its design, the hole eliminates the possibility of a crab finding the bait by sight, taste, or touch. Thus, a crab locates the hole by chance or through the use of olfaction. Unbaited holes were used as controls (C), which were placed on either side of experimentals (E) to make an E, C, E, C, transect. Each assay had equal numbers of control and experimental holes. A goodness-of-fit test was used to compare the frequency of responses to each baited trap series. Test series were conducted until the minimum number of responses in any category was five, in order to satisfy the assumptions of the statistical analysis. The null hypothesis that responses were independent of the

bait was tested using a G statistic with 1 df after correction for continuity (Sokal and Rohlf, 1981).

Baited holes contained one fish head (6–10 hr old), which weighed approximately 100 g; several (three to four) mole crabs (total weight 25 g); or one to two pieces of horse manure (50 g). One filter pad (4.25 cm in diameter), soaked in a saturated skatole–seawater solution, was used per hole. One quarter of a peeled banana (40 g) was used and one tablespoon of Superman brand peanut butter was used (20 g) per hole.

Usually, 40 holes were placed in a horizontal transect every 3 m, just below the high water mark. Data were pooled from two to six nights using the same test substances. Holes were dug in an interval 30 min before sunset and baited 15 min before the beginning of the assay. Assays were generally run for 90 min and began just after dark. The line of holes was checked every 15 min using a 6-V dive light (bulb: GE H7550 halogen; changeable Technacell 6-V battery EP640). Any crab found touching the wire mesh cover was collected and held until the end of the assay to prevent counting any animal twice. To rate the attractiveness of the substances, tests were normalized with respect to time and surface area for odor release. First, all control responses were normalized with respect to the lowest value. Each substance's experimental response was divided by its normalized control value giving an attractiveness adjusted for crab activity. Then, the time-adjusted attractiveness figure was divided by the approximate surface area of the odorant.

Observations. Crab activities were observed over three summers (May to October 1985–1987). Initially, assays were conducted on a schedule, but after two seasons, field assays were conducted immediately after dark only on nights when, in our experience, crabs were highly active. Crab activity was assessed visually and correlated with wind speed, temperature, time of the tide, and phase of the moon. Crabs outside the boundaries of the study areas were observed during other times, primarily to determine what they were eating. Because observations of ovigerous females were extremely rare (T. Wolcott, personal communication), these were actively searched for.

To study the response of the crabs to volatile cues, crabs were observed approaching a hidden odor source. One $30 \times 30 \times 15$ -cm hole was dug in the middle of site 1, just below the high water mark, 15 min before dark. Red snapper (1 kg), known from assays to be attractive, was placed in this hole. A dim red light (600 nm) was fastened to the top of a wooden pole buried in the sand 30 cm from the hole, so that the light was 1 m above the sand. Ghost crabs were not predicted to see this wavelength of light (Cronin and Forward, 1988). The illuminated area was about 3.0 m in diameter. A yarn tell-tale was tied to the top of the pole to gauge wind direction. The observer sat 2 m upshore of the hole, facing the water. In this position the prevailing wind direction was

from the observer's right to left. For 1 hr, beginning 30 min after sunset, the approach of crabs to the hole was observed. Direction, pattern of movement, body posture, and general behavior of the crabs were noted.

RESULTS

General Observations. During May through September, ghost crabs leave their burrows shortly after dark. They remain near the burrow mouth briefly and then either move to the water to forage along the tide lines or to actively pursue prey (*Donax* and *Emerita*) at the water's edge. Most crabs caught feeding in the surf zone were eating *E. talpoida*. Copulations were observed approximately 10% of the nights. Cannibalism was observed approximately 5% of the nights. At the new and full moon, hatched eggs and inactive larvae were found on females before they entered the water. Larval release was after dark within 40 min of high tide. When temperatures were below 20°C, crabs were inactive. Activity was reduced on nights with wind greater than 17 km/hr.

The paths of nine crabs were recorded during the 90-min interval in which the single pit baited with 1 kg of red snapper was observed. Each crab was followed closely when it approached within 3 m of the pit. Seven of the crabs approached from downwind of the bait. These crabs either moved directly to the pit or moved upwind, paused, moved 10–30 cm laterally, and then moved directly to the pit. All crabs had an elevated body posture, accomplished by extension of the walking legs to approximately 60% of maximum. All eventually stood directly on top of the odor source and attempted to feed. At this point crabs were captured. Two crabs approached the pit from the upwind direction, came within 60 cm of the pit and walked by. Neither crab showed the elevated body posture, and both crabs passed by without stopping.

Field Assay Responses. As previously mentioned, the data have been divided into the categories of carrion, plants, and feces. The responses of crabs to pitfalls baited with animal flesh (Figure 1A) were 3.6 times greater than the controls for mole crabs ($G = 7.8$, $df = 1$, $P < 0.01$) and 3.0 times the response to controls for red snapper ($G = 8.8$, $df = 1$, $P < 0.01$). The experimental to control ratio for responses to plant material (Figure 1B) was slightly lower than that for carrion. Crabs responded significantly to banana ($G = 9.0$, $df = 1$, $P < 0.01$), but not to peanut butter ($G = 3.7$, NS). In the feces category (Figure 1C) the response to skatole was 3.0 times greater than controls ($G = 9.4$, $df = 1$, $P < 0.01$), whereas the response to horse manure did not differ from that of the controls ($G = 1.7$, $df = 1$, NS).

Relative Attractiveness to Volatile Stimuli. Relative attractiveness data are

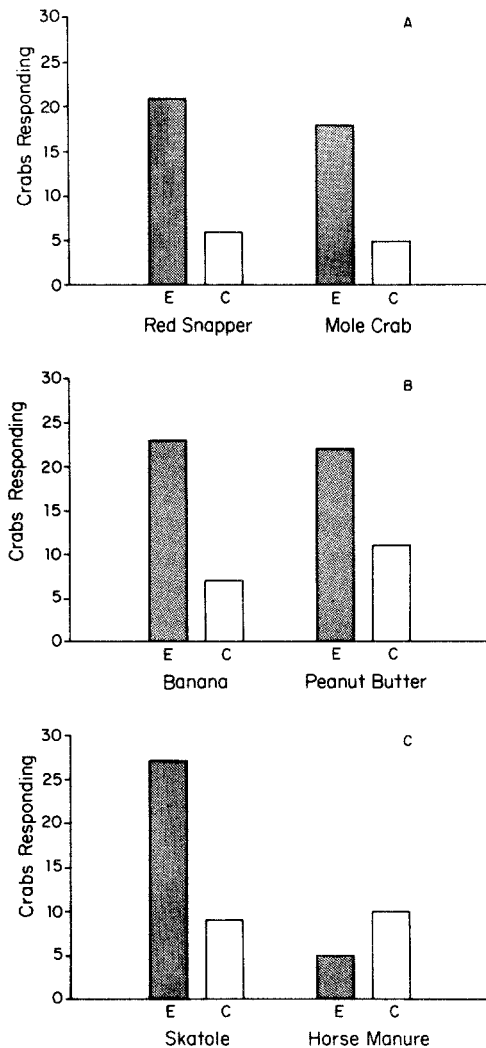

FIG. 1. (A) Field responses of ghost crabs to the complex odors of two animal remains: red snapper (*Lutjanus campechanus*) and mole crabs (*Emerita talpoida*). E is the response to flesh; C is the response to control. (B) Field responses of ghost crabs to the complex odors of two plants: banana and peanut butter. E represents the response to plant odors; C is the response to controls. (C) Field responses of ghost crabs to the pure compound skatole, 3-methylindole, and the complex odor of feces represented by horse manure. E signifies the response to odors; C is the response to controls.

TABLE 1. ADJUSTED ATTRACTIVENESS OF TEST SUBSTANCES TO GHOST CRAB

Substance	Adjusted attractiveness	Surface area (cm ²)	Relative attractiveness (adjusted attractiveness/surface area)
Skatole	10.0	14.2	0.7
Mole crab	13.0	50.3	0.3
Banana	11.4	201.1	0.06
Snapper	12.5	706.9	0.02
Peanut butter	5.0	201.1	0.02
Horse manure	-2.5	201.1	-0.01

summarized in Table 1. Skatole and mole crabs were the most attractive. Bananas, snapper, and peanut butter were an order of magnitude less attractive. Horse manure was not attractive.

DISCUSSION

Detection of volatile odors would enhance the ability of terrestrial scavenging crabs to function. An omnivorous scavenger would be expected to respond to odors that signal potential food sources. Substances from three categories of odors: animal, plant, and feces, were attractive to ghost crabs. Skatole, mole crabs, banana, and red snapper were significantly attractive. Peanut butter and horse manure were not. Use of volatile compounds as food cues is thus a certainty. The response of ghost crabs to odor cues or pheromones for other purposes remains to be demonstrated.

Scavengers and predators should respond to a wide range of odor cues and could be responding for two reasons: a crab may investigate an unusual odor or cues that are characteristic of food sources (Hazlett, 1971; Robertson et al., 1980, 1981). Decarboxylated amino acids such as skatole, putresceine, and cadaverine are primary by-products of bacterial decomposition (Trott and Robertson, 1984) and are characteristic of high nitrogen sources such as carrion and feces. Decarboxylated amino acids cue cheliped flexion in ghost crabs (Trott and Robertson, 1984) and, as in the case of skatole, may also attract crabs from a distance.

The field assay tested whether or not a crab investigated an odor source. The field assay is a measure of a directed response evoked after odor detection. The extent to which a crab investigates an odor may depend upon the source's

desirability as a food item. Changes in sensitivity to common odors dependent upon dietary intake would diversify diet. Rittschof et al. (1985) demonstrated that if fed a certain food for several days, *C. rugosus* did not respond behaviorally to the odor of that food. It is possible that ghost crabs can smell horse manure but do not respond to the odor. Horses live in the area of the study, and manure is not a limiting factor. In manure-limited situations, ghost crabs may also respond to manure as do hermit crabs (Rittschof and Sutherland, 1986).

Ghost crabs responded to skatole and not to horse manure. Manure is a complex odor that includes skatole (Stecher, 1960). This inconsistency can be explained by the dietary intake argument described above (ghost crabs have been observed dining on manure). If sensitivity to odorants is decreased with exposure, as observed with aquatic snails (Rittschof et al., 1984), then extremely high levels of skatole (saturated solutions) might overcome the loss in sensitivity due to consumption. Another possibility is that other components in manure interfere with the response.

Wolcott (1978) reported that on high-energy beaches 91% of the ghost crab's dietary intake comes from predation. He emphasized that ghost crabs are also facultative scavengers. On lower-energy ocean beaches such as our study site, *E. talpoida* is less prevalent and *D. variabilis* is scarce. *E. talpoida* and *D. variabilis* constitute 87% of prey species in Wolcott's study. At our site, crabs caught feeding in the surf zone were eating *E. talpoida*. Scavenging appeared to be a prominent strategy in our study area. Although ghost crab eyesight is impressive (Daumer et al., 1963), observation of ghost crabs shows that they consistently obtain information through other senses, such as touch and olfaction. The use of the other senses is most apparent in situations where vision has little input. Vision by compound eyes is limited at long distances and obviated at short distances by the location of the target in relation to the eyes (Cronin, 1986).

Wolcott (1978) reported that crabs moved to the water immediately upon emerging from their burrows. We observed animals lingering near the burrow mouth upon emerging. Trott (1987) stated that *O. gaudichaudii* can maximize net energy intake by correlating foraging intensity with food density. This same strategy appears at our site, but the crabs are using olfaction as well as their contact chemoreception. We hypothesize that upon emerging from their burrows, the crabs first "test the air" for a potential food source. If they smell something on the beach or in the drift-line, they investigate. If not, they go on to the surf line and prey upon *E. talpoida* and *D. variabilis*. Crab approach patterns in response to odors are similar to those of moths flying to an odor source (David et al., 1982) and tube-nosed birds to wick-emitting volatile odors (Hutchison and Wenzel, 1980). These patterns suggest an integrated upwind approach to an odor source.

Banana and skatole, two odors that we have shown to be attractive to ghost crabs, are also attractive to *C. rugosus* (Rittschof and Sutherland, 1986). Hermit crabs and ghost crabs evolved from different aquatic ancestors. The responses observed could be a result of convergent evolution, or detection of volatile cues may have been a capability of an aquatic ancestor.

Observations suggest that land hermit crabs detect volatile cues with their large foliose antennules (Rittschof and Sutherland, 1986). Ghost crab antennules are greatly reduced and concealed behind the rostral plate in an aqueous medium. We find it unlikely that the antennules are solely responsible for orientation to volatile cues and hypothesize instead that hairs on the dactyls function in odor detection. Dactyl hairs have already been shown to act as contact chemoreceptors (Trott and Robertson, 1984). The leg hairs of the American lobster (*Homarus americanus*) have also been shown to have such functions (Derby and Atema, 1982). When orienting to an odor source, crabs were observed to maintain a higher body posture than at other times. Perhaps this posture could give better air flow to the dactyl hairs.

If crustacean food search can be mediated by volatile cues, then volatile compounds may also mediate other major biological functions such as mating. We pose the hypothesis that ghost crabs use a pheromone communication system similar to that of terrestrial insects. The use of volatile compounds as pheromones by crustaceans is an area that has not been investigated. Future studies will use receptive male and female crabs as "bait" in the holes to test this hypothesis.

Acknowledgments—We wish to thank everyone who helped with the field work. Special thanks go to E. Herzog, H. Holden, J.T. Katzen, A. Pacifico, Jr., S.S. Tilly, K.V.O., P. Vahteri, L. Barlow, A. Carducci, and the anonymous reviewers who made many valuable suggestions and greatly improved the manuscript. We also wish to thank Richard Forward, Jr., for helpful discussion about crab eyes. Supported in part by a URC grant to D.R.

COLONIZATION OF SOUTHERN BEECH BY *Platypus caviceps* (COLEOPTERA: PLATYPODIDAE)

G. YTSMA

Forestry Research Centre
Forest Research Institute
P.O. Box 31-011, Christchurch, New Zealand

(Received February 16, 1988; accepted May 19, 1988)

Abstract—The role of host- and beetle-produced odors in the colonization of southern beech (*Nothofagus* spp.) by the pinhole borer *Platypus caviceps* Broun was investigated. Host-selecting males attacked the crown zone of a recently felled tree. Beetle emergence and dispersal were influenced by temperature, and sparse colonization continued over the 30 days of the study. Field tests using naturally baited traps indicated that male colonization of southern beech can be accounted for by attraction to host odors alone and that subsequent female response is to a male-released sex pheromone acting alone or in combination with host odors.

Key Words—Host colonization, sex pheromone, ambrosia beetle, *Platypus caviceps*, Coleoptera, Platypodidae, *Nothofagus*, southern beech.

INTRODUCTION

The pinhole borers *Platypus caviceps* Broun, *P. apicalis* White, and *P. gracilis* Broun attack healthy or stressed living and recently felled southern beech (*Nothofagus* spp.) in New Zealand. *P. apicalis* and *P. gracilis* attack a wide range of hosts whereas *P. caviceps* attack is almost solely restricted to southern beech. As possible vectors of a pathogenic fungus (*Sporothrix* sp.) *Platypus* beetles are a major cause of death and hidden decay among beech trees. Because of this relationship, *Platypus* beetles influence the economics of management of New Zealand beech forests. As the world's hardwood resource dwindles and attempts to manage natural and planted stands increase, understanding the behavior of *Platypus* beetles could be vital.

Primary attraction in the genus *Platypus* has been associated with host

odors, particularly ethanol and/or monoterpenes (Samaniego and Gara, 1970; Elliot *et al.*, 1983; Shore and McLean, 1983; Fatzinger, 1985). After initial attack by the host-selecting sex (*Platypus* males), subsequent buildup of attack has been associated with male-released aggregation pheromones (Madrid *et al.*, 1972; Renwick *et al.*, 1977; Milligan, 1982; Milligan *et al.*, 1988; Milligan and Ytsma, 1988).

Of the New Zealand species, *P. apicalis* and *P. gracilis* exhibit mass attack behavior mediated by aggregation pheromones (Milligan, 1982; Milligan *et al.*, 1988; Milligan and Ytsma, 1988; Ytsma, 1988). *P. caviceps*, however, attacks only sparsely, suggesting that aggregation pheromones may not be used during host colonization. This paper describes the role of host- and beetle-released odors in *P. caviceps* attack on beech and gives information on the behavioral pattern of attack.

METHODS AND MATERIALS

Two field studies were carried out during January–March 1987 in beech forest dominated by *Nothofagus solandri* (Hook.f.) Oerst. in Ashley State Forest, Canterbury, New Zealand, where a ground survey indicated a low- to medium-level population of *P. caviceps*. These studies were designed to (a) observe the colonization behavior on a felled tree, and (b) investigate the role of host- and beetle-released odors as attractants.

Colonization of Felled Tree. The colonization of a previously unattacked healthy, felled beech tree (dbh = 0.41 m, ht = 10.2 m) was observed. Fresh attacks were counted and marked daily between 1400 and 1600 hr for the first 30 days after the tree was felled. Two multiple-funnel traps, similar to those designed by Lindgren (1983) but using only six funnels, were placed either side of the base (0–3 m), center (3–6 m), and crown (6–10 m) of the felled tree to sample incoming beetles. Beetles were removed from the traps daily, counted, and sorted by sex.

Field Trapping. Logs infested with *P. caviceps* were obtained from west coast beech forest and transported to our Rangiora field station where they were stored under black polythene. Approximately equal numbers of adult males and females emerged randomly from November to May (Ytsma, unpublished data). Beetles were collected from these source logs (Milligan, 1982), and the males were induced to attack billets of beech (Ytsma, 1986). Males were allowed two days to establish tunnels, as preliminary tests indicated that before this time few males in tunnels were attractive to female beetles (i.e., they had not begun pheromone release). Infested billets containing about 25 male attacks and similar uninfested billets cut from the same logs with clusters of 25 holes drilled in each were used as baits for field trapping.

At each of three sites (50 m apart) multiple funnel traps that intercepted beetles 25–100 cm above ground level were suspended over an infested billet, an uninfested billet, and on an unbaited control, each set grouped to form a triangle with 3-m sides. The billets were wrapped in gauze to prevent fresh beetle access. Catches were removed daily, counted, and sorted by sex. If, after four consecutive days, no more beetles were trapped at a site, fresh billets were used and trap positions rerandomized. Since the data from each site were not significantly different, they were pooled for analysis. Means were compared for significant differences using the paired *t* test and Student's *t* test (Snedecor and Cochran, 1980).

RESULTS

Colonization of Felled Tree. Within two days of felling, the foliage began to wilt and the first two attacks were detected. A total of 56 sparse attacks occurred during the 30-day postfelling observation period, with 49 (70%) located in the crown zone. The base of large branches was often the site of attack in the crown. No "spillover" of attack was found in standing trees near the felled tree.

Females were usually found occupying the tunnels of males within three to eight days after attack. Apart from two males that survived in their tunnels for about 15 days, no live males were found in tunnels without a female. Of the marked tunnels, 11 (20%) were empty or had only a female occupant. This may be the result of predation by insectivorous birds.

A total of eight male and 24 female *P. caviceps* were intercepted by the traps placed adjacent to the felled tree for a period of 30 days. Most beetles (five males and 17 females) were caught in the crown zone, with only two males and eight females, and one male and one female caught in the center and base zones, respectively. The predominance of females caught in traps may be due in part to the presence of a male-released sex pheromone attracting only females and a tendency for males (the pioneer sex) to disperse to new hosts.

Most males observed flew and located the felled tree between 1500 and 2000 hr, although seven attacked between 1000 and 1200 hr. Flight activity of *P. caviceps* observed in the field coincided with the emergence of beetles from source logs used to infest the billets. The morning activity observed for some beetles could be accounted for if beetles did not always fly directly to colonize the felled tree but spent some time in the forest duff. These beetles would resume activity earlier the following day than freshly emerged beetles because they were not buffered from temperature changes by being deep within the tree, but were able to fly immediately when ambient conditions were suitable.

During a four-day period of comparatively warm weather (26–31°C), there

TABLE 1. MEAN NUMBERS OF *Platypus caviceps* CAUGHT IN FUNNEL TRAPS SUSPENDED ABOVE UNINFESTED OR MALE-INFESTED BEECH BILLETS (ASHLEY FOREST, JANUARY-MARCH 1986)

Treatment	Males (mean \pm SE) ^a	Females (mean \pm SE) ^a	Replicates ^c
Uninfested billet	2.8 \pm 0.66	1.3 \pm 0.27 ^{*b}	15
Male-infested billet	1.8 \pm 0.44 ^a	51.6 \pm 7.04 ^{c***}	15

^aMeans within columns are significantly different at $P < 0.05$ (a) or $P < 0.001$ (c) by paired t test.

^bResponses of sexes significantly different at $P < 0.05$. (*) or $P < 0.001$ (***) by Student's t test.

^cReplicate = catch per trap per 5- to 10-day interval.

were 23 attacks, representing 41% of the total attacks, and two males and 10 females representing 38% of the total beetles were intercepted in the funnel traps. No fresh attacks were observed, or beetles trapped, while temperatures were $< 12^{\circ}\text{C}$. This suggests that emergence may be clumped, depending to some extent on ambient temperatures.

Field Trapping. More males than females were attracted to uninfested billets but females dominated the catch in traps above male-infested billets ($P < 0.001$) (Table 1). In addition, significantly more males were caught in traps above uninfested billets than in those above male-infested billets, and significantly fewer females were caught in traps above uninfested billets than in those above male-infested ones. Neither sex responded significantly to unbaited (blank) traps as only one male and one female were caught during 15 replications.

Infested billets remained attractive to beetles for about seven to 10 days, with 26 males and 663 females (86% of the total catch) being caught during their first six days in the field.

DISCUSSION

The strong preference of *P. caviceps* for the crown zone of the felled tree may be due to the release of volatiles from this most rapidly drying (water stressed) zone. In beech forests, *P. caviceps* often survives in drier material than *P. apicalis* or *P. gracilis* (Ytsma, unpublished data). The gradual buildup of isolated attacks over time suggests that the males responded primarily to tree condition. Previous observations (Ytsma, unpublished data) have indicated that *P. caviceps* males prefer to attack trees with the highest growth rates in a stand,

possibly because more fissuring of the bark releases more volatiles. Roberts (1968, 1969) found a similar preference in other platypodids: *P. hintzi* Shauf, *Doliopygus serratus* Strohm, and *Trachyostus ghanaensis* Schedl, as did Milligan (1979) for *P. apicalis* and *P. gracilis*. This suggests that high local concentrations of phloem volatiles may be important in the siting of *Platypus* attack (Ytsma, 1986). The pattern of attack seemed to be related, at least to some extent, to ambient temperatures, as has been found for many other bark and ambrosia beetles.

Like the other New Zealand *Platypus* species, males of *P. caviceps* were attracted by host odors and were the tunnel-initiating sex. However, unlike the other two species (Milligan, 1982; Milligan et al., 1988; Milligan and Ytsma, 1988; Ytsma, unpublished data), *P. caviceps* males in tunnels attracted predominantly females, and male response could be accounted for by attraction to host odors alone. This is clear evidence that *P. caviceps* males release a sex pheromone rather than an aggregation pheromone. This has not been previously recorded for Platypodidae.

Although attack was sparse and scattered over time, nearly all the live males in tunnels had female partners. This suggests that the male-released pheromone is efficient in attracting females and does not require the presence of large numbers of males to be effective. Roberts (1968) also found that it was unusual among the sparse attacks of *T. ghanaensis* to find a male alone in its tunnel. The pattern of response to host odors and male-released sex pheromone described for *P. caviceps* may therefore be characteristic of other ambrosia beetles that do not aggregate during colonization of the host.

Acknowledgments—I wish to thank the staff at Ashley Forest for allowing use of their forest and gratefully acknowledge the advice given by J. Orwin in reviewing the manuscript.

(Received January 19, 1988; accepted May 23, 1988)

Abstract—Chemical analysis of the eggs spawned by five *Sinularia* soft corals (Octocorallia, Alcyoniidae) collected in the central region of the Great Barrier Reef, Australia, revealed the presence of the known cembranoid diterpenes epoxy pukalide and/or pukalide in all cases. Examination of the colonies from which the eggs were released one month before spawning and also some time after spawning failed to detect either diterpene in the coral tissue. The three dimensional structures of pukalide and epoxy pukalide, as determined by the single-crystal X-ray technique, are reported for the first time. The wide distribution of pukalide and epoxy pukalide and of related compounds within the octocorallia is discussed.

Key Words—*Sinularia* spp., spawning, soft coral, pukalide, epoxy pukalide, structure determination, diterpene, octocorals.

INTRODUCTION

Soft corals (Cnidaria, Anthozoa, Octocorallia) have proven to be an extremely rich source of terpenoid natural products (Tursch et al., 1978; Faulkner, 1984,

1986, 1987). A number of studies have implicated secondary metabolites in the chemical defence of soft corals, either as toxins (Bakus, 1981; Tursch, 1982; Coll et al., 1982b; Coll and Sammarco, 1983) or as feeding deterrents (Tursch et al., 1978; La Barre, 1984; La Barre et al., 1986). Other studies have shown that terpenes are involved in competitive interactions between soft corals and their neighbors. Thus, soft corals have been shown to exert allelopathic effects on neighboring scleractinian corals (Sammarco et al., 1983), and soft coral terpenes have been detected in seawater around soft corals (Coll et al., 1982a) and have been shown to kill scleractinian corals at 5–10 ppm (Coll and Sammarco, 1983). The important roles played by secondary metabolites in the survival strategies of mature colonies of soft corals has thus been established. It seemed logical to carry this research forward into aspects of soft coral reproduction.

Soft corals are colonial marine invertebrates that reproduce both asexually by budding and colony division and sexually (Bayer, 1973). Sexual reproduction in the octocorallia proceeds via a number of different strategies including broadcast spawning [e.g., *Alcyonium digitatum* (Hartnoll, 1975), *Lobophytum* spp. (Yamasato et al., 1981; Bowden et al., 1985), *Sarcophyton* spp. (Benayahu and Loya, 1986), *Sinularia* spp. and *Cladiella* spp. (Alino et al., 1987)], surface brooding of fertilised eggs [e.g., *Clavularia* sp. (Alino, unpublished results), *Efflatounaria* sp. (Dinesen, 1985), *Capnella gaboensis* (Farrant, 1985), and *Parerythropodium fulvum fulvum* (Benayahu and Loya, 1983)], and by internal fertilization [e.g., *Xenia* spp. (Gohar, 1940; Benayahu and Loya, 1984, 1985)].

Because the pioneering work on the synchronized mass spawning of scleractinian corals on the Great Barrier Reef was carried out in Townsville (Harrison et al., 1984), we were able to collect and investigate the chemistry of the eggs spawned by soft corals, which occurred at approximately the same time (Harrison et al., 1984). A report on our investigation of chemical differences between the eggs spawned by *Lobophytum* spp. and the postspawning colonies has appeared (Bowden et al., 1985; Coll et al., 1987). We here report parallel chemical studies on the genus *Sinularia*, in which six colonies from two different sites in the Townsville region of tropical North Queensland were investigated over several spawning seasons.

METHODS AND MATERIALS

Collections

Australia. Techniques for the collection of eggs were developed during 1983 and eggs were collected from a *Sinularia* sp. (SM 83/1) during the spawning at Magnetic Island (146°51'E; 19°09'S) in October 1983. The modified plankton net used for the collection of the buoyant eggs has been described

(Bowden et al., 1985). A small sample of the soft coral colony was collected for chemical analysis several days after spawning, frozen, and freeze dried.

During spawning at Magnetic Island in November 1984, eggs were collected from a *Sinularia* sp. (SM 84/1), identical species to that studied in 1983, and portions of the colony were sampled four weeks before spawning, and one and 180 days after spawning. The tissue was frozen and freeze dried. Samples of the spawned eggs were frozen on collection and freeze dried prior to chemical analysis.

In Pioneer Bay on Orpheus Island (146°18'E; 19°09'S) in November 1984, a number of female colonies of *Sinularia* spp. (SM 84/6, SM 84/19, SM 84/20, SM 84/21) were sampled, and the tissue stored frozen and freeze dried for chemical assessment. During the spawning in December 1984, eggs were collected from these colonies, frozen, and freeze dried prior to extraction and chemical analysis.

Hawaii. Colonies of *Sinularia abrupta* Tixier-Durivault 1970 were collected off a pocket beach near the Blowhole, Oahu (157°50'W; 21°28'N) in 1973. Subsequent collections of *S. abrupta* from nearby sites were made in September 1984 (Moku Manu Island, Kaneohe Bay) and December 1984 (Blowhole and off Queen's Beach). Colonies were stored frozen.

Chemical Assessment

The freeze dried eggs and coral tissue from the Australian *Sinularia* colonies were each separately extracted with dichloromethane and the terpenoid components isolated from the crude extracts by chromatography on silica gel (see Bowden and Coll, 1986). Complete separations and quantitative and qualitative comparisons were performed using a Waters 6000A solvent delivery system for high-pressure liquid chromatography (HPLC) in conjunction with a Waters R401 refractive index detector, and two silica gel HPLC columns in series (Techsil 5 silica and Hewlett Packard Si-100 7 μ m) with ethyl acetate-light petroleum (35:65) as eluent. Structural assignments were initially made on the basis of [¹H]- and [¹³C]NMR comparisons with reported values. Other physical parameters (e.g., mp, [α]_D, etc.) unambiguously confirmed the identity of the major metabolites. Thin layer chromatography (TLC) was used initially to assess the absence or presence of metabolites in certain extracts. Frozen colonies of *Sinularia abrupta* from Hawaii were extracted with ethanol before chromatography, as reported elsewhere (Missakian et al., 1975).

X-Ray Crystallographic Determinations

Preliminary X-ray photographs of pukalide (from *S. abrupta*) (Missakian et al., 1975) showed orthorhombic symmetry. Accurate lattice parameters, determined from a least-squares fitting of 15 diffractometer measured 2θ values,

were $a = 9.048(1)$, $b = 12.562(1)$, and $c = 19.134(3)$ Å. Systematic extinctions, crystal density, and the presence of chirality were uniquely accommodated in space group $P2_12_12_1$ with one molecule of composition $C_{21}H_{24}O_6$ forming the asymmetric unit. All unique diffraction maxima with $2\theta \leq 114^\circ$ were collected using variable speed, 1° ω -scans and graphite monochromated Cu $K\alpha$ radiation (1.54178 Å). Of the 1516 reflections surveyed, 1444 (95%) were judged observed [$F_o > 3\sigma(F_o)$] after correction for Lorentz, polarization, and background effects.

The structure was solved routinely using the MULTAN system of programs (Main et al., 1980; Leonowicz, 1978; Hirotsu and Arnold, 1980; Hirotsu and Van Duyne, 1985; Motherwell, 1978). The first E synthesis revealed a plausible 18-atom fragment, which was completed using Fourier syntheses. Full-matrix least-squares refinements with anisotropic nonhydrogen atoms have converged to a standard crystallographic residual of 0.088 for the observed reflections.

Single-crystal X-ray diffraction analysis of epoxy-pukalide (from *Placogorgia* sp.) (Li, 1986) was performed. Lovely multifaceted crystals of epoxy-pukalide were grown from ethanol saturated with water. Preliminary X-ray photographs displayed orthorhombic symmetry, and accurate lattice constants of $a = 12.372(2)$, $b = 9.129(1)$, and $c = 17.097(2)$ Å were obtained from a least-squares fit of 15 diffractometer measured 2θ values. The systematic extinctions, crystal density, and presence of chirality were uniquely accommodated by space group $P2_12_12_1$ with one molecule of composition $C_{21}H_{24}O_7$ forming the asymmetric unit. All unique diffraction maxima with $2\theta \leq 114^\circ$ were collected on a computer-controlled four-circle diffractometer using graphite monochromated Cu $K\alpha$ radiation (1.54178 Å) and variable speed 1° ω -scan. After correction for Lorentz, polarization, and background effects, 1317 (86%) of the 1532 unique reflections were judged observed and used in subsequent calculations. A phasing model was obtained from a multiresolution tangent formula approach, and a partial molecular model was extended by weighted Fourier techniques (Main et al., 1980; Leonowicz, 1978; Hirotsu and Arnold, 1980; Hirotsu and Van Duyne, 1985; Motherwell, 1978). After partial least-squares refinements, the hydrogen atoms were located in a difference electron density synthesis. Further refinement with anisotropic nonhydrogen atoms and isotropic hydrogens have converged to a standard crystallographic residual of 0.060 for the observed reflections.

RESULTS

Chemical analysis of a postspawning sample of soft coral and of the eggs released from the same coral (*Sinularia* sp., SM 83/1) in November 1983 revealed significant chemical differences. The major metabolites in the egg

extracts were pukalide and the then unreported diterpene epoxy-pukalide. The coral tissue contained none of these diterpenes. It was initially assumed that the spawning samples had become confused, as neither pukalide nor epoxy-pukalide were present in the postspawning sample of SM 83/1. The reliability of this early result was confirmed during the 1984 spawning (see Table 1).

Table 1 summarizes the comparative analyses of eggs and coral tissue from the five *Sinularia* soft corals collected near Townsville. The analyses were performed to determine the presence or absence of pukalide and epoxy-pukalide; the nature of other terpenoids present in the soft corals is not reported. Subsequent analysis of these and other *Sinularia* colonies during the 1986 and 1987 spawnings revealed the reproducibility of these findings (Heaton, 1988).

Chemical analysis of colonies of *Sinularia abrupta* collected near the Blowhole, Oahu, in 1973 afforded pukalide in 0.01% yield (Missakian et al., 1975). Subsequent collections between 1975 and the present, including the collections of several morphologically different colony types of *S. abrupta* from a number of sites in 1984, failed to afford pukalide.

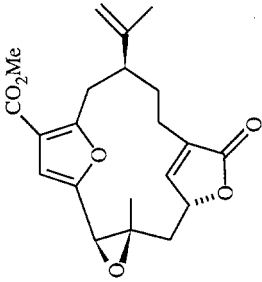

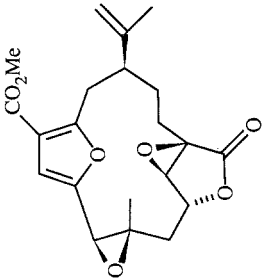

In the course of these chemical investigations, the single crystal X-ray structure determinations of pukalide (Missakian et al., 1975) and epoxy-pukalide (Li, 1986) were obtained and the ORTEP views of these molecules so determined appear in Figure 1. Tables 2 and 3 list the fractional coordinates of pukalide and epoxy-pukalide.¹

DISCUSSION

Our studies of the chemical composition of eggs spawned by soft corals reveal significant differences between the terpenoid composition of the eggs and the terpenoid composition of the pre- and postspawning colonies. Thus *Lobophytum compactum* eggs contained significant amounts of the diterpene thunbergol while this compound was not present in pre- or postspawning colonies. By contrast, *L. crassum* eggs contained none of the major terpenoid 13-hydroxylobolide component present in the pre- and postspawning colony (Bowden et al., 1985). Again, the eggs of *L. microlobulatum* contain the diterpene decaryiol and its precursor 3,4-epoxynephtenol, whereas the coral tissue contained only decaryiol. 3,4-Epoxynephtenol was not detected in the coral tissue from which the eggs were released (Coll et al., 1986). Clearly, the chemical composition of soft coral eggs is not just a random deposition of the usual soft coral terpenes in the eggs. It appears to be specific with respect to both content and timing. Furthermore, each *Lobophytum* species appears to have different diterpenes specific to the ovulation process.

¹ Complete crystallographic tables, including calculated and observed structure factors and thermal parameters, have been deposited with the Cambridge Crystallographic Centre: Dr. Olga Kennard, University Chemical Laboratory, Lensfield Road, Cambridge CBL 1EW U.K.

TABLE 1. CHEMICAL ANALYSIS OF SEVERAL SIMILIARIAN SOFT CORAL COLONIES AND EGGS RELEASED THEREFROM^a

^aStandard deviations of the least significant figures are given in parentheses. The isotropic equivalent thermal parameter is given for anisotropic atoms (denoted by an asterisk).

The results depicted in Table 1 show that, in the case of a number of *Simularia* species, the terpenes epoxypukalide and/or pukalide are present only in the eggs and are probably formed during the month prior to spawning. This implies that these compounds are synthesized within the eggs and may have some function. A number of possible roles may be considered. It is possible that pukalide and epoxypukalide play a defensive role, either in relation to fish predation or in relation to pathogens in the water column, which may use the fertilized eggs and planulae as a food source. The former suggestion does not appear to be correct, for on the night of spawning, colonies releasing eggs can be identified by the presence of a cloud of small fish above the colony. The fish eat large quantities of eggs with no obvious ill effects (J. Coll, personal observations). The possibility that the compounds may be effective in protecting the planktonic (planula) phase of the corals has not been borne out by subsequent microbiological study (P. Alino, unpublished results).

In a dioecious broadcast spawning coral, some chemicals in the eggs must

serve a role in chemotaxis, i.e., they must attract sperm to the released eggs. We have recently implicated lipophilic molecules in this role for a *Lobophytum* species (Coll et al., 1987). It is possible that pukalide and epoxy-pukalide may play such a role, although their nature, and the quantities present in the eggs seem to be out of character with known chemotactic substances (Moore, 1977). Usually the amounts are much less than those reported here. Further investigation of this phenomenon is scheduled for the next annual spawning.

Yet another role possible for pukalide and epoxy-pukalide may be as a chemical release factor for ovulation. In the final stages of egg production, it is possible that these compounds are biosynthesized within the eggs until a threshold concentration is reached, at which time egg release occurs. Steroidal hormones play this type of role in animals; it is not impossible that terpenes like pukalide might play this role in invertebrates. Many other specific roles might be suggested: these include chemicals that prevent hybrid formation and act as muscle relaxants on the polyp to ease the release of eggs from the polyp, or as a juvenile hormone.

Pukalide and pukalide-like compounds are widespread among the Octocorallia (see Faulkner, 1984, 1986). They may be among the most highly oxygenated terpenes known. Lophotoxin, isolated together with pukalide, in 0.2% dry weight from *Lophogorgia rigida*, is certainly among the most toxic (Fenical et al., 1981). The isolation of trace amounts of pukalide from *Lophogorgia rigida* (Fenical et al., 1981), of trace amounts of epoxy-pukalide from *Leptogorgia setacea* (Ksebati et al., 1984) and from the deep sea gorgonian *Placogorgia* sp. (Li, 1986), and the inability to re-isolate pukalide (1) from *Sinularia abrupta* (Klein, 1986) may all be explained on the basis of the involvement of pukalide and epoxy-pukalide in the spawning of a large number of different soft corals. It seems likely that many of these isolations were fortuitous, i.e., that the initial collections coincided with the spawning season.

Structural elucidation of pukalide, epoxy-pukalide, and lophotoxin has been based on spectroscopic deduction and chemical interconversion. Because of the interdependence of these structural assignments and the availability of two as yet unpublished X-ray crystallographic determinations, it was decided to publish the structures in this report. The molecules now appear to be common components in a large number of octocorallian systems; it is essential that their structures be secure and their stereochemical parameters completely defined. Fortunately, both the original structure proposed for pukalide (Missakian et al., 1975) and for epoxy-pukalide (Ksebati et al., 1984) were correct, but it is important that all researchers in this area have the confidence of X-ray structures for these apparently important molecules.

At this point in time, the exact function of pukalide and epoxy-pukalide remains a mystery. Neither compound appears to be particularly toxic or antibiotic. They may yet be shown to be chemotactic substances or to play a role

in ovulation. Their three-dimensional structures and physical properties are secure, and they are available for testing; future research will seek to define their function. Unlike many other natural products, these compounds appear to be present in the majority of species of the genus *Sinularia* and only present in the eggs of these corals during the month prior to ovulation. In this sense, they are clearly distinguished from the majority of natural products.

Acknowledgments—Financial support is acknowledged from the Australian Marine Science and Technologies Grants Scheme, from the New York Sea Grants scheme, from the National Institutes of Health (USA, NIH CA 24487) and from field surveys of *Sinularia abrupta* in Hawaii and subsequent chemical screening was carried out by Dr. David Klein, and from the University of Hawaii Sea Grant College Program, U.S. Department of Commerce, Institutional Grant MA81AA-D-0070. We thank him for this data. Taxonomic verification and curation of soft corals involved in this study were provided by Phil Alderslade, Curator of Coelenterates, Northern Territory Museum, Fanny Bay, Darwin, Northern Territory, Australia. His help is gratefully acknowledged.

ALLELOPATHY, CHEMICAL COMMUNICATION, AND PLANT DEFENSE

J.V. LOVETT, M.Y. RYUNTYU, and D.L. LIU

*Department of Agronomy and Soil Science
University of New England
Armidale, N.S.W. 2351, Australia*

(Received March 1, 1988; accepted May 23, 1988)

Abstract—Allelopathy is identified particularly with chemical activity between plants; entomologists refer to allelochemicals in a broader context. Recent work shows that several groups of compounds associated with allelopathy also play a part in communication between plants and other organisms. It is argued that such communication is part of the similarities in plant and animal responses to stress and may contribute to plant defense.

Key Words—Allelopathy, allelochemicals, mitochondria, phagocytosis.

INTRODUCTION

Chemicals are frequently employed in the defense systems of animals, even when physical defenses are well developed (Cogger, 1979). Plants also have physical adaptations for defense and produce a wide spectrum of secondary chemical compounds (Levin, 1976), some of which are active in allelopathy. Several compounds associated primarily with allelopathy, defined as biochemical interactions between plants (including microorganisms traditionally placed in the plant kingdom), appear to have a wider role in plant self-defense (Lovett, 1982a).

Reese (1979) uses the term "allelochemical" to describe "nonnutritional chemicals produced by one organism that affect the growth, health, behavior or population biology of other species". Biological reaction to such compounds characteristically is one of attraction or stimulation at low concentrations, with the response becoming increasingly one of repulsion or inhibition as the con-

centration increases. The phenomenon of "hormoligosis" (Luckey, 1968), in which toxic insecticides at very low concentrations act as growth stimulants, is analogous.

Plants respond in this manner to many organic and some inorganic chemicals, for example, aluminium (Bennet et al., 1987). Chemicals developed for management of other organisms, for example, insecticides (Chapman and Allen, 1948), will sometimes elicit this type of response in plants.

Monoterpenoids are one group of natural compounds for which such responses have been documented in a range of organisms. Examples include insect larvae (Selander et al., 1974); bacteria and a yeast (Andrews et al., 1980); feeding behavior of mammals (Sheehy and Winward, 1981; Welch and McArthur, 1981; White et al., 1982); and fungal growth (Franich et al., 1982). Similar compounds are allelopathic (Muller, 1966).

Allelochemicals may, therefore, be considered as part of a network of communication in which disparate organisms give similar responses to similar compounds or families of compounds. Plants producing biologically active compounds at relatively high concentrations may be perceived as utilizing chemical defenses.

Plant allelochemicals frequently induce stress in other plants. Such stress may contribute to interference between plants; again, a dimension of defense. We report here on observations of responses to allelopathic stress in some plant species and identify further similarities with responses of other organisms to allelochemicals.

METHODS AND MATERIALS

Linum usitatissimum L. (linseed) seedlings were grown in bioassay (Lovett and Duffield, 1981) over a dilution series of the allelochemical benzylamine, produced in leaf washings of the cruciferous weed *Camelina sativa* L. Crantz (Camelina) (Lovett and Duffield, 1981), with sterile water as the control. Seedlings of *Sinapis alba* L. (white mustard) were grown under similar conditions and exposed to a dilution series of the allelochemicals gramine and hordenine, produced by *Hordeum vulgare* L. (barley) (Overland, 1966). Radicle length of all seedlings was measured after five days of incubation at 24°C in the dark.

The methods of Jones and Varner (1967) and Reeve and Crozier (1975) were used to assess the release and activity of α -amylase in barley, as described by Lovett and Potts (1987).

Thin sections of linseed and white mustard root tips for electron microscopic examination were prepared using a modification of the technique of Lorber and Muller (1976) as described by Levitt et al. (1984).

RESULTS AND DISCUSSION

Radicle length of seedlings of *Linum usitatissimum* L. (linseed) showed the characteristic response to the allelochemical benzylamine (Figure 1). *Sinapis alba* L. (white mustard) showed a similar response to the alkaloids gramine and hordenine produced by *Hordeum vulgare* L. (barley) during germination (Figures 2 and 3).

These responses may be termed secondary effects (*sensu* Winter, 1961) as they reflect primary metabolic disruptions. Interference with the ability of germinating seedlings of linseed (Lovett, 1982b) and *Helianthus annuus* L. (sunflower) (Levitt et al., 1984) to use food reserves has been suggested as an example of such disruption. Reese (personal communication) notes that inhibition of efficiency in converting ingested food is a response of insects to ingested allelochemicals. An example is the response of premature weevils to α -terpineol (Figure 4). In these data of Selander et al. (1974) we note that it is the juvenile form that, like young seedlings, may be most susceptible to biologically active chemicals.

Impaired enzyme activity, identified by Rice (1984) as one primary target for allelopathic activity, may explain a reduced ability to metabolize food reserves such as starch in plants. Recent data indicate that the response of α -amylase, involved in the breakdown of starch, to the allelochemical scopolamine (Lovett et al., 1981) is similar to that observed for gross morphological characteristics such as radicle length (Figure 5). Roshchina et al. (1986) reported

FIG. 1. The response in radicle length of linseed to benzylamine (data from Lovett and Duffield, 1981).

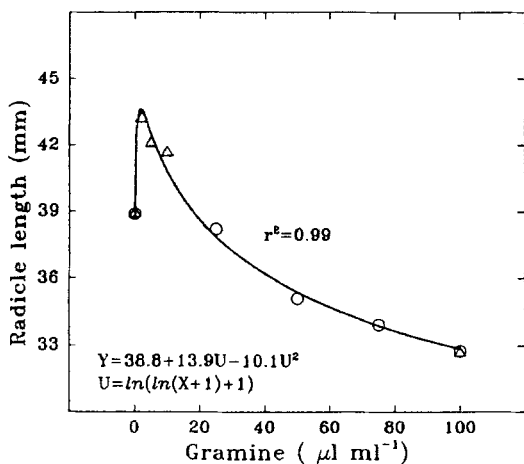

FIG. 2. The response in radicle length of white mustard to gramine (data from Liu and Lovett, 1987).

a similar effect of the alkaloid capsaicine on photosynthetic electron transport in isolated pea chloroplasts. Thus, responses in radicle length or other gross morphological parameters may be explained in terms of similar responses at the level of the cell.

Transmission electron microscopy of linseed and white mustard root tips showed a similar response to allelopathic stress in the root tip cells (Figures 6–

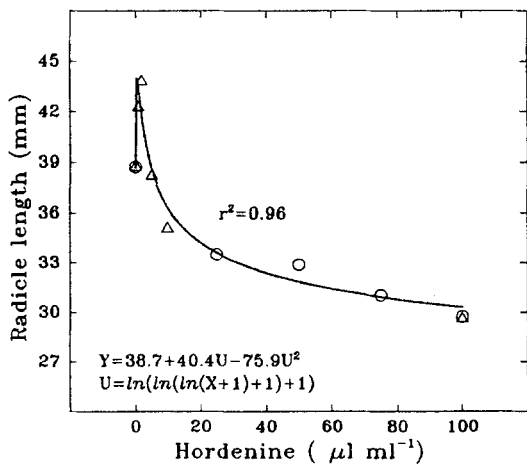

FIG. 3. The response in radicle length of white mustard to hordenine (data from Liu and Lovett, 1987).

8). While control cells showed distinct nuclei, intact organelles, and some small vacuoles (Figures 6 and 8a), increasing concentration of allelochemicals brought about increases in number and size of vacuoles and evidence for phagocytosis (Figures 7 and 8b). Nuclei became less distinct as the concentration of allelochemicals increased and some mitochondria showed evidence of disorganization (Figures 7b-7d and 8b).

FIG. 6. Linseed root tip, sterile water control. Scale bar = 1 μ m. CW = cell wall; V = vacuole; M = mitochondrion; N = nucleus; NU = nucleolus.

Matile (1984) has discussed the detoxification of potentially toxic plant metabolites and highlights the vacuole as a compartment where these toxins may be sequestered. The consistent response of plant root tip cells to allelopathic stress, in which vacuolar development is prominent, shows similarities to those observed in response to other stresses. For example, similar responses occur following invasion by plant parasitic nematodes of root cells of *Apium graveolens* L. (celery) (Bleve-Zacheo et al., 1979) or exposure of *Allium cepa* L. (onion) to heavy metals such as lead (Wierzbicka, 1987). There are close similarities also between the plant vacuoles described here and, for example, autophagic vacuoles in mammals such as the rat (Ahlberg et al., 1982). The limits to which these analogies can be extended is the subject of continuing work in which the roles and relationships of vacuoles, vesicles, endoplasmic reticulum, Golgi apparatus, and mitochondria are being investigated (Lovett et al., 1987; Lovett and Ryuntyu, 1988).

While several metabolic pathways are common to plants and animals, plants differ from animals in important respects, such as lacking a nervous system. We suggest that the evidence presented here points to allelochemicals as important communicators between plants and other organisms. Allelochemicals may attract or repel organisms associated with plants and may contribute to plant

defense under stress, a role analogous to that of chemicals produced by animals (Edmunds, 1974).

Matile (1975) has drawn attention to the similarities of some lytic phenomena in plants and animals. Autophagic vacuoles are one example and may also

be part of a common response to stress, suggesting that further analogies will become apparent as the combined disciplines of morphology, cytology, and biochemistry are brought to bear on allelopathic phenomena.

(Received January 14, 1988; accepted May 24, 1988)

Abstract—A model system involving several *Nicotiana* species containing novel nicotine alkaloids was used to study heritability and expression of alkaloid production in leaf trichomes. The three species that comprise the section Repandae (*N. repanda*, *N. stocktonii*, and *N. nesophila*) were hybridized with either *N. tabacum* or *N. sylvestris* (neither of which produces *N*-acynornicotine). The progeny of the hybrid with *sylvestris* produced the *N*-acynornicotines at a level found in the Repandae parent. *Nicotiana repanda* was crossed to *N. tabacum*, and the F₂ progeny produced the alkaloid at the same level as the original Repandae parent. Inheritance of the ability to acylate normicotine in Repandae species is inherited in hybrids in a dominant manner. These and other data obtained suggest that the *N*-acyltransferase that acylates normicotine in Repandae species inherited in hybrids is in a dominant manner and that the regulatory sequence(s) for the gene is expressed in leaf trichomes when the gene is in a foreign *Nicotiana* background.

Key Words—*Nicotiana* sp., Repandae, trichomes, nicotine, alkaloids, *Manduca sexta*, Lepidoptera, Sphingidae, acynornicotines.

INTRODUCTION

Host-plant resistance has long been recognized as an attractive and viable pest defense strategy (Painter, 1951; Kogan, 1982; Maxwell and Jennings, 1980). The most conventional approach to accessing new forms of insect resistance has involved intra- and interspecific hybridizations, but crossing barriers may prevent access to potentially effective forms of resistance in related species. Several approaches for gaining access to resistance in sexually incompatible species are now available. These include use of bridging species, plant tissue culture procedures, and transfer of cloned genes. We are not aware of examples of commercial exploitation of any of these three approaches for suppression of insect attack. Further, there are no examples whereby a given insect resistance trait was moved into a commercial cultivar background in independent applications of each of these approaches. Thus, it is difficult to assess the individual or combined potential of these three approaches. Such a comparative study would be of considerable theoretical and practical interest.

Perhaps one reason for the lack of progress in this area is that such a comparative study would require the combined efforts of plant geneticists, insect physiologists, and organic chemists to provide firm documentation that the given antibiosis chemical is heritable and is expressed at levels effective against the target insect.

Cultivated tobacco, *Nicotiana tabacum* (L.), is protected from insect attack by nicotinoid alkaloids, which have been the mainstay of previous approaches to breeding for insect resistance (Burk and Chaplin, 1976). However, one lepidopteran pest of tobacco, *Manduca sexta* (L.), is resistant to nicotine through an effective combination of target site insensitivity and nicotine excretion mechanisms (Self et al., 1964; Morris, 1984). We have found that a group of wild *Nicotiana* species (section Repandae, comprised of species *repanda*, *stocktonii*, and *nesophila*), which is highly resistant to the hornworm, produces a group of novel nicotinoid alkaloids, *N*-acylnornicotines (NacylNN), which is extremely toxic to this insect (Jones et al., 1985; Huesing and Jones, 1987; Severson et al., 1985b, 1987). This alkaloid group, which is very easily detected by thin-layer chromatography (TLC), results from a single, terminal enzymatic addition to nornicotine (Zador and Jones, 1986), a substrate found in commercial tobacco (Severson et al. 1985a).

The *Manduca sexta*-*Nicotiana* system is attractive as a model system for testing new concepts and various approaches to gene transfer for insect resistance. This insect-plant system has the following attractive features: (1) a highly effective antibiosis chemical in wild plant hosts; (2) a structurally defined antibiosis factor; (3) an antibiosis chemical whose expression is easily scorable; (4) an antibiosis chemical that is a synthetic extension of one of the best characterized biochemical pathways of plant secondary product metabolism, the nicotine pathway; (5) an antibiosis chemical, which, being derived by a single

enzymatic addition to a terminal pathway, is likely to be inherited as a simple genetic trait, facilitating genetic analysis; and (6) the enzyme which produces this antibiosis chemical is currently being purified for future genetic engineering experiments (Jones et al., 1987), facilitating direct comparison of molecular biology and the above-described gene transfer approaches. Furthermore, hybrids of Repandae species *N. tabacum* derived from (1) classical direct crossing (Pittarelli and Stavely, 1975), (2) use of bridging species (Burk, 1967), and (3) plant tissue culture (Reed and Collins, 1978) are currently available.

In these experiments we have applied plant genetics, insect physiology, and organic chemistry toward defining and documenting the successful transfer of *N*-acetylornicotine production into *N. tabacum*.

METHODS AND MATERIALS

Plant Material. The interspecific hybrid combinations investigated in this study are summarized in Table 1. Seed stocks were obtained from J.W. DeVerna, Campbell Institute for Research and Technology, Davis, California; G.W. Pittarelli, USDA-ARS, Beltsville, Maryland; S.M. Reed, N.C. State University, Raleigh, North Carolina; and V.A. Sisson, USDA-ARE, Oxford,

North Carolina. With the exception of hybrid combination IIB, the specific methods used to produce these hybrids have been reported previously and will only be summarized here. The first hybrid (I) is an interspecific bridge-cross originally designed to transfer disease-resistant germplasm for a donor species (*N. repanda*) through an intermediate or transfer species (*N. sylvestris*) into a recipient species (*N. tabacum*). In hybrid IIA an autotetraploid form of *N. repanda* (RR/RR) was crossed with diploid *N. tabacum* (TT) and the resulting sesquidiploid (RR/T) back-crossed to NC 95, and then three times to the tobacco cultivar Md 609. Hybrid IIB was produced in a similar manner except that the sesquidiploid (RR/T) was colchicine treated to produce a hexaploid plant (RRRR/TT), which was subsequently studied in the F₂ generation. Using fertilized ovule culture techniques, hybrids between *N. stocktonii* and *N. nesophila* with *N. tabacum* (III and IV) were achieved. Allotetraploid hybrids were obtained from callus culture of F₁ hybrid plants and the allotetraploids were back-crossed to diploid *N. tabacum*. Hybrid combination V resulted from a cross between *N. gossei* as the maternal parent with a Florida cigar-wrapper variety of *N. tabacum*. Plants of the initial sterile F₁ hybrid were treated with colchicine to produce a fertile allotetraploid. Finally, two different hybrids were generated using in vitro fertilization techniques to cross *N. benthamiana* with a *N. tabacum* parent. Allotetraploid derivatives, identified as C1 and C3, were each back-crossed to the breeding line SR1. *Nicotiana gossei* and *N. benthamiana* are members of the section *Suaveolentes*. These species have been shown to be resistant to *M. sexta*; however, the biochemical basis of their resistance is unknown. These crosses allow a comparison with the transfer of the defined resistance of the *Repandae* section.

Seed of all of these materials were germinated in Petri dishes in a 1-cm-deep Murashige and Skoog plant growth medium (Murashige and Skoog, 1962). After the seedlings had attained a height of ca. 1 cm, they were then transferred to 4 × 4-cm peat pots and raised to maturity in the greenhouse. When possible, both the wild parents and the cultivar were also planted to determine the pattern of alkaloid or resistance transfer.

Antibiosis toward M. sexta. Leaf material from the crosses with *N. repanda* was surface extracted at the vegetative (prebud) stage, separated by TLC, and stained with CNBr-paraaminobenzoic acid to determine if high amounts of surface alkaloids were present. A minimum of 15 leaves, one from each of 15 plants, was extracted. All leaves were chosen from the middle third of the plant. If the NacylNN was observed after staining, these plants were bioassayed with second instar *M. sexta* larvae by means of a four-day bioassay (Jones et al., 1985). In the case of the *N. benthamiana* material, all plants were bioassayed regardless of the TLC analysis. A minimum of 10 larvae were used in each bioassay, with the results being pooled for analysis.

Determination of NacylNN Content of Leaves. To determine the NacylNN content of the leaf exudate of the *Repandae* parents and their hybrids, six sam-

ples of 15 leaves were extracted and the extracts dried under vacuum. After weighing, a known quantity of exudate extract was obtained. Two 1-mg aliquots of each exudate extract were spotted to silica TLC, the plate developed, the appropriate region scraped and eluted, and the concentration of NacylNN determined spectrophotometrically. The amount of NacylNN per milligram of exudate and the amount per square centimeter of leaf surface were determined.

The quality and quantity of the common *Nicotiana* alkaloids nicotine, nor-nicotine, anabasine, anatabine, and *N*-formyl and *N*-acetyl nornicotine were analyzed on Superox capillary column with N-P detection, as described by Severson et al. (1984). The *N*-acyl and OH-NacylNN compounds were analyzed on a SE-54 capillary column after conversion of hydroxylated compounds to trimethylsilyl ethers. Components were characterized by GC retention and GC-MS data.

Statistical Analysis. Data on larvae scored in various categories during the experiment were converted to percentages for analysis. All repetitions of the bioassays were pooled for analysis. All categories are assumed to be mutually exclusive. Since decisions concerning which plant species to use in a breeding program will be based on whether the species is resistant and the magnitude of its resistance, confidence intervals were used in the analysis. Approximate 95% confidence limits for the difference between percentages were generated using the statistic, $|P_1 - P_2|$, $\pm t_{\alpha} \sqrt{[P_1(1 - P_1)/n] + [P_2(1 - P_2)/n]}$, with $\alpha = 0.05$. The occurrence of a type I error for a given inference on the magnitude of the difference between treatment effects will not affect the validity of inferences made on other treatment comparisons for the experiment. Therefore, we chose the *t* statistic for both its asymptotic power and amenability to a comparison-wise confidence interval structure, the latter being absent in some other procedures (Jones, 1984; Jones and Matloff, 1986). All treatments were compared to *N. tabacum* (KY 14), for analysis.

RESULTS

Section Repandae

All three species comprising this Repandae section (*N. nesophila*, *N. repanda*, and *N. stocktonii*) induced high levels of mortality, at least 80%, and adverse effects on both larval growth and feeding (Table 2). The confidence interval indicates that *N. repanda* produces a minimum 62% additional mortality above that of KY 14 (*N. tabacum*) (Table 3). In addition, none of the larvae fed heavily on the Repandae species, nor did any larvae reach the third instar.

The quantity of NacylNN per milligram of exudate in *N. repanda* was $83 \pm 4.5 \mu\text{g}$, or $10.7 \pm 0.58 \mu\text{g}/\text{cm}^2$ of leaf surface. The quality of the alkaloid was confirmed by GC as predominantly the β -hydroxy NacylNN (Table 4).

Nicotiana repanda X *N. sylvestris* (I). This hybrid caused high levels of

^a95% confidence intervals (*t* statistic) that do not contain zero between upper and lower confidence limits (denoted by *) are equivalent to a hypothesis test in which $P < 0.05$. 95% confidence limits are lower and upper, respectively. For "mortality" and "feeding," the differences are the wild parent minus KY 14; for "attain third instar" the differences are KY 14 minus wild parent.

TABLE 4. DISTRIBUTION (PERCENTAGE BASIS) OF COMMON NICOTINOID ALKALOIDS AND Nacy|INN FORMS IN LEAF EXUDATE OF *Nicotiana* SPECIES AND HYBRIDS^a

Species or hybrids	Anatabine	Anatabine	Nicotine	Normicotine	Acetyl-Formyl Normicotine	Nacy INN	OH-Nacy INN
<i>N. tabacum</i>	1.00	2.11	94.5	0.5	2.02

^aPlant leaves were surface extracted by submersion in acetonitrile for 6 sec. The extract was dried under vacuum and then analyzed for the distribution of nicotine alkaloids and Nacy|INN forms.

larval mortality, while the *N. sylvestris* parent imparted no resistance and did not adversely affect larval growth and feeding (Table 2). The hybrid imparted 72% mortality, and the confidence interval indicates that this hybrid will induce a minimum of 36% mortality above that of KY 14 (Table 3). Only 8% of the larvae feeding on this cross fed heavily, and the confidence interval indicates that the hybrid will permit a minimum of 58% fewer larvae feeding heavily than on KY 14 (Table 3). No larvae attained the third instar while feeding on this cross.

This cross produced 11.2 ± 1.0 μg of NacylNN per cm^2 of leaf surface or 140 ± 2.4 $\mu\text{g}/\text{mg}$ exudate. The quality of the nicotinoid alkaloids was very similar to that of the parent *N. repanda*. With respect to *N*-acylnornicotines, there was a distinct shift toward C_{12} and C_{13} forms in the hybrid at the expense of C_{14} and C_{15} forms (Table 4).

Nicotiana repanda X *N. tabacum* (IIA). This hybrid produced only low levels of mortality and had little adverse effect on larval growth and feeding (Table 2). Further, it failed to produce consistent levels of NacylNN. Some of the plants occasionally produced the alkaloid at the lower limits of detection on TLC. GC analysis showed that the long chain (C_{12} - C_{16}) NacylNN forms were absent (Table 4).

Nicotiana repanda X *N. tabacum* (IIB). This cross produced high levels of mortality and adversely affected larval growth and feeding (Table 2). This was comparable to the *N. repanda* X *N. sylvestris* hybrid with 74% mortality, and the confidence interval indicates it will cause an additional minimum 49% mortality above that of KY 14 (Table 3). Furthermore, no larvae fed heavily nor did they attain the third instar while feeding on this hybrid. This hybrid produced an abundant level of NacylNN, with 6.83 μg of NacylNN per cm^2 or 97.5 ± 13.5 μg of NacylNN per mg exudate. As with the *N. repanda* X *N. sylvestris* hybrid, the quality of the nicotinoid alkaloids was very similar to that of the *N. repanda* parent. Also similar was the shift in *N*-acylnornicotines toward the C_{12} and C_{13} forms (Table 4).

Other Repandae Hybrids (III, IV). Most of the hybrids of tobacco with *N. stocktonii* or *N. nesophila* failed to affect larval growth and development differently than *N. tabacum*. One of the crosses (R 25) imparted 33% mortality (10% mortality above that of the KY 14 control) (Tables 2 and 3). However, the percentage of larvae feeding heavily was not significantly different from KY 14. It is interesting to note that the morphology of this hybrid most closely resembles that of *N. tabacum*. TLC analysis showed that over 95% of the leaf exudate alkaloid in the hybrids was nicotine. In some crosses, very low levels of *N*-formyl/*N*-acetyl nornicotine were present. Topical application of 1 mg of crude exudate from this hybrid to each of 10 second-instar larvae produced 20% mortality, confirming the low toxicity of the exudate and a resistance factor below a level detectable by TLC.

N. tabacum X *Nicotiana benthamiana* (VIA and VIB). As demonstrated by Burk and Stewart (1971), *N. benthamiana* produced high levels of mortality (71%) to *M. sexta* larvae (Table 2). The confidence interval indicates that it will induce a minimum 44% additional mortality above KY 14 (Table 3). In addition, only 42% of the larvae that fed on *N. benthamiana* fed heavily, and the confidence interval indicates that the species induces an additional 16% fewer larvae feeding heavily than on KY 14. Only 24% of the larvae that fed on this species attained the third instar (minimum of 55% fewer larvae will reach this growth stage than on KY 14, by confidence interval). None of the *N. benthamiana* hybrids produced levels of mortality near that of the wild parent (Table 2). This analysis is further complicated by the fact that the biochemical basis of resistance in this wild species is not known; hence there is no marker with which to trace the transfer of the resistance into the hybrid. Also, while both retained high nicotine content, only one gained *N*-formyl/*N*-acetylNIN production (Table 4).

Nicotiana gossei X *N. tabacum* (V). *Nicotiana gossei* produced 33% mortality to hornworm larvae. According to the confidence interval, we can expect that this hybrid will cause a minimum of 10% additional mortality above that of KY 14 (Table 3). The percentage of larvae feeding heavily on this species was not significantly different from the KY 14 control. Not surprisingly, the hybrid of this species and *N. tabacum* failed to produce significant levels of mortality and did not adversely affect larval growth and feeding (Table 2).

Hybrid Trichome Morphology. Inasmuch as NacylNIN is produced in leaf trichomes (Zador and Jones, 1986), it was relevant to examine the trichome types in hybrids that did or did not produce the compound. The leaf trichomes of *N. repanda* differ from those of *N. sylvestris* in that they are more stout, less densely placed on the leaf, and are more heavily exudated (Figure 1A,B). The hybrid between these two species expressed trichome characteristics intermediate between those of the parents (Figure 1C). In contrast, the trichome characteristics of the hybrid between *N. repanda* and MD 609 were very similar to *N. tabacum* (Figure 1D,E). This hybrid did not produce NacylNIN, whereas the former hybrid did.

DISCUSSION

In the present study, we have examined NacylNIN production and insect resistance in *Nicotiana* species and hybrids with tobacco. A total of five Repandae hybrid types and two Suaveolentes hybrid types were examined. Two of the Repandae hybrids expressed the *N*-acylnornicotine-based insect resistance, while the other three showed little or no expression of *N*-acylnornicotines.

The interpretation of results of hybridizations using *N. repanda* is expedited by the ease of testing for *N*-acylnornicotine in the leaf exudate. Wide

FIG. 1. Scanning EM of trichomes on the leaf surface of various *Nicotiana* spp. and wide species hybrids. (A) *N. sylvestris* (65X), (B) *N. repanda* (65X), (C) *N. sylvestris* X *N. repanda* hybrid (65X), (D) *N. tabacum* (KY 14) (65X), (E) *N. repanda* X *N. tabacum* (135X).

species hybridization between *N. tabacum* and *N. repanda* has long been considered difficult or impossible due to problems of seeding lethality (Iwai et al., 1985; Reed and Collins, 1978; Pittarelli and Stavely, 1975), and previous reports of this hybridization have not been repeated. However, the uniqueness of the *N*-acylnornicotines makes them an unambiguous marker, and there can be no doubt that the hybrids we have examined contain *N. repanda* genetic material. This marker should be useful in rapid confirmation of the success of other or future hybridization efforts using *N. repanda*.

In most previous studies, little correlation was found between the quality of alkaloids in a given *Nicotiana* species and its phylogenetic position (Smith, 1942; Smith and Abashian, 1963; Saitoh et al., 1985). However, it has recently been shown that the *N*-acylnornicotine group of alkaloids is in high concentration in the leaf exudate of all three members of the section Repandae, and it does not occur in such abundance in the exudate of any other *Nicotiana* species (Huesing and Jones, 1987; Severson et al., 1985a,b, 1987).

Both of the hybrids with *N. repanda* found to express *N*-acylnornicotine synthesis have been reported previously to possess disease resistance (Pittarelli and Stavely, 1975; Burk, 1967), and in the bridging species study, the hybrid obtained after the second bridge cross also expressed disease resistance (Burk, 1967). Those results are very interesting in relation to recent data that the *N*-acylnornicotines possess antibacterial activity (Cutler et al., 1986). Perhaps this group of compounds, so toxic to *M. sexta*, will also be found to be the basis, at least in part, for the disease resistance that has made *N. repanda* such appealing material in breeding efforts. The original hybrid obtained through the bridge cross is now being back-crossed to *N. tabacum* (Gwynn, personal communication). It will be interesting, from a genetic and a practical perspective, to monitor expression of the alkaloid and its associated insect resistance in each back-cross generation. Advances in plant tissue culture techniques have now made it possible to obtain novel wide species hybrids, and although there has been interest in this approach with respect to insect resistance (Heinrichs et al., 1985), no positive results have been published. In the present study hybrids between *N. tabacum* and Repandae species produced by fertilized ovule culture (Reed and Collins, 1978) were examined. The hybrid did not express the gene for insect resistance. More research needs to be done on the genetics of the chromosomal material from the Repandae parent which was transferred in the two successful hybrids we examined.

Researchers studying inheritance of alkaloids in wide species hybrids have been exasperated, in some cases, by the apparent complexity of factors governing alkaloid biosynthesis. Smith and Abashian (1963) commented on the need for a simple genetic system to create a base of information upon which studies of more complex systems could be done. The synthesis of *N*-acylnornicotine in Repandae species and hybrids with them appears to offer such a system.

The data reported by the present study (Table 4) using this system provide information relative to inheritance of nicotinoid alkaloids and interactions in the expression of alkaloid biosynthesis. The data suggest the following:

1. Formylation–acetylation is distinct from long-chain *N*-acylation. The evidence for this conclusion is that both *N. repanda* and *N. stocktonii* have formylation–acetylation and *N*-acylation activity, but the hybrid *N. repanda* X MD 609 possesses only formylation–acetylation activity. Also, the hybrid C3 X SRI as well as *N. sylvestris* have formylation–acetylation activity but no *N*-acylation activity. These data also confirm that long-chain *N*-acylation is enzymatic, instead of just an organochemical condensation of free carboxyl groups and pyrrolidine nitrogens. Otherwise, the above-mentioned species and hybrids would not show specificity for formylation/acetylation activity.

2. The formylation–acetylation and *N*-acylation activities are competitive for the same normicotine substrate pool. The evidence for this conclusion is that in *N. sylvestris* formyl–acetylINN comprised 67% of the leaf surface alkaloids, while in its hybrid with *N. repanda* (which produced *N*-acylINN) this percentage dropped to 18%. If the normicotine substrate for formylation–acetylation was inaccessible to the *N*-acyltransferase, formation of long-chain NacylINN would not have occurred in the hybrid at the expense of production of *N*-formyl/*N*-acetylINN. Since acylation occurs in the trichomes (Zador and Jones, 1986), the normicotine that finds its way to the leaf surface as *N*-formyl/*N*-acetylINN does not become formylated–acetylated prior to arrival in the trichomes. That is, formylation–acetylation must occur in the trichomes for it to be competitive with *N*-acylation. On this basis, it would be predicted that formyl–acylINN is in disproportionately low abundance in the leaves of trichomeless mutants. It would also be predicted that at least a part of the formylation–acetylation activity is enzymatic; otherwise the alternative spontaneous organochemical reaction could occur anywhere in the plant (on route to the leaf) uncompetitively with *N*-acylation.

3. Formylation–acetylation activity and anabasine biosynthesis are not linked, and either can appear in hybrids of parents which do not express them. The evidence for these conclusions is the differences in proportional expression of formyl–acylINN and anabasine in C1 X SR1 vs. C3 X SR1. Furthermore, formyl–acetylINN do not occur in the *N. benthamiana* parent of these two hybrids. Also, proportional production of anabasine by the hybrid *N. repanda* X MD 609 was much higher than that of either parent species. Further, the dramatic proportional increase in biosynthesis of formyl–acylINN in C3 X SRI was at the expense of nicotine, rather than anabasine, which is consistent with formylation–acetylation being a terminal, instead of an early, biosynthetic step.

4. The gene for expression of *N*-acyltransferase is probably expressed in a dominant manner. The evidence for this conclusion is that NacylINN was produced in the *N. repanda* X *N. sylvestris* hybrid at a level similar to that of

the *N. repanda* parent. Also, a similar level of expression was observed in the *N. repanda* X *N. tabacum* (MD 872) hybrid. If the inheritance of the allele for *N*-acylnornicotine production follows from a straightforward segregation pattern, it would be anticipated that most plants of these two hybrids would carry one or two alleles. The hybrid with *N. repanda* involving three back-crosses to Md 609 would not be expected to yield, without selection, a large number of plants carrying an allele for *N*-acylnornicotine production, and the plants from this cross were not observed to be strongly resistant, as a group, to *Manduca sexta*. Nornicotine production in *N. tabacum* is substantially the end of the nicotine biosynthesis pathway prior to secretion of nornicotine into the metabolically inert (for nornicotine) leaf exudate. A priori, it would be anticipated that *N*-acylation of nornicotine prior to secretion would be expressed in a dominant manner. Similar reasoning has been used to explain the dominant inheritance of nicotine demethylation to nornicotine (Legg et al., 1969). These data suggest that if the chromosome carrying the *N*-acyltransferase allele is not lost in early generations of a breeding program, then the gene for the enzyme will be fully expressed in the foreign background, given comparable level of substrate.

5. The length of the acyl chain of *N*-acylINN is a manipulatable character. The evidence for this conclusion is that the C₁₄ and C₁₅ forms were predominant in the parent Repandae species, while the C₁₂ and C₁₃ acyl forms were predominant in the hybrids (Table 4). This aspect is very important in view of recent data that the length of the acyl chain directly influences the toxicity of the compound to *M. sexta* larvae (Scarborough and Jones, unpublished data). In a test of C₂-C₁₆ forms, they found that C₁₄ and C₁₆ forms were significantly more toxic than forms with shorter chain length. These data reinforce the point that the fatty acid composition of the background into which the *N*-acyltransferase is placed may permit full expression of the biosynthetic capacity of the enzyme and yet not be proper for production of the forms of NacylINN toxic to *M. sexta*.

The tractability of the genetics of NacylINN production system, the effectiveness of the NacylINN against *M. sexta*, and the ease of monitoring expression of NacylINN biosynthesis also make the *Nicotiana*-*M. sexta* system optimal for testing the concept of genetically engineering plants for nonprotein insect resistance factors. There has been increasing interest in the application of plant molecular biology for the transfer of insect resistance genes (Brill, 1985), but current efforts have focused on genes for which the protein product is, in itself, the toxic agent (Crawford, 1986). The focus on toxic proteins is due to the perception that transfer of genes for production of nonprotein factors will entail the transfer of a number of genes belonging to a biosynthetic pathway (Foard et al., 1983). It has been suggested, however, that many of the plant resistance compounds occurring in wild plant species are only one or a few enzymatic steps away from a substrate already occurring in the cultivated plant. Therefore,

transfer of the gene(s) for the terminal enzymatic modification of that substrate is a logistically practical approach (Jones et al., 1987). The *M. sexta*-*N. tabacum*-*N*-acetylornicotine interaction appears well suited as a model system for testing concepts in the molecular biology of plant resistance to insects and for comparison of such an approach with conventional, bridging species and plant tissue culture methods.

HOST EGG KAIROMONES ESSENTIAL FOR EGG-LARVAL PARASITOID, *Ascogaster reticulatus* WATANABE (HYMENOPTERA: BRACONIDAE)
II. Identification of Internal Kairomone

(Received November 17, 1987; accepted June 1, 1988)

Abstract—Several components of an internal kairomone were identified inside eggs of the host, *Adoxophyes* sp. (Lepidoptera: Tortricidae), that releases egg deposition of the egg-larval parasitoid, *Ascogaster reticulatus* Watanabe (Hymenoptera: Braconidae). Pupal hemolymph with the same activity as an internal host egg kairomone was used as a convenient test sample. Heat-treated pupal hemolymph was chromatographed on a Sephadex G-25 column. Each fraction was bioassayed and reacted with ninhydrin. The active fractions were ninhydrin-positive. Each fraction was placed onto an amino acid analyzer, which showed that the amino acids were most abundant in active fractions. Among 22 amino acids, alanine, arginine, glycine, histidine, isoleucine, leucine, methionine, proline, serine, tryptophan, and valine were active. The mixture of these active amino acids was as active as the egg-mass homogenate at the same ratio and concentration, suggesting that the most important component as the kairomone in a host egg is the mixture of several amino acids.

Key Words—Kairomone, oviposition stimulant, amino acid, parasitoid, *Ascogaster reticulatus*, Hymenoptera, Braconidae, *Adoxophyes* sp., Lepidoptera, Tortricidae.

INTRODUCTION

For the artificial rearing of insect parasitoids, oviposition by adults into artificial substrates is often necessary (Thompson, 1986). Among factors involved in the process of host acceptance, semiochemicals have been found to play important roles (Arthur, 1981). Different chemical cues may lead the parasitoids to oviposit in this process, like most of the parasitoids locating their hosts with a series of cues (Vinson, 1977).

Both external and internal kairomones were found to be essential for oviposition of the egg-larval parasitoid, *Ascogaster reticulatus* Watanabe (Hymenoptera: Braconidae) by using Parafilm-based artificial eggs (Kainoh and Tatsuki, 1988). External kairomone, needed for host location and acceptance was extracted with 70% ethanol from egg masses of the host, *Adoxophyes* sp. (Lepidoptera: Tortricidae) (Kainoh et al., 1982). The internal kairomone, needed for oviposition, was extracted with water from host eggs. Interestingly, the same activity was found in the extracts not only from host eggs but also from host larvae and pupae, and even larvae of other lepidopterous and coleopterous insects (Kainoh and Tatsuki, 1988). These results indicate that the internal kairomone is a universal substance(s) and is common in insect hemolymph.

There are just a few cases in which the oviposition stimulant inside the host was identified in parasitoids, i.e., *Itopectis conquisitor* (Say) (Ichneumonidae) (Arthur et al., 1969, 1972; Hegdekar and Arthur, 1973) and *Trichogramma pretiosum* Riley (Trichogrammatidae) (Nettles et al., 1982, 1983).

In the present paper, the internal kairomone was identified by chemical analysis combined with a bioassay using the Parafilm-based artificial egg, and possible role of the chemical is discussed in relation to host specificity.

METHODS AND MATERIALS

Insects. Female parasitoids used in the present experiments were obtained from the stock culture in the University of Tsukuba. The rearing and maintenance of the parasitoids were based on the method by Kainoh and Tamaki (1982) and Kainoh (1986). Emerged adults were sexed, and the females were put into containers (15 cm diam. × 12 cm high) at 20 females per container. Three-day-old virgin females were used for bioassay.

Bioassay. An artificial egg for the bioassay was described by Kainoh and Tatsuki (1988). It consists of two sheets of Parafilm and a test solution (30 μ l) between them. The external kairomone [0.06 egg mass equivalent (EME)] was applied on the upper Parafilm to elicit the oviposition behavior. A 3-day-old female parasitoid was allowed to oviposit on this artificial egg for 30 min, and

the number of parasitoid eggs laid in the test solution was counted under a dark-field stereomicroscope.

Collection of Sample. Since host egg masses are too small to collect hemolymph, and the supernatant of the homogenized host pupae was as active as that of egg masses (Kainoh and Tatsuki, 1988), host pupal hemolymph was used for the sample. This was based on the assumption that the active chemical(s) in the host egg must also be present in the pupae. The frozen pupae were cut with a blade and put into a centrifugal tube (1.5 cm diam. \times 7.5 cm long) with a horizontal mesh filter in the middle of the tube. It was centrifuged at 7000g for 30 min, and the greenish supernatant (hereafter designated as crude hemolymph) was pipetted out and kept in a freezer (-20°C) until use.

Heat Stability. The pupal hemolymph (5 ml) in a test tube was heated in a water bath (100°C) for 10 min, and it was centrifuged at 7000g for 30 min. The supernatant (2.4 ml) was diluted stepwise with distilled water from two to 64 times. The activity of each sample of heated hemolymph was compared with that of diluted sample of the crude hemolymph.

Ion-Exchange Column Chromatography. To analyze the pupal hemolymph, a cation-exchange resin (Amberlite IR-120) column ($15 \times 90\text{mm}$) was used. After 2 ml of the crude pupal hemolymph was loaded on the column, 100 ml of distilled water was passed through the column and the washing was collected. Then the sample was eluted twice each with 100 ml 4 N HCl. The eluates were concentrated to dryness under reduced pressure and taken up in 10 ml distilled water. These water and 4 N HCl eluates were neutralized with 0.1 N NaOH solution before bioassay. Then 2 ml crude hemolymph was diluted with 100 ml distilled water and treated the same way as the 4 N HCl eluates. The diluted sample (10 ml) was neutralized and bioassayed as the control.

Sephadex G-25 Column Chromatography. For further analysis of the pupal hemolymph, column chromatography with Sephadex G-25 (fine) was performed. Since the heated pupal hemolymph was active in the heat stability experiment, it was used as a sample. A sample of 2 ml heated pupal hemolymph, which was treated as in the heat stability experiment, was loaded on the column ($15 \times 970\text{ mm}$) and eluted with 250 ml distilled water. The flow rate was adjusted to ca. 15 ml/hr. Each fraction of 5 ml was collected, and the UV absorbance was monitored at 280 nm. The first bioassay was performed for every other fraction ($N = 3/\text{sample}$) and the second for every fraction from 27 to 33 ($N = 3-6/\text{sample}$).

Amino Acid Analysis. Total amount of amino acids of each fraction from Sephadex G-25 column chromatography was estimated by ninhydrin procedure. Fractions 25-38, including active fractions, were chromatographed using an amino acid analyzer (Hitachi, model 835).

To determine the amino acid composition of host materials, 50 *Adoxophyes*

sp. egg masses (ca. 0.2 g) were homogenized with 1 ml of 2% sulfosalicylic acid (SSA) solution in a glass mortar with a pestle to remove protein and centrifuged at 7000g for 10 min. The supernatant was diluted 10 times with 0.02 N HCl. Next the crude pupal hemolymph (100 μ l) of *Adoxophyes* sp. was mixed with 200 μ l of 2% SSA solution and centrifuged at 7000g for 10 min. The supernatant was diluted 10 times with 0.02 N HCl. These samples were loaded on an amino acid analyzer after filtration through a membrane (pore size: 0.45 μ m).

Activity of Amino Acids. In order to determine the active amino acids, ovipositional activity of the following authentic L-form amino acids was tested; α -alanine (α -Ala), β -alanine (β -Ala), arginine (Arg), aspartic acid (Asp), asparagine (Asn), cysteine (Cys), cystine [(Cys)₂], glutamic acid (Glu), glutamine (Gln), glycine (Gly), histidine (His), isoleucine (Ile), leucine (Leu), lysine (Lys), methionine (Met), phenylalanine (Phe), proline (Pro), serine (Ser), threonine (Thr), tryptophan (Trp), tyrosine (Tyr), and valine (Val). Each amino acid was dissolved in distilled water at the concentration of 0.1 M and 0.01 M, but slightly soluble amino acids were only at 0.01 M or saturated solution. The pH of each solution was adjusted to 7 with 0.01–0.1 N HCl or 0.01–0.1 N NaOH. Their ovipositional activity was compared to those without pH adjustment. Some of the active amino acids (histidine, methionine, proline, and serine), at various concentrations and without pH adjustment, were prepared and bioassayed. In the case of histidine, saturated solutions were prepared at 0.27 M.

Activity of Amino Acid Mixture. The two mixtures of authentic amino acids were prepared at the same concentrations of amino acids as in the host egg-mass homogenate and the pupal hemolymph. Based on the amino acid composition (Table 1) and active amino acids (Table 2), one mixture of 11 active amino acids (Ser, Pro, Gly, α -Ala, Val, Met, Ile, Leu, Trp, His, Arg) and another mixture of 20, including the 11 active and nine inactive or slightly active ones, were prepared in the concentrations corresponding to those of the egg-mass homogenate and the pupal hemolymph. These mixtures were bioassayed with and without pH adjustment by 0.1 N HCl or 0.1 N NaOH.

To compare the activity of above mixtures with that of host egg-mass homogenate, 50 egg masses (ca. 0.2 g) were homogenized with 1 ml distilled water and centrifuged at 7000g for 10 min for the supernatant to be bioassayed ($N = 35$).

RESULTS

Heat Stability. There was no ovipositional activity in the original pupal hemolymph and those diluted twice and four times. The activity was found at eight and 16 times dilutions, with the highest activity at 16 times ($\bar{X} = 47.4$).

In the case of heated hemolymph, activity emerged at four, eight, and 16 times dilution with the highest activity at 8 times ($\bar{X} = 52.2$).

Ion-Exchange Column Chromatography. There was no ovipositional activity in the eluate of distilled water from ion-exchange column chromatography, but the activity emerged from the first eluate of 4 N HCl ($\bar{X} = 30.2$). The second eluate of 4 N HCl was slightly active ($\bar{X} = 2.2$). The activity of the first 4 N HCl eluate was not significantly different ($P < 0.05$) from the control ($\bar{X} = 23.0$), but that of the second eluate was significantly lower ($P < 0.05$) than the control as determined by Duncan's multiple range test.

Sephadex G-25 Column Chromatography. The activity was found in fractions 29–31 from Sephadex G-25 column chromatography (Figure 1). The peak of the ovipositional activity was in fraction 30 with 31.7 eggs in average. The ninhydrin coloration peak was found in fractions 28–30.

Amino Acid Analysis. Among the fractions from Sephadex G-25 column, most of the peaks of the amino acids were in fractions 29–31 (Table 1), and the total concentration of 22 amino acids was highest in fraction 30 (29: 4.7, 30: 7.2, 31: 4.7 mM), which coincided with the activity peak.

In the egg-mass homogenate, glutamine, glutamic acid, arginine, and histidine were abundant; however, α -alanine and proline were most abundant in the pupal hemolymph (Table 1).

Activity of Amino Acids. There were 11 active amino acids, i.e., α -alanine, arginine, glycine, histidine, isoleucine, leucine, methionine, proline, serine,

tryptophan, and valine (Table 2). Among these, 0.1 M solutions of histidine and methionine were most active both at pH 7 and without pH adjustment. Histidine was still active even at 0.01 M. α-Alanine, leucine, and valine were less active (0.1 M). The activity of glycine and serine increased with pH adjustment (pH 7), but in isoleucine and proline, it decreased with pH adjustment. Only slight activity was found in the 0.1 M solution of β-alanine (pH 7), 0.1 M cysteine (pH 7), 0.1 M lysine (pH 7), 0.1 M and 0.01 M phenylalanine (pH 7), and in the saturated solution of cystine (0.5 mM) (pH 5.9). The 0.01 M arginine was active after pH adjustment, although the 0.1 M solution was not so active even after pH adjustment.

In the dose-response relationship of methionine, the highest activities were obtained at 0.05 M ($\bar{X} = 90.7$), 0.1 M ($\bar{X} = 92.7$), and 0.2 M ($\bar{X} = 93.7$) (Figure 2). The activity of histidine increased to the maximum ($\bar{X} = 89.4$) as

TABLE 3. ACTIVITY OF AMINO ACID MIXTURE SIMULATING THE HOST EGG-MASS HOMOGENATE FOR OVIPOSITION OF *A. reticulatus*

No. of amino acids mixed ^a	pH ^b	No. of tests	Ovipositional activity (avg. No. eggs) ^c
11	8.7	15	6.5 ± 4.4 c
	7.0	15	62.1 ± 6.9 b
20	6.5	15	92.3 ± 4.0 a
	7.0	15	73.7 ± 9.7 b
Egg-mass homogenate ^d	6.9	35	56.9 ± 4.7 b

^aMixtures of 11 active amino acids and 20 amino acids including inactive ones [except Cys and (Cys)₂] were tested. The ratio and concentration were based on Table 1.

^bThe pH was adjusted to 7 with 0.1 N HCl or 0.1 N NaOH.

^cValues are $\bar{X} \pm SE$ ($N = 10$). Means followed by the same letters are not significantly different (5% level) as determined by Duncan's multiple-range test.

^dFifty host egg masses were homogenized with 1 ml of distilled water ($N = 35$).

the concentration increased to 0.1 M, then slightly decreased ($\bar{X} = 73.2$) in the saturated solution (0.27 M). In the case of histidine and proline, the maximum activity was obtained at 0.1 M, and it decreased as the concentration increased; however, serine had the highest activity ($\bar{X} = 34.3$) at 0.05 M. In the highest concentrations of proline (1 M) and serine (0.5 M), the activity was only slight or null.

Activity of Amino Acid Mixture. Activity of the mixtures of both 11 and 20 amino acids in the concentration simulating the egg-mass homogenate was not significantly different at pH 7 from that of real egg-mass homogenate ($\bar{X} = 56.9$) (Table 3).

In the case of amino acid mixtures simulating the pupal hemolymph (Table 4), all the mixtures were active, although the pupal hemolymph was inactive. There was no significant difference of activity between the 11 and 20 amino acid mixtures at pH 7.

DISCUSSION

An internal kairomone of *A. reticulatus* was identified as amino acids, which explained the nonspecific ovipositional response to the hemolymphs of several insects of different orders shown by Kainoh and Tatsuki (1988).

The ovipositional activity of diluted pupal hemolymph shows the optimum

TABLE 4. ACTIVITY OF AMINO ACID MIXTURE SIMULATING HOST PUPAL HEMOLYMPH FOR OVIPOSITION OF *A. reticulatus*^a

	7.0	15	95.1 ± 6.6 a
Pupal hemolymph	6.4	10	0 c

^aSee Table 3 footnotes

concentration for oviposition in both crude and heated hemolymph. These data suggest that the active material(s) in the pupal hemolymph is inactive in higher concentrations, otherwise masking or inhibitory substance(s) are included in the pupal hemolymph. The different activity peaks of the two samples may be due to some effect of the material(s) in crude pupal hemolymph.

Ion-exchange column chromatography shows that the active material(s) is positively charged. Sephadex G-25 column chromatography (Figure 1) and amino acid analysis of each fraction from the column (Table 1) show that the activity of pupal hemolymph is due to amino acids. Of 22 amino acids (Table 2), 11 are active at pH 7 and/or with no pH adjustment. The pH of some of these amino acid solutions does not seem to critically affect activity.

Dose-response curves with some amino acids (Figure 2) show that the higher the concentration above 0.1 M, the lower the activity, except methionine, which may be due to the inhibitory effect of higher amino acid concentration. This result cannot explain the inactivity of crude pupal hemolymph, since the mixture of authentic amino acids in a concentration simulating the pupal hemolymph is active (Table 4). Some material(s) in the crude pupal hemolymph may mask the activity of the amino acids. Similar dose-response curves of amino acids were shown by Arthur et al. (1972), in which each active amino acid has an optimum concentration for oviposition of *I. conquisitor*.

The activity of mixtures of 11 and 20 amino acids (pH 7) was not significantly different from that of the egg-mass homogenate at the same ratio and concentration (Table 3). This shows that the main components of the internal kairomone can be the mixture of amino acids. The mixture of 11 active amino

acids (total concn: 7.2 mM) simulating the egg-mass homogenate was active ($\bar{X} = 62.1$) at pH 7 (Table 3), although the individual amino acid was not so active in 10 mM ($\bar{X} = 8.8$, range:0–55.0, $N = 11$) at pH 7 (Table 2). This shows the synergistic effect of the active amino acids.

There are some parasitoid species in which several amino acids have been identified as internal kairomone from the host. In a pupal parasitoid, *I. conquisitor*, the mixture of serine (0.5 M), arginine (0.05 M), leucine (0.065 M), and magnesium chloride (0.025 M) was more effective than the host hemolymph in inducing oviposition (Arthur et al., 1972). Also, in an egg parasitoid, *Trichogramma dendrolimi* Matsumura, leucine, phenylalanine, isoleucine, and histidine were found to be active oviposition stimulants by using artificial eggs (Wu and Qin, 1982). Judging from these cases including *A. reticulatus*, amino acids seem to be common as an internal kairomone for inducing oviposition of endoparasitoids.

Glycine and serine were identified as stimulants for antennal drumming and ovipositor insertion from the host egg-mass hair (scales) in *Tetrastichus schoenobii* Ferriere (Eulophidae) (Du et al., 1982). In *Apanteles cypris* Nixon (Braconidae), trehalose and eight amino acids (leucine, phenylalanine, aspartic acid, serine, cystine, alanine, valine, and threonine) were identified as searching stimulants from the host larval frass (Hu and Chen, 1987). In these species, other specific substance(s) may act as another kairomone to determine their host specificity. In *A. reticulatus*, a specific substance is the external kairomone (Kainoh et al., 1982), which may be the critical factor to determine the host specificity of this species (Kawakami and Kainoh, 1986).

The total amino acid concentration of pupal hemolymph (74 mM) (Table 1) seemed to be higher than the egg hemolymph, considering the total free amino acid concentration (ca. 35–55 mM) of eggs of other lepidopterous species, i.e., *Philosamia ricini*, *Antherae pernyi*, and *Corcyra cephalonica* (Xie et al., 1982). The low concentration of free amino acids in the eggs may be critical for the development of parasitoid larvae, especially for egg parasitoids.

An artificial egg used for the present bioassay can be used to collect parasitoid eggs effectively, which will make it possible to develop an artificial rearing method with artificial media. In the case of *T. pretiosum*, oviposition and in vitro rearing systems are now being developed with artificial eggs (Xie et al., 1986). In larval or egg-larval parasitoids, the method will be more complex and needs intensive research; however, this direction of research will give us some informative cues to find new techniques for biological control.

Acknowledgments—We thank Dr. W.C. Nettles, Jr. of the USDA for critical reading of, and comments on, an earlier draft and Mr. K. Koyama of this institute for providing amino acids. This study was supported in part by a Grant-in-Aid for Scientific Research Work No. 61790201 from the Ministry of Education, Science and Culture, Japan.

METAL COMPOSITION AS A NATURAL MARKER IN ANTHOMYIID FLY *Delia radicum* (L.)

R. KOWALSKI,¹ S.E. DAVIES, and C. HAWKES

Department of Biological Sciences
Plymouth Polytechnic

(Received February 23, 1988; accepted June 1, 1988)

Abstract—Graphite furnace and flame atomic absorption spectroscopy were used to make quantitative determinations of a range of metallic cation contents of wet-ashed female individuals of *Delia radicum* (L.) from a laboratory culture reared under controlled conditions and freeze-dried upon emergence. Analyses were done for seven elements: Fe, Zn, Cu, Pb, Al, Mg, and K. The quantities of K and Mg present were positively related to the dry weight of individual flies, while the others showed an exponential decrease in concentration with increasing fly weight. This difference is attributed to the different roles of surface adsorption of metals with higher oxidation states and the high absorption efficiencies of those existing as oxidation states 1 and 2. The weight of the insect is therefore a major factor in determining the individual's chemoprint. The implications of this observation for other studies are discussed.

Key Words—Graphite furnace, heavy metals, chemoprints, *Delia radicum*, Diptera, Anthomyiidae, surface adsorption, oxidation states, metal cations.

INTRODUCTION

Dempster et al. (1986) described how the naturally occurring chemical composition of insects may act as a population marker for discriminating between populations under three assumptions: (1) a pattern of elements builds up in the individual insect during its growth and persists into the imago; (2) this pattern is not destroyed by adult feeding or aging; and (3) the pattern of elements is

¹Present address: The Agricultural Education and Training Unit, The Polytechnic Wolverhampton, Castle View, Dudley DY1 3HR, U.K.

characteristic of the locality in which the individual passed through its life cycle, so that the variation between populations outweighs the variation within populations. This technique is most commonly referred to as chemoprinting and appears to have application in studies of insect dispersal (McLean et al., 1979; Turner and Bowden, 1983; Bowden et al., 1984; Dempster et al., 1986).

A diversity of analytical approaches has been used based upon X-rays, and the validity of some of the results obtained has been questioned. Bowden et al. (1979) noted that the relative methods based upon X-ray energy-dispersive spectroscopy (XES) used in the earliest attempts at chemoprinting (McLean and Bennett, 1978; Turnock et al., 1979) had disadvantages compared with the quantitative analysis of specific elements by X-ray fluorescence microanalysis (XRF). The question of analytical sensitivity for these methods is discussed at length by Bowden et al. (1985).

As a consequence of the uncertain validity of X-ray methods, we felt that it would be advantageous to develop a reliable quantitative technique that was not based upon X-rays. Furthermore, we felt that the different selections of elements used for discrimination even within single species (Bowden et al., 1984, 1985) demanded a better understanding of how the elements selected for chemoprinting are actually accumulated in the insect. One special requirement of chemoprinting is that there should be a characteristic nature to any pattern for a given locality or population (Dempster et al., 1986).

Smock (1983) and Darlington et al. (1986) drew attention to the processes of absorption and surface adsorption in determining the concentration of elements in aquatic insect tissue. With these studies in mind, we investigated the use of atomic adsorption spectroscopy (AAS) for analyzing elemental composition of individual adult cabbage root flies [*Delia radicum* (L.); (Diptera; Anthomyiidae)] from cultures maintained in the laboratory as a preliminary to using chemoprinting to study dispersal of this species in the field. In particular, any surface area-to-volume effects were examined to ascertain their potential influence upon discrimination between different sources of insects.

METHODS AND MATERIALS

Rearing of Insects. We used a culture of *D. radicum* maintained at Plymouth Polytechnic for five years originating from locally captured wild flies. The controlled conditions were $20 \pm 1.5^\circ$ C, 16 hr light, and $60 \pm 5\%$ relative humidity, and the culturing technique was similar to that in Finch and Coaker (1969).

Eggs from a culture cage were inoculated onto a single swede (*Brassica napus* L.), and the pupae produced were subsequently isolated. On emergence, the adult flies were frozen and freeze-dried to constant weight.

Preparation and Analysis of Insects. The dried female flies were weighed on a Cahn Automatic Electro-balance 29 (Cahn Instruments, Inc., Cerritos, California), to 0.1 μg . Each fly was placed singly in a numbered vial. Boyden (1974) emphasized the advisability of using as wide a range of specimen weights as possible in studies to evaluate the effect of weight on metal concentrations. Therefore, we took 11 representatives from the range 2–3 mg, nine from the range 3–4 mg, six from 4–5 mg, three from 5–6 mg, and one above 6 mg, the only one of this weight available.

All glassware was acid washed, soaked for 48 hr in 2 M hydrochloric acid, 48 hr in nitric acid, rinsed three times in deionized distilled water, and then dried (Rowland, 1982). Each fly was placed in a dry digestion tube and 1 cm^3 of concentrated Aristar grade nitric acid (BDH Chemicals, Poole, Dorset, U.K.) added. Digestion was then undertaken on a programmable digestion system (Tecator Ltd, Bristol, U.K.). Upon completion, the digests were diluted to 50 cm^3 with deionized distilled water.

Several elements were measured in the samples by atomic absorption spectroscopy, using a Varian AA.975 series atomic absorption spectrometer (Varian Tectron Pty. Ltd, Springvale, Australia), either by flame AAS or by electrothermal atomization with a graphite tube atomizer (details in Ebdon, 1982, McKenzie, 1982).

Analytical reliability was checked by taking a bulk sample of a further 25 female flies with dry weights in the range of 3.3–4.4 mg (total weight of 99.6262 mg) and digesting them in 5 cm^3 of concentrated Aristar grade nitric acid, made back up to 5 cm^3 after digestion with deionized distilled water, and analyzed by flame AAS.

Precision of the method was tested by using 10 replicates of a standard solution for each calibration range analyzed as part of each batch run on the instrument.

RESULTS

Seven of the elements occurred in quantities suitable for measurement by these methods (Ebdon, 1982). The analyses of flies, the bulk sample, and the standard replicates are summarized in Table 1. The results for the bulk sample lie within the range for individual flies and are in accord with measurements of metal concentrations made in other species (Levy and Cromroy, 1973; Cohen et al., 1985).

Table 2 and Figure 1 present the regression analyses for \log_{10} concentration of each metallic cation against \log_{10} dry weight of the fly obtained in this study. There was a steep decline of concentration with increase in fly weight for Al, Pb, Fe, Cu, and Zn, and a shallower decline for K and Mg. A representative

plot of the former pattern is demonstrated in Figure 2 for Pb, showing the considerable change in concentration of the metal over a very limited range of fly weights, at the smallest weights of flies available, validating the selection of the representative weights of individuals used in this study. The latter pattern is characterized by the total quantity of metal contained in the individual, being directly proportional to the dry weight. This relationship is shown for K in Figure 3.

DISCUSSION

Bowden et al. (1984) have pointed out that the use of a method of analysis that allows identification of elements, rather than the relative parameters described as "regions of interest" produced by earlier studies (e.g., McLean and Bennett, 1978; McLean et al., 1979; Turnocket et al., 1979), has the advantage of enabling us to specify unequivocally the elements that make up the chemoprints. For those metallic cations that do not occur in quantities within the analytical range of flame AAS, graphite furnace AAS represents a very satisfactory analytical technique. It is capable of giving measurements of enough elements to provide an adequate chemoprint for individual cabbage root flies.

This study of a laboratory population of *D. radicum* has confirmed observations made in studies of metal uptake by aquatic insects and reviewed by Smock (1983). Furthermore, his identification of two types of general relationships between metal concentration and weight were also confirmed.

Metals that show no disproportionate effect of insect weight upon metal

FIG. 2. Relationship between dry weight (mg) and lead concentration ($\mu\text{g/g}$) in individual female cabbage root fly.

concentration, such as K, Mn, and Na, were identified by Smock (1983) as type 1 in his study of *Stenonema modestum* (Banks) and *Stenacron interpunctatum* (Say) (Ephemeroptera; Heptageniidae). We did not measure Na, and Mn did not occur in measurable quantities, but we would include Mg as type 1 since it shows the characteristic relationship of quantity of metal against dry weight exemplified in Figure 3. This relationship occurs where absorption, rather than adsorption, is the more important factor determining metal concentration, since both the number of potential binding sites (e.g., tissues, fluids, enzymes, etc.) and body weight increase simultaneously. Metals of this type tend to have high absorption efficiencies and to exist in low oxidation states and simple ionic forms, which favor absorption as the major mode of accumulation.

Metals of the second type (type 2) show an exponential decrease in concentration with increasing body size, which is linked to the absence of a simple relationship between the quantity of metal present and the individual's dry weight. Smock (1983) identified four type 2 metals, namely, Co, Cr, Fe, and Sc, and linked this effect to the surface adsorption method of accumulation

FIG. 3. Relationship between dry weight (mg) and amount of potassium (μg) in individual female cabbage root fly.

typical of elements with higher oxidation states and existing in complex ionic forms. We were unable to measure the low concentrations of Co or Cr in *D. radicum* by AAS, but Fe, Zn, Al, Pb, and Cu all appeared to be of this type. Darlington et al. (1986) placed Cu in type 2 in their study of *Plectrocnemia conspersa* (Curtis) (Trichoptera; Polycentropodidae), and Rainbow and Moore (1986) placed Cu, Fe, Pb, and Zn in type 2 in their study of amphipods (Crustacea: Amphipoda).

The fact that the weight of an organism can play a major part in determining the concentration of metal cations in its tissues has a significant impact upon our attempts to use chemoprinting to discriminate between sources of insects. The implication is that two insects of different weights, coming from different localities or host plants and subject to differing concentrations of metals in their environments, can have identical concentrations of those metals in their tissues. Conversely, insects from the same locality and environment could have different concentrations of metals or ratios of metals by virtue of being of unequal weight. In order to discriminate between insects from different sources, a new variable, dry weight, must be introduced and the relationships between concentrations and dry weight established.

In light of this, it is possible to interpret the study of discrimination of *Noctua pronuba* (L.) (Lepidoptera; Noctuidae) by Bowden et al. (1984). The elements that they measured by XRF were divided into a major group composed of K, P, S, Mg, Ca, and Cl, which could be used for discrimination, and a minor group of Zn, Si, Al, Fe, Cu, Mn, Ni, Cr, and Ti, which could not. The major group metallic cations seem to be of type 1, where weight has little influence, and the minor ones of type 2, where weight is of considerable significance. Their omission of weight as a variable would, therefore, be expected to reduce the reliability of the type 2 elements for discrimination purposes. Indeed we speculate that, since it was possible to use some type 2 metallic cations (e.g., Zn, Fe, and Al) in the study of *Rhopalosiphum padi* (L.) (Homoptera; Aphididae) undertaken by the same authors (Bowden et al., 1985), this may reflect the absence of significant differences in the weight of the individuals in question.

We conclude that an awareness of the effects of the processes of absorption and surface adsorption in the accumulation of metals in individual insects is useful in the development of chemoprinting. Those metals for which absorption is the dominant process of accumulation may be most useful in discrimination, but a wider range of metals is likely to become available for such purposes if the weight of the individual is considered and concentration-weight relationships are used in the analysis.

Acknowledgments—We are most grateful to Mr. P. Smithers, who maintains the cultures at the Polytechnic, and to Mr. B. Field of Varian Associates Ltd., Walton-on-Thames, for technical advice on the Varian AA.975/GMT 95 furnace. The first author was in receipt of a Research Fellowship from Devon Local Education Authority while this worked was undertaken.

SEX PHEROMONE COMPONENTS OF CORN STALK
BORER *Sesamia nonagrioides* (LEF.)¹
Isolation, Identification, and Field Tests

B.E. MAZOMENOS

Institute of Biology
N.R.C. "Democritos" P.O. Box 60228
GR 153 10 Aghia Paraskevi, Greece

(Received March 23, 1987; accepted June 6, 1988)

Abstract—Z-11-Hexadecenyl acetate (Z11-16:OAc), dodecyl acetate (12:OAc), Z-11-hexadecenol (Z11-16:OH), and Z-11-hexadecenal (Z11-16:Ald), were found in pheromone gland extracts of female *Sesamia nonagrioides* (Lef.) [Lepidoptera: Noctuidae]. These four components were also present in airborne volatiles collected from calling virgin females in a 65:18:8:9 ratio. Hexadecyl acetate (16:OAc) was also detected but found to be inactive. The identification was based on multicolumn GC analysis, mass spectrometry, and field activity. Z11-16:OAc is the major sex pheromone component; the addition of the secondary components individually decreased male captures. The blend of the four synthetic components in 69:15:8:8 ratio was highly attractive to males; 200 µg per trap was the most effective concentration in field tests.

Key Words—(Z)-11-Hexadecenyl acetate, dodecyl acetate, (Z)-11-hexadecenal, (Z)-11-hexadecenol, *Sesamia nonagrioides*, Lepidoptera, Noctuidae, sex pheromone.

INTRODUCTION

The corn stalk borer, *Sesamia nonagrioides* (Lef.) [Lepidoptera: Noctuidae], is an important corn pest in many Mediterranean and central African countries (C.I.E., 1979). We reported previously (Mazomenos, 1984) that virgin female abdominal tip extracts attracted males and that the pheromone produced is a multicomponent pheromone. Two pheromone components were identified as

¹Lepidoptera: Noctuidae.

Z-11-hexadecenyl acetate (Z11-16:OAc) and Z-11-hexadecenol (Z11-16:OH) by Sreng et al. (1985). The same authors reported that hexadecyl acetate (16:OAc) was present in the pheromone gland extracts, but its biological activity was not established.

Here we report minor components of the sex pheromone of *S. nonagriodes* that improve male captures in field tests.

METHODS AND MATERIALS

Insects. The insects used in this study were collected as larvae or eggs from infested corn plants. The larvae were separated according to their instar, transferred to artificial diet (Tsitsipis et al., 1983), and allowed to continue their development under laboratory conditions. The temperature was kept at $27 \pm 2^\circ\text{C}$ with a 16:8 hr light-dark regime and relative humidity of $60 \pm 5\%$. The diet was replaced once a week. The eggs were transferred onto a filter paper impregnated with 0.3% propionic acid in Petri dishes for incubation at 27°C . After the four- to five-day incubation period, the emerged larvae were placed on artificial diet. Larval development under the conditions described lasted ca. 30-40 days.

The pupae were kept under the same conditions until moth emergence. Insects were sexed at the pupal stage, five to six days after pupation. The female adults were transferred in an incubator at 25°C with 16:8 hr light-dark regime, while males were placed in a large bioassay cage in a separate room, operated under the same conditions.

Pheromone Collection. The pheromone was collected from the pheromone glands of 2- to 3-day-old virgin females exhibiting calling behavior; the peak of calling occurred in the fifth hour into the dark phase. The glands were removed with forceps and extracted in ether for 20 min. The ether extracts were filtered and concentrated through a 8-cm Vigreux column.

Airborne volatiles from virgin females were collected using a Teckmar GLS-1 closed looping concentrator. Females 2 to 4 days old were placed in the 1-liter sampler during the dark period, and the volatiles emitted from the females were swept by the recirculating headspace gas and absorbed on 1.5 mg of activated charcoal. The trap was then removed and a collection vial was connected to the trap on the end close to the charcoal. Aliquots of $5 \mu\text{l}$ hexane were added twice to the trap. The bottom of the trap-vial assembly was cooled with a Dry Ice cube. This caused the air in the vial to contract, creating a partial vacuum that pulled the solvent through the charcoal. After pulling the solvent down, it was pushed back through the charcoal three times by warming the bottom of the trap with hand contact. The extracts collected were subjected to GC analysis.

Gas Chromatography–Mass Spectrometry. Concentrated crude extracts were injected on a 2-m × 1.8-mm (ID) column packed with 5% Carbowax 20 M on Chromosorb G/HP 80–100 mesh; the column temperature was held at 90°C for 10 min and then was programmed to 180°C at 6°/min. Nitrogen was used as carrier with a flow of 20 cc/min. Consecutive 3-min fractions were collected in liquid-nitrogen-cooled glass capillaries, and each was tested for biological activity in laboratory bioassays. The active fractions recovered from the Carbowax 20 M column were further purified on a 2-m × 1.8-mm (ID) column packed with 3% OV-101 on Chromosorb Q 80–100 mesh operated isothermally at 180°C and collected in 1-min fractions. The active peaks were analyzed on 3% OV-101 (2 m × 1.8 mm ID) on Chromosorb Q 80–100 mesh at 180°C; 5% DEGS (2 m × 1.8 mm ID) on Chromosorb G H/P 80–100 mesh at 160°C; and 15% OV-225 (2 m × 1.8 mm ID) on Chromosorb Q 80–100 mesh at 150°C.

The mass-spectral analyses of the active components were performed using a GC-MS Finnigan MAT 112s spectrometer in the electron-impact mode. The GC glass column was 3.05 m × 0.32 cm (ID), packed with 3.5% OV-101 on Chromosorb Q 100–200 mesh. Helium was the carrier gas at a flow rate of 25 cc/min.

Chemicals. Z11–16:OAc, Z11–16:Ald, and Z11–16:OH were obtained from Sigma Chemical Co. (St. Louis., Missouri); and 12:OAc was synthesized in our laboratory. The components were found to be 96–98% pure when analyzed by GC on OV-101 and OV-225 columns.

Bioassays. Bioassays were conducted in a screen cage described by Mazomenos (1984). Usually 25–40, 1- to 3-day-old males were present in the cage during the bioassay. The bioassays were conducted 5–6 hr into the dark phase under a uniform low level of light (ca. 5 lux). Samples of the crude extract and the fractions obtained during the purification were pipetted onto a piece of Whatman No. 1 filter paper that was suspended about 3 cm below the top of the cage. The response of the males to the sample was observed for 10 min. During each testing period samples were tested individually. The same volume of solvent on filter paper was used as control.

Field Tests. For the field tests conducted during August 13–September 15, 1985, July 3–30, and September 3–October 2, 1986, funnel-type moth traps (Phytophyl, Averof 16, Athens, Greece) were suspended across a corn field in Kopais, central Greece, 1.5 m above the ground, approx. 50 m apart. In 1985, the traps were baited with rubber septa (J12 7 × 11 mm, A.H. Thomas Co., Philadelphia) loaded with 250 µg of each pheromone component and blends containing the Z11–16:OAc and one, two, or three secondary components. In 1986, the traps were baited with different concentrations of the four-component blend. Three replicates for each treatment were used in a complete randomized design. A slow-release formulation of DVP (Vapona) was used as killing agent.

Traps were serviced once a week. Weekly trap catches were subjected to $\log(x + 1)$ transformation prior to statistical analysis. Mean comparisons were made with Duncan's multiple-range test (Steel and Torrie, 1960).

RESULTS AND DISCUSSION

Gas Chromatographic Analysis. Female pheromone gland extracts were injected on a Carbowax 20 M column and collected in 3-min fractions. The fractions were tested for biological activity in laboratory bioassays. Activity was found in the fractions eluted 9–12 (fraction 4) and 21–24 (fraction 8) min after injection. Further purification of the active fractions on OV-101 column resulted in the isolation of two active components with retention times of 4.3 and 18.7 min for fractions 4 and 8, respectively. The retention times of the two components corresponded to those of synthetic 12:OAc and Z11-16:OAc.

GC-MS analyses of the two components supported the chromatographic data. The mass spectrum for component with a retention time of 4.3 min showed diagnostic peaks of m/z 228 for P and 168 for P-60. This spectrum was identical with that obtained for the synthetic 12:OAc. The mass spectrum for the component with a retention time of 18.7 min established that it was a C₁₆ monounsaturated acetate (m/z 282 for P and 222 for P-60). The double-bond geometry and position are not revealed by the spectrum, but the spectrum was identical to that of synthetic Z11-16:OAc.

These two synthetic components tested separately or in combination in laboratory bioassays produced an activity level less than that elicited from the crude extract. Since Z11-16:OH and 16:OAc have been reported as sex pheromone components (Sreng et al., 1985), we reexamined the pheromone gland extracts and the airborne volatiles collected from virgin females. Three other components were found that had retention times matching those of monounsaturated 16:OH and 16:Ald and saturated 16:OAc. Since the 16:OAc and 16:OH were reported (Sreng et al., 1985) to be of Z-11 configuration, it was assumed that the 16:Ald detected was also of the Z-11 configuration; no other aldehydes were considered. Hexadecyl acetate had no effect on male behavior and was not included in field tests. The ratio of the other four components Z11-16:OAc/12:OAc/Z11-16:Ald/Z11-16:OH was found to be 65:18:8:9, respectively. In laboratory tests, the components Z11-16:OH and Z11-16:Ald, when tested individually, were not attractive to males; however, when the two components were added to the two acetates (Z11-16:OAc and 12:OAc), male attractiveness was increased.

Field Tests. Results of field experiments indicated that Z11-16:OAc attracted quite a high number of males. The blend of the four synthetic com-

ponents in a 69:15:8:8 ratio (similar to that found in the female volatiles) attracted more males than Z11-16:OAc alone (Table 1). The secondary components, 12:OAc, Z11-16:Ald, and Z11-16:OH, when added individually to the Z11-16:OAc in 20, 10, and 10% amounts, respectively, decreased male captures. On the other hand, male capture were increased when two of the three secondary components were added to Z11-16:OAc.

The effect of the pheromone concentration on male captures was studied in 1986, during July with low insect population and in September when the insect population density was high. Concentrations ranging from 50 to 400 $\mu\text{g}/\text{trap}$ were tested, and all attracted males. A trend of higher male attraction was observed in traps baited with 200 μg of the pheromone blend (Table 2).

The results confirmed that Z11-16:OAc is the major sex pheromone component. Many moths of the Noctuidae family are known to use Z11-16:OAc as their major sex pheromone component; *Sesamia inferens* (Nesbitt et al., 1976), *Pseudaletia unipuncta* (Hill and Roelofs, 1980; McDonough et al., 1980; Farine et al., 1981), and *Mamestra brassicae* (Descoins et al., 1978).

Some of these species require the addition of the corresponding alcohol or aldehyde for optimum attraction. The three components were isolated from the species *Mamestra suasa* (Toth et al., 1986) and are essential for male attraction of the cutworm moth, *Crymodes devastator* (Steck et al., 1980). Dodecyl acetate has also been isolated from other lepidopterous species (Inscocoe, 1982), and in most cases this compound acts as a synergist.

In our field tests, traps baited with Z11-16:OAc also attracted a high num-

Abstract—(Z)-11-Octadecenyl acetate (Z11-18:Ac) was identified as the aggregation pheromone of *Drosophila mauritiana*, *D. yakuba*, and *D. rajasekari*. The amount of pheromone in the ejaculatory bulb of male flies increased with age, reaching plateau levels of ca. 240, 800, and 1100 ng/fly for *D. mauritiana*, *D. yakuba*, and *D. rajasekari*, respectively. Thirty to 50% of the pheromone in the ejaculatory bulb was transferred to the female during mating, with the majority transferred to the female's reproductive tract. In the subsequent 6-hr period, over half the pheromone in the female's reproductive tract was transferred to the surroundings. In a wind-tunnel olfactometer, Z11-18:Ac was attractive to *D. yakuba* and *D. mauritiana*; however, *D. rajasekari* required food or food odors in combination with Z11-18:Ac to demonstrate aggregation activity. Z11-16:Ac and Z11-20:Ac were not attractive for *D. mauritiana*, *D. yakuba*, and *D. rajasekari*. For all three species, food was synergistic with Z11-18:Ac and both sexes were attracted.

Key Words—*Drosophila mauritiana*, *Drosophila yakuba*, *Drosophila rajasekari*, Diptera, Drosophilidae, (Z)-11-octadecenyl acetate, *cis*-vaccenyl acetate, aggregation pheromone.

INTRODUCTION

Aggregation pheromones have been demonstrated and characterized in species from two subgroups of the *melanogaster* species group (Bartelt et al., 1985; Schaner et al., 1987, 1989a,b). *D. melanogaster* and *D. simulans*, of the *melanogaster* subgroup, were attracted to (Z)-11-octadecenyl acetate (Z11-18:Ac). Z11-18:Ac was produced by mature males, transferred to females during mat-

ing, and emitted by mated females within 6 hr after mating (Bartelt et al., 1985; Schaner et al., 1987). These data suggested that the predominant aggregation pheromone for the *melanogaster* subgroup was Z11-18:Ac.

On the other hand, *D. malerkotliana* and *D. bipectinata*, of the *ananassae* subgroup, were attracted to (Z)-11-eicosenyl acetate (Z11-20:Ac). Z11-20:Ac was produced by mature males, and although they had no Z11-18:Ac, they were as attracted to Z11-18:Ac as to an equal quantity of Z11-20:Ac (Schaner et al., 1989a,b). *D. ananassae*, also of the *ananassae* subgroup, produced mostly Z11-18:Ac but some Z11-20:Ac and was attracted to Z11-18:Ac but not to Z11-20:Ac when tested alone (Schaner et al., 1989b). However, Z11-20:Ac in combination with Z11-18:Ac was significantly more attractive than Z11-18:Ac alone.

Here we demonstrate, identify, and characterize the aggregation pheromone of three additional members of the *melanogaster* group: *D. mauritiana*, *D. yakuba* of the *melanogaster* subgroup, and *D. rajasekari* of the *suzukii* subgroup.

METHODS AND MATERIALS

Flies and Extracts. *D. mauritiana* (strain 14021-0241), *D. yakuba* (strain 14021-0261), and *D. rajasekari* (strain 14023-0361) were obtained from the National *Drosophila* Species Resource Center at Bowling Green, Ohio. The flies were reared on Instant *Drosophila* Medium Formula 4-24 (Carolina Biological Supply Co., Burlington, North Carolina) in 1-liter jars and in 3.5×10 -cm vials under a light-dark cycle of 16:8 hr and ambient laboratory temperatures.

Flies were separated by sex when 0-6 hr old, aged in 3.5×10 -cm food vials to 6-7 days and extracted at that time by soaking the flies in hexane at room temperature for 24 hr. The crude extracts were fractionated on open columns of silicic acid (Bartelt and Jackson, 1984) eluted with hexane; 10% ether in hexane; 50% ether in hexane; and 10% methanol in methylene chloride. Quantitative and preparative gas chromatography (GC), and gas chromatography-mass spectrometry (GC-MS) were conducted as described previously (Bartelt and Jackson, 1984; Schaner et al., 1989a).

Bioassays. Bioassays were conducted in a wind-tunnel olfactometer (Bartelt and Jackson, 1984) containing ca. 1000 (0- to 2-day-old) flies that had been without food and water for approximately 2 hr. An extract, fraction of an extract, synthetic compound, or control solvent (along with 10 μ l of acetone as a co-tractant for *D. rajasekari*) was applied to filter paper strips inserted around the lip of a glass vial. Each bioassay test consisted of placing two differently treated vials, to be compared, into the olfactometer for 3 min. After 3 min, the vials

were capped and removed, and the captured flies were sexed and counted. Tests were separated by 7–10 min, and as many as 50 tests could be run in a day after stocking the olfactometer once. The bioassay data were transformed to the log ($x + 1$) scale before analysis to stabilize variance, and analysis was done by the method of Yates (1940).

Production, Transfer, and Dispersal of Pheromone. The methods were fully described previously (Schaner et al., 1989a). Briefly, ejaculatory bulbs were removed from adult male flies at various ages, extracted with hexane, and analyzed by GC. The transfer of pheromone during mating was quantitated by removing the reproductive tract of females and the ejaculatory bulb and ducts of males immediately after mating. The organs were crushed with the head of a dissecting pin, extracted with hexane, and analyzed by GC relative to an internal standard.

RESULTS

Identification of Aggregation Pheromone. The hexane extract of 6- to 7-day-old male flies, but not female flies, showed aggregation activity in bioassay (Table 1). Both sexes responded similarly to all preparations tested. Chromatography of the male crude extracts resulted in fractions with some limited activity, but in each case the 10% ether–hexane fraction was equal to or better than the aggregation activity of the crude extract in bioassay (Table 1). Gas chromatography of the 10% ether–hexane fraction revealed that one peak was common to the fraction from all three species. The peak common to each fly was identified as (*Z*)-11-octadecenyl acetate (Z11-18:Ac) by comparing retention times on GC with synthetic Z11-18:Ac (Sigma Chemical Co., St. Louis, Missouri), GC-MS, GC-MS of the dimethyl disulfide reaction product (Nichols et al., 1986), and retention time of synthetic Z9-18:Ac and *E*9-18 = Ac (Sigma Chemical Co.) on GC (Schaner et al., 1989a).

In comparative bioassays, the 10% ether–hexane fraction accounts for all of the aggregation activity of the crude extract (Table 2). When fly-produced Z11-18:Ac (purified from the 10% ether–hexane fraction) was assayed at the same quantity, the Z11-18:Ac accounted for all of the aggregation activity of the 10% ether–hexane fraction. Likewise, synthetic Z11-18:Ac caught the same number of flies as did the crude and 10% ether–hexane fraction.

Pheromone Synergism with Fermenting Food Odors. The combination of synthetic Z11-18:Ac and fermenting food acted synergistically in aggregation activity (Table 3). Fermenting food attracted significantly more flies than Z11-18:Ac alone, but the presentation of Z11-18:Ac along with fermenting food showed 3-, 7-, and 3-fold increases in the bioassay catch for *D. mauritiana*, *D. yakuba*, and *D. rajasekari*, respectively.

Z11-18:Ac + food	17.0 c	146.1 d	59.2 c
Control hexane	1.7 a	0.5 a	1.1 a

^aZ11-18:Ac is in hexane solvent at 200 ng, 250 ng, and 300 ng for *D. mauritiana*, *D. yakuba*, and *D. rajasekari*, respectively. The fermenting food is Instant *Drosophila* Medium yeasted for 24 hr.

^bMeans followed by the same letter were not significantly different at the 5% level (LSD).

Chain-Length Specificity in Aggregation Activity. The specificity of the fly's response to certain chain-length Z11-alcohol acetates was tested. Z11-18:Ac was preferred over Z11-16:Ac and Z11-20:Ac (Table 4). Only the Z11-18:Ac was significantly better than the control solvent in attracting *D. mauritiana*, *D. yakuba*, and *D. rajasekari*.

Dose Response of Z11-18:Ac. As the dose of Z11-18:Ac was increased, the mean catch of all three species increased (Figure 1). The response for *D. mauritiana* continued to increase at 250,000 ng of Z11-18:Ac with no indication of a plateau. The response did not increase as rapidly between 2500 and 25,000 ng of Z11-18:Ac for *D. yakuba*, and between 3000 and 30,000 ng of

TABLE 4. SPECIFICITY FOR ACETATE ESTER STRUCTURE IN AGGREGATION BIOASSAY

Treatment ^a	Mean bioassay catch (N = 12)

Z11-20:Ac	1.9 a	0.7 a	1.1 a

^aThe acetate ester treatments were 200 ng, 700 ng, and 300 ng for *D. mauritiana*, *D. yakuba*, and *D. rajasekari*, respectively. Each treatment for *D. rajasekari* included 10 μ l of acetone as a co-attractant.

^bMeans followed by the same letter were not significantly different at the 5% level (LSD).

FIG. 1. Dose-dependent aggregation response to the mean Z11-18:Ac content of one mature male fly (relative activity = 100). Solid line for *D. mauritiana*, dashed line for *D. yakuba*, and dotted line for *D. rajasekari*.

Z11-18:Ac for *D. rajasekari*, suggesting that the response might be reaching a plateau (Figure 1).

Location, Transfer, and Release of Z11-18:Ac. In each case, the ejaculatory bulb of male flies contained Z11-18:Ac. With increasing age, there was an increase in Z11-18:Ac in the bulb up to a plateau at five days for *D. yakuba*, and six days for *D. rajasekari* and *D. mauritiana* (Figure 2). The plateau level was ca. 240, 800, and 1100 ng/fly for *D. mauritiana*, *D. yakuba*, and *D. rajasekari*, respectively (Figure 2).

During mating, Z11-18:Ac was transferred from the ejaculatory bulb of the male to the reproductive tract of the female in each species (Table 5). In *D. mauritiana* and *D. yakuba*, ca. 50% of the Z11-18:Ac in the ejaculatory bulb was transferred to the reproductive tract of the female. *D. rajasekari* males transferred ca. 30% of the Z11-18:Ac to the female (Table 5).

In the 6 hr after mating, mated female *D. mauritiana* released nearly 60% of their Z11-18:Ac to the surrounding vial, and mated female *D. rajasekari* and *D. yakuba* released over 50% of their Z11-18:Ac to the surroundings (Table 5). The amount of Z11-18:Ac on the fly minus the reproductive tract remained nearly constant. Mated male flies of all three species and virgin male *D. mauritiana* released some Z11-18:Ac to the surroundings.

FIG. 2. Z11-18:Ac content in the ejaculatory bulb of male flies as they age. Solid line for *D. mauritiana*, dashed line for *D. yakuba*, and dotted line for *D. rajasekari*.

DISCUSSION

The production of Z11-18:Ac and the specific response to Z11-18:Ac by *D. mauritiana* and *D. yakuba* are consistent with the concept that the aggregation pheromone of the *melanogaster* subgroup is Z11-18:Ac. The remainder of the *melanogaster* subgroup is yet to be investigated, but a GC peak corresponding to Z11-18:Ac has been observed from extracts of male *D. sechellia* (Luyten, 1982), suggesting that all species of the *melanogaster* complex produce Z11-18:Ac. *D. rajasekari* (of the *suzukii* subgroup) is like the members of the *melanogaster* subgroup in that they produce and respond specifically to Z11-18:Ac.

In the species of the *melanogaster* group, there is considerable variation in the amount of Z11-18:Ac in the ejaculatory bulb of sexually mature male flies: *D. melanogaster* has ca. 1400 ng/fly (Bartelt et al., 1985), *D. rajasekari* has ca. 1000 ng/fly, *D. simulans* (Schaner et al., 1987) and *D. yakuba* have ca. 800 ng/fly, and *D. mauritiana* has ca. 240 ng/fly of Z11-18:Ac.

A comparison of the amount of Z11-18:Ac transferred to the female during a complete mating shows that *D. melanogaster* (Bartelt et al., 1985) and *D. simulans* (Schaner et al., 1987) each transferred ca. 420 ng/fly of Z11-18:Ac to the female whereas *D. yakuba* and *D. rajasekari* transferred ca. 230 ng/fly, and *D. mauritiana* transferred ca. 120 ng/fly. All of the flies transferred the bulk of the Z11-18:Ac into the reproductive tract of the female, and she subsequently transferred the Z11-18:Ac to the surroundings. The mechanism of transfer of the aggregation pheromone to the surroundings by mated females is unknown; but the majority of the transfer occurs in the first 6 hr after mating (Bartelt et al., 1985; Schaner et al., 1987, 1989a). In contrast, both mated and virgin *D. ananassae* males released more Z11-18:Ac to the surroundings (ca. 38 ng/fly) than mated females did (5 ng/fly) in a 12-hr period, suggesting that males are the primary releasers of aggregation pheromone for *D. ananassae* (Schaner et al., 1989b).

There does not appear to be a plateau of maximum dose of Z11-18:Ac for aggregation response in the members of the *melanogaster* subgroup so far tested. The dose-response curve did not plateau up to 10,000 ng for *D. simulans* (Schaner et al., 1987), up to 25,000 ng for *D. yakuba*, and up to 250,000 ng for *D. mauritiana*.

In summary, aggregation pheromone activity has been demonstrated in *D. mauritiana* and *D. yakuba* of the *melanogaster* subgroup and in *D. rajasekari* of the *suzukii* subgroup of the *melanogaster* species group. (Z)-11-Octadecenyl acetate was attractive alone in *D. mauritiana* and *D. yakuba* but required food odors to be attractive in *D. rajasekari*. The pheromone can be isolated from the ejaculatory bulb of sexually mature male flies but not from virgin female flies. During mating, there is a transfer of the pheromone to the female's reproductive

tract. Within 6 hr after mating, the females release the majority of the pheromone to the surroundings where it could synergize the attraction of food odors for flies of both sexes.

COMPARISON OF SEX PHEROMONE COMPOSITION
AND PHEROMONE-MEDIATED MALE BEHAVIOR
OF LABORATORY-REARED AND WILD
Heliothis zea (LEPIDOPTERA: NOCTUIDAE)

(Received June 1, 1988; accepted June 11, 1988)

Abstract—Analysis of ovipositor extracts of lab-reared (> 120 generations) and wild *Heliothis zea* indicated small but significant differences in the percent composition of the four aldehyde components of the sex pheromone. (Z)-11-hexadecen-1-ol (Z11-16:OH) was present in both populations and amounted to only 2.8% of the total pheromone. There was no significant difference in four of the six behavioral categories between lab-reared and wild males exposed to the four-component sex pheromone in the flight tunnel. Ninety and 84% males flew to the pheromone source, respectively. However, with the addition of Z11-16:OH to the pheromone blend, none of the wild males flew upwind to the stimulus source, whereas 36% of the lab-reared males completed the flight. It is suggested that prolonged inbreeding in closed quarters rendered these males less discriminating to qualitative differences in a pheromone blend.

Key Words—Corn earworm, *Heliothis zea*, Lepidoptera, Noctuidae, pheromone, (Z)-11-hexadecen-1-ol, laboratory rearing.

INTRODUCTION

Ovipositor extracts of the corn earworm, *Heliothis zea* (Boddie), Klun et al. (1979, 1980a) were reported to contain four 16-carbon aldehydes as components of its sex pheromone. Recently, Teal et al. (1984) reported the presence

of (*Z*)-11-hexadecen-1-ol (*Z*11-16:OH) in the pheromone gland extracts of *H. zea* females. However, Pope et al. (1984) did not detect *Z*11-16:OH in volatile collections made from *H. zea*. To the best of our knowledge, all previously reported pheromone identifications of *H. zea* were carried out on insects that had been in laboratory culture on meridic diets for many generations. The present study was conducted to determine if prolonged laboratory rearing caused any changes in the qualitative composition of the female sex pheromone and male behavioral responses to pheromonal stimuli.

METHODS AND MATERIALS

All experimental insects were obtained from the Southern Field Crop Insect Management Laboratory, Stoneville, Mississippi. Laboratory-reared insects had been in culture on a wheat-germ diet for over 120 generations under a 15:9 hr light-dark photoperiod (the culture was originally started at the Southern Grain Insects Research Lab in Tifton, Georgia, and subsequently subcultured at Stoneville, Mississippi). These insects were shipped to Beltsville as first-instar larvae on the wheat-germ diet. Wild insects were collected as larvae from cotton, in the vicinity of Stoneville, fed cotton squares and bolls, and shipped as mature larvae. At Beltsville, the insects were reared in environmental chambers maintained under a reverse 16:8 hr light-dark photoperiod and temperatures of 26°C and 22°C during the light and dark phases, respectively. Pupae were sexed and placed in separate chambers. Adults were provided a 10% sucrose solution. Wild *H. zea* females produced a negligible amount of pheromone unless provided with a host plant (Raina, 1988). On the other hand, lab-reared females did not require the presence of a host plant for pheromone production. In order to avoid any discrepancy, females of both populations were provided with cotton squares in the cages.

Pheromone extractions were made from ovipositors of single females in their third scotophase (54 hr posteclosion) as described by Raina et al. (1986a,b). The extracts were analyzed for the five known components using the internal standard method of quantitative analysis. Instrumentation and chromatographic conditions were the same as described by Raina et al. (1986a).

Behavioral response of lab-reared and wild males to four-component [(*Z*)-11-hexadecenal (*Z*11-16:Ald), (*Z*)-7-hexadecenal (*Z*7-16:Ald), (*Z*)-9-hexadecenal (*Z*9-16:Ald), and hexadecanal (16:Ald)] and five-component (the above four plus *Z*11-16:OH) synthetic blends was tested in a flight tunnel previously described by Raina et al. (1986c). Synthetic pheromones containing 230 ng of *Z*11-16:Ald (the percentage of *Z*11-16:Ald, *Z*7-16:Ald, *Z*9-16:Ald, 16:Ald, and *Z*11-16:OH was 91.4, 0.6, 1.5, 3.8, and 2.7, respectively) were applied to 4 × 0.5-cm filter paper strips. A freshly treated strip was used for each replicate. In a preliminary flight-tunnel test, conducted at a light intensity of 5

lux (from red incandescent bulbs), the wild males showed no response to the pheromone, whereas the lab-reared males responded with normal behavior. Subsequently, it was determined that wild males would respond only if the light intensity was < 2 lux. All the tests were therefore conducted at 0.5 lux red light. Male responses for the following six behavioral categories were monitored: (1) activation (rapid body movement and wing fanning); (2) time to activation (elapsed time from exposure to pheromone to start of the wing fanning); (3) upwind flight in plume (divided into two subcategories: (a) in which the males followed the pheromone plume to its source, and (b) in which the males flew only part of the distance and then flew out of the plume); (4) flight time (time from commencement of the flight in plume to arrival at the source); (5) copulatory attempt (represented by the males that flew upwind to the source, landed on it, and attempted copulation as visualized by extension of the claspers and bending of the abdomen); and (6) time spent by the males on the source. Forty-five males from each population were tested for each pheromone treatment.

Percentages of each component of the sex pheromone were statistically analyzed by *t* test for differences between lab-reared and wild females. The time variables were analyzed after log transformation. Time to activation was analyzed as a 2×2 factorial, other time variables were analyzed by one-way analysis of variance, since wild males did not fly to the five-component blend. Frequency variables were analyzed by 2×4 or 2×3 contingency table analysis depending on whether there were three or four variables.

RESULTS

Pheromone Composition. Gas chromatographic analyses of heptane extracts of ovipositors from both lab-reared and wild females showed five peaks whose retention times on polar and apolar columns were coincident with authentic Z11-16:Ald, Z7-16:Ald, Z9-16:Ald, 16:Ald, and Z11-16:OH. The average amount of Z11-16:Ald produced by wild and lab-reared females was 102.5 and 117.8 ng/female. The extracts from wild females contained a significantly higher percentage of Z11-16:Ald than did the extracts from lab-reared females. However, the extracts from lab-reared females contained a significantly higher percentage of the remaining three aldehydes when compared to those from the wild (Table 1). The quantity of Z11-16:OH was 2.8% in extracts from both types of females.

Male Behavior. All test males were activated when presented with either four- or five-component pheromone blends. Lab-reared males were activated in significantly less time than wild males in response to both the four- and five-component blends (Table 2). There was no significant difference in the percentage of the lab-reared and wild males that flew upwind to the four-compo-

the five-component blend as compared to the four-component blend. There was no statistically significant difference in the number of lab-reared and wild males that, having flown to the four-component source, landed on it and attempted copulation. Of the lab-reared males that flew to the five-component source, only 50% landed and attempted copulation. Time spent by the lab-reared males on the four-component source did not differ significantly from that spent on the five-component source. Wild males spent significantly less time on the four-component source as compared to the lab-reared males.

DISCUSSION

Prolonged lab rearing did not appear to change the qualitative composition of *H. zea* female sex pheromone. The percentage of each of the four aldehydes was similar to that reported by Klun et al. (1980a). The presence of Z11-16:OH in ovipositor extracts of *H. zea* females, representing 27.9% of the total pheromone was reported by Teal et al. (1984). However, we observed a much smaller proportion of this component. The difference may be due to the highly polar solvent (ethyl ether) that was used by Teal and coworkers for their extractions compared to the less polar heptane that we used. Z11-16:OH has been reported in the ovipositor extracts of all *Heliothis* species for which the sex pheromones have been identified (Klun et al., 1980b, 1982; Nesbitt et al., 1979; Raina et al., 1986a). However, only in the case of *H. phloxiphaga*, was Z11-16:OH shown to be a component essential for the elicitation of male response (Raina et al., 1986a). In *H. zea*, Teal et al. (1984) speculated that Z11-16:OH may be an immediate precursor of the corresponding aldehyde. This may also explain why Z11-16:OH was not detected in the volatiles collected from calling *H. zea* females (Pope et al., 1984).

In contrast to minor changes in pheromone blend quality, the behavioral responses of lab-reared males were markedly different from those of the wild males. The requirement of very low light intensity (0.5 lux red light) for the wild males to respond to the sex pheromone reflects the conditions in their natural habitat. Even on full-moon nights the light intensity is no greater than 0.3 lux (Shorey and Gaston, 1964). In *Trichoplusia ni*, for example, the males required 10,000-fold more pheromone at 30 lux to elicit behavioral response equivalent to that obtained at 0.3 lux (Shorey and Gaston, 1964). Lab-reared *H. zea* males appear to have lost the requirement for very low light intensity as a prerequisite for them to be able to respond to the sex pheromone.

The most important single parameter in the behavioral repertoire of males in response to the sex pheromone is the upwind flight to the source. It was very evident that the addition of Z11-16:OH caused a complete obliteration of this response in the wild males. However, about 82% of lab-reared males initiated upwind flight in pheromone plume and about 36% made it to the source. Of

those that flew to the source, only 50% landed and attempted copulation. In a field study, Teal et al. (1984) reported that blends containing 1% or more of Z11-16:OH reduced trap capture of *H. zea* to that of unbaited traps. All these results suggest that even though Z11-16:OH is present in *H. zea* female ovipositor extracts, it is not a component of the sex pheromone that is released by the females. In fact, Z11-16:OH in *H. phloxiphaga* sex pheromone is very important in maintaining sex pheromone specificity between this species and *H. zea* (Raina et al., 1986a).

Prolonged rearing appeared to have adversely affected the ability of *H. zea* males to discriminate the presence of Z11-16:OH in the pheromone blend. It is, therefore, very important in evaluating the role of various components in the sex pheromone of a species, either to conduct a parallel field test or to use insects that have not been in laboratory culture for extended periods.

Acknowledgments—We thank Larry Douglass, Animal Science Department, University of Maryland, for statistical analysis of the data.

CHEMICAL COMPOSITION OF DEGRADING
MANGROVE LEAF LITTER AND CHANGES
PRODUCED AFTER CONSUMPTION BY
MANGROVE CRAB *Neosarmatium smithi*
(Crustacea: Decapoda: Sesarmidae)

MARTIN J. NEILSON¹ and GEOFFREY N. RICHARDS²

*Department of Chemistry and Biochemistry
James Cook University of North Queensland
Townsville, Queensland 4811, Australia*

(Received April 20, 1988; accepted June 13, 1988)

Abstract—The leaves of the mangrove *Ceriops tagal* contained 3.2–4.1% (all percentages relate to dry weight) of D-1-*O*-methyl-*muco*-inositol previously unreported in mangroves. They consisted of 37% aqueous acetone-water-soluble material, 18% water-insoluble polysaccharides, and ca. 50% polyphenols, which include soluble and insoluble tannins and lignin. The polysaccharide component sugars were glucose, arabinose, uronic acids, mannose, xylose, galactose, and rhamnose in the proportions 28:26:22:10:7:5:2, respectively. The leaves were pectate rich, and the low level of glucan was presumed to consist mainly of cellulose. After four weeks of biodegradation, ca. 60% of the acetone-water-soluble material was lost from the leaves. Degradation processes greatly altered the polysaccharide components in the leaves. Pectates were rapidly degraded, while other polysaccharides, although reduced proportionately, resisted degradation at about the same level, and all component sugars were found in the 8-week-old leaves. “Apparent lignin” contents increased from 15 to >30% during biodegradation up to eight weeks. The yields of the major fractions in corresponding fecal material from *Neosarmatium smithi* showed a similar trend to the diets. An enrichment of the insoluble residue was noticeable due to the digestion of dialyzable material. The fecal carbohydrate content was greatly reduced (7–11%) and the “apparent lignin” increased (27–39%) due to its resistance to degradation. All dietary polysaccharide component sugars were found in the

² Present address: Wood Chemistry Laboratory, University of Montana, Missoula, Montana, 59812.

fecal residues, including some uronic acids. The leaves also contained a readily water-soluble fraction (15%) which consisted of pectates strongly complexed with proanthocyanidins.

Key Words—Mangrove, detritus, tannins, carbohydrates, polysaccharides, D-1-O-methyl-muco-inositol, *Neosarmatium smithi*.

INTRODUCTION

The degradation of mangrove leaf litter is a dominant factor in the ecology of mangrove swamps, and the detritus is an essential nutrient source for the ecosystem food chain (Odum and Heald, 1975). For example, litter may be decomposed by microorganisms (Bunt et al., 1979; Cundell et al., 1979; Benner and Hodson, 1985) and crustacea (Malley, 1978; Leh and Sasekumar, 1985; Giddins et al., 1986; Poovachiranon et al., 1986; Robertson, 1986).

Detailed chemical studies have been made on leaf composition with respect to its elements (Spain and Holt, 1980; Kotmire and Bhosale, 1980), organics—lipids, sterols, hydrocarbons (Hogg and Gillan, 1984; Ghosh et al., 1985), and low-molecular-weight carbohydrates (Popp, 1984). Other studies (Jamale and Joshi, 1976; Bhosle et al., 1976; Sumitra-Vijayaraghavan et al., 1980) have used proximate analyses only to obtain information about leaf composition and decomposition. However, there have been few specific studies (Benner et al., 1984) on the detailed chemistry of mangrove leaf cell walls, in particular the polysaccharides and their primary degradation processes. Understanding the factors that control the degradation of the walls is of great ecological significance.

Plant cell walls inherently resist digestion in animals, due largely to their water-insoluble constituents. For example, only half the wall polysaccharides are digested during passage through a ruminant (Dekker et al., 1972). This study looks at specific chemical changes occurring in leaf litter degrading at the mud surface (Giddins et al., 1986) and also provides information on the detailed composition of undigested leaf material after passage through the mangrove crab *N. smithi* (Crustacea: Decapoda: Sesarmidae).

Interest also focused on the low-molecular-weight carbohydrates (or free sugars), since they arguably play a significant role in osmotic adjustment in halophytes such as mangroves (Flowers et al., 1977; Popp, 1984).

METHODS AND MATERIALS

General. The conditions for drying samples were: 1 mm Hg, P₂O₅, <40°C, 16 hr. All dialysis tubing, molecular weight (mot wt) cutoff 12,000–14,000, was thoroughly preextracted with distilled water throughout these

experiments. Total phenolics were measured using Folin-Ciocalteu reagent (Hartree, 1972). Condensed tannins were estimated by the vanillin HCl (Broadhurst and Jones, 1978) method with catechin as a reference. Where necessary, carbohydrates were estimated colorimetrically using methods as applied in Neilson et al. (1986a). In the phenol-sulfuric acid method, values were corrected for any absorbance at 485 nm produced by a blank where the phenol reagent was replaced by water (see later).

Sodium chloride in leaves was estimated from sodium determinations made by atomic absorption spectrometry (AAS) with a Varian Techtron atomic absorption spectrophotometer AA6. Milled (<40 mesh) samples (ca. 100 mg) were extracted with double-distilled water (300 ml), first with stirring at 70°C for 30 min (Birch, 1975) and second with sonication for 30 min. Samples were vacuum filtered, residues washed, and the filtrates and washings made up to 500 ml for analysis by AAS.

Samples and Feeding Experiments. Mature green and senescent leaves from *C. tagal*, the collection of senescent leaves subjected to biodegradation for zero to eight weeks (S2, etc. . . . , two-week biodegradation, etc. . . .) and feeding experiments with *N. smithi* are fully described in Giddins et al. (1986).

Fractionation Procedures. Initially leaf fractions were isolated as outlined by Blake and Richards (1970). However, a more direct approach using acetone and (ethylenedinitrilo)tetraacetic acid (EDTA) or water extractions was favored for the bulk of this work (Neilson et al., 1986a). The procedure was modified (Giddins et al., 1986) in order to remove microbial and mud contamination from S2 to S8 leaves. Acetone-insoluble material was dried and weighed and combined acetone extracts were filtered, concentrated to dryness, and weighed. Corresponding fecal samples F2 to F8 (Giddins et al., 1986) were treated similarly but without the homogenization and sonication steps. The proanthocyanidin/polysaccharide complex initially described in Neilson et al. (1986a) was present in the EDTA-soluble fraction.

Dried acetone extracts (0.1 g) and also acetone-insoluble fractions (0.1 g) were extracted with absolute methanol (5 ml) (Ribereau-Gayon, 1972a) for 1 hr at 30°C. Extracts were then centrifuged and total phenolics and condensed tannins measured.

Analysis of Free Sugars. The dried aqueous ethanol soluble fraction (6.1 g) (see Table 2 below), was extracted with water (3×10 ml). Centrifugation (20,000g for 30 min) was needed to remove insoluble material from the first extract, while the two subsequent extracts were centrifuged 2000g for 10 min. Pellets were recovered and represented 27% of the total fraction. The clear reddish brown supernatants were combined and deionized using tandem columns of Amberlite resins IR 120 (H) and then IR 45 (OH) (100 ml of each). The neutral eluent was concentrated to dryness and weighed (37% of the fraction). The resins removed 36% of the fraction, about half of which was sodium chloride.

High-performance liquid chromatography (HPLC) was used to quantify the free sugars in 5% w/v solutions of the deionized water-soluble material. The conditions were: eluent, water-acetonitrile, 30:70, v/v; flow, 1.5 ml/min; temperature, 25°C; column, Radial-PAK L.C. cartridge μ Bondapak NH₂ (8 mm \times 10 cm) (Waters Associates, USA). Fructose and glucose were poorly resolved under these conditions. For preparative HPLC, water-acetonitrile, 25:75, v/v; 3 ml/min and 100 μ l injections of sample solution were used.

Thin-layer chromatography (TLC) was on cellulose sheets (Merck) with ethyl acetate-pyridine-water-*n*-butanol-acetic acid, 5:4:4:10:2, v/v as the solvent (Hoton-Dorge, 1976). Two detection systems were used: (1) silver nitrate-sodium hydroxide (Trevelyan et al., 1950; Hough and Jones, 1962), and (2) *p*-aminohippuric acid (Hoton-Dorge, 1976). Sheets were eluted three times with intermediate drying.

For the gas-liquid chromatography (GLC) of TMS derivatives of carbohydrates, the conditions were: column, 3% SE-30 on Chrom W-HP 80-100; 100°C + 10°C/min to 250°C. For the derivatization with *N*-trimethylsilylimidazole (Pierce, USA) reaction temperature (60-80°C) and time (5-150 min) varied according to solubility of standards and samples. Inositol was used as the internal standard.

Nuclear magnetic resonance (NMR) spectra of solutions in deuterium oxide (5% w/v) were recorded (δ) with a JEOL JNM-MH 100 MHz spectrometer at 29°C with acetone and sodium 4,4-dimethyl-4-silapentane-1-sulfonate as internal references.

The optical rotation was read with a Perkin-Elmer model 141 polarimeter.

Polysaccharide and "Apparent Lignin" Analysis of Fractions. Fractions were subjected to total acid hydrolysis based on modified Saeman conditions (Saeman et al., 1954), prior to assaying. Samples (15-25 mg) were weighed into a tared centrifuge tube (10 ml), triturated with 72% w/w sulfuric acid (100 μ l) at 30°C, and kept in a desiccator with occasional stirring for 1 hr. Water was added (2.8 ml), and the tube and contents were tared prior to secondary hydrolysis under reflux for 3 hr at 100°C. The mixture was cooled, weight was adjusted with water (if necessary), mixed, centrifuged (1000g, 10 min), and aliquots were taken for phenol-sulfuric assay and uronic acid measurement. The remaining known volume was then transferred to a second centrifuge tube and neutralized (pH paper) with barium carbonate at 60°C. After cooling, methyl α -D-glucopyranoside (2%, 0.25 ml) was added as internal standard, the tube contents were thoroughly mixed, and the precipitated salts were removed by centrifugation.

The glyucose composition in the neutralized acid hydrolysates was determined by GLC of the derived alditol acetates. A Hewlett-Packard 5890A gas chromatograph was used with flame-ionization detection and fitted with a vitreous-silica capillary column (BP20, 0.22 μ m, 12 m \times 0.22 mm, S.G.E., Mel-

bourne, Australia). Conditions were: oven 235°C, injector 250°C, detector 300°C, helium carrier gas 0.43 ml/min, split ratio 1:85. A newly developed column (BP225, 0.1 μ m, 25 m \times 0.22 mm, S.G.E.) was also used for separation of alditol acetates isothermally at 220°C with hydrogen carrier gas at 40 cm/sec and with either inositol or allose (3 mg) added immediately after secondary hydrolysis as the internal standard.

The neutralized hydrolysate (0.5 ml) in a 40-ml test tube was reduced with sodium borohydride (2% w/v, 0.5 ml) for 90 min at 30°C. The excess borohydride was destroyed by adding glacial acetic acid dropwise until evolution of hydrogen was complete. The solution was cooled to 0°C and *N*-methylimidazole (2 ml) (McGinnis, 1982) and acetic anhydride (6 ml) were added, the latter with caution. After 5 min, the reaction mixture was cooled, chloroform (5 ml) added, and the solution washed with water (2×5 ml). The organic phase was dried with anhydrous sodium sulfate, evaporated to dryness in a stream of nitrogen, and redissolved in acetone (0.5 ml) for GC.

Peaks were identified by cochromatography with added authentic sugars and quantified as anhydro sugars using a Hewlett-Packard 3392A integrator-recorder, using response factors relative to the internal standard derived from standard sugars subjected to the total analytical procedure including hydrolysis.

The insoluble residues produced on acid hydrolysis were washed free of acid with water (3×10 ml), vacuum dried, and weighed. These crude lignin samples were ashed (600°C, 4 hr), and the weight was adjusted for the ash yield and reported as "apparent lignin."

The protocol used here to analyze plant cell walls allows neutral sugars, uronic acids, and apparent lignin to be determined simultaneously and permits a mass balance to be made, which may be used to check the accuracy of the overall method. The total acid hydrolysis conditions of primary hydrolysis at 30°C for 1 hr, dilution to 0.41 M sulfuric acid, and then 3 hr at 100°C are critical for the quantitative generation of carbohydrate monomers from wall polysaccharides. Using correction factors (relative response factors) derived from subjecting authentic sugars to the total analytical procedure, including hydrolysis, the reproducibility of the procedure is demonstrated in Table 1. Three mixtures each containing seven sugars produced factors that had standard deviations of $\leq \pm 0.079$, $N = 3$. Furthermore, Avicel cellulose was $>90\%$ recovered as glucose when analyzed by the method.

RESULTS AND DISCUSSION

Green (66% moisture) and senescent (68% moisture) leaves were first fractionated using a classical approach for isolation of plant polysaccharides (Blake and Richards, 1970). Plant material was isolated and separated sequentially into

TABLE 1. PRECISION OF RELATIVE RESPONSE FACTORS IN ALDITOL ACETATE PROCEDURE RELATIVE TO METHYL α -D-GLUCOPYRANOSIDE (INTERNAL STANDARD) AS UNITY

operationally defined fractions, namely, hot water (HW), cold water (CW), ammonium oxalate (pectic substances), chlorite (removes lignin, which produces a cellulose and hemicelluloses fraction) and sodium hydroxide (hemicelluloses) (Table 2). Apparent lignin was also measured using 72% sulfuric acid (Adams, 1965). Similar fraction yields were obtained for the two types of leaves except for CW extracts (9.1 vs. 16.9%) and lignin (17.9 vs. 12.1%). Since both CW extracts contained similar proportions of carbohydrate (6.2 vs. 5.4%

TABLE 2. DISTRIBUTION OF COMPONENTS IN MATURE GREEN AND SENESCENT LEAVES OF *Ceriops tagal* OBTAINED BY TRADITIONAL FRACTIONATION PROTOCOL (BLAKE AND RICHARDS, 1970)

Fraction	Leaf dry wt (%)	
	Green	Senescent
80% ethanol soluble ^a	38.8	36.7
Chloroform soluble	0.5	0.2

Hemicelluloses B	4.6	4.3
α -Cellulose	10.6	8.7

^aIncludes low-molecular-weight carbohydrates (free sugars), salt(s), and water-insoluble material.

of leaf dry weight), this major difference could only be attributed to a change in the noncarbohydrate, predominantly proanthocyanidin component (see later). The major fraction was obtained as the 80% ethanol extract (ca. 37%), and this material was analyzed for free sugars.

Bonded-phase HPLC analysis of the water-soluble extract from 80% ethanol-soluble material showed two well-resolved peaks, I and II (area ratio 4:1), which coeluted with fructose and sucrose standards, respectively. TLC using detection systems 1 and 2, confirmed the presence of sucrose but not fructose or glucose. Both systems detect fructose, but, although system 1 showed apparent fructose in the sample, system 2 did not. GLC analysis of the TMS derivatives of the water-soluble components showed two components: sucrose and a compound almost coeluting with authentic fructose, retention time relative to inositol (R_{it}), 0.79 vs. 0.78.

Following isolation by preparative HPLC, [^1H]NMR spectroscopy confirmed that peak I was not fructose. The presence of a singlet resonance at δ 3.40 indicated a methoxyl group, and the remaining partially resolved resonances at δ 4.03–3.54 suggested that peak I may be a monomethyl cyclitol (Angyal and Odier, 1983) and in particular 1-*O*-methyl-*muco*-inositol (Angyal and Kondo, 1980). Integration of the spectrum supported this identification. A [^1H]NMR spectral comparison showed that peak I was not pinitol, which has a methoxyl group shift of δ 3.59. Furthermore, there was little similarity in the respective ring proton patterns. [^{13}C]NMR spectroscopy of peak I with complete decoupling showed that the molecule had a plane of symmetry. Chemical shifts relative to acetone at δ 30.6 were observed at: 82.1 (C-OCH_3), 72.6 ($2 \times \text{C}$), 70.4, 70.2, 68.5, and 58.1 (OCH_3). Peak I was observed to be optically active $[\alpha]_D^{20} = -25.2^\circ$ (c 0.28, water), and these combined data suggested that the unknown compound was (-)-1-*O*-methyl-*muco*-inositol (MMI) (Angyal et al., 1967). Comparative [^{13}C]- and [^1H]NMR spectroscopy with authentic MMI gave unequivocal identification.

Quantitative HPLC analysis with relative responses determined from authentic compounds gave only MMI and sucrose as 3.2% and 0.8% of the total dry weight of fresh green *C. tagal* leaves. Senescent leaves were shown to contain MMI (4.1%) and sucrose (0.8%); a minor peak with retention time relative to MMI (0.80) was also observed but not identified.

MMI has been found in most gymnosperms and some angiosperms (Dittrich et al., 1971). Its occurrence has not been reported in mangrove species, although a significant amount of pinitol has been reported in various mangrove species including *C. tagal* (Popp, 1984). However, GC alone was used for the identification of the "pinitol." Since it was not possible to resolve pinitol from MMI using the various chromatographic conditions described in our work, the now positive identification of MMI, by NMR spectrometry, intimates that Popp was mistaken in designating the *O*-methyl derivative as pinitol.

Anomalies in anticipated carbohydrate compositions were observed in the major operationally defined fractions obtained using traditional methods, e.g., α -cellulose contained arabinose and glucose in equal proportions, and contained 7% uronic acids instead of mostly glucose. High levels of uronic acids and arabinose also were found in most of the other fractions isolated in this way. So, although the yield of pectic substances from conventional oxalate extraction was low (4–6%), it was apparent that in total the leaves consisted of unusually high proportions of pectic substances. To circumvent the difficulties in interpreting these compositional data and consistent with a desire to preserve the chemical integrity of the leaf constituents, a simpler approach was chosen that produced extractives, EDTA (or water) -soluble and -insoluble components (Table 3). These fractions were then analyzed in detail (Table 4 and 7). Corresponding *N. smithi* fecal material was also studied using this approach (Tables 5 and 6).

As mangrove leaves contain a high content of (poly)phenolic material, an effort was made to estimate the contribution of flavonoids to the total phenolics in absolute methanol extracts of the major components of the leaves, namely the aqueous acetone extracts and EDTA-insoluble fractions (Table 3). The Folin-Ciocalteu reagent (Price and Butler, 1977) for total phenolics and the vanillin reaction (Burns, 1971; Ribereau-Gayon, 1972b), specific for phloroglucinol ring functionality in condensed tannins were evaluated.

Quantification was precluded by the presence of a colloidal haze in the Folin-Ciocalteu assay solutions of all samples, except intact senescent leaves (S0), which could not be removed by centrifugation (3000g, 10 min). Nevertheless, in qualitative terms, the total phenolics decreased from very high to very low in the extracts from S0 through to S8. The disappearance of these

^cGreen and senescent leaves contain 7.4 and 7.2% sodium chloride, respectively.

^dSenescent leaves subjected to biodegradation for two weeks, etc. . . . (Giddins et al., 1986).

components is due to leaching and to microbial degradation (Cundell et al., 1979; Giddins et al., 1986; Benner et al., 1986). Negligible amounts of the phenolics were found in the insoluble walls of the leaves, but further extraction of the walls with absolute acetone removed material that was soluble in absolute methanol and gave a strong Folin-Ciocalteu reaction with no haze.

Although this approach therefore was not applicable to these extracts, the above observations did reflect the complex nature of the phenolics in the leaves and exemplifies the inherent difficulty in estimating the contribution of condensed tannins to total phenolics in ecological studies (Mole and Waterman, 1987).

The leaching and degradative processes are further confirmed in Table 3 where there was a large reduction in the amount of acetone-soluble (pigments, free sugars, flavonoids, etc.) and polymeric water-soluble material contained in the aging leaf detritus. Without allowing for dry matter disappearance data, the relative proportion of the insoluble fraction which includes the cell walls, remained constant with time. The increased amount of dialyzable material (< 14,000 mol wt) in the older leaves is also indicative of the depolymerization processes occurring during decomposition.

Two capillary columns (BP20 and BP225) were evaluated for neutral sugar analysis. On the BP20 column, several artifact peaks eluted at R_t (retention time relative to internal standard) < 0.488 (vs. rhamnose 0.615), while mannose coeluted with inositol ($R_t = 1.537$), and glucose eluted before galactose (R_t s = 1.636 and 1.676, respectively). The BP225 column, on the other hand, eluted the artifact peaks at $R_t < 0.344$ (vs. rhamnose 0.485) and gave good separation of mannose, galactose, glucose, and inositol (R_t s = 1.122, 1.212, 1.292, and 1.335, respectively).

The carbohydrate data for the insoluble fraction (Table 4) show that green and senescent leaves have about the same amount of neutral sugars, while the senescent leaves have more uronic acids (predominantly galacturonic acid). The leaves have similar quantities of arabinose and glucose, which is unusual for the higher plants, and are rich in uronic acids. It is also worth noting that low yields of glucose indicate an unusually low concentration of cellulose in these mangrove leaves, especially since some of the glucose must be present as starch. This observation was supported by the low yield (ca. 9–11%) of α -cellulose (Table 2). The analyses confirmed that mangrove leaves have a large amount of pectic material. The composition changed dramatically during degradation. After eight weeks, carbohydrates were reduced by 70%, while apparent lignin content doubled, presumably because of the relative resistance of lignin to biodegradation. The apparent lignin material also includes insoluble polymers from the thick waxy cuticle that is characteristic of mangrove leaves. All of the carbohydrate constituents were reduced by biodegradation, but generally there was preferential digestion of pectates, reflected by the large reduction in arabinose

^a Determined by colorimetric assay against D-galacturonic acid standard.

and uronic acids. These data indicate that biodegradation of mangrove leaves introduces 182 g/kg dry matter of total carbohydrates into the environment for utilization as an energy source by microorganisms and higher animals. The unaccounted-for material from the analyses was 39–44% for green and senescent leaves and 23–41% for the degraded leaf samples. Since there is only ca. 3% protein in both types of leaves (Giddins et al., 1986), the discrepancy is most probably explained by the presence of acid-labile polyphenolic material, which has not been investigated further. The problem is associated with the large amount of tannins in mangrove leaves. Residual insoluble tannins have been observed in the neutral detergent fiber residues of other plant species that contain high levels of phenolics (Reed, 1986; McArthur, 1987).

Analysis of the *N. smithi* fecal material from crabs fed on leaf litter (Tables 5 and 6) shows that the crab does not utilize all of the available energy (carbohydrate) but releases into the environment energy in the form of undigested carbohydrates. All dietary constituent sugars were detected in the feces. The insoluble fraction contained a greatly reduced amount (7–11%) of carbohydrate and an enriched amount (27–39%) of apparent lignin. However, unlike the diet material, the fecal matter has reached a constant level of residual carbohydrate and higher lignin contents, indicating that a digestion-resistant fraction containing ca. 13.5% carbohydrate, which includes uronic acids, survives passage through the gut of *N. smithi*. The relative proportions of carbohydrate show that all polysaccharides are degraded to some extent by *N. smithi*'s digestive system and in particular there appears to be some cellulase activity, since the arabinose-to-glucose ratio increases from 0.68 to 0.90.

The composition of the water-soluble fraction in mangrove leaf detritus is given in Table 7. The complex trends in glycoside contents reflect the complex

^aTrace.

chemical nature of this material and of the degradative processes. The large quantity of acid-insoluble residue (phlobaphenes) and the formation of pink anthocyanidins in the acid hydrolysates is indicative of the high proportion of proanthocyanidin material in this fraction (Ribereau-Gayon, 1972c). The amount of anthocyanidins was highest in the extracts from green leaves and declined rapidly to be just detectable in S4 leaves. The neutral monosaccharide composition of the water-soluble fraction after hydrolysis was similar to that of the insoluble fraction, with arabinose, galactose, and glucose being the major sugars, while rhamnose, fucose, xylose, and mannose were the minor ones. The polysaccharide component in these fractions contained 35–89% uronic acids. These results confirm that pectates are complexed with or bonded to the proanthocyanidin. Poor recoveries were obtained from the analysis of these water-soluble fractions, and once again this loss could only be explained by the presence of a large amount of polyphenolic material that is acid-labile. In this case, agreement was obtained between GC and corrected phenol-sulfuric acid values for the carbohydrate measurements. However, it should be noted that due to interference by flavonoids, significant errors may result when the carbohydrate contents in flavonoid-rich materials are determined by phenol-sulfuric acid analysis (Rahman and Richards, 1987). A corresponding soluble fraction from *Rhizophora stylosa* was designated flavoglycan (Neilson et al., 1986a) during the preliminary investigation of the diagenesis of mangrove leaves, implying covalent linkages between flavonoid and polysaccharide components. One of us (G.N.R.) has subsequently found evidence that condensed tannin-polysaccharide complexes involve strong noncovalent interpolymer bonding (Rahman and Richards, 1988), and further studies are continuing on these complexes.

The leachate from mangrove leaves introduces a large amount of organic material into the mangrove environment. If the tannin concentrations in the soluble fraction are high, then the leachate is inhibitory to the uptake by organisms (Benner et al., 1986; Alongi, 1987), and this inhibition will extend to any carbohydrate material that may be bound to the tannins. Furthermore, leachable tannins have been demonstrated to significantly reduce consumption rates of mangrove leaves by *N. smithi* (Neilson et al., 1986b) prior to leaching. Nevertheless, Benner et al. (1986) have shown that 42% of some leachates can be utilized by microorganisms and are therefore available to animals in the estuarine food web.

Acknowledgments—Authentic D-1-O-methyl-muco-inositol was kindly provided by Professor S.J. Angyal. This study was financially supported by grants from the Australian Marine Science and Technology Grants Scheme.

Abstract—Male *Eulaema cingulata* (Fabricius) (Apidae: Euglossini) possess large cephalic labial glands that secrete a mixture of lipids. In the process of fragrance collection, males secrete the labial gland lipids onto the substrate. The mixture of lipids and fragrances is then taken up by the front tarsal brushes and transferred to the hind tibial organs. The labial gland secretions apparently serve as a nonpolar solvent and carrier that increases the efficiency of fragrance collection.

Key Words—Euglossini, *Eulaema cingulata*, Hymenoptera, Apidae, labial gland, lipid, fragrance, orchid, tibia.

INTRODUCTION

Euglossine bees (Apidae: Euglossini) are conspicuous members of the neotropical bee fauna. Male euglossine bees are noted for their unique behavior of collecting fragrances from flowers of orchids, aroids, and other plants and from rotting wood and fruits. The male bees possess numerous morphological specializations related to fragrance collection. Their front tarsi are modified into moplike brushes and their hind tibiae possess a deeply invaginated, hair-filled cavity. The male bees brush the surface of a flower or other source with the front tarsal brushes and then transfer the fragrance compounds (mostly mono- and sesquiterpenes and aromatics) to the hind tibial organs. We still do not know what the male bees do with the collected fragrances. Dressler (1982)

reviewed the biology and fragrance-collecting behavior of male euglossines; additional relevant works include Kimsey (1980, 1984), Schemske and Lande (1984), and Ackerman (1983).

Earlier investigation of male euglossine exocrine glands (Williams and Whitten, 1983) showed that the chemical contents of the cephalic glands and the hind tibial organs are similar; both contain a mixture of normal acetates, alcohols, alkanes, alkenes, and other lipids. Careful dissection and analyses have revealed that these cephalic lipids are produced by the labial glands, and not by the mandibular glands as we reported earlier. The hind tibial organ may also contain a variety of fragrance compounds including mono- and sesquiterpenes and simple aromatics.

The morphology of the hind tibial organ suggests that it may be more than a passive storage area for fragrances. The structure of the male hind tibia was summarized by Dressler (1982), and the ultrastructure of the tibial organ was studied by Cruz-Landim et al. (1965). The anterior surface of the hind tibia bears an elongate sunken pit ("scar") filled with long hairs. The collected fragrances are placed on these hairs and are drawn into the interior of the tibia by capillary action. A narrow canal connects the scar with the interior of the organ. The interior is filled with tangled, branched hairs that form a spongelike structure. Cruz-Landim et al. (1965) describe two distinguishable layers of glandlike tissue lining the organ. The presence of pinocytotic vesicles, microvilli, and numerous mitochondria suggest that the tissue is metabolically active, possibly involved in secretion or uptake of compounds and that it is not just a passive storage organ.

The presence of the same set of lipids in both the labial glands and the hind tibia is puzzling. Earlier, we hypothesized that the labial secretions might serve as pheromones, similar to their role in bumble bees (Williams and Whitten, 1983). We now present evidence that the male bees secrete large quantities of labial gland lipids onto fragrance-laden substrates, mop up the mixture with their front tarsal brushes, and then transfer the mixture to the hind tibial organs. These secretions probably serve as a nonpolar solvent to increase the efficiency of fragrance collection.

METHODS AND MATERIALS

In the present study, we posed the following questions: (1) What hexane-extractable lipids occur in the labial glands and hind tibial organs of male *Eulaema cingulata*? (2) Do the male bees secrete lipids onto the substrate from which they are collecting fragrances?

We studied the fragrance-collecting behavior of bees at two types of fragrance-bearing substrates: one artificial and the other naturally occurring. The

first consisted of squares of filter paper baited with skatole, a fragrance chemical known to attract *Eulaema cingulata*. The natural substrate consisted of wounded bark and wood of a leguminous tree, *Dalbergia cubilquitensis* Pittier, used for shading cacao at the study site. For several years, we have observed male *Eulaema cingulata* brushing on discolored trunk wounds of several of these trees. The wounds are mildly fragrant, and the bees are probably attracted by sesquiterpenes produced by the fungus-infected wound.

Field work was conducted during December 1986 at Estación Experimental La Lola near Siquirres, Limón Province, Costa Rica. Although the vegetation consists of managed cacao groves, the area supports high populations of several euglossine species. Samples (hexane extracts of plant or bee parts or of filter paper) were returned to Florida and analyzed by gas chromatography-mass spectrometry (GC-MS) using a Hewlett-Packard 5995B with a 30-m methyl silicone capillary column. Oven temperature was programmed from 40 to 290°C at 8°C/min; injection port temperature was 300°C. Most compounds were identified by comparison with authentic standards, and spectra of unidentified compounds were searched against the NBS mass spectral library.

Bee Gland Contents. Male *E. cingulata* were attracted to 4 × 4-cm blotter pads saturated with skatole. Eight bees were collected and the heads and hind tibiae extracted separately in vials containing 1.0 ml hexane. Samples were analyzed by GC-MS.

Lipid Secretion Experiment. To determine whether the male bees secrete lipids onto a fragrance-laden substrate during brushing activity, we allowed bees to brush on a filter paper substrate suspended over a fragrance source (blotter paper saturated with skatole). A 4-cm² hole was cut in the top of a plastic petri dish. A 9-cm round piece of filter paper was perforated with 5–10 holes using a paper punch to facilitate diffusion of skatole vapors. The paper was then secured to the inner surface of the cover. A small pad of blotter paper saturated with skatole was attached to the inside of the Petri dish bottom. The assembled dish allowed the skatole vapor to diffuse through the holes in the paper. Bees could brush on the surface of the paper without contacting the concentrated skatole below. Subsequently, the filter paper could be extracted and analyzed without the interfering presence of large amounts of skatole. Skatole-baited dishes were distributed in each of two habitats at La Lola during February 27–March 2. Initially, two dishes were suspended in cacao trees in the relatively open *Dalbergia* site and another two in the densely shaded Barker cacao site. For each of two subsequent days, three dishes were placed in each of these habitats. In order to estimate the number of bees visiting each paper, the number of bees present at each paper was recorded at two 2-hr intervals throughout the day. After 12 hr, the filter papers were removed and extracted with 2 ml of hexane. The extracts were analyzed by GC-MS.

Fragrance Accessibility. In order to test the hypothesis that bees might

deposit greater quantities of lipids on "dry" substrates that are not saturated with fragrances than on substrates that are saturated with fragrance compounds, we set out six skatole-baited Petri dishes in the Barker cacao site for 12 hr. Three of these dishes had the fragrance inaccessible on the blotter paper, as described above, whereas in the other three dishes the skatole was applied directly to the surface of the filter paper where bees could have direct contact with it. Collection and extraction of the lipids deposited on the filter paper were conducted as described above for the lipid secretion experiment.

Observations of Bee Behavior. We observed the behavior of bees at the skatole-baited Petri dishes to determine whether or not bees utilize their mouthparts, legs, and other structures in the deposition of lipids on substrate surfaces. While engaged in brushing behavior, the bees are much less wary than normal and can be approached slowly and observed at close range (0.5 m or less).

Dalbergia Tree Samples. To determine the distribution of compounds within the tree, samples of twigs, leaves, bark, and wood were collected and extracted in hexane. A tree corer was used to sample tree wounds. The cores were cut into 3-mm segments, and the segments were extracted separately in 1 ml of hexane. Samples were analyzed by GC-MS.

Bioassays. Crude field bioassays were conducted with several of the major compounds of the labial secretions of *Eulaema cingulata*, with extracts of *E. cingulata* heads, and with samples of *Dalbergia* wood. The compounds tested were synthetic tetradecyl, hexadecyl, and octadecyl acetates and all possible combinations of these compounds. One drop of the pure compound (or 1:1 v/v mixture) was applied to a blotter pad tacked at breast height on cacao trunks. Individual hexane extracts of male *E. cingulata* heads were applied to blotter pads ($N = 5$). All samples were monitored for bee activity for 5 min every hour from 800 to 1800 hr for one day. Core samples were taken from healthy, undamaged *Dalbergia* trunks ($N = 3$) and also from discolored tree wounds ($N = 3$).

RESULTS

Bee Organs. The major compounds present in the labial glands of male *E. cingulata* are tetradecyl, hexadecyl, and dodecyl acetates (Table 1). A series of normal alkanes and alkenes ranging from C_{25} to C_{33} is also present. The rank order of abundance of these compounds is highly consistent among individuals. The total quantity of labial gland lipids is more variable, ranging from 0.2 to 5.9 mg (mean = 4.6 mg).

The hind tibial organs contain the same set of compounds that is present in the labial glands, plus several other classes of compounds (Table 1). A wide variety of monoterpenes, sesquiterpenes, and aromatics may be present. These

compounds give the tibial extracts a perfumelike odor. The kind, number, and quantity of these fragrance compounds varies greatly among individual bees; this variation presumably reflects the varied sources (flowers, fungi, etc.) from which the compounds are collected. A second class of compounds in the tibial organs is tentatively identified as high molecular weight waxy esters. One homologous series consists of tetradecyl, hexadecyl, and octadecyl octadecenoates. The quantities of these waxy esters vary greatly among individual bees, and it is uncertain whether they are collected from floral and/or fungal sources or whether they are secreted by the bees. Some of these waxy esters may be present in the labial glands in small quantities.

Lipid Secretion Experiment. Most of the papers were heavily visited by fragrance-collecting male *E. cingulata* and *Euglossa dodsoni* Moure during the morning and early afternoon. After 12 hr, the exposed area of the filter paper was translucent, as though grease had been applied to the paper. The hexane extracts of the papers (Table 2) contained large quantities of the same lipids present in the labial glands of *E. cingulata*. Representative chromatograms of extracts of labial gland, hind tibia, and papers are shown in Figure 1. Also present were smaller amounts of the lipids present in the labial glands of *Euglossa dodsoni*, such as eicosenyl-1,20-diacetate and eicosenol. The quantity of total lipids deposited on the filter papers ranged from 2 to 55 mg (mean = 16.5 mg). The largest quantity represents about 12 glandular equivalents of *Eulaema* labial secretions deposited in 12 hr.

Dalbergia Bark Wounds. The wounds in the *Dalbergia* bark that attract *E. cingulata* are either natural, caused by insect damage, or are man-made wounds such as machete cuts. The natural wounds appeared as small holes (1–2 cm diameter) or fissures in the bark on either the main trunk at heights up to 5 meters or on small stump sprouts at the base of the tree. Fresh machete wounds

did not attract bees, but bees were observed at machete wounds that were 3–6 months old. The wounds visited by bees did not produce a liquid exudate, but the surface of the exposed wood was colored dark brown.

We observed male bees collecting fragrances from the wounds during vis-

FIG. 1. Representative total ion chromatograms of hexane extracts of *Eulaema cingulata* labial gland (A), hind tibia (B), and filter paper substrate (C) on which the bees had brushed. Note the qualitative similarity of the three chromatograms, except for the fragrance compounds present in the hind tibia (peaks from 4 to 12 min.).

its to La Lola over several years. Bees were seen at the wounds during November 1984, March and September 1985, and July and December 1986. No bees were seen during February 21–24, 1986. Most fragrance-collecting activity occurred between 800 and 1600 hr.

Analyses of extracts of the core samples from the tree wounds revealed three classes of compounds (Table 1). The first consists of several unidentified sesquiterpenes. The major sesquiterpene also occurs in the fragrance of the euglossine-pollinated orchid *Polycynis gratiosa* (Whitten, unpublished); therefore, it is likely that this compound is attractive to some euglossines. The second class of compounds includes all the major lipids found in the labial gland extracts of *Eulaema cingulata*. The third class of compounds consists of a group of unidentified compounds with distinctive mass spectra in which the base peak is also the apparent molecular ion. These compounds do not occur in the bee glands or in the fragrance of any orchid we have analyzed. Analyses of 3-mm segments of the core revealed that the lipids are present only in the surface layers of the wood (the outer 6 mm). The sesquiterpenes and the unidentified compounds are present deeper into the wood, including the heartwood (36–42 mm deep); the areas that contain these compounds are colored dark reddish brown and produce a pleasant aroma. The healthy, unpigmented wood from 12 to 33 mm deep contained no hexane-extractable compounds and was not fragrant.

Microscopic examination of wood sections from the tree wounds stained with lactophenol cotton blue revealed fungal hyphae; one sample from the pith of a wounded stump sprout revealed fruiting bodies suggestive of *Fusarium*. Fungal hyphae could not be detected in the highly discolored wood and heartwood because the ergastic substances masked the stain.

Bioassays. The field bioassays using the *Dalbergia* healthy bark and wood and the *Eulaema* cephalic extracts did not attract bees, but core samples of the tree wounds began attracting male *E. cingulata* within minutes of removal from the tree. Both the surface layer of the wound and also the deeper heartwood were fragrant and attracted male bees ($N = 4$, surface; $N = 6$, heartwood).

Bee Behavior. Although fragrance-collecting bees can be observed at close range, the rapidity of movements makes observations of behavior difficult. On all substrates, the bees land on the substrate and usually touch the substrate rapidly with their half-open mandibles. The substrate is then brushed intensely with the front tarsal brushes, with the antennae touching the same area of the substrate. Brushing may continue for up to $1\frac{1}{2}$ min. The bees then hover and transfer the collected material from the front tarsi to the basitarsal comb of the midleg, and then to the slit of the hind tibial organ. This behavior has been described in detail by Kimsey (1984). However, the bees occasionally wipe the mouthparts with the front tarsal brushes during hovering and transfer behavior. Our observations suggest that labial secretions might be applied to the substrate

either directly via the mouthparts or indirectly via the front tarsal brushes. More careful observations with high speed cinematography are necessary to determine how the lipids are applied to the substrate.

DISCUSSION

Male euglossines possess large cephalic labial glands that produce copious amounts of various lipids. The hind tibial organs also contain these lipids, together with a variety of fragrant compounds presumably collected from flowers or fungus-infected wood. The labial gland secretions of male euglossines are chemically similar to those of *Bombus* and other apid bees (see review by Duffield et al., 1984). Male *Bombus* appear to use their labial gland secretions to mark territories and to attract females (Kullenberg et al., 1970, 1973). There is no evidence that euglossines use their labial secretions in a similar manner (Kimsey, 1980), and we know of no reports of marking behavior in euglossines.

It is possible that the lipids are secreted by the hind tibial organs or by the front tarsi, but the size and contents of the labial glands makes them the most probable source. We presume that the lipid secretions are also applied to the surface of orchids and other flowers visited by fragrance-collecting male euglossines. Unfortunately, none of the euglossine-pollinated orchids (e.g., *Catasetum*) were in flower at the field site during our study. The accessible vs. inaccessible fragrance experiment showed that the bees applied large amounts of lipids to the substrate in both cases.

The *Dalbergia* wounds that attract male *E. cingulata* contain a large number of chemicals whose origin and attractiveness to the bees is uncertain. The data presented above suggest (but do not prove) that the bees are attracted to the wounds by volatile sesquiterpenes produced by microorganisms in the wound or produced by the infected wood. The lipids are present only in the surface layers of the infected wood. This superficial distribution is consistent with the hypothesis that the bees secrete these lipids onto the wood and that the lipids are not secreted by the tree or by fungi.

We hypothesize that these lipids are used by the bee to increase the efficiency of fragrance collection by serving as a nonvolatile, nonpolar solvent to dissolve and retain the fragrance compounds. In the process of brushing and the transfer of fragrances to the hind tibiae, there might be considerable loss of highly volatile monoterpenes due to the rapid air currents around the hovering bee. Also, the fragrances might evaporate from the surface of the hind tibial slit before being drawn into the inner cavity of the tibia. By mixing the fragrances with an oily carrier such as the labial secretions, the losses due to evaporation should be greatly reduced, and the efficiency of fragrance collection might be greatly improved. The use of lipids to dissolve and retain flower fra-

grances has long been used by the perfume industry in the "enflourage" technique. In this method, flowers are laid upon sheets of glass that are coated with a thin layer of grease. The volatile fragrances emitted by the flowers dissolve into the grease, and the grease is removed and extracted to produce a floral essence. It appears that euglossine bees use lipids in a similar manner to collect and retain floral "perfumes."

The data presented above suggest that fragrance-collecting euglossines might accumulate large amounts of labial gland lipids in the hind tibial organs. Since the bees may live and collect fragrances for several months, some mechanism must exist for removing lipids from the tibial organ; otherwise, the organ would quickly fill with nonvolatile lipids. We speculate that the labial lipids are taken up selectively across the highly invaginated inner lining of the tibial organ, leaving the fragrance compounds in the tibial cavity, and that the lipids are either catabolized or are translocated back to the labial gland for reuse. The interior surface of the tibial organ, with its high surface area and metabolically active lining, appears well-adapted for the uptake of chemicals from the cavity. The transport of the lipids might occur via a lipophorin transport system, as described in other insects by Chino and Downer (1982). Tracer experiments indicate that deuterated hexadecyl acetate is rapidly translocated from the hind tibiae to the labial gland (Whitten and Williams, unpublished).

If such translocation and recycling of labial gland lipids does occur, then the glandular and fragrance collecting apparatus of male euglossines can be regarded as a sort of chemical conveyor belt. The labial gland secretions are applied to the substrate and carry the fragrances into the hind tibial organ, and then the lipids might be recycled to the labial gland for reuse. Such recycling of lipids might be adaptive in two ways. First, it removes lipids from the hind tibial cavity, thereby preventing it from filling with lipids and allowing further uptake of fragrances. Second, it conserves an energetically expensive exocrine product.

This study does not address what the bees do with the collected fragrance compounds; tracer experiments with labeled fragrances have not been performed. At present, there is no evidence that the fragrance compounds are metabolized or are translocated from the hind tibial organ. We hypothesize that the male bees accumulate large quantities and varieties of fragrances in their tibia and that the fragrances are somehow used in the courtship of female bees. The fragrances contained in the hind tibia can volatilize from the organ, and live, captive bees are fragrant to the human nose (and presumably to other bees). The tibial "bouquet" might serve as an indicator of male fitness to females.

The role of euglossine labial secretions in fragrance collection represents a novel use of labial secretions among bees. However, fragrance-collecting behavior has also been reported from anthophorid bees (Norden and Batra,

1985). Male *Centris* chew the stems of parsnip plants and absorb the fragrant juices in specialized labral "moustaches." The bees then mark objects in their territories by rubbing the objects with the moustaches. It would be interesting to analyze the applied juices to determine whether *Centris* might also use labial gland secretions as a carrier for plant volatiles.

Acknowledgments—Field work was supported by a grant from the American Cocoa Research Institute to A.M. Young, and laboratory work was supported by the Florida State Museum. We wish to thank the staff of CATIE and Estación Experimental La Lola for their cooperation and hospitality.

QUANTITATIVE BIOASSAY FOR CHEMOTAXIS WITH PLANT PARASITIC NEMATODES

Attractant and Repellent Fractions for *Meloidogyne incognita* from Cucumber Roots

(Received April 21, 1988; accepted June 15, 1988)

Abstract—A simple, flexible, and quantifiable bioassay for the attraction or repulsion of plant parasitic nematodes to or from root fractions or pure substances is described. Accurate gradients of volatile and nonvolatile substances can be measured and established. The method entails placing the nematodes in narrow agarose tracks such that their movement is essentially linear and the distance a population has traveled away or toward a given substance can be monitored with time. Plastic plates, each containing 10 such tracks, are described. The method is illustrated with second-stage larvae of *Meloidogyne incognita* and a volatile attractant and nonvolatile repellent fraction obtained from cucumber roots.

Key Words—Chemotaxis, bioassay, nematodes, *Meloidogyne incognita*, attractants, repellents, cucumber roots, gradients.

INTRODUCTION

In 1925, Steiner proposed that plant parasitic nematodes located their hosts by chemoreception (Steiner, 1925). In support of this view, it is now well established that nematodes accumulate about the roots of host plants (Lownsbery and Viglierchio, 1960, 1961; Azmi and Jairajpuri, 1977; Prot, 1980; Prot and Van Gundy, 1981). Moreover, a range of plant parasites including *Heterodera schachtii* and *Meloidogyne hapla* (Viglierchio, 1961), *M. javanica* (Riddle and Bird, 1985), *Aphelenchoides besseyi* (Lee and Evans, 1973), *Hirschmanniella*

oryzae (Bilgrami et al., 1985), and others (Green, 1971) has been demonstrated to be attracted or repelled by plant roots and their emissions. Furthermore, a leaf attractant for *Orrina phyllobia* has been extracted from *Solanum elaeagnifolium* (Robinson and Saldana, 1988). However, none of the substances responsible for any of these interactions has been isolated or identified. While knowledge of the character of root emissions has increased (Schwab and Leonard, 1984; Thompson, 1985), no specific set or subset of these compounds has been delineated that elicits chemotaxis from nematode parasites.

On the other hand, β -myrcene has been found to be a potent attractant for the pine wood nematode *Bursaphelenchus xylophilus* (Ishikawa et al., 1986). In addition, simple inorganic salts of Na^+ , Mg^+ , Cl^- , and OAc^- have been reported recently to attract *Rotylenchulus reniformis* (Riddle and Bird, 1985). The polar structures AMP and cyclic AMP were also attractive to this species, as were germinated host plant seeds. In contrast, *M. javanica* was only attracted to tomato seeds. An apparently general attraction to carbon dioxide (Klinger, 1965; Pline and Dusenbery, 1987) and oxygen (Dusenbery, 1983) has been noted. The response of male *Heterodera glycines* to a variety of substances has been examined (Huettel and Jaffe, 1987). The literature (with reference to the free-living nematode *Caenorhabditis elegans*) has been summarized (Dusenbery, 1983; Ward, 1973). Potential mechanisms for host or prey recognition have been reviewed (Dusenbery, 1983; Zuckerman and Jansson, 1984), and host or prey lectin-nematode carbohydrate interaction has been proposed as a general basis of recognition. The subject of recognition in plant diseases (primarily fungal) has also been generally reviewed (Daly, 1984).

Apart from plant roots, certain nematophagous fungi are known to attract nematodes (Zuckerman and Jansson, 1984; Balan et al., 1976; Klink et al., 1970; Jansson and Norderling-Hertz, 1983). Infection occurs specifically at the chemosensory organ (Jansson and Norderling-Hertz, 1983). Again, no structures have been forthcoming, but a lectin-carbohydrate interaction is suspected (Zuckerman and Jansson, 1984). It should be noted that root exudates can also be repellent (Diez and Dusenbery, 1986) and, in addition, have long been known to induce hatching of certain nematodes (Balam et al., 1949; Carroll, 1958; Hartnell et al., 1960; Jatala et al., 1977; Turner and Stone, 1981; Tanda, 1985). The structure of one such hatching entity, glycinoecleptin, has been characterized recently (Fukuzawa et al., 1985). A variety of simple chemicals can also produce this effect (Clarke and Shepherd, 1966; Jantzen, 1968; Okada, 1972; Greet, 1974; Clarke and Hennesey, 1983). Molting can also be induced by carnation root diffusates (Rhoades and Linford, 1959) and other substances (Shepherd and Clarke, 1971). The potential importance of these various chemosensory processes to nematode control has been summarized by Dusenbery (1987).

Several methods have been employed to assess the attractiveness of materials to nematodes. These range from photographing the tracks (Riddle and Bird,

1985; Ward, 1973) of the animals placed at the perimeter of an agar Petri plate as they move or not to the center (where the attractant is placed) to a video monitoring of all movements with time (Pline and Dusenbery, 1987; Dusenbery, 1983). Simply counting the nematodes in zones of a Petri plate at various distances from the root fragment has also been employed (Bilgrami et al., 1985), as has the aggregation of nematodes under paper disks placed upon such plates (Robinson and Saldana, 1988).

Our bioassay is designed around the concepts of simplicity and effective linear movement of the nematodes. We wanted: (1) the ability to quantitate both nematode movement and chemical gradient; (2) reproducibility; (3) flexibility of individual experimental design (e.g., competition between two attractants, a variety of concentrations, etc.); (4) the capacity to use very small amounts of substance as attractant or repellent; (5) a design that would not lose volatiles, and (6) to give the nematodes equal opportunity to move away from or toward a substance or fraction. In this work we describe such an assay and illustrate its effectiveness with attractant and repellent fractions obtained from cucumber roots for second-stage larvae of the plant parasite *Meloidogyne incognita*.

METHODS AND MATERIALS

¹⁴C-Labelled glycerine, glycine, and *n*-propanol were commercial samples (New England Nuclear) and used without purification. Agarose was obtained from International Biotechnology, Inc.

Second-stage larvae of *M. incognita* (MiL₂) were obtained from female egg masses isolated from tomato roots. Cut roots were blended in 3% commercial bleach. Eggs were washed through 40- and 170-mesh screens and collected on a 500-mesh sieve and washed. They were placed on a filter paper above a deep Petri plate. Hatching was best at 26°C. After collection and storage at 15°C, the settled larvae are concentrated by decanting.

Cucumber root exudates and fractions were obtained by three procedures. The first consisted of immersing the roots of young plants in tap water and aerating them for one day. In the second, larger batches of plants grown in vermiculite were leached once after four days and resupplied with fresh water. After 24 hr, the water from the root matrix was withdrawn. The third procedure, similar to the second, entailed holding the plants in a large pan in a sealed glove bag. Gases and volatiles from the aeration were passed through a series of traps.

Aqueous exudate fractions (6 liters) were filtered and concentrated on a rotary evaporator at 45°C and water pump pressure of ~20 mm. The dry concentrate was either extracted directly with cold 95% ethanol or triturated with 10 ml of water and extracted with methylene chloride. The methylene chloride extract was stripped on the rotary evaporator and dissolved in 1 ml of 95%

ethanol. The distillate and constituents of the ice or CO₂ trap preceding the water pump were also extracted with methylene chloride, concentrated, and taken up in ethanol. Note: 1 μ l of neat ethanol used in the bioassay procedure (see below) had no effect upon the nematodes.

Bioassay. We have designed a block and lid bioassay device from Lucite (polymethyl methacrylate), transparent plastic blocks that contain 10 parallel tracks, 90° V grooves 2 mm deep and 4 mm across the top. Each groove is 7.5 cm long. The block is sealed at each end. Corners are rounded. Overall outer dimensions are 9 × 8.5 × 1.3 cm. All faces are polished and flat. In addition, each block is fitted with a transparent gasket and lid; the lid has the same outer dimensions as the block but is thinner (0.5 cm). The lid is manufactured such that when screwed to the bottom block (a thumb screw at each corner) ten 1-mm holes in it are aligned exactly with the center of each track. The thin flexible gasket is lined at right angles to the tracks from the center out every 0.5 cm. A small center section is cut from the gasket to allow access to the tracks from the holes in the lid. The gaskets were cut from a polyester "plain paper copier transparency film" (Minnesota Western). The lines were copied onto the gasket sheet with a photocopying machine. One of the "race blocks" is sketched close to actual size in (Figure 1). (Appropriately placed holes in the gasket can replace the center cutout. This latter form of gasket is more appropriate for testing volatile substances.) The unit is arranged such that examination of the plates with a dissecting scope allows one to see the grid marks (gasket) and the nematodes along the various sections of each track.

For maximum nematode mobility and visibility, each groove is supplied with 150 μ l of warm 0.8% agarose. Thus, each 0.5-cm section of the 7.5-cm track contains 10 μ l of matrix. In this way, the level of the matrix in each groove is about $\frac{2}{3}$ up from the bottom. This allows for a layer of air over each entire track length. Substances or root fractions are injected or not into the end of each agarose track via hypodermic syringe. The gasket and lid are fastened in place. After a suitable time, the nematodes are injected in aqueous suspension into the center of each track via the alignment holes; usually 50–100 animals in 1 μ l are placed in each track. Because of condensation, counts are best made with the tracks upside down. Counting nematodes in a track requires 5–10 min; events are recorded at specific times as the number of nematodes in each section. Several concentrations and controls can be run on the same block in each experiment.

Gradients. Concentration time gradients for glycerine, glycine, and *n*-propanol in the tracks were determined using ¹⁴C-labeled substances. Thus, 1 μ l of an aqueous solution of substrate is injected into the end of each track such that the end 0.5-cm section will be at the desired concentration (e.g., 10⁻³ M). At intervals, tracks were sectioned at each 0.5 cm and each section was dis-

persed in Packard Insta-Gel Counting Solution and counted with a Packard Tri-carb model 3255 liquid scintillation counter with automatic external standard. Reproducibility of gradient concentrations in each section was $\pm 5\%$. Several gradients are shown in Figure 2.

Quantifying the Assay. While the graphs of nematode population with time (Figures 3-5) allow a qualitative assessment of attraction or repulsion by visual examination, these data can be more simply quantified. We define an attractant-repellent ratio at time t as $(A/R)_t$. This is equal to the ratio of the population densities weighted for the distance they have moved towards or away from a given substance or fraction. Thus, for any track or for the average counts from a number of replicate tracks summation $A = \Sigma(N)(D)$ where N = the number of nematodes in each 0.5-cm section and D is the distance of the center of the section from the middle starting point. For our tracks the fixed D values are

FIG. 2. Gradients of glycerine, glycine, and *n*-propanol.

0.25, 0.75, 1.25, 1.75, 2.25, 3.25, and 3.5 cm. The units for *A* are nematode-centimeters (*n*-cm). A similar expression represents *R*. In this case the counts are taken from the center towards the end of the plate away from the side end into which the test fraction is placed. In our work we have arbitrarily chosen to add the substrate to the end section at the right side of the plate. Thus, in the figures, movement to the right represents attraction and movement to the left represents repulsion. Finally, for control runs, the *A/R* ratio should equal 1. From many repeated control runs we find $A/R = 1 \pm 0.2$. The data in Figure 4 illustrate one set of trials representing the average of four individual tracks on two separate plates. The number of animals in the corresponding section in each track was summed and divided by 4. The $(A/R)_i$ was calculated using the average *N* for each section. We have used this as a standard procedure throughout. That is, all the plots in Figures 3-5 are an average of three to four individual tracks and the reported *A/R*s are calculated from the average *N* values. As an

FIG. 3. Response of second-stage larvae of *Meloidogyne incognita* (MiL₂) to cucumber distillate (placed at right side).

FIG. 4. Control response of MiL_2 .

illustration of reproducibility, the A/R values for each track at 6.5 hr in Figure 4 are 1.0, 1.1, 0.8, and 1.2 (average, 1.0 ± 0.2). For controls, the averaged A/R values are reproducible within $\pm 20\%$ as indicated above. A repellent fraction with an $(A/R)_5 = 0.33_3$, when tested one month later showed $(A/R)_5 = 0.33_3$. However, we find generally that the precision with the attractant and repellent fraction is also $\pm 20\%$. While statistically valid interpretation may be made with smaller differences, we have chosen to designate an attractant frac-

FIG. 5. Response of MiL_2 to cucumber concentrate (placed at right side).

tion as one demonstrating an $(A/R)_5 > 2$ and a repellent fraction as one possessing an $(A/R)_5 < 0.5$. With this nematode the A/R at 5 hr or 20-24 hr could be used. The former is quicker to obtain, and we employ a single count (in replicate) at this time as a standard. These ratios will vary, of course, with the concentration of substance originally employed and the nature of its gradient.

As a precautionary procedure, once the plates are inoculated with nematodes, they are stored in styrofoam boxes and placed in an incubator at 24°C

between counts. This is about 1°C above the average laboratory temperature. This procedure minimizes any thermal response by these animals.

RESULTS AND DISCUSSION

The time when nematodes are inoculated into the tracks can be crucial. Thus, if a suitable gradient has not been established, the nematode sensory apparatus could be either swamped or have nothing to detect. In either case, animals will move away or toward the substance with equal intensity. The ideal situation would be to have a very low concentration of chemical at the center of the track with increasing concentration to one side and none or little to the other. Measured gradients with glycerine, glycine, and *n*-propanol are shown in Figure 2. The correct gradient pattern is established in 22–24 hr for these water-soluble substances. Thus, we have arbitrarily chosen 22 ± 2 hr as the time interval (ΔT) between addition of test fraction and inoculation of the nematodes. For unknown volatiles we have varied ΔT from 5 to 24 hr. Best results were obtained with ΔT s of 20–24 hr. With *n*-propanol a gradient was established even though 80% of the original material was lost to the atmosphere in this time.

Typical results with two fractions from cucumber roots and a control set are shown in Figures 3–5. Appropriate *A/R*s are in the figures; each plot represents an average count from three to four individual tracks.

There are several notable features. First of all, the control runs exhibit an *A/R* at all times of approximately one. For this set, $A/R = 1 \pm 0.1$ but from many experiments of this kind, we find the general range to be 1 ± 0.2 . Figures 3–5 also illustrate the development of population densities with time. As noted in the experimental section, a replicated count at 4.5–5 hr reliably assesses the nematode response. While counts can be taken at any time, we have chosen 5 hr as standard for the routine assessment of characteristic response. Different larval stages and different species may react at different rates. An initial qualitative scan with time is essential for fixing a routine regimen. Responses can also vary with the viability of a population. For example, in some runs, the animals can be dead at the 24 hr count or sooner. The best time is the shortest that allows the response to be reliably assessed. With this nematode, repeat counts at 10 min, 1, 2, 4, 6, 12, and 24 hr established the 4- to 6-hr period as the best counting time.

Figure 3 illustrates the attraction of *Mi* larvae to a fraction of the “distillate” from cucumber roots. Clearly, the 1-hr count was already indicative of the response. The *A/R* ratio does increase at longer times, but it is not necessary to wait 24 hr for the pattern to emerge.

Figure 5 depicts the response of the second-stage larvae to a repellent frac-

tion obtained from the "concentrate." Again, a clear response is discernible in 4–6 hr.

Finally it should be noted that neither of these cucumber fractions increases the speed of nematode movement, that is, the population densities at 4.5 hr in these illustrations are greatest at 1.5 cm in all cases. With repeated measurements we find the average rate of locomotion of this larval stage is ~ 1.5 cm/5 hr. or 0.3 cm/hr. This result is in agreement with those assessed by more elaborate means (Pline and Dusenbery, 1987). On the other hand, if a given substance were to cause an increase in the rate of movement, the assay would have the capacity to detect it.

It should be emphasized that pheromones (Bone, 1980) could play a role in the movements observed but they cannot explain them; that is, at the outset and in the early stages, even numbers of animals are left and right of center. Moreover, while the responses of different populations may differ, these factors too are eliminated from significance by the experimental design. Thus a slower or longer time may be required for the plate to "develop," but any observed response is valid. In all cases, in every track, a population is essentially run against itself. In addition, "controls" can be run on the same plate.

In summary, this bioassay offers a clear interpretation of attraction or repulsion that can be quantified. Thus, with known structures, precise gradients and relative attraction indices can be established with specific animals. Moreover, the method can be applied to the detection of unknown attractants and repellents. We are currently exploring the nature of these unknown substances, and we are beginning to build a base of responses of second-stage larvae of *Meloidogyne incognita* and other nematodes and larval stages to a variety of known substances.

Surprisingly, different fractions of the same plant root contain both an attractant and a repellent. The former is volatile (steam distillable). The latter is not. Speculation as to the significance of this in the life cycle of the plant-nematode interaction is appealing but an explanation awaits the structure of the substances and the timing of their generation.

Acknowledgments—We thank Mr. Dan Rios for skillful manufacture of the test plates.

STRIKE-INDUCED CHEMOSENSORY SEARCHING OCCURS IN LIZARDS

WILLIAM E. COOPER, JR.

*Department of Biology
Auburn University at Montgomery
Montgomery, Alabama 36193*

(Received April 5, 1988; accepted June 23, 1988)

Abstract—Strike-induced chemosensory searching (SICS), previously known only in snakes, is experimentally demonstrated in a lizard, *Varanus exanthematicus*. Tongue-flicking rate was significantly greater after striking the prey than following three control conditions. The occurrence of SICS in a varanid lizard suggests that SICS may serve to help relocate dropped or escaped prey not only in snakes, but in other squamates that use the tongue as a chemosensory sampling device during foraging. This in turn suggests the need for further studies of the taxonomic distribution of SICS in squamates and of its relationship to tongue use during foraging and feeding.

Key Words—Lacertilia, *Varanus exanthematicus*, Varanidae, prey odor, tongue-flicking, chemosensory searching.

INTRODUCTION

Strike-induced chemosensory searching (SICS), an elevated tongue-flicking rate observed in snakes following biting, presumably helps these predators to find and follow odor trails of released or escaped prey. It is distinct from trailing itself, being restricted to the increased tongue-flicking rate (Chiszar et al., 1983). The term SICS may thus be interpreted as a poststrike elevation in tongue-flicking rate with no necessary implication that SICS facilitates location of prey by lizards. The elevation in tongue-flicking rate is a specific sequel of striking; rattlesnakes show much higher tongue-flick rates after striking prey than after detecting prey odors (Chiszar and Scudder, 1980). Rattlesnakes also follow scent trails of prey with higher probability after striking and envenomating than after merely seeing (and perhaps smelling by primary olfaction) the prey with-

out striking (Golan et al., 1982). SICS has been studied primarily in venomous snakes that employ a strike-release-trail strategy, which allows them to eat dangerous prey with a greatly reduced chance of being injured (e.g., Chiszar and Scudder, 1980; Chiszar et al., 1982, 1983, 1985, 1986; O'Connell et al., 1982, 1985; Radcliffe et al., 1986).

SICS has also been demonstrated recently in two species of nonvenomous snakes that do not use a strike-release-trail strategy (Cooper et al., 1988). Thus, SICS may have evolved initially to facilitate location of prey known to be nearby, prey that escaped after being bitten. If this hypothesis is correct, SICS might well occur in any squamate that uses the lingual-vomer nasal system extensively during foraging. Occurrence of SICS in a widely foraging lizard such as a monitor (*Varanus*) would be consistent with this hypothesis but would greatly diminish the tenability of the hypothesis that SICS evolved initially in venomous snakes as part of the strike-release-trail strategy.

It was felt that varanids were the lizards most likely to exhibit SICS because varanids have advanced snakelike tongue structure and function, tongue-flick extensively during social situations and during active foraging, and accurately discriminate prey odors from control odors in tongue-flicking tests. Members of the family Varanidae are noted for tongue-flicking during social encounters, especially at their outsets (Auffenberg, 1981; Moehn, 1984; Davis et al., 1986), and during active foraging (Vogel, 1979; Auffenberg, 1981, 1984). The mechanism of transport of chemical cues from the tongue to the vomeronasal organ has not been directly demonstrated in any lizard and the tongue's tips appear not to enter the vomeronasal cavity in monitors (Oelofsen and van den Heever, 1979). However, molecular transfer from tongue to vomeronasal epithelium has been shown in the garter snake (*Thamnophis sirtalis*) (Halpern and Kubie, 1980). Furthermore, there is ample evidence that lizards of several families respond to prey odors and conspecific odors detected by tongue-flicking (e.g., Burghardt, 1973; Duvall, 1979; Simon, 1983; Cooper and Vitt, 1984, 1986; Von Achen and Rakestraw, 1984). In the only laboratory study of varanid responses to prey odors, *V. exanthematicus* fed a consistent diet of mice (*Mus musculus*) in the laboratory show significantly higher tongue-flick attack scores in response to cotton-tipped applicators bearing mouse odors than to those bearing water or cologne (Cooper, 1988).

Varanid tongues appear to be more structurally and functionally specialized as chemosensory sampling devices for the vomeronasal system than those of other lizards. The lingual structure is more similar to that of snakes than that of other lizards in being long and narrow with highly developed tines (McDowell, 1972) and in being devoid of taste buds (Schwenk, 1985). In *V. exanthematicus* the tongue is primarily a chemosensory sampling device that plays no part in food transport during feeding (Smith, 1982). During tongue-flicking, a greater relative area of air is sampled by varanids than by other

lizards. The relative area sampled is comparable to or greater than that of several species of advanced snakes (Gove, 1979).

This study was designed to determine whether SICS occurs in the savannah monitor, *Varanus exanthematicus*. Because this lizard does not normally release living prey after biting, it was necessary to pull the prey from the lizard's mouth. This further required an experimental control for effects on tongue-flicking rate of handling the lizard in addition to the usual controls for disturbance caused by opening the cage, presence of the experimenter, and visual prey cues.

METHODS AND MATERIALS

Seven savannah monitors obtained from a commercial dealer were between 284 and 352 mm snout-vent length. Although these lizards appear to feed primarily on invertebrates in the field (Cisse, 1972), they readily consume mice (*Mus musculus*) in the laboratory. The lizards were housed in a laboratory building having translucent walls and a retractable roof that was opened on clear days. They were housed individually in $49 \times 49 \times 32$ cm glass terraria. Each terrarium contained a sand substrate and water bowl and was covered by a hardware cloth top. Prior to the experiment, the lizards were fed almost exclusively living adult mice.

Each individual was tested in four stimulus conditions, one per day, in random sequence, on May 25-29, 1987, at temperatures from 32.8 to 34.5°C; no tests were conducted on May 27. One condition was a disturbance control (forceps condition) for effects of the presence of the experimenter's hand and opening the cage on tongue-flicking rate. In this condition, the cage top was opened and the experimenter's hand and feeding forceps were placed in the cage for 10 sec and then removed. The ends of the forceps were positioned approximately 10 cm anterior to the monitor's head in this and the other conditions. The second experimental condition consisted of visual presentation of a living adult mouse (mouse condition) for 10 sec without allowing the lizard to closely approach or attack. If the lizard attempted to attack, the mouse was immediately withdrawn. The third stimulus condition served as a control for the effects of pulling bitten prey and lizard apart (pull condition). In this condition, the lizard was pulled away from the mouse just before biting the mouse. When immediate attack seemed probable, as indicated by the lizard's approach and posturing, the experimenter rapidly withdrew the mouse and simultaneously grasped the lizard, pulling it away from the mouse to prevent any oral contact. In the fourth stimulus condition, the mouse was pulled out of the lizard's mouth immediately after having been bitten (strike condition).

Tongue-flicks were counted in all conditions for 2 min after termination of the experimental stimulus. Data were analyzed for homogeneity of variance by

Hartley's test, were square-root transformed, and then were analyzed by a repeated measures design (randomized blocks). Individual comparisons among means were made using Newman-Keuls tests (Winer, 1962). Statistical tests were two-tailed with $\alpha = 0.05$.

Although counterbalancing the order of conditions would have been preferable to randomization, too few specimens were available. The sequences actually used showed little deviation from an incompletely counterbalanced design. In the first two and second two trials, the conditions occurred with the following frequencies: forceps condition (3, 3), mouse condition (2, 4), pull condition (3, 3), and strike condition (2, 4). Sequence had no effect on rank tongue-flick rate for individuals. The two lizards in which the strike condition came last had much higher rates in the strike trial than in the others, indicating that the effect does not disappear due to rapid habituation to the general experimental situation.

Testing for the presence of SICS is a difficult experimental problem because handling or similar mechanical disturbance cannot be readily avoided. The experimental design used here seems drastic at first encounter. It is initially somewhat disturbing or offensive because experimenters usually take great pains to avoid disturbing subjects in behavioral studies. Two problems are that (1) the increase in tongue-flicking rate attributed to striking could have merely represented greater disturbance in the strike condition than in the other conditions and (2) there is no adequate control for tactile stimulation to the mouth resulting from pulling the prey out of it. In the study on SICS in nonvenomous snakes, these problems were addressed by determining tongue-flick rates in garter snakes in a control study. In each trial, the experimenter picked up a snake and then forced into its mouth a cotton-tipped applicator bearing either distilled water only or distilled water plus prey odor. Tactile stimuli and mechanical disturbance were identical in the two conditions, yet the snakes emitted much higher tongue-flick rates in the 5 min following the fish odor presentation (Cooper et al., 1988). Thus, it appears that neither mechanical disturbance nor tactile stimulation to the mouth produce spurious indication of SICS and that the experimental design used is appropriate.

Pulling the monitors by hand is an essential control condition for this experiment because separating the lizards from bitten prey required pulling the prey out of their mouths by simultaneously grasping lizard and prey. Pulling is a rather drastic disturbance in both the strike and pull conditions. Grasping a snake in itself may produce an increase in tongue-flicking rate (Scudder and Burghardt, 1983). In a study of SICS in garter snakes (*Thamnophis sirtalis parietalis*) and corn snakes (*Elaphe g. guttata*), pulling the snakes and visually presenting prey induced roughly equal increases in tongue-flick rate (Cooper et al., 1988). Importantly, in both species, a significant further increase occurred when the snakes were allowed to strike prior to being pulled.

RESULTS

The monitors tongue-flicked in all conditions, often at substantial rates when exposed to prey. There was substantial behavioral variation among individuals in tongue-flicking rates, with one individual having the highest rate in three of the four conditions and another the lowest in two of four. Attack behavior also varied in its dependence on chemical cues. One lizard attacked immediately in all conditions, with no apparent chemosensory investigation. Its data were discarded, reducing the sample size for analysis to six. Tongue-flicking rates in the 2 mins following stimulus removal differed greatly among treatments, with the highest rates being elicited by strikes and the lowest by merely opening the cage and presenting a hand (Figure 1).

Because between-condition variances were not homogeneous (Hartley's $F_{\max} = 34.17$; $df = 4, 5$; $P < 0.05$), data were subjected to square-root transformation. Variances of the transformed data were homogeneous ($F_{\max} = 9.25$; $df = 4, 5$; $P > 0.05$). Using transformed data, the main treatment effect was

FIG. 1. Tongue-flicks emitted by *Varanus exanthematicus* in the 2 min following removal of the experimental stimuli. F = presentation of empty forceps for 10 sec. M = presentation of forceps and mouse for 10 sec. P = pulling lizard away from prey just prior to strike. S = lizard allowed to strike prey, but prey then removed. Data shown are means (horizontal lines) ± 1 SE.

highly significant ($F = 20.54$; $df = 3, 15$; $P < 0.001$). Newman-Keuls tests revealed that the mean tongue-flicking rate following striking was significantly greater than that in each of the other conditions at $P < 0.01$. Visual presentation of the mouse plus pulling the lizard away from mouse when striking was imminent (pull condition) induced significantly higher tongue-flicking rates than did the disturbance control (forceps condition) without prey ($P < 0.05$), but the substantial difference between rates for visual presentation alone (mouse condition) and for disturbance (forceps condition) did not quite attain significance. Neither did the rates for visual presentation of prey (mouse condition) and visual presentation plus pulling the lizard (pull condition) differ significantly.

DISCUSSION

The primary finding is that SICS occurs in a lizard. A poststriking increase in tongue-flicking rate greater than that attributable to disturbance associated with entering the cage, visual and possibly airborne prey odor cues, or handling of the lizard is evident from the individual comparisons between treatment means. SICS has been known until very recently only in venomous snakes, in which it occurs in numerous viperid and elapid species. The first hints that it might also occur in nonvenomous snakes were that garter snakes showed higher tongue-flicking rate to swabs following trials in which they struck than after trials not involving striking (Burghardt, 1969) and bull snakes (*Pituophis melanoleucus*) showed elevated tongue-flicking rates after swallowing (Chiszar et al., 1980). SICS has recently been discovered in at least two nonvenomous colubrid snakes (Cooper et al., 1988), a colubrine constrictor (*Elaphe guttata*), and a natricine nonconstrictor (*Thamnophis sirtalis*). That SICS has evolved de novo in varanid lizards and three ophidian lines seems highly unlikely. Thus, SICS may be primitive in these groups rather than having evolved convergently to support a strike-release-trail strategy in viperids and certain elapids.

If, as appears to be the case, SICS did not evolve initially to support a strike-release-trail strategy, other functions must be sought in varanid lizards and nonvenomous snakes. A lizard or snake, venomous or nonvenomous, biting a prey item may receive oral chemical stimuli sufficient to locate and identify the prey after it has escaped or been dropped. By using the tongue to gather chemical stimuli from its environment for vomeronasal analysis, a squamate could increase its chances of relocating a prey item. It is because the prey is known to be nearby and perhaps injured that the intensive chemical monitoring of SICS is adaptive. In this view, SICS was probably present in snakes prior to adoption of the strike-release-trail strategy, but was immediately useful in locating and following the scent trail of prey released after envenomation (Cooper et al., 1988). Although SICS is probably homologous in lizards, non-

venomous snakes, and venomous snakes, its features may have been evolutionarily molded to enhance its function in the strike-release-trail context. Quantitative comparisons of SICS parameters in venomous and nonvenomous snakes should reveal any such changes. It should be noted, however, that further experiments are needed to establish that the increased tongue-flicking rate actually functions to help locate prey.

Given that SICS is shared by snakes and varanid lizards, its taxonomic distribution among lizard families is of interest. SICS may occur in numerous families, but if its role is primarily location of escaped prey, as hypothesized, it is likely to be fully expressed primarily in groups of active foragers that use the tongue to locate prey. It may well be entirely absent in lizard families such as Iguanidae (e.g., Evans, 1961; Simon et al., 1981, for *Sceloporus jarrovi*) and Agamidae (Cooper, unpublished data), which do not appear to use the tongue to find prey. According to one hypothesis, snakes originated from platanotan stock (McDowell, 1972), i.e., the lizard families Helodermatidae, Varanidae, Lanthnotidae, and three extinct related families. This hypothesis would be supported if SICS among lizards were restricted to this lineage.

Responses of lizards and nonvenomous snakes to the experimental conditions used for varanids are congruent. In both species of nonvenomous colubrids (Cooper et al., 1988) and in *V. exanthematicus*, visual presentation of prey and pulling the predator away from the prey induced higher tongue-flicking rates than did the disturbance control; striking induced a still greater rate. The only difference of significance in the pattern is that the tongue-flicking rate elicited by visual presentation was not quite significantly greater than that following disturbance in the lizard but was so in the snakes. The similarity of response by lizards and snakes in these conditions further hints at possible homology of SICS in varanid lizards and snakes. It should be recognized that proprioceptive cues and oral tactile stimulation produced by striking and thus consistently associated with SICS are absent in the control conditions. Thus, the stimuli eliciting SICS are not necessarily chemical but could be at least in part tactile.

The tongue-flicking rate during the 2 min following striking in *V. exanthematicus* (46/min) was within the range reported for venomous snakes, but below that recorded for two nonvenomous colubrids. Tongue-flicking rates during the same interval range vary from slightly under 20 to over 70/min for various viperids (Chiszar et al., 1980, 1983, 1985; O'Connell et al., 1981, 1982), between 40 and 60/min for several elapids (O'Connell et al., 1985, Radcliffe et al., 1986), and for the nonvenomous colubrids *Elaphe g. guttata* and *Thamnophis s. sirtalis*, ca. 60 and 72.5/min (Cooper et al., 1988). The large rate differences within families and overlaps among families suggest that varanid lizards fall within the normal response range for snakes. However, further interpretation is difficult because numerous features other than inherited taxonomic differences presumably affect these rates, including temperature,

hunger, prey type, prey odor, prior diet, and experimental treatments, among others.

Visual prey cues plus possible airborne prey odors elicited tongue-flick rates considerably higher than did disturbance without such cues, but the difference was not quite statistically distinct (Newman-Keuls observed value = 9.92; value for significance at 0.05 = 11.65). Because the sample size was small and the variability in tongue-flicking rate high, it seems likely that the large difference in tongue-flicking rates represents a true inequality of response. In all three families of snakes studied, brief visual presentation of prey induces elevated tongue-flicking rates (e.g., Chiszar et al., 1985; O'Connell et al., 1985; Radcliffe et al., 1986; Cooper et al., 1988). Activation of tongue-flicking by visual prey stimuli is presumably an investigatory behavior functioning to confirm the visual cues and, if the prey is no longer in sight, to increase the probability of relocating it.

Acknowledgments—This study was partially supported by contract DE-AC09-76SR00819 between the United States Department of Energy and the Savannah River Ecology Laboratory (SREL), a unit of the University of Georgia's Institute of Ecology. Additional support was obtained from a grant-in-aid awarded by Auburn University at Montgomery (AUM). Data were collected and analyses were done primarily during W.E.C.'s stay at SREL as a visiting faculty research participant; writing was done at AUM. I thank Justin Congdon and Whit Gibbons for providing laboratory facilities and helping to make the visit pleasant and productive and Bud Fischer and Roger Anderson for laboratory help.

Abstract—Aqueous extraction and HPLC separation techniques were used to quantify two major bromophenols naturally present in the red alga *Neorhodomela larix*: lanosol (2,3-dibromo-4,5-dihydroxybenzyl alcohol) and its 1,4-disulfate ester. Maximum concentrations of each compound were as high as 1.5% on a wet mass basis. The within-plant distributions of lanosol and its ester were highly variable on centimeter scales: adjacent portions often varied by an order of magnitude in bromophenol content. Some bromophenol variation was related to algal phase, location within the algal thallus, and reproductive status. Bromophenol concentrations were higher in exterior vegetative regions and some reproductive structures (cystocarps and tetrasporangial branchlets) than in interior vegetative regions or male reproductive structures (spermatangial stichidia). In contrast to results reported for harvested *N. larix*, there was no evidence that the intact *in situ* algae released either compound into seawater.

Key Words—*Neorhodomela larix*, red alga, lanosol, 2,3-dibromo-4,5-dihydroxybenzyl alcohol, lanosol 1,4-disulfate ester.

INTRODUCTION

The abundance of bromophenols within the red alga *Neorhodomela (Rhodomela) larix* (Turner) Masuda (Masuda, 1982) implies important roles for the compounds, perhaps as deterrents to grazing or fouling. One barrier to under-

standing the ecological effects of the bromophenols has been uncertainty about precisely which and how many bromophenols are present within the intact algae. One bromophenol extractable from *N. larix* is lanosol (2,3-dibromo-4,5-dihydroxybenzyl alcohol). Other variants of lanosol described from *N. larix*, especially organic ethers, appear to have been artifacts of extraction in organic solvents (Scheuer, 1973; Glombitza and Stoffelen, 1972; Weinstein et al., 1975; Saenger et al., 1976; Higa, 1981). In particular, 2,3-dibromo-4,5-dihydroxybenzaldehyde, which was abundant in ethyl acetate extracts (Phillips and Towers, 1981), was not identified in subsequent methanol extracts (Phillips and Towers, 1982a). Weinstein et al. (1975) argued that lanosol itself was a product of hydrolysis during extraction and that the only bromophenol actually present in *N. larix* was the disulfate ester, 2,3-dibromo-5-hydroxybenzyl-1',4'-disulfate, presumably as the potassium salt. We have developed aqueous extraction and separation techniques that reveal the simultaneous presence of lanosol and the disulfate ester in *N. larix*. We have also observed millimeter- to centimeter-scale variability in the concentrations of both compounds within the algal thalli. Contrary to previous work with harvested algae (Phillips and Towers, 1982b), we find no evidence that either compound is released into solution by intact plants *in situ*.

METHODS AND MATERIALS

Specimens of *N. larix* were collected in 1986 and 1987 from Boiler Bay, 17 miles north of Newport on the central coast of Oregon. Algae were carried in plastic bags on ice to Oregon State University's Hatfield Marine Science Center at Newport, where they were examined under a dissecting scope to determine life-history phase (male gametophyte, cystocarpic female gametophyte, tetrasporophyte) and reproductive status (relative abundance and condition of reproductive structures). Thalli were cut transversely into roughly centimeter-long sections. Each section was measured, blotted dry, weighed, and then frozen individually. If macroscopic epiphytes were present on a section, their abundance was recorded and they were removed before the section was weighed. Of the approximately 30 sections produced from each plant, we analyzed a subset that included all main axis and branch tips, all sections of at least one branch, at least one section from base and mid-axis regions, one section from each of the reproductive status categories, and all sections whose reproductive status was observed to be intermediate or higher. In June 1987, additional algal sections were further dissected into (1) the cortex (outer pigmented region) of the main axis, (2) the medulla (inner, nonpigmented region) of the main axis, (3) the spikelike ultimate branchlets of the main axis and larger lateral branches, and (4) reproductive structures. Reproductive structures

included spermatangial stichidia from males, cystocarps from females, and stichidial-like branchlets bearing tetraspores from tetrasporophytes.

The frozen sections, weighing 10–150 mg, were homogenized for 4 min in 150 μ l of distilled deionized water and then for 2 min more following the addition of 1 ml of phosphate–borate buffer (KH_2PO_4 , H_3BO_4 , and KCl each at 50 mM, adjusted to pH 6.9 with HCl). Homogenization was done by hand in 5-ml glass tissue grinders. The pH of the homogenate was adjusted to 10.0 with NaOH to keep the phenols in solution as the homogenate was centrifuged and then filtered (through 0.2 μ m PTFE membranes). The filtrate was then reacidified to pH 6.0 with 2 N HCl, a pH at which the phenols were stable for at least 24 hr. An internal standard, 2,3-dichlorophenol, was added to all samples before homogenization to monitor recovery of halogenated phenols by this extraction technique. Residual algal material from an aqueous extraction was homogenized again in chloroform to test aqueous extraction efficiency. The chloroform extracts were then analyzed using the same chromatographic conditions as used for the aqueous extracts.

Subsamples (200 μ l) of the acidified aqueous solutions were chromatographed on a Hamilton PRP-1 column (7.0 mm diameter, 30.5 cm long, with 10 μ m particle size). The bromophenols were separated using combined gradients of pH (acidic to basic) and solvent (aqueous to organic); mobile-phase compositions, gradient parameters, and flow rates are given in Table 1. Once separated, the bromophenols were detected by their absorbance at 280 nm, near

^aCompositions of the four mobile phase solutions were: A, 10 mM NaH_2PO_4 with 18 mM ammonium acetate, pH 4.5; B, 10 mM Na_2HPO_4 with 18 mM ammonium acetate, pH 10.0; C, 90% methanol, 10% distilled deionized water; D, 100% acetonitrile. All changes in composition were by linear gradients.

λ_{\max} for many bromophenols. The basic mobile phases (final pH ≥ 10.0) enhanced detection: extinction coefficients of many phenols increase greatly in basic solutions. Disulfate ester was identified by coretention with an authentic standard (graciously provided by J. Craigie) (Figure 1) and by comparison of its UV spectrum to authentic material; it was quantified using response factors generated from the authentic material. Lanosol was identified and quantified in the same manner (Figure 1) using standards derived from the ester standard by 15-minute hydrolysis at pH 1.2 and 100°C. Disulfate ester and lanosol were

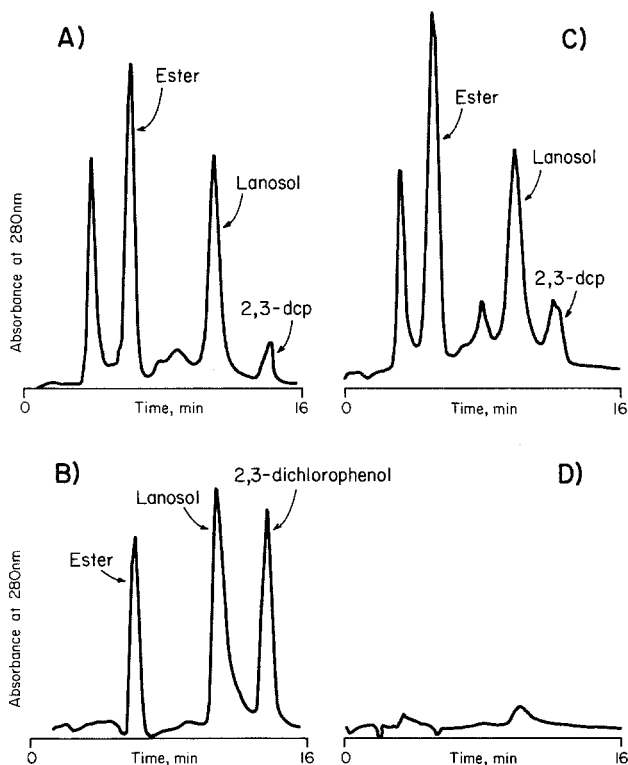

FIG. 1. Chromatograms of bromophenols extracted from *N. larix*. (A) Aqueous extract of a cystocarpic female collected in July 1986 showing ester, lanosol, and 2,3-dichlorophenol peaks as well as peak of more polar material eluting before the ester. (B) Standards: 15 μg ester, 29.8 μg lanosol, and 3.7 μg 2,3-dichlorophenol per injection. (C) Aqueous extract of a reproductive tetrasporophyte collected in October 1986. Ester and lanosol concentrations per 200 μl injection were 22.8 and 20.7 μg , respectively, from a 35.8-mg section of the alga, giving concentrations of 3504 and 3177 $\mu\text{g/g}$ fresh weight of ester and lanosol, respectively. (D) Chloroform extract of the residual algal material from C. Neither ester nor lanosol was evident above the gradient baseline values.

added to some algal samples before homogenization and then processed with and without acidic hydrolysis to determine the stability of the two compounds under the extraction conditions. Bromophenol concentration data were subjected to two multivariate analyses of variance, with phase (male, female, tetrasporophyte) and thallus part (tips, midsections, basal portions) or phase and reproductive status as variables, respectively.

We considered several options for storing algae between collection and analysis. In one comparison, extracts of frozen individual algal pieces had more lanosol and ester than extracts of refrigerated pieces, suggesting that freezing improved extraction, presumably by disrupting plant structure. Frozen algae were easier to homogenize than fresh or refrigerated plants. In a second comparison, algae frozen in a mass (20–50 g wet mass), rather than as individual pieces, showed variable and occasionally increased lanosol and ester concentrations with time, perhaps because biological activity was not quickly or thoroughly arrested in the time required to completely freeze the larger mass of algae. Based on these comparisons, we chose to freeze algal pieces individually until analysis.

Immersion experiments were conducted in the field in April, July, and August of 1987 to determine whether the algae released bromophenols after exposure to air at low tide. We gently immersed single axes or branches of exposed intact attached *N. larix* for intervals of 1–120 min in tubes containing 10 ml of ambient seawater. After the algae were removed from the tubes, the tubes and their liquid contents were kept cool and dark during transport to the laboratory. There, we added 3.3 ml of saturated KCl in seawater to the 10-ml immersion solutions to decrease the solubility of the bromophenols. The entire solutions were then passed through phenyl solid-phase extraction columns (3 ml column volume, 200 mg sorbent). The columns were rinsed with 400 μ l hexane to remove some of the water and associated salts. Phenols retained on the extraction columns were eluted with three 333- μ l volumes of methanol and chromatographed as above, after centrifugation to remove precipitated salts remaining in the methanol. Disulfate ester was added to some solutions as the algae were immersed to determine extraction efficiencies and stability during collection and transport. In August, several plants were scraped and nicked slightly with razor blades to determine whether abrasions or incisions might induce bromophenol release.

RESULTS

The combination of aqueous extraction with high pH chromatographic mobile phases resulted in a sensitive and effective technique for the identification and quantification of bromophenols. Detection limits under these conditions were ≤ 10 ng for both lanosol and the disulfate ester. This sensitivity

allowed bromophenol measurements of algal pieces as small as 5–10 mg wet (damp dry) mass. The extraction itself was efficient: homogenization times longer than the 6 min reported here did not result in greater recovery of either lanosol or its disulfate ester. Grinding residual algal materials in chloroform after aqueous homogenization extracted no additional lanosol, ester, or other UV-absorbing materials (Figure 1D). Individual sections of frozen algae subsampled over the course of three months showed no significant changes in lanosol or ester content (see Table 3, discussed below).

Recoveries of the bromophenols from the extraction process were reliably high. Recoveries of the internal standard, 2,3-dichlorophenol, added as part of the homogenization buffer, were consistently 61–68% (Table 2). The missing 2,3-dichlorophenol was probably adsorbed to particulate fractions or to filter or container surfaces. Such losses were not evident when lanosol or the disulfate ester were added directly to algal samples (Table 3, below); both brominated compounds are more hydrophilic than 2,3-dichlorophenol.

Lanosol and the disulfate ester were found in every section of all seven plants measured from the April collections (Table 2) and in all dissected portions from the June collections. The presence of lanosol was not an artifact of

ester hydrolysis during extraction. Disulfate ester added to samples before homogenization was entirely recovered as ester. Lanosol added to samples was likewise entirely recovered as lanosol. When acid hydrolyses were included as part of extraction, the total lanosol resulting from hydrolysis of a subsample of a piece of algae was, with only one exception, very close to the sum of lanosol plus ester (in lanosol equivalents) in another unhydrolyzed subsample (Table 3). These results were remarkable in light of within-thalli variability of the compounds. In addition to demonstrating the simultaneous presence of ester and lanosol in *N. larix* and the complete conversion of the former to the latter by hydrolysis, the results in Table 3 show the temporal stability of the bromophenol concentrations in frozen individual sections of the algae: more than three months elapsed between analyses with and without hydrolysis.

Other UV-absorbing compounds were evident in chromatograms of some of the algal extracts (Figure 1), some with UV spectra characteristic of phenols. An intensely absorbing polar peak was the most frequently observed of these

unidentified compounds; others were less absorbant or less abundant and less frequent in occurrence. None of the unidentified compounds had obvious relation to algal part, algal phase, or ester or lanosol concentration.

Amounts of lanosol in single sections of algae collected in April 1987 ranged from 791 to 17509 $\mu\text{g/g}$ wet mass; amounts of disulfate ester ranged from 416 to 16,430 $\mu\text{g/g}$ (Table 2). The maximum total bromophenol (lanosol plus ester) contents of individual sections were 15,000 to more than 30,000 $\mu\text{g/g}$, 1.5–3% by wet mass. If wet mass to dry mass ratios are ≥ 2 (six algal sections we measured had ratios near 5), some sections of these algae contained more than 6% bromophenols by dry weight.

All sections of tetrasporophytes and most sections of male and female gametophytes collected in April 1987 contained more lanosol than ester. The only sections containing much more ester than lanosol were small secondary branches and small developing branches on the main axis of gametophytes (e.g., Figure 2). None of the reproductive sections of tetrasporophytes had especially

FIG. 2. Computer-generated outline of a cystocarpic female *N. larix* (female 3 in Table 2) collected in April 1987 showing ester and lanosol concentration and reproductive status for each of 33 sections of the alga. Section lengths and branch points in outline are in proportion to actual measurements; the intact alga was 19.2 cm long.

high concentrations of either bromophenol. Some sections of female gametophytes containing cystocarps did have high bromophenol concentrations, especially of lanosol (Figure 2). In some thalli, tips of lateral branches or of the main axis contained high concentrations of the two bromophenols, but in other thalli the highest concentrations were found midway along axes or branches or at the intersection of branches with the main axis. There was, as a consequence, intense fine-scale variability: adjacent 1- to 2-cm-long pieces differed in lanosol or ester content, often by a factor of 2 and sometimes by factors of 10 (Figure 2). The multivariate analyses of variance identified significant differences in ester content according to phase, plant part, and reproductive status, along with significant phase \times part and phase \times reproductive status interaction terms. For lanosol, only the two interaction terms were significant.

Analyses of the dissected portions of *N. larix* collected in June showed that ester and lanosol were largely in the external portions of the vegetative portions of thalli: ultimate branchlets and cortical portions of the main axis had higher concentration ranges of ester and lanosol than did the central medulla of the main axis (Figure 3). Comparison of reproductive structures of these algae indi-

FIG. 3. Lanosol and ester concentrations in reproductive portions of three *N. larix* collected in June 1987: one male, one cystocarpic female, and one reproductive tetrasporophyte. Numbers over the bars indicate the number of samples of each dissected portion analyzed. Symbols indicate the source of the reproductive structures: M = male (spermatangial stichidia), F = female (cystocarps), T = tetrasporophyte (stichidial-like branchlets bearing tetraspores).

^fValue from the only one of five thalli treated which released detectable amounts of any bromophenol.

cated lowest bromophenol concentrations in male structures and higher concentrations in carposporophytes and tetrasporangial branchlets (Figure 3).

There was no evidence in any of the immersion experiments conducted in April, June, and August of 1987 that lanosol or ester was released by *in situ* intact axes or branches of exposed algae once the axes or branches were immersed in seawater (Table 4). Moreover, neither lanosol or ester was detected in seawater draining naturally across a bed of *N. larix* in April. Ester standards and ester added to the immersion solutions were completely retained by the solid-phase extractions and easily detectable in the subsequent chromatography. Thus, the absence of bromophenols in the immersion solutions seems definitive evidence that the compounds were not released by these intact algae. When thalli in August were intentionally damaged with razor blades to mimic grazing or other physical damage, a slight release of ester was observed in only one of five nicked thalli (Table 4).

DISCUSSION

It is inherently possible that compounds are altered during the extraction and isolation processes involved in analyzing chemical compositions of plants. When the ecological activity of the compounds is under investigation, analyses and subsequent manipulations must be made of the compounds in or close to their native form. It is evident from literature cited in the introduction that sol-

vent extractions have not provided an accurate description of bromophenols intrinsic to, as opposed to extractable from, *N. larix*. The aqueous extraction techniques described here indicated that there were two major bromophenols present simultaneously in these *N. larix*: lanosol and its disulfate ester. Both compounds were stable under these extraction and chromatographic conditions. If hydrolysis was included during extraction, ester was converted to lanosol. Previous investigations employing hydrolysis would not have detected the ester. In addition to lanosol and its ester, other compounds were sporadically present, but those had lesser absorbance and have yet to be identified as bromophenols. It appears, therefore, that the bromophenol products of aqueous extractions of these algae are representative of the intrinsic bromophenol content. Aqueous extractions have the added advantage of being faster and safer than conventional extractions involving organic solvents, although careful control of pH must be maintained throughout.

In addition to improving the accuracy of extraction techniques, we have improved the sensitivity. The improved sensitivity is primarily a result of having the compounds in basic mobile phases as they pass the detector: extinction coefficients of most phenols increase by 10^2 to 10^3 at high pH (Scott, 1964). Using high pH solutions requires polymeric solid phases and increases preventive maintenance of HPLC components in contact with buffers, but the result is much greater within-thallus resolution. The improved resolution is made possible by a large reduction in the amount of algal material needed for measurement, from grams of materials required for previously described organic solvent extractions to milligrams of materials by these aqueous extraction techniques. Not surprisingly, improved resolution reveals chemical patterns and variability previously unrecognized, within and among individual algae according to phase, location, reproductive status, and other factors as yet unidentified. This chemical complexity is on spatial scales that might be recognized by and pertinent to grazers or fouling organisms but that cannot be recognized in analyses of whole thalli.

Neither lanosol nor its ester was uniformly abundant within whole *N. larix* thalli. Furthermore, these compounds did not occur in consistent or predictable gradients in the algae, for example, from base to tip. It appears that there is local production or accumulation of the compounds within the alga, perhaps in response to local growth, reproductive conditions, local grazing, or fouling stimuli. The usual techniques involved in estimating or identifying deterrent effects, such as grinding whole plants for artificial diets or presenting large plant portions in choice experiments, may miss biologically relevant information if within-plant variability of potential deterrent compounds on these scales is not considered.

Although various pharmacological activities have been described for lanosol and to a lesser extent the disulfate ester (Mautner et al., 1953, McLachlan

and Craigie, 1966; Glombitza et al., 1974), we currently do not know the ecological effects of either compound on grazers or epiphytes of *N. larix*. The effects do not seem to involve release of the compounds into solution, as these algae did not release bromophenols. If ester or lanosol concentrations within *N. larix* sampled in the immersion experiments were 1000–10,000 $\mu\text{g/g}$ as in other plants analyzed, release by 1 g of plant material immersed in 10 ml of seawater for an hour must have been less than 0.001–0.0001%/hr in order to be below our 10-ng detection limits. The previous evidence for release of bromophenols by *N. larix* was calculated to be 0.3–1.6%/hr and suggested to be at a maximum in summer months. That evidence came from algae harvested from brackish tidepools, cleaned and washed, transported, rewashed, immersed for 48 hr, then washed again before being reimmersed for measurements of exudation (Phillips and Towers, 1982b). Our measurements were made in the spring and summer directly on algae in the intertidal zone, without harvesting and with minimal handling. *N. larix* exist in a very turbulent environment along the open Oregon coast, conditions that may preclude effective algal influence on surrounding solutions by release of chemicals.

Our observations of fine-scale variation in bromophenol content within *N. larix* come largely from plants collected in April 1987. Within those samples, there were indications that bromophenol content might vary according to reproductive status or growth, both of which vary seasonally. Other factors influencing bromophenol content might be related to tidal height or to latitude. However, investigations of large-scale factors without an appreciation of the considerable fine-scale within-thallus variation in bromophenols could result in confusion or misinterpretation. Now that we are aware of fine-scale variability, we can explore the causes and consequences of variation on that scale and then integrate the fine-scale information into investigations of larger-scale patterns.

(Received May 19, 1988; accepted June 29, 1988)

Abstract—A method has been developed for detecting tannin-binding proteins in the saliva of herbivores. The method is simple and requires only small quantities of crude saliva. The saliva of deer, a browsing ruminant, has been compared to that of domestic sheep and cow, which are grazing ruminants. The browser, which normally ingests dietary tannin, produces tannin-binding proteins, while the grazers do not produce such proteins. The tannin-binding protein from deer saliva is a small glycoprotein containing large amounts of proline, glycine, and glutamate/glutamine. The protein is not closely related to the proline-rich salivary proteins found in rats and other nonruminant mammals.

Key Words—Tannin, saliva, ruminant, proline-rich protein, electrophoresis, deer, sheep, cattle, grazers, browsers.

INTRODUCTION

Dietary tannins may affect herbivores by reducing protein digestibility (Rhoades and Cates, 1976; Robbins et al., 1987a) or by systemic toxicity (Dollahite et al., 1966; Martin et al., 1987). Successful herbivores have developed mechanisms for overcoming these adverse effects. For example, some insects have modified digestive tracts in which tannin does not complex protein (Martin et al., 1987). In tree locusts, absorbed phenolics are not toxic but are utilized in

synthesis of the cuticle (Bernays and Woodhead, 1982). Rats synthesize salivary proline-rich proteins (PRPs) in response to tannin-containing diets (Mehansho et al., 1983). PRPs apparently protect rats by binding to the tannin and preventing its interaction with other proteins. Salivary tannin-binding proteins could also minimize absorption of tannins and reduce their toxicity.

We are currently seeking to evaluate differences in the abilities of various ruminants along the grazer-to-browser continuum to consume tannin-containing diets. Grazers consume virtually tannin-free diets and have a minimal ability to tolerate soluble phenolics, while browsers normally consume a variety of phenolic-containing plants and are well prepared to tolerate phenolics (Robbins et al., 1987b). The saliva of mule deer (*Odocoileus hemionus hemionus*), a browser, contains two to three times more nitrogen than the saliva of grazers such as cows or domestic sheep (Robbins et al., 1987b). Deer saliva is more proline rich than cow or sheep saliva and has a greater tannin-binding capacity than the saliva of the grazers (Robbins et al., 1987b). These findings suggest that the tolerance of browsers for dietary tannins may be due, in part, to the production of salivary PRPs. We have developed new methodology that facilitates the detection of tannin-binding proteins in saliva samples and have applied those methods to a detailed characterization of the salivary proteins of deer and sheep.

METHODS AND MATERIALS

Electrophoresis. Nondenaturing, discontinuous, pH 8.3 polyacrylamide gels (Davis, 1964) were used for identification of tannin-binding proteins. The gels were poured in a 1-mm slab gel apparatus using Laemmli's (1970) modification of the method, omitting the sodium dodecyl sulfate (SDS). The acrylamide concentration varied linearly from 7.5% at the top of the gel to 12% at the bottom of the gel, and the bisacrylamide was 0.2% throughout the gel. The stacking gel contained 3.0% acrylamide and 0.08% bisacrylamide. The gels were run at a constant voltage of 300 V for 10–12 hr at 4°C with 0.05% bromophenol blue as the tracking dye.

SDS gels were run to establish whether the composition of saliva changed when animals were fed tannin. The gels were prepared as described by Laemmli (1970). The resolving gel contained 12% acrylamide, 0.3% bisacrylamide, and 0.1% SDS. The stacking gel contained 3.0% acrylamide, 0.08% bisacrylamide, and 0.1% SDS. Samples were prepared by mixing the sample with β -mercaptoethanol, glycerol, SDS, and bromophenol blue and heating the mixture in a boiling water bath for 4 min to denature the proteins. The gels were run at a constant voltage of 90 V for 20 hr at room temperature.

After running either type of electrophoresis, the proteins were fixed in the gels with a mixture of 26% ethanol, 14% formaldehyde, and 60% water for 1 hr, followed by 1–12 hr in a mixture of 50% methanol, 12% acetic acid (Steck et al., 1980). The formaldehyde fixation step is essential for retaining small, proline-rich proteins in the gel throughout the staining procedure. The proteins were then stained with a sensitive silver stain (Merril et al., 1981) or with Gelcode silver stain (Pierce Chemical Co., Rockford, Illinois 61105). The SDS was washed out of SDS gels with a mixture of 10% ethanol and 5% glacial acetic acid before staining.

Assay for Tannin-Binding Proteins. A sample of crude saliva (30 μ l) or an aqueous solution of isolated salivary protein (30 μ l of a 4 μ g/ μ l solution) was mixed with a 50% methanol solution of tannin (10 μ l containing 0.5–5 μ g of tannin), and the mixture was incubated for 6–9 hr at 4°C. The sample was centrifuged at 800g and the supernatant mixed with 5 μ l of glycerol and 5 μ l of 0.05% bromophenol blue before loading onto a native gradient gel. Control samples were mixed with 50% methanol but no tannin. In the presence of tannin, tannin-binding proteins did not enter the gel or had altered electrophoretic mobility. These proteins could thus be identified by comparing the electrophoretic pattern of proteins in control samples to the pattern in the presence of tannin.

A variety of tannins were used to establish whether the tannin-binding proteins exhibited tannin-specific binding. Quebracho tannin (Asquith and Butler, 1985), sorghum tannin (Hagerman and Butler, 1980), and tannic acid (Hagerman and Klucher, 1986) were purified by a combination of ethyl acetate extraction and Sephadex LH-20 chromatography. Tannin-containing extracts were prepared using 50% methanol (3.7 ml/g tissue) and a microcolumn extraction technique (Hagerman, 1988). Plants used included maple leaves (*Acer rubrum*), fireweed flowers (*Epilobium angustifolium*), and red-osier dogwood leaves (*Cornus stolonifera*) (Robbins et al., 1987a).

Isolation of Tannin-Binding Protein. Saliva samples were collected from a resting female deer with surgically constructed esophageal fistula and immediately frozen. After thawing, the saliva was mixed with an equal volume of 10% (w/v) trichloroacetic acid. Twenty minutes later the mixture was centrifuged for 15 min at 10,000g and the precipitate was discarded. The cloudy supernatant liquid was brought to pH 7 and clarified by addition of a few drops of a concentrated solution of sodium hydroxide. The supernatant was dialyzed against distilled water at 4°C and lyophilized to produce a white or tan powder consisting of salivary PRPs.

Salivary PRPs were electrophoretically separated on native gradient gels. The region of the gel containing the tannin-binding protein was cut out of the gel, minced into small pieces, and eluted from the gel into 4 vol of pH 8.8 Tris

(0.375 M). The eluate was dialyzed for 24 hr against water, and the dialysate was concentrated to 80 μ l using a Minicent-10 ultrafiltration device (BioRad Labs, Richmond, California 94804). A fraction of this material was evaluated for purity on an SDS gel, and the remainder was hydrolyzed in vacuo with 6 N Sequanal HCl (Pierce Chemical Co.) at 110°C for 24 hr. The hydrolyzate was dried under nitrogen and the amino acid analysis performed in duplicate by the Protein Structure Laboratory (Davis, California 95616).

The apparent molecular weight of the tannin-binding protein was determined by SDS gel electrophoresis. The sample was dissolved in equal volumes of solution A (1.6 ml glycerol, 0.4 g SDS, 2 mg bromophenol blue, and 8.4 ml water) and solution B (2 ml of 0.5 M Tris HCl, 1 ml of β -mercaptoethanol, and 7 ml water), heated in a boiling water bath for 4 min, and applied to the gel. Molecular weight standards were bovine serum albumin (66,000), egg albumin (45,000), trypsinogen (24,000), and β -lactoglobulin (18,400).

pH Dependence of PRP-Tannin Interactions. Purified condensed tannin from sorghum grain (Hagerman and Butler, 1980) was immobilized on epoxy-activated Sepharose (Sundberg and Porath, 1974). Suction-dried activated Sepharose (12 g) was mixed with 50 mg of the tannin, and 10 ml of 0.5 M Na_2CO_3 was added. The mixture was shaken gently at room temperature for 24 hr, and the gel was then washed as described by Armstrong (1976). Control affinity gel was prepared by reacting epoxy-activated Sepharose with 1 M ethanolamine instead of tannin. The affinity gels were stored at 4°C.

Small columns (5 ml) were prepared with the tannin and control affinity gels and were equilibrated at pH 8.0 (0.05 M Tris). Deer salivary PRPs (0.3 ml of a 4 mg/ml aqueous solution) were applied to the gels, which were then washed successively with 2-ml aliquots of pH 8.0, pH 6.0 (0.05 M phosphate), pH 4.0 (0.05 M acetate), and pH 2.0 (0.05 M glycine) buffers. The columns were then washed with 2 ml of 1% SDS. The eluate from each pH was collected and concentrated to a volume of about 30 μ l with a Minicent-10 ultrafiltration device. The concentrated samples were prepared for SDS gel electrophoresis as described above.

Survey of Saliva for Diet-Induced Changes in Protein Composition. Saliva samples were collected from resting esophageal-fistulated animals (two deer, two sheep) at various times during feeding trials and were immediately frozen. For analysis, samples were thawed, and a 40- μ l aliquot of each sample was mixed with 3 μ l of β -mercaptoethanol, 5 μ l of glycerol, and 5 μ l of solution A. The samples were then heated in a boiling water bath for 4 min, and 40 μ l of the mixture was applied to an SDS gel. After electrophoresis, the gels were stained and examined to determine whether new proteins were present in animals fed tannin-containing diets.

RESULTS AND DISCUSSION

Identification of Tannin-Binding Proteins. A method for identifying proteins with high affinity for tannins has been developed and applied to saliva from grazing and browsing ruminants. Seven major proteins are separated by native gel electrophoresis of deer saliva (Figure 1). When deer saliva is incu-

FIG. 1. Treatment of deer and sheep saliva with tannin. Saliva samples were mixed with tannin, incubated, and centrifuged before electrophoresis on a native gel. Proteins were fixed and stained with silver stain as described in the text. Tannin-binding proteins are indicated with arrows. The major tannin-binding protein, a, has an electrophoretic mobility of 0.64; b has a mobility of 0.66–0.67; c has a mobility of 0.69. Lane 1, bovine serum albumin (standard); lane 2, female deer saliva plus 50% methanol; lane 3, female deer saliva plus 0.8 μg tannic acid in 50% methanol; lane 4, male deer saliva plus 50% methanol; lane 5, male deer saliva plus 0.8 μg tannic acid in 50% methanol; lane 6, sheep (tannin-free diet) saliva plus 50% methanol; lane 7, sheep (tannin-free diet) saliva plus 0.8 μg tannic acid in 50% methanol; lane 8, sheep (tannin-containing diet) saliva plus 50% methanol; lane 9, sheep (tannin-containing diet) saliva plus 0.8 μg tannic acid in 50% methanol.

bated with a small amount of tannic acid before the electrophoresis, one major and two minor bands disappear, suggesting that the three proteins are bound to the tannin. The sheep saliva contains only one major protein band, which is unaltered by the addition of tannic acid to the sample (Figure 1). These results confirm earlier analyses of saliva from deer, sheep, and cattle in which a competitive binding assay was used to establish that deer saliva contains large amounts of tannin-binding protein but that sheep or cow saliva contains very little tannin-binding protein (Robbins et al., 1987b).

The electrophoretic method provides a simple means for surveying samples for tannin-binding proteins. The saliva is not purified or concentrated before electrophoresis. Very small amounts of tannin are required to detect the tannin-binding proteins. Both insoluble and soluble (Hagerman and Robbins, 1987) tannin-protein complexes are detected; insoluble complexes are centrifuged away from the sample before electrophoresis, and soluble complexes have different electrophoretic mobility than native, uncomplexed protein. The method is only useful for detecting complexes that form near pH 8, since the electrophoresis is run at pH 8.3. However, physiologically significant salivary protein-tannin interactions are expected to occur near pH 8 since the pH of saliva is between 7 and 9 (Robbins, 1983).

The major tannin-binding protein in two individual deer has an electrophoretic mobility of 0.64 (Figure 1). There is some heterogeneity in the minor tannin-binding proteins. For example, in the saliva from the female deer (Figure 1, lanes 2 and 3), the electrophoretic mobilities of the minor tannin-binding proteins are 0.66 and 0.67. In the saliva from the male deer (Figure 1, lanes 4 and 5), the mobilities of the minor tannin-binding proteins are 0.67 and 0.69. This heterogeneity may be due to differences in the size, amino acid composition, or glycosylation of the proteins. Proteins with electrophoretic mobilities similar to the mobilities of the tannin-binding proteins were also detected in the crude saliva of two other deer, but these proteins were not extensively characterized.

Isolation of Tannin-Binding Proteins. The tannin-binding salivary proteins of rodents are PRPs (Mehansho et al., 1983), and preliminary experiments with deer saliva suggested that ruminant tannin-binding proteins may also be proline rich (Robbins et al., 1987b). Deer saliva was treated with trichloroacetic acid, and the native gel electrophoresis assay for tannin-binding proteins was used to establish that the soluble material, which includes the PRPs (Mehansho et al., 1983), contained the tannin-binding proteins. The tannin-binding protein was further purified by electrophoresis. The isolated material contained one major protein and traces of a second, higher-molecular-weight protein (Figure 2). The major protein was retained by an ultrafiltration membrane with a molecular weight cutoff of 10,000 and had an apparent molecular weight of 19,000 by

FIG. 2. Purification of tannin-binding protein from deer saliva. The tannin-binding protein was purified by trichloroacetic acid fractionation and native gel electrophoresis as described in the text. SDS gel electrophoresis was run to assess the purity of the isolated protein. The trichloroacetic acid-soluble fraction of the saliva is shown in lane 1; the purified protein is shown in lane 2. The major tannin-binding protein (a) and a minor tannin-binding protein (b) are indicated. Lane 3 contains molecular weight markers. The other lanes contain materials from an unrelated experiment.

SDS gel electrophoresis. Glucosamine and galactosamine were released from the tannin-binding protein upon acid hydrolysis, suggesting that the protein is glycosylated, like some PRPs from other mammals (Mehansho et al., 1985).

The tannin-binding protein from deer saliva contains larger amounts of proline, glutamate/glutamine, and glycine than of the other amino acids (Table 1). The protein does not contain any sulfur-containing amino acids and contains low amounts of the aromatic amino acids. The protein is thus superficially similar to the PRPs found in several mammals (Bennick, 1982; Mehansho et al., 1983, 1985). However, several amino acids, such as valine and isoleucine, which are not abundant in the PRPs of other mammals, were present in the deer tannin-binding protein. The differences in amino acid composition show that

TABLE 1. AMINO ACID COMPOSITION OF TANNIN-BINDING PROTEIN FROM DEER SALIVA^a

^aThe protein was purified by trichloroacetic acid fractionation and electrophoresis as described in the text. The amino acid composition was determined after acid hydrolysis. Values shown are the average of two independent determinations. Tryptophan was not determined.

^bTannin-induced PRP described by Mehansho et al. (1983).

^cTannin-induced glycosylated PRP described by Mehansho et al. (1985).

the tannin-binding proteins from deer saliva are not identical to the PRPs found in saliva of nonruminant mammals. It is possible that salivary proteins of each animal are adapted to the particular tannin-containing foods consumed by that animal. Further studies of the amino acid composition and sequence of proteins from various animals are required to clarify the relationship between the tannin-binding protein of deer and PRPs of other mammals.

Interactions between Tannin-Binding Proteins and Tannin. The trichloroacetic acid-soluble, PRP-enriched fraction of deer saliva was used to characterize the interaction between the tannin-binding protein and various tannin samples. Electrophoretic analysis showed that the protein interacted with purified hydrolyzable or condensed tannin and with crude tannin from a variety of plants. The tannin-binding protein did not interact with plant extracts that had been treated with polyvinylpyrrolidone to adsorb the tannin and other polyphenolics (Loomis and Battaile, 1966), demonstrating that the interaction involved tannin and not some other protein-binding component of the extract.

Addition of polyvinylpyrrolidone to a mixture of tannin and the PRPs reversed the interaction between the salivary protein and tannin, suggesting that polyvinylpyrrolidone has a higher affinity for tannin than the salivary tannin-binding protein. The tannin-binding protein did not interact with tannin in the presence of SDS. Tannin-salivary protein complexes could be dissociated with SDS.

The complex of tannin and tannin-binding protein was soluble under all conditions examined. After incubating tannin with the PRP-enriched fraction of deer saliva, the mixture was centrifuged. No precipitate was visible. Part of the supernatant was electrophoresed on a native gel, and the remainder electrophoresed on an SDS gel. As expected, the tannin-binding protein had interacted with the tannin and could not be seen in the native gel. However, the tannin-binding protein was visible in the SDS gels. The SDS dissociated the tannin-protein complex so that the protein entered the gel and ran with its usual electrophoretic mobility. Thus, the tannin-binding protein was not part of an insoluble tannin-protein complex, which would have been pelleted during the centrifugation step. Viscosity data (S. Mole, Purdue University, unpublished) also suggests that proteins in deer saliva form soluble complexes with tannins. The tendency of the tannin-binding protein to form soluble complexes with tannin may be a consequence of glycosylation. Most proteins form insoluble complexes with tannin, except when large excesses of protein are present (Hagerman and Robbins, 1987; Mole and Waterman, 1987). However, glycoproteins tend to form soluble rather than insoluble complexes with tannin (Asquith et al., 1987).

The salivary protein has a high affinity for tannin. The native gel electrophoresis assay was used to compare the affinity of several proteins for tannin. In the presence of a 40-fold weight excess (10-fold molar excess) of bovine serum albumin or a fivefold weight excess (equimolar) of ribulose biphosphate carboxylase/oxygenase, the tannin preferentially bound the salivary protein. The high affinity of the salivary protein for tannin suggests that, during the chewing/rumination process, dietary tannin may interact with the salivary tannin-binding protein. Other proteins, including dietary proteins, may not complex any tannin in the presence of the salivary tannin-binding protein.

Tannin-protein interactions are pH dependent (Hagerman and Butler, 1978). For example, bovine serum albumin is precipitated by tannin only at pH values near 5, while ribulose biphosphate carboxylase/oxygenase is precipitated between pH 6 and pH 7 (Martin and Martin, 1983). The gastrointestinal tract of ruminants has regions of pH varying from pH 2 (abomasum) to pH 9 (saliva) (Robbins, 1983). If salivary tannin-binding proteins protect other proteins from tannin at all stages of the digestive process, the salivary proteins must form complexes that are stable over this range of pH values. Since the tannin-binding protein forms soluble rather than precipitable complexes with tannin, conventional precipitation assays could not be used to examine the pH

dependence of tannin-salivary protein complex formation. Instead, condensed tannin was immobilized on an insoluble matrix, and the binding of salivary proteins to the gel was examined as a function of pH.

In preliminary experiments, the immobilized tannin bound proteins in a pH-dependent fashion; for example, bovine serum albumin was bound to the derivatized matrix only at pH values near 5 (Suchar, 1987). The control matrix that was not derivatized with tannin did not bind protein. The deer salivary tannin-binding protein was bound to the derivitized gel at pH 8 and was not washed off the gel by sequential treatment with solutions of pH 6, pH 4, or pH 2. The tannin-binding protein and two minor higher-molecular-weight salivary proteins were recovered from the gel in an SDS wash that followed the pH 2 wash. One of the higher-molecular-weight proteins is the minor tannin-binding protein that copurified with the major tannin-binding protein in other experiments (Figure 2, band b). The remaining salivary proteins were not bound by the gel or were washed from the gel with the pH 6 wash. These results suggest that the tannin-binding protein could bind dietary tannin in the mouth of the deer and that the complex would be stable at pH values encountered during transit of the entire digestive tract. We are currently investigating the stability of the complexes in the presence of proteases, bile salts, and other constituents of the digestive tract that may disrupt tannin-protein complexes (Martin et al., 1987).

Induced Synthesis of Tannin-Binding Proteins. In some rodents, synthesis of PRPs is induced by dietary tannins (Mehansho et al., 1983, 1985). To determine whether synthesis of salivary tannin-binding proteins was induced in deer or sheep, saliva was collected at intervals during a feeding trial. The saliva was examined with SDS gel electrophoresis, which resolves more proteins and is more sensitive than native gel electrophoresis. No new proteins were detected in the saliva of two individual deer (Figure 3A) during a 10-day feeding trial with diets containing 2% tannic acid. These results confirm the results of previous analyses of the saliva from animals on this feeding trial, in which neither crude nitrogen nor tannin-binding capacity changed during the experimental period (Robbins et al., 1987b). The deer used in this experiment were adult animals and had been exposed to dietary tannin in several earlier experiments. It seems likely that these animals have already adapted to dietary tannin and produce salivary tannin-binding proteins continuously. In experiments with deer not previously exposed to tannin, it might be possible to detect induction of synthesis of salivary tannin-binding proteins analogous to the induction observed in some rodents.

No new proteins were observed in the saliva collected from two individual sheep during the feeding trial with 2% tannic acid (Figure 3B). There are only about 12 proteins in the sheep saliva, while there are at least 20 proteins in the deer saliva. The sheep had never been exposed to dietary tannin before this

FIG. 3. Saliva composition during a feeding trial. Saliva samples were taken from animals before (day -1) and on the third, sixth, and tenth day of a feeding trial in which 2% tannic acid was incorporated into the diet. The cows were not given tannin-containing diets. The samples were electrophoresed on SDS gels as described in the text. Four lanes on left of each gel contain molecular weight markers. (A) Lane 1, female deer, day -1; lane 2, female deer, day 3; lane 3, female deer, day 6; lane 4, female deer, day 10; lane 5, male deer, day -1; lane 6, male deer, day 3; lane 7, male deer, day 6; lane 8, male deer, day 10. (B) Lane 1, sheep, day -1; lane 2, sheep, day 3; lane 3, sheep, day 6; lane 4, sheep, day 10; lane 5, cow NMSU, #2507; lane 6, cow NMSU, #2509; lane 7, cow, horned Hereford #2; lane 8, cow, polled Hereford #10.

feeding trial, so the absence of induced salivary tannin-binding proteins suggests that these animals, like hamsters (Mehansho et al., 1987), do not produce tannin-binding salivary proteins in response to tannin-containing diets. Alternatively, it might be argued that longer exposure times, higher levels of dietary tannin, or a different source of dietary tannin may be necessary for induction of protein synthesis in sheep.

Although cattle were not fed tannins, saliva from four cattle was analyzed electrophoretically (Figure 3B). Only one protein was detected in the cow saliva, in agreement with its low nitrogen content (Robbins et al., 1987b).

In all of these studies, saliva was collected from esophageally fistulated, resting animals. We plan to evaluate saliva collected from chewing animals and from individual salivary glands in future studies.

CONCLUSIONS

The saliva of deer, a browsing animal, has been compared to that of domestic sheep and cow, which are grazing animals. The browser, which normally ingests dietary tannin, produces tannin-binding proteins, while the grazers do not produce such proteins. We postulate that browsers may minimize nitrogen loss and toxicity due to dietary tannin by complexing the tannin efficiently with salivary tannin-binding proteins. According to our model, grazers do not produce tannin-binding proteins, so dietary tannin may be bound by other proteins during the chewing and rumination process. If this hypothesis is true, the feces of browsers on tannin-containing diets should contain tannin-salivary protein complexes that have passed intact through the digestive tract, while the feces from grazers should contain complexes between tannin and dietary or nonsalivary, endogenous protein. Furthermore, grazers may be more susceptible to toxic effects of tannins than are browsers, which are protected by tannin-binding proteins.

A method has been developed for detecting tannin-binding proteins in the saliva of herbivores. The method is simple and requires only small quantities of crude saliva. To establish whether other grazers and browsers follow the pattern observed with deer, sheep, and cows, saliva from a variety of other grazing and browsing ruminants should be analyzed. In addition, the method could be used to screen nonruminants for salivary tannin-binding proteins that may provide an effective defense against this common plant allelochemical.

(Received January 13, 1988; accepted June 29, 1988)

Abstract—Ovipositor washings from virgin female *Spodoptera exempta* (Walker) (Lepidoptera: Noctuidae) were analyzed by high-resolution gas chromatography (GC) linked to a male electroantennogram (EAG). GC retention times of the two major EAG responses observed were consistent with their assignment as (Z)-9-tetradecenyl acetate and (Z,E)-9,12-tetradecadienyl acetate, as previously identified. However, three other EAG responses were also noted that had GC retention times consistent with (Z)-9-tetradecenal, (Z)-9-tetradecen-1-ol, and (Z)-11-hexadecenyl acetate. The components were present in the ratio of 100:5:1.5:3.5:4, respectively. Further analysis of the ovipositor washings by GC linked to a mass spectrometer (GC-MS) confirmed these findings and indicated the presence of a sixth component consistent with (Z)-11-tetradecenyl acetate present at 2% of the major component. In field tests carried out in Kenya, (Z)-11-hexadecenyl acetate was the only newly identified component to enhance the catch of the original two-component mixture when presented in their natural ratio. The addition of (Z)-9-tetradecen-1-ol reduced catch, while (Z)-9-tetradecenal and (Z)-11-tetradecenyl acetate had no apparent effect.

Key Words—*Spodoptera exempta*, Lepidoptera, Noctuidae, sex pheromone, (Z)-9-tetradecenyl acetate, (Z)-9-tetradecenyl acetate, (Z)-11-tetradecenyl acetate, (Z,E)-9,12-tetradecadienyl acetate, (Z)-9-tetradecen-1-ol, (Z)-11-hexadecenyl acetate.

INTRODUCTION

The African armyworm, *Spodoptera exempta* (Walker) (Lepidoptera: Noctuidae), is a serious but sporadic pest of graminaceous crops, including forage grasses, maize, wheat, rice, and millet, throughout Africa. It is also known to occur in Southeast Asia, Philippines, New Guinea, and Australia (Haggis, 1986). Beevor et al. (1975) identified two components of the female sex pheromone as (Z)-9-tetradecenyl acetate and (Z,E)-9,12-tetradecadienyl acetate in the ratio of 100:5. These were field tested in Kenya by Campion et al. (1976) and found to be highly attractive to male *S. exempta*, although the catches were significantly less than those with a light trap.

S. exempta has been shown to be a migratory moth from both indirect (Brown et al., 1969) and direct evidence (Rose and Dewhurst, 1979; Riley et al., 1983; Rose et al., 1985). By tracking their progress using pheromone and light traps over many years and relating these data to weather movements, it is now possible to forecast when and where outbreaks of armyworm larvae may occur (Haggis, 1986).

However, outbreaks do not take place throughout the year but appear to be seasonally restricted to coincide with rain-bearing wind movements, such as the intertropical convergence zone (Tucker and Pedgley, 1983; Haggis, 1986). In most years, there is a gap of two to four months after the rainy season in which few, if any, outbreaks are reported (Haggis, 1986). There do not appear to be major return migrations towards the equatorial region where the first seasonal outbreaks are recorded, and low density, nonmigrating populations of insects are thought to survive until more favorable conditions permit further population growth (Rose, 1979; Nyirenda, 1985). In order to study areas with low population levels, it is important to maximize the ability of the pheromone trap to attract and catch males of the target species. This is particularly important when closely related sympatric species, such as *Spodoptera triturrata* are present and known to be attracted to a similar pheromone (Blair and Tannock, 1977; D.J. Chamberlain, personal communication). As part of this process, this paper describes a reexamination of the sex pheromone derived from adults of the gregarious-phase larvae (Faure, 1943) and the preliminary field evaluation of the new compounds found.

METHODS AND MATERIALS

Insect Material. In order to carry out chemical and electrophysiological analyses, sixth-instar larvae were field collected in Kenya, reared on fresh grass, and allowed to pupate in bowls containing dry sandy soil. Pupae were dispatched by air to London, where they were sexed and maintained in an environmental cabinet on a reversed 12-hr light, 12-hr dark cycle, with temperatures alternating from 25°C to 22°C and a relative humidity of 70%. Adult moths were highly excitable and so were maintained with a 10% sucrose solution in groups of no more than 10 per container (Perspex, 28 × 15 × 9 cm) with tissue paper to discourage flying.

Pheromone Collection. Ovipositor washings were prepared in hexane as described by Sower et al. (1973), using virgin female moths between 1 and 4 days old and usually between 8 and 9 hr into the dark phase. Volatiles from 2- to 3-day old virgin female moths were collected on charcoal filters (5 mg) as previously described (Grob and Zurcher, 1976; Nesbitt et al., 1979; Tumlinson et al., 1982).

Gas Chromatography (GC). GC analyses were conducted on a Carlo Erba Fractovap 4160 instrument fitted with a Grob split/splitless injector (220°C) and flame ionization detector (220°C). Fused silica capillary columns (25 m × 0.32 mm ID) were used coated with polar CP Wax 57CB (chemically bonded Carbowax 20 M; 0.21 μm film thickness; Chrompack), highly polar OV275 (dicyanoallyl silicone; 0.2 μm film thickness; Chrompack), or nonpolar CP Sil 5CB (chemically bonded methyl silicone; 0.12 μm film thickness; Chrompack). Carrier gas was helium (linear velocity 40 cm/sec). All injections were made with the split valve closed for 40 sec onto a column held at 70°C for 2 min, then temperature programmed as indicated in the tables. Retention times of the compounds identified in the ovipositor washings, entrainments, and their synthetic analogs are summarized in Table 1. Temperature-programmed conditions were used that allowed the retention times to be converted to equivalent chain lengths (ECLs) relative to the retention times of straight-chain acetates; thus, for example, tetradecyl acetate = 14.00 (Harris and Habgood, 1966). Retention times of series of geometrical isomers and the natural compounds were usually obtained under isothermal conditions, so their retention times are quoted in minutes.

Mass Spectrometry (GC-MS). Electron impact mass spectra were obtained on a Finnigan ITD 700 with open split interface to a Carlo Erba 5130 GC fitted with split/splitless injector (220°C) and fused silica capillary column (25 m × 0.32 mm ID) coated with BP20 (chemically bonded Carbowax 20 M; 0.2 μm film thickness; S.G.E.). Carrier gas was helium (23 cm/sec). The oven tem-

perature was held at 70°C for 2 min, then programmed to 120°C at 20°C/min and then at 4°C/min to 220°C.

Electroantennography (EAG). Simultaneous recording of EAG responses from male antennae to GC column effluent were conducted essentially as described by Beevor et al. (1986), except that the indifferent microelectrode was inserted into an interstitial membrane at the proximal end of one flagellum and the recording electrode inserted into an interstitial membrane at the distal end of the other flagellum. Eluting compounds were deemed to have caused an EAG response if the amplitude of the response was at least 10% greater than the average of responses to fractions eluting before and after it. GC columns and operating conditions were as described above. EAG responses to synthetic compounds were tested by pulsing nitrogen through a Pasteur pipet containing 5 ng of the test compound applied in 2 μ l of hexane, under conditions described by Beevor et al. (1986).

Synthetic Chemicals. (*Z,E*)-9,12-Tetradecadienyl acetate was obtained from Food Industries Ltd. (U.K.) in 1978 and contained 99.4% *Z,E*, <0.1% *E,Z*, 0.2% *Z,Z*, and 0.36% *E,E*. The *E,Z*, *E,E*, and *Z,Z* isomers of 9,12-tetradecadienyl acetate were obtained from the Institute of Pesticide Research, Wageningen, The Netherlands.

Wittig reaction with potassium *tert*-butoxide in THF between the triphenylphosphonium salt of 9-bromo-1-nonanol and (*E*)-2-pentenal gave a mixture of (*Z,E*)- and (*E,E*)-9,11-tetradecadienyl acetate. Similar reaction between the triphenylphosphonium salt of 8-bromo-1-octanol and (*E*)-2-hexenal gave the isomers of 8,10-tetradecadienyl acetate. These conjugated dienes could be iso-

merized to the thermodynamic equilibrium mixture of isomers by exposure to sunlight of a hexane solution containing a catalytic amount of iodine (cf. Beevor et al., 1986). Monounsaturated alcohols, acetates, and aldehydes were obtained by standard Wittig or acetylenic routes. The *Z* isomers used in field tests contained no more than 2% of the corresponding *E* isomers.

Field Tests. Field trials of synthetic pheromone mixtures were conducted in a mixture of cotton, maize, and fallow fields at the Cotton Research Station (Kibos, Kenya) in 1986 and 1987. Pheromone dispensers were white rubber septa (Aldrich, catalog No. Z10,072-2) impregnated with 0.1 ml of a hexane solution containing 1 mg of the pheromone blend and an equal weight of 2,6-*tert*-butyl-4-methylphenol (BHT) as antioxidant.

In 1986, sticky disk traps (60 cm diameter; Biological Control Systems Ltd., Treforest, Mid Glamorgan, U.K.) were used, fastened to a wooden T-shaped support 1.5 m above ground level. The pheromone dispenser was suspended at the center beneath a small inverted V-shaped roof to protect it from direct sunlight. Subsequent field work was conducted with funnel traps (8 cm diameter yellow funnel with white collecting box and green lid 3 cm above funnel rim; Biological Control Systems Ltd., U.K.), which were found to be as effective as disk traps and easier to maintain (Murlis et al., unpublished results). Each trap was fastened to an inverted L-shaped metal support 1.5 m from ground level. Lures were not changed during a trial. The traps were placed in circles containing one replicate of each treatment with at least 25 m between nearest neighbors and at least 100 m between replicates. Treatments were randomly assigned to each trap within a replicate and moved on one position clockwise each day, at which time the trap catch was recorded and discarded. The mean nightly catches were transformed to $\log(x + 1)$ to stabilize the variance, before subjecting them to analysis of variance. Differences between means were tested for significance at the 5% level by Duncan's multiple-range test (DMRT).

RESULTS AND DISCUSSION

Structure Determination. Initial analyses of ovipositor washings by linked GC-EAG on polar CP Wax 57CB and OV-275 and nonpolar CP Sil 5CB columns confirmed the presence of (*Z*)-9-tetradecenyl acetate (Z9-14:Ac) and (*Z,E*)-9,12-tetradecadienyl acetate (*Z,E*9,12-14:Ac) in the ratio of 20:1 as the major EAG active compounds, as described by Beevor et al. (1975). Pheromone yields of up to 200 ng of Z9-14:Ac were obtained from the ovipositor washings, but 20 ng was more usual. The reasons for this difference were not investigated. Increasing the quantity of extract tested (equivalent to 80 ng of Z9-14:Ac) and using temperature programmed runs to cover the range of reten-

tion times typical of lepidopteran pheromone components between decyl and eicosyl acetates, it became apparent that there were three additional EAG active compounds that had not been previously observed. Each of these compounds constituted 5% or less of the major component, Z9-14:Ac, by GC peak height.

Relative GC retention times of these compounds in ECLs are tabulated in Table 1 together with those of a sixth compound detected by GC-MS and identified by comparison of GC retention times with synthetic analogs. For convenience, the compounds are designated I-VI on the basis of their elution order on a polar CP Wax 57CB column.

Compound I displayed GC retention times characteristic of either a dodecyl acetate or a tetradecenal. The absence of ions at m/z 61 ($\text{Me}\cdot\text{COOH}^+$) and m/z 166 (M-60) (Figure 1) from the MS, which are indicative of a dodecyl acetate (Buser and Arn, 1975; Löfstedt et al., 1982), suggested it was a tetradecenal isomer. This was supported by the presence of an ion at m/z 192, which could have arisen through the loss of water from a tetradecenal (Gudziniowicz et al., 1976) or a loss of CH_3COOH from a tetradecadienyl acetate. The latter would be excluded on the basis of retention time. The position and geometry of the double bond were established as the (Z)-9 isomer by comparison of GC retention times with a range of synthetic analogs on polar CP Wax 57CB and nonpolar CP Sil 5CB columns (Table 2).

The GC retention times (Table 1) and MS [m/z 61, 194 (M-60)] (Figure 1) of compounds II and III indicated they were tetradecenyl acetate isomers. Comparison of their relative retention times with the complete range of tetradecenyl acetate isomers on polar CP Wax 57CB and the nonpolar CP Sil 5CB column with (Z)-12-tetradecenyl acetate as an internal standard (Nesbitt et al., 1986) showed that retention times of compound II were consistent only with those of Z9-14:Ac, as found by Beevor et al. (1975), and retention times of compound III were consistent only with those of (Z)-11-tetradecenyl acetate (Z11-14:Ac). No EAG response was recorded at any time to Z11-14:Ac, presumably because it eluted just after the two major EAG-active compounds in the extract, namely, Z9-14:Ac on the polar columns and Z,E9,12-14:Ac (compound IV) on the nonpolar. Linked GC-EAG analyses with synthetic mixtures of these compounds in the same relative amounts also failed to yield a response to Z11-14:Ac.

The MS of compound IV was characteristic of a tetradecadienyl acetate (M-60 at m/z 192; m/z 61) (Figure 1), and comparison of GC retention times of the isomers of 9,12-, 9,11-, and 8,10-tetradecadienyl acetates on polar CP Wax 57CB and nonpolar CP Sil 5CB columns confirmed the original assignment of Z,E9,12-14:Ac (Beevor et al., 1975) (Table 3).

Compound V had GC retention times (Table 1) and MS (M-18 at m/z 194; no m/z 61) (Figure 1) consistent with a tetradecen-1-ol isomer. Comparison of its GC retention times with those of a range of synthetic tetradecen-1-

FIG. 1. Total ion chromatogram, m/z 40–300, and mass chromatograms of m/z 61, 71, 82, 166, 192, 194, and 222 of an extract corresponding to five female *S. exempta* abdominal tips. m/z 61 is an ion typical of acetates, while m/z 71 is typical of saturated hydrocarbons, and m/z 82 is typical of unsaturated straight-chain compounds. Ions at m/z 166, 194, and 222 are produced by loss of CH_3COOH from dodecanyl, tetradecanyl, and hexadecanyl acetates, respectively, or loss of H_2O from the corresponding alcohols. Similarly, ions at m/z 192 are characteristic of the loss of CH_3COOH from tetradecadienyl acetates or H_2O from tetradecenals and tetradecadienols. Phomone components are labeled as in the text. Straight-chain hydrocarbons are labeled hc.

o1 isomers under isothermal conditions on both polar and nonpolar columns, using (*Z*)-12-tetradecen-1-ol as an internal standard, showed them to be consistent only with those of (*Z*)-9-tetradecen-1-ol (*Z*9-14:OH) (Table 4).

GC retention times (Table 1) and MS [m/z 61, 222 ($M-60$)] (Figure 1) of compound VI were consistent with those of a hexadecenyl acetate. All the hexadecenyl acetate isomers were available for comparison of their GC retention times with those of compound VI except (*Z*)- and (*E*)-2-hexadecenyl acetates. However, by analogy with the GC retention times of tetradecenyl acetate isomers, which follow a similar pattern (Nesbitt et al., 1986), (*Z*)- and (*E*)-2-hexadecenyl acetates could be excluded as candidates for compound VI. The GC retention times of compound VI were consistent only with those of (*Z*)-11-hexadecenyl acetate (*Z*11-16:Ac) on all three columns used (Table 5).

Analysis of entrained volatiles from virgin females by GC-EAG and GC-MS indicated that the pheromone released by the female was similar to that found in ovipositor extracts. Yields of up to 50 ng/female/night of the major component *Z*9-14: Ac were collected. To ensure the entrainment apparatus was functioning, a synthetic mixture of 100 ng of each compound except *Z*11-14: Ac was placed on aluminium foil. Recovery was between 50 and 80% for each compound in 4 hr.

The relative EAG responses of the six compounds identified in the female ovipositor washings at the 5-ng level were: I, 0.77 mV; II, 1.63 mV; III, 1.19 mV; IV, 2.46 mV; V, 1.0 mV; VI, 0.83 mV; and solvent blank, 0.6 mV.

GC-MS also confirmed the presence of a complete series of straight-chain saturated hydrocarbons (HC) in varying amounts from 21 HC to 29 HC, in the extracts (Figure 1). No EAG responses were ever observed to these compounds in linked GC-EAG analyses.

Field Tests. In order to assess the effect of individual compounds on male attractancy to pheromone traps, field trials conducted in 1986 compared the total mixture of six compounds, in their naturally occurring ratio, with five-component mixtures in which either *Z*9-14: Ald, *Z*9-14: OH, *Z*11-14: Ac, or *Z*11-

16:Ac had been removed. Z9-14:Ac and Z,E9,12-14:Ac were present in all lures tested because they were assumed to be necessary for attraction.

Removal of either Z9-14:Ald or Z11-14:Ac was found to have no effect on trap catch compared to the total mixture. However, removing Z11-16:Ac significantly reduced catch and removing Z9-14:OH significantly increased catch (Table 6).

The two-component mixture of Z9-14:Ac and Z,E9,12-14:Ac in their naturally occurring ratio of approximately 100:5, caught significantly more males than the six-component mixture, although it was significantly less attrac-

tive than the five-component mixture in which Z9-14:OH had been removed. For comparative purposes, the "standard" lure used throughout East Africa, (Nyirenda, 1985, Haggis, 1986), a 100:7.5 mixture of Z9-14:Ac and Z,E9,12-14:Ac, was also included in the trial. Catches with this were not significantly

different from those of either the two-component mixture with the natural ratio of compounds or the five-component mixture without Z9-14:OH, although the latter did catch 10% more moths (Table 6).

Because of the antagonistic nature of Z9-14:OH, it was not included in field trials conducted in 1987. Table 7 shows the results from a trial in which individual components were removed from the resulting five-component mixture. The most dramatic result was obtained by the removal of Z,E9,12-14:Ac, which resulted in no catch at all. Differences between catches for the other

treatments were not significant, although in each case mixtures without Z11-16:Ac caught fewer moths.

The 1986 trials had also indicated that the 100:7.5 mixture of Z9-14:Ac and Z,E9,12-14:Ac may be more attractive than the 100:5 mixture. In order to check this and provide a further comparison between the five-component blend and the two-component blend a trial was undertaken in which 5, 7.5, or 10% Z,E9,12-14:Ac was added to the two- and five-component mixtures (Table 8). In each case the five-component mixture caught significantly more moths, confirming previous results. There was no difference in catch between those with mixtures containing 5 or 7.5% Z,E9,12-14:Ac, although the addition of 10% reduced catch significantly in both cases.

The only newly identified compound to show any potential for increasing attractancy in the field from the 1986 field tests was Z11-16:Ac. In order to confirm this, the "standard" two-component mixture was compared with mixtures in which between 2.5 and 10% Z11-16:Ac had been added. In each case, the addition of Z11-16:Ac increased catch significantly above that of the two-component mixture, although the actual amount added did not seem to be important (Table 9).

CONCLUSION

This reassessment of the female sex pheromone of the African armyworm, *Spodoptera exempta*, has confirmed the presence of Z9-14:Ac and Z,E9,12-14:Ac, in the ratio of 100:5 (Beever et al., 1975). In addition, four new com-

pounds, Z9-14:Ald, Z11-14:Ac, Z9-14:OH, and Z11-16:Ac, were characterized from virgin female ovipositor washings and volatiles. These compounds were present at 1.5, 2, 3.5, and 4% of the major component, respectively. Field tests confirmed that Z9-14:Ac and Z,E9,12-14:Ac are essential for attractiveness and showed that addition of Z11-16:Ac at 2.5-10% of the major component could significantly increase catches. Using a 1 mg loading of pheromone, the other compounds identified had no effect at the naturally occurring level except Z9-14:OH, which significantly reduced catch.

The study was conducted with the intention of maximizing trap catch for use in the East African monitoring system without incurring high cost. For this reason, compounds of commercial purity were used. Z9-14:Ac currently employed in the network contains approximately 2% of the *E* isomer, which could have an effect on behavior. Similarly, it was important that the effective lifetime of the lures was closely related to those used in the regional monitoring system, although the loading used may not have been optimal for testing the effects of the minor components.

Z9-14:Ac, Z11-14:Ac, Z9-14:OH, and Z,E9,12-14:Ac are commonly found in the sex pheromones of Noctuidae and the genus *Spodoptera* in particular (Arn et al., 1986). However, Z9-14:Ald and Z11-16:Ac have only previously been identified in North American species, such as *Spodoptera frugiperda* (Mitchell et al., 1985; Tumlinson et al., 1986), and Z11-16:Ac in *Spodoptera eridania* (Teal et al., 1985) and *Spodoptera sunia* (Bestmann et al., 1988).

The apparent lack of effect of Z9-14:Ald and Z11-14:Ac on trap catch, at the levels tested, does not necessarily mean they do not influence insect behavior. Pheromones are generally considered to be species specific (Cardé and Baker, 1984), so where a number of closely related sympatric species have

pheromone components in common, it may be anticipated that the other, often minor, components could be involved in deterring cross-attraction (Grant et al., 1988; Linn et al., 1987). *Spodoptera triturrata* is sometimes caught in *S. exempta* traps, and so it is conceivable that, in order to ensure species specificity, all the components presently identified, except perhaps Z9-14:OH, will have to be included in the lures. Wind-tunnel studies and further field trials are now in progress in an attempt to elucidate the possible role of the minor components in inter- and intraspecific chemical communication.

Acknowledgments—The authors would like to thank Dr. D.J.W. Rose, Dr. L.D.C. Fishpool, Mr. W.W. Page, and Mr. C.F. Dewhurst, ODNRI, for their invaluable comments and assistance with field work; Mr. W.Y.K. (Received March 25, 1988; accepted June 30, 1988)

Abstract—Behavior of males of *Hydraecia micacea* (Esper) responding to virgin females and to synthetic pheromone blends were investigated in a laboratory wind tunnel. The synthetic blend consisted of saturated 14:Ac (68.9%), Z9-14:Ac (3.4%), E11-14:Ac (14.6%), and Z11-14:Ac (13.1%). Virgin females were significantly better lures than the four-component synthetic blend for most behaviors. By deleting components individually from the four-component blend, Z9-14:Ac, Z11-14:Ac, and saturated 14:Ac were found to be necessary for communication but E11-14:Ac was found to have no effect on typical pheromone-mediated reproductive behaviors. Close-range studies suggested that chemicals of low volatility, released from moths, were important in eliciting copulation attempts. Field studies reinforced laboratory findings regarding the effectiveness of different lures and indicated that *Heliothis* traps were the most effective for monitoring.

Key Words—*Hydraecia micacea*, Lepidoptera, Noctuidae, potato stem borer, sex pheromones, field trapping, reproductive behavior, tetradecenyl acetate, (Z)-9-tetradecenyl acetate, (E)-11-tetradecenyl acetate, (Z)-11-tetradecenyl acetate.

INTRODUCTION

The potato stem borer moth, *Hydraecia micacea* (Esper), is a periodic pest of numerous crops (Deedat et al., 1983). In the northeastern United States and

southern Canada, the major impact of this insect is on corn, which suffers from wilting of the axial leaves due to larvae feeding within the corn stalk. Although eggs are laid on leaves of weed grasses that surround fields, larvae migrate into fields, and consequently the incidence of damage caused by the insect is correlated directly with the presence of suitable grass oviposition sites (Deedat and Ellis, 1983). Population levels are variable between fields, and, while damage is usually restricted to the outer 20 rows, crop loss in some fields can be as high as 80% (Tetor, 1980).

Synthetic sex pheromones of Lepidoptera are used widely as lures for population monitoring and have potential for use in pest control, particularly when the pest species is distributed in isolated, low-density populations (Plimmer, 1982). We felt that the potato stem borer (PSB) was a good candidate for studies aimed at the development of pheromone-based control programs because reports of PSB infestations fit the criteria outlined above. However, prior to the development of control methods, it is necessary that the pheromone-mediated behavior be thoroughly understood. Consequently, we undertook laboratory study on aspects of the reproductive biology that are regulated by semiochemicals for this insect. Here we report the results of studies of the responses of PSB males to females and to various synthetic blends of pheromone components identified in earlier studies (Teal et al., 1983).

METHODS AND MATERIALS

General. Potato stem borers were reared at 25°C as described by West et al. (1985) using a diet modified from Hinks and Byers (1976). The insects were from a laboratory stock into which field-collected males were introduced each year. Insects were sexed as pupae and transferred to separate rooms that had reversed light cycles. The conditions were 14 hr: 10 hr (light-dark) with temperature at 26°C and 24°C (photophase-scotophase) and relative humidity of 55%. Emergence was checked 30 min prior to scotophase, and adults were transferred to nylon screen cages measuring 30 × 30 × 30 cm, which contained cotton wicks soaked with 10% sucrose solution. Insects used for all laboratory trials were 2 to 5 days old.

Chemical Solutions and Lure Formulations. All chemicals used for formulation of synthetic lures were purchased from Sigma Chemical Co. (St. Louis, Missouri) and were purified by high-performance liquid chromatography using a 25 × 2.5-cm (OD) 5- μ m silica column coated in situ with 15% AgNO₃ (Heath and Sonnet, 1980). The compounds were eluted with toluene. All chemicals were at least 99% pure as determined by capillary gas chromatographic (GC) analysis.

Analyses of pheromone component purity were conducted using 30 m ×

0.25 mm ID SPB-1 and Supelcowax 10 columns (Supelco, Bellefonte, Pennsylvania). Ratios of blend components were verified using both columns. Samples were run isothermally in the split mode at 165°C. Hydrogen was used as the carrier gas at a linear flow velocity of 38 cm/sec. A Hewlett-Packard (Avondale, Pennsylvania) 5790 GC equipped with a flame ionization detector and interfaced with a Hewlett-Packard 3390A integrator was used for all analyses.

White rubber septa (Sigma Chemical Co., St. Louis, Missouri, catalog No. S5509), used as pheromone dispensers, were Soxhlet extracted with methylene chloride for 24 hr and air dried prior to loading. Blends of synthetic compounds (see Table 1) loaded into lures included 500 μg of the four-component blend identified by Teal et al. (1983), which included tetradecenyl acetate (14:Ac) (68.9%), (Z)-9-tetradecenyl acetate (Z9-14:Ac) (3.4%), (E)-11-tetradecenyl acetate (E11-14:Ac) (14.6%), (Z)-11-tetradecenyl acetate (Z11-14:Ac) (13.1%), and blends from which one of the above components had been deleted. Blends were applied in 200 μl of isooctane to the large well of the septum, and septa were allowed to stand in a fume hood for two days to allow for solvent evaporation.

Bioassays. All laboratory studies were conducted 5–8 hr into the scotophase, which coincided with the peak period of pheromone release by females (West et al., 1984). Tests were conducted in a 2.0 \times 1.0 \times 0.5-m Plexiglas flight tunnel housed in a room with the same photoperiod, temperatures, and humidity maintained in rooms used to house adults. The excurrent end of the flight tunnel was fitted to a fume hood controlled by a variable transformer. Air was pulled through the tunnel at 0.5 m/sec and expelled outside the building.

Lures for all studies, including females, and synthetic blends, were housed in an 8 \times 10 \times 10-cm Plexiglas holding cage with aluminum screen on two opposing sides to allow for air flow through the cage. The holding cage for all trials was positioned in the center of the tunnel about 30 cm from the upwind end. All males used were quiescent before the trial. Males were transferred individually to a 2 \times 2 \times 8-cm Plexiglas cage suspended in the center of the tunnel about 15 cm from the downwind end. Males were used once, then discarded, with the exception of males flown to blanks. These insects were flown to a lure that contained pheromone 24 hr after exposure to blank lures. Males were allowed 1 min for activation, a behavior identified by ambulation and wing fanning. If activation did not occur within this time, the moth was discarded. Otherwise, the trial lasted 5 min. Behaviors were recorded on audiocassette tape and later transcribed.

Male response to females was established by using five to six virgin females that had been observed calling for at least 5 min in the holding cage. When the male behavioral repertoire was established, observed behavior frequencies were tabulated in first order, preceding–following transition matrices from which ethograms were derived as outlined by Stevenson and Poole (1976) and Fagen and

Young (1978). To determine if individual transitions occurred greater than chance, $(\text{observed} - \text{expected})/\text{expected}^{0.5}$ must have been greater than chi-square value at $0.05/(dF)^2$ [when the degrees of freedom (dF) equaled 72 as determined from the transition matrix]. The most probable sequence of behaviors was determined using standard normal deviates calculated from significant chi-square values using the binomial test (Siegel, 1956).

When synthetic blends were tested, two rubber septa were enclosed in aluminum screen and suspended on the downwind screen of the cage used to hold lures or females in earlier studies. The role of individual pheromone components was studied by eliminating a single compound from the four-compound blend (Table 1). The percentages of moths exhibiting each behavior to each lure were calculated. Responses to each of the three-component blends, the four-component blend, and to virgin females were compared using a chi-square test of independence with Yates' correction at $P = 0.05$ (Steel and Torrie, 1980).

Field Studies. Six different lures were used in three different traps in a 6×3 factorial design for field studies. The five synthetic lures were the same as those used in flight tunnel studies, and the sixth was a pair of caged virgin females. Synthetic blends were tested using one rubber septum. The trap designs used were Heliiothis Trap (Albany International, Needham Heights, Massachusetts), Pherocon 1-C (Zoecon corp., Palo Alto, California), and a cone-orifice trap (Struble, 1983) that had the rubber septa suspended centrally. Traps were set with all lures standardized at 1 m high.

Trap catches were counted and trap positions were rerandomized every other day from August 8 to 25, 1985, in a field near Alma, Ontario. Traps were positioned in two adjacent fields where the highest PSB infestation occurred

along the common hedgerow and extended to a grassy L-shaped strip through one of the fields. Traps were positioned 30 m apart. Septa were not changed, but females were replaced after counts were taken. No traps were filled to capacity when counts were taken. Both lure and trap-catch data were transformed by $(X + 1)^{0.5}$ before being subjected to analysis of variance and Duncan's new multiple-range test (Anonymous, 1982).

Close-Range Behavior. The roles of chemical cues and vision in eliciting copulation attempts were tested using wind-tunnel bioassays. Virgin females were used as the pheromone source to satisfy the assumption that the sex pheromone blend was correct.

Two distances were used to test chemical cues in eliciting copulation attempts. Virgin females were placed in screen tubes, measuring 2 cm in diameter, which were placed inside the holding cage at two distances from the downwind screen of the holding cage. At the farthest position, the females were 2–4 cm from the downwind screen of the holding cage, while they were less than 2 cm from the screen at the closer distance. The holding cage was placed in the flight tunnel as described earlier.

The two conditions to test vision were the presence or absence of a model. The model was a dead male rinsed with acetone, impaled on a fine wire and positioned inside the same holding cage used previously. The wings of the model were spread to simulate the outline of a calling female.

Only responses from males that landed on the holding cage were recorded. Four comparisons were made. Two comparisons tested the effect of the model at each distance, and two tested the effect of distance with and without the model. New models were used with each pheromone source. A test of proportion with the *Z* statistic was used for statistical analysis (Steel and Torrie, 1980).

RESULTS AND DISCUSSION

Male Behavior to Virgin Females. The behavioral repertoire of males responding to calling females included activation, random flight, upwind orientation, hovering, landing, searching the site, attempted copulation, casting downwind, reorientation, and stopping (Figure 1). Activation included ambulation, wing fanning, and antennal grooming. Random flight involved movement through the entire volume of the tunnel and included short bouts (< 1 min) of sitting or walking on the tunnel walls. Orientation was identified as wide horizontal and vertical sweeps in the downwind half of the tunnel with slow upwind movement and progressively narrower sweeps closer to the pheromone source. Hovering was indicated by stationary flight within 10 cm downwind of the holding cage, and landing indicated that the male had contacted the holding cage. Searching consisted of a combination of behaviors performed while on

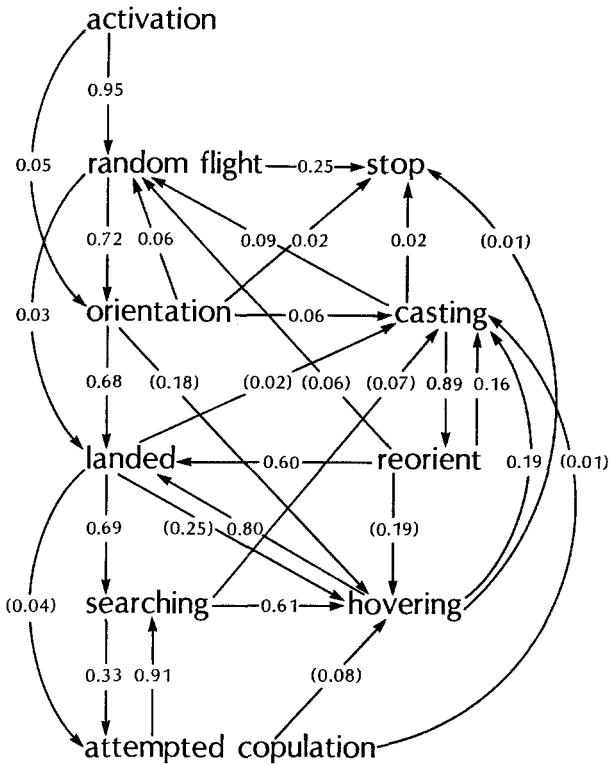

FIG. 1. Ethogram of response of male PSB to calling virgin female PSB in wind-tunnel bioassays. Numbers represent the conditional probability of a moth performing a behavior after exhibiting the previous behavior. Numbers in parentheses represent transitions occurring at a frequency not greater than chance ($N = 67$).

the holding cage that included walking vertically and horizontally and turning both clockwise and counterclockwise. Searching was always accompanied by rapid wing-fanning. Attempted copulation was typically a lateral curving of the abdomen to either left or right. Casting was direct downwind flight, usually in an upward arc, after the male had oriented to the lure. Reorientation was upwind flight to the pheromone source after having oriented previously. Males were regarded as stopped when they sat on a wall for at least 1 min.

Behavioral responses of males to calling females were highly variable (Figure 1), but use of the binomial test allowed for the identification of the most probable sequence of behaviors (Figure 2). PSB males typically oriented to the females within ca. 1 min, with landing on the source usually initiating a cyclic series of behaviors. Landing led to searching, which was interspersed with

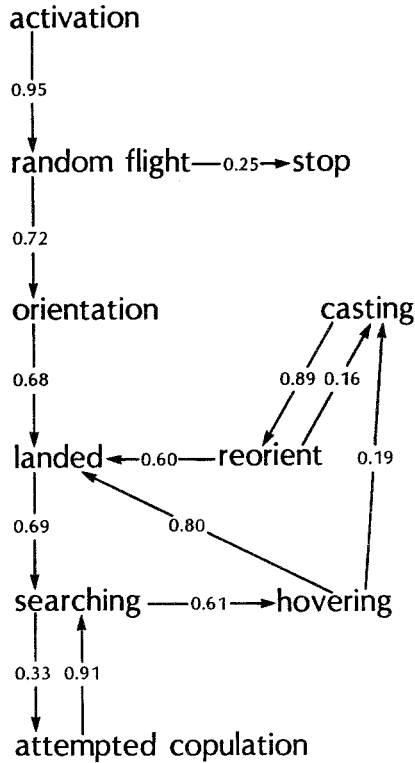

FIG. 2. Ethogram of the most probable sequence of response of male PSB in the wind tunnel. Numbers represent the most probable sequence of behaviors from the comprehensive ethogram of Figure 1 ($N = 67$).

attempted copulations. Copulation attempts were made only when the female was opposite the male on the downwind screen of the holding cage. Subsequent hovering was followed by a return to landing. This cycling could last the duration of the trial. Some males had a larger cycle of behaviors that included casting after hovering and then reorienting back to the source. Male PSB were usually active through the end of the trial. Blank lures elicited only random flight in the wind tunnel, indicating that upwind orientation behavior was induced by pheromones.

Response to Synthetic Blends in the Wind Tunnel. No blend of synthetic components was as effective as females in eliciting behaviors (i.e., orientation, landing, copulation) necessary for successful mating in a single attempt (Table 1). This reduction in response was not due solely to the significant decreases in the number of males orienting upwind but due also to combined reductions in

the numbers of males orienting, landing, and attempting to copulate. Studies with other noctuid species, for example, *Heliothis phloxiphaga* Grote and Robinson (Raina et al., 1986) and *H. virescens* (Teal et al., 1986), have shown that synthetic blends of pheromone components are capable of reproducing or surpassing virgin females in attractiveness and ability to elicit reproductive behaviors. Consequently, the four-component pheromone blend used in this study and identified by Teal et al. (1983) does not accurately represent the complete sex pheromone released by as many as five to six females of the potato stem borer.

Differences in behavioral response between the synthetic lures and calling females could be due to components missing from the blend and/or inaccurate component ratios and release rates. Reevaluations of sex pheromone blends of other species have often resulted in the addition of components which, although present in small quantities, were important for either maximizing pheromone-induced behaviors in the wind tunnel or for increasing trap catch (Bjostad et al., 1984; Sparks et al., 1979).

Subsequent studies by Teal and Tumlinson (1987) indicated the presence of picogram amounts of a series of 14-carbon alcohols in ethyl ether extracts of the pheromone gland of calling female PSB. These alcohols are the immediate precursors of the acetates identified for the PSB by Teal et al. (1983) and may be released in the pheromone blend by female PSB in minute amounts. Consequently, these compounds could be critical for effective signaling, while still being precursors for the acetate compounds. This supposition is supported by a study of *H. phloxiphaga* conducted by Raina et al. (1986) in which minute amounts of (*Z*)-11-hexadecen-1-ol, a compound known to be the immediate precursor of the aldehyde present in the greatest amount in the volatile pheromone blends of *Heliothis* spp. (Teal and Tumlinson, 1987), is critical for effective communication. Other unidentified components also may be present in the pheromone blend of PSB females.

Ratios of components have been reported to differ between gland extracts and volatile blends in other Noctuidae (Bjostad et al., 1980; Teal et al., 1985, 1986) and in other lepidopteran families (Hill et al., 1975; Roelofs et al., 1975; Hill and Roelofs, 1981). Evaluation of the volatile pheromone blend released by calling PSB females will allow for the elucidation of the actual components, ratios, and release rates of the pheromone.

Although none of the synthetic blends tested was as effective as females in inducing males to perform behaviors associated with pheromone communication (i.e., orientation, landing, etc.), most blends were as effective as females in causing males to enter flight (Table 1). No behaviors were affected when E11-14:Ac was deleted from the four-component blend. This suggests that E11-14:Ac does not play a role in chemical communication by this species. However, we cannot exclude the possibility that this compound affects as yet

undefined behaviors of conspecific males or that it may play a role in reproductive isolation between the PSB and other closely related species. Fewer males approached to within 10 cm of lures that did not contain Z11-14:Ac than when either the four- or three-component blend that lacked E11-14:Ac was tested. The decrease in the number of approaches also resulted in fewer males landing when Z11-14:Ac was deleted with respect to the blend lacking E11-14:Ac. Consequently, Z11-14:Ac appears to affect close range orientation by males. Deletion of 14:Ac resulted in significant reductions, with respect to either the four-component or three-component blend lacking E11-14:Ac, in the number of males that landed on the holding cage. Similarly, the blend lacking Z9-14:Ac was less effective than the blend lacking E11-14:Ac in inducing males to land. However, no single compound appeared to be responsible for the release of a specific behavior and, consequently, the totality of the blend may be as important as the blend constituents in stimulating pheromone-mediated reproductive behavior.

Field Trapping Studies. Results of field trapping studies that employed different lures and trap types are given in Table 2. Trap design accounted for the greatest variation in catch as is indicated by the fact that *Heliothis* traps always caught some males when baited with any lure, whereas males were captured in double-cone traps only when these traps were baited with females. The success of the *Heliothis* trap was probably the result of the large lower aperture. After approaching or landing on lures in flight-tunnel studies, males commonly cast back downwind. Therefore, moths that flew up and away from the lures positioned beneath these traps would fly into the trap. Once inside, the lower rim probably prevented most moths from crawling down and out of the trap. The Pherocon trap requires insects to land in order to be captured. Consequently, lures that did not induce landing or close-range approach in the flight

TABLE 2. MEAN NUMBER OF MALE PSB CAPTURED PER SAMPLING PERIOD IN DIFFERENT TRAP TYPES BAITED WITH VARIOUS PHEROMONE LURES

tunnel (i.e., those that lacked either Z11-14:Ac or 14:Ac) were ineffective in these traps. Pherocon traps baited with lures lacking Z9-14:Ac also did not capture males in field studies. This may be explained by the low incidence of landing in the flight-tunnel study, coupled with the chance of escape from the trap glue by these large moths.

It was expected that cone-orifice traps would catch moths only when baited with females for two reasons: first because males would spend considerable time searching and crawling into these traps, and second because the levels of activity to the synthetic blends were significantly lower for all behavioral criteria examined in the flight tunnel than those recorded when females were tested. The relatively low number of insects caught in cone-orifice traps when females were used as lures may be explained by plume shape. *Heliothis* traps and Pherocon 1-C traps probably had the least plume disruption because their exposed lures probably produced an omnidirectional effect with respect to wind. Cone-orifice traps were unidirectional with respect to wind, however, and probably had poor flow through the trap most of the time because of variable wind direction. Struble (1983) found cone-orifice type traps generally had lower catches of Lepidoptera than omnidirectional designs.

There was also a good correlation between the capture of males in *Heliothis* traps with different lures and the ability of those lures to elicit reproductive behaviors from males in wind-tunnel bioassays. Numbers of males caught using the four-component blend or the blend missing E11-14:Ac were not significantly different. The fact that neither of these synthetic lures was different from females suggests an inconsistency between these field data and wind-tunnel studies. However, wind-tunnel studies employed groups of five to six females caged in a relatively large container that enabled females to call undisturbed, while field studies employed only two females housed in small cages, which increased contact between insects. Consequently, the difference between the laboratory and field may be the result of much smaller amounts of pheromone released by females used in field studies. Deletion of Z11-14:Ac from lures used in the field caused a reduction in captures that is correlated with the fact that this compound affected both the approach and landing of insects in flight-tunnel studies. Similarly, deletion of 14:Ac resulted in reduced capture. The intermediate numbers captured in *Heliothis* Traps baited with lures that did not contain Z9-14:Ac reflect the fact that while the number of males that both approached and landed on these lures in the flight tunnel was reduced with respect to more effective blends, the reduction was not significant.

Close-Range Reproductive Behavior. The fact that few insects landed or performed subsequent searching and that none attempted to copulate in response to any of the synthetic blends in the wind tunnel, coupled with the results of field studies that indicated the four-component blend and three-component blend lacking E11-14:Ac were as effective as females in traps, suggested that factors

other than the compounds identified from the gland extracts played a role in the reproductive behavior of these insects. Therefore, we conducted studies on the close-range reproductive behaviors of these moths. There were few attempted copulations when caged females were farther than 2 cm from the downwind screen of the holding cage and no behavioral differences between presence or absence of the model at that distance (Figure 3). Copulation attempts increased when the female was less than 2 cm from the downwind screen, but the increase was significant only when the model was absent (Figure 3).

Clearly, factors associated with proximity of the sexes were important in eliciting copulation attempts. These factors were probably chemical, since tactile cues were eliminated by the two layers of aluminum screen that separated the sexes. Since three pairs of males were observed attempting male-male copulations in preliminary trials when females were positioned greater than 2 cm from the downwind holding cage screen, these chemical cues do not appear to be restricted to the female sex pheromone blend. Chemicals of low volatility released from moth scales may be a cue. Acetone-washed males used as models may have been stripped of these chemical cues.

Grant et al. (1987) reported contact pheromones found in scale extracts of white-marked tussock moth females, *Orgyia leucostigma* (J.E. Smith), that released copulatory behavior from the males. Similarly, Ono (1981) found the presence of scales could induce interspecific copulation attempts in three species

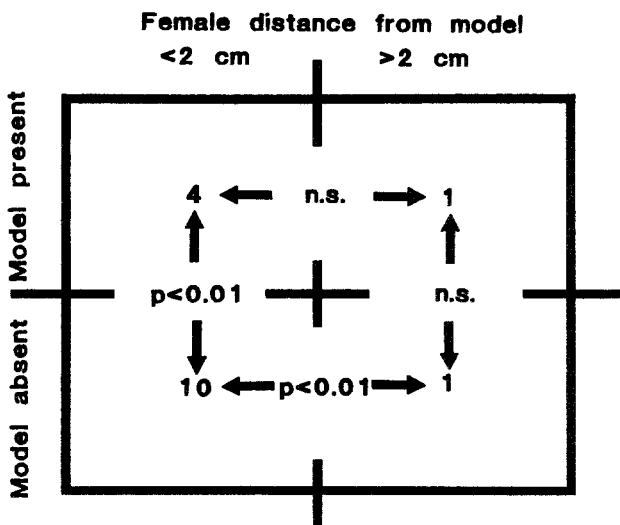

FIG. 3. Number of male PSB attempting to copulate with caged female PSB both with and without the model, and at two distances, in the wind tunnel. Arrows indicate pairwise comparisons made using the Z statistic at $P = 0.05$ ($N = 10$ in each cell).

of phycitid moths. Male PSB may require similar compounds to release the copulatory response. If so, present studies indicated that for the PSB, chemicals can be perceived at short distances and that male contact with the female is not necessary to elicit a copulatory response.

Visual stimuli played a secondary role to chemical cues in eliciting copulation attempts because any factor that decreased copulation attempts with the model present was more important than vision. It was expected that the model with females less than 2 cm distant would elicit the same behaviors as males responding to unrestricted females. However, the reverse occurred. Inhibition in response to the model at close range may be the result of either chemicals from the model that inhibited behavior, or because close-range chemicals from a female less than 2 cm away were not perceived due to disrupted air flow around the model. It is not possible to determine from these data, however, what role visual cues do play in eliciting copulation attempts from male PSB. The role of visual cues is variable in the Noctuidae, but for most, it is secondary to an accurate sex pheromone blend in eliciting close-range behaviors (Shorey, 1964; Shorey and Gaston, 1970; Carpenter and Sparks, 1982).

In conclusion, our studies suggest that the four compounds identified from extracts of the pheromone gland of females of *H. micacea* are of importance in semiochemical communication. However, disparities observed in flight-tunnel studies between synthetic lures and females suggest that this blend does not accurately represent the one released by females. This could be the result of the lack of as yet unidentified compounds important for communication, inappropriate release rate, or incorrect ratios, or all of these factors.

(Received March 28, 1988; accepted June 30, 1988)

Abstract—Petrol and ethanolic extracts of six asteraceous weeds were added to artificial diets to screen for growth inhibition and mortality of the variegated cutworm, *Peridroma saucia* (Hbn). Petrol and ethanolic extracts of *Artemisia tridentata* and *Chamomilla suaveolens* and ethanolic extracts of *Chrysothamnus nauseosus* and *Centaurea diffusa* severely inhibited larval growth at five times the natural concentrations. The two *C. suaveolens* extracts and the ethanol extract of *A. tridentata* were active at the natural concentration (100%) and were further examined at 20, 40, 60, and 80% of this level. Inhibition of larval growth was directly related to concentration for each of the three extracts tested. EC₅₀s (effective concentration to inhibit growth by 50% relative to controls) for the three extracts were 36–42% of the naturally occurring level in the plants. Nutritional indices were calculated for second-instar *P. saucia* feeding on the active *A. tridentata* EtOH extract and the petrol extract from *C. suaveolens*. Addition of the active *A. tridentata* EtOH or the *C. suaveolens* petrol extract to the diet resulted in significant reduction in the relative growth rate of larvae, although the *A. tridentata* extract was much more inhibitory. Dietary utilization was significantly lower for larvae fed the *A. tridentata* EtOH extract.

Key Words—*Artemisia tridentata*, *Chamomilla suaveolens*, *Chrysothamnus nauseosus*, *Peridroma saucia*, Lepidoptera, Noctuidae, growth inhibition, plant extracts, pest control.

INTRODUCTION

Insect growth inhibitors (e.g., feeding deterrents) may provide effective tools for integrated crop management systems by protecting crops from herbivory

while avoiding destruction of the beneficial insect complex (Bernays, 1983). For example, recent studies suggest that some of the pyrethroids show promise at sublethal doses because they deter feeding and inhibit insect growth (Kumar and Chapman, 1984; Dobrin and Hammond, 1985).

Plants provide an abundant source of new chemicals to examine as pest control agents, including growth inhibitors. Recently, the presence of novel pesticidal compounds from some plants has been examined (Delle Monache et al., 1984; Villani and Gould, 1985; Lane et al., 1987). The acute insecticidal activity of many plants is known (Crosby, 1971), but only more recently have they been examined for insect growth inhibitors (Grainge et al., 1985).

The highly evolved plant family Asteraceae includes many temperate weeds and is a rich source of chemical constituents (Heywood et al., 1977). For example, asteraceous plants contain sesquiterpene lactones that inhibit larval growth in several insect species (Mabry and Gill, 1979; Isman and Rodriguez, 1983).

Chronic feeding bioassays are used to assess the insect growth-inhibitory activity and lethality of ethanolic and petrol extracts from big basin sagebrush (*Artemisia tridentata* Nutt.), diffuse knapweed (*Centaurea diffusa* Lam.), pineappleweed [*Chamomilla suaveolens* (Pursh) Rydb. = *Matricaria matricarioides* (Less.) Porter], common rabbitbush [*Chrysothamnus nauseosus* (Pallas) Britton], tansy ragwort (*Senecio jacobaeae* L.), and goat's-beard (*Tragopogon dubius* Scopoli). (Plant nomenclature follows Taylor and MacBride, 1977.) The target insect for these bioassays is a polyphagous noctuid, the variegated cutworm, *Peridroma saucia* (Hbn). *P. saucia* is an important economic pest, occasionally causing serious damage to horticultural crops in Canada (Beirne, 1971) and the United States (Capinera, 1978; Crumb, 1929). The overall objective of this research is to screen plant extracts as potential pest control agents.

METHODS AND MATERIALS

Plant Extracts. Air-dried plants, collected from southern British Columbia, were finely ground in a Wiley mill. Plant species, parts extracted, location, and the harvest dates are listed (Table 1). Powdered plant material (200 g) was extracted for 24 hr in 1 liter of either petrol (boiling range 30–60°C) or 95% aq EtOH at room temperature (21°C). The slurry was filtered, rinsed, and the extracts reduced under vacuum to 10–60 ml, depending on their viscosity.

Initial Screening. Extracts fivefold those naturally occurring (dry weight plant powder/dry weight artificial diet) were admixed with the dry portion of the artificial diet (Bioserv Inc., Frenchtown, New Jersey; No. 9682), and the carrier solvent was removed in a fume hood. Controls consisted of artificial diet similarly treated with the carrier solvent alone. Upon hatching, two neonate *P. saucia* larvae from our laboratory colony were placed on ca. 2-g (wet weight)

TABLE 1. PLANT SPECIES, COMPONENTS EXTRACTED, HARVEST LOCATIONS IN BRITISH COLUMBIA AND DATES OF MATERIAL BIOASSAYED IN INITIAL SCREENING^a

Plant species	Components extracted	Location	Harvest date
<i>Artemisia tridentata</i>	stms, lvs, fls ^a	Summerland	10-83
<i>Centaurea diffusa</i>	stms, lvs, fls	Kamloops	10-83
<i>Chrysothamnus nauseosus</i>	stms, lvs	Keromeos	5-84
<i>Chamomilla suaveolens</i>	whole plant	Vancouver	5-84
<i>Senecio jacobaea</i>	stms, lvs	Abbotsford	5-84
<i>Tragopogon dubius</i>	stms, lvs, fls	Hedley	5-84

^a stms = stems, lvs = leaves, fls = flowers. *A. tridentata* and *C. nauseosus* consisted of 1-year-old growth. All other species consisted of the entire aboveground portion of the plant at the time of harvest (the roots were included only with *C. suaveolens*).

aliquots of diet in 30 ml plastic cups. Fifteen cups per treatment and 15 treatments were randomized in clear plastic boxes at room temperature. For the tabulated presentation, larval growth was measured as a percentage of the controls after 14 days, based on live larval weights. For the analysis, live larval weights were \log_{10} transformed prior to an analysis of variance and mean larval weights were separated using Tukey's studentized range (HSD) test.

Plant Powder and Residue Experiment. The plant residue remaining from the initial extraction and the unextracted plant powders were assayed for bioactivity on the *P. saucia* neonates. Biological activity observed in the residue, but not present in the initial extract screening, could then be further examined. The dry portion of the diet consisted of 50% Bioserv No. 9682 with an equivalent portion of residue or plant powder (1:1 w/w). Control diet was prepared using one part powdered cellulose (alphacel) to one part artificial diet. An additional treatment consisted of the standard diet (full portion) without cellulose. This treatment was used to determine the effect of the control diet, diluted with cellulose, on larval growth. The experimental design was the same as in the previous experiment.

Second Screening. The most inhibitory extracts were chosen for a further feeding bioassay. Artificial diets were freshly prepared using natural concentrations (dry wt plant/dry wt diet) of the plant extracts. Control diets were treated with petrol alone. *P. saucia* neonates were individually placed on ca. 1 g of diet ($N = 25$) and allowed to feed for 11 days and then weighed. Surviving larvae were placed on control diet to determine the persistence of growth inhibitory effects through pupation to adult emergence.

Dose-Response Experiment. Four concentrations (20, 40, 60, and 80% of natural conc. dry wt/dry wt) of the ethanolic extract of *A. tridentata* and both

extracts of *C. suaveolens* were assayed as above with ethanol and petrol controls. *P. saucia* larvae were counted, weighed after 15 days, and then allowed to feed on the control diet until pupation. The pupation and emergence were recorded for each treatment.

Sensitivity of Older P. saucia Larvae. To determine how the biological activity of the plant extracts was influenced by larval age, another dose-response experiment was initiated with older caterpillars. Neonate *P. saucia* larvae were fed for six days on the standard control diet. The resulting second-instar larvae (ca. 7 mg) were then transferred to the treatment diets ($N = 25$). The bioassay and analysis were as previously described in the neonate *P. saucia* dose-response experiment.

Detailed Growth Analysis of P. saucia Larvae Feeding on A. tridentata and C. suaveolens Extracts. To distinguish between behavioral and physiological contributions to larval growth inhibition, a detailed growth analysis was initiated on second-instar *P. saucia*. Larvae (10.9 ± 1.5 mg, $N = 15$) were fed diets at their natural concentrations (100% dry wt/dry wt). An EtOH extract of *A. tridentata* and a petrol extract of *C. suaveolens* were compared with the standard diet treated with petrol. The duration of the experiment was 48 hr, although larvae were weighed at 24 hr as well as 48 hr to determine relative feeding and growth rates over the two 24-hr periods. Except where otherwise indicated, all measurements are based on dry weights. Growth indices were calculated as described by Scriber and Slansky (1981).

RESULTS AND DISCUSSION

Table 2 shows the growth inhibitory effects of crude plant extracts at five times the natural concentration (dry wt/dry wt) on *P. saucia* larvae fed artificial diet. Six extracts exhibited sufficient antibiosis (*sensu* Painter, 1951) to advance to the second screening. No larvae survived on the diets with ethanolic and petrol extracts of *A. tridentata* and *C. suaveolens* and the ethanolic extracts from *C. nauseosus* and *C. diffusa* were similarly active. The *S. jacobaeae* ethanol extract also was significantly different from the control, but it was not considered sufficiently active for further screening.

The results of the unextracted plant powder and residue experiment are shown in Table 3. The efficiency of the extraction process in removing inhibitory factors is shown by testing the extracted plant material for remaining larval growth inhibition. When diet with unextracted plant powder severely inhibited *P. saucia* larval growth, at least one of the extracted residues was shown to have had the growth inhibitory agents removed. Specifically, the diet containing the unextracted *C. suaveolens* plant powder produced significantly smaller larval weights and higher mortality than both residues. Larvae fed the extracted residue diets from *C. suaveolens* grew as well or better than control-fed larvae.

TABLE 2. EFFECTS OF WEED EXTRACTS^a INCORPORATED INTO ARTIFICIAL DIET ON GROWTH AND SURVIVAL OF NEONATE *P. saucia* IN AN INITIAL SCREENING BIOASSAY

^b*N* = 30.

^cTreatments followed by the same letter are not significantly different, Tukey's studentized range (HSD) test, *P* = 0.05.

In addition, no survivors were observed among the *P. saucia* larvae fed the *A. tridentata* plant powder diet. Moreover, the weights of larvae fed the ethanol-residue diet were not significantly different from the control. The extracts from these residues were also shown to be the most active *P. saucia* larval growth

inhibitors (Table 4). These results demonstrate that when insect growth inhibitors were present in unextracted plant powders, they were nearly always removed by one or both solvents.

P. saucia larvae fed diet without cellulose were, on the average, over two and a half times heavier than those fed diet containing cellulose. Dietary cellulose may reduce growth of *P. saucia* larvae by a dilution of phagostimulatory nutrients or by the physical presence of more fiber in the diet. The addition of plant powders, however, did not always reduce larval growth. Larvae fed seven of the 18 treated diets gained higher weights than the control with cellulose (Table 3). This increase in growth is attributed to the control diet having been diluted 50% with cellulose, which is nutritionally inferior, whereas the extracted powders may contribute nutrients and phagostimulants.

The results of the second screening experiment are comparable to those of the plant powder experiment. Diet containing the ethanolic extract of *A. tridentata* resulted in 100% mortality of *P. saucia* larvae (Table 4). In addition, larvae fed diets of both *C. suaveolens* extracts grew significantly less and had reduced survivorship compared to larvae fed control diet. These results concur with the plant powder experiment in that diets incorporating unextracted *A. tridentata* and *C. suaveolens* powders were the most biologically active towards *P. saucia* larvae.

Larvae surviving the second screening were transferred to control diet to examine the latent effects of growth inhibition. Healthy *P. saucia* moths emerged from all treatments with larval survivors. These treatments, therefore, do not appear to cause any irreversible physiological damage to the growing larvae or pupae. Reproductive viability of the adults has yet to be determined.

TABLE 4. EFFECTS OF SELECTED WEED EXTRACTS INCORPORATED INTO ARTIFICIAL DIET AT NATURAL CONCENTRATIONS ON WEIGHT AND SURVIVAL OF NEONATE *P. saucia* FED FOR 11 DAYS

^aN = 25 neonate larvae.

^bTreatments followed by the same letter are not significantly different ($P = 0.05$) using Tukey's studentized range (HSD) test.

Figure 1 shows the results of the dose-response experiment using ethanol and petrol extracts of *C. suaveolens* and the *A. tridentata* ethanolic extract at four concentrations. *P. saucia* larval weight was inversely related to the plant extract concentration for all three crude extracts. The resulting EC_{50} s (effective concentration to inhibit larval growth by 50%) were 36, 39, and 42% for the *C. suaveolens* EtOH and petrol extract and *A. tridentata* EtOH extract, respectively. Larval growth inhibition could result from behavioral factors (e.g., feeding deterrence), physiological factors (e.g., microsomal enzyme suppression), or both.

Survival of *P. saucia* larvae was also concentration dependent for each extract. Survivorship, however, showed a nonlinear response (Figure 1). Pooled results from two dose-response experiments indicate that low dietary concentrations (0–40% natural concentration) of the plant extracts had little effect on survival. The highest dietary concentration (80%) usually resulted in significantly reduced survival. This suggests a threshold concentration for mortality.

Antibiosis increased with concentration, as shown by the results of both survival and growth inhibition (Figure 1). Dose-dependent antibiosis is evident initially as larval growth inhibition and then, at higher doses, as both increased growth inhibition and mortality. The mode of action of the bioactive plant extracts on *P. saucia* larvae transferred to control diet and allowed to pupate and then emerge, showed no apparent physiological effects.

Age-dependent effects were also examined in a dose-response experiment. Six-day-old larvae appear more tolerant to the plant extracts than neonates. For example, even at an extract concentration of 80%, larval mortality was consistently 15% or less; at the same concentration, growth was 33, 52, and 72%

FIG. 1. Percent growth relative to control growth and percent total mortality of *P. saucia* neonates fed ethanolic extracts from (a) *A. tridentata*, (b) *C. suaveolens*, and (c) a petrol extract from *C. suaveolens* admixed to artificial diets ($N = 25$ larvae per concentration with each extract). Standard deviation is given by error bars on the growth points.

of controls for the *A. tridentata* EtOH and the *C. suaveolens* EtOH and petrol extracts, respectively. Decreasing sensitivity to allelochemicals with increasing larval age is well known for other insect species (Reese, 1983; Isman and Duffey, 1982).

Insect growth inhibition could result from behavioral factors (e.g., feeding deterrence), physiological factors (e.g., microsomal enzyme suppression), or both. The results of a detailed growth analysis of second-instar *P. saucia* fed diets containing the *A. tridentata* EtOH extract and the *C. suaveolens* petrol extract are shown in Table 5. The relative growth rate (RGR) is a product of relative consumption rate (RCR) and dietary utilization. The RGR for larvae fed diets with the *C. suaveolens* petrol extract was 70% of the control-diet fed larvae. The majority of this growth inhibition appears to be associated with behavioral factors, as indicated by the significantly lower RCR, whereas dietary utilizations did not differ significantly from the control. The *P. saucia* larvae fed diets with the *A. tridentata* EtOH extracts produced even lower growth rates than larvae fed the *C. suaveolens* extract. This severe growth inhibition, however, appears largely due to physiological effects shown by the extremely low dietary utilization (ECI) even though the RCR was 60% of the controls.

Separate consideration of the RGRs over the 48-hr experiment revealed an interesting phenomenon. The RGR for larvae fed the *C. suaveolens* petrol extracts was 51% of the controls during the first 24-hr period, but in the second

24-hr period the growth rate accelerated to equal the RGR of the control. In contrast, the RGR for *P. saucia* larvae fed the *A. tridentata* EtOH diet was significantly lower ($P = 0.05$) than the controls for both 24-hr periods at 27 and 29% of control fed larval RGR, respectively. This suggests that growth inhibitors that decrease nutrient utilization in insects may be more persistent crop-protection agents than behavioral feeding deterrents.

Bioactivity of these extracts is not restricted to *P. saucia* larvae. Larvae of another polyphagous noctuid, the alfalfa looper, *Autographa californica* Speyer, tested in a chronic feeding dose-response experiment as described above, resulted in EC_{50} s of ca. 10–20% for all three extracts (unpublished data). These EC_{50} s are about half the observed EC_{50} s for *P. saucia* larvae, and no *A. californica* larvae survived the 60 or 80% concentrations. Unlike *P. saucia* larvae, mortality of *A. californica* appears to be linearly related to concentration when tested at the same levels, even though the relative inhibitory activity of the three extracts was the same for both species. Differences in sensitivity of noctuid species to the same allelochemicals may be related to metabolic and sensory differences. In choice experiments, Jermy et al. (1981) showed that Colorado potato beetle larvae, *Leptinotarsa decemlineata* (Say), are inhibited from feeding on leaf disks coated with an ethanolic extract from *A. tridentata*. These results suggest the biological activity of the *A. tridentata* extract may have a broad spectrum of activity on phytophagous insects.

Many secondary metabolites have been isolated from *A. tridentata* (Table 6), and some are reported to have insect growth and feeding inhibitory activity. Monoterpenes (Buttkus et al., 1977; Welch and McArthur, 1981), coumarins (Brown et al., 1975; Murray et al., 1982), and sesquiterpene lactones (Kelsey and Shafizadeh, 1979) have been previously extracted as major components of *A. tridentata*. Jermy et al. (1981) bioassayed the sesquiterpene lactone deacetylmatricarin and reported good feeding deterrent activity against larval Colorado potato beetle. They noted that significant feeding deterrent activity remained in the extract even after removal of deacetylmatricarin, indicating that more than one compound was responsible for the deterrence. Wisdom et al. (1983) tested five sesquiterpene lactones against *H. zea* and found that only a guaianolide from *A. tridentata*, dehydroleucodin, significantly reduced growth. Table 6 lists some of the candidate active ingredients that may also have a role in the biological activity of the *A. tridentata* extract.

Screening crude plant extracts in the laboratory is the initial step in their development as pest control agents. Potent insect growth inhibitors may have a use where resistance to insecticides is a problem (Bernays, 1983) and where pest managers are integrating biological and cultural controls into crop protection strategies. Further investigations of the *A. tridentata* extract will be focused on field studies to assess the practical application of these extracts.

(Received April 5, 1988; accepted June 30, 1988)

Abstract—*Acrolepiopsis assectella* and *Plutella xylostella* frass volatiles, trapped on Tenax GC, were examined by capillary gas chromatography. In both moths, the same three disulfides, dimethyl, dipropyl, and methyl propyl, were the most abundant substances, but in different proportions. The synthetic disulfides elicited the same behavioral response by the parasitoid, *Diadromus pulchellus* as frass. The plant origin of these substances is discussed.

Key Words—*Diadromus pulchellus*, Hymenoptera, Ichneumonidae, disulfides, frass, *Acrolepiopsis assectella*, *Plutella xylostella*, Lepidoptera, Acrolepiidae, Plutellidae, leek, *Allium porrum*, cabbage, *Brassica oleracea*.

INTRODUCTION

The odor of the leek, *Allium porrum* L., is characterized by the presence of specific sulfur-containing substances, thiosulfonates, that rapidly degrade into disulfides. Similarly, crucifers emit isothiocyanates that are specific sulfur-containing substances.

The locomotor activity of *Diadromus pulchellus* Wesm. (Hymenoptera: Ichneumonidae), an endoparasitoid of the young nymph of the leek moth, *Acrolepiopsis assectella* Zell. and of the diamondback moth, *Plutella xylostella* L.

(Thibout, 1988) is stimulated by the odor of both leek and cabbage, especially by that of leeks when they are attacked by leek moth larvae. Paradoxically, among the substances present in these odors, the least specific are the disulfides, which are the most active in olfactometry and electroantennography (Lecomte and Thibout, 1983, 1984, 1986; Lecomte and Pouzat, 1985). In fact, the frass odor from host larvae is more stimulatory for *D. pulchellus* than the odor from the plants (Lecomte and Thibout, 1986; Thibout et al., 1988). Frass odor has been analyzed by gas chromatography, and a simple test enables a determination of the stimulation by the volatile substances.

METHODS AND MATERIALS

Instrumentation. Analytical gas chromatography (GC) was performed with a Varian 3300 chromatograph equipped with on-column injection, FID and FPD detectors in the sulfur mode, and a S.G.E. fused silica WCOT column, 25 m long, 0.32 mm ID, 0.5 μm thick film of BP 20, equivalent to Carbowax 20 M.

Materials. Dipropyl disulfide (DS P₂) and dimethyl disulfide (DS M₂) were obtained from Merck. Allyl isothiocyanate (NCS Al) and dimethyl trisulfide (TS M₂) were purchased from Kodak.

Methyl propyl disulfide (DS MP) was synthesized by oxidizing an equimolar mixture of the CH₃S⁻ and C₃H₇S⁻ ions through controlled potential electrolysis carried on a gold electrode of great area in aprotic dipolar media (*N,N*-dimethyl acetamide). These thiolate ions had been previously generated in the same solvent from symmetrical disulfides by electrochemical reduction (Iversen and Lund, 1974). Reoxidation yielded a mixture containing about 30% dimethyl disulfide, 40% methyl propyl disulfide, and 30% dipropyl disulfide. The absence of other substances was verified by NMR spectroscopy and GC.

Trapping and Isolation. Head-space frass volatiles emitted at ambient temperature in a 0.005-m³ closed receptacle were trapped for 1 hr on a cartridge (4 mm diameter, 20 mm long) containing Tenax GC 60–80 mesh (30 mg) directly connected to a Gillian LFS 113 pump. Trapped substances were extracted with ether (1 ml) and then injected or submitted to the bioassay.

Identification. Sulfur compounds were identified by their GC retention times in comparison to those of authentic samples. Most of these reference substances had previously been identified in the degraded odor of *Allium* (Auger et al., 1989).

Bioassay. The action of odors on the host searching behavior of *D. pulchellus* was evaluated by measuring its locomotor activity directly in the rearing screened cage (40 × 30 × 24 cm) containing approximately 400 adults of both sexes. Every 30 sec for 20 min, the numbers of parasitoids on two 1-cm² pieces of paper were noted; one piece was impregnated with the test substance, the

other with the solvent (control). The results of 40 observations were compared by the Wilcoxon test.

The source of *D. pulchellus* and breeding and laboratory conditions have been described in detail elsewhere (Lecomte and Thibout, 1983, 1984, 1986): 16:8 hr light-dark, 25°C light and 15°C dark, relative humidity 60 ± 5% light and 70 ± 5% dark.

Frass was removed from the breeding cages of each species. Their larvae were fed on their respective host plants: cabbage, *Brassica oleracea* L., for *P. xylostella* and leek, *A. porrum*, for *A. assectella* under conditions 18:6 hr light-dark, 26°C light and 18°C dark, relative humidity 60 ± 5% light and 75 ± 5% dark. Frass was refrigerated in a closed receptacle until the required amount (1 g) was obtained.

RESULTS

The odor of *A. assectella* frass includes essentially sulfur compounds (Figure 1), of which the three most abundant are dimethyl, dipropyl, and methyl propyl disulfides. The propyl radical was more abundant than the methyl radical, with the propyl-methyl ratio varied from 3 to 10 between experiments.

The odor of *P. xylostella* larval frass contained the same three sulfur compounds, but the methyl group was about as abundant as the propyl group, and some dimethyl trisulfide was also present (Figure 2).

Dimethyl and dipropyl disulfides as well as the odors of the *A. assectella* and *P. xylostella* frass tested on the activity of *D. pulchellus* all had a significant effect, since the number of parasitoids observed on the papers with odor was always greater than that observed on the control papers ($P < 0.001$) (Table 1).

DISCUSSION

Dimethyl, dipropyl, and methyl propyl disulfides from both *A. porrum* and *B. oleracea* seem to be responsible for the effect of *A. assectella* and *P. xylostella* frass on the activity of *D. pulchellus*. Humid frass emits greater quantities than dry frass, as has been reported earlier (Van Leerdam et al., 1985).

The variation of the propyl-methyl ratio in *A. assectella* frass could not be related to frass age or water content. This variation is perhaps due to the part of the leek consumed by the larvae, since the proportions of sulfur volatiles of *Allium* differ, depending on the part of the plant (Mackenzie and Ferns, 1977). The precursors, methyl cysteine sulfoxide, and propyl cysteine sulfoxide, yield thiosulfonates by an enzymatic reaction when the leaves are crushed. These compounds degrade rapidly, especially into disulfides (Auger et al., 1989). In addition, microorganisms can also degrade these precursors (Murakami, 1960).

^aR = ratio of the numbers of parasitoids on two papers, to one of which volatiles were applied, the other served as a control.

Therefore, it is not surprising that the sulfur compounds of *Allium* are transformed to disulfides during larval digestion. The propyl group is predominant in the leek (Auger et al., 1989), much more so than in the frass of the larvae that consume the same leek.

The result obtained for *P. xylostella* frass is very similar to the above, even though the odor of crucifers includes not only disulfides, but much more specific sulfur compounds, isothiocyanates (Bailey et al., 1961). For example, the odor of the cabbage *B. oleracea*, cut and analyzed with the techniques used for the frass odors, includes a majority of dimethyl disulfide and allyl isothiocyanate, a small amount of methyl propyl disulfide heretofore not reported in crucifers, and only traces of dipropyl disulfide (Figure 3). Also, only methylcysteine sulf-oxide, highly abundant, has been identified in crucifers (Tsuno, 1958b; Mae et al., 1971).

If we admit a common biosynthetic origin for the substances identified in the frass of the two species, it thus appears that the proportion of methyl-propyl groups tends to become equal during passage from the plant to the frass. Digestion of the leek moth larvae would preferentially concentrate the substances arising from minor amounts of methyl group precursors in *Allium*, and the digestion of the diamondback moth would preferentially concentrate the substances arising from minor amounts of propyl group precursors in the crucifers. It thus appears that the most abundant precursors cannot be totally transformed, or else that each insect sorts ingested substances differently in its digestive tube.

It would be interesting to determine if these disulfides are specific to the frass of species fed on *Allium* and crucifers by examining the frass odors of other plant-eating larvae. It should also be established if the larvae ingest the precursors directly or, alternatively, substances arising from them. These precursors, in fact, exist only in species closely related to *Allium*, e.g. *Hipheion uniflorum* (Tsuno, 1958a) or crucifers, e.g. *Adenocalymma alliaceum* (Apparao

et al., 1981), whereas disulfides and especially dimethyl disulfide are sometimes encountered in the odor of plants belonging to other families.

This example of the chemical relationships between host plant, plant herbivore, and entomophage shows the plant origin of the chemical messengers that enable the entomophage to find its host via its frass. This system is possible only when relationships among the various trophic levels are very specific. Another example of this type has been observed in *Camponotus sonorensis* (Elzen et al., 1984).

Acknowledgments—We are grateful to J.C. Landre for his technical help during this work.

(Received May 12, 1988; accepted June 30, 1988)

Abstract—Laboratory-reared and wild, fruit-reared adults of the Oriental fruit fly, *Dacus dorsalis* Hendel, were tested for response to methyl eugenol at various ages. Virgin laboratory (2, 4, 6, 8, and 10 days old) and wild (7, 11, 15, 19, and 23 days old) flies were released into an outdoor field cage and trapped over a two-day period. Response of males increased with age as ca. 32% and 22% of laboratory and wild males responded at 2 and 7 days of age, respectively, while ca. 93% of both strains responded at 10 and 23 days of age, respectively. These correspond approximately to the ages at which they reach sexual maturity. Female response did not increase with age and fluctuated between 15% and 29% for the laboratory strain and 10% and 45% for the wild strain. The age-related response profiles, when integrated with sexual maturation curves, indicate that one of the major reasons the male-annihilation technique is effective is because methyl eugenol is able to attract 40–50% of male flies prior to the onset of sexual maturation.

Key Words—*Dacus dorsalis*, Oriental fruit fly, Diptera, Tephritidae, methyl eugenol.

INTRODUCTION

Methyl eugenol is the most effective known lure for attracting male Oriental fruit flies, *Dacus dorsalis* Hendel (Howlett, 1915; Steiner, 1952; Steiner and Lee, 1955; Mitchell et al., 1985). It also attracts many other Dacinae males (Hardy, 1973; Drew and Hooper, 1974, 1981). *D. dorsalis* males feed voraciously on methyl eugenol and usually do so until they die (Steiner, 1952). Steiner et al. (1965, 1970) developed the use of methyl eugenol to successfully

eradicate *D. dorsalis* populations from Rota and other Mariana Islands by air-dropping fiberboard squares saturated with lure-toxicant formulations. This male annihilation method also was used successfully against other *D. dorsalis* populations in the Amami Islands (Ushio et al., 1982) and the Okinawa Islands (Koyama et al., 1984). Presently, the Marianas and Japan are both free of *D. dorsalis*.

Here we report studies on the response to methyl eugenol of various ages of *D. dorsalis* reared in the laboratory on artificial diet (Tanaka et al., 1969) compared with wild flies reared from naturally infested fruits. Also, we compare the present data with sexual maturation data of *D. dorsalis* from Wong et al. (1982).

METHODS AND MATERIALS

Laboratory Oriental fruit flies used in the study had been in culture for ca. 400 generations (at least 32 years, with ca. 12 generations per year). The wild flies were collected as mature larvae from naturally infested papayas, *Carica papaya* L., and guava, *Psidium guajava* L., from the islands of Kauai and Oahu, Hawaii. Two days before eclosion, pupae were dyed with powdered pigments (Day-Glo Arc Yellow, Day-Glo Neon Red, Day-Glo Signal Green, Calco Blue, and Tinopal SFG) using different colors for different ages of flies. The dyed pupae were placed in screened cages (61 × 38 × 37 cm) separated by age group and provided with ICN hydrolyzed protein (Nutritional Biochemical, Cleveland, Ohio), sugar, honey, and water, as needed for survival of newly emerged adults (Keiser and Schneider, 1969). One day after eclosion, flies were separated by sex while immobilized in a refrigerated room (5–7°C) and then transferred to screened cages and held at ambient room condition (average temperature 26.4°C; range 24.6–27.8°C; 66–74% relative humidity under natural daylight supplemented with fluorescent light) until ready for testing. Previous laboratory tests using the same laboratory strain and the same wild population (Wong et al., 1982) had shown differences (both sexes) in physiological ages of the two strains of flies; i.e., sexual maturation of 90% or more was reached under these conditions in ca. 10 days with laboratory-reared flies and in ca. 24 days with wild flies. Therefore, in this study tests were made when laboratory flies were 2, 4, 6, 8, and 10 days old and when wild flies were 7, 11, 15, 19, and 23 days old. The tests were made in two outdoor screened cages (2.5 × 2.5 × 2.5 m). In each of two cages, we released 100 unmated flies of each sex and age, laboratory-reared flies in one and wild flies in the other. Water and sugar were provided in each cage. All releases were made at 0730 hr. A plastic trap (Steiner, 1957) containing a mixture of 99% methyl eugenol and 1% naled by volume in a cotton wick (4 cm long × 2 cm diam.) (Steiner et al., 1965)

was placed in each outdoor cage at 0800 hr, then replaced with another identical baited trap containing methyl eugenol and naled hourly until 1600 hr. The flies become inactive at night and during this time are not attracted to methyl eugenol (Steiner, 1952). These traps were in operation during two days for each release. The test was replicated five times. The numbers of flies trapped for the first day and for the two-day totals were recorded. Temperature and relative humidity ranged from 24 to 27°C and from 68 to 94%, respectively, during testing days. Percentage means were transformed using the arcsine procedure before analysis (Snedecor and Cochran, 1967). Fly age means within laboratory or wild classes were compared with Duncan's (1955) multiple-range test, while male-female differences within each age group were compared with a paired *t* test.

RESULTS AND DISCUSSION

Of the 1677 laboratory-reared and 1487 wild *D. dorsalis* males recovered from traps baited with methyl eugenol, 93.4% and 93.2%, respectively, were taken on the first day. Males of both strains gradually increased their responses to the baited traps with age (Table 1). Roughly 32% and 22% of laboratory and wild males responded on both days (2-day totals) when 2 and 7 days old, respectively, while roughly 93% of both strains responded when 10 and 23 days of age, respectively [$P < 0.05$, Duncan's (1955) multiple-range test]. The response of laboratory females did not vary significantly with age [$P > 0.05$, Duncan's (1955) multiple-range test] and fluctuated between ca. 15% and 29%. The response of wild females was much lower, fluctuating between 4% and 10%, with the response at seven days (4%) being significantly different from the response at 19 days (10%) [$P < 0.05$, Duncan's (1955) multiple-range test]. Although laboratory and wild female mean responses have not been compared directly in Table 1, the magnitude (ca. threefold) of the difference between strains clearly supercedes any effect due to possible difference in physiological age and contrasts sharply with the very similar responses for the males of each strain. The responses of males and females are significantly different from each other at all ages for both strains ($P < 0.05$, *t* tests) (Table 1).

As shown in Figure 1, males of both strains began to respond to methyl eugenol before any were sexually mature. Indeed, 40-50% of males of both strains responded before their respective ages of earliest mating. Also shown in Figure 1 are mating data from Wong et al. (1982), which provide a comparison of mating response with male attractancy. Best-fitting linear regressions for percentage response (*Y*) of laboratory-reared and wild males of different ages (*X*) to traps baited with methyl eugenol are: $Y = 5.6(X) + 19.8$ ($r = 0.995$) and $Y = 2.8(X) + 6.1$ ($r = 0.992$), respectively, and for laboratory-reared and wild males mated at different ages are: $Y = 10.0(X) - 22.4$ ($r = 0.987$) and $Y =$

FIG. 1. Response of laboratory-reared (L) and wild (W) *Dacus dorsalis* males of different ages to traps baited with methyl eugenol and 1% naled in outdoor cages, Honolulu, Hawaii. Values shown are arcsine transformed percentage means for five replicates (trapped) and 10 replicates (mated). Lines at each point represent ± 2 standard errors. Data on mating of laboratory-reared and wild flies obtained from Wong et al. (1982).

5.2(X) - 55.4 ($r = 0.993$), respectively. When males were older (8-day-old laboratory and 23-day-old wild males), responses to the lure matched sexual maturation rates for each strain. Mating percentages of the following five age groups were significantly different from each other for the lab strain: 1-3 days, 4-5 days, 6 days, 7-8 days, and 9-11 days [$P < 0.05$, Duncan's (1955) multiple-range test]. For the wild strain, five age groups were significantly different from each other: 12-13 days, 14-15 days, 16-17 days, 18-20 days, and 21-24 days. The results differed from those of other workers. We found that significant attractancy to methyl eugenol by male *D. dorsalis* can occur prior to sexual maturation; others found that attraction of *D. dorsalis* (Umeya et al., 1973; Ito and Iwahashi, 1974) and *Dacus opiliae* Drew & Hardy (Fitt, 1981) was correlated with sexual maturity. However, Steiner (1952) reported that sexually immature *D. dorsalis* (as young as 1 day old) males responded to methyl eugenol.

Of the total males recovered in traps, most flies were taken within the first 3 hr after they were released, 89 and 92% for laboratory-reared and wild males, respectively. However, if flies had been released in the afternoon instead of in the morning, males would probably have responded just as well because Steiner (1952) found that methyl eugenol is effective at dawn and dusk as well as throughout the day but does not attract male flies at night. In the field, Naka-

gawa and Urago of this laboratory (unpublished data) found that wild *D. dorsalis* males had two peak response periods, one early in the morning and the second in the mid-afternoon.

The possible existence of an insensitive strain of *D. dorsalis* males to methyl eugenol has been reported by Ito and Iwahashi (1974). In Chichi Jima of the Ogasawara Islands of Japan, researchers selected a strain of male flies that was recaptured in a frequency consistently lower than that for control flies. Because of this finding, the eradication program used against *D. dorsalis* in the Ogasawara Islands involved a combination of male annihilation and sterile insect release methods (Habu et al., 1980). However, eradication of *D. dorsalis* in the Okinawa Islands was by the male annihilation method alone (Koyama et al., 1984), suggesting that at least in Okinawa, *D. dorsalis* was completely sensitive to methyl eugenol.

Females were less responsive than males to traps baited with methyl eugenol. However, significant numbers of mated and unmated flies (576 laboratory-reared and 171 wild females) were caught. The responding females on the first day of testing (average of 86% for all ages) were probably all virgins because they would not be able to mate until near sunset. Kobayashi et al. (1978) found that *D. dorsalis* mates just before dusk. These results differ sharply from those of Steiner (1952), who found that only virgin *D. dorsalis* females were slightly responsive to methyl eugenol in the laboratory. We also found that the proportions of females responding were much higher for both strains at all ages than reported by Steiner (1952), suggesting that the experimental design contributed to higher than expected female yield, in proportion to male yield. During large-scale pilot tests against *D. dorsalis* in the Bonin and Mariana Islands between 1960 and 1963, sexually mature virgin females were attracted to, and killed by, poisoned methyl eugenol placed on baited stations or in traps. The attraction occurred only when populations of males were almost depleted, as indicated by catches of < 1 male per trap per day (Christenson, 1963; Steiner et al., 1965).

One of the major reasons the male annihilation technique is highly effective in eradicating *D. dorsalis* populations (Steiner et al., 1970; Koyama et al., 1984) is because 40–50% of the male flies are attracted to methyl eugenol-toxicant mixtures and killed before any become sexually mature.

Acknowledgments—We sincerely appreciate the technical assistance of Mohsen Ramadan from our laboratory.

PATTERNS OF DEPOSITION OF URINE CONTAINING
CHEMOSIGNALS THAT AFFECT PUBERTY AND
REPRODUCTION BY WILD STOCK MALE AND
FEMALE HOUSE MICE (*Mus domesticus*)

LEE C. DRICKAMER

(Received May 16, 1988; accepted July 5, 1988)

Abstract—House mice release chemosignals in their urine that influence the timing of puberty and reproductive condition in conspecific females. These experiments tested the possibility that mice depositing urine containing chemosignals that affect puberty and reproduction do so differentially with respect to urine cues from conspecifics. Mice were tested in cages containing samples of urine or water on cotton in wire mesh capsules protruding from the cage floor. Their urine deposition patterns were recorded on squares of filter paper positioned below the cages. Males deposited more urine than females housed in groups, estrous females, diestrous females, or prepubertal females. All groups of mice deposited urine in a nonrandom fashion with regard to urine cues from conspecifics. Male mice deposited more urine near locations previously soiled by females than near water or other males. Grouped females deposited more urine near male urine cues and avoided depositing urine near urine from other group-housed females. Both estrous and diestrous female mice deposited more urine near males than near other urine cues or water, possibly to attract mates. Prepubertal females avoided depositing their urine near male urine and urinated more near urine from grouped females than near other urine types or water. Young females may be avoiding possible male mates until they have attained puberty. This avoidance behavior may enhance the long-term reproductive success of the females that otherwise might mature and mate at too young an age.

Key Words—House mice, urinary chemosignal, puberty, reproductive strategy, urine deposition, estrous, diestrous, mouse density, *Mus domesticus*.

INTRODUCTION

The age of first vaginal estrus in female house mice can be altered by social cues and urinary chemosignals from conspecifics (Vandenbergh, 1983; Drickamer, 1986a). Housing young females with adult male mice or treating young females with urine from male mice, female mice in estrus, and female mice that are pregnant or lactating all result in accelerated onset of puberty (Vandenbergh, 1967, 1969; Colby and Vandenbergh, 1974; Drickamer and Murphy, 1978; Drickamer and Hoover, 1979; Drickamer, 1986b). Housing young females with other young or adult females, or treating them with urine from grouped females results in delays in the onset of puberty (Vandenbergh, et al., 1972; Drickamer, 1974, 1977). The urinary chemosignals that influence sexual development have been explored from a variety of perspectives including timing effects, hormonal involvement for donors and recipients, density and dominance effects, volatility, doses, etc. (see Vandenbergh, 1983; Drickamer, 1986a).

Urine cues from conspecifics also influence the reproductive condition of adult female mice, including cues from males (Whitten, 1957; Bruce, 1960; Parkes and Bruce, 1962; Kimura, 1971) and other females (Whitten, 1959; Hoover and Drickamer, 1978). These phenomena involving the reproductive physiology and behavior of adult females have been explored from a variety of perspectives, including many of those mentioned above with regard to chemosignal effects on puberty (see Bronson, 1979; Marchlewska-Koj, 1983; McClintock, 1983; Vandenbergh, 1983, for reviews).

Urine marking by mice has been studied both in the laboratory and under natural conditions (Bronson, 1976; Hurst, 1987) and with respect to identification of groups or individuals (Jones and Nowell, 1974; Cox, 1984), the tendency to investigate novel surroundings (Maruniak et al., 1974; Matthews, 1980), urination as a social response (Reynolds, 1971), differential urination patterns dependent upon social rank in males (Desjardins et al., 1973), and the possible use of urine cues as territorial boundary marks (Mackintosh, 1973; Harrington, 1976). The urinating "posts" described by Welch (1953) and later reported by Hurst (1987) may function with respect to territory, although Hurst (1987) has suggested that the posts may also be related to orientation and detection of novel stimuli in the environment. Urine cues, in the form of posts or surface deposits may therefore serve several functions simultaneously.

Mechanisms underlying these urine deposition behaviors and their significance have been investigated with respect to sex steroids (Maruniak et al., 1975; Kimura and Hagiwara, 1985) and genetics (Beauchamp et al., 1986).

Using a laboratory stock of mice (C3M/Me-Mg), Wolff and Powell (1979) found that female mice made significantly more urine spots on filter paper dur-

ing proestrus and estrus than at other stages of the cycle, with a dramatic decline after estrus. In a laboratory study involving circular arenas, male mice produced more urine spots that were more regularly dispersed, whereas female mice produced fewer urine deposits with more clumped distribution patterns (Powell and Wolff, 1982). Further, Wolff and Powell (1984) reported that male mice tended to urinate more in locations that had been previously marked with urine; they tended to deposit more urine spots on areas with cues from proestrous and ovariectomized females than areas containing cues from other females. Females deposited more urine at the time of estrus than at other stages of the estrous cycle. Females deposited more urine near urine from intact than castrated males.

One topic pertaining to the puberty-influencing urinary chemosignals that has not been investigated concerns the patterns of urine deposition by male and female mice with respect to cues from conspecifics. Is it possible that mice may be depositing their urine differentially with respect to cues from conspecifics? If so, there could be significant consequences for the effects of the chemosignals in the urine on physiological mechanisms controlling sexual maturation in young females and the reproductive condition of adult females.

The two experiments performed here were designed to assess the following questions. (1) Do mice differentially deposit their urine depending upon what other urine cues are present in the environment? (2) Do mice deposit their urine in a manner that might enhance the physiological effects of any puberty-influencing chemosignals or chemosignals affecting reproductive condition of adult females contained in that urine?

METHODS AND MATERIALS

General Methods. The mice used for these experiments were third and fourth generation descendents of a stock of wild house mice (*Mus domesticus*) trapped near West Simsbury, Connecticut. All mice were maintained in opaque polypropylene cages measuring 28 × 15 × 15 cm deep with fitted wire lids containing food and water receptacles. A bedding of ground wood shavings was changed once each week. Pregnant female mice were given cotton squares for making nests. Wayne Lab Blox and water were provided ad libitum to all mice throughout the experiments, except for the 22-hr periods that mice were in the test cage. All colony cages and the test apparatus were housed in the same two rooms throughout the 18 months of the study. These rooms were maintained at 21–25°C and 30–60% relative humidity on a 12-hr dark: 12-hr light daily regimen with overhead fluorescent lights on from 0600 to 1800 hr.

Mice used for collection of urine and those used as test subjects were produced by mating adult male and female wild stock mice for a total of 84 pairs

producing sufficient litters for these experiments. Mice were weaned from their parents at 25 days of age and housed in like-sex groups or individually until needed. Details of housing arrangements are specified with each experiment.

Experiment I. The first experiment was designed to assess the urine deposition patterns of wild stock house mice presented with a choice between a conspecific urine cue and water.

Five different groups of test subjects were used: (1) sexually experienced adult females (ages 90–145 days) grouped with eight mice per cage for at least 30 days prior to testing; (2) sexually experienced adult males (ages 90–185 days) housed individually for at least 20 days prior to testing; (3) sexually experienced adult females (ages 85–130 days) in vaginal estrus on the day of testing; (4) sexually experienced adult females (ages 85–130 days) in vaginal diestrus on the day of testing; and (5) prepubertal females (ages 35–45 days) weaned at 25 days of age and housed individually until testing. For groups (3) and (4), daily vaginal smears were taken to determine which females were in estrus and diestrus.

For each experimental group, 96 mice were tested. The test apparatus consisted of a 0.5×0.5 -m stainless-steel cage with solid walls, a wire mesh floor, a wire mesh top, and short legs to suspend the cage 3 cm above the table top. The mesh in the floor contained 4 squares/cm². For each trial, two previously unused squares (3×3 cm) of fine screen mesh (25 squares/cm²) were pushed upward through the floor in diagonally opposite corners of the cage. A ball of sterile cotton was placed inside this pocket of fine screen. A syringe was used to inject 0.2 cc of urine or water into the center of each cotton ball. A flip of a coin determined which square was injected with urine and which with water for each separate trial. A piece of filter paper measuring 0.5×0.5 m was positioned directly below each test cage.

Using this apparatus, the urination patterns of mice were tested in the presence of water vs. urine from (a) adult males, (b) grouped adult females, (c) estrous females, (d) diestrus females, (e) prepubertal females, and (f) against water. The mice used for collecting the urine cues were the same groups of mice used as test subjects. No mouse was handled for urine collection for two days prior to or one day after being used as a test subject in the apparatus. Urine was collected by holding each mouse over a Petri dish and gently squeezing the flanks. Fresh urine was collected each day for use in the test cages. This required collecting urine from 15–20 mice of each type. Separate Petri dishes and syringes were maintained for each urine type. Sixteen mice of each treatment group were tested for each combination of test stimuli.

The test procedure involved placing a mouse in the apparatus for 22 hr after having placed urine on the cotton balls and filter paper under the cage. The filter paper was marked with appropriate information about the test subject

and the nature and location of the urine and water test stimuli. At the end of the test period, the mouse was removed and returned to its original cage.

The pieces of filter paper were scanned with an ultraviolet light (Desjardins et al., 1973) and all urine spots were marked. The marked filter paper was then placed on top of a grid on a light table. The scoring grid measured 20×20 squares (each grid square was $2.5 \times 2.5 = 6.25 \text{ cm}^2$). Three types of scoring data were obtained: (1) the total number of squares in the pen containing any urine (maximum = 400), (2) the number of squares within a 3-cm radius surrounding each stimulus source (maximum for each source = 36), and (3) the pattern of distribution of urine throughout the test cage was measured by dividing the grid into 25 sections of four squares each. A mouse that deposited urine in all sections of the test cage could receive a score of 25. Data from the first dependent variable were used to assess possible differences in total squares marked for the different test groups. They were also used in conjunction with the second dependent variable to assess the percentage of squares containing urine near the stimuli in relation to the total squares containing urine. The third dependent variable was used to assess the overall distribution of urine deposition in the test cage for each treatment group. One-way analyses of variance were used to determine significant patterns of variation across the treatment groups for each dependent variable.

The second dependent variable was used to assess possible differential responses within each of the five test groups to the two stimuli presented to each test mouse. To do this, a ratio of squares marked near the urine source to the squares marked near the water source was computed for each trial. Because of problems with variance heterogeneity and skewness, we then took the natural log of each ratio (Lenington, 1983; Egid and Lenington, 1985); we would expect to find ratios greater than 0 if the test mice were depositing more urine near the stimulus cotton that contained urine and ratios less than 0 if the test mice were depositing more urine near the water cue. For the test situation with water in both stimulus cotton balls, the ratio should not differ significantly from 0. For each test group, these ratios were subjected to a one-way analysis of variance and then Duncan's new multiple-range test with $\alpha = 0.02$.

Experiment II. The second experiment was designed to assess the possible differential urine deposition patterns for three type of mice: males, grouped females, and prepubertal females when mice were presented with pairs of urine stimuli in the two cotton balls used in the test apparatus for each trial. The five test pairs of urine used were: (a) males vs. grouped females, (b) males vs. estrous females, (c) males vs. prepubertal females, (d) estrous females vs. diestrous females, and (e) estrous females vs. prepubertal females.

The apparatus and procedures for each trial were identical to those in experiment I. For these trials, 75 different mice were tested from each of the

three groups with 15 mice used for each of the five different pairs of urine stimuli injected into the cotton balls. One-way analyses of variance were performed within each pair of urine stimuli followed by post-hoc tests of ratios of squares containing urine within the 3-cm radius of each stimulus.

RESULTS

Experiment I. Adult males deposited urine in more total squares throughout the test cage and in more squares within the 3-cm radii around the stimuli on average than mice in the other groups (Table 1); the other groups did not differ from one another for either dependent variable. The same pattern of significant differences was true for measures of the proportion of squares containing some urine that were within the 3-cm radii and the total number of squares (of a possible maximum of 72 for the two stimulus circles combined) that contained urine (Table 1). For the separate measure of the total distribution pattern of urine in the test cage, there were no significant differences across the five test groups (Table 1).

Grouped female mice (Figure 1A) deposited urine in more squares near male urine than near water, but deposited urine in more squares near water than

near urine from grouped females. The responses of grouped females to the other urine-water pairs did not differ from the expected value of 0.

Adult male mice (Figure 1B) deposited urine in significantly more squares near urine cues from females than water. The response of males to male urine did not differ from the expected value of 0.

The patterns of responses by estrous and diestrous females were similar (Figures 1C, D). These mice deposited urine in significantly more squares near males than water, but deposited urine in more squares near water than urine from grouped females. Their responses to the other urine-water pairs did not differ from the expected value of 0.

Prepubertal females (Figure 1E) deposited urine in significantly more squares near the water cue when tested against male urine, but urinated in more squares near the grouped female urine than the water. There was an overlapping pattern of responses by the prepubertal females to the other urine-water pairings, but none of these tests resulted in significant differences from the expected value of 0.

Experiment II. When tested with male urine vs. grouped female urine, both male and prepubertal female test subjects deposited urine in significantly more squares around the urine cue from grouped females, whereas grouped females as test subjects deposited urine more often near the male urine cue (Figure 2A). When the test pair consisted of either male urine vs. estrous female urine or male urine vs. prepubertal female urine, a pattern of results similar to that seen for male urine vs. grouped female urine was observed (Figures 2B, C). For the test pairs involving estrous female urine vs. diestrous female urine and estrous female urine vs. prepubertal female urine, male mice deposited urine in significantly more squares near the urine from estrous females, and both grouped females and prepubertal females exhibited urination patterns that did not differ from the expected value of 0 (Figures 1D, E).

DISCUSSION

These experiments provide the bases for three conclusions: (1) In the test situation used, male mice deposited urine in more total squares than other test groups, but did not differ from the other treatments in terms of the overall dispersion pattern of urine deposition. (2) Male mice deposited significantly more urine near stimulus sources than other types of test mice. (3) All mice appeared to differentially deposit urine near specific urine cues in at least some test situations.

Male mice marked more than the other types of mice tested. This finding is in agreement with other published data (Reynolds, 1971; Maruniak et al.,

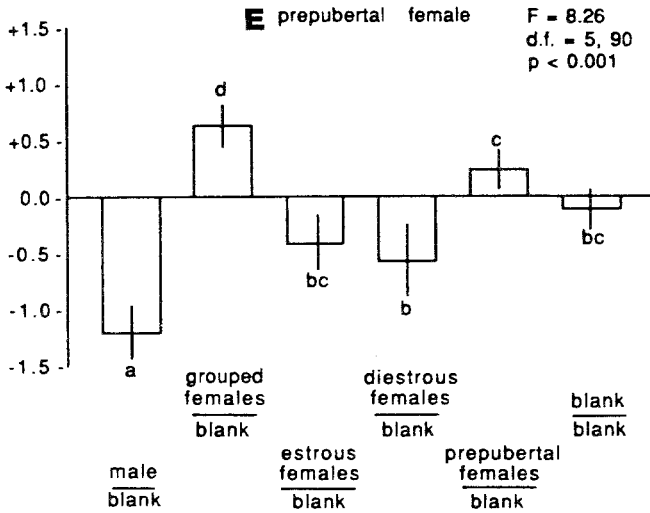

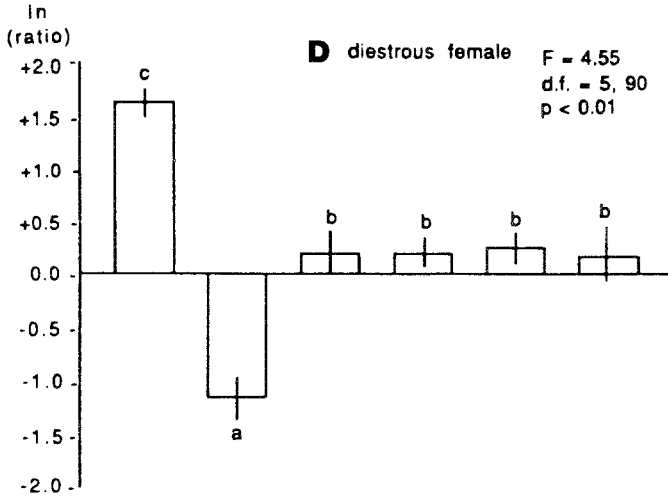

FIG. 1. Means of natural logarithms of ratios for numbers of grid squares containing urine in 3-cm-diameter circles surrounding two urine sources (± 1 SEM = vertical lines). Each of five types of test mice: (A) grouped females, (B) males, (C) estrous females, (D) diestrous females, and (E) prepubertal females, were tested with five types of urine vs. water (designated as "blank"), shown at the bottom of the figure. A control test

URINE SOURCES

involved water at both stimulus locations. Sixteen mice of each type were tested with each of the six treatment pairings. The F ratios from one-way analyses of variance and associated probabilities are shown for each test mouse type. Within each experiment, those bars not marked with the same letter are significantly different at the 0.02 level using Duncan's new multiple-range test. A mean ratio of 0 denotes that approximately equal proportions of grid squares were marked around each of the two stimulus sources; significant deviations above or below the line indicate greater numbers of grid squares containing urine near the urine cue or water respectively.

FIG. 2. Means of natural logarithms of ratios for numbers of grid squares containing urine in 3-cm-diameter circles surrounding two urine sources (± 1 SEM = vertical lines). Male mice, grouped female mice, and prepubertal female mice (test mouse type) were each tested using five different pairs of urine stimuli: (A) male urine vs. grouped female urine, (B) male urine vs. estrous female urine, (C) male urine vs. prepubertal female urine, (D) estrous female urine vs. diestrous female urine, and (E) estrous female urine vs. prepubertal female urine. Fifteen mice of each type were tested with each of the five pairs of urine sources. Analyses were run for each of the five urine combinations tested; the F ratios from one-way analyses of variance and associated probabilities are shown. Within each urine combination, those bars not marked with the same letter are significantly different at the 0.02 level using Duncan's new multiple-range test. A mean ratio of 0 denotes that approximately equal numbers of grid squares were marked around each of the two stimulus sources; significant deviations above or below the line indicate greater numbers of squares marked near the designated urine source.

FIG. 2. Continued.

1975; Powell and Wolff, 1982; Kimura and Hagiwara). The finding in experiment I that males disperse their urine throughout a test cage is also in agreement with previous reports (Powell and Wolff, 1982), although these data may be viewed as contrasting with earlier findings reported for *Mus* (Desjardins et al., 1973) that indicated specific patterns of urine deposition restricted in overall distribution to specific areas of a test cage. The present data also indicate that the stock of wild mice used for these investigations does not counter-mark as frequently as has been reported by Wolff and Powell (1984). Hurst (1987) also comments on the failure to find extensive counter-marking by male mice in her natural setting. Males consistently deposited more urine near cues from females in both experiments. In experiment II they deposited more urine near urine from estrous females than either diestrous or prepubertal females. It would appear that male mice deposit their urine in a fashion that could enhance the onset of puberty in young female mice encountering the urine and in a manner that would affect the reproductive physiology of conspecific adult females to enhance their estrous cycles; in both instances the effects would be to increase the number of potential mates available for reproduction.

Grouped female mice clearly avoided the urine of other grouped females in terms of their patterns of urine deposition. They also deposited less urine

near estrous or diestrous females than near other cues in paired choice situations. They provided neutral responses toward urine from prepubertal females. The most significant reaction of grouped females in the test situation was to deposit significantly more urine near male urine when possible. It thus appears that females may be (1) avoiding the odor of other grouped females, remaining away from possible effects of the urinary chemosignal from females housed under high-density conditions that delays the onset of puberty (Vandenbergh et al., 1972; Drickamer, 1977), and (2) leaving urine cues at sites they associate with males, signaling their presence as possible mates. This last finding concurs with the report by Wolff and Powell (1984) regarding female counter-marking on sites previously marked by males.

Estrous and diestrous female mice responded in similar ways in the test situations used here. They consistently avoided grouped female urine and left significant urine deposits near urine from males. Their responses to prepubertal female urine and to urine from estrous and diestrous females were neutral in both experiments. As with the grouped females, it is possible these females are avoiding urine that could retard their reproductive condition while leaving scent cues near sites associated with males to indicate their presence as possible mates. Data from experiment I indicate that both estrous and diestrous females marked the same total area of the test cage. This may be in contrast to the report by Wolff and Powell (1979) that females in proestrus and estrus deposited more urine spots than females at other stages of the estrous cycle. It is possible that the methods of measuring urine deposition are different enough in these two studies that the comparison is not valid. Also, these experiments measured estrous and diestrous stages only of wild stock mice, whereas Wolff and Powell (1979) were concerned with all stages of the cycle and used a laboratory strain.

Lastly, prepubertal females avoided male urine and tended to deposit significantly more of their urine near urine from grouped females. This conclusion is supported by data from both experiments. The responses of prepubertal females to the other urine cues were generally neutral. The responses by prepubertal females to grouped female and male urine are directly opposite to the responses recorded for other types of females tested. Why should prepubertal females behave so differently than adult females? One possible explanation lies in a recent report regarding the long-term consequences of early and late puberty in female mice with respect to reproduction (Drickamer, 1988). Young female mice that are accelerated in their sexual development have a higher mortality rate early in life, produce fewer litters, and have, on average, smaller litters than females that are delayed in attaining puberty. Thus, by avoiding contact with male urine and not exposing themselves to a chemosignal that could accelerate their sexual development, young females may be escaping some negative consequences. In addition, as has been suggested by Bronson (1979), young females may avoid male urine containing the puberty-accelerating chemosignal until after dispersal.

Both male and female mice exhibit active patterns of urine deposition in the presence of other urine cues from conspecifics. Some of these observed patterns suggest that female mice may be regulating their reproductive physiology by exposing or not exposing themselves to particular urine stimuli. Other data support the conclusion that mice of both sexes will, under appropriate conditions, seek to mark in the same area as that used by a conspecific of the opposite sex, providing the basis for exchanging information on the whereabouts of potential reproductive partners.

DESCRIPTION OF SEXUAL BEHAVIORS OF *Drosophila*
rajasekari
The Role of (Z,Z)-7,11-Heptacosadiene

(Received April 18, 1988; accepted July 7, 1988)

Abstract—The courtship behaviors and cuticular hydrocarbons of *Drosophila rajasekari* are described. Sexually mature males orient, tap, follow, vibrate their abdomens, extend and vibrate their wings, and attempt copulation during courtship. They perform these behaviors in response to immature and mature *D. rajasekari* of both sexes, and their courtship activities are facilitated by light. The predominant cuticular hydrocarbon found in both sexes is (Z,Z)-7,11-heptacosadiene (HCD), a compound known to be used as a courtship-stimulating sex pheromone by another fruit fly, *D. melanogaster*. Therefore, it is not surprising that *D. melanogaster* males actively court both males and females from the *D. rajasekari* stock. However, HCD is apparently not used by *D. rajasekari* as a courtship-stimulating pheromone since mature *D. rajasekari* males do not court *D. melanogaster* females, which produce large quantities of HCD.

Key Words—Courtship, pheromones, (Z,Z)-7,11-heptacosadiene, *Drosophila rajasekari*, *Drosophila melanogaster*, Diptera, Drosophilidae.

INTRODUCTION

Since Sturtevant's classic paper in 1915, many studies have concentrated on the cues that mediate sexual behavior in *Drosophila*. In the most commonly studied situation, that of a *D. melanogaster* male courting a virgin conspecific female, the male performs an elaborate series of courtship behaviors that are elicited by visual, olfactory, and tactile cues provided by the female (reviewed by Tompkins, 1984). In this species, the major olfactory cue is a 27-carbon alkadiene

known as (Z,Z)-7,11-heptacosadiene (HCD) (Antony and Jallon, 1982; Antony et al., 1985). This compound is produced in large quantities by mature females but is not found in males (Antony and Jallon, 1982). It is this strong sexual dimorphism for a courtship-stimulating pheromone that causes *D. melanogaster* females to be sexually attractive while mature *D. melanogaster* males are not.

Drosophila rajasekari was first described (Sreerama Reddy and Krishna Murty, 1968) from collections made in Mysore, India, and, based on morphological features, was assigned to the *suzukii* subgroup of the *melanogaster* species group in the subgenus *Sophophora*. Our preliminary chemical analysis of these flies indicated that little sexual dimorphism existed in terms of their cuticular hydrocarbons. In addition, we were interested to discover that the major cuticular compound produced by *D. rajasekari* males and females was HCD.

D. rajasekari thus represents a species in which the major cuticular hydrocarbon is HCD (like *D. melanogaster* females) but, unlike the situation in *D. melanogaster*, they show no gross sexual dimorphism for cuticular hydrocarbons. Accordingly, we set out to analyze the sexual behaviors of *D. rajasekari* and to determine whether or not they also use HCD as a courtship-stimulating pheromone.

METHODS AND MATERIALS

Stocks. The *D. rajasekari* stock, strain 14023-0361, was obtained from the National Drosophila Resource Center in Bowling Green, Ohio. The *D. melanogaster* stock, Canton-S strain, was obtained from L. Tompkins at Temple University in Philadelphia, Pennsylvania. Both stocks were maintained in mass culture on Formula 4-24 Instant *Drosophila* Medium (Carolina Biological Supply, Burlington, North Carolina) under a 16:8 light-dark cycle at ambient laboratory temperature. All flies were collected within 3 hr of eclosion and separated by sex under CO₂ anesthesia. Males were stored individually, while females were stored in groups of 2-20 in vials containing media.

Extraction and Analysis of Cuticular Hydrocarbons. Cuticular compounds were extracted from individual flies by soaking them in 100 μ l of hexane for 1 min (Scott, 1986). Extracts from large groups of flies were made by soaking the flies in hexane for 24 hr, followed by chromatography over silica eluted with hexane (Bartelt and Jackson, 1986). Hydrocarbons were separated by degree of unsaturation on a AgNO₃ HPLC column (Bartelt et al., 1986a). Alkanes and alkenes were eluted with 5% toluene in hexane, and alkadienes were eluted with 25% toluene in hexane. Gas chromatography (GC) was performed on a 30-m DB-1 capillary column programmed from 150 to 300°C at

10°/min, and a 30-m DB-225 capillary column programmed from 150 to 200°C at 5°/min. A 30-m DB-5 capillary column was utilized for introduction into a VG-MM16 mass spectrometer. Each peak was characterized by its equivalent chain length based on the comparison of the retention time of the peak with the retention times of an internal standard of paraffin hydrocarbons, area integrated on a Hewlett Packard 3380A integrator, mass spectra of saturated hydrocarbons (Blomquist et al., 1987), and mass spectra of the dimethyl disulfide reaction products (Nichols et al., 1986; Vincenti et al., 1987) for the unsaturated hydrocarbons.

Behavioral Assays. Behavioral assays were performed between 9:00 AM and 9:00 PM at room temperature. For each assay, a "test male" and a "sex object" (a male or female fly used to elicit courtship from the test male) were aspirated without anesthesia into a cylindrical plastic chamber (vol ca. 0.2 cm³) and observed for 500 sec. During each observation period, the courtship index (CI), the percentage of the observation period that the test-male spent performing any of the courtship behaviors toward the sex object (Tompkins et al., 1980), was recorded.

To determine the age at which *D. rajasekari* males become sexually mature, 6-hr- to 6-day-old males were tested with females of the same age. Flies tested at 6 hr and 12 hr were collected within 15 min of eclosion. The CI and the behaviors performed by each male were recorded, and males were judged to be sexually mature at an age at which they performed all of the sexual behaviors, copulated with females, and had CIs as high as males that were one day older (see McRobert and Tompkins, 1987).

Sexually mature males were then tested with *D. rajasekari* males and females of various ages, as well as mature (3 to 5 days old) *D. melanogaster* females, to identify sexually attractive flies. In tests in which two males were tested together, one of the males had the distal tip of one wing removed as a marker. In half of these tests, the courting male was marked; in the other half, the "sex object" male was marked.

To determine whether *D. rajasekari* males were able to perform courtship in the dark or whether *D. rajasekari* males and females were attractive in the dark, flies were tested under a red photographic safelight. Since *Drosophila* do not respond to red light (McEwen, 1918), this condition mimics the effects of total darkness while allowing the observer to monitor the sexual behavior of the flies. In these tests, mature *D. rajasekari* males were paired with *D. rajasekari* "sex objects" (mature males or females) and their behaviors in "darkness" were compared to behaviors performed by males under normal room lights. Additionally, *D. rajasekari* "sex objects" were tested for their ability to elicit courtship from mature (3 to 5 days old) *D. melanogaster* males in the light and the dark.

RESULTS

Preliminary analysis of the cuticular hydrocarbons from sexually mature *D. rajasekari* males and females indicated that there was little sexual dimorphism in their cuticular hydrocarbons (Table 1). More detailed analyses revealed that the major cuticular component and the only alkadiene from both males and females was a 27-carbon alkadiene, which was identified as 7,11-heptacosadiene (HCD) by interpretation of the mass spectra of its dimethyl disulfide addition products (Figure 1). When the double bonds are separated by one, two, or three methylene groups, the tetrathiomethyl addition results in four-, five-, or six-membered cyclic thioesters substituted with two alkyl chains each containing a methylthio group alpha to the ring (Vincenti et al., 1987). Fragmentation of the dialkyl cyclic thioester between carbons 7 and 8 resulted in mass peaks at 145 and 357 *m/e*. Loss of CH₃-SH from the 357 ion resulted in a peak at 309 *m/e*. Likewise, fragmentation between carbons 11 and 12 resulted in mass peaks at 271 and 231 *m/e*. Subsequent loss of CH₃-SH from the 231 ion resulted in a peak at 183 *m/e*. The other peaks were also consistent with mass spectra of a

tetrathiomethyl addition product of a 27-carbon alkadiene. The double bonds were determined to be *Z,Z* by coelution with synthetic (*Z,Z*)-7,11-heptacosadiene.

Alkadienes elute from the AgNO_3 -impregnated silica HPLC column in the order (*E,E*)-, (*E,Z*)-, (*Z,E*)-, and (*Z,Z*)-alkadienes (Bartelt et al., 1986b, and unpublished data), and the 7,11-heptacosadiene from *D. rajasekari* eluted with (*Z,Z*)-alkadienes. The 7,11-heptacosadiene also eluted from both the DB-1 and DB-225 GC columns with the same retention time as (*Z,Z*)-7,11-heptacosadiene from *D. melanogaster*, establishing the *D. rajasekari* HCD as (*Z,Z*)-7,11-heptacosadiene.

Sexually mature *D. rajasekari* males performed an elaborate series of behaviors during courtship (Figure 2). These behaviors included orientation, in which the male positioned himself to face the female; tapping, in which the male contacted the female with his foretarsi; following, in which the male chased the female when she moved away; vibration of the abdomen, in which the male's abdomen vibrated up and down while the male oriented toward the female; wing vibration, in which the male extended one wing and vibrated it (presumably to produce a courtship song); wing extension display, in which the male moved in front of the female, faced her, extended both wings, and made a "scooping"

FIG. 2. Courtship behaviors of *Drosophila rajasekari* males: (A) orientation; (B) tapping; (C) extension and vibration of one wing; (D) vibration of the abdomen; (E) wing extension display; (F) attempted copulation.

forward motion with both wings; and attempted copulation, in which the male curled his abdomen under himself and attempted to mount the female.

These behaviors are similar to those performed by courting *D. melanogaster* males, which also orient, tap, follow, extend and vibrate one wing (to produce a courtship song), and attempt copulation. Additionally, *D. melanogaster* males perform a behavior known as licking, where they attempt to contact the courted fly with their proboscis. *D. melanogaster* males do not, however, perform the wing extension display, nor do they vibrate their abdomens as vigorously as do *D. rajasekari* males.

The ontogeny of *D. rajasekari* courtship is summarized in Table 2. Only

TABLE 2. ONTOGENY OF *D. rajasekari* COURTSHIP^a

Age of flies	Mean CI	Number of males performing each behavior
6 hr	3 ± 3	7 None, 2 OTF, 1 OTFWeVAc
12 hr	54 ± 9	1 None, 6 OTFWeV, 3 OTFWeVAc
1 day	60 ± 9	4 OTFWeV, 6 OTFWeVAc
2 days	70 ± 7	3 OTFWeV, 7 OTFWeVAc
3 days	82 ± 5	2 OTFWeV, 7 OTFWeVAc, 1 OTFWeVAc COP
4 days	81 ± 5	1 OTFWeV, 9 OTFWeVAc
5 days	73 ± 8	2 OTFWeV, 8 OTFWeVAc
6 days	79 ± 3	9 OTFWeVAc, 1 OTFWeVAc COP

^aCI = mean ± SE. *N* = 10 for all tests. Behaviors recorded were O, orienting; T, tapping; F, following; We, wing extension; V, abdomen vibration; Ac, attempted copulation; COP, copulation. None = no courtship.

three of the 6-hr-old males performed any of the courtship behaviors, and their CIs were very low. At 12 hr, 1 day and 2 days old, the CIs of the males were much higher, and the majority of the males performed all of the behaviors. At 3 days old, the CIs were at their highest level, the majority of the males performed all of the behaviors, and one male successfully copulated within the observation period. Males that were 4 to 6 days old were not significantly different from 3-day-old males in terms of CIs or behaviors performed. Therefore, it was concluded that males become sexually mature (as defined in Methods and Materials) at the age of 3 days.

Drosophila rajasekari females that were 3 to 5 hr, 1 day, and 3 to 5 days old were all sexually attractive to mature *D. rajasekari* males. In addition, 3- to 5-hr-, 1-day-, and 3- to 5-day-old *D. rajasekari* males also elicited courtship from mature *D. rajasekari* males, although the 1-day- and 3- to 5-day-old males were significantly less attractive than the 3- to 5-hr-old males ($P < 0.001$; Mann-Whitney test). These results are summarized in Table 3.

Since mature *D. rajasekari* males performed courtship toward 3- to 5-day-old *D. rajasekari* females and males in white light, they were then tested for their ability to perform courtship toward those flies in the dark (Table 4). Only one *D. rajasekari* male courted in the dark. This male oriented, tapped, and extended his wing in response to a *D. rajasekari* female.

Table 4 also shows the results of courtship tests involving *D. melanogaster* and *D. rajasekari*. As expected, *D. melanogaster* males performed vigorous amounts of courtship in response to *D. rajasekari* males and females in both the light and dark experimental conditions. Mature *D. rajasekari* males did not, however, actively court *D. melanogaster* females.

TABLE 3. COURTSHIP OF SEXUALLY MATURE *D. rajasekari* MALES IN RESPONSE TO DIFFERENT "SEX OBJECTS"^a

Sex object	Mean CI of <i>D. rajasekari</i> males
3- to 5-hr-old <i>D. rajasekari</i> female	76 ± 3
1-day-old <i>D. rajasekari</i> female	68 ± 10
3- to 5-day-old <i>D. rajasekari</i> female	82 ± 5
3- to 5-hr-old <i>D. rajasekari</i> male	67 ± 4
1-day-old <i>D. rajasekari</i> male	22 ± 8
3- to 5-day-old <i>D. rajasekari</i> male	17 ± 8

^aCI = mean ± SE. *N* = 10 for all tests. The *D. rajasekari* males whose courtship was recorded were 3 to 5 days old. In tests in which two males were tested together, one of the males had the tip of one wing removed. In half the tests the courting male's wing was clipped; in the other half, the sex object's wing was clipped.

TABLE 4. COURTSHIP IN THE LIGHT AND IN THE DARK

Courting male	Sex object	Illumination	CI
<i>D. rajasekari</i>	<i>D. rajasekari</i> female	light	82 ± 5
<i>D. rajasekari</i>	<i>D. rajasekari</i> female	dark	2 ± 2
<i>D. rajasekari</i>	<i>D. rajasekari</i> male	light	17 ± 8
<i>D. rajasekari</i>	<i>D. rajasekari</i> male	dark	0 ± 0
<i>D. rajasekari</i>	<i>D. melanogaster</i> female	light	1 ± 0
<i>D. melanogaster</i>	<i>D. rajasekari</i> female	light	78 ± 6
<i>D. melanogaster</i>	<i>D. rajasekari</i> female	dark	60 ± 8
<i>D. melanogaster</i>	<i>D. rajasekari</i> male	light	90 ± 3
<i>D. melanogaster</i>	<i>D. rajasekari</i> male	dark	40 ± 3

^aCI = mean ± SE. *N* = 10 for all tests. Dark = illuminated by red light. Light = illuminated by white incandescent light. All flies were 3 to 5 days old. In tests in which two males were tested together, one of the males had the tip of one wing surgically removed. In half the tests the courting male's wing was clipped, in the other half, the sex object's wing was clipped.

DISCUSSION

We have shown that little sexual dimorphism exists with respect to the cuticular hydrocarbons extracted from *D. rajasekari* males and females. In addition, a detailed analysis revealed the major cuticular component of these flies to be the 27-carbon alkadiene, (*Z,Z*)-7,11-heptacosadiene (HCD).

Our behavioral assays have shown that *D. rajasekari* males perform a complex series of courtship behaviors prior to mating and that these males are sexually attracted to other *D. rajasekari* males as well as *D. rajasekari* females. Additionally, *D. rajasekari* males and females are attractive both when they are young and when they are mature. This situation is similar to that found in *D. melanogaster* in that virgin females are attractive throughout their lives, but different in that *D. melanogaster* males, which are attractive when immature, lose their sex appeal as they mature (Jallon and Hotta, 1979; McRobert and Tompkins, 1983; Curcillo and Tompkins, 1987). The sex appeal of *D. rajasekari* males declines as they age, but mature males still elicit relatively high levels of courtship from other males.

D. rajasekari females and males were also sexually attractive to *D. melanogaster* males. Furthermore, since *D. melanogaster* males performed vigorous courtship displays toward *D. rajasekari* females and males in the absence of light, the cues responsible for the initiation of this cross-species courtship behavior are probably olfactory. Of course, this is not unexpected, since mature *D. rajasekari* produce large quantities of HCD, a compound known to be a major courtship-stimulating pheromone in *D. melanogaster* (Antony and Jallon, 1982; Antony et al., 1985).

On the other hand, *D. rajasekari* males performed almost no courtship in response to *D. melanogaster* females, which are known to produce large quantities of HCD. These results suggest either that *D. rajasekari* males are not stimulated to court by HCD or that *D. melanogaster* females produce some compound that inhibits the courtship of *D. rajasekari* males. If the first of these possibilities is true, then the sex appeal of *D. rajasekari* females and males to mature *D. rajasekari* males must be caused by some factor other than HCD. This stimulus could be visual, olfactory, or both. The fact that one *D. rajasekari* male courted a *D. rajasekari* female in the dark indicates that there may be some olfactory cue involved, but it is unlikely that this cue is HCD.

In summary, our results further substantiate the fact that (Z,Z)-7,11-heptacosadiene (HCD) stimulates courtship from mature *D. melanogaster* males, even when this courtship-stimulating cue is provided by flies that are not *D. melanogaster* females. Furthermore, *D. rajasekari* represents a species in which males and females produce large quantities of HCD, but do not apparently use it as a courtship-stimulating pheromone.

TERPENE ALCOHOL PHEROMONE PRODUCTION BY
Dendroctonus ponderosae AND *Ips paraconfusus*
(COLEOPTERA: SCOLYTIDAE) IN THE
ABSENCE OF READILY CULTURABLE
MICROORGANISMS¹

(Received April 4, 1988; accepted July 11, 1988)

Abstract—*Dendroctonus ponderosae* Hopkins and *Ips paraconfusus* Lanier of both sexes produced most of their complement of terpene alcohols at normal to elevated levels in the absence of readily culturable microorganisms. However, there was some evidence that microbial involvement may be required by male *I. paraconfusus* to produce ipsenol and ipsdienol at normal levels. Increased levels of certain terpene alcohols found in axenically reared or streptomycin-fed beetles suggest that symbiotic microorganisms may be responsible for breaking down pheromones and other terpene alcohols. There was also evidence for microbial involvement in the production of the antiaggregation pheromone verbenone in *D. ponderosae*. This compound was not produced in quantifiable levels by axenically reared or streptomycin-fed beetles exposed to α -pinene as vapors or through feeding, but was found in wild *D. ponderosae* exposed to α -pinene through feeding on bolts of lodgepole pine, *Pinus contorta* var. *latifolia* Engelmann.

Key Words—*Dendroctonus ponderosae*, *Ips paraconfusus*, Coleoptera, Scolytidae, pheromones, terpene alcohols, axenic-rearing, bark beetles, microorganisms.

INTRODUCTION

The role of symbiotic microorganisms in pheromone production by bark beetles has previously been studied by isolating and culturing these microbes and examining their capacities to produce terpene alcohol pheromones *in vitro*. Certain species of microorganisms found in association with scolytids produced some of their hosts' terpene alcohol pheromones when exposed to monoterpene precursors of those pheromones (Brand et al., 1975; Chararas et al., 1980). This finding is not surprising since these microorganisms are exposed in nature to the same monoterpenes as the host beetles, and many species of microorganisms can oxidize monoterpene hydrocarbons (Bhattacharyya et al., 1960; Prema and Bhattacharyya, 1962; Shukla et al., 1968; Fonken and Johnson, 1972; Keislich, 1976). However, there is little evidence that microbe-produced terpene alcohols are being used in nature as pheromones by the host beetles or that these compounds are even being produced by the symbionts in quantities that are biologically significant to the host beetles.

In order to assess the importance of the microbial contribution to overall pheromone production, it is essential to ascertain the metabolic capabilities of beetles that are relatively free of microbial symbionts. Chararas (1980) claimed that after *Ips sexdentatus* Boerner, *Ips typographus* (L.), and *Ips acuminatus* Gyllenhal had been fed a wide-spectrum antibiotic, their frass showed slightly reduced attractiveness to other beetles of the same species. Chararas also reported that the frass of antibiotic-fed beetles had more of the monoterpenes α -pinene, β -pinene, and Δ^3 -carene, and less of the conversion products of these compounds, than did frass from normal beetles. Byers and Wood (1981), found that *Ips paraconfusus* (Lanier) that were fed streptomycin were unable to convert myrcene to the pheromones ipsenol and ipsdienol, while the synthesis of *cis*-verbenol from α -pinene was not inhibited. They interpreted these results to indicate that symbiotic bacteria sensitive to streptomycin are involved in the synthesis of ipsenol and ipsdienol and that *cis*-verbenol is either synthesized by insect cells or by microorganisms that are unaffected by streptomycin at the concentrations used. However, while these results suggest that microorganisms are involved in pheromone production by *Ips* species, treatment of insects with dietary antibiotics can produce adverse physiological effects in the insects (Greenberg, 1970). It is possible that reductions in pheromone production through streptomycin-feeding (Chararas, 1980; Byers and Wood, 1981) were the result of such effects.

Axenic rearing is a useful technique for the study of symbiosis in insects (Rodriguez, 1966; Vanderzant, 1974). The development of a technique for rearing bark beetles axenically (Bedard, 1966; Whitney and Spanier, 1982) has

provided an opportunity to study the production of pheromones by bark beetles with reduced levels of microorganisms without the use of antibiotics.

The mountain pine beetle, *Dendroctonus ponderosae* Hopkins, and the California five-spined ips, *I. paraconfusus*, were chosen for this study because their pheromone chemistry is fairly well understood and because much of the research that has indicated that microorganisms are involved in the production of bark beetle pheromones has been conducted on *I. paraconfusus* (Brand et al., 1975; Byers and Wood, 1981), and *Dendroctonus* species (Brand et al., 1976, 1977; Brand and Barras, 1977).

D. ponderosae infests living *Pinus* species throughout western North America (Wood, 1982). Females convert the host tree monoterpene α -pinene to the aggregation pheromone *trans*-verbenol (Hughes, 1973; Pitman, 1971) and a variety of other terpene alcohols such as myrtenol and *cis*-verbenol. Two bicyclic ketals, *exo*-brevicommin and frontalin, which are of uncertain biosynthetic origin (Vanderwel and Oehlschlager, 1987), are apparently concentration-dependent, multifunctional pheromones, acting to promote aggregation (Rudinsky et al., 1974; Conn et al., 1983; Borden et al., 1983, 1987) or antiaggregation (Rudinsky et al., 1974; Pitman et al., 1978; Ryker and Rudinsky, 1982; Ryker and Libbey, 1982; Borden et al., 1987). *endo*-Brevicommin (Ryker and Rudinsky, 1982), verbenone (Ryker and Yandell, 1983; Borden et al., 1987), pinocarvone (Libbey et al., 1985), and ipsdienol (Hunt and Borden, 1988) all have activity as antiaggregation pheromones, while the monoterpenes α -pinene (Pitman, 1971), myrcene, and terpinolene (Billings et al., 1976; Conn et al., 1983; Borden et al., 1983) act as synergistic kairomones in promoting aggregation.

I. paraconfusus is usually found in weakened or fallen *Pinus* species in Oregon, Nevada, and California (S.L. Wood, 1982). It also infests the upper boles of trees killed by the western pine beetle, *Dendroctonus brevicomis* LeConte and in some cases kills the upper crown of mature ponderosa pines, *Pinus ponderosa* Laws or entire young trees (Struble and Hall, 1955). *I. paraconfusus* converts α -pinene to *cis*-verbenol (Renwick et al., 1976) and myrcene to ipsdienol (Byers et al., 1979; Hendry et al., 1980) and then ipsenol (Fish et al., 1979). It utilizes ipsenol, ipsdienol, and *cis*-verbenol as aggregation pheromones (Wood et al., 1968).

Conn et al. (1984) established that axenically reared *D. ponderosae* and *I. paraconfusus* are capable of producing certain terpene alcohol pheromones. However, their results were somewhat inconsistent, and they did not establish whether axenically reared insects are capable of producing these compounds at levels equal to normal insects with their full complement of microorganisms. Our objective was to assess in as comprehensive and definitive a manner as

possible the effects of axenic rearing and antibiotic feeding on the production of terpene alcohols and ketones from α -pinene and myrcene in both sexes of *D. ponderosae* and *I. paraconfusus*.

METHODS AND MATERIALS

Collection of Insects and Host Material. Lodgepole pines, *P. contorta* var. *latifolia*, infested with *D. ponderosae* and uninfested lodgepole and ponderosa pine, *Pinus ponderosa* Laws., were collected near Princeton, British Columbia. Adult *I. paraconfusus* were obtained from D.L. Wood (Department of Entomological Sciences, University of California-Berkeley, California 94720), and a colony was maintained on ponderosa pine bolts. Adult *D. ponderosae* and *I. paraconfusus* were collected daily after they emerged from caged logs kept at 27°C. Emerged beetles were stored on moistened paper towels at 2–4°C in loosely capped, screw-top jars. When beetles were needed for experiments, jars that had been stored a maximum of two weeks were rewarmed to room temperature, and normal and healthy-appearing individuals were selected.

Axenic Rearing. An axenic rearing technique (Whitney and Spanier, 1982) was used to obtain beetles that were devoid of readily culturable microorganisms. The outer bark was shaved off fresh pine bolts (lodgepole pine for *D. ponderosae* and ponderosa pine for *I. paraconfusus*), and the exposed phloem was removed and cut into 1-cm² pieces. The phloem was frozen at –25°C, ground in a prechilled Waring blender, and passed through No. 12 mesh screen. Grinding and sieving were conducted in a –25°C walk-in cold-room, and the ground phloem was stored in plastic bags at –20°C. When diet was required for insect rearing, the phloem was thawed, and water and dehydrated brewer's yeast were added at 50% and 10%, respectively, of the weight of the phloem. The mixed diet was dispensed into 19 × 55-mm shell vials at approximately 0.75 g/vial using a 10-ml plastic syringe with the bottom removed. The vials were capped with Morton stainless-steel culture closures (18 mm), pasteurized in an Amsco isothermal sterilizer for 1.0 hr at 85°C, held at room temperature for four days, and then repasteurized. This double treatment of the vials in the isothermal sterilizer yielded sterile diet.

Adult female *D. ponderosae* or male *I. paraconfusus* were individually caged onto fresh bolts of lodgepole or ponderosa pine, respectively, using gelatin capsules (Lanier and Wood, 1968). After 24 hr, a mate was introduced to each capsule and the bolts were kept at 26–28°C. After 10 days for *D. ponderosae* or seven days for *I. paraconfusus*, the bark was removed. Using a blunt probe, the eggs were collected from the parent galleries, transferred to moistened filter paper in a Petri dish, sealed in a plastic bag to prevent moisture loss,

and incubated at 22–24°C in the dark. Incubating eggs were examined twice daily for *D. ponderosae* and three times daily for *I. paraconfusus*. Fourth-stage eggs (Reid and Gates, 1970) were surface-sterilized in 0.1% mercuric chloride (Fisher Scientific Co., Fair Lawn, New Jersey), rinsed six times in sterile distilled water, and placed individually in the vials of sterilized diet. Sterilized Pasteur pipets were used to transfer the eggs and the procedure was performed aseptically on a sterile air bench. The eggs were allowed to mature to adults in the vials, and emergent, axenically reared adults remained in the rearing vials until used in experiments.

Checks for aerobic microorganisms in the sterilized diet, as well as externally and internally from all stages of the developing axenically reared insects, were done on malt extract agar, potato dextrose agar, and plate count agar. Axenically reared adult beetles were also examined for microorganisms on their exposed cuticle using scanning electron microscopy.

Antibiotic Feeding. An antibiotic feeding technique similar to that developed by Byers and Wood (1981) was used to obtain beetles with reduced levels of symbiotic microorganisms. A mixture of 35 g of powdered cellulose (alpha-cellulose, Sigma Chemical Co., St. Louis, Missouri), 8 g of sucrose and 22 g of ground pine phloem (lodgepole and ponderosa pine phloem for *D. ponderosae* and *I. paraconfusus*, respectively) was added to 62 ml of distilled water containing 10 mg of streptomycin sulfate (Sigma) per milliliter of water. The ingredients were thoroughly mixed and then dispensed into 19 × 55-mm shell vials at approximately 0.75 g/vial using a 10-ml plastic syringe with the bottom removed. An adult beetle was added to each vial and the insects were allowed to feed for 96 hr at 22–24°C. Petri dishes were not used as in Byers and Wood (1981), as the use of individual vials made it possible to eliminate from the experiment beetles which did not feed.

Maturation Experiments. The term “wild” in this paper indicates that the beetles have not had their normal complement of microorganisms removed or reduced. When wild adults of a known age were required, the bark was removed from infested bolts and pupae were collected, placed in Petri dishes containing moistened filter paper, and examined daily until eclosion (the term “eclosion” in this paper refers specifically to molt from pupa to adult; posteclosion age refers to the number of days as an adult). Callow adults were removed from the Petri dishes and allowed to mature in individual vials until reaching the desired age (we use “mature” to designate beetles of the posteclosion age at which peak levels of terpene alcohol production were observed to occur). Since fungi found in the pupal chamber are thought to be important in the maturation feeding of callow scolytids (Whitney, 1971; Barras, 1973), moistened bark from around the pupal chambers in the infested bolt was included in each vial.

Vials containing axenically reared individuals were examined daily near

the time of eclosion so that the maturity of adult beetles used in experiments was known.

Pheromone Production and Extraction Techniques. Pheromone production was induced using one of two methods: (1) Beetles that had bored in the inner bark of pine logs for 24 hr were chipped out and held over Dry Ice until a sufficient number had accumulated for dissection. (2) Beetles were placed individually in upright, open-ended glass cylinders (1.4 cm ID) (Conn, 1981) inside a 500-ml glass jar. Open vials (1.8 ml screw-cap) containing 25 μ l of the pheromone precursors α -pinene and/or myrcene were also placed in the jar, and the jar was sealed and held in the dark for 24 hr.

Beetle abdomens were removed using fine forceps, and immediately immersed in 100 μ l of double-distilled pentane in individual 1.8-ml glass vials over Dry Ice. The excised abdomens included the hindgut, Malpighian tubules, and a large portion of the midgut. Each abdomen was macerated with the tip of a spatula in the pentane over Dry Ice, and the vial was then sealed and allowed to sit at room temperature for approximately 15 min. The pentane extract was then transferred with a syringe into a clean vial. The macerated tissue was rinsed twice each with 25 μ l of double distilled pentane at room temperature, and this was added to the clean vial, which was then closed with a Teflon-lined screw-cap, and stored at -20°C .

Gas Chromatographic Analyses. Single beetle extracts were analyzed on a Hewlett Packard 5880A gas chromatograph equipped with a capillary inlet system and a flame ionization detector. A glass capillary column (30 m \times 0.66 mm ID) coated with SP-1000 (Supelco, Inc., Bellefonte, Pennsylvania) was used with the temperature set at 120°C for 2 min, and then increasing by $4^{\circ}\text{C}/\text{min}$ to 180°C . The injection port temperature was 260°C , the flame ionization detector temperature was 275°C , and helium was used as the carrier gas. A known quantity of 3-octanol was added to the distilled pentane used to extract the abdomens, and the same quantity of 2-octanol was added following extraction. The area under the 3-octanol peak was used as a reference for calculating the quantities of each compound present in each sample, and the ratio of 3- to 2-octanol recovered was used to monitor the loss of volatile compounds during the extraction process.

Each day that samples were analyzed by gas chromatography, a standard sample made up of 2- and 3-octanol, α -pinene, myrcene, *cis*- and *trans*-verbenol, myrtenol, verbenone, ipsenol, ipsdienol, and myrcenol was also analyzed for comparison of retention times. In addition, these compounds were periodically added to an abdominal extract, and that mixture was analyzed to ensure correct identification by cochromatography with unknown compounds in the extract. Selected extracts were analyzed using gas chromatography-mass spectroscopy to ensure proper identification of compounds. For most samples, the detection limit for compounds of interest was set at 5 ng/abdomen.

Experiments Conducted. Twenty-one experiments were conducted with *D. ponderosae* and *I. paraconfusus* adults of both sexes, with experiment number and objectives as outlined below. Details of experimental treatments and replicates are given in Tables 1-3, and Figures 1-3.

Female D. ponderosae.

- I. To assess the effect of axenic rearing or streptomycin feeding on the conversion of α -pinene into terpene alcohols.
- II. To assess the effect of maturation on the ability of axenically reared beetles to produce terpene alcohols.
- III. To compare the effect of various degrees of maturation on the ability of axenically reared and wild beetles to produce terpene alcohols.
- IV. To compare the levels of terpene alcohol production by mature, axenically reared beetles, mature, wild beetles, and emerged, wild beetles.
- V and VI. To compare the effects of streptomycin-feeding on terpene alcohol production in beetles exposed to α -pinene either as vapors or through feeding.
- VII. To determine the effects of axenic rearing on the conversion of ingested α -pinene into terpene alcohols.
- VIII. To determine the ability of females to convert myrcene into terpene alcohols.

Male D. ponderosae.

- IX and X. To determine the effects of axenic rearing and streptomycin feeding on the conversion of α -pinene (experiment IX) and myrcene (experiment X) vapors into terpene alcohols.

Male I. paraconfusus.

- XI and XII. To compare the effect of various degrees of maturation on the ability of axenically reared and wild beetles to produce α -pinene-derived (experiment XI) and myrcene-derived (experiment XII) terpene alcohols.
- XIII. To compare the levels of myrcene-derived terpene alcohol production by mature, axenically reared beetles; mature, wild beetles; and emerged, wild beetles.
- XIV. To compare the levels of terpene alcohol production by mature, axenically reared beetles; mature, wild beetles; and emerged, wild beetles.
- XV. To assess the effects of streptomycin-feeding on terpene alcohol production in wild beetles exposed to α -pinene vapors.

- XVI and XVIII. To determine the effects of streptomycin feeding (experiment XVI) or axenic rearing (experiment XVIII) on terpene alcohol production in beetles exposed to α -pinene through feeding.
- XVII. To compare the efficacy of two different batches of streptomycin in reducing the production of myrcene-derived terpene alcohols.
- XIX. To compare the levels of terpene alcohol production in beetles exposed to myrcene vapors, myrcene and α -pinene vapors simultaneously, or the myrcene and α -pinene encountered while feeding on bolts of *P. ponderosa*.
- XX. To determine the effects of distending the guts of *I. paraconfusus* with powdered cellulose on the conversion of myrcene vapors to ipsdienol and ipsenol.

Female I. paraconfusus.

- XXI. To determine the effects of axenic rearing and streptomycin feeding on the conversion of α -pinene vapors into terpene alcohols.

Statistical Analysis. The pheromone data were tested for homogeneity of variances using Cochran's *C* test as well as the Bartlett-Box *F* test using SPSS^x (1983). The data were heteroscedastic; therefore, they were analyzed using the Kruskal-Wallis test (Sokal and Rohlf, 1981) followed by a nonparametric multiple comparisons test (Conover, 1980, p. 231), $P < 0.05$.

RESULTS AND DISCUSSION

Axenically Reared Beetles. During axenic rearing, the few vials with visible signs of contamination were discarded. In one batch of axenically reared *D. ponderosae*, there were many contaminated vials, and closer examination revealed numerous mites in the vials. These mites, which are frequently associated with wild *D. ponderosae*, are small enough that they can enter the shell vials after capping with the steel culture closures. Contamination with mites, and the fungi that they carry, was subsequently avoided by ensuring that the capped vials were not handled or stored in areas of the laboratory where wild beetles were handled.

Checks for aerobic microorganisms in the vials of sterilized diet, as well as externally and internally from all stages of axenically reared *D. ponderosae* and *I. paraconfusus*, revealed no microorganisms. In developing the technique, Whitney and Spanier (1982) had conducted even more extensive culturing on axenically reared *D. ponderosae*, which also revealed no microorganisms. In addition, no microorganisms other than brewer's yeast cells were observed on

the external cuticular surface of axenically reared adults examined by scanning electron microscopy.

Although all of the above checks and precautions indicate that beetles obtained using the axenic rearing technique are likely to be truly axenic, it is possible that transovarially transmitted, obligate symbionts may still be associated with these beetles. Therefore, we refer to beetles obtained using this technique as "axenically reared" or "microbe reduced," and not "axenic."

Of the *D. ponderosae* eggs that were surface sterilized and placed in vials of sterilized diet, generally 60–80% survived to adulthood. Only 40–60% of axenically reared *I. paraconfusus* survived, probably because the eggs of this species are more fragile and were more easily damaged during handling.

Initial Experiments on Pheromone Production by Axenically Reared Beetles. Experiment 1 (Table 1) failed to verify the results of Conn et al. (1984) in which female *D. ponderosae* free of readily culturable microorganisms contained far more *trans*-verbenol than wild control beetles. Rather, axenically reared beetles in experiment 1 contained *trans*- and *cis*-verbenol and myrtenol at levels too low to be quantified (Table 1, experiment I). Streptomycin-fed beetles and wild controls also contained unusually low levels of these terpene alcohols (Table 1, experiment I).

In a subsequent experiment, beetles from the same batch of axenically reared, female *D. ponderosae*, which were allowed to mature for a further 14 days, produced significant levels of *trans*- and *cis*-verbenol, and myrtenol when exposed to α -pinene vapors (Table 1, experiment II). Normal levels of production were found in wild, control beetles. The quantities of *trans*- and *cis*-verbenol produced by axenically reared beetles in this experiment were not significantly different from those produced by wild emerged beetles, although the production of myrtenol was significantly different in the axenically-reared individuals (Table 1, experiment II).

Effect of Maturation on Terpene Alcohol Production in Female D. ponderosae. The axenically reared female *D. ponderosae* in experiment I were fully darkened adults, and it was initially assumed that they had reached physiological maturity. However, since individuals taken from the same batch 14 days later produced terpene alcohols at higher levels (Table 1, experiment II), and because no record was made of the age of the axenically reared females used by Conn et al. (1984), we hypothesized that maturation beyond the point of darkening of axenically reared *D. ponderosae* was required before peak terpene alcohol production occurred.

To test this hypothesis, we exposed axenically reared females of varying posteclosion ages to α -pinene vapors. Axenically reared individuals of 5 and 15 days posteclosion produced *trans*- and *cis*-verbenol and myrtenol at relatively low levels, while levels in beetles of 25 and 35 days posteclosion were much higher than those in wild emerged beetles (Figures 1–3). Thus a three- to four-week maturation period is apparently required before adult *D. ponderosae*

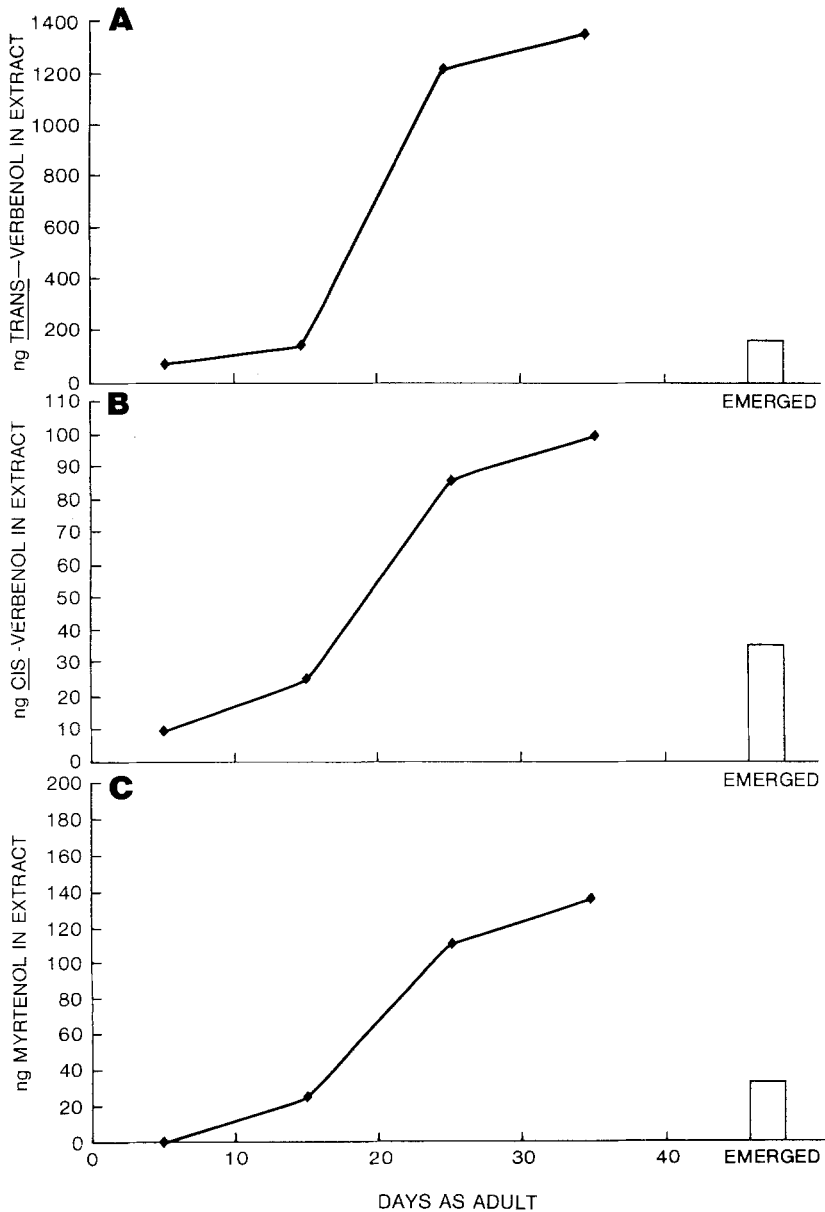

FIG. 1. Quantities (nanograms) of *trans*-verbenol (A, D), *cis*-verbenol (B, E), and myrtenol (C, F), produced in experiment III by individual axenically reared (A-C) and wild (D-F) female *D. ponderosae* of various posteclosion ages that were exposed to α -pinene vapors. Numbers of beetles used for each treatment were as follows. Axenically reared: 5 days, 9; 15 days, 10; 25 days, 10; 35 days, 8. Wild, group 1: 6 days, 6; 16 days, 6; 27 days, 6; 40 days, 9. Wild, group 2: 5 days, 11; 15 days, 8; 25 days, 10; 35 days, 10.

FIG. 1. Continued.

develop maximal enzymatic capacity for the oxidation of α -pinene into terpene alcohols.

Since the posteclosion age of *D. ponderosae* is evidently important in determining the physiological maturity of axenically reared beetles, much of the data reported by Conn et al. (1984) must be questioned. Although Conn et al. (1984) did establish that axenically reared *D. ponderosae* can produce terpene alcohol pheromones, it is likely that the generally low levels of production of these compounds reported by Conn et al. (1984) simply reflect the use of immature beetles. The production of very high levels of *trans*-verbenol by axenically reared female *D. ponderosae* in one experiment (9900 ng/beetle) probably indicates the fortuitous use of mature beetles.

The pattern of terpene alcohol production in relation to age for wild female *D. ponderosae* was different than that for axenically reared individuals (Figure 1). During the first 15 days posteclosion, the production of *trans*- and *cis*-verbenol and myrtenol in two groups of beetles was moderate to high, then declined sharply, and returned to higher levels in older beetles (Figure 1). The terpene alcohol production in wild callow adults of 5–15 days posteclosion is not likely to be due to production by microorganisms since wild beetles of 18–25 days posteclosion, which should have the same complement of symbiotic microorganisms, produced terpene alcohols at much lower levels (Figure 1). Possibly the *cis*- and *trans*-verbenol and myrtenol produced by wild beetles of 5–15 days posteclosion is metabolized from derivatized α -pinene sequestered by the insects as larvae or pupae (Hughes, 1975), rather than by conversion of inhaled α -pinene vapors. Axenically reared callow adults could not produce significant quantities of terpene alcohols from sequestered precursors since the monoterpenes in the ground phloem in the axenic diet are virtually eliminated during the sterilization process (Table 2). The increase in terpene alcohol production in wild beetles 25 days posteclosion would, as in axenically reared beetles, be due to the maturation of the enzyme systems responsible for oxidizing the monoterpenes encountered as the mature adult attacks a new host.

The peak levels of terpene alcohol production were generally much higher

TABLE 2. EFFECT OF PASTEURIZATION ON MONOTERPENE CONTENT OF GROUND PHLOEM IN AXENIC DIET

<i>Pinus ponderosa</i>	78	90

in wild beetles of 27–40 days posteclosion than in wild emerged beetles (Figure 1). This difference apparently indicates that wild emerged beetles are not yet capable of peak pheromone production. There is evidence that certain species of bark beetles undergo a period of obligatory dispersal before they become responsive to olfactory signals associated with their hosts or other beetles. Flight exercise was found to increase positive responses to attractive semiochemicals in *Dendroctonus frontalis* Zimmerman (Andryszak et al., 1982), *Dendroctonus pseudotsugae* Hopkins (Bennett and Borden, 1971), *Trypodendron lineatum* (Olivier) (Graham 1959, 1962; Bennett and Borden, 1971), and *Scolytus multistriatus* (Marsham) (Choudhury and Kennedy, 1980). It is thought that beetles that are not yet responsive to attractive semiochemicals contain higher levels of lipids and that these individuals become responsive through a metabolic feedback process activated through flight exercise (Atkins, 1966, 1969). We hypothesize that a period of lipid metabolism through flight exercise may also be necessary before pheromone production can reach its maximum. In this way healthy, lipid-rich beetles could disperse farther from trees in which they developed before being able to produce large quantities of attractive pheromones. This longer dispersal would be of adaptive advantage, particularly under epidemic conditions, as these individuals would be more likely to encounter suitable hosts, thus assuring an adequate supply of high-quality phloem in which to feed and breed. A long dispersal flight would also enable individuals to interbreed with beetles from other populations. Older, wild beetles (reared as pupae and held 35–40 days posteclosion), which show much higher levels of pheromone production than wild emerged beetles (Figure 1), may be metabolically similar to emerged beetles that have completed a dispersal flight. They have probably lost lipid reserves through walking exercise in the Petri dishes and also may have faced a low-quality diet due to drying out of the phloem on which they were fed. Sanders (1983) showed that starvation or walking activity released host-positive responses in host-negative *Pityogenes chalcographus* (L.). Similarly, Gries (1984) showed that *I. typographus* that were denied a chance to fly became host-responsive only after incurring a mean weight loss equivalent to that lost during a 7-km flight. Therefore, we hypothesize that the older wild beetles shown in Figure 1 have foregone a dispersal flight due to decreasing lipid reserves and have become physiologically ready to attack new hosts, detoxify monoterpenes present in those hosts, and release aggregation pheromones at high levels.

When pupae were collected from infested bolts for use in the wild beetle maturation experiments, the beetles from two additional infested bolts from the same tree were allowed to emerge naturally. The average period of time between eclosion to adults in the Petri dishes and emergence of wild beetles from infested bolts was approximately 30 days. This is a very rough estimate of the time that adults wait before emerging in nature, since the infested bolts were held in cages

at approximately 27°C, and this elevated, constant temperature, in combination with the accelerated drying of the phloem, probably resulted in accelerated emergence. Nonetheless, this result supports the hypothesis that the 35-to-40-day posteclosion adults in Figure 1 were metabolically equivalent to emerged and dispersed adults, which would be expected to produce terpene alcohols at higher levels than emerged beetles.

An alternative explanation for 27-to-40-day posteclosion beetles producing higher levels of terpene alcohols than emerged beetles (Figure 1) is that the adults that were collected as pupae and allowed to mature on phloem strips may be microbe-deficient. Since these beetles did not feed *in situ* as callow adults, they may possess a microbial fauna that is substantially reduced or different from wild emerged individuals. Some of the microorganisms that would be present at reduced levels may utilize the terpene alcohols as substrates, metabolizing them into other products.

Although Figure 1 indicates that wild emerged beetles are apparently not capable of maximal terpene alcohol production, wild emerged beetles were used as a standard control for comparison in all subsequent experiments with axenically reared and streptomycin-fed beetles.

Effect of Maturation on Terpene Alcohol Production in Male I. paraconfusus. To test whether the physiological maturity of axenically reared *I. paraconfusus* also affects the beetle's ability to oxidize monoterpenes, males of varying posteclosion ages were exposed to α -pinene and myrcene vapors. Axenically reared individuals of five and 13 days posteclosion produced *trans*- and *cis*-verbenol and myrtenol at relatively low levels, while beetles of 18 and 26 days posteclosion produced these compounds at levels much higher than those in wild emerged beetles (Figure 2). Adults that were allowed to mature to 69 days posteclosion showed declining levels of terpene alcohol production. Wild beetles also matured in their ability to oxidize α -pinene (Figure 2), but, with the exception of myrtenol, did not exhibit the early peak in terpene alcohol production noted in young *D. ponderosae* adults (Figure 1). High levels of mortality prevented the testing of wild *I. paraconfusus* beyond 28 days posteclosion.

The peak levels of terpene alcohols produced by wild *I. paraconfusus* were only half of those produced by axenically reared beetles (Figure 2). In contrast to *D. ponderosae*, the peak levels of terpene alcohols produced by mature, wild *I. paraconfusus* did not exceed the production by wild emerged beetles (Figure 2). Oxidation products of myrcene, such as ipsdienol and ipsenol, were not generally detectable at quantifiable levels in either axenically reared beetles or wild controls exposed to myrcene vapors.

Axenically reared male *I. paraconfusus* of eight days posteclosion that were exposed to myrcene through feeding on bolts of *P. ponderosa* were unable to produce ipsenol and ipsdienol at measurable levels, while beetles of 24 and 32 days posteclosion produced these pheromones at levels similar to those in wild

FIG. 2. Quantities (nanograms) of *trans*-verbenol (A), *cis*-verbenol (B), and myrtenol (C), produced in experiment XI by individual male *I. paraconfusus* of various posteclosion ages that were exposed to α -pinene vapors. Numbers of beetles used for each treatment were as follows. Axenically reared: 5 days, 10; 13 days, 11; 18 days, 12; 26 days, 11; 70 days, 10. Wild: 4 days, 7; 15 days, 5; 29 days, 5.

emerged beetles (Figure 3). When mature (24 days posteclosion), axenically reared individuals were fed on ponderosa pine bolts, they contained ipsenol and ipsdienol at levels that were not significantly different from those in mature wild beetles or wild emerged beetles (Table 3, experiment XIII).

As with *D. ponderosae*, Conn et al. (1984) did not report the posteclosion ages of *I. paraconfusus* used in their experiments. Although they did establish that axenically reared *I. paraconfusus* are capable of producing terpene alcohol pheromones, the generally low levels of production that they report probably

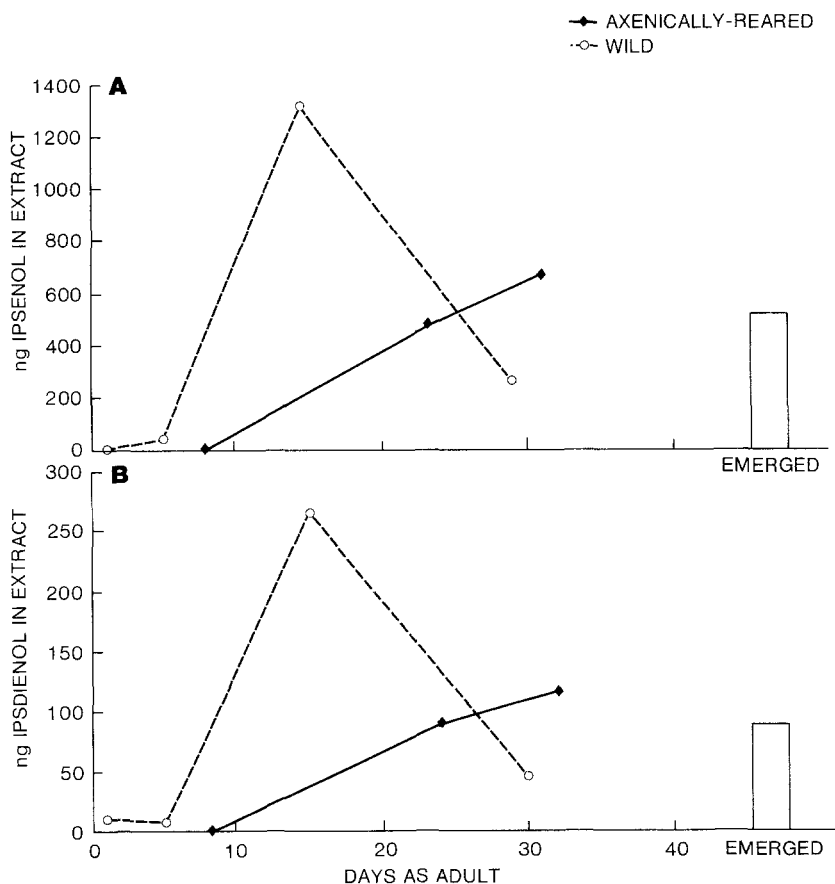

FIG. 3. Quantities (nanograms) of ipsenol (A), and ipsdienol (B), produced in experiment XII by individual male *I. paraconfusus* of various posteclosion ages that were fed on bolts of ponderosa pine. Numbers of beetles used for each treatment were as follows. Axenically reared: 8 days, 7; 24 days, 10; 32 days, 12. Wild: 1 day, 9; 5 days, 9; 15 days, 13; 30 days, 8.

reflect the use of axenically reared beetles that were not yet mature. The maturation period required before adult *I. paraconfusus* can convert myrcene into ipsenol and ipsdienol (Figure 3) and before adult *I. paraconfusus* and *D. ponderosae* can convert α -pinene into *cis*- and *trans*-verbenol and myrtenol (Figures 1 and 2) may explain why immature *I. paraconfusus* were unattractive to conspecifics when introduced into new hosts (Wood and Vité, 1961; Vité and Gara, 1962; Borden, 1967). It also may explain why immature female *D. frontalis* (Bridges, 1982) and *D. brevicomis* (Byers, 1983) were less capable of converting α -pinene to *trans*-verbenol than older females. Byers (1983) also found that immature male *I. paraconfusus* were not able to produce ipsenol and ipsdienol, although he reported that immature beetles were capable of producing normal amounts of *cis*- and *trans*-verbenol and myrtenol from α -pinene.

Microbial Involvement in α -Pinene Vapor Oxidation. Mature, axenically reared, female (Table 1, experiment IV) and male (Table 1, experiment IX) *D. ponderosae* produced more *trans*- and *cis*-verbenol and myrtenol upon exposure to α -pinene vapors than wild, emerged beetles. In addition, streptomycin-fed *D. ponderosae* females produced more of these terpene alcohols than wild, emerged beetles in one of two experiments (Table 1, experiments V and VI). Streptomycin-fed male *D. ponderosae* also produced more of these terpene alcohols than wild, emerged males (Table 1, experiment IX). Similarly, mature, axenically reared, male *I. paraconfusus* also produced more *trans*- and *cis*-verbenol and myrtenol upon exposure to α -pinene vapors than wild, emerged beetles (Table 3, experiment XIV). Mature, axenically reared, female *I. paraconfusus* (Table 3, experiment XXI), and streptomycin-fed male (Table 3, experiment XV) and female (Table 3, experiment XXI) *I. paraconfusus* also produced these terpene alcohols at levels not significantly different from wild, emerged beetles.

Evidently both male and female *D. ponderosae* and *I. paraconfusus* that have had their natural levels of symbiotic microorganisms reduced through axenic rearing or streptomycin feeding are capable of converting α -pinene vapors into the terpene alcohols *trans*- and *cis*-verbenol and myrtenol at levels equal to or significantly greater than those found in wild control beetles. These results confirm that readily culturable microorganisms are not solely responsible for the production of terpene alcohols in these beetles. The fact that terpene alcohol levels were significantly higher in microbe-reduced than in wild beetles in several experiments indicates that certain microorganisms may metabolize the available α -pinene precursor into other products, so that the α -pinene is unavailable to the beetles, or that they may utilize the terpene alcohols as substrates, metabolizing them into other products. In these ways the microorganisms present in wild bark beetles could regulate the levels of the aggregation pheromones, *trans*-verbenol in *D. ponderosae* and *cis*-verbenol in *I. paraconfusus*, preventing them from reaching excessive levels and disposing of them once aggregation

^aData analyzed using the Kruskal-Wallis test followed by a nonparametric multiple comparisons test (Conover, 1980; p. 231), $P < 0.05$. Means within a column for each experiment followed by the same letter are not significantly different.

is complete. Alternatively, it is possible that reducing the levels of microorganisms in the beetles through axenic rearing or streptomycin feeding may reduce the levels of microorganisms that are mildly pathogenic to the beetles and that the resultant healthier beetles simply produce higher levels of terpene alcohols. In support of this hypothesis, Gueldner et al. (1977) found reduced levels of pheromone production in boll weevils, *Anthonomus grandis* Boheman that were artificially contaminated with *Streptococcus* sp., *Micrococcus varians* Migula, and *Enterobacter aerogenes* Hormaeche and Edwards, all isolated from apparently normal, insectary-reared weevils.

Two Sites and Two Methods of α -Pinene Oxidation. While axenically reared or streptomycin-fed *D. ponderosae* readily produced *trans*- and *cis*-verbenol and myrtenol from α -pinene vapors, axenically reared beetles were unable to produce *trans*-verbenol from ingested α -pinene (Table 1, experiment VII). This result suggests that there are two production systems for this pheromone, one by the beetle's own enzymes and one by symbiotic microorganisms. The low levels of *trans*-verbenol in extracts of wild beetles fed on lodgepole pine probably result from the conversion of α -pinene by microorganisms in the gut. The high levels of *trans*-verbenol, *cis*-verbenol, and myrtenol in extracts of axenically reared and streptomycin-fed *D. ponderosae* exposed to α -pinene vapors would then be due to oxidation of inhaled vapors by the beetle's own enzymes.

Since axenically reared *D. ponderosae* produce *trans*-verbenol from inhaled, rather than ingested α -pinene (Table 1, experiments IV and VII), it is likely that the conversion does not occur in the gut, as suggested for other scolytids (Pitman et al., 1965; Zethner-Møller and Rudinsky, 1967). *trans*-Verbenol is probably produced in the hemolymph, transported through the Malpighian tubules into the hindgut, and released through the anus. This explanation is consistent with Hughes' (1973) finding of *trans*-verbenol and other monoterpene oxidation products in the hemolymph of *D. ponderosae* and his hypothesis that terpene metabolism occurs outside the gut.

Wild female *D. ponderosae* that had fed in lodgepole pine bolts for 24 hr contained significant amounts of verbenone, while axenically reared individuals contained only trace quantities (Table 1, experiment VII). However, after exposure to α -pinene vapors, neither wild nor axenically reared female *D. ponderosae* contained quantifiable levels of verbenone (Table 1, experiment IV), even when the extracts were concentrated to approximately 5 μ l over a stream of nitrogen before gas chromatographic analysis. Similarly, exposure to α -pinene vapors does not result in verbenone production by *D. frontalis* (Renwick et al., 1973), or *D. brevicomis* (Byers, 1983). Therefore, the production of verbenone by female *D. ponderosae* is probably due solely to the conversion of beetle-ingested precursor by gut microorganisms. This suggests that *D. ponderosae* is dependent on its symbiotic microorganisms for the production of verbenone, its

principal antiaggregation pheromone (Ryker and Yandell, 1983; Libbey et al., 1985; Borden et al., 1987).

Microbial Involvement in Myrcene Oxidation. Both axenic rearing and streptomycin feeding reduced the levels of (*E*)-1-myrcenol (1-myrcenol = 2-methyl-6-methylene-octa-2,7-dien-1-ol) and an unknown product in male *D. ponderosae* exposed to myrcene vapors (Table 1, experiment X). The levels of (*Z*)-1-myrcenol were reduced by streptomycin feeding, while the reduction caused by axenic rearing was not significant. This is further evidence that microorganisms are partially responsible for the production of certain conversion products of monoterpenes in this species. However, streptomycin-fed and wild control females exposed to myrcene vapors for 24 hr produced (*Z*) and (*E*)-1-myrcenol and an unknown product at similar levels (Table 1, experiment VIII).

Axenically reared or streptomycin-fed male *D. ponderosae* that were subsequently exposed to myrcene vapors contained ipsdienol at levels that were not significantly different from those in wild, emerged beetles (Table 1, experiment X). None of the females tested produced detectable levels of ipsdienol (Table 1, experiment VIII).

Two Pheromone Production Systems. The hypothesis that both the beetle and its symbiotic microorganisms can produce *cis*- and *trans*-verbenol, as well as other terpene alcohols, is consistent with the report by Chararas et al. (1980) that the frass of *I. sexdentatus*, *I. typographus*, or *I. acuminatus* that had been fed a wide-spectrum antibiotic showed reduced attractiveness to conspecifics. Chararas et al. (1980) also reported that the frass of antibiotic-fed beetles had more α -pinene, β -pinene, and Δ_3 -carene and less of their conversion products than normal beetles. They concluded that microbial conversion was responsible for a portion of total pheromone production, but provided minimal methodological details and presented no data to support this conclusion.

The existence of two pheromone production systems, beetle and microbial, is also consistent with what is known about polysubstrate monooxygenases (PSMOs). PSMOs are enzymes that catalyze numerous oxidation reactions that render lipophilic compounds, such as monoterpenes, hydrophilic, so that they can be more easily excreted. They are likely the most important enzymes involved in the metabolism of foreign substances, such as monoterpenes (Sturgeon and Robertson, 1985), and compounds that inhibit PSMO activity have been shown to inhibit partially terpene alcohol pheromone production in *D. ponderosae* (Hunt and Smirle, 1988). Since PSMOs are believed to be present in all aerobic organisms (Brattsten, 1979), and since bark beetles and their microorganisms are frequently exposed to monoterpenes that are toxic to both the insects (Smith, 1965; Reid and Gates, 1970; Coyne and Lott, 1976; Raffa and Berryman, 1983) and their symbiotic microorganisms (Cobb et al., 1968;

Shrimpton and Whitney, 1968; DeGroot, 1972; Raffa et al., 1985), it is logical that both would use PSMOs to oxidize monoterpenes.

Effect of Streptomycin on I. paraconfusus. In experiment XVI (Table 3) streptomycin feeding resulted in virtual elimination of the production of ipsdienol and ipsenol, a result in agreement with those of Byers and Wood (1981). However, in experiment XVII (Table 3), streptomycin-feeding caused a significant, but not total, reduction in ipsdienol and ipsenol production. Although the streptomycin used in these two experiments was from the same batch, there were several months between the experiments. Therefore, newly purchased streptomycin was used to determine whether the streptomycin in experiment XVII had lost some of its activity. However, the levels of ipsenol and ipsdienol in beetles fed the old or the new streptomycin were not significantly different (Table 3, experiment XVII).

Our *I. paraconfusus* colony was initiated with beetles from the Sierra Nevada, and should have been very similar to those used by Byers and Wood (1981). We had reared these beetles through several generations by the time experiment XVII (Table 3) was done, and it appears that this resulted in a shift of the population of insects or their symbiotic microorganisms toward some characteristic that promoted resistance to the effects of streptomycin.

Streptomycin Feeding vs. Axenic Rearing. There was only one discrepancy between the results obtained using axenically reared or streptomycin-fed beetles. The levels of ipsenol and ipsdienol in axenically reared and wild male *I. paraconfusus* were not significantly different (Table 3, experiments XIII and XVIII). However, streptomycin-feeding of male *I. paraconfusus* significantly reduced the production of these terpene alcohols (Table 3, experiments XVI and XVII), as previously shown by Byers and Wood (1981). This anomaly could indicate that the reduction in ipsenol and ipsdienol production due to streptomycin feeding may be caused by toxic effects on insect cells rather than the elimination of certain microorganisms. This hypothesis appears to be somewhat unlikely since the production of *cis*- and *trans*-verbenol and myrtenol is not affected by streptomycin-feeding. Alternatively, the conversion of myrcene to ipsenol and ipsdienol could be performed by symbiotic microorganisms that are eliminated by streptomycin feeding but not by axenic rearing. These microorganisms would have to be transovarially transmitted, obligate symbionts to avoid elimination through axenic rearing and detection during the culturing of axenically reared beetles. Some evidence for transovarial transmission of bacteria in bark beetles has previously been reported (Buchner, 1965).

Vapors vs. Feeding—"Contact" and "Frass" Pheromones. In most bark beetles, myrcene is converted to ipsdienol and ipsenol more efficiently if the exposure is through feeding, while α -pinene is converted to *cis*- and *trans*-verbenol and myrtenol more efficiently following exposure to vapors (Vité et al., 1972). Experiment XIX (Table 3) confirms that this trend is also true for *I.*

paraconfusus. When males were exposed to α -pinene and myrcene vapors simultaneously, conversion of α -pinene to *trans*- and *cis*-verbenol and myrtenol was much more efficient than conversion of myrcene to ipsenol and ipsdienol. When beetles were exposed only to myrcene vapors, slightly more ipsenol and ipsdienol were produced, but the effect was not significant. However, when beetles were exposed by feeding to the myrcene and α -pinene in ponderosa pine bolts, the conversion of myrcene to ipsenol and ipsdienol was much more efficient than with vapor exposure, while the conversion of α -pinene was significantly less efficient (Table 3, experiment XIX). As a result, experiments with *I. paraconfusus* generally used vapor exposure to study the conversion of α -pinene, and feeding to study the conversion of myrcene.

Hughes and Renwick (1977) proposed that the production of ipsenol and ipsdienol by newly emerged *I. paraconfusus* is prevented by neural inhibition that is removed by distension of the gut during natural feeding. Hughes and Renwick (1977), working with *I. paraconfusus*, and Harring (1978), working with *Pityokteines curvidens* Germ. and *Pityokteines spinidens* Reit., were able to induce the production of ipsenol and ipsdienol by distending the guts of insects with an injection of air before exposing them to myrcene vapors. This approach was criticized by Byers (1981), who suggested that the distension of the gut with air would enhance the diffusion of myrcene vapors in the gut, thus promoting pheromone synthesis artificially by increasing precursor diffusion to the site of synthesis. Our approach to this problem was to distend the guts of *I. paraconfusus* by feeding them with powdered cellulose and then expose the beetles to myrcene vapors. This treatment resulted in a 3.5-fold increase in ipsenol content and a slight increase in ipsdienol content compared to controls (Table 3, experiment XX). However, these differences were not significant due to the large numbers of zeros in the data.

D. ponderosae also convert α -pinene more efficiently through vapor exposure than through feeding (Table 1). Female beetles fed on lodgepole pine phloem produced very little *cis*- and *trans*-verbenol and myrtenol (Table 1, experiment VI), while beetles exposed to α -pinene vapors produced much larger quantities of these terpene alcohols (Table 1, experiment VI). In contrast to *I. paraconfusus*, male *D. ponderosae* exposed to myrcene vapors produced large quantities of ipsdienol, as well as (*Z*)- and (*E*)-1-myrcenol (Table 1, experiment X), while males fed on bolts of lodgepole pine did not produce these products in quantifiable amounts.

Since myrcene is generally converted more efficiently through feeding and α -pinene is converted more efficiently through vapor exposure, ipsdienol has been termed a "frass" pheromone, while *cis*- and *trans*-verbenol are termed "contact" pheromones (Vité et al., 1972). Our data, as well as those of Byers (1982) and Hughes (1974), indicate that in *Dendroctonus* species myrcene is actually oxidized much more efficiently with vapor exposure than with feeding.

This conclusion is in agreement with the hypothesis presented by Vité et al. (1972), suggesting that aggressive bark beetles, such as *D. ponderosae*, begin oxidizing monoterpenes upon initial contact with a new host, while less aggressive species, such as many *Ips* species, depend on feeding for the conversion of monoterpenes. Aggressive bark beetle species, which attack healthy, resinous trees, must use rapid aggregation in mass-attacking their hosts to overcome host tree resistance. It is therefore logical that they would depend on rapidly produced contact pheromones. Less aggressive species, which generally attack trees with weakened or nonexistent defenses, can postpone mass attack until pioneer individuals have established, through feeding and defecation, that the host phloem is of suitable quality.

CONCLUSIONS

We have found that physiological maturation is required before axenically reared bark beetles can produce terpene alcohol pheromones maximally from monoterpenes. Our data provide a rationale for the extended maturation feeding by bark beetles prior to emergence from their brood host. Premature emergence would result in an unfit beetle incapable of producing optimal amounts of pheromone.

Since the reduction in levels of microorganisms in *I. paraconfusus* through antibiotic feeding reduces the production of ipsenol and ipsdienol, while axenic rearing or antibiotic feeding of *D. ponderosae* does not reduce the production of terpene alcohols, it appears that *I. paraconfusus* is more dependent on its symbiotic microorganisms than is *D. ponderosae*. Because it is a very aggressive bark beetle, *D. ponderosae* requires a very active enzyme system to rapidly detoxify the monoterpenes encountered in the hosts, as well as to produce large quantities of aggregation pheromones rapidly in order to attract enough individuals to overcome host resistance. However, *I. paraconfusus* generally breeds in fallen or cut trees (S.L. Wood, 1982), which have reduced levels of monoterpene-rich resin. These beetles do not require as efficient an enzyme system because the host environment is less toxic than that for *D. ponderosae* and also because a less rapid and less efficient production of aggregation pheromones is adequate in overcoming host resistance. Thus *I. paraconfusus* can rely partially on microorganisms for the production of terpene alcohols, while *D. ponderosae* is apparently capable of performing this conversion without microorganisms.

Although the production of normal or elevated levels of pheromones and other terpene alcohols by axenically reared *D. ponderosae* and *I. paraconfusus* does not rule out the possibility that symbiotic microorganisms may be involved in the production of these compounds, it does indicate that readily culturable microorganisms are not required for this process. Since the reports in the lit-

erature that describe the production of coleopteran pheromones in vitro by their symbionts (Hoyt et al., 1971; Brand et al., 1975, 1976; Chararas et al., 1980) involve readily culturable microorganisms, our conclusion is that there is no direct evidence that symbiotic microorganisms are required for pheromone production in the Coleoptera, with the exception of the antibiotic feeding studies conducted here and by Byers and Wood (1981). Our data do add support to the assertion that certain microorganisms are capable of oxidizing monoterpenes, but establish that *D. ponderosae* and, to a certain extent, *I. paraconfusus* are capable of producing large quantities of terpene alcohol pheromones in the absence of readily culturable microorganisms.

In contrast to the aggregation pheromones and other terpene alcohols examined during this study, there is considerable evidence for significant microbial involvement in the production of the antiaggregation pheromone verbenone by *D. ponderosae*. This ketone was not produced in quantifiable levels by axenically reared or streptomycin fed beetles that were exposed to α -pinene as vapors or through feeding. However, significant quantities of verbenone were found in wild *D. ponderosae* that were exposed to α -pinene through feeding on bolts of lodgepole pine. This result suggests that verbenone is not formed by the beetle, but is produced from *trans*-verbenol by microorganisms in its gut. This hypothesis is supported by reports that yeasts capable of converting verbenols to verbenone have been isolated from *D. ponderosae* (Hunt and Borden, 1989) and *I. typographus* (Leufvén et al., 1984). We hypothesize that similar oxidative metabolism of terpene alcohols by microorganisms may be responsible for the significantly lower levels of these compounds in wild beetles than in microbe-reduced beetles. In this way microorganisms would regulate pheromone levels in the host insects.

Acknowledgments—We thank Dr. H.S. Whitney for helpful suggestions in the planning of the research; Dr. A. Leufvén for valuable comments on the manuscript; T.E. Guthrie, W.D. Brown, and L.J. Chong for field and laboratory assistance; and Drs. H.D. Pierce, Jr., K.N. Slessor, and G.G.S. King for assistance with the chemical analysis.

(Received May 23, 1988; accepted July 11, 1988)

Abstract—An increase in resistance to the two-spotted spider mite (TSSM), *Tetranychus urticae* Koch, is observed in field-grown strawberry plants during the period from flowering to postharvest. This seasonal phenomenon was investigated to determine the influence of the metabolic sink, that is, fruiting in the plant. Removal of flowers and fruit and partial removal of foliage did not alter the pattern of resistance of the strawberry plant to TSSM. Bioassays were conducted in concert with chemical analyses. Headspace chemicals emitted from foliage samples were entrained in air and trapped on Tenax, identified, and compared with those entrained in nitrogen and trapped. Terpenes were among the major compounds entrained in air, whereas alcohols were obtained with nitrogen. The air-entrained headspace compounds did not appear to correlate quantitatively with the development of mite resistance in the control plants or those subjected to metabolic sink (flower and fruit) removal. Evidence was obtained for the presence of heretofore unreported strawberry foliage headspace components, namely, (Z)-3-hexenyl 2-methylbutyrate, (Z)-3-hexenyl tiglate, (E)- β -ocimene, (Z)- β -ocimene, α -farnesene, and germacrene D.

Key Words—*Tetranychus urticae*, two-spotted spider mite, Acari, Tetranychidae, strawberry resistance, metabolic sink removal, volatile foliage compounds, headspace entrainment.

INTRODUCTION

Strawberry plants develop seasonally correlated resistance to the two-spotted spider mite (TSSM) *Tetranychus urticae* Koch (Shanks and Barritt, 1975; Rodriguez and Rodriguez, 1987). Plants are susceptible to mite attack in early spring, during prebloom and flowering, but become resistant after fruit harvest in June. Based on the observation that resistance to TSSM increases after fruit development and harvest, the question arose as to the possible relationship of fruit development and maturation to the phenomenon of resistance. It was postulated that the development of flowers and fruit acts as a metabolic sink that may change metabolic patterns in the leaves and thereby alter resistance of the plant to mites (Hamilton-Kemp et al., 1988). Accordingly, we decided to remove flowers, fruit, and foliage from strawberry plants to determine whether the development of resistance in plants would be affected. Previous studies were made to determine the profile of volatile compounds emitted by the foliage (during resistance development) using nitrogen as the entrainment gas (to prevent oxidation). Recently, Buttery et al. (1987) demonstrated that aerobic conditions (air entrainment) could be used to collect volatiles with good recovery of compounds representing different chemical classes. In the present studies, air-entrained volatiles were compared with those compounds entrained with nitrogen and the effect of metabolic sink removal on volatiles was examined.

METHODS AND MATERIALS

Plant Material. Redchief strawberry plants (*Fragaria ananassa* Duch.) were grown in field plots at the University of Kentucky farm in Lexington. Standard cultural practices were followed, but pesticides were not applied to the plants. Treatments were in a randomized complete block with four replicates. Plants were treated in the following ways: (A) control, normal flowering and fruiting were allowed to proceed; (B) inflorescence was removed at first bloom; (C) all fruit was removed two weeks after first bloom; (D) two thirds of the foliage (two lateral trifoliate leaflets) was removed from plants two weeks after first bloom and fruiting was permitted; (E) two thirds of the foliage was removed two weeks after first bloom and fruiting was not permitted. Fruit was harvested when ripe in treatments A and D.

Bioassay. The detached leaf disk bioassay was carried out as described previously (Hamilton-Kemp et al., 1988). Leaves were collected for bioassay on five different sampling dates in 1987: April 28, May 12, May 19, June 3, and June 17, which corresponded to flowering, fruit initiation, start of fruit harvest, completion of fruit harvest, and two weeks postharvest for control plants, respectively. Five leaflets from each of four field replicates were collected for bioassay, making a total of 20 leaflets per sampling date for each treatment. Analysis of variance and Duncan's multiple-range test were performed on the data.

Headspace Analyses. Headspace analyses were carried out using Tenax traps (Hamilton-Kemp, et al., 1988) except that harvested leaves were analyzed intact rather than being cut into segments. Air and nitrogen (both high purity, compressed) were used as entrainment gases. For comparison of volatiles entrained by air and those entrained by nitrogen, leaflets were harvested in mid-June and samples were divided into two 100-g portions and analyzed simultaneously. Comparisons of air-entrained volatiles were made at different times during the season. Plants studied included those that were allowed to develop fruit normally and those that were not allowed to fruit. Harvesting was done in late April, mid-May, and mid-June, which corresponded to the following stages of development on control plants: flowering, fruiting, and two weeks after fruit harvest. All headspace sampling experiments described above were carried out three times, except those at flowering which were done twice.

Compound Identification and Quantitation. Compounds were analyzed by GC using a 60-m \times 0.32-mm ID Carbowax 20 M column and GC-MS as described previously (Hamilton-Kemp et al., 1988). Spectra and GC retention data were compared with those of compounds obtained from commercial suppliers or from Tenax-trapped headspace samples that we prepared from previously established plant sources. (*E*)- and (*Z*)- β -Ocimene were obtained from clover foliage (Buttery et al., 1984); α -farnesene and germacrene D were obtained from ylang ylang oil (Buttery et al., 1986). (*Z*)-3-Hexenyl 2-methylbutyrate and (*Z*)-3-hexenyl tiglate were obtained from Bedoukian Inc., Danbury, Connecticut. Kovats' indices for headspace compounds were determined following the method of Perry (1981).

Following adsorption of volatiles on a Tenax trap, compounds were removed for quantitation by extraction with three 10-ml portions of hexane. The hexane extracts were combined and concentrated to approximately 1 ml in a microstill equipped with a Vigreux column. To the concentrated solution, 1.67 μ g of cumene was added as an internal standard. An aliquot of the concentrated solution was analyzed by GC, and peak areas of leaf volatiles relative to that of the internal standard were determined. Data were analyzed by analysis of variance and Duncan's multiple-range test.

RESULTS AND DISCUSSION

Metabolic Sink Removal and TSSM Resistance. Results of the bioassays carried out to determine the effect of sink removal and stress induced by defoliation on TSSM resistance of plants are presented in Table 1. Plants with flowers and fruits removed showed increased vegetative growth, which was manifested in increased size of leaflets. A steady increase in mite resistance developed in all plants and treatments until the final sampling period in mid-June, which was about two weeks after fruit harvest in control plants. The resistance was observed for both the immature forms and the adult forms of TSSM (Table 1). This pattern of resistance development is well documented (see review paper Rodriguez and Rodriguez, 1987). The present study also demonstrated that removal of metabolic sinks (flowers and fruits) did not generally alter the expression of high seasonal resistance of strawberry plants to mites.

In the studies of the effects of defoliation stress, it was expected that partial defoliation of the plants would result in a reduction of plant vigor and perhaps alter the ability of the remaining foliage to resist mite infestation. However, the

^aTreatments: A—control with normal fruiting; B—flowers removed at first bloom; C—fruit removed two weeks after B; D—defoliated $\frac{2}{3}$ at final bloom, normal fruiting; E—defoliated $\frac{2}{3}$ at final bloom, fruit removed.

^bMeans in each column followed by the same letter are not significantly different ($P > 0.05$) according to Duncan's multiple-range test.

bioassays showed that the remaining foliage on both treatments developed resistance to mites (Table 1).

Hence, the treatments selected to remove the metabolic sink and prevent normal ontogeny of fruit and to induce physiological stress through defoliation of strawberry plants did not markedly change the general seasonal resistance trends observed in previous studies. The bioassay results show that all plants tested became resistant to TSSM over the period from flowering in early spring to after fruit harvest in mid-June.

Air vs. Nitrogen Headspace Entrainment and New Compounds. Air was used as entrainment gas in the present experiments and compared to nitrogen entrainment of strawberry volatiles used previously (Hamilton-Kemp et al., 1988). Qualitative and quantitative analytical differences were obtained with the two gases (Table 2). Notably, there were more types, and larger quantities,

of alcohols and their esters obtained in a nitrogen than in an air atmosphere. The formation of volatile alcohols may have been due to higher activities of alcohol dehydrogenase enzymes, which have been found under anaerobic conditions in various plant species (Davies, 1980). These enzymes may effectively reduce aldehydes to their corresponding alcohols. Phenolic salicylates also were found in nitrogen-entrained isolates; they increased after fruit harvest (Hamilton-Kemp et al., 1988), which may indicate a generally increased potential for formation of phenolic compounds in late-season plants. Nonvolatile phenolic compounds have been associated with plant resistance to certain insects, as discussed elsewhere (Feeny, 1976; Stipanovic, 1983).

During air entrainment, terpene hydrocarbons were emitted, and these comprised a major part of the volatiles found. Mass spectral and chromatographic evidence was obtained for *E* and *Z* isomers of β -ocimene and the sesquiterpene hydrocarbons α -farnesene and germacrene D (Tables 2 and 3). Another major sesquiterpene was isolated that could not be identified from available spectra. The fact that these compounds were found in higher levels in air may indicate that they turn over rapidly and/or are not generated effectively in nitrogen.

In addition to the terpene hydrocarbons, the results from interpretation of mass spectra and subsequent comparison with authentic compounds provided evidence for infrequently reported esters of leaf alcohol [(*Z*)-3-hexen-1-ol], namely (*Z*)-3-hexenyl 2-methylbutyrate and (*Z*)-3-hexenyl tiglate. These compounds probably form from the high available levels of leaf alcohol that can be esterified with an assortment of acids that occur free in the strawberry plant.

Air-Entrained Volatiles and Metabolic Sink Removal. Greater quantities of compounds were emitted from young actively growing plants in late April dur-

ing flowering than from plants analyzed at other times (Table 4). Furthermore, several compounds present during this period were not detected or were present only in trace amounts at later sampling times. There were numerous, primarily small, peaks in the samples, which were not identified, even though the major components entrained by air were identified.

Generally, there were no statistically significant differences between the volatiles in control and deflowered plants. Thus, the removal of the metabolic sink did not markedly affect emissions of foliage headspace compounds. There did not appear to be consistent changes in air-entrained volatiles from control or deflowered plants, which corresponded with the steady increase in plant resistance to mites that was observed.

Clearly, there was considerable variation in the quantitative data obtained and used in comparisons. This may have been partially due to the small quantities of compounds emitted by the plant samples. Other investigators also have noted considerable variation in quantities of volatiles obtained from one sampling to another (Buttery et al., 1987). We observed in one case that there was a decrease in overall yield of volatiles obtained from strawberry foliage within 12 hr following heavy rainfall on field-grown plants. The precipitation may

have washed volatiles from the foliage or prevented movement of volatiles from the sources of emission on the tissue.

From the present research using air entrainment of volatiles, there did not appear to be direct correlations with the strawberry volatile composition and development of resistance to TSSM. The appearance and increase in salicylates during the growing season seen in the earlier studies (Hamilton-Kemp et al., 1988) using nitrogen may have been an effect caused by the anerobic nitrogen atmosphere. However, the increase in salicylates over the growing season may indicate an increased potential for phenolic compound synthesis as the plants aged during the season (as discussed earlier).

In summary, the experimental results showed that foliage resistance to immature and adult forms of TSSM continued to develop even though the metabolic sinks, namely flowers and fruits, were removed and plants were subjected to partial defoliation. It was evident that the factors that caused the expression of resistance were not tied to the normal ontogeny of fruiting and were not modified by physiological stresses associated with defoliation. One environmental factor that may be pertinent for future study is day length, as photoperiod occurring in the field over the fruiting season could initiate the development of plant resistance to TSSM. Past preliminary experiments indicated that the development of resistance in greenhouse-grown plants (in contrast to field-grown plants) did not occur in a predictable pattern, and this observation may be consistent with lack of control of day length. It also was clear from strawberry foliage analyses that the patterns of volatiles obtained in air were different from those obtained in nitrogen. Metabolic sink removal did not significantly change volatile emissions from the foliage. Although these compound types have been postulated to be factors in the interaction of plants with certain insects (cf. Siegler, 1983; Finch, 1986), there does not seem to be a correlation between volatiles entrained by air and the development of strawberry resistance to mites. Foliage volatiles may play a role in strawberry interactions with other insects and pathogens as has been observed in other plant species.

BIOLOGICAL ACTIVITY OF SYNTHETIC
HYDROCARBON MIXTURES OF
CUTICULAR COMPONENTS OF
THE FEMALE HOUSEFLY
(*Musca domestica* L.)

(Received February 23, 1988; accepted July 15, 1988)

Abstract—Mixtures of (*Z*)-9-alkenes (C₂₁–C₃₃), *n*-alkanes (C₂₁–C₃₃), and mono- and dimethylalkanes (C₂₇, C₂₉), as components of the cuticular lipids washed from the female housefly (*Musca domestica* L.), were synthesized and assayed for their biological activity on male houseflies. The (*Z*)-9-alkenes and their hydrogenated *n*-alkanes were synthesized from jojoba wax components by the appropriate chain elongation. The methylalkanes were prepared by Grignard coupling reaction of the appropriate alkyl halides, catalyzed by Li₂CuCl₄. Six- to 7-day-old virgin male houseflies exhibited the highest mating strike activity toward 6- to 7-day-old virgin females. The mating strike activity of the synthetic hydrocarbons was studied by exposing 6- to 7-day old virgin males to petrol-ether-rinsed 1 to 2-day-old dead females treated with these chemicals. (*Z*)-9-Tricosene was the most active hydrocarbon tested when it was applied in amounts of 10 μg to a washed dead female. Amounts of 5 μg of (*Z*)-9-tricosene did not cause sexual activity in the males. Mixture of (*Z*)-9-alkenes showed low activity when applied at 10-μg amounts. However, when mixtures were made of 5 μg of (*Z*)-9-tricosene with 5 μg of each of certain mixtures of (*Z*)-9-alkenes, the striking activity became as high as that of 10 μg of (*Z*)-9-tricosene. This might be a synergism effect. The mixtures of *n*-alkanes, as well as the mono- and dimethylalkanes, showed moderate activity. When (*Z*)-9-tricosene was added to these materials no increase in male activity was observed.

Key Words—Housefly, *Musca domestica*, Diptera, Muscidae, sex pheromone, (*Z*)-9-tricosene, (*Z*)-9-alkenes, *n*-alkanes, monomethylalkanes, dimethylalkanes, jojoba wax.

INTRODUCTION

(*Z*)-9-Tricosene, also known as muscalure, is the main active component of the sex pheromone of the female housefly (*Musca domestica* L.) (Carlson et al., 1971). It has been demonstrated, however, that the total wash of the cuticular surface from the female (but not from the male) is 7–10 times more active towards the male than is (*Z*)-9-tricosene alone, and the hydrocarbon fraction is four to nine times more active than muscalure (Uebel et al., 1976). These findings are in contrast to previous work by Rogoff et al. (1973), who could not find higher activity of female homogenate as compared to (*Z*)-9-tricosene.

Uebel et al. (1976) showed that the cuticular hydrocarbons are composed of several groups of compounds. Further work by Nelson et al. (1981) revealed the complexity of the cuticular hydrocarbons washed from both females and males; three major groups of long-chain hydrocarbons were present: (1) (*Z*)-9-alkenes, (2) *n*-alkanes, and (3) mono- and dimethylalkanes.

Comparison between female and male 4-day-old flies showed that most of the components appear in both sexes, but in different ratios (Table 1). The (*Z*)-9-alkenes are minor components in the female but major ones in the male; (*Z*)-9-tricosene constitutes only 4.3% of the total mixture in the female [ca. 30% of the (*Z*)-9-alkenes] and is completely missing in male washings (Table 2). Silhacek et al. (1972b) showed that while there is no change in the contents of cuticular hydrocarbons in the male, the amounts of C₂₃ and C₂₉ hydrocarbons in the female increase at the expense of (*Z*)-9-heptacosene during the posteclosion period and before mating. Dillwith et al. (1983) showed that (*Z*)-9-tricosene is biosynthesized up to the age of 6 days (by which time the female ovaries have matured) mainly at the expense of (*Z*)-9-heptacosene and to some degree of (*Z*)-9-nonacosene.

Studies on the activity of different groups of synthetic chemicals have been conducted previously. A 7:3 mixture of (*Z*)-9-tricosene and (*Z*)-9-heneicosene

was claimed to cause higher biological activity than did pure (Z)-9-tricosene (Mansingh et al., 1972), although this is unconfirmed (Carlson et al., 1974; Richter, 1974; Richter et al., 1976). Both lower and higher homologs (C₁₉-C₂₉) as well as different isomers, as single components, showed lower and higher activity (Carlson et al., 1971, 1974; Mansingh et al., 1972; Rogoff et al., 1973; Uebel et al., 1976). Mixtures of (Z)-9-alkenes (C₁₈-C₂₅) also showed some activity (Richter et al., 1976). Preliminary studies on mixtures of (Z)-9-alkenes, prepared from jojoba wax (Shani, 1979), showed activity comparable to muscalure (Carlson, personal communication). Mixtures of *n*-alkanes did not show any enhanced activity even when added to (Z)-9-tricosene (Silhacek et al., 1972a; Uebel et al., 1976). Several mono- and dimethylalkanes were also found to be active (Uebel et al., 1976; Rogoff et al., 1980; Adams and Holt, 1987). Two oxygenated products [(Z)-9,10-epoxytricosene and (Z)-14-tricosene-10-one] were claimed to be active (Uebel et al., 1978), but it was later shown that these chemicals were not active in odor tests (Adams et al., 1984). In a recent paper it was reported that the nonhydrocarbon fraction increased copulatory attempts, but not mating strikes (Adams and Holt, 1987).

The biological importance of the various components of the female cuticular hydrocarbons is not fully known, and it would be tedious to evaluate each component singly for its activity. In addition, the mixture of components, and not a single component, is often the active substance. Synergism effect could be another factor in the activity of mixtures. We thus sought a readily available

source that could supply several components in one preparation in order to study the activity of such mixtures. The source is found in jojoba wax. Based on these considerations and early encouraging results from jojoba wax preparations (see above), we widened our studies.

We report here on the synthesis of (*Z*)-9-alkenes and their hydrogenated *n*-alkanes from jojoba wax (I) (composition, Table 3), i.e., two groups of the chemicals typically found in cuticular washings, and of two methylalkanes and two dimethylalkanes. We then studied the biological activity of all the above-mentioned mixtures.

METHODS AND MATERIALS

The synthesis of the (*Z*)-9-alkenes from jojoba wax followed our previously published procedure (Shani, 1979). The fractions collected in the distillation step were distilled in a wide range of temperatures in order to keep the

Hydrogenation of the (Z)-9-alkenes (0.25-0.45 g) (II-XIII) in 30 ml ethanol and 3 ml petroleum ether together with 10-20 mg of 5% Pd/C was conducted at atmospheric pressure to yield 90-96% of saturated hydrocarbons (XIV-XXII). All NMR spectra showed two peaks at δ 0.75-0.85 and 1.1-1.3.

The mono- and dimethylalkanes synthesis followed the same procedure as for the elongation of jojoba derivatives (Shani, 1979).

GLC analyses were performed with a Packard model 417 chromatograph

on a 2-m × 2-mm ID glass column, 10% SP 2300 on acid-washed Chromosorb W at 190°C. GC-MS measurements were performed on a Varian MAT-112 instrument.

Insects. The houseflies were collected during the summer of 1984 from a cowshed at Kibbutz Hatzerim (near Beer-Sheva). They were reared in the laboratory in net cages 20 × 20 × 30 cm and supplied with water and a sugar solution on cotton wool. The temperature was 27 ± 1°C, the relative humidity 70–80%, and the photophase–scotophase was 14:10 light–dark. On the fifth day, the water was replaced by milk on cotton wool where the females later laid their eggs. Each day the cotton wool was replaced, and the “old” cotton wool was placed in a bowl of milk powder with wheat bran in which the larvae were reared. Within an hour after emerging, adult flies were cooled to 5°C and then sexed. Males and females were kept separately in 1-liter beakers (70–100 flies each) containing sugar and water and covered with filter paper.

Bioassay. On the day the flies were tested, the males were anesthetized with diethyl ether and put in fresh plastic Petri dishes (9 cm in diameter). Five males were placed in each dish, and 10 dishes were assayed or tested in each experiment (total of 50 males). Each dish was covered with a plastic cover

having a hole in its center through which the female model treated with the test chemical was introduced into the dish. The hole was then plugged with cotton wool. The males recovered from anesthesia within an hour, after which the experiment commenced. The female models (1–2 days old), previously frozen at -5°C , were then washed with petroleum ether, air dried in the sun for 5 min, and finally treated with the test chemicals. The test chemicals, prepared in petroleum ether solution, were applied to the back of the female and left there for 10–15 min so that the solvent could evaporate. One treated dead female was then introduced to each dish. The test, which was then started immediately, consisted of counting the number of mating strikes for 15 min (with the exception of the preliminary study designed to evaluate the proper age of the males and females, which lasted for 30 min). The mating strike behavior was taken to step 4 in the following sequence of male behavior towards live or dead unwashed female houseflies or towards dead washed flies treated with the chemicals to be tested: (1) apathy—completely ignoring the female; (2) low frequency of approaching the female—standing next to her for a few seconds only; (3) excited jumping next to the female; (4) Climbing on the female's back and initiating courtship; and (5) approaching the female for a second and immediately running away, followed 5 min later by jumping, running, and erratic behavior (this occurred when too high concentrations of certain chemicals were tested).

Before each experiment, the activity of a sample of virgin males (6 to 7 days old) was checked with dead unwashed females (6 to 7 days old). Only a population found to be active was used in the experiments. If the tested males did not show any activity towards the test materials, then the washing from the female was reapplied to her to verify its activity. These double checks proved both that the males were sexually active and that the tested chemicals caused either little or no activity.

For each experiment, fresh males and females were used in new Petri dishes. All the tests were run between 9 AM and 1 PM. In some cases the males became "contaminated" with the tested chemicals and sometimes homosexual activity was observed. Only experiments in which the homosexual activity was nil or very low are reported here.

RESULTS AND DISCUSSION

We have already shown that jojoba wax (I) is a suitable source of long-chain (*Z*)-9-alkenes (Shani, 1979), since it is a mixture of long-chain esters (Miwa, 1971; Graille et al., 1986) composed mainly of C_{18} – C_{24} acids and alcohols having a *Z* double bond in the appropriate position. The synthesis is based on elongation of the corresponding jojoba components by short alkyl chains (C_3 – C_9), as described in Scheme 1. Because of the difference in com-

SCHEME 1.

position of the esters, as shown in Table 3, three different mixtures are obtained by reduction or hydrolysis (as shown in Scheme 1) from one elongation procedure and a total of 12 mixtures by applying four different alkyl chains. After purification and distillation, the relative compositions of the fractions that were later studied were measured on a GLC (Tables 4-6). These fractions were later hydrogenated to the *n*-alkanes, thus having the same composition of the olefin mixtures.

The NMR spectra showed no olefinic hydrogens in the hydrogenated products.

The mono- and dimethylalkanes were synthesized by Li_2CuCl_4 -catalyzed coupling of a Grignard reagent with the appropriate alkyl halide (Tamura and Kochi, 1974), as described in Scheme 2.

The first step in the bioassay was to determine the most active age of virgin males toward virgin females. The results are summarized in Table 7 and in Figures 1 and 2, where the curves represent a specific age (in days) of females and males, respectively. It is clear that between the ages of 5 and 8 days, the virgin males are active towards 5- to 8-day-old virgin females (killed immediately before the experiment). This finding is not in agreement with that of Silhacek et al. (1972b), who claimed that maximum male activity towards female washings was at the age of 2 days. Mansingh et al. (1972) and Adams et al. (1984) found the age of 3 days suitable for these experiments. Richter et al.

(1976) studied the activity of 5- to 10-day-old males. The maximum amount of (*Z*)-9-tricosene on the female was obtained at the age of 6 days (starting at the age of 4 days) according to Dillwith et al. (1983). Rogoff et al. (1973) found high pheromone production during the age period of 4–8 days; Adams et al. (1984) studied the activity from day 1 until day 7; and Adler et al. (1984) measured the cuticular lipids of the female at the age of 10 days. The thorough study of Nelson et al. (1981) was performed on 4-day-old males and females. As our findings cover broad age ranges for both males and females, we may conclude that the best age for study of both sexual activity of males and sex pheromone composition of females is 6–7 days, i.e., the age selected for our studies. On the other hand, because no activity was found towards 1- to 2-day-old females, we selected these young females as the carriers for the chemicals to be tested, after washing them with petroleum ether.

An additional reason for selecting females as models and not applying the pseudofly test (knots) stemmed from the possible effect of vision on the sexual behavior of the males (Richter et al., 1976). After completion of our studies, we found that Adams and Holt (1987), in their very recent study, could detect a lower degree of reaction of males, as compared with females, towards knots in most experiments. No significant difference was detected between the reaction of males toward male and female models and towards 3-day-old female controls.

Each experiment was preceded by confirming the sexual activity of a male sample of a population towards a freshly killed female and ensuring that, after washing the female with petroleum ether, the typical activity of the male disappeared. Reapplication of this washing to the female's back stimulated resumption of the activity of the males.

The next step was to determine the optimum amount of the chemicals to be tested. There are conflicting reports on the quantity needed per housefly. Silhacek et al. (1972a), Carlson et al. (1974), and Morgan et al. (1974) applied milligram amounts of tricosene and other components, while Rogoff et al. (1980), Nelson et al. (1981), Dillwith et al. (1983), and Adams and Holt (1987) found and/or applied microgram quantities. Uebel et al. (1976, 1978) and Richter et al. (1976) applied 100–200 μg of the tested chemicals, while Adler et al. (1984) found only nanogram quantities of tricosene per female. It is possible that this small amount was a function of the very late age (10 days) of the flies tested (see above). Increasing the amount of applied tricosene from 1 to 100 μg per female showed that the maximum activity of males occurred at 10–25 μg of (*Z*)-9-tricosene, while at 1–5 μg no activity was found, and at 50–100 μg the males behaved erratically (level 5 of our grading, see Methods and Materials). Therefore, we measured the activity with 10–25 μg of tested materials and compared it to that obtained with 10 μg of tricosene. These quantities are in the range of the physiological composition as discussed recently by Adams

and Holt (1987). They applied 4 μ g of tricosene, which was found to be about 4.3% of the total wash and about 30% of the (Z)-9-alkenes fraction (see Tables 1 and 2); thus 10 μ g of our (Z)-9-alkenes (Table 8) and 5 μ g of the (Z)-9-alkenes-tricosene mixtures (Table 9) are consistent with the quantities used by Adams and Holt (1987). However, since Adams and Holt applied 7 μ g of the methylalkane fraction (about 36% of total wash, Table 1), it could be that the amounts of 10–15 μ g each of our single components are too high (see below).

^aThe mean numbers are given per dish (five males) for a 15-min test period. Those means followed by the same letter are not significantly different from each other at $P = 0.05$ (Student's t test).

We found that 10 μg of tricosene caused high activity of the males, up to 6.9 ± 1.3 mating strikes per dish of five males for 15 min. Qualitative comparison (Table 7 and Figures 1 and 2) between the behavior of the males toward dead unwashed females (which showed 12.6 ± 1.74 mating strikes per dish of five males for 30 min) and toward tricosene clearly demonstrates that this component of the (*Z*)-9-alkene fraction is the main component responsible for mating striking activity. Other components are probably involved in the complete sequence (Adams and Holt, 1987).

The tested chemicals were divided into three groups according to the main categories of hydrocarbons found on the housefly cuticle. The synthetic (*Z*)-9-alkenes mixtures tested represent 10 different compositions (out of the possible 12), and their effect on the sexual activity of the male is summarized in Table 8. Except for mixture II, all showed low activity as compared with tricosene. Comparison of the relative composition of (*Z*)-9-alkenes (Table 2) and the composition of the synthetic alkenes (Tables 4–6) shows that none match exactly. However, when mixtures of some of these synthetic chemicals with tricosene were applied, a significant increase in activity was found (Table 9). Still, some inconsistency was observed in that similar compositions did not always cause the same activity (entries 1 and 4 or 2 and 7 in Table 9). It could be that the minor components, which were not taken into account here, are partly responsible for the different activities of the various mixtures. On the other hand, mixtures that are different in composition (Table 9, entries 4 and 6 or 5 and 6) caused similar activity in males. These results do not point to a simple answer with regard to the effect of (*Z*)-9-alkenes on the male mating strike activity caused by tricosene. One possible explanation for these and previous inconsistent results could be a synergism effect of certain (*Z*)-9-alkenes in the synthetic mixtures, which resemble or even are identical to the natural cuticular hydrocarbons washed from the female.

The effect of *n*-alkanes on males was studied by Silhacek et al. (1972a), who found that a mixture of 10 mg of even-numbered chains from C_{20} to C_{36} showed low activity and a mixture of C_{25} – C_{30} was inactive. Uebel et al. (1976) found that the saturated hydrocarbons alone, separated from the female cuticular washing, showed no activity, but a mixture of 65% of saturated and 35% of unsaturated hydrocarbon fractions was 8–10 times more active than muscalure. They also found that when a mixture of tricosene and saturated C_{27} , C_{28} , C_{29} , and C_{30} straight chains was studied, no increase in mating strike was found as compared with tricosene. Our results show that the low to medium activity (1.4–4.5 mating strikes per dish, five males), as compared with tricosene (6.9 mating strikes per dish), fluctuated when the *n*-alkanes were studied alone or as mixtures with tricosene. In this case we could not see the enhancing effect of tricosene as appeared with the (*Z*)-9-alkenes (see above). These findings are in accordance with those of Uebel et al. (1976). It is interesting to note that

50% of the female cuticular hydrocarbons (see Table 1) are *n*-alkanes. It is likely that the hydrocarbons serve as the "solvent" in which the active components are retained to lengthen their active period.

The methylalkanes comprise a rich mixture of mono- and dimethylalkanes, substituting many sites along the chains and also differing in length (Nelson et al., 1981). Their content is more than a third of the female cuticular hydrocarbons (Table 1), but the amount of each component is probably very small. The major groups are derived from C₂₇, C₂₉, and C₃₁ (8.7, 17.4 and 5.7%, respectively). Therefore, any selection of specific methylalkanes to be tested for biological activity is arbitrary. In spite of this, Uebel et al. (1976) and Rogoff et al. (1980) could show enhanced activity caused by several methylalkanes, such as 11-methylheptacosane, 13-methylheptacosane, 11-methylnonacosane, 13-methylnonacosane and 4,8-dimethylheptacosane, when mixed with tricosene, although the individual methylalkanes were significantly less active than tricosene. We prepared 11-methylnonacosane (XXIII), 5-methylheptacosane (XXIV), 7,11-dimethylheptacosane (XXV), and 5,9-dimethylheptacosane (XXVI). These components are present in the larger fractions of the methylalkanes (Nelson et al., 1981). The intermediate activity of these compounds (2.9–3.6 average number of mating strikes per dish, five males) is slightly increased when applied as a mixture with tricosene but is not significantly different from their activity as single components. We used ratios of 2:1 methylalkane-tricosene; in the case of 11-methylnonacosane (XXIII), however, increasing the ratio of XXIII slightly enhanced the activity from 2.4 to 3.3 mating strikes per dish. As mentioned above, it could be that the amounts we applied were too high with regard to physiological quantities, as determined in another strain (Adams and Holt, 1987). As long as there is no quantitative information on the methylalkane fraction of the cuticle, studies on the individual components are less likely to succeed.

The results of our study confirm that (*Z*)-9-tricosene is the main active component of the sex pheromone produced by the female housefly, which initiates mating strike activity in the male. The (*Z*)-9-alkenes associated in the cuticular lipids probably act as synergists to muscalure. Both *n*-alkanes and methylalkanes, comprising 86% of total cuticular female hydrocarbons, show low to medium activity, although the addition of (*Z*)-9-tricosene does not enhance it. This leaves open the question whether these components have any biological importance in the sex pheromone activity of the housefly. They probably serve as the matrix from which the sex pheromone [(*Z*)-9-tricosene and the oxygenated components] is slowly released and kept from chemical degradation. Minor synergism activity could be attributed to some methylalkanes.

Acknowledgments—We thank Mr. H. Oren for assistance in rearing the houseflies and Prof. Y. Schlein for valuable suggestions about the entomological aspects of the study.

Abstract—2-Acylcyclohexane-1,3-diones produced in the mandibular glands of *Ephestia kuehniella* Zeller (Lepidoptera: Pyralidae) fifth instars acted as arrestment and host-trail following kairomones for the parasitoid, *Bracon hebetor* (Say) (Hymenoptera: Braconidae). The behavioral response of the parasitoids to the kairomone varied with kairomone concentration and distribution. However, only small differences in activity were noted for the different mandibular gland components. *B. hebetor* females that encountered filter paper patches impregnated with the kairomone exhibited antennation and probing behavior. Females followed trails formed with 2-[(Z,E)-12,14-hexadecadienoyl]cyclohexane-1,3-dione in the same manner exhibited with host-made trails. At concentrations of 1.0 $\mu\text{g}/\text{mm}$ and above, trail following was interrupted by frequent probing.

Key Words—*Bracon*, *Ephestia*, Lepidoptera, Pyralidae, Hymenoptera, Braconidae, kairomone, host selection, parasitoid, foraging, ketones, 2-acylcyclohexane-1,3-diones.

INTRODUCTION

Bracon hebetor (Say) is a gregarious larval ectoparasitoid of stored-product moths in the family Pyralidae (Ulyett, 1945; Hagstrum and Smittle, 1978; Krombein *et al.*, 1979). Host larvae from genera such as *Plodia* and *Ephestia* live gregariously in stored grains, cereals, nuts, and dried fruit, often building to very high densities in warehouses. *B. hebetor* prefers late-instar hosts after they move to the surface to wander in search of a pupation site (Benson, 1973). Murr (1930) was the first to present evidence that *B. hebetor* females are arrested by and search the substrate contacted by hosts. Once located, the female injects a small quantity of venom into the host which induces complete paralysis in 15 min (Piek *et al.*, 1978). After paralysis, females mount and externally examine the host. If the host is found to be acceptable, the female oviposits, usually placing the clutch of eggs on the side of the host in contact with the substrate.

The presence of host kairomones along with the high reproductive rate and short generation time of *B. hebetor* offer opportunities for manipulating this parasitoid in the management of stored-product larvae (Hagstrum and Smittle, 1978). Here we report the source and identification of arrestment and trail following kairomones for *B. hebetor* produced by *Ephestia kuehniella* Zeller fifth instars.

METHODS AND MATERIALS

E. kuehniella larvae were reared on cornmeal in 2 liter plastic containers maintained at 27°C, 70% relative humidity, and a 16:8 light-dark photoperiod. *B. hebetor* adults were maintained in 50-ml glass culture tubes and fed a 50% honey solution daily. Hosts used in culture maintenance were parasitized in 100 × 15-mm Petri dishes. Both the *E. kuehniella* and *B. hebetor* cultures had been maintained in the laboratory for approximately three years. Parasitized hosts were held at 27°C, 70% relative humidity, and a 16:8 light-dark photoperiod. Parasitoid development from egg to adult emergence took ca. 13 days.

All parasitoids used in the study were 6–7 days old and were exposed to hosts two days prior to use in an experiment. No parasitoid was used more than once during the study. Bioassays were conducted in 100 × 15-mm Petri dishes lined with Whatman No. 1 filter paper. A 1-cm circle was drawn with a pencil in the middle of the filter paper to which materials for bioassay were applied. The area within the 1-cm circle is hereafter referred to as a patch. No more than two females were exposed to any patch. All experiments were conducted during daylight hours at 25°C and ca. 40% relative humidity.

In previous studies it was found that several stored-product pyralid larvae secrete material from their mandibular glands while feeding and moving (Cor-

bet, 1971; Mudd and Corbet, 1973, 1982; Mossadegh, 1978; Mudd, 1983). Thus, we initially examined the behavioral response of *B. hebetor* females to an ether extract of the mandibular glands from two *E. kuehniella* fifth instars. The two glands from each larva were removed with forceps under Ringer's saline, and placed in 200 μ l of ether. The extract was then uniformly applied to the 1-cm patch of the Petri dish bioassay chamber. Patches with only ether applied served as negative controls. After evaporation of the ether, *B. hebetor* females were introduced individually into the Petri dish and observed. A positive control consisted of restricting four *E. kuehniella* fifth instars for 5 hr to a patch by a 1-cm circular plastic lid. The larvae and any frass pellets were removed from the patch before individually introducing females for observation.

The response of *B. hebetor* females to these treatments was based upon the number of wasps that positively responded to the patch and the duration of the patch visit. A positive response was characterized by antennation of the substrate, a reduced walking speed, and probing with the ovipositor. A patch visit was designated as beginning when a female first entered the patch and ending when a female left the patch for more than 30 sec. The 30-sec value for having left a patch was adopted because, on occasion, a female would walk beyond the patch border only to return quickly and resume searching. Although arbitrary, the 30-sec value was a reliable indicator of a patch visit. Any time spent outside of the patch border was not included in the time recorded for a patch visit. *B. hebetor* walking speed outside of and within the patch was estimated by measuring the distance traveled by 20 females in the last 5 sec before encountering the patch and the first 5 sec after entering the patch. The distances traveled during these periods were recorded by tracing the wasp's path on the cover of the Petri dish bioassay chamber with a felt pen. Such tracing did not appear to disturb the parasitoids. The distance traveled was calculated using a map measurer.

The response of *B. hebetor* to the previously isolated and characterized 2-acylcyclohexane-1,3-diones and 4-hydroxylated compounds from *E. kuehniella* mandibular glands (Mudd, 1983; Mudd *et al.*, 1984) (Figure 1) was then examined. The compounds listed in Figure 1 were obtained by the methods outlined by Mudd (1983). Fractions IA and IB chromatographed as single components (Mudd *et al.*, 1984) and were tested as such. Doses of 0.01, 0.1, 1.0, and 10.0 μ g in ether were applied uniformly to the 1-cm patch as described previously. After evaporation of the ether, *B. hebetor* females were individually introduced into the Petri dish where the response to and duration of the patch visit was recorded. As with testing of the mandibular gland extracts, a positive response was characterized by a reduced walking speed, antennation, and probing of the substrate.

Testing of trail-following activity by *B. hebetor* was performed by uni-

FIG. 1. Compounds identified from mandibular gland secretions of *E. kuehniella* that were tested with *B. hebetor*. Components 1-14 are listed with the appropriate side chain, and the unseparated components 2-4 and 9-11 designated as fractions IA and IB, respectively.

formly applying an ether solution of component 1 (see Figure 1) in a 3-cm-diameter circle on Whatman No. 1 filter paper with a syringe at 0.01, 0.1, and 1.0 $\mu\text{g}/\text{mm}$. A negative control consisted of an ether-only trail, and a positive control consisted of allowing two wandering stage *E. kuehniella* fifth instars to crawl for two rotations around the inside wall of a 3-cm Petri dish lid. After evaporation of the ether or removal of the *E. kuehniella* larvae, *B. hebetor* females were introduced individually into the Petri dish and observed. A positive response was recorded if, upon contact with the trail, females followed the compound or host track for a minimum of one rotation. Females were removed from the assay chamber after departing from the trail or if one rotation was completed.

RESULTS

All *B. hebetor* females responded to patches with *E. kuehniella* mandibular gland extract or on which *E. kuehniella* fifth instars had crawled, but no females responded to the ether control (Table 1). Before encountering the patch, *B. hebetor* females generally walked in a straight path across the Petri dish floor. Movement immediately prior to and directly after a patch encounter showed no directed movement toward the patch. However, when the edge of a mandibular gland extract or host-contaminated patch was encountered, females began to antennate the patch edge.

After entering the patch, the movement of females was characterized as a combination of orthokinetic movement within the patch combined with a klinotactic response to the patch border. While searching within the patch, females reduced their walking speed as they antennated, probed, and turned. Outside of the patch mean walking speed was 1.38 cm/5 sec \pm 0.59 SD ($N = 20$), while

TABLE 1. PERCENTAGE OF *B. hebetor* FEMALES RESPONDING TO AND MEAN TIME SPENT IN PATCHES MADE BY *E. kuehniella* FIFTH INSTARS AND MANDIBULAR GLAND EXTRACT

Patch type	Females tested (N)	Positive response (%) ^a	Mean patch duration (sec \pm SE) ^b

Ether (control)	25	0	1.4 \pm 0.2†

^aResponse was characterized by a female exhibiting arrestment, antennation, and probing behavior (see Methods and Materials).

^b $F(2, 115) = 48.6, P < 0.0001$; means followed by the same symbol are not significantly different (SNK multiple comparison procedure, $\alpha = 0.01$).

within the patch mean walking speed was $0.37 \text{ cm/5 sec} \pm 0.24 \text{ SD}$ ($N = 20$). When females encountered the patch border, they usually turned sharply back toward the patch while continuing to antennate. Mean examination time for females in patches treated with mandibular gland extract or on which host larvae had crawled were similar, but females spent very little time in patches treated with ether only (Table 1).

The amounts of time *B. hebetor* spent in patches treated with increasing concentrations of the isolated 2-acylcyclohexane-1,3-diones, 4-hydroxy compounds, and ether control are presented in Table 2. At concentrations of 0.01 and 0.1 μg of material per patch, there was a tendency for females to spend more time in patches treated with components 1 and 8. However, at higher concentrations females responded similarly to all the components. There was usually little response to patches treated with 0.01 μg of the isolated mandibular gland components. The only exception to this was a slight antennation response to components 1 and 8. Females continuously antennated patches treated with 0.1 μg of all the components and probed patches treated with components 1 and 8. Females were arrested, antennated, and probed patches treated with 1 or 10 μg of all the components. At these higher concentrations, it was common for females to spend 5–10 min antennating and probing the substrate before leaving the patch (Table 2).

B. hebetor females followed trails made by application of component 1 or by *E. kuehniella* fifth instars but did not follow trails of ether only (Figure 2). The percentage of females that followed trails of component 1 for at least one

^aSee Figure 1. Twenty females were tested for each component concentration.

FIG. 2. Percent response of *B. hebetor* females that successfully followed for at least one rotation a circular trail made by component 1 (see Figure 1), *E. kuehniella* fifth instars, and ether.

rotation increased with kairomone concentration. Although most females partially followed trails of component 1 at a concentration of 0.1 and 0.01 $\mu\text{g}/\text{mm}$, less than half the females tested followed trails for one rotation. However, at a concentration of 1 or 10 $\mu\text{g}/\text{mm}$, the percentage of responding females did not differ from the percentage of females that responded to trails made by *E. kuehniella* larvae ($\chi^2 = 2.1$; $df = 4$; $P > 0.25$). When encountering a trail made by component 1 or by host larvae, females were initially arrested but then quickly turned in the direction of the trail and began following. Females antennated the trail continuously while following and often probed the trail at concentrations of 1.0 and 10 $\mu\text{g}/\text{mm}$. While trail following, females characteristically walked a zigzag route in which each antenna moved alternately across the trail.

DISCUSSION

In this study, we find that the 2-acylcyclohexane-1,3-diones and 4-hydroxylated compounds produced by the mandibular glands of *E. kuehniella* fifth instars act as kairomones for the larval ectoparasitoid *B. hebetor*. These compounds elicit an arrestment, antennation, and probing response when present in a patch, and a trail following response when deposited linearly. The behavioral responses observed for the isolated mandibular gland components are similar to those observed for *B. hebetor* encountering patches upon which *E. kuehniella* fifth instars had crawled or the trails they deposit while wandering in search of a pupation site (Murr, 1930; Mossadegh, 1978).

Previous study found that the same mandibular gland compounds active for *B. hebetor* elicited antennation and ovipositor thrusting behavior by the endoparasitoid *Venturia* (= *Nemeritis*) *canescens* Grav. (Mudd and Corbet, 1982; Mudd *et al.*, 1984). These compounds are also reported to serve as an

epideictic pheromone for *E. kuehniella* (Corbet, 1971). Documented examples of compounds produced from the same host having kairomonal activity for more than one parasitoid species are still not common (Kennedy, 1979; Aldrich *et al.*, 1984; Dicke *et al.*, 1984; Nordlund *et al.*, 1987). However, with host species or particular host stages often supporting multiple parasitoid species, such situations might be more common than the literature currently suggests. In addition, the hosts of generalist parasitoids may share common kairomones. *B. hebetor* and *V. canescens* both parasitize the larvae of several stored-product pyralids (Ulyett, 1945; Benson, 1973; Salt, 1976; Hagstrum and Smittle, 1978), many of which are known to produce mandibular gland secretions (Mudd and Corbet, 1973; Mossadegh, 1978). Preliminary characterization of *Ephestia cautella* mandibular gland secretions has demonstrated the presence of 2-acylcyclohexane-1,3-diones similar to those already characterized for *E. kuehniella* (Strand and Williams, unpublished results). These compounds also elicit a strong behavioral response in *B. hebetor*. Further studies of other *Ephestia*, *Plodia*, and *Cadra* species may indicate that a series of related compounds is produced in the larval mandibular glands, which have kairomonal activity for *B. hebetor* and *V. canescens*. Indeed, recent studies of the aforementioned pyralid hosts suggest that quantitative and qualitative differences exist in the 2-acylcyclohexane-1,3-diones present in frass and mandibular gland extracts (Mudd, 1983; Kuwahara *et al.*, 1983; Nemoto *et al.*, 1987).

While host-produced compounds may act as kairomones for more than one parasitoid species, their activity and the behavioral responses they elicit may differ. As with *V. canescens*, the mandibular gland components with a conjugated unsaturated side chain (components 1 and 8) elicit the greatest response at low concentration in *B. hebetor*. However, unlike *V. canescens* (Mudd *et al.*, 1984), the hydroxyl group at C-4 does not seem to alter component activity for *B. hebetor*. Also unlike *V. canescens*, high patch concentrations (1 and 10 μg) of all of the components elicited a strong behavioral response in *B. hebetor*.

Behaviorally, the responses of *B. hebetor* are consistent with its ectoparasitic habit and preference for ultimate instar hosts. Females antennate and search substrates permeated with the *E. kuehniella* kairomones, but they also follow kairomone trails. Wandering *E. kuehniella* final instar larvae apparently deposit mandibular gland material on the substrate, and *B. hebetor* is capable of following this trail. This is in contrast to *V. canescens*, which prefers earlier instar hosts that remain in the substrate and which are located by the wasp through ovipositor probing. The characteristic movement of the antennae across a trail by *B. hebetor* is similar to several descriptions of trail pheromone following behavior of ants in which chemotropotactic and klinotactic trail-following components have been reported (Matthews and Matthews, 1978; Haynes and Birch, 1985).

It should be noted that in this study, females with previous oviposition

experience on *E. kuehniella* were used. The response of inexperienced females or females that have previously encountered other pyralid hosts may differ both qualitatively and quantitatively. Further characterization of how these kairomones influence *B. hebetor* foraging and orientation is currently being investigated.

Acknowledgments—We would like to thank J.A. Johnson for assistance in rearing *E. kuehniella* and *B. hebetor*, and W.E. Burkholder for comments and useful suggestions on the manuscript.

Abstract—The Dufour gland of *Crematogaster scutellaris* stores a mixture of long-chain primary acetates bearing a cross-conjugated dienone (Scheme 1, 1a-c). The poison gland contains two highly active enzymes: an acetate esterase and an alcohol oxidase. During venom emission, the constituents of both glands mix and accumulate on the sting, where the formation of the highly electrophilic aldehydes (Scheme 1, 2a-c) from their acetate precursors is initiated. Acetic acid, produced during the reaction, acts as alarm pheromone. The toxicity of the acetates (Scheme 1, 1a-c) and of the crude secretion has been assessed by topical application on *Myrmica rubra*. The acetate-containing secretion from the Dufour gland was less toxic than the enzymatically altered secretion that was rich in aldehydes. The production of acids (Scheme 1, 3a-c) was an artifact resulting from the nonenzymatic oxidation of the unstable aldehydes.

Key Words—*Crematogaster scutellaris*, ants, Hymenoptera, Formicidae, Dufour gland, contact poisons, esterase, alcohol oxidase, alarm pheromone, aldehydes.

INTRODUCTION

Ants of the genus *Crematogaster* are characterized by a spatulate sting, which is not a suitable injection device (Buren, 1958). In many species, the venom is emitted as a froth that accumulates on the spatulate portion and at the base of the sting, from whence it can be applied easily to the integument of attacking insects. Application is further facilitated by the fact that the abdominal tip can be pointed in nearly all directions. Indeed, *Crematogaster* species are remarkable among the ants by their ability to raise the abdomen forward and over the thorax and head. The hypertrophied Dufour gland of *Crematogaster*, which is connected to the sting, is considered to be the origin of the venom (Maschwitz, 1975; Buschinger and Maschwitz, 1984). During venom emission, an alarm pheromone is also emitted, which mediates a general excitement (i.e., frenzied alarm) in the aggregations of workers inside and outside the nest (Leuthold and Schlunegger, 1973).

In a preceding paper, we reported that the venom of *C. scutellaris* contained a series of C_{23} long-chain derivatives, characterized by the presence of a cross-conjugated dienone linked to either a primary acetate (Scheme 1, 1a-c), an aldehyde (Scheme 1, 2a-c), or a carboxylic acid function (Scheme 1, 3a-c). The aldehydes 2a-c are powerful electrophiles and could be responsible for the toxicity of the venom (Daloze et al., 1987). However, the aldehydes are highly unstable and cannot be stored as such in the Dufour gland. We report here that the Dufour gland of *C. scutellaris* only stores the acetates 1a-c and that aldehyde production is triggered at the moment of discharge of the esters to the exterior by mixing with enzymes located in the simultaneously discharged fluid of the poison gland. This enzymatic reaction also liberates acetic acid, which is responsible for the alarm reaction observed in grouped ants. The production of homologous acids 3a-c is an artifact resulting from nonenzymatic oxidation of the aldehydes 2a-c.

METHODS AND MATERIALS

Biological Material. Portions of dead pine logs containing ant colonies were collected in south of France near Salernes and Banyuls. These colonies could be maintained in these pieces of log for several years in the laboratory, merely by feeding them continuously with a solution of brown sugar and freshly killed cockroaches.

Chemical Analyses. The venom of workers was collected as described previously (Daloze et al., 1987) on bits of filter paper that were immediately dropped into *n*-hexane or CH_2Cl_2 . For the kinetic studies, the venom was collected in the same manner, but the filter papers were maintained at $19 \pm 1^\circ C$

for 0, 5, 10, or 15 min before being dipped into CH₂Cl₂. The resulting solutions were analyzed by photodensitometry using TLC plates (Merck Silicagel G F 254); eluent 1: hexane-acetone 8:2; eluent 2: CH₂Cl₂. The compounds were made visible by quenching of the UV fluorescence of silica. Absorbances were measured at 250 nm on a Shimadzu CS 930 dual-wavelength TLC scanner. Percentages given in Table 1 are mean values, obtained by averaging the values of three replications. Similar assays were performed under a nitrogen atmosphere. Enzyme specificity assays were conducted in 0.05 M phosphate buffer (pH 7.0), containing 0.1% of Tween 60 as detergent. One or 2 μg of the acetate substrate was suspended into 20 μl of the buffer solution, and two poison glands were added. After sonication for 2 min, the solution was incubated for 20 min at 20°C, then extracted twice with 5 μl of CH₂Cl₂. The organic extract was spotted on a TLC plate and analyzed for the presence of alcohol or aldehydes.

As previously reported (Daloze et al., 1987), neither the major constituents

^aMean and standard deviation of three replications.

(a-c) of each fraction (1-3) of the secretion nor the corresponding alcohols (4a-c) produced by the enzyme under nitrogen can be separated from each other by TLC. The alcohols 4a-c were isolated by preparative TLC (eluent 1), and identified by mass spectrometry (Micromass VG 7070). Acetic acid was identified by GLC (25-m OV-1 capillary column, Varian 3700) after derivatization with *N*-methyl-*N*-*t*-butyldimethylsilyl trifluoroacetamide (Schooley et al., 1985) and coinjection with a similarly derivatized authentic sample.

RESULTS

Variation in Proportions of Constituents in Stored Venom. Variations in the proportions of the chemical constituents in the venom depend on how the venom was handled after its collection on paper. Two factors are particularly critical: (1) the nature of the storage solvent, and (2) the time elapsed between emission of the venom and its immersion in solvent. Mixtures of 1a-c, 2a-c, and 3a-c were always found when the storage solvent was *n*-hexane or when the venom was immersed in the solvent 5 or 10 min after its emission. In contrast, only acetates 1a-c were detected by TLC when the venom was placed in CH₂Cl₂ at the very instant of discharge (Figure 1). These observations strongly suggest that *C. scutellaris* uses a defensive mechanism involving the storage of relatively stable acetates and the emission of highly reactive electrophilic aldehydes via enzymatic conversion.

Storage of Precursor in the Dufour Gland. Dufour glands of workers were dissected in H₂O and the glandular fluid briefly extracted with CH₂Cl₂. TLC analyses demonstrated the presence of acetates 1a-c only. The same results were obtained when the dissected glands were crushed on bits of filter paper and kept in contact with air for several hours before extraction. Thus, the acetates are the only precursors stored in the Dufour gland. Their transformation into aldehydes must be mediated by catalysts from another origin.

FIG. 1. Redrawn thin-layer chromatographic plates showing the kinetics of ageing of the venom in open air: (A) venom immediately immersed in CH_2Cl_2 ; (B) venom immersed in CH_2Cl_2 after 5 min; (C) venom immersed in CH_2Cl_2 after 15 min; (a) acetates (1a-c); (b) aldehydes (2a-c); (c) acids (3a-c); I, eluent: hexane-acetone, 8:2; II, eluent: CH_2Cl_2 .

Poison Gland as Source of Enzymes Responsible for Aldehyde Production.

In contrast to the above-mentioned results, when dissected Dufour and poison glands were crushed together on a piece of filter paper, left to sit for 15 min, and subsequently extracted with CH_2Cl_2 , TLC analyses showed the presence of mixtures of acetates (1a-c) and aldehydes (2a-c) accompanied by traces of acids (3a-c) (Figure 2). Crushing Dufour glands with pieces of fat body only led to the recovery of the acetates. Thus, the poison gland appears to contain the requisite enzymes to transform the Dufour gland acetates into the corresponding aldehydes. This type of transformation requires two enzymes, an acetate esterase and an alcohol oxidase. The evidence presented below shows that both kinds of enzymes are operative in the defensive secretion of *C. scutellaris*. The fact that only traces of acids were observed suggest that these are not formed by an enzyme-mediated process, but rather by air oxidation of the highly reactive aldehydes. This reactivity is further demonstrated by a spontaneous rearrangement that will be described at the end of this paper.

Identification of Acetic Acid in Secretion. The hydrolysis of acetates 1a-c, triggered by the acetate esterase should produce acetic acid and the alco-

FIG. 2. Redrawn TLC (eluent: CH_2Cl_2) showing the pattern obtained by: (A) extraction of dissected Dufour gland after 15 min; (B) extraction of dissected Dufour and poison gland crushed together for 5 min; (C) as in B for 15 min; (a) acetates (1a-c); (b) aldehydes (2a-c); (c) acids (3a-c).

hols 4a-c. Venom emission by workers is always accompanied by a characteristic odor of acetic acid. The presence of acetic acid in venom samples was indeed demonstrated by GLC of its *t*-butyldimethylsilyl derivative and was always correlated with the presence of the aldehydes (2a-c). The other products of acetate hydrolysis, namely the alcohols 4a-c could never be isolated from crude venom extracts, presumably because their oxidation into the aldehydes is too fast. The alcohols, however, could be trapped under nitrogen.

Accumulation of Alcohols (4a-c) under Nitrogen. The venom, collected on pieces of filter paper, was immediately placed under a nitrogen atmosphere. Under these conditions, TLC analyses of the venom extracts showed that after 1 hr, about 30% of the acetates was transformed into a more polar fraction (Figure 3). The R_f of the latter suggested that it could be the corresponding alcohols (4a-c). Preparative TLC (eluent 1) afforded 0.5 mg of this fraction whose EI-MS (M^{++} at m/z 348 and 346; fragments at m/z 330, 328, 320, 318, 302, 300, . . .) confirmed it contained the alcohols 4a-c.

This result demonstrated that the aldehydes arise from the alcohols under the action of an oxygen-dependent alcohol oxidase. The marked slow-down of acetate hydrolysis under nitrogen (see below and Table 1) may be ascribed to the well-known phenomenon of product inhibition (Mahler and Cordes, 1969),

FIG. 3. Redrawn TLC (eluent: hexane-acetone, 8:2) showing the aging of the venom under N_2 : (A) venom immediately immersed in CH_2Cl_2 ; (B) venom after 20 min; (C) venom after 1 hr; (a) acetates (1a-c); (d) alcohols (4a-c).

because the alcohols were not removed from the reaction medium by the oxidase, which is inhibited under N_2 .

Semiquantitative Analysis of Kinetics of Aldehyde Production. The venom, collected on bits of filter paper, was kept in air and dipped in CH_2Cl_2 at different time intervals. TLC analyses of the resulting solutions were performed by photodensitometry at 260 nm. Typical results are shown in Figure 1, and the variations of the percentages of acetates and aldehydes with time are given in Table 1. Furthermore, if the same experiments were run with *n*-hexane as storage solvent, mixtures always resulted, even if attempts were made to stop the transformation at time zero. These results show that the enzyme is still active in hexane. Under our experimental conditions, $47.2\% \pm 6.5$ of the acetates were metabolized into the aldehydes in 5 min (Table 1).

Substrate Specificity of Acetate Esterase. Enzyme activity was first determined *in vitro* on the natural substrates 1a-c in 0.05 M phosphate buffer, in the presence of poison gland extracts. Under these conditions, about 50% of 1a-c were metabolized into the alcohols 4a-c in 20 min. The same experiment performed on *n*-octadecylacetate afforded small amounts of octadecanol, thus showing that the esterase of *C. scutellaris* is not strictly substrate-specific. No aldehydes were produced under these conditions.

Spontaneous Rearrangement of Aldehydes (2a-c). We would like to dis-

cuss here the structure of an artifact that is repeatedly obtained during storage and handling of the secretion of *C. scutellaris*. This artifact, which is less polar than the other derivatives, is obtained in good yields by chromatography of the secretion under daylight on Sephadex LH 20 as described previously (Daloze et al., 1987). It must be derived from the aldehydic fraction (2a-c), since the latter disappears during the chromatographic process.

The spectroscopic properties of the artifact [MS: M^{+} at m/z 346 and 344; UV: λ max 235 nm; IR: ν C=O 1800 cm^{-1} ; ^1H NMR: δ 6.20, 1H, δt , 15.8 and 7 Hz; δ 5.89, 1H, d, 15.8 Hz; δ 5.35, 2H, t, $J = 4.7$ Hz; δ 5.20, 1H, t, $J = 2.6$ Hz; δ 3.27, 2H, m; characteristic signals of a (Z,Z)-diene are also present at δ 6.24, bd, and 5.43, m] strongly suggest its components should have structures 5a-c. This hypothesis was confirmed by decoupling experiments in ^1H NMR ($J_{2,3} = 2.5$ Hz; $J_{5,6} = 15.8$ Hz; $J_{6,7} = 6.5$ Hz; $J_{2,5} = 2.0$ Hz; $J_{3,5} = 1.0$ Hz) and by comparison of the spectral properties of 5a-c with those of model compounds [e.g., α -angelica lactone (Gagnaire and Payo-Subiza, 1963; Hirsch and Szur, 1972)]. The formation of this type of lactone from 4-oxo-2-enals has been well documented (Hirsch and Szur, 1972; Macleod et al., 1977).

Biological Activities of Secretion. Toxicity was measured by counting dead ants (*Myrmica rubra*) observed 48 hr after topical application of 0.1 μl of hexane solution of the compounds. It was not possible to measure the toxicity of pure aldehydes because of their instability. Thus, the toxicity of pure acetates dissolved in hexane was compared to that of the crude secretion kept in dry air during 20 min before its extraction with hexane. The aldehydic content of this secretion was not precisely determined, but substantial amounts of aldehydes together with acetates and acids were detected by TLC (see also Table 1). Only five ants of 20 were found dead 48 hr after 30 μg of the acetates per ant was applied, whereas 19 ants of 20 were dead or paralyzed when the same amount of crude secretion was applied ($P < 0.00001$, Fisher exact probability test). No mortality was observed with pure hexane. It is important to note that 30 μg is about half of what can be collected as a mean in one *Crematogaster* ant by gently squeezing it between fingers (Daloze et al., 1987). Thus, the secretion was more toxic after the enzymatic transformation than before transformation when the acetates alone were present.

C. scutellaris feeding in groups are excited and dispersed in the presence of acetic acid vapors, as demonstrated by placing a bit of filter paper impregnated with acetic acid on a platform 1 cm above ants feeding at its basis.

DISCUSSION

The cooperation between the Dufour and the poison glands in the production of topical poison and alarm pheromone is unique in ants. However, it is worth mentioning that the content of the poison gland of many hymenopterans, includ-

ing ants, is rich in enzymes, among others, esterases (Schmidt, 1982), and the esterase needed to hydrolyze the acetates stored in the Dufour gland is not strongly specific. The uniqueness of the *Crematogaster* system arises more from the particular chemistry of the Dufour gland secretion than from the enzymatic participation of the poison gland. In most ants, the Dufour gland secretion is lipophilic but usually contains much simpler and lighter aliphatic derivatives or sesquiterpenes (Blum and Hermann, 1978; Attygalle and Morgan, 1984).

Similar defensive strategies based on the storage of stable precursors in specialized reservoirs and their transformation by enzymes into highly reactive compounds have already been reported in other arthropods (e.g., Eisner et al., 1963; Schildknecht et al., 1968; Aldrich et al., 1978). The enzymatic transformation of aliphatic acetates into aldehydes by an acetate esterase and an oxygen-dependent alcohol oxidase has been well documented recently in the biosynthesis of aldehydic moth pheromones (Morse and Meighen, 1984, 1986). The enzymes of *Crematogaster* are still active when dissolved in hexane, a well-known property of esterases and related enzymes (Tanaka et al., 1981, Fukui and Tanaka, 1985). However, catalytic activity was totally lost in CH_2Cl_2 , thus indicating that catalysis is due to an enzyme rather than an organic catalyst.

The alarm reaction induced by the vapor of acetic acid is certainly not specific and can be induced by many "nonspecific irritants" (sensu Eisner, 1972), such as volatile acids, aldehydes, or terpenes (Boevé, 1988). However, since acetic acid is produced during poison emission and since it is the only volatile compound detected in the secretion, it is most probably responsible of the alarm pheromonal function of the secretion described by Leuthold and Schlunegger (1973). A more refined analysis of this alarm communication would require a quantification of the emission rate of acetic acid during the enzymatic reaction, which is beyond the scope of this paper.

As expected, the precursor acetates were found to be less toxic than the secretion enriched with the strongly electrophilic aldehydes. The enzymatic transformation of acetates into aldehydes is far from being instantaneous. In our experiments, only half of the acetates was transformed 5 min after their secretion, and significant amounts of acetates still persisted after 15 min. This slow reaction could be in part an artifact of our collecting process, during which we tried to collect as much material as possible by gently squeezing the ants between our fingers. During normal emission, less acetates could be secreted at once and more quickly transformed. However, a "delayed" defense offers obvious advantages, especially since the toxin is unstable. The total conversion of esters to aldehydes in an instant would be an all-or-nothing strategy, because the aldehydes would quickly lose their activity by spontaneous oxidation to acids and rearrangement. On the other hand, a foe contaminated by a mixture that progressively releases its toxins, while penetrating the organism, will be handicapped for a longer time.

Acknowledgments—We thank Prof. M. Van Haelen for the photodensitometry measurements, Dr. R. Ottinger for the [¹H]NMR spectra, Mr. C. Moulard for the mass spectra, and Dr. S. Duffey, for critical reading of the manuscript.

SECONDARY ATTRACTION AND FIELD ACTIVITY OF
BEETLE-PRODUCED VOLATILES IN
Dendroctonus terebrans

THOMAS W. PHILLIPS, JAMES L. NATION,

(Received March 28, 1988; accepted July 22, 1988)

Abstract—Controlled infestation of *Dendroctonus terebrans* (Olivier) on bolts of slash pine, *Pinus elliottii* Engelm. var. *elliottii*, elicited greater attraction of wild conspecifics than uninfested bolts. Secondary attraction was not apparent, however, to standing slash pines that had received volunteer attacks, when compared with attraction to unattacked but susceptible trees. Hindguts from in-flight or attacking female *D. terebrans* contained frontalin, and those from in-flight or attacking males contained *exo*-brevicommin. *Trans*-pinocarveol, *cis*-verbenol, *trans*-verbenol, myrtenal, verbenone, myrtenol, and other compounds were produced by both sexes during gallery construction in host trees. Synthetic frontalin, when deployed with a standard host odor mixture of turpentine and ethanol, was very attractive to male *D. terebrans* in field-trapping experiments. The addition of either *exo*-brevicommin or *endo*-brevicommin to the frontalin-turpentine combination negated the attractive effect of frontalin for males. *Trans*-verbenol, myrtenol, and verbenone had little effect on *D. terebrans* behavior. Responses of females did not differ among treatments in any of the 11 field experiments.

Key Words—*Dendroctonus terebrans*, Coleoptera, Scolytidae, bark beetles, pheromones, primary attraction, secondary attraction, host selection, frontalin, *exo*-brevicommin

INTRODUCTION

In the phases of host selection exhibited by scolytid bark and ambrosia beetles (Wood, 1982), the concentration of colonizing beetles on suitable hosts is purportedly facilitated by pheromones, or "secondary attractants" (after Borden

et al., 1975), from beetles that make the initial selections and those that follow. Pheromones and their behavioral roles are demonstrable and well documented in the relatively few species of tree-killing bark beetles that colonize living trees in large groups over short time periods (reviewed by Borden, 1982). The majority of scolytids, however, colonize recently dead, dying, or severely stressed trees; host-selection behavior has received little research in these species. Some studies of pheromones in species that colonize moribund trees have failed to demonstrate obvious occurrence of beetle-produced attractants or have implicated a greater importance for host odors as attractants (e.g., Lanier, 1983; Millar et al., 1986; Lanne et al., 1987).

The black turpentine beetle, *Dendroctonus terebrans* (Olivier), has been credited with killing healthy pine trees (*Pinus* spp.) that are mechanically injured, as well as those that are stressed or severely weakened (Kowal and Coyne, 1951; Smith and Lee, 1957; Merkel, 1981). Turpentine, the volatile component of pine oleoresin (Mirov, 1961), has been known for some time to be a potent attractant for *D. terebrans* (Hopkins, 1909). Fatzinger (1985) quantified the attraction of *D. terebrans* to turpentine-baited traps over several seasons, and he and Phillips et al. (1988) showed that ethanol would synergistically increase the attraction of beetles to turpentine. Siegfried et al. (1986) reported that no individual monoterpene component of turpentine, nor an artificial mixture of monoterpenes, was as attractive to *D. terebrans* as natural turpentine distilled from oleoresin. The strong attraction exhibited by black turpentine beetles to host odors has led some researchers to suggest that the species does not use pheromones (e.g., Vité et al., 1964; Billings, 1985).

Earlier studies have suggested that black turpentine beetles may use pheromones in host selection or reproductive behavior. Smith (1963) found that *D. terebrans* attacks were more likely to occur on trees previously attacked that season compared to unattacked trees, thus suggesting that secondary attractants may be produced by the initiating attackers. Godbee and Franklin (1976) demonstrated that *D. terebrans* were attracted to trees on which pine bolts were hung that were artificially infested with either male or female *D. terebrans*. Hughes (1973, 1975) identified several terpene oxidation products, some that were known to be pheromones in other scolytids, from hindguts of black turpentine beetles that had been feeding in cut sections of host trees or exposed to vapors of host terpenes. Payne et al. (1987) also identified several known bark beetle pheromones from *D. terebrans* and demonstrated biological activity of some of them in electrophysiological and behavioral studies.

We had three main objectives for the studies reported below. First, we wanted to determine if host material infested with *D. terebrans* is more attractive to wild *D. terebrans* than uninfested host material. Second, we wished to identify volatile compounds produced by *D. terebrans* while attacking host trees.

Third, we investigated the activity of these beetle-produced volatiles as attractants for conspecifics in the field.

METHODS AND MATERIALS

Study Area. All of the field studies described below were conducted on forest land managed by the Owens-Illinois Corporation in Alachua County, Florida, about 14 km east of Gainesville. Slash pine, *Pinus elliottii* Engelm var. *elliottii*, was the predominant commercial tree species and ranged in age from newly planted seedlings to 27-year-old trees in pure, even-aged stands.

Studies of Secondary Attraction. Three separate field studies were conducted to determine if host material infested with *D. terebrans* was more attractive than host material alone. Our first experiment (experiment 1, conducted from July 24 to October 9, 1986) examined the possibility that slash pine trees that were naturally infested with *D. terebrans* were more attractive to wild *D. terebrans* than mechanically injured but uninfested trees. Full-grown slash pines, approximately 30 cm diameter at breast height (DBH; 1.37 m above groundline) and 18 m tall, that had received 8–15 aboveground attacks by *D. terebrans* (as assessed by appropriate-sized entrance holes and resinous “pitch tubes”) were searched for and located near the edge of stands adjacent to logging roads. We were particularly careful not to select trees that had visible evidence of being under attack by other bark- or wood-boring insects, those struck by lightning, or those having experienced similarly obvious physical trauma. For each attacked tree, an unattacked and apparently healthy control tree of similar dimensions and orientation to the stand edge was selected about 20–30 m away. Injuries in the form of axe blazes made at 45° angles into the sapwood from ground line to breast height (BH) were applied to each unattacked tree, the number of axe blazes being equal to the number of visible *D. terebrans* attacks on the corresponding attacked tree. A 16-unit Lindgren funnel trap (Phero Tech Inc., Vancouver, British Columbia, Canada) was placed within 30 cm of each experimental tree by hanging it, facing the logging road, from a PVC pipe standard so that the collection jar was within 10 cm of the ground. Five such attacked–unattacked tree experimental units were established over a six-week period, and beetles caught in traps were collected every two to three days over a four-week period for each unit. Most experimental units were unsuitable after four weeks because either the unattacked trees become attacked by *D. terebrans* or one or both trees in a unit displayed evidence of attacks by other species of bark- or wood-boring insects.

In a second experiment (experiment 2), conducted from June 29 to September 4, 1987, we also studied the response of *D. terebrans* to attacked and

unattacked trees. Each experimental unit was comprised of two mature, apparently healthy, unattacked slash pines that were 20–30 m apart along the edge of a stand bordered by a logging road. Each of the two trees was physiologically stressed by applying about 20 ml of a 4% aqueous solution of the herbicide paraquat (1,1'-dimethyl-4,4'-bipyridinium dichloride) to each of two horizontal axe frills, with lengths equal to one third the bole's circumference, made opposite each other at BH. Such paraquat treatments are known to cause resin-soaking of the xylem tissue around the wound (Roberts, 1973) and make trees attractive to and susceptible to attacks by *D. terebrans* (Siegfried et al., 1986). One of the two trees was then protected to prevent *D. terebrans* attacks by covering the bottom 2 m of the bole with 18 × 16 mesh aluminum screening and by spraying 1 m above the screening, as well as the root collar region below the screening, with a 2% solution of Lindane insecticide (from a 20 EC formulation). Sixteen-unit funnel traps were placed in front of each tree as in the previous experiment. Eight such experimental units (replicates) of protected and unprotected stressed trees were established with no less than 100 m between units. Beetles were collected from traps, and trees were checked for attacks every one to two days. Beetles caught at either tree in a unit were classified as preattack beetles until one or more attacks were observed on unprotected trees, after which trapped beetles were classified as postattack samples. *D. terebrans* response was monitored for four weeks into the postattack period for each unit.

Our last field study of secondary attraction (experiment 3), conducted from June 12 to June 24, 1987, was an experiment in which the attractiveness of slash pine log bolts that were artificially infested with *D. terebrans* was compared with that of uninfested bolts. Two mature trees of similar dimensions were felled, and two bolts, each 130 cm long by 25–30 cm diam., were cut from the basal section of each tree; cut ends were immediately placed in buckets of water to prevent excessive drying, and the bolts were returned to the laboratory. Wild *D. terebrans* were live-captured in funnel-traps baited with a mixture of turpentine and ethanol (see below). Thirteen 4-mm holes for introducing beetles were drilled to the sapwood at 45° angles on each of the four bolts and the following beetle-infestation treatments were randomly assigned: (1) 13 females, (2) 13 males, (3) 13 females with 13 males introduced 12 hr later, and (4) 13 holes with no beetles as the control. Beetles were confined in holes with 4 × 4-cm pieces of screening and all four bolts were securely covered with 18 × 16 mesh aluminum screening to prevent attacks by other insects. Bolts were taken to the field and deployed in traps for the experiment. We used a modification of Fatzinger's (1985) bounce column trap, in which the blackened stovepipe was replaced with our screened bolt. Each bolt was placed upright in a plastic wading pool (1.2 m diam. by 23 cm deep) filled with 20 liters of soapy water and stabilized with three guy wires from the top of the bolt to side of the pool. The trap was designed so that *D. terebrans* and other responding insects

would hit the screened bolt and then drop into the soapy water. Experimental bolts were randomly assigned to four traps spaced 40 m apart in a line along the edge of a 20-year-old stand. Bolts were kept in place for two days, after which trapped beetles were collected and the bolts randomly reassigned to the traps. Five such two-day trapping periods were conducted.

Extraction and Identification of Beetle Volatiles. Wild *D. terebrans* were either live-trapped in flight or excised from galleries in naturally attacked trees during the summers of 1986 and 1987 for gas chromatographic (GC) analysis of volatiles present in their hindguts. Upon collection, beetles were immediately placed in a cooler at 5°C and returned to the laboratory for dissection and extraction. Volatiles from individual beetles were extracted by removing the hindgut and associated tissues (part of the midgut, malpighian tubules, and some fat body), placing it in 20 μ l of chilled pentane in a 1.5-ml screw-top septum vial (Pierce Chem. Co., Rockford, Illinois), macerating briefly with a probe, and sonicating for 15 sec in a sonicating cleaner. An internal standard of 3-octanol (424 ng) was added at the time of extraction for GC quantification of volatiles in individual beetle samples. Groups of 5–10 hindguts were pooled in other samples and extracted in the same way with about 10 μ l of pentane per hindgut.

Volatiles extracted from hindguts were analyzed on a Varian 3700 GC equipped with a flame ionization detector and a Hewlett Packard 3390A recording integrator. Two different capillary GC columns were used in the splitless mode under the following conditions: (1) a 10-m \times 0.53-mm Superox FA fused silica column (Alltech Associates, Inc., Deerfield, Illinois), injector 160°C, detector 180°C, column held at 60°C for 10 min then programmed at 1°/min to 100°C and held for 20 min, He carrier gas flow at 34.0 cm/sec at 100°C; (2) a 30-m \times 0.25-mm DB-1 fused silica column (J and W Scientific, Inc., Folsom, California), injector 180°C, detector 250°C, column held at 50°C for 12 min then programmed at 2°/min to 75°C and held for 45 min, the flow at 25.1 cm/sec at 100°C. Identifications were initially made on GC by comparing retention times of unknowns on each column with those of available standards that we suspected were present in *D. terebrans*. Our GC identifications were confirmed and additional compounds identified in a few representative samples using coupled GC–mass spectroscopy (MS). Two different GC–MS instruments were used, each with a 30-m DB-1 column.

Field Activity of Synthetic Beetle Volatiles. Eight separate trapping experiments were conducted in 1986 and 1987 to assess the activity of synthetic formulations of volatiles identified from *D. terebrans*. Source, purity, release devices, and release rates of test compounds are given in Table 1; details of the individual experiments are given in Table 2. In addition to field-testing compounds found in *D. terebrans* hindguts, we also tested *endo*-brevicomins, which was reported from male *D. terebrans* by Payne et al. (1987). In experiments

TABLE 1. SOURCE, PURITY, RELEASE DEVICES AND RELEASE RATES OF VOLATILE MATERIALS USED IN TRAPPING STUDIES OF *D. terebrans*

Material	Source	Purity (%) ^a	Release device	Release rate (mg/24 hr) ^b

with synthetics, we utilized a 1:1 mixture (v/v) of turpentine and 95% ethanol as a representative host odor attractant (as in Phillips et al., 1988). We also used 16-unit funnel traps hung from PVC pipe standards for these experiments, except for experiment 10, in which we used bounce column traps (Fatzinger,

1985) to maximize beetle catches. Traps were positioned 20–30 m apart in recent clear-cut areas adjacent to residual mature (20–25 years) stands of slash pines. Each experiment used as many traps as there were treatments. Treatments (baits) were randomly assigned to traps for a given time period (one to three days), after which trapped beetles were collected; baits were replaced with fresh material and treatments randomly assigned again to traps so that each trapping period represented a block in a randomized block design. Synthetic beetle volatiles were evaporated separately from small glass vials (Table 1) that were secured in wooden holders equipped with a small aluminum roof to protect them from excessive sun and rain. Vial holders and turpentine-ethanol dispensers were hung from the fourth funnel from the bottom (about 45 cm above ground line) on funnel traps, or from the top of the stovepipe (about 1.2 m above ground line) on bounce column traps.

Data Analysis. Data on field responses of *D. terebrans* were processed using the Statistical Analysis System package. Because of the occurrence of many zero counts, raw data from each experiment were transformed by the calculation of $y = \sqrt{x + 0.5}$. Transformed data were then subjected to analysis of variance followed by means comparisons with the Student-Newman-Keuls test (for experiments with three or more treatments) or Students' *t* test (for experiment with two treatments). Differences in the sex ratio of beetles responding to different treatments were analyzed by computing the percentage of females responding per replicate for each treatment, transforming percentages via $y = \arcsin\sqrt{\%x}$, and then performing analysis of variance and means comparisons as before.

RESULTS

Naturally attacked and mechanically injured slash pines were similarly attractive to *D. terebrans* (Table 3). Although the total number of beetles responding to the five attacked trees was about twice that responding to injured trees over the four-week period (228 vs. 115), differences in numbers caught were not statistically significant (e.g., $P = 0.24$ for sexes combined). In our second experiment (Table 4), protected and unprotected stressed trees were equally attractive prior to *D. terebrans* attacks (an average period of $14.3 \pm 3.7 \text{ SE}_{\bar{x}}$ days), and lack of a difference in attractiveness persisted after the unprotected trees each received two to three *D. terebrans* attacks. Thus, these first two experiments provided no evidence for secondary attraction due to attacking beetles. Results from known numbers of *D. terebrans* artificially introduced into cut bolts (Table 5), however, did demonstrate secondary attraction of *D. terebrans* to conspecifics on host material. Although responses of

TABLE 3. RESPONSE OF *D. terebrans* OVER FOUR-WEEK PERIOD TO SLASH PINES THAT WERE NATURALLY ATTACKED OR MECHANICALLY INJURED BUT NOT ATTACKED IN EXPERIMENT 1

Tree type	Mean ($SE_{\bar{x}}$) number caught at trees ^a		Mean % females ^a
	Females	Males	
Attacked	23.8 (11.8)	21.8 (9.4)	49.1 (3.3)
Injured controls	9.2 (6.7)	11.8 (8.6)	35.2 (10.3)

^aThe *t* tests detected no significant differences ($P > 0.05$) in the number of either sex or the percentage of females trapped at either type of tree ($N = 5$).

TABLE 4. RESPONSE OF *D. terebrans* TO PARAQUAT-TREATED SLASH PINES PROTECTED OR UNPROTECTED FROM ATTACKS IN EXPERIMENT 2

Tree type	Preattack period: Mean ($SE_{\bar{x}}$) number caught per day at trees ^a		Mean % female
	Females	Males	
Protected	7.3 (5.7)	6.4 (4.7)	54.7 (7.0)
Unprotected	3.6 (1.6)	5.2 (2.6)	50.2 (7.7)
Tree type	Postattack period: Mean ($SE_{\bar{x}}$) number caught in first week ^a		Mean % female
	Females	Males	
Protected	5.0 (1.6)	5.5 (1.6)	40.8 (6.8)
Unprotected (attacked)	7.4 (4.7)	7.3 (3.9)	36.0 (8.7)

^aThe *t* tests detected no significant differences ($P > 0.05$) in the number of either sex or the percentage of females trapped at each type of tree in either the preattack or postattack periods ($N = 8$).

TABLE 5. RESPONSE OF *D. terebrans* TO SLASH PINE BOLTS ARTIFICIALLY INFESTED WITH CONSPECIFIC BEETLES IN EXPERIMENT 3

Treatment	Mean ($SE_{\bar{x}}$) number caught per replicate ^a		Mean % females ^a
	Females	Males	
Bolt only	2.0a (0.7)	0.8a (0.4)	56.0ab (17.7)
Bolt + 13 males	4.6a (2.4)	3.4ab (2.1)	73.4a (11.5)
Bolt + 13 females	1.4a (0.9)	5.2bc (1.9)	12.6b (5.7)
Bolt + 13 females + 13 males	3.6a (1.7)	7.8c (2.4)	21.2b (8.8)

^a Means in a column with the same letter are not significantly different ($P > 0.05$, Student-Newman-Keuls test, $N = 5$).

females were not significantly different among treatments, males displayed higher responses to bolts with females only or females plus males, over blank bolts or bolts with males only. The sex ratios of responding beetles were strongly in favor of males for treatments containing females and in favor of females for bolts containing just males.

GC analyses of hindguts from individual beetles trapped in flight (Figure 1) revealed that females contained one major volatile compound, the bicyclic ketal frontalinalin, and males contained another major volatile, the bicyclic ketal *exo*-brevicominalin. Beetles that were actively constructing galleries in living trees contained a complex mixture of volatiles in pentane extracts of hindguts (Figure 2). Again, females produced frontalinalin and males contained *exo*-brevicominalin, but hindgut extracts from both sexes contained similar complements of monoterpene hydrocarbons, presumably from the host trees' oleoresin, and the following oxygenated monoterpenes: *trans*-pinocarveol, *cis*-verbenol, *trans*-verbenol, myrtenal, verbenone, and myrtenol. Identifications of the bicyclic ketals and the oxygenated terpenes were confirmed with GC-MS analyses. These compounds were looked for but never found in extracts of slash pine oleoresin. Not all of the compounds reported here were found in every *D. terebrans* sample analyzed (e.g., *cis*-verbenol was not detected in the female extract shown in Figure 2), but every beetle collected from active galleries had detectable levels of *trans*-verbenol and myrtenol. On occasion, we detected up to seven minor components in both sexes, mostly eluting in the region of the terpene alcohols, but these have yet to be identified. Details of quantitative estimates of volatiles

FIG. 1. GC records (DB-1 column) of single-hindgut pentane extracts from one female (top) and one male (bottom) *D. terebrans* captured in flight June 2, 1987; S = solvent peak, AT = sensitivity of recording integrator increased by two orders of magnitude, IS = internal standard of 3-octanol. Identities of peaks and estimated sample quantities of beetle compounds are: 1, frontalin, 462.9 ng; 2, α -pinene; 3, β -pinene; 4, *exo*-brevicommin, 170.8 ng.

produced by individual *D. terebrans* during gallery construction will be reported elsewhere.

Frontalin was a potent attractant for male *D. terebrans* when deployed with a turpentine-ethanol mixture (Tables 6, 7, and 9). In experiment 1 (Table 6), females displayed no significant difference in response among the five treatments, but males were significantly attracted to turpentine plus frontalin, and their response to turpentine plus *endo*-brevicommin was not different from that to

FIG. 2. GC records (DB-1 column) of single-hindgut pentane extracts from one female (top) and one male (bottom) *D. terebrans* excised from a 7-day-old gallery in a slash pine, June 2, 1987; S = solvent peak, AT = attenuator of recording integrator increased by two orders of magnitude, IS = internal standard of 3-octanol. Identities of host-derived peaks in both records are 2, α -pinene; 3, β -pinene; peaks a, b, c, and d in the male record are unknowns. Identities and estimated sample quantities of peaks in the female record are: 1, frontalinal, 127.7 ng; 5, *trans*-pinocarveol, 476.9 ng; 7, *trans*-verbenol, 11,708.9 ng; 8, myrtenal, 1929.5 ng; 9, verbenone, 925.8 ng; 10, myrtenol, 5071.0 ng. Peak identities and estimated quantities in the male record are: 4, *exo*-brevicommin, 66.1 ng; 5, *trans*-pinocarveol, 74.9 ng; 6, *cis*-verbenol, 377.6 ng; 7, *trans*-verbenol, 15,532.0 ng; 8, myrtenal, 227.5 ng; 9, verbenone, 1578.4 ng; 10, myrtenol, 8738.2 ng.

turpentine only. Frontalin and turpentine each displayed low attractiveness when deployed singly, but the increased attractiveness of their combination indicates a synergistic effect for males. In experiment 5 (Table 7), females again displayed similar low responses to all treatments, while males were attracted to

TABLE 7. RESPONSE OF *D. terebrans* TO TURPENTINE (T), FRONTALIN (F), AND *endo*-BREVICOMIN (nB) IN EXPERIMENT 5

Treatment	Mean (SE \bar{x}) number caught per replicate ^a		Mean % females ^a
	Females	Males	
T	2.8a (1.4)	4.3a (1.8)	38.9a (4.9)
T + nB	2.5a (1.5)	1.3a (0.3)	41.4a (23.9)
T + F	3.3a (1.7)	29.5b (13.4)	12.3a (3.2)
T + F + nB	5.0a (1.7)	7.3a (2.6)	30.8a (10.7)

^aMeans in a column with the same letter are not significantly different ($P > 0.05$, Student Newman-Keuls test, $N = 4$).

the combinations of turpentine and frontalin. Addition of *endo*-brevicommin to the frontalin-turpentine mixture reduced the response of males to the level of that to turpentine only. Although *exo*-brevicommin exhibited no obvious attractive effect for males or females when deployed either singly or in combination with turpentine (experiment 6, Table 8), it did significantly reduce the attractiveness of turpentine plus frontalin in a manner similar to that of *endo*-brevicommin (experiment 7, Table 9). Here again, females did not display significantly different responses among the treatments deployed. The combination of the two brevicommin isomers had the same effect on turpentine-frontalin activity as did either applied individually.

Trans-verbenol, myrtenol, and verbenone showed little or no attractive activity for *D. terebrans* (Table 10). The combinations of *trans*-verbenol or myrtenol each with turpentine did not significantly alter beetle response over that to turpentine only. The response of males to a combination of verbenone and turpentine was lower than the response of males to just turpentine; this result was not corroborated in experiment 9 (Table 11). Verbenone decreased the response of males to frontalin and turpentine, but this effect was not statistically significant. Neither *trans*-verbenol nor myrtenol significantly affected response of beetles to turpentine plus frontalin (experiment 10, Table 12). The combination of *trans*-verbenol and myrtenol with frontalin and turpentine was more attractive to male *D. terebrans* than *trans*-verbenol with turpentine and frontalin (experiment 11, Table 13). As before, the responses of female *D. terebrans* did not differ among treatments.

DISCUSSION

Our experiment with artificially infested bolts provided good evidence that *D. terebrans* on a host can induce a secondary attraction of conspecifics. Secondary attraction was not clearly manifested in studies with standing trees, but several caveats diminish the importance of these results. With naturally attacked trees, we could not control the "quality" of the trees by knowing the exact numbers of attacks, ages of attacks, numbers of each sex attacking, and type

or intensity of agent(s) that predisposed the trees to attack. In paraquat-treated trees, we partially controlled the predisposing stress on the tree but not the timing or number of attacks. Moreover, we feel that the level of host odors from these stressed and injured trees may have been so high and attractive as to override any effects of beetle attacks on them. The lower levels of host odors from artificially infested bolts probably allowed the effects of attacking beetles to be detected.

The volatiles we identified from *D. terebrans* hindguts are typical of compounds found in other *Dendroctonus* species. We never detected the compound *endo*-brevicommin, although it was reported from *D. terebrans* males by Payne et al. (1987). *D. terebrans* in north Florida may not produce *endo*-brevicommin, but we cannot rule out transient production that went unsampled or production at levels below our detection sensitivity. The terpenoids *trans*-pinocarveol, *cis*-verbenol, *trans*-verbenol, myrtenal, verbenone, and myrtenol that we found in both sexes are common metabolic products of pine bark beetles feeding on host material or simply exposed to vapors of host monoterpenes (e.g., Hughes, 1973, 1975). If these terpenoids prove to have little or no behavioral activity for *D. terebrans*, as our field tests with three of them suggest, they may simply represent metabolic detoxification products of the beetles (White et al., 1980) and/or associated microorganisms (Brand et al., 1975; Conn et al., 1984).

We repeatedly showed that frontalin, a female-produced compound, was very attractive to male *D. terebrans* when it was deployed with a turpentine-

ethanol mix. The male-produced *exo*-brevicommin was not behaviorally active alone or with turpentine but had the effect of blocking the activity of frontalin and turpentine for males. This effect was also seen for *endo*-brevicommin, although this compound was not detected in our experimental beetles. The attractive nature of frontalin with turpentine and the blocking effect of *endo*-brevicommin were demonstrated earlier by Payne et al. (1987). The apparently equal activity of *exo*- and *endo*-brevicommin suggests that *D. terebrans* do not distinguish between the two geometric isomers. The bicyclic ketals used for these experiments were racemic formulations. Pure enantiomers, or the naturally occurring ratio of enantiomers, may elicit different responses from *D. terebrans*, as was shown for *D. frontalis* (Vité et al., 1985). Additionally, different release rates of these compounds may elicit different behavioral responses.

The synthetic oxygenated terpenes had little behavioral effect on responses of *D. terebrans* compared with those of the bicyclic ketals. Verbenone may have an inhibitory or blocking effect against male response to attractants, but this will require more rigorous testing. Verbenone is a reputed inhibitor or "antiaggregation pheromone" in a number of scolytids (Borden, 1982). We found no evidence that *trans*-verbenol enhances the response of *D. terebrans* to turpentine, as Fatzinger et al. (1987) reported. In fact, our data show decreases in the responses of *D. terebrans* to traps containing *trans*-verbenol compared with those to other treatments, but these differences were not always significant. The supplier of our synthetic *trans*-verbenol indicated that it contained less than 0.3% verbenone. If verbenone is an inhibitor of response by *D. terebrans* males, it is possible that small amounts of verbenone present as a contaminant in the *trans*-verbenol, or verbenone produced via autooxidation (Borden et al., 1986) of *trans*-verbenol in baits, could account for lowered responses to *trans*-verbenol. As with other semiochemicals, release rate and enantiomeric composition of *trans*-verbenol could be important variables affecting beetle behavior.

Clearly, *D. terebrans* utilizes pheromones in its behavioral repertoire; yet our studies and those of others point to the very strong attraction of these beetles to host odors. We trapped relatively high numbers of *D. terebrans* at physiologically stressed and injured trees (Table 4), whether or not they were attacked. *D. terebrans* does not exhibit a "mass attack" of the magnitude seen in more aggressive scolytids for which pheromones play an important role in host selection. Smith (1963) reported an average of 28.6 attacks per tree by *D. terebrans* over an entire season; compare this with attack densities of 73 attacks/m² for *D. ponderosae* (Raffa and Berryman, 1983) or 5–10 attacks/100 cm² for *D. frontalis* (Fargo et al., 1978) over several meters of bole surface within days or weeks. The importance of pheromones, therefore, in host location by *D. terebrans* is not straightforward.

Pheromones of *D. terebrans* may be more important in sexual behavior

than in host-selection behavior. The idea that many bark beetle pheromones could be considered sex pheromones was suggested earlier by Alcock (1982). In each of our eight experiments with synthetic volatiles and one with infested bolts, only males displayed different behavioral responses to the various treatments; females responded to all treatments equally. Research to date indicates that both sexes of *D. terebrans* will fly to suitable host trees in response to host odors. Our studies lead us to suggest that males are attracted to females by the frontalin they produce when on a host, and that response of other males to frontalin can be interrupted by *exo*-brevicomin released by males that arrived earlier. Since we showed significant responses only by males to frontalin and *exo*-brevicomin, we feel it is appropriate to refer to these compounds as sex pheromones, rather than as aggregation or antiaggregation pheromones.

Acknowledgments—We are very grateful to H.D. Pierce and A.C. Oehlschlager of Simon Fraser University, and W.M. Whitten and N.H. Williams of the Florida State Museum, for performing GC-MS analyses on some of our samples. Technical assistance in various phases of this work was provided by M. Simms and T. Estrin. We thank C.W. Fatzinger of the U.S. Forest Service for helpful discussions and for providing turpentine and various pieces of equipment. We appreciate reviews of the manuscript made by T.H. Atkinson and M.P. Popp. T.L. Payne kindly shared his prepublication manuscript with us and provided stimulating discussion. W.D. Bedard suggested the provision of water to cut pine bolts that were to be used for infested-bolt studies. This research was funded by grant 85-CRCR-1-1690 from the USDA. This paper represents Florida Agricultural Experiment Station Journal Series No. 8860.

BEHAVIORAL ACTIVITY OF OPTICAL ISOMERS OF
5,9-DIMETHYLHEPTADECANE, THE SEX
PHEROMONE OF *Leucoptera scitella* L.
(LEPIDOPTERA: LYONETIDAE).

Abstract—Among the pure stereoisomers of 5,9-dimethylheptadecane, a previously identified sex pheromone component of *Leucoptera scitella* L., only the *S,S* isomer yielded trap captures in the field. The addition of the other stereoisomers had no effect on catches. The addition of low percentages of racemic 5,9-dimethylhexadecane, a previously identified minor component in the sex pheromone, did not influence trap catches or alter behavior of males approaching an attractant source in the field.

Key Words—Mountain-ash bentwing, *Leucoptera scitella*, Lepidoptera, Lyonetidae, (*R,R*)-5,9-dimethylheptadecane, (*R,S*)-5,9-dimethylheptadecane, (*S,R*)-5,9-dimethylheptadecane, (*S,S*)-5,9-dimethylheptadecane, 5,9-dimethylhexadecane, trapping, behavior, sex pheromone, asymmetric synthesis.

INTRODUCTION

The sex pheromone of the mountain-ash bentwing, *Leucoptera scitella* L. (Lepidoptera: Lyonetiidae) has recently been identified as 5,9-dimethylheptadecane (Francke et al., 1987). Although a synthetic mixture of all four possible ster-

eoisomers captured significant numbers of male *L. scitella* in field trapping tests, it was not determined which of the optical isomer(s) carries biological activity.

Also, during the previously mentioned identification project, small amounts of 5,9-dimethylhexadecane were found to be present in pheromone collections (Francke et al., 1989). No attempt has been made so far to determine the biological activity of this compound.

The objective of the present study was to study whether only one or more of the pure stereoisomers were needed for behavioral activity and whether the addition of the racemic minor component influenced activity of the active isomer(s) of the main component in the field.

METHODS AND MATERIALS

Chemicals. The four stereoisomers of 5,9-dimethylheptadecane were synthesized (Leikauf, 1988) by coupling enantiomerically >99.8% pure (*R*)- and (*S*)-2-methyldecyl bromide with (*R*)- and (*S*)-3-methylheptanal. Preparations of these compounds involved as key steps asymmetric alkylations of chiral propionates (Schmierer et al., 1981) and conjugate additions of butyl copper complexes to chiral crotonates (Helmchen and Wegner, 1985). Products of these reactions were purified by medium-pressure liquid chromatography to ensure diastereomeric purities of >99.9%. The coupling was carried out by a Grignard reaction. The resultant hydroxyl groups were removed by reduction of the corresponding mesylates with lithium triethylborohydride. Stereoisomeric purities of the final products must be >99.8%, as only synthetic procedures not involving bonds directly attached to the chirality centers were employed.

Chemical purity was determined by GLC-MS (Hewlett-Packard 5890 A/5970; fused silica capillary column DB-1, 30 m × 0.3 mm). Each of the stereoisomeric 5,9-dimethylheptadecanes contained traces of hydrocarbons introduced in the reduction step by the lithium triethylborohydride solution employed (Aldrich). Optical rotations were measured on a Perkin-Elmer polarimeter 241 (temperature: 21°C).

(*R,R*)-5,9-Dimethylheptadecane was 98% pure, $[\alpha]_D = -2.1$ ($c = 2.1$, chloroform).

(*5R,9S*)-5,9-Dimethylheptadecane is denoted *R,S* isomer in the following purity: 97%, $[\alpha]_D = -1.5$ ($c = 2$, chloroform).

(*5S,9R*)-5,9-Dimethylheptadecane is denoted *S,R* isomer in the following purity: 96%, $[\alpha]_D = 1.1$ ($c = 2.1$, chloroform).

(*S,S*)-5,9-Dimethylheptadecane is denoted *S,S* isomer in the following purity: 96%, $[\alpha]_D = 2.1$ ($c = 2$, chloroform).

Pure racemic mixtures of 5,9-dimethylheptadecanes and -hexadecanes were obtained from Prof. W. Francke (Hamburg, F.R.G.).

Trapping Tests. Test traps of similar design to Tetra traps with flaps (Arn

et al., 1979), but made from transparent polyethylene sheets, were used. Chemicals were applied in 10- μ l hexane solutions to 1-cm pieces of rubber tubing (commercial product, obtained from Borászati Szaküzlet, Budapest). Traps in one replicate were hung at about 1.5 m in the foliage of apple trees, at ca. 2–3 m from each other, composing a rectangle. The positions of the traps within the rectangle were changed clockwise every one to two days (Érd), or once weekly (Dunaharaszti, Halásztelek). On these occasions trapped moths were counted and sticky inserts renewed. The distance between replicates ranged from 30 to 100 m.

At Érd (Pest County, Hungary) and Halásztelek (Pest County, Hungary) tests were set up in commercial apple orchards, while at Dunaharaszti they were placed in backyard gardens having various orchard trees and vegetables apart from apple trees.

Direct Observation of Male Behavior. Studies of male behavior close to the attractant source in the field were conducted using a 20 \times 20-cm flat, transparent plastic sheet. The dispenser with the attractant was attached to a slot in the middle of this platform. The sheet was placed into the crown of a tree at the height of ca. 1.5 m, and the behavior of approaching males was described into a cassette recorder, then transcribed in the lab. The observer was stationed at 1–2 m crosswind from the sheet.

Observations were conducted on several occasions in July and August 1987, in a backyard garden at Remete Kertváros (Budapest, Hungary) and in a commercial apple orchard at Halásztelek, typically from 11 AM until 1 PM.

The dispenser of the attractant consisted of a small piece (10 \times 10 mm) of filter paper attached to a small piece of metal wire. Compounds to be tested were applied in 10- μ l hexane solutions to the filter paper on the spot, a few minutes before starting the observations. Observations with such a dispenser were carried out during ca. 30 min, then both the dispenser and the platform holding it were discarded. For observations with a new dispenser, new platforms were used also.

Observations started when a male could be seen approaching at 50–70 cm from the platform. The males were scored for locating the attractant source and displaying bursts of wing buzzing. The number of visits to the source per male was also recorded. Time spent from landing on the plastic platform to locating the source, spent on the source per male, and spent on the source per visit was also measured.

RESULTS

Trapping. In trials of pure stereoisomers of 5,9-dimethylheptadecane as single attractant compounds at both sites, the *S,S* isomer caught an outstanding number of males (Figure 1). Catches of the other stereoisomers did not signif-

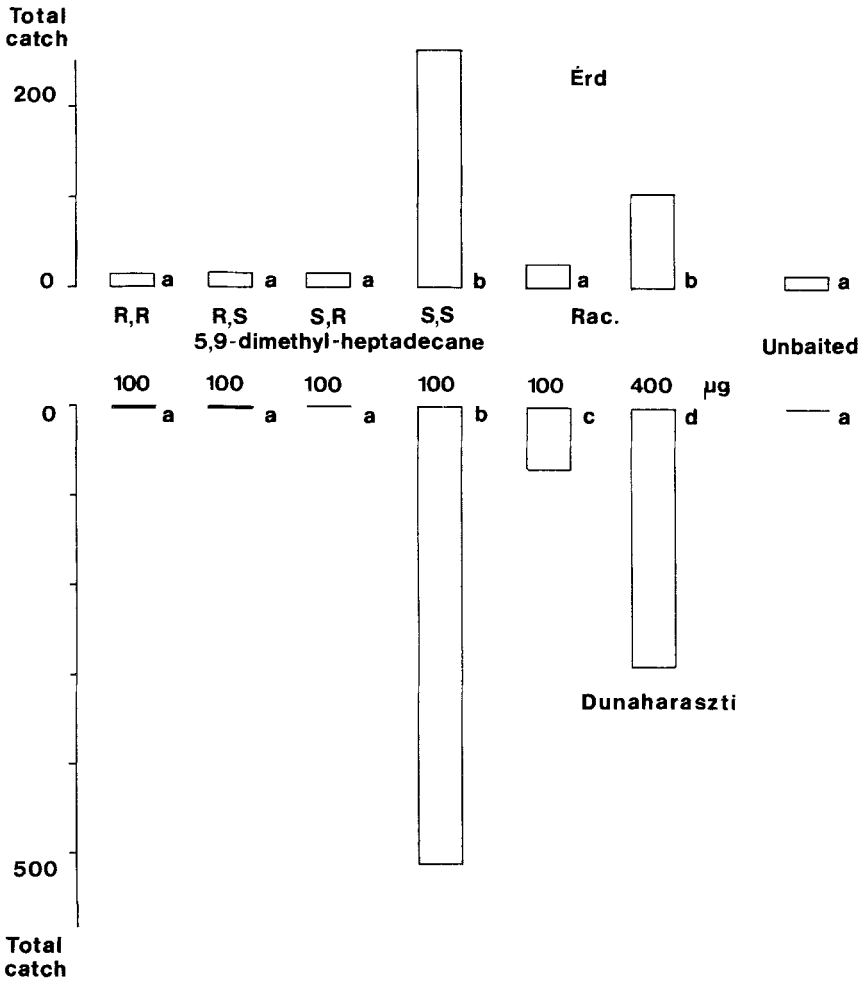

FIG. 1. Captures of male *L. scitella* in traps baited with pure stereoisomers or a racemic mixture of 5,9-dimethylheptadecanes, and unbaited traps. Catches with same letters are not significantly different at $P = 5\%$ by Duncan's NMRT after $\log(x + 1)$ transformation of data. Érd: May 8–19, 1987; four replicates. Dunaharaszti: May 9–21, 1987; four replicates.

icantly differ from the unbaited control. The 100-µg dose of the racemic mixture caught significantly more males than the control only at the site having a higher population density (Dunaharaszti). The catch of the 400-µg dose of the racemic mixture was higher at Érd, not differing from that of the *S,S* isomer.

Low percentages of the racemic mixture of 5,9-dimethylhexadecanes added to the *S,S* isomer did not alter catches (Figure 2) at either site.

Binary mixtures of the *S,S* isomer with the other stereoisomers (ratio: 1 : 1) also caught as many males as the *S,S* isomer alone (Table 1).

In a dosage test, the best catches were obtained with the highest dose of the *S,S* isomer at both the low and high population density sites (Érd, and Halásztelek, respectively) (Figure 3). Lower doses caught gradually decreasing numbers.

No other moth species was attracted to any of the baits in these tests.

Direct Observations of Male Behavior. When setting up a new attractant source, males approached after a few minutes. They moved inside the canopy of trees and, instead of flying freely, flew from one leaf to another in short spurts (not covering more than ca. 15–20 cm on any one occasion) and spent considerable time walking on the leaves or branches before flying further. On most occasions, arriving at the edge or outside corner, they turned against the wind, and remained standing, spreading and slightly moving their antennae before flying again. As they got closer, the males alighted on the platform hold-

ing the attractant source, at a distance of several centimeters from the source. Once on the platform, they searched for the attractant source exclusively by walking; in no case was the characteristic zigzag flight approach to the source (common to many other moths) observed.

In some cases, males walking on the platform displayed a short burst of wing buzzing, characteristic of the courtship sequence of this species (a detailed description of courtship behavior of *L. scitella* will be published elsewhere).

Arriving at close proximity (less than 1 cm) to the source, these bursts of wing buzzing repeatedly followed each other, and the male climbed up to the filter paper and spent considerable time walking and searching on it. In most cases during this time, it also displayed numerous bursts of wing buzzing.

On several occasions males left the filter paper, walked down to the platform, and then returned for more visits. After one or more visits to the source, males left, in most cases by flying up from the filter paper, and disappearing among the nearby leaves.

In the observations, males responded similarly to both (*S,S*)-5,9-dimethylheptadecane alone and to its mixture with racemic 5,9-dimethylhexadecanes (3%).

Responses to the two attractants did not show significant differences in percentages locating the source, percentages of males displaying bursts of wing buzzing, and number of visits to the source per male (Table 2). Average time spent from landing on the platform to source location was also very similar. This was also true for time spent on the source per male, or per visit.

TABLE 2. RESPONSES OF *L. scitella* MALES APPROACHING ATTRACTANT SOURCES WITH SYNTHETIC PHEROMONE COMPONENTS IN THE FIELD^a

Source (total dose 1 μ g)	Males locating source (%)	Males with burst(s) of wing-buzzing (%)	Visits to source per male	Time (sec) spent

(<i>S, S</i>)-5,9-Dimethyl- heptadecane	71a (<i>N</i> = 24)	71a (<i>N</i> = 24)	1.9a (<i>N</i> = 17)	37.3a (<i>N</i> = 18)	76.9a (<i>N</i> = 18)	37.8a (<i>N</i> = 36)
(<i>S, S</i>)-5,9-Dimethyl- heptadecane + rac- 5,9-dimethyl- hexadecane (3%)	71a (<i>N</i> = 14)	64a (<i>N</i> = 14)	1.3a (<i>N</i> = 10)	34.5a (<i>N</i> = 10)	57.7a (<i>N</i> = 10)	43.6a (<i>N</i> = 13)

^aData with same letters within a column do not significantly differ at $P = 5\%$ (χ^2 test in % locating source and % with wing buzzing bursts; elsewhere Student's *t* test) (In "visits to source per male," only males that did contact the source were evaluated).

DISCUSSION

The results obtained in the trapping tests clearly substantiate that the *S,S* isomer was behaviorally active. Furthermore, other stereoisomers did not synergize or inhibit catches with the *S,S* isomer. This coincides with the fact that catches of a four times higher dosage of the racemic mixture of 5,9-dimethylheptadecanes were close to the level of catch of the pure *S,S* isomer.

On the basis of the above, we conclude that, although behavioral activity is carried exclusively by the *S,S* isomer, a racemic mixture of 5,9-dimethylheptadecanes would compose a usable constituent in practical baits for monitoring *L. scitella*. Since in the dosage test of the pure *S,S* isomer no saturation level was reached, we recommend using higher (several milligrams) doses of the racemic mixture for practical purposes.

Among taxonomically related Lepidoptera, the only known sex pheromone has been identified as 14-methyl-1-octadecene for *Lyonetia clerkella* L. (Sugie et al., 1984). In later studies of this species, only the *S* isomer possessed field activity (Sato et al., 1985). Similar to the case of *L. scitella* in this study, the other enantiomer did not influence catches of *L. clerkella*, and the racemic mixture could be used for practical purposes (Sato et al., 1985).

No increase in trap captures was observed when small percentages of racemic 5,9-dimethylhexadecane, which was found previously to be present in pheromone effluvia of females (Francke et al., 1989), were added to (*S,S*)-5,9-dimethylheptadecane.

Also, there was no outstanding difference in the behavior of males approaching an attractant source containing a mixture of the heptadecane and hexadecane vs. the heptadecane alone. Consequently, in this study we failed to show any behavioral activity for the previously identified minor component 5,9-dimethylhexadecane. It is possible, however, that this compound influences behavioral events not studied here or other aspects of reproductive behavior.

Acknowledgments—The authors are greatly indebted to Prof. W. Francke for supplying the racemic compounds and for useful advice in the course of the project.

This research was partially supported by grants OTKA 1000 of the Hungarian Academy of Sciences, OMF 5.4, and by the Fond der Chemischen Industrie.

(Received March 2, 1988; accepted July 25, 1988)

Abstract—Unlike many secondary plant substances, a wide range of concentrations (4–1000 mM) of magnesium sulfate, applied to dry beans, significantly increased egg-laying by the dry bean weevil in binary choice tests, in favor of treated seeds. No other magnesium-containing compounds studied exerted such an effect, nor was a similar response noted on treated beans in no-choice situations. The total number of eggs laid per female was in the same range in both types of test. Variably enhanced or suppressed oviposition responses were shown on magnesium sulfate-treated secondary hosts and on nonhosts or on indifferent substrates. No specific behavior by egg-laying bean weevil females on Mg-treated seeds could be detected. The results are explained by assuming the functioning of magnesium as a supernormal stimulus for egg-laying. However, a physiological effect on neuromuscular synaptic transmission, as a consequence of probable Mg uptake resulting in a decreased propensity to move, is also hypothesized.

Key Words—Magnesium sulfate, oviposition, bean weevil, *Acanthoscelides obtectus* Say, Coleoptera, Bruchidae, supernormal stimulus, neuromuscular synaptic depression.

INTRODUCTION

In many biochemical and physiological processes of various species, including man, the presence of magnesium ions is considered to be indispensable (Aikawa, 1981; Ferment and Touitou, 1985). As for insects, water-soluble magnesium compounds usually are deterrent (Dethier, 1968; Simpson, 1978). However, a

strong preference was shown by egg-laying females of egg parasitoids (*Trichogramma* spp.) for artificial host eggs containing higher or close to host hemolymph levels of magnesium and potassium acting synergistically (Nettles et al., 1982, 1983).

In the presence of plant allelochemicals and of inorganic substances applied to dry bean seeds, egg-laying by the bean weevil, *Acanthoscelides obtectus* Say (Coleoptera, Bruchidae), has been depressed to various extents (Muschinek et al., 1976; Jermy and Szentesi, 1978; Szentesi, 1983). Among the substances examined to date, only magnesium sulfate showed the opposite effect, i.e., egg-laying was enhanced by magnesium-treated beans as compared to untreated ones (Jermy and Szentesi, 1978). To our knowledge, no other data exist in the literature concerning the role of magnesium in influencing oviposition in phytophagous insects.

Jermy and Szentesi (1978) briefly indicated the preference showed by the bean weevil for magnesium-treated beans; it was the aim of the present paper to investigate the nature and extent of this preference, examining: (1) the range of compounds eliciting a similar response, (2) the stimulus situation in which the preference is manifested, and (3) whether preference is accompanied by specific behavioral patterns. There is also discussion of two possible modes of action: (1) whether magnesium-treated beans represent a supernormal stimulus, and (2) whether possible uptake of magnesium sulfate might result in changes of behavior reflecting a neurophysiological effect.

METHODS AND MATERIALS

The dry bean weevils were obtained from a mixture of wild (heterogeneous) populations maintained in the laboratory for at least three years on dry beans (Szentesi, 1972). Freshly emerged adults were sieved, kept in glass jars lined with corrugated paper strips, and supplied with 10% honey-water. Adults mated in the jar and were used at the age of 4 days.

Oviposition was measured in choice and no-choice tests on treated and untreated beans. The surface of the seeds was coated with a given compound by a method described by Muschinek et al. (1976). In short, 0.25 ml of a compound's solution or suspension was dried onto the surface of 10 g seeds by a cold or warm (about 93–96°C) airstream for 1 min.

The quantity of magnesium salts, both administered and naturally present, was determined by chemical analysis and by atomic absorption spectrophotometry (AAS). The results are given as percentage magnesium in relation to absolute dry matter (Table 1).

The uniformity of magnesium sulfate deposits on coated surfaces was assessed on 8-mm-diam. (201-mm² surface) glass beads, treated by the standard

procedure with 37 mM magnesium sulfate. Microscopic examination has shown that there were 7.1 ± 0.7 (mean \pm SE) magnesium sulfate crystals per square millimeter on the glass beads. The size of the crystals varied between 0.04 and 0.87 mm.

Titrimetry showed that the loss of chemicals during treatment was within the range of 5-10% and that individual seeds received, e.g., in case of 111 mM concentration, 0.103 mg magnesium sulfate per square millimeter of seed surface.

Magnesium sulfate was incorporated into pills. Pills of different kinds consisting of bean pod or seed powder, potato starch, and cellulose powder were prepared in various compositions. As sticking materials, distilled water, glycerine and soluble cellulose, to which magnesium sulfate was added to give a 100 mM concentration, were used. The 6-mm-diam. pills were prepared with a pharmaceutical device. These were dried at 45°C and used for oviposition tests. The pills of different types weighed 91 ± 2 (SD) to 165 ± 7 mg.

In choice tests, solvent-treated and coated leguminous seeds were offered

in 10-cm-diam. Petri dishes divided into four sections. Opposite sections contained the same stimulus. Ten males and 10 females were confined in each dish for 10 days. For no-choice tests, 2.8×5 -cm size vials were used, each having three or four pieces of oviposition material and three to four males and females. The vials were covered with pieces of linen cloth.

Tests were conducted in total darkness, at 23°C and 60–70% relative humidity, without food or water for the adults. The number of eggs laid per female was used for evaluation. Preference was expressed by a discrimination quotient (DQ) (David and van Herrewage, 1970) (see legend of Figure 1). Statistical evaluations were done on the basis of the number of eggs laid [Wilcoxon's signed-ranks test, Student's t test, or Duncan's new multiple-range (DNMR) test; Steel and Torrie, 1960; Sokal and Rohlf, 1969].

All chemicals used were of analytical grade, unless otherwise stated.

FIG. 1. Dose-response curve of egg-laying *A. obtectus* females to beans in binary choice tests treated with magnesium sulfate at different concentrations. Values are expressed as discrimination quotient (DQ) (David and van Herrewage, 1970) given by the ratio: (No. of eggs laid on treated - No. of eggs laid on control)/Total No. of eggs laid. To obtain a percentage value, the ratio is multiplied by 100. Concentrations: 1.3, 4, 12, 37, 111, 333, 1000, and 3000 mM. SE = standard error (bars). Means followed by the same letters are not significantly different at the 1% probability level (DNMR test for ESS).

Experiments with Magnesium Sulfate on Bean Seeds. Eight millimolar levels of $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ were examined from 1.3 to 3000 (Figure 1). Magnesium sulfate of two purity grades, different lengths of treatment time, cold and warm application, as well as different exposure times of treated seeds to ovipositing adults were also tested.

Experiments with Other Magnesium or Sulfate Compounds. In addition, other magnesium compounds (Table 3) were tested at 111 mM. Some of them were applied as suspensions in 2% potato starch solution, while aqueous solutions were used for the rest. Other sulfate-containing compounds and sulfuric acid were also tried (Table 3).

Experiments with Magnesium Sulfate on Various Oviposition Substrates. Heterogeneous-type bean weevil females lay eggs on a range of substrates (Pouzat, 1975; Basky, 1977; Szentesi, 1976; Jermy and Szentesi, 1978). Occasional and secondary hosts (peas, lentils, and soybeans), and partially or totally indifferent substrates (e.g., glass beads, starch + cellulose pills, dry seed cotyledon devoid of testa) were also treated with magnesium sulfate (111 mM conc.). These substrates were offered both in choice and no-choice tests for egg-laying.

Experiments on Direct Effect of Magnesium Sulfate on Adult Behavior. Twenty 2- to 4-day-old *A. obtectus* females deprived of egg-laying but mated were allowed to oviposit on control and 111 mM Magnesium sulfate-treated seeds. Single seeds with hilum upright were stuck to the bottom of 2.8×5 -cm glass vials. Homogeneous illumination (1900 lux) was provided. Temperature inside the open vial was 30°C . Individual mated females were put onto the beans and allowed to perform preovipositional behavior, which was observed through a binocular microscope and simultaneously tape-recorded.

Bean weevil adults can take up magnesium sulfate from treated seed surfaces, and this might affect behavior. For "voluntary" uptake, 3-day-old mated females were allowed to move and lay eggs on untreated or treated seeds, among which cotton wicks were placed containing 1 ml honey-water or honey-water + 10 or 100 mg magnesium sulfate. The cotton wicks were replaced daily (five females per Petri dish; 11 replicates). For "forced" uptake of magnesium sulfate two groups of adults were confined in cages without beans for three days. The cages were kept at 28°C , and drinking of honey-water containing the salt (100 mg/ml) was ensured. "Magnesium drunk" adults (10 males and 10 females) were transferred onto dry beans (15 replicates). In both cases locomotor activity of adults was monitored for 3-4 hr daily for four to nine days, at 15-min intervals. The eggs laid were also counted.

In a choice test, presence of a mated female in the treated or untreated section was recorded hourly, 3-8 hr/day, for 13 days. Light intensity was 600 ± 300 lux (299 replicates).

The effect of "built-in" magnesium on moving activity was examined by rearing the bean weevils both in control pills containing 0.5% magnesium sul-

fate (near the range occurring in whole seeds of legumes: Nehring et al., 1972, cited by Szabó, 1980; Spector, 1956, cited by Mándy et al., 1980), and in treated ones containing 1, 2.5, and 5% of magnesium sulfate. Pills were infested with a single egg each. The adults that emerged were put onto untreated bean seeds in Petri dishes. Ambulatory movement of six adults (three females and three males) per replicate was recorded for nine days for 4–8 hr/day at half-hour intervals (seven to nine replicates).

RESULTS

AAS analysis revealed that bean seed coat, bean pod, and bean pod stem contained approximately two to three times more magnesium than whole seeds of some bean varieties or than bean cotyledon alone. Leguminous seeds were in the same range as dry beans, while soybeans contained a slightly higher percentage (Table 1).

Effects of Bean Seeds Covered with Magnesium Sulfate. In choice tests beans treated with 4–330 mM magnesium sulfate were significantly preferred for egg-laying with a maximum at 37 mM (Figure 1). In no-choice tests, the number of eggs laid with a concentration spectrum of 4–3000 mM ranged between 37 ± 7 (mean \pm SD) and 44 ± 8 , and none of the values was significantly different. On control beans, females laid 37 ± 8 eggs. Also, beans were equally preferred whether treatment was applied warm or cold (Table 2). Preference for treated seeds gradually decreased as treatment time increased. Impurities in the compound (e.g., other unknown inorganic elements) or ways of treatment did not influence preference (Table 3).

Effects of Other Magnesium or Sulfate Compounds. No bean seeds treated with other magnesium or sulfate-containing compounds were preferred in choice tests, although some proved to be neutral. The sulfate moiety alone slightly depressed egg-laying (Table 3).

Effects of Magnesium Sulfate Administered to Various Oviposition Substrates. Generally, preference for other magnesium sulfate-treated leguminous seeds and for treated bean seed coat pills increased (Table 4). In spite of the magnesium treatment, indifferent substrates (e.g., glass beads, starch pills) were not preferred. Females laid significantly ($P = 0.5\%$) more eggs on peeled halved bean cotyledons treated with magnesium sulfate (Table 4).

Results of Behavioral Experiments. No specific behavior related to magnesium sulfate treatment was observed. The exploratory phase comprising palpation, chewing into and around the hilum, etc., as well as preoviposition and egg deposition phases, all seemed to be performed in the same manner on magnesium-treated and control beans.

Free access to 10 or 100 mg magnesium sulfate/ml honey–water did not result in a decrease of moving activity during the nine days of observation (Table 5).

TABLE 2. EGG-LAYING RESPONSE OF *A. obtectus* FEMALES TO EXPOSURES AND TREATMENTS OF 111 mM MAGNESIUM SULFATE ON DRY BEANS IN BINARY CHOICE TESTS ($N = 9-14$)

TABLE 5. MOVING ACTIVITY OF *A. obtectus* ADULTS AFTER VOLUNTARY AND FORCED UPTAKE OF MAGNESIUM SULFATE FROM DRINKING WATER (HONEY-WATER) (*N* = 11-15)

Solution	Moving activity (mean ± SD) per female per 15 min (observational units)	
	Free access	Forced uptake
10 mg magnesium/ml (untreated beans)	0.11 ± 0.09a	—
100 mg magnesium/ml (untreated beans)	0.09 ± 0.07a	0.11 ± 0.06A
Honey-water only (magnesium-treated beans)	0.12 ± 0.09a	—
Honey-water only (untreated beans)	0.11 ± 0.8a	0.19 ± 0.05B

a = NS; A and B = $P \ll 0.1\%$ (Student's *t* test, $t_{\text{calc.}} = 8.149$, $df = 118$).

The rate and amount of magnesium uptake by the females is unknown, although they were observed drinking honey-water containing the salt. Mortality was the same for all groups during the observation period.

“Forced” uptake of magnesium significantly decreased moving activity (Table 5). The number of eggs laid by the two groups were: 75.3 ± 2.5 (control) vs. 33.2 ± 6.1 (“magnesium-drunk”) (mean \pm SD) eggs per female ($P < 0.1\%$, Student’s t test, $t_{\text{calc.}} = 14.08$, $df = 28$). High mortality ($37.3 \pm 11.8\%$ vs. $3.0 \pm 4.1\%$) occurred among “magnesium-drunk” adults by the third day of observation.

Mated females stayed significantly more frequently on magnesium-treated beans in choice tests. During 13 days, 200 females were found on 12,500 occasions on, under, or in the immediate vicinity of magnesium-treated beans vs. 7994 occasions on untreated ones ($P = 1\%$, Wilcoxon’s signed-ranks test for paired observations). The egg-laying response reflected the same preference for magnesium-treated seeds [32.4 ± 14.7 (mean \pm SD) vs. 26.6 ± 14.2 eggs, $P = 0.1\%$, $t_{\text{calc.}} = 3.43$, $N = 200$].

Adults that emerged from pills containing elevated magnesium during their larval development did not show any decreased level of moving activity following emergence.

DISCUSSION

Phytophagous insects live in a chemically extremely diverse milieu where a multitude of plant chemicals carry information. The principal components of this milieu are organic molecules. In contrast, inorganic substances are only very rarely the basic determinants of acceptance or rejection, although some insects do show characteristic responses to them (Dethier, 1968; Simpson, 1978). Earlier studies cited by Dethier (1953) on taste and oviposition perception of electrolytes by several species of insects, listed magnesium ions among the unacceptable cations, albeit not among the most unacceptable ones.

The experiments carried out in this study not only strengthened the earlier finding (Jermy and Szentesi, 1978), namely, that ovipositing females preferred magnesium-treated bean seeds, but they also revealed that a relatively wide (circa 100-fold) concentration range (4–330 mM) of magnesium sulfate “stimulated” egg-laying (Figure 1). Such direct stimulation by magnesium and other cations acting synergistically has been shown so far only in an egg-parasitoid (Nettles et al., 1982, 1983). Thus, this is the only known case of magnesium sulfate by itself enhancing oviposition of a phytophagous insect species.

The AAS analysis revealed that the distribution of magnesium is more or less specific in the host plant (Table 1). The results of whole seed analyses agree with data in the literature (see references in Table 1). Some plant parts

(seed testa, pod, and stem) contain approximately twice as much magnesium as the whole seed and three times more than seed cotyledon alone. As bean weevil females come into contact with the seed coat during oviposition, the pronounced preference for the seed could be partially explained by the presence of this single influential factor, although other chemicals acting on the olfactory and gustatory systems, as well as shape or size, etc., of the oviposition substrate are also important (Avidov, 1965; Pouzat, 1974a,b, 1975; Szentesi, 1976).

As for the perception of magnesium deposits on the treated seeds, Chapman (1977) has shown that insect gustatory receptors can respond to solid substances. Uptake of magnesium deposits from the bean surface is likely to occur, since ejection and uptake of small quantities of saliva by the bean weevil, while examining the seed surface, can regularly be observed (Huignard, personal communication; Szentesi, unpublished). That magnesium ions might be able to bond to substances on the surface of dry seeds during surface treatment seems improbable. Binocular (and scanning electron) microscopic examinations have revealed no conspicuous changes on the surface of the treated seeds. A chemical alteration of the seed surface, although possible, is unlikely.

Treatment time did alter the oviposition response, namely, the longer the coating process took the less acceptable the seed became (Table 2). No explanation is suggested for this phenomenon. (Usual treatment time never exceeded 1 min.) The biased egg-laying response had occurred by two days and did not show a further change from then on (Table 2).

Other magnesium- or sulfate-containing compounds showed either oviposition inhibition, namely, the water-soluble ones, or were ineffective (the weakly or not soluble compounds) (Table 3). The anion moiety alone could not be responsible for the preference for magnesium sulfate, since sulfuric acid treatment and other sulfate-containing chemicals did not increase the acceptability of bean seeds (Table 3).

The females responded positively not only to treated dry beans, but also to other leguminous seeds following magnesium treatment. For instance, the ovipositional status of lentil, pea, and bean cotyledon devoid of testa, and pills incorporating bean seed coat improved relative to their own respective controls, although their suitability for egg-laying without magnesium treatment was relatively low (Table 4). On the other hand, although soybeans were relatively highly rated for oviposition by *A. obtectus* females (Jermy and Szentesi, 1978), magnesium sulfate treatment decreased this status. Starch pills, a poor egg-laying substrate were even inferior after magnesium treatment, while glass beads remained neutral in effect.

Direct observation of egg-laying females on magnesium sulfate-treated beans did not reveal any specific behavioral pattern related to the presence of

this salt. However, an arrestant effect of magnesium sulfate was proven in choice tests in which females were found significantly more frequently staying on treated beans, resulting also in a significantly higher number of eggs laid on such seeds. This arrestment effect seems to support the notion that magnesium-treated bean seeds may function as a supernormal stimulus for the bean weevil females, as defined by Manning (1972). The natural magnesium content of seed testa, acting together with factors such as shape, specific organic substances, etc., provide the normal stimulus pattern, while an additional 20–40% increase of magnesium by treatment with the salt represents supernormality. As a result, in choice tests magnesium-treated seeds were more readily oviposited upon (Figure 1), while in a no-choice situation there was always the same number of eggs laid on both types of seeds. The latter merely refers to the maximum response possible and that magnesium sulfate alone does not stimulate egg-laying.

Supernormality presupposes a stimulus situation in which choice can be exercised, or in which essential stimuli (shape, size, coloration, etc.) are strongly emphasized (McFarland, 1981). Although, such exaggerated behavioral responses are mostly documented in insects to visual stimuli (Prokopy, 1969; Magnus, 1958), the case reported here may indicate the effect of a supernormal chemical stimulus.

The above reasoning does not exclude another explanation on physiological grounds considering that, during thorough palpation and “licking” of the treated surface, some magnesium sulfate must be ingested. Considering the many important roles of magnesium in a living organism (Bara, 1977; Aikawa, 1981; Levine and Coburn, 1984; Ferment and Touitou, 1985), it has been shown that excess magnesium ions might depress both neuromuscular and other types of synaptic transmission, as shown in insects by Hoyle (1955), Callec (1974), Fukami et al. (1984); in mollusks by Burton et al. (1987); and in vertebrates by del Castillo and Engbaek (1954), Ault et al. (1980), Artemenko and Gerasimov (1984), and others. The depression would then result in a low propensity to move. However, an observable reduction in moving activity was found only when adults of *A. obtectus* were forced to take up magnesium sulfate with drinking water (Table 5) and not in the case of free access to magnesium-containing drinking water or when having developed in pills with elevated salt concentration. Nevertheless, it cannot be excluded that a very slight decrease in propensity to move, which may easily escape direct observation, may result in longer stays on treated beans, i.e., in increased number of eggs laid on them. This is the more likely since the behaviorally active doses that were applied in the study were well within the range found effective in other studies (e.g., Nettles et al., 1982, 1983; del Castillo and Engbaek, 1954).

CONCLUSIONS

The preference of egg-laying by *A. obtectus* females for magnesium sulfate-treated beans can be explained partly by the two hypotheses, although the functioning of magnesium sulfate as a supernormal chemical stimulus seems more probable. It is also likely that females do not find a situation in nature where such a preference could be exercised; therefore, the adaptive significance of the behavior is highly questionable. However, a possible implication would be that an increase of magnesium concentration in the hemolymph or blood of hibernating or overwintering animals provides a means of freeze-resistance (Aikawa, 1981). Magnesium uptake by bean weevil adults could serve a similar purpose as they also hibernate as adults. However, both hypotheses and, especially, the latter speculation would need further investigation to clarify the details sufficiently.

Acknowledgments—I thank Drs. T. Jermy (Budapest, Hungary), J. Huignard (Tours, France), and W. Blaney (London, U.K.) for comments and suggestions and for grammatical correction of the manuscript; J. Kocz for carrying out the AAS analysis; and Mrs. M. Mydlo and T. Tihanyi for valuable assistance.

FEMALE SEX PHEROMONE OF IRIS BORER,
Macronoctua onusta (LEPIDOPTERA:
NOCTUIDAE)

(Received April 21, 1988; accepted July 25, 1988)

Abstract—Chromatographic and mass spectrometry studies of heptane extracts of the ovipositors of the iris borer, *Macronoctua onusta*, showed that the females produce several compounds that are the same as those produced by females of the tobacco budworm, *Heliothis virescens*. In trapping experiments, a mixture of (Z)-11-hexadecenal, (Z)-11-hexadecen-1-ol, and (Z)-9-tetradecenal (94:4:2) proved to be the minimum set of compounds required to cause effective capture of iris borer males in the field.

Key Words—(Z)-11-Hexadecenal, (Z)-11-hexadecen-1-ol, (Z)-9-tetradecenal, iris, iris borer, *Macronoctua onusta*, tobacco budworm, *Heliothis virescens*, Lepidoptera, Noctuidae.

INTRODUCTION

The iris borer (*Macronoctua onusta*, Grote) is the major lepidopterous pest insect in iris (*Iris versicolor* L.) throughout much of North America. Larvae, feeding in rhizomes, can destroy entire iris beds. Adults of the species are nocturnal and they emerge, mate, and females lay eggs on iris in the fall (September–October). Eggs hatch in spring, and larvae feed in the leaves and then bore into the rhizomes (Schread, 1970; Neiswander, 1961). We became interested in determining the composition of the female sex pheromone of this insect because it was thought that a synthetic replica of the pheromone might prove useful to iris growers wishing to monitor flight activity of the pest.

We report that the array of pheromonal compounds produced by the iris borer female resembles those previously found in the female tobacco budworm, *Heliothis virescens* (Fabricius) (Klun et al., 1980; Teal et al., 1986), and that a mixture of *Z*-11-hexadecenal, (*Z*)-11-hexadecen-1-ol and (*Z*)-9-tetradecenal (94:4:2) is the minimum set of compounds required to effectively cause capture of iris borer males in the field.

METHODS AND MATERIALS

Insects. In August 1983 and 1984, rhizomes infested with late-instar larvae of the borer were collected from iris beds in the vicinity of Beltsville, Maryland, transplanted to potting soil, and held in a greenhouse. Pupae of the borer were recovered from the pots and transferred to screen-covered plastic containers containing ca. 5 cm moist soil to await emergence of adults. Adult females were held at ambient conditions of the greenhouse for two to three days after emergence. At that time, their ovipositors were excised at the onset of scotophase, soaked in ca. 25 μ l heptane/ovipositor for ca. 10 min, and then the solvent was drawn away from the ovipositors and stored at -4°C in a screw-cap vial. In one case, a set of six ovipositors was extracted twice: first by a brief soak (10 min) in 100 μ l heptane followed by soaking in a second volume of solvent for 1 hr. The onset of scotophase was selected as the time for preparation of extracts because previous work (Schread, 1970) indicated that the adults mate nocturnally, and we surmised that pheromone titers in the females would likely be highest at that time. In all, we obtained extracts of four females in 1983 and 10 females in 1984 that permitted analyses by capillary gas chromatography (GC), using polar and nonpolar columns (Klun and Huettel, 1989), and also analysis by combined GC-mass spectrometry (MS), using instruments and operating conditions described by Klun et al. (1982).

Attempts to obtain additional adult females by rearing early-instar field-collected larvae on artificial diets of the European corn borer (Reed et al., 1972) and corn earworm (Burton, 1970) were unsuccessful. Consequently, supplies of insects for chemical and field studies were severely restricted throughout this research and virgin females were available for inclusion in field trapping experiments in only the first year of the study.

Chemicals and Male Trapping Tests. All compounds were previously synthesized at the Insect Chemical Ecology Lab and were purified by preparative liquid chromatography using two 25-cm \times 10-mm (ID) stainless-steel tubes packed with 20% AgNO_3 -impregnated 10 μ m Spherisorb and toluene as eluant. All compounds were geometrically pure and were greater than 95% chemically pure according to GC analyses. In field trapping tests, conducted during October 1984–1987, mixtures of the compounds identified from female ovipositor

extracts were applied in microgram amounts to either cotton dental rolls (1984 season) or rubber septa (Thomas Scientific, catalog No. 1780-J07) that were positioned in Pherocon 1C, or *Heliothis* Scentry (1986 field tests only) insect traps (Great Lakes IPM, Vestaburg, Michigan 48891). The cotton rolls were used initially in the field tests because one of us (J.A.K.) had used them previously in a study of the tobacco budworm pheromone (Klun et al., 1980) and found that, when an appropriate mixture of compounds was evaporated from cotton rolls in field traps, they caused capture of males more effectively than traps baited with four virgin tobacco budworm females. Inasmuch as the compounds we were dealing with were the same as those of the tobacco budworm, we reasoned that cotton was a suitable substrate to use in the iris borer field tests. The cotton rolls were replaced nightly, while fresh septa were positioned in the traps weekly. The septa were chosen as evaporative substrates for the bulk of the field tests for convenience and because they have been used routinely to control the evaporation of compounds in studies of the pheromone systems of many moths (Heath et al., 1986). When Pherocon 1C traps were used, the lower interior surface of the traps was coated with Tack Trap to ensure trap-capture efficiency at the cool nighttime temperatures of October; Tack Trap is a polymer that is less viscous than the adhesive normally used by the commercial manufacturer. Virgin iris borer females were individually hung in traps within a small cylindrical cage. Traps were suspended ca. 1 m from the ground on stakes driven into the ground. The traps, containing specific mixtures of compounds, were positioned in urban areas known to have iris plantings. Traps were ca. 10 m apart, and all tests were replicated over time and were conducted using a randomized complete block design with 1–20 km between blocks (replicates). Duncan's multiple-range test was applied to test for significant differences between mean total male captures across replicates for each treatment.

RESULTS AND DISCUSSION

GC and GC-MS. Figure 1 shows the chromatogram obtained by analysis of an aliquot of sample (ca. 0.2 female equivalent) of the combined ovipositor extracts of four iris borer females in 1983 with a Carbowax 20 M capillary column. This analysis and subsequent analyses of samples taken from other extracts showed that they all contained the nine pheromone-like compounds. The identities of these compounds were first established by coincidence of their retention times with standard compounds on Carbowax 20 M and DB-1 capillary columns, and then all of them were verified by GC-MS; the mass spectra of compounds detected were identical to those of the standard compounds. The percentage composition of the pheromonal compounds in extracts of four females, the combined extracts of six females (rinse and soak), three females,

HC₁ = tricosane; HC₂ = pentacosane. Other peaks in the chromatogram were contaminants in the solvent or did not appear regularly from one analysis to another.

and an individual female are shown in Table 1. It is noteworthy that the set of compounds produced by females of the iris borer are similar to those produced by the tobacco budworm, *Heliothis virescens* (Teal et al., 1986); all compounds found in the tobacco budworm, with exception of Z7-16:Ald, occur in the iris borer. The major component in the extracts was (*Z*)-11-hexadecenal (Z11-16:Ald), with exception of a solution obtained by soaking the ovipositors in the solvent for an hour; it contained (*Z*)-11-hexadecen-1-ol (Z11-16:OH) in greatest abundance (57%). Inasmuch as the 10-min rinse of the same ovipositors contained proportionately less alcohol than that obtained by prolonged

extraction, it is probable that the large quantity of alcohol found in the extracts is reflective of a comparatively large alcohol metabolic pool that exists within the pheromone gland. The alcohol in the iris borer is quite likely a biosynthetic precursor of Z11-16: Ald; in *Heliothis*, Tumlinson and Teal (1987) have shown that an alcohol oxidase in the insect cuticle is responsible for generation of pheromonal aldehydes, and it is reasonable to suspect that a similar enzyme occurs in the iris borer. The next most abundant compound in the iris borer extracts was hexadecanal (16: Ald) along with traces of tetradecanal (14: Ald), (Z)-9-tetradecenal (Z9-14: Ald), tetradecan-1-ol (14: OH), (Z)-9-hexadecenal (Z9-16: Ald), (Z)-9-tetradecen-1-ol (Z9-14: OH), and hexadecan-1-ol (16: OH).

In the first field-trapping experiment (1984), three mixtures of compounds and virgin females were deployed (Table 2). Treatment 1 contained all pheromonal compounds identified in the female extracts with exception of the trace amounts of 14: OH and 16: OH; these were excluded to minimize the possible number of permutations of compounds to be tested. The ratio of Z11-16: Ald to Z11-16: OH (73:27) in treatment 1 approximated the ratio observed in ovipositor extracts of 1983. Treatment 2 lacked Z11-16: OH, and treatment 3 differed from treatment 1 in that the Ald-OH ratio was arbitrarily set at 96:4. Proportionately less alcohol was selected for treatment three because we surmised that the ratio observed in the female extracts overestimated the amount of alcohol that the females might actually release when calling for a mate. The

trapping test (table 2) indicated that this assumption was sound because the 96:4 ratio caused capture of more males than the 73:27 ratio or the virgin females. Thus, the 96:4 Ald-OH ratio probably is a better approximation of the ratio produced by the female than is the 73:27 ratio found in the ovipositor extracts. Similar results were obtained by Raina et al. (1986) in a study of the female sex pheromone of another noctuid moth, *H. phloxiphaga*. They found that a combination of Z11-16:Ald: Z11-16:OH was critical for elicitation of optimal response from males and that proportionately less alcohol than that

found in female extracts was the more effective male lure. Such a phenomenon has also shown to be the case for *H. virescens* (Ramaswamy et al., 1985; Shaver et al., 1987); with levels of alcohol at 0.25–1% of Z11–16:Ald field trap captures were enhanced, but at 5.9% Z11–16:OH (ca. the highest amount found in gland extracts according to Klun et al., 1980) captures were suppressed. In case of the iris borer, the question of what ratio is actually released by the female can only be answered definitively by analysis of the volatiles produced by the females. The 1984 trapping test definitively showed, however, that Z11–16:OH was an essential pheromonal component; no males were captured when it was deleted from the stimulus.

Data collected in field tests from 1985 through 1987 (Table 2) revealed that the minimum set of compounds required to effectively cause capture of iris borer males was a mixture of Z11–16:Ald, Z11–16:OH, and Z9–14:Ald (94:4:2). This mixture can be used as a male attractant for monitoring flights of the pest.

Acknowledgments—We thank Dr. Meyer Schwarz for synthesis of many of the compounds used in this study, E.D. DeVilbiss for gathering mass spectra, and E.C. Uebel for technical assistance.

Abstract—In an investigation of potential chemical activity of fire-sensitive shrubs in Florida's sand pine scrub community, bioassays of foliar washes of *Conradina canescens* showed significant inhibitory activity on three native grasses that are known to fuel frequent surface fires; inhibition was concentrated seasonally in spring and summer. Application of runoff from *Conradina* leaves to one of the grasses caused a 50% reduction in growth over a 20-week period. Isolation of the biologically active fractions from the fresh leaves of *C. canescens* yielded numerous monoterpenes, a number of which were identified from a GC-MS reference library and/or MS comparison to authentic compounds: 11 from the diethyl ether extract, 11 from steam distillation, and four from the foliar leaf wash. Numerous other monoterpenes present in the extractions were unknown. The terpenoid fraction completely inhibited seed germination of one of the native grasses and of lettuce. Saturated aqueous solutions of nine of the monoterpenes inhibited germination and radicle growth of two native grasses. SEM views of the leaf surfaces of *Conradina* reveal secretory trichomes that appear to be the source of the monoterpenes as well as the triterpene, ursolic acid. The biological activity of *C. canescens* as a fire-sensitive component of the scrub community is reviewed in light of the chemical evidence.

Key Words—Allelopathy, fire, monoterpenes, trichomes, *Conradina canescens*, *Pinus*, *Schizachyrium scoparium*.

INTRODUCTION

Two different plant communities exist on the upland, well-drained sands of Florida: the sand pine scrub characterized by sand pine [*Pinus clausa* (Chapm. ex Engelm.) Vasey ex Sarg.] with a dense shrub cover but no herbaceous ground cover, and the sandhill or high pineland dominated by longleaf pine (*P. palustris* Mill.) with a complete graminoid ground cover but few shrubs (Chapman, 1932; Laessle, 1958; Garren, 1943). Fire is a frequent feature of the sandhill, burning through the deciduous surface fuels every three to eight years (Williamson and Black, 1981). However, healthy scrub, which is evergreen, burns infrequently, about once in 50 years or once per generation of the dominant sand pine, which regenerates via serotinous cones (Harper, 1915; Richardson, 1977). As scrub and sandhill communities both occur on upland sandy soils, they are intermingled and contiguous throughout the Gulf Coastal Plain. The difference in fire susceptibility is remarkable in that fires sweep through the sandhills until they encounter patches or strands of scrub, where often they are extinguished by changes in the fuel and live vegetation. Webber (1933) called the scrub "a fire-fighting machine," although recognition of the differences between scrub and sandhill trace back to the last century. Nash (1895) noted that "The scrub flora is entirely different from that of the high pine land, hardly a single plant being common to both; in fact these two floras are natural enemies and appear to be constantly fighting each other. . . .," and Whitney (1898) reiterated that "it is an impressive sight to stand at the border line between the scrub and the high pine land and notice the difference in the character of the vegetation."

In the absence of surface fires in the sandhills, the woody species from the scrub will colonize (Laessle, 1958; Veno, 1976). They grow well in the sandhills, often faster than in the scrub, unless a surface fire sweeps through the graminoid ground cover and kills them (Veno, 1976; Hebb, 1982). Large shrubs and especially groups of shrubs may escape mortality, if graminoid growth around them has been suppressed. Therefore, we have been investigating the hypothesis that shrubs from the scrub produce chemicals that inhibit the growth of the grasses and perhaps pines, which provide the fuel for surface fires that otherwise would kill the shrubs. In particular, we are focusing on the early colonizers of the scrub community.

One such species is *Conradina canescens* (Torr. & Gray) (Lamiaceae), a small, evergreen mint, that is endemic to the sand pine scrub community. Its distribution is highly disjunct with two major populations—one on the Gulf coast from Horn Island, Mississippi, to just south of Tallahassee, Florida, and the other concentrated on Florida's Central Ridge in Highlands and Polk counties. In both locations the species is a relatively common shrub, reaching 2 m in height where scrub vegetation is colonizing and in full sunlight, but it diminishes in abundance under the canopy of sand pine and the subcanopy of oaks,

characteristic of mature scrub. The small (2×10 mm), recurved leaves of *Conradina* release a strong mintlike or terpenoid odor when crushed, whereas undamaged leaves emit no odor.

METHODS AND MATERIALS

Foliage from several *Conradina* shrubs was collected monthly from a site near Sun Ray, Florida. Care was taken to cut the stems so as not to tear the leaves in order to prevent the release of internally bound compounds. In the laboratory, 50 g of foliage was placed in 500 ml of distilled water for 24 hr under refrigeration at 8°C. The resulting leaf wash was filtered, and 5 ml was added to 30 target seeds placed on a sheet of Whatman No. 1 filter paper in a 10-cm-diameter Petri dish (Richardson, 1985; Williamson et al., 1988). Seeds of three native sandhill grasses, *Schizachyrium scoparium* (Michx.) Nash, *Andropogon gyrans* Ashe, and *Leptochloa dubia* (HBK.) Nees, were used as target species, each in four replicate dishes kept in the dark at 26°C. Control dishes given distilled water were not adjusted for pH or osmolarity because the *Conradina* leachates were within ranges (5–7 pH, 2–9 mOsm) that did not influence seed germination and growth.

Results of the treatment means (T) were compared to the control means (C) each month in a one-way analysis of variance (ANOVA) with four samples per monthly treatment. The magnitude of inhibition or stimulation is reported as RI, a response index that gives the percentage inhibition of the treatment relative to the control (a negative RI) or the percentage inhibition of the control relative to the treatment (a positive RI, when stimulation occurs). RI values allowed parametric comparisons (Williamson and Richardson, 1988).

A second bioassay was performed by misting water (6 mm/hr) over potted *Conradina* shrubs in a growth chamber and collecting the foliar runoff in glass funnels. Then the runoff was used to water flats ($5 \times 25 \times 60$ cm) of sandhill soil sown with 300 seeds of *Andropogon gyrans*. Control flats were given equal amounts of water. Flats were fertilized to field capacity every 18 days with Peters 20:20:20 (N/P/K). Throughout the experiment the seedlings were thinned only when a plant's leaves reached beyond the stems of its neighbors, so thinning occurred when plants reached a common size, but not necessarily at the same time. After 140 days, each remaining plant was removed from the flat and oven-dried at 105°C for three days, and the weights of leaves and roots were recorded.

Plant material for chemical analysis was collected from Dauphin Island, Alabama, on October 8, 1983, and again from Perdido Key, Alabama, on June 15, 1984. The sites are within 50 km of each other and probably are part of the same population.

Crude extracts of air-dried stems and of air-dried leaves were obtained by sequential use of petroleum ether (PE), diethyl ether (EE), and ethyl alcohol (EtOH) as follows: plant material was soaked in the solvent for 48 hr at 8°C, then filtered by suction and dried before soaking in the next solvent (de la Peña, 1985). Thereafter, the plant material was washed with 60°C ethyl alcohol and finally EtOH-Soxhlet extracted. Solvents were rotary evaporated below 50°C.

Saturated aqueous solutions were prepared from each of the five residues of the crude extracts of both stems and leaves and then tested for biological activity with Petri dish bioassays on *Schizachyrium scoparium*, the same native grass employed in the monthly bioassays. Replication varied from two to four dishes of 30 seeds. In addition, parallel bioassays were performed with commercial lettuce (*Lactuca sativa*).

Inhibitory activity was concentrated predominantly in the EE fraction from the leaves, so further chemical analysis was concentrated there. Silica gel column chromatography of the EE fraction yielded 80 fractions, which were combined according to results of thin-layer chromatography (TLC) into 11 fractions for subsequent bioassays. Biological activity was again concentrated in one sample, EE 6-7, which caused nearly complete inhibition of seed germination. Fractionation of EE 6-7 on a silica gel column yielded 59 fractions, which were combined according to TLC results to give 19 fractions for bioassays; from these, one sample, EE 6.16-6.24 was as inhibitory as EE 6-7. The EE 6.16-6.24 was analyzed using gas chromatography-mass spectral analysis (GC-MS) to identify the components of the mixture. The GC-MS analyses were performed on a Hewlett-Packard model 5985 instrument. A 30-m bonded silica capillary column was used for the GC-MS analysis, under the following conditions: injection temperature 250°C, column temperature program 60° for 1 min., followed by 5°/min. increases to 210°, temperature retained at 210° for 5 min. Compounds were identified by using the computerized MS spectral search system from Hewlett-Packard: Flavor-Fragrance, 59817D National Bureau of Standards Subset Library. Identities of some compounds were further corroborated by comparison of retention times and mass spectra to known standards.

Because many of the compounds in the EE active fraction appeared to be volatile organics, a steam distillation of *Conradina* foliage was undertaken. Fresh leaves in distilled water were boiled with the vapors trapped in an attached condenser. The distillate was extracted with diethyl ether, dried with anhydrous magnesium sulfate, filtered, and concentrated in a rotatory evaporator. The residue, labeled SD (steam distillation), was analyzed (GC-MS) for identification of compounds.

In order to determine compounds that might leach from foliage in precipitation, fresh leaves of *Conradina* were extracted with distilled water as follows: 360 g were twice soaked in 3 liters of distilled water for 3 days at 8°C, and the aqueous extract reextracted with ethyl acetate; the organic layer was dried with

anhydrous magnesium sulfate, filtered, and the solvent rotary evaporated. The 0.6-g residue, labeled Soak, was analyzed (GC-MS) to identify components of the mixture.

Nine of the monoterpenes, identified from the active fractions of *Conradina*, were tested for biological activity on two native grasses, *Leptochloa* and *Schizachyrium*, in triplicate Petri dish bioassays, as described earlier, 30 seeds per dish. Most of these monoterpenes are low-molecular-weight, nonpolar entities, whose solubilities in water have never been determined, so saturated aqueous solutions were prepared for the bioassays here.

Scanning electron micrographs of the surface of the leaves were examined for possible trichomes, as sources of production of active compounds. Both fresh leaves and fresh leaves dipped in an organic solvent, dichloromethane (DCM), were examined.

RESULTS AND DISCUSSION

The monthly bioassays of *Conradina* leaf washes showed similar effects on the three sandhill grasses, with *Leptochloa* experiencing the most inhibition, *Andropogon* the least, and *Schizachyrium* intermediate (Table 1). Simple ANOVAs of each month's data produced significant inhibition of germination in 52% of the monthly tests—in 88% for *Leptochloa*, 44% for *Schizachyrium*, and 25% for *Andropogon*. Inhibition of radicle length was about half as frequent—in 28% of the monthly tests overall, 50% for *Leptochloa*, 22% for *Schizachyrium*, and 12% for *Andropogon*. The frequency of the significant results suggested that inhibition occurred regularly, but not every month.

Species differences in the magnitude of the monthly responses followed

closely their differences in the frequency of significant inhibitions. Average percent inhibition of germination was 22% relative to the control overall—34% for *Leptochloa*, 17% for *Schizachyrium*, and 9% for *Andropogon* (Table 1). Inhibition of radicle length was only 8% of the control overall—13% for *Leptochloa* and 10% for *Schizachyrium*, whereas the control was 3% less than the treatment (stimulation) with *Andropogon* (Table 1). For the three species combined, monthly inhibition averaged 22% for germination and 8% for radicle length.

Monthly variation in bioassay effects was large but by no means random. Inhibition of germination of the three grasses rose to a sharp peak in June and was distinctly absent in the winter months (Figure 1). Inhibition of radicle length seemed to be concentrated in the spring, with less predictable seasonal variation the rest of the year. The monthly germination responses (RI) were negatively correlated with 30-year averages for precipitation ($r = -0.74$, $P = 0.01$) and temperature ($r = -0.72$, $P = 0.01$), so inhibition of germination was concentrated in the warm, wet months—exactly the growing season in central Florida (Figure 1). Radicle length responses were not correlated with precipitation ($r = -0.14$, $P = 0.70$) or temperature ($r = -0.49$, $P = 0.15$).

Application of leaf mist collected from *Conradina* to seedlings of *Andropogon gyrans*, growing in flats of sandhill sand, caused significant ($P = 0.05$)

FIG. 1. Dashed lines show the mean monthly responses (RI) of three sandhill grasses treated with leaf washes of *Conradina canescens* relative to grasses given water controls. Negative RI values are inhibition and positive RI values are stimulation for germination (circles) and radicle length (squares). Solid lines show the 30-year monthly precipitation mean (circles) and the 30-year monthly temperature mean (boxes) near the site (NOAA 1983).

inhibition of growth at the end of the 140-day experiment. Seedlings watered with *Conradina* mist weighed only 48% of the control plants (2.4 ± 0.2 g versus 4.0 ± 0.6 g). Root weights from the *Conradina* treatment were not different from the control (1.0 ± 0.3 g versus 0.9 ± 0.1 g), but leaf weights in the treatment were only 43% of the control (1.4 ± 0.3 g versus 3.1 ± 0.5 g). Height of the grasses given the treatment was only half that of the control plants (43 ± 4 cm versus 86 ± 7 cm). Thus, inhibition of growth was quite strong in the mist test but was not apparent in the Petri dish bioassays with *Andropogon*.

Two possible mechanisms could account for the difference. Growth in the Petri dish tests was limited to one week, but in the mist experiment growth was continued for 20 weeks; therefore, inhibition of *Andropogon* may be limited to later in development. Second, in the Petri dish bioassays, the *Conradina* leachate was applied only once at the beginning of the bioassay, which requires seven days for germination followed by seven days for growth, but in the mist experiment the leaf rinse was applied every three days. If the active compounds are volatiles, as is suggested below, then they may have dissipated from the Petri dishes before radicle growth commenced. The dishes were not sealed, nor were any of the bioassays performed in limited gas volumes, as has been the case in other bioassay studies of volatiles (Muller et al., 1964; Muller, 1965; Muller and del Moral, 1966; Fischer, 1986).

Chemical analysis of *Conradina* foliage revealed a variety of monoterpenes, as is the case with other allelopathic mints (Muller et al., 1964; Muller, 1965; Muller and del Moral, 1966; Fischer, 1986). Many of them were known compounds found in the GC-MS reference library and then confirmed by comparison to standards (Table 2). The diethyl ether (EE) extract produced 11 known monoterpenes, many of them, such as 1,8-cineole, camphor, borneol, and *p*-cymene, inhibitors of seed germination and plant growth (Fischer, 1986). The steam distillation produced 11 known monoterpenes, and the leaf soak produced four known monoterpenes (Table 2). Some (seven of 11) of the known monoterpenes from steam distillation and all of them from the leaf soak (four of four) were also present in the EE extract. The GC traces of the steam distillation and the leaf soak revealed a large number of suspected monoterpenes (lower-molecular-weight compounds) that were not known from the reference library—an indication that *Conradina canescens* contains a highly unique complement of volatile compounds.

Petri dish bioassays of nine of the monoterpenes, applied to *Leptochloa* and *Schizachyrium*, revealed complete inhibition of germination by five compounds and statistically significant inhibition of germination in each case with one exception—cineole did not inhibit *Leptochloa* (Table 2). Where germination did occur, there was subsequent evidence for inhibition of radical growth in most cases, although sample sizes were limited by the small numbers of

germinating seeds (Table 2). Thus, saturated aqueous solutions of most of the monoterpenes tested provided strong phytotoxicity. In these tests the Petri dishes were not sealed, and volatilization of the monoterpenes was quite evident from their odors in the test room, especially the first few days of the experiment. Exactly how such compounds are transmitted to the soil solution in nature remains an enigma, although in chaparral volatiles appear to settle and adsorb on lipophilic clay particles and seed/seedling membranes (Muller and del Moral 1966).

Florida's sandy soils are considerably less lipophilic, but monoterpenes may reach the soil in water runoff. One line of our research suggests that monoterpenes may be associated with biological surfactants that reduce their volatility and increase their solubility in water (Fischer, 1986; Fischer et al., 1988). In the case of *Conradina*, a known triterpene, ursolic acid, composed 6% of the dry weight of the plant and 50% of the crude EE extract (de la Peña, 1985). In acridine dye tests, ursolic acid produced micelles (de la Peña, 1985; Williamson et al., 1988). Therefore, the bioassays with monoterpenes alone (Table

2) may underestimate their activities in nature if they form micelles with ursolic acid or other organic compounds.

Scanning electron micrographs of the leaf surfaces of *Conradina* showed numerous nonglandular, filamentous trichomes as well as fewer glandular, spherical ones. The latter were surrounded and covered by the former, and cross-sections through the latter revealed secretory cells under a fold of the cuticle that harbored the secretion (Figure 2). Similar glandular and nonglandular trichomes are found in some, but not all, mint species (Metcalf and Chalk, 1965). Dipping the leaves in a polar solvent such as diethyl ether or dichloromethane (DCM) dissolved the fold of cuticle and the underlying secretions, whereas the filamentous trichomes remained intact. The resulting DCM extract contained monoterpenes as well as ursolic acid.

In summary, the preliminary results presented here indicate that aqueous washes of foliage of *Conradina canescens* seasonally inhibit germination of

FIG. 2. At left is a cross-section through the leaf and through a glandular trichome on the leaf lower surface; trichome consists of the fold of cuticle, the pocket that contained the secretion, and the underlying secretory cells. At right is the upper leaf surface showing the nonglandular trichomes covering a spherical glandular trichome. Line in the lower right of each micrograph is 50 μm .

native grasses. The washes contain monoterpenes that are probably the source of the antibiosis. The monoterpenes are packaged on the leaf surface with ursolic acid as secretions of trichomes. The secretions are under the cuticle, but rinsing the leaves gives a leachate that contains the monoterpenes, so the leaves appear to provide a leachable source of phytotoxins. Thus, allelopathy may function to prevent the accumulation of fine fuel (grass litter) around *Conradina* shrubs, which otherwise suffer mortality in surface fires. The effects of the allelopathic inhibition relative to other kinds of biological interactions such as competition and herbivory have not yet been investigated, so its importance in nature is still unresolved.

CHANGES IN LEAF MONO- AND SESQUITERPENE METABOLISM WITH NITRATE AVAILABILITY AND LEAF AGE IN *Heterotheca subaxillaris*

CHARLES A. MIHALIAK¹ and DAVID E. LINCOLN

Department of Biology
University of South Carolina
Columbia, South Carolina 29208

(Received May 16, 1988; accepted July 26, 1988)

Abstract—The concentration of leaf mono- and sesquiterpenes is greater in nitrate-limited than in nitrate-rich *Heterotheca subaxillaris* plants and is highest in young leaves and declines with leaf age. To determine whether rates of volatile terpene synthesis and/or loss vary with nitrate availability and leaf age, incorporation of ¹⁴C from photosynthetically fixed ¹⁴CO₂ and the subsequent loss of label was measured in plants grown under nitrate-limited and nitrate-rich conditions. ¹⁴C incorporation into mono- and sesquiterpenes was greater in nitrate-limited than in nitrate-rich plants and was highest in young leaves and declined with leaf age. Incorporation continued for several days after exposure, while loss of label was slow until leaves were 4–6 weeks old. These results suggest that the higher leaf volatile terpene content observed under nitrate limitation apparently results from increased synthesis per leaf and accumulation of mono- and sesquiterpenes in immature leaves of nitrate-poor plants. Furthermore, volatile terpene synthesis is highest in young leaves, declines with leaf age, and is very low in older leaves. Carbon used for synthesis of this pool may be derived from both current photosynthesis as well as carbon transported to young leaves from older leaves. These data are consistent with hypotheses that predict that greater levels of carbon-based chemical defenses occur in plants under nutrient limitation. The apparent low metabolic cost of maintenance (i.e., slow turnover) of the accumulated terpenoid pool would limit the energetic cost of volatile terpenes as a chemical defense.

Key Words—*Heterotheca subaxillaris*, Asteraceae, monoterpene, sesquiterpene, nitrogen, leaf age, metabolism, turnover, chemical defense, biosynthesis.

INTRODUCTION

Reduced plant nitrate availability results in increased accumulation of leaf mono- and sesquiterpenes in *Heterotheca subaxillaris* and may reduce leaf consumption by herbivores (Mihaliak and Lincoln, 1985; Mihaliak et al., 1987). The higher leaf volatile terpene content with nitrate limitation could be due to increased synthesis resulting from changes in allocation of carbon and energy to the sites of terpene synthesis (i.e., in the secretory cells of glandular trichomes). Accumulation of volatile leaf terpenes is thought to be linked to the relationship between photosynthetic rate and the utilization of photosynthate within a leaf (Croteau et al., 1972b; Loomis and Croteau, 1980). Increased leaf nonstructural carbohydrate content in plants growing under low nitrogen conditions (Chapin, 1980; Chapin et al., 1986) may provide an enhanced carbon and energy source for terpene synthesis. Thus, assuming the rate of terpene catabolism is not affected by nitrate availability, increased terpene synthesis at low nitrate supply would result in a higher concentration of leaf terpenes. Alternatively, monoterpenes undergo turnover (Burbott and Loomis, 1969), and slower catabolism could also result in the accumulation of leaf volatiles in nitrate-poor plants.

The concentration of leaf mono- and sesquiterpenes is often highest in young leaves and declines with leaf age (Burbott and Loomis, 1969; Crankshaw and Langenheim, 1981; Mihaliak and Lincoln, 1985). Rapid synthesis of mono- and sesquiterpenes occurs in young leaf tissue (Burbott and Loomis, 1969; Croteau and Loomis, 1972). As leaves age, the rate of terpene synthesis is thought to decline, and the leaf volatiles that accumulated in long-term pools (i.e., in glandular trichomes) may be catabolized (Croteau et al., 1981; Croteau 1984).

The objective of the current experiment was to measure ^{14}C incorporation and loss from the leaf mono- and sesquiterpenes of *Heterotheca subaxillaris* to determine whether: (1) volatile terpene biosynthesis in young leaves of nitrate-limited plants is greater than in comparable leaves of nitrate-rich plants; (2) turnover of volatile terpenes differs with nitrate availability; and (3) volatile terpene synthesis declines with leaf age.

METHODS AND MATERIALS

Heterotheca subaxillaris (Lam.) Britton and Rusby (Asteraceae) (camphorweed) is a herbaceous annual/biennial species that occurs in old fields, disturbed sites, and open sandy areas throughout the southern United States. Forty-one mono- and sesquiterpenes have been identified from the leaves of *H. subaxillaris* (Lincoln and Lawrence, 1984). Seeds collected from a single maternal parent (to reduce genetic variation) at the Clemson University Sandhill

Agriculture Experimental Station near Columbia, South Carolina, were germinated on filter paper and then transferred to a nonnutritive potting media of perlite, vermiculite, and sand (1 : 1 : 1) when the plants were less than 1 week old. The plants were watered on alternate days with either tap water or one of two nutrient solutions, which differed only in the concentration of nitrate (either 1.5 mM or 15.0 mM nitrate) (Mihaliak and Lincoln, 1985) and were maintained on a 12-hr photoperiod in an environmental growth chamber (26°C day, 20°C night) under a light intensity of 260 $\mu\text{mol}/\text{m}^2/\text{sec}$ of photosynthetically active radiation.

Four rosette-stage plants per day were simultaneously exposed to $^{14}\text{CO}_2$ in a sealed Plexiglas chamber (26.63 liter volume). The labeling procedure began 1 hr after the start of the light cycle for all plants when $^{14}\text{CO}_2$ was generated from aqueous $^{14}\text{C}[\text{NaHCO}_3]$ (56 mCi/mmol, 25 μCi per plant) by injecting perchloric acid through a rubber septum into a beaker containing the $^{14}\text{C}[\text{NaHCO}_3]$. During exposure, air in the chamber was circulated with a small electric fan and light was provided using a 400 W mixed-metal halide high-pressure sodium lamp (650 $\mu\text{mol}/\text{m}^2/\text{sec}$ of photosynthetically active radiation at plant height). Air temperature in the chamber remained within 2°C of the ambient laboratory temperature (24°C) during the exposure period. After a 30-min exposure, unincorporated $^{14}\text{CO}_2$ was flushed from the Plexiglas chamber through KOH traps and the plants were returned to the environmental chamber.

Leaves of four different ages from rosettes in each nitrate treatment were analyzed: 1 week old (immature, expanding leaves), 2 weeks old (at or near full expansion), 4 weeks old (mature leaf), and 6 weeks old (senescent necrosis beginning). Each observation reported for leaves 1 or 2 weeks old when labeled is an average of 2 leaves sampled from different plants. The observations reported for 4- and 6-week-old leaves are usually for a single leaf sample. After removal, leaves were immediately placed on dry ice, transported to the laboratory, and weighed. The leaves were then either prepared for analysis or briefly stored at -70°C until sample preparation occurred.

The volatile terpene fraction of each leaf was captured using a microdistillation apparatus modeled after that of Godefroot et al. (1981) and Rijks et al. (1983). The apparatus is designed to collect the steam-distillable, pentane-soluble fraction from small amounts of leaf material and allows for efficient capture (routinely greater than 90%) of volatile mono- and sesquiterpenes from a single leaf. The leaf was boiled in a 50-ml round-bottom flask that contained 10 ml of distilled water and a known amount of internal standard (*n*-tetradecane). Approximately 3 ml of pentane was used to trap the volatiles in a 10-ml round-bottom flask, and Teflon boiling chips were added to both flasks. To ensure that pentane extraction would begin before any volatile material was distilled from the leaf, the flask containing pentane was heated for approximately 3 min before heating the flask containing the leaf and water. After a 1-hr distillation,

the pentane (which contained the volatiles) was recovered and evaporated under a stream of nitrogen to a volume of approximately 75 μ l.

The volatile terpene content of each leaf was determined by gas chromatography using a SP-1000 fused silica capillary column, flame ionization detector, and a digital integrator (GC temperature program of 50–175°C at 5°C/min. with 5- and 18-min initial and final isothermal periods, respectively). After GC analysis, ^{14}C incorporation into the volatile terpenes was quantitated using a liquid scintillation counter (Packard Tricarb Series 4000; Beckman Ready-Solv NA was used as the scintillation cocktail). No quenching occurred when excess amounts of distillate from unlabeled *H. subaxillaris* leaves was added to a labeled sample. The presence of the measured ^{14}C in the mono- and sesquiterpenes was confirmed by gas radiochromatography using a gas chromatograph equipped with a thermal conductivity conductor, an AT-1000 stainless-steel column (150°C isothermal analysis) and a Packard model 894 Gas Proportional Counter.

RESULTS

Incorporation of ^{14}C into mono- and sesquiterpenes was greater in immature leaves of nitrate-limited plants than in nitrate-rich plants. Under nitrate-rich conditions, ^{14}C incorporation per leaf into the volatile terpene pool of immature leaves showed a pattern of rapid incorporation and loss over the first 4 hr followed by another period of increased incorporation beginning 10 hr after exposure (Figure 1). Immature leaves of nitrate-limited plants did not exhibit, within the first 6 hr, the same pattern as was observed under nitrate-rich conditions. Instead, a steady increase in total radioactivity per leaf of the volatiles occurred over the first 24 hr following exposure (Figure 1). By 24 hr after exposure, incorporation into the volatile terpene fraction of immature leaves of nitrate-limited plants was nearly twice as high as in comparable leaves of nitrate-rich plants on a per leaf basis, and nearly fivefold higher on a per milligram leaf basis. There was no apparent diurnal trend in the quantity of leaf volatile terpenes over this period (Figure 1, inset).

As leaves aged, incorporation per leaf into the volatiles declined in both treatments. The 2-week-old leaves of nitrate-limited plants exhibited a rapid increase and loss of label similar to immature leaves of nitrate-rich plants, including a second increase in specific activity 10 hr after the exposure (Figure 1). Under nitrite-rich conditions, little initial incorporation occurred during the first 6 hr after exposure in 2-week-old leaves, but the level of incorporation had risen by 24 hr, although to a lower specific activity than in immature leaves. The 4- and 6-week-old leaves of plants under both nitrate regimes exhibited essentially no incorporation into the volatile terpenes (Figure 1).

The highest levels of ^{14}C incorporation occurred between 1 and 28 days

FIG. 1. Short-term time course of ^{14}C incorporation from $^{14}\text{CO}_2$ into volatile terpenes in leaves of four ages from *Heterothecha subaxillaris* rosettes grown under nitrate-limiting and nitrate-rich conditions. Inset: The volatile terpene content of the 7- and 14-day-old leaves. \circ = 1 week old, \square = 2 weeks old \triangle = 4 weeks old, ∇ = 6 weeks old.

after labeling in the expanding leaves of plants from both treatments (Figure 2). Incorporation per leaf into the terpene pool was, on average, 2.1 times higher in expanding leaves (1 week old) from nitrate-limited plants than in equivalent leaves from nitrate-rich plants. Over the course of the experiment, the variation in incorporated ^{14}C in the mono- and sesquiterpenes between the duplicate samples for each measurement was approximately 40% of the mean. In both treatments, incorporation into 2-week-old leaves was lower than in immature leaves, and the 4- and 6-week-old leaves of plants exhibited essentially no incorporation during the entire experiment (Figure 2).

Loss of label from the terpene pool occurred between 28 and 42 days after exposure in both treatments. By the 42-day sampling period, senescence had begun in the leaves of plants from both nitrate treatments. Similarly, loss of label from 2-week-old leaves of nitrate-rich plants occurred between 10 and 28 days after exposure. No trend in loss of label from the terpene pool was observed among leaves from 2-week-old, nitrate-limited plants.

The volatile terpene concentration was significantly higher in leaves of nitrate-limited plants (which show greater levels of incorporation into the volatile terpenes) than of nitrate-rich plants ($F = 7.4$, $P < 0.01$, $df = 1, 57$, two-

FIG. 2. Long-term time course of ^{14}C incorporation from $^{14}\text{CO}_2$ into volatile terpenes in leaves of four ages on *Heterotheca subaxillaris* rosettes growth under nitrate-limiting and nitrate-rich conditions. Inset: The volatile terpene content of the 7- and 14-day-old leaves. \circ = 1 week old, \square = 2 weeks old, \triangle = 4 weeks old, ∇ = 6 weeks old.

way ANOVA), and the quantity of volatile terpenes declined with leaf age in both treatments ($F = 7.7, P < 0.001, df = 3,55$, two-way ANOVA; interaction not significant, $P = 0.6$) (Figure 3A). The decline in leaf volatile terpene content as leaves aged coincided with the loss of label from older leaves that

FIG. 3. (A) The mean volatile terpene concentration (\pm SE) of four ages of leaves from *Heterotheca subaxillaris* rosettes grown under nitrate-limited and nitrate-rich conditions. (B) The mean fresh weight (\pm SE) of *H. subaxillaris* leaves from plants grown under nitrate-limited and nitrate-rich conditions.

had been labeled when immature (Figure 2). The leaves of nitrogen-rich plants were fully expanded after 14 days and leaves of nitrate-limited plants were fully expanded between 14 and 28 days (Figure 3B). Thus, ^{14}C incorporation into the volatile terpenes occurred primarily in expanding leaves.

The enhanced terpene synthesis in immature leaves of nitrate-limited plants is also observed when differences in synthesis are compared on a leaf weight basis. The mass of 1-week-old leaves from nitrate-limited plants is 20% less than comparably aged leaves from N-rich plants, whereas the rate of terpene synthesis and the mass of volatile terpenes per leaf are both greater in these smaller leaves (Figure 1). Similarly, changes in volatile concentration over leaf life are influenced by changes in leaf weight (Figure 3), but appear to result more from differences in synthesis early in leaf growth.

DISCUSSION

The higher concentration of leaf mono- and sesquiterpenes with decreased nitrate availability apparently results from increased synthesis into a slowly catabolized (metabolically stable) volatile terpenoid pool in young leaves. The enhanced biosynthesis may have resulted from greater carbon availability at the site of synthesis. Mono- and sesquiterpene synthesis is thought to be an energy deficient process because the isolation of volatile terpene metabolism (i.e., in secretory cells of glandular hairs) restricts the availability of carbon and energy to the sites of terpene synthesis (Croteau et al., 1972b, Loomis and Croteau, 1980). However, leaf nonstructural carbohydrate content increases with nitrate limitation (Fritsch and Jung, 1984; McNaughton, 1985; Chapin, 1980; Chapin et al., 1986). Metabolism of this carbohydrate pool could enhance carbon and energy availability for terpenoid synthesis by increasing the local supply of acetyl-CoA and energy to terpenoid-producing cells (Croteau et al., 1972b). On the other hand, increasing the carbon supply to peppermint plants via an enriched CO_2 atmosphere does not alter volatile terpene accumulation or presumably the local availability of carbon for synthesis (Lincoln and Couvet, 1989). Thus, changes in the quantity of leaf volatiles that have been observed in response to a range of abiotic environmental factors (e.g., Lincoln and Langenheim, 1979; Mihaliak and Lincoln, 1985; Gershenzon, 1984) may result from altered rates of volatile synthesis.

Photosynthate used for volatile terpene biosynthesis may be derived from current photosynthate as well as from carbon transported to young leaves from older leaves. The rapid ^{14}C incorporation into and loss from leaf volatiles of plants from both nitrate treatments (i.e., over the first 6 hr after exposure) suggests that current photosynthate is utilized for volatile terpenoid biosynthesis. Studies on other classes of terpenoids also suggest that current photosynthate may be used in synthesis of isoprenoids (Keene and Wagner 1985; Ramachan-

dra Reddy and Rama Das, 1987; Schulze-Siebert and Schultz, 1987). Incorporation of $^{14}\text{CO}_2$ into a metabolically stable volatile terpenoid pool was apparent 6–10 hr after exposure and continued for several days, suggesting that carbon could be transported into the immature, terpene-synthesizing leaves from older leaves. Furthermore, we were able to measure ^{14}C in the volatiles of immature leaves from plants that had been exposed to $^{14}\text{CO}_2$ 42 days prior to harvesting these leaves, albeit at low levels (up to 230 cpm ^{14}C above background). Incorporation into the volatiles of these immature leaves must have come from a carbon pool assimilated weeks before the sampled leaves were initiated.

The rate of volatile terpene biosynthesis is greatest in young leaves and declines precipitously with leaf age. Furthermore, the terpene pool that accumulated when the leaf was expanding is lost through catabolism, transport, or volatilization only when the leaf nears senescence. The long-term volatile terpene pool is thought to be secreted into glandular trichomes (Croteau, 1984) and, once secreted, the volatiles are apparently not susceptible to turnover or loss until the leaf nears senescence. Thus, the decreased concentration of mono- and sesquiterpenes commonly observed as leaves age (Figure 3) (Burbott and Loomis, 1969; Crankshaw and Langenheim, 1891; Mihaliak and Lincoln, 1985) apparently results initially from a reduced rate of volatile terpene synthesis as leaves become fully expanded, but ultimately from loss of the metabolically stable terpene pool.

Other detailed studies that have measured short-term $^{14}\text{CO}_2$ uptake and loss from mono- and sesquiterpenes of young leaves indicated that turnover occurred rapidly (i.e., less than 24 hr) with the highest level of incorporation occurring approximately 6 hr after labeling (Burbott and Loomis, 1969; Croteau et al., 1972a). The current results show two patterns: an initial uptake and loss of label and, additionally, maximum incorporation several days after exposure and loss several weeks later. The contrast between the results of the current study and some previous investigations may be due to previous studies being conducted with plant cuttings (Burbott and Loomis, 1969; Croteau et al., 1972a), while the current experiment was conducted with intact plants. An early study of $^{14}\text{CO}_2$ incorporation into leaf volatile terpenes of intact plants (*Pinus silvestris*) also demonstrated maximum incorporation into the leaf volatiles several days after exposure (Sukhov, 1958).

Mono- and sesquiterpenes are thought to function as chemical defenses against leaf-eating insects because a higher leaf volatile terpene content often reduces leaf consumption by herbivores (e.g., Mabry and Gill, 1979; Harborne, 1982; Mihaliak et al., 1987). The increased synthesis of leaf volatiles under nitrate limitation in *H. subaxillaris* is consistent with hypotheses that suggest that plants growing in nitrogen-limiting environments will allocate more carbon to leaf chemical defense than plants in nitrogen-rich environments (Janzen,

1974; Bryant et al., 1983; Coley et al., 1985; Mihaliak and Lincoln, 1985). Furthermore, the current results are consistent with the suggestion that carbon allocation to allelochemicals should reflect leaf value (i.e., the potential net carbon gain from the leaf tissue) (Rhoades, 1979; Gulmon and Mooney, 1986). Carbon allocated to synthesis of volatile terpenes is highest in young leaves, declines with leaf age, and does not occur in old leaves. Loss (e.g., catabolism) from the volatile terpene pool of older, less productive leaves suggests a reduced investment in defense as well as a possible recovery of carbon and energy that could be used for growth, reproduction, or the chemical defense of new leaves.

Production of plant chemical defenses that exhibit rapid turnover are thought to be energetically "costly" for plants to produce and maintain (Coley et al., 1985; Gulmon and Mooney, 1986). In the current experiment, the major pool of leaf volatiles was a metabolically stable pool in which turnover appears to be slow until leaves near senescence. This lack of rapid turnover would limit the energetic cost of mono- and sesquiterpenes as leaf chemical defenses.

Acknowledgments—We thank M. Luce for his assistance in developing the scintillation procedures, the Clemson University Sandhill Agricultural Experiment Station for access to the field site, and the Institute of Biological Chemistry, Washington State University, for use of their gas radiochromatograph. We are also grateful to R. Croteau, J. Gershenzon, T. Hallahan, and A. Huang for providing valuable comments on previous versions of this manuscript. (Received December 22, 1987; accepted July 28, 1988)

Abstract—Many snakes discharge malodorous fluids from paired scent glands in the base of the tail when they are disturbed. A number of authors suggest that these secretions repel predators. Scent gland secretions of the western diamondback rattlesnake (*Crotalus atrox*), or dichloromethane extracts of them, were presented to coyotes (*Canis latrans*) in three field tests, and to domestic dogs (*Canis familiaris*) in two kennel tests, to determine whether responses of possible benefit to snakes are elicited. Free-ranging coyotes visited and rubbed and rolled at stations containing scent gland secretions in perforated plastic capsules more frequently than at those containing untreated or dichloromethane-treated capsules. Responses to dichloromethane extracts of scent gland secretions subjected to rotary evaporation were not significantly different from those to dichloromethane. Pure and mixed breeds of dogs presented with filter papers treated with dichloromethane or a dichloromethane extract of scent gland secretions mouthed (licked, bit, or ate) secretion-treated papers more frequently. Staffordshire terriers presented with filter papers treated with dichloromethane or dichloromethane extracts of snake scent gland and alligator (*Alligator mississippiensis*) paracloacal gland secretions exhibited urination postures to snake secretion-treated papers more frequently than to dichloromethane-treated papers, but responses to snake- and alligator-treated papers did not differ significantly. There was no indication that canids are repelled by scent gland secretions.

Key Words—Canidae, coyote, *Canis latrans*, dog, *Canis familiaris*, rattlesnake, *Crotalus atrox*, scent glands.

INTRODUCTION

Reptiles produce a variety of secretions thought to repel predators. In only a few studies, however, have their natural products been tested for antipredator activity (Eisner et al., 1977; Kool, 1981; Weldon, 1988).

Scent glands are paired exocrine organs in the tail of all snakes (Bellairs, 1950; Whiting, 1969). These glands typically release fluids, which are thought to discourage predators (Fitch, 1960, 1965; Burkett, 1966; Klauber, 1972), from two openings at the posteriolateral margin of the cloaca when snakes are disturbed. Several species of ants (Gehlbach et al., 1968) and several snakes (Watkins et al., 1969), including ophiophagous species, are repelled by the scent gland secretions of the Texas blindsnake (*Leptotyphlops dulcis*). A preliminary test indicated that some North American carnivores are reluctant to approach or eat food treated with desert kingsnake (*Lampropeltis getulus splendida*) secretions (Price and LaPointe, 1981), but there are no quantitative tests of the reactions by mammalian predators to these substances.

Rattlesnakes (genus *Crotalus*) typically discharge, and sometimes spray, scent gland fluids when molested (Klauber, 1972; Duvall et al., 1985). Since many mammals are resistant to snake venom (Perez et al., 1978), defenses other than striking and envenomation—such as scent gland discharge—may be useful against these predators. Canids are one group of carnivores with which rattlesnakes interact. We report here tests of the reactions of coyotes (*Canis latrans*) and domestic dogs (*Canis familiaris*) to scent gland secretions of the western diamondback rattlesnake (*Crotalus atrox*).

This study was conducted to determine whether responses of possible benefit to snakes are elicited in canids by scent gland secretions. Our field tests were designed primarily to test coyotes, although data on other vertebrates visiting our scent stations are presented. The series of field experiments involved different methods of chemical sample preparation or presentation, since the results of each test suggested questions that were addressed by modifications in subsequent designs. None of the field tests involved direct observation of the behavior of coyotes. Rather, inferences were made regarding coyotes' responses on the basis of impressions left in the soil or from other telltale deposits. Domestic dogs were tested to allow direct observation of canids' responses to scent gland secretions.

METHODS AND MATERIALS

Coyotes

Responses to rattlesnake scent gland secretions were conducted at the Chaparral Wildlife Management Area, a 6151-hectare ranch located in the Rio Grande Plains region of Texas in Dimmit and La Salle counties, and at the La

Copita Research Area, a 1093-hectare ranch located in Jim Wells County, approximately 15 km south of Alice, Texas. The average annual rainfall at the Chaparral and La Copita areas is 84 and 68 cm, respectively. The vegetation of both areas is dominated by honey mesquite (*Prosopis glandulosa*) and includes brazil (*Condalia obovata*) and prickly pear cactus (*Opuntia rigidula*). In addition to coyotes, eastern cottontail rabbits (*Sylvilagus floridanus*), striped skunks (*Mephitis mephitis*), raccoons (*Procyon lotor*), badgers (*Taxidea taxus*), javelina (*Tayassu tajacu*), and rodents were observed at both sites at the time of testing. Five *C. atrox* were seen during the study in the Chaparral area. *C. atrox* also occurs at the La Copita area, but none were observed during our tests.

First Field Study. The purpose of this study was to assess the repellency of scent gland secretions. Secretions from adult *C. atrox*, captured during March in Nolan and Brazos counties, Texas, were collected by manually pressing the base of the tail and allowing the scent gland exudates to flow into glass vials. The area of the cloaca from which scent gland secretions are released is shown in Figure 1. Two milliliters of dichloromethane (CH_2Cl_2) were added to each vial, and they were stored at -20°C . A metal spatula was used to apply 5–6 mg of the scent gland secretions or a commercially available coyote attractant, Carman's Canine Distant Call Lure (CDCL; Russ Carman, Milford, Pennsylvania), to cellulose sponges ($1 \times 1 \times 0.5$ cm) that had been immersed in water,

FIG. 1. Cloacal area of female *Crotalus atrox* showing papilla (arrow) from which scent gland secretions are discharged.

boiled for 20 min, and dried; control sponges received 0.3 ml of CH_2Cl_2 . The sponges were placed into perforated plastic capsules. One side of each capsule was pierced by a nail to secure it in the soil. All capsules were prepared within 24 hr of the first day of field presentations. They were kept in sealed glass jars until used.

Coyote responses to scent gland secretions were evaluated at the Chaparral area during July and August by using a scent station survey method, similar to that described in tests of coyote attractants (Turkowski et al., 1979, 1983). One hundred twenty scent stations were established, each within 2 m of roads extending 80 km into the study site, approximately 0.5 km apart on alternate sides of the road. Each station was comprised of two circular clearings (diameter = 1 m), 1–2 m apart, created by removing vegetation and sifting soil. A soft brush was used to smooth the soil surface so that tracks and other signs of animal activity could be discerned. A scent capsule was placed by hand (covered with a plastic glove) at the center of each circle. One clearing at each scent station received a capsule containing CDCL. Of the other clearings, half received capsules containing sponges treated with rattlesnake scent gland secretions; the other half received capsules containing sponges treated with CH_2Cl_2 . Capsules containing scent gland secretions and plain CH_2Cl_2 were placed at alternate scent stations.

Only one clearing per scent station typically is prepared during field surveys (e.g., Turkowski et al., 1979). We used two clearings during our first field study, one for the CDCL to attract coyotes. We expected coyotes to avoid scent gland secretions (cf., Price and LaPointe, 1981). We therefore deemed it necessary in this initial study to attract subjects to the proximity of scent gland samples so that an aversion could be distinguished from cases in which capsules were ignored. This experiment was not designed to evaluate the attractiveness of scent gland secretions, a property that was considered in subsequent tests.

Scent stations were inspected between 0700 and 1200 hr for evidence of animal activities occurring over the previous 24 hr during each of five consecutive days. The following information was scored from marks or deposits left within a 1 m diameter of the center of each circle: (1) visiting vertebrates, identified by their footprints, (2) defecation, (3) urination, as evidenced by small circular depressions (sometimes still moist when examined) in the soil, (4) rubbing and/or rolling, as evidenced by body depressions in soil and hairs deposited on ground or attached to scent capsules (Figure 2), (5) scratching and digging, and (6) pulling up capsules. Contaminated, damaged, or missing capsules were replaced each day, and the soil surface was smoothed by a brush. Scent stations on which tracks could not be identified, including those disturbed by wind or rain, were classified as "inoperable" and were reset with no data recorded from either clearing at the station.

FIG. 2. A plastic capsule containing *Crotalus atrox* scent gland secretions. The depression in the soil and hairs on the capsule indicate rubbing and rolling by a coyote.

Second Field Study. The purpose of this study was to assess the attractiveness of scent gland secretions. Scent gland secretions were obtained, stored at -20°C , and applied to sponges, as previously described; control sponges were untreated. Capsules containing untreated sponges or ones treated with scent gland secretions or CDCL were placed at stations at the La Copita area during March. Each scent station consisted of one circular clearing (diameter = 1 m) of smooth, sifted soil, located within 2 m and on alternate sides of the road. A total of 51 scent stations, 17 for each condition, were established. Stations were monitored for three consecutive days, where measures described for the first field study were scored.

Third Field Study. The purpose of this study was to determine whether behaviorally active chemicals from scent gland secretions can be extracted in an organic solvent and can survive rotary evaporation. Scent gland secretions were obtained and stored as described above. Approximately 80 ml of CH_2Cl_2 were added to the secretions, they were filtered, and the filtrate was placed on a rotary evaporator to remove the solvent. A 1.0 mg/ml solution of the residue of the scent gland secretions was prepared in CH_2Cl_2 , and 0.3 ml of this solution was applied to sponges; control sponges received 0.3 ml of CH_2Cl_2 .

Scent stations, comprised of one circular clearing each, were prepared at the Chaparral area during November. A capsule containing a sponge treated with scent gland secretion extract, CH_2Cl_2 , or CDCL was placed at each station. Sixty-six scent stations, 22 for each condition, were prepared and monitored for three consecutive days using measures described for the previous studies.

Domestic Dogs

Scent gland secretions, collected in vials as previously described, were transported on dry ice and stored at -70°C . A total of 30 ml of CH_2Cl_2 was added to the vials in 5-ml aliquots. After the addition of each aliquot, the vials were shaken for 1 min, a pipette was inserted beneath a layer of insoluble materials to draw off the CH_2Cl_2 , and the extract was filtered. The concentration of CH_2Cl_2 -soluble substances in the filtrate was determined by transferring 5 ml of the solution to a vial, immersing the vial in a water bath (45°C) under N_2 , and weighing the residue after drying for 24 hr in vacuo. A 5 mg/ml solution of secretions was prepared from the original (unevaporated) solution in an attempt to conserve volatile compounds.

Filter papers (diameter = 4.3 cm) each were treated with 0.5 ml of the scent gland solution; control papers received 0.5 ml of CH_2Cl_2 . The papers were air-dried for 5 min under a hood, placed into glass Petri dishes, covered, and kept at -70°C for several hours before use.

A total of 102 domestic dogs (*Canis familiaris*), pure and mixed breeds, was tested. They were housed individually in $1.2 \times 2.4 \times 2.7$ -m kennels, provided with water ad libitum, and fed between 1030 and 1200 hr. No information on the history of the subjects was available. All dogs had occupied their kennels at least 24 hr before testing.

Each dog was presented with snake-scented and control filter papers taped to the center of a 7×13 -cm metal plate. A plate with filter paper was inserted under the front of the kennel into a 15×15 -cm area designated by a chalk line drawn on the floor. The dogs' tendencies to enter the chalked area and paw at, sniff (by placing the snout within an estimated 5 cm from the paper), mouth (lick, bite, or eat the paper), and rub and roll on the paper were scored for 2 min to each condition. Two minutes elapsed between presentations, which were counterbalanced. All testing was done between 1200 and 1600 hr.

A separate test was done with 19 adult (> 10 months old) Staffordshire terriers, maintained in their home kennels ($1.5 \times 4.9 \times 1.8$ -m to $4.9 \times 7.6 \times 2.4$ -m) for at least three months. The sex of subjects was recorded. Dogs were presented with filter papers treated with plain CH_2Cl_2 and CH_2Cl_2 extracts of secretions of rattlesnake scent glands or American alligator (*Alligator mississippiensis*) paracloacal glands. Paracloacal glands are paired exocrine organs (not homologous with scent glands) in the cloacal walls of crocodylians, and are suspected of containing pheromones. An analysis of these secretions indicates a variety of esters, 3-methylbutanoates, free fatty acids, and other compounds (Weldon et al., 1988). The paracloacal gland secretions, collected from adult male alligators during September in Port Arthur, Texas, were included here as an additional control condition.

Both rattlesnake and alligator secretions were stored in vials with several ml of CH_2Cl_2 . They were filtered after adding 30 ml in 5-ml aliquots of CH_2Cl_2 to the samples, as described above.

Aliquots of snake scent gland and paracloacal gland extracts were weighed, and the solutions from which they were derived were dissolved in CH_2Cl_2 to give 6.3 mg/ml solutions, 0.5 ml of which was applied to filter papers. Control papers received 0.5 ml of CH_2Cl_2 . The papers were air-dried for at least 5 min before being presented to the dogs.

The filter papers were taped to metal plates and placed in the dogs' home kennels by their owners. Each dog was presented with control, snake-scented, and alligator-scented papers for 2 min each in a Latin-square design. Sniffing, mouthing, pawing, rubbing and rolling, and urination postures (leg-lifting and squatting) were scored; since it was not always clear whether micturition occurred, we conservatively scored the occurrence of only the associated squatting or leg-lifting postures. One to two minutes elapsed between presentations. Tests were run between 1000 and 1700 hr, before the dogs were fed.

RESULTS

Coyotes

First Field Study. The chi-square test was used in all field data analyses. Omitting those scent stations classified as inoperable, 756 observations remained for analysis. The most common vertebrates visiting scent stations over the five-day test period are listed in Table 1. Visitation rates to scent stations by all species combined did not differ significantly ($P > 0.40$) from day to day. Visitation rates of coyotes for days 1–5 were 21%, 36%, 36%, 27%, and 32%, respectively ($P > 0.50$).

Coyotes visited 33% of the scent stations in the Chaparral area. There was

^a CDCL was present at every station so that there were twice as many observations as for the other two treatments.

^b Means with different letters are significantly ($P < 0.05$) different.

no evidence on the basis of visitations alone that coyotes discriminated between treatments ($P > 0.50$), indicating their failure to avoid rattlesnake scent gland chemicals (Table 1). A significantly greater frequency of rubbing and rolling occurred at snake secretion-scented stations than occurred at control stations ($P < 0.01$). No significant differences were detected in the frequency with which snake secretion-scented or control capsules were disturbed ($P > 0.60$), or in urinations that occurred at snake secretion-scented or control stations ($P > 0.20$). Defecation and ground-scratching occurred at frequencies too low to permit analysis.

A comparison of coyotes' responses to capsules treated with snake scent gland secretions and coyote attractant, CDCL, on adjoining circles indicated no significant differences between these conditions with respect to rates of visitation ($P > 0.50$), capsule-pulling ($P > 0.30$), urination ($P > 0.10$), defecation ($P > 0.10$), or ground-scratching ($P > 0.60$). Coyotes rubbed and rolled at 9% of snake secretion-scented stations, but this response did not differ significantly ($P > 0.10$) from the rate at which this occurred (14%) at CDCL stations. Coyotes rubbed and rolled during 30% of their visits to snake secretion-scented stations; they did so at 41% of the CDCL stations visited.

Other taxa, particularly rodents, were frequent visitors at scent stations (Table 1). There were no differences in visitation rates at snake secretion-scented and control stations for rodents ($P = 0.14$) or lagomorphs ($P = 0.89$), indicating a failure to avoid rattlesnake scent gland chemicals. We also failed to detect significant differences in visitations at snake secretion-scented and control stations for raccoons ($P > 0.60$), striped skunks ($P > 0.20$), and javelina ($P > 0.50$), but visitation rates for these taxa were low.

No behavioral responses other than capsule-pulling were recorded for animals other than coyotes, and in many of these instances the capsules appeared to have been kicked or trampled inadvertently. Almost all of the capsules remained within the 1 m circle where species other than coyotes were involved. Coyotes typically carried the capsule at least several meters. There were 18 instances in which the capsules with any of the three stimuli were pulled by all other species combined, for a frequency of 2%, in contrast to 24% for coyotes.

Second Field Study. After eliminating inoperable stations at La Copita, a total of 146 observations remained for analysis (Table 2). Visitation rates of coyotes for days 1–3 were 22%, 10%, and 14%, respectively.

No significant differences were detected in the frequency with which coyotes visited snake secretion- and CDCL-treated stations ($P > 0.05$), but visits to both of these were higher than to the control stations ($P = 0.05$). Nearly all capsule-pulling was directed at scent gland secretions and CDCL; the difference between these was slight. Rubbing and rolling was not observed at control stations, but it occurred at 10% and 11% of the snake secretion- and CDCL-treated

TABLE 2. FREQUENCY OF RESPONSE (%) BY COYOTES AND OTHER MAMMALS AT LA COPITA RESEARCH AREA TO SCENT STATIONS WITH RATTLESNAKE SCENT GLAND SECRETIONS, UNTREATED CONTROL, AND COYOTE ATTRACTANT (CARMAN'S CANINE DISTANT CALL LURE)

stations, respectively. Coyotes rubbed and rolled during 71% and 83% of their visits to stations with scent gland secretions and CDCL, respectively.

Evidence of visits by other vertebrates was indicated at the scent stations (Table 2). No significant differences in visits were noted where the sample sizes for these taxa were adequate for chi-square comparisons.

Third Field Study. After eliminating inoperable stations at the Chaparral area, a total of 196 observations remained for analysis (Table 3). Visitation rates of coyotes for days 1-3 were 26%, 21%, and 38%, respectively.

The CDCL stations were visited by coyotes more frequently than were either snake secretion-scented or CH₂Cl₂-treated stations ($P < 0.05$). Capsule-pulling and rubbing and rolling were the only behavioral measures recorded in numbers adequate for analysis. Evidence of both responses was observed more frequently at the CDCL stations than at those treated with either scent gland secretions or CH₂Cl₂ ($P < 0.05$). The frequency with which snake secretion-scented capsules were pulled did not differ significantly ($P < 0.05$) from that

observed with CH_2Cl_2 -treated capsules; however, no rubbing and rolling was observed in response to CH_2Cl_2 -treated capsules.

Raccoons visited 11% of the scent stations, most frequently those containing CDCL ($P > 0.10$) (Table 3). Lagomorphs and rodents were frequent visitors, but only the former exhibited differences in visitation rates for the three conditions, visiting CDCL stations less frequently than either snake secretion- or CH_2Cl_2 -scented stations ($P < 0.05$). Other species visited stations too infrequently for chi-square analyses.

Domestic Dogs

Of the 102 dogs tested in the kennel survey, 77 exhibited one or more of the scored behaviors during either control or experimental presentations. Only data from these responding individuals are presented and subjected to statistical

analyses (Table 4). The chi-square test indicates that dogs mouthed filter papers treated with the CH_2Cl_2 extract of scent gland secretions more than controls ($P < 0.05$). No other significant differences between conditions were detected.

Of the 19 Staffordshire terriers tested, 12 exhibited one or more of the scored behaviors during either control or experimental presentations. Only data from these responding individuals are presented here and subjected to statistical analyses. Rubbing and rolling was observed during 0, 1, and 3 sessions, and urination postures during 1, 2, and 6 sessions with CH_2Cl_2 , paracloacal gland secretions, and scent gland secretions, respectively. All urination postures, except one in which a female urinated directly on an alligator-scented paper, were exhibited by males. No significant differences were detected between conditions for rubbing and rolling. The Fisher exact-probability test, which was used due to the small sample size, indicates that urination postures occurred during significantly more sessions with scent gland secretions than with CH_2Cl_2 ($P < 0.05$), but responses to snake- and alligator-treated papers did not differ significantly ($0.10 > P > 0.05$).

DISCUSSION

The reactions of predatory mammals to snake scent gland secretions were observed by Price and LaPointe (1981), who presented desert kingsnake (*Lampropeltis getulus splendida*) exudates on food to badgers, coyotes, and other North American carnivores. The coyotes' responses were not specifically described, but Price and LaPointe (1981) characterized the overall reactions to scent gland secretions by the carnivores they examined as "aversionary."

The results of our first two field experiments indicate that coyotes rubbed and rolled on rattlesnake scent gland secretions, as they did on the coyote attractant, CDCL. In our third field test, however, rubbing and rolling did not occur to scent gland extracts at a rate significantly different from that to CH_2Cl_2 ,

although this behavior was indicated at a significantly higher rate to CDCL. This suggests that the chemicals eliciting rubbing and rolling are not retained (in sufficient quantities) following our methods of extraction, rotary evaporation, and field presentation. Domestic dogs in both our kennel tests also failed to rub and roll on CH_2Cl_2 extracts of scent gland secretions significantly more often than on control papers. Scent gland compounds insoluble in CH_2Cl_2 , i.e., glyco- or mucoproteins and acid mucopolysaccharides (Whiting, 1969; Blum et al., 1971), likely were denatured or removed by our extraction methods. These substances may provide a matrix for the retention of volatile, behaviorally active chemicals.

Bullard (1982) states that most, if not all, canids rub and roll on putrefying materials. Fox and Cohen (1977) report rubbing and rolling by a variety of canids to natural and synthetic substances, including skatole and propionic acid. Although sterols and fatty acids have been indicated in snake scent glands (Blum et al., 1971; Simpson et al., 1988), Oldak (1976) failed to detect these or other nonpolar lipids in his thin-layer chromatograms of crotaline scent gland secretions, including those of a rattlesnake. Razakov and Sadykov (1986) identified fatty acids from the scent glands of the mamushi (*Agkistrodon halys*), indicating that these compounds are present in at least some crotalines. Chemicals in the secretions of *C. atrox* need to be identified and tested as synthetic analogs to determine those that elicit canid responses.

In our study, Staffordshire terriers exhibited urination postures more frequently to rattlesnake secretion extracts than to CH_2Cl_2 , but snake- and alligator-treated papers did not differ significantly in their effects. Urination (or urination posturing) was not scored during our first kennel survey, and it occurred at too low a frequency for statistical analysis during our field studies. The tendency of canids to urinate on conspecific urine deposits often is interpreted as a form of scent marking. Urination also may be elicited by "novel" odors, such as those arising from other species' feces (Fox and Cohen, 1977). Kool (1981) noted that the dingo (*C. familiaris*) urinated on a turtle's (*Chelodina longicollis*) Rathke's gland secretions, which are hypothesized to deter predators. In Kool's study, as with ours, the adaptive significance of eliciting urination in canids is not obvious.

Neither are the aversive properties of scent gland secretions evident from our results. In the first field study, designed to measure the potential repellency of snake scent gland secretions, coyotes visited capsules containing these exudates at a rate that was not significantly different from that to capsules containing CH_2Cl_2 . In the second field study, designed to measure the potential attractiveness of rattlesnake scent gland secretions, coyotes visited stations containing secretion extracts significantly more often than those containing untreated capsules and at a rate not significantly different from that to CDCL. This is worth noting since CDCL has been developed specifically as a lure for these

carnivores and is one of the most effective commercial attractants available (Turkowski et al., 1983).

We did not test the palatability of untreated scent gland secretions in our experiments, thus, we cannot relate our results directly to those of Price and LaPointe (1981). However, the tendency of dogs to mouth snake secretion-scented filter papers and that of coyotes in the field to pull up (presumably by mouth) snake secretion-scented capsules does not support the hypothesis that these materials are distasteful. Palatability studies using whole, untreated scent gland substances are needed.

Scent gland secretions could interfere with predation in ways other than by having aversive effects. Rubbing and rolling, for example, could distract canids from predatory attack. Even the elicitation of mouthing could be advantageous for snakes if scent gland chemicals direct attacks toward the tail, and away from their head and trunk, in a way analogous to that in which visually directed predators are diverted by snake tail displays (Greene, 1987). Insight into the mechanisms by which scent gland secretions benefit snakes could be obtained by observing interactions between snakes and predators and, perhaps, by comparing the survivorship of intact snakes with that of those from which these glands have been surgically removed.

Scent glands are homologous among extant snakes. Since the common ancestor of Recent snakes lived during the Upper Cretaceous (Rage, 1987) this can be considered a minimum age for these organs. Carnivores did not appear until during the Tertiary (Ewer, 1973). Given this chronology, it is clear that snake scent glands did not evolve as a response to these mammalian predators. The antipredator function(s) of the exudates produced in these organs needs to be tested on other taxa, e.g., varanid lizards and crocodylians.

Functions and effects other than the production of predator repellents have been attributed to scent glands, including that of pheromone release. Although experiments suggest that blindsnake (*Leptotyphlops dulcis*) scent gland chemicals attract conspecifics (Watkins et al., 1969), attempts to elicit trail-following with these substances in other snakes have failed (reviewed in Ford, 1986). Graves and Duvall (1988) report that airborne presentations of scent gland chemicals from the prairie rattlesnake (*C. viridus*) elicit increased heart rates in conspecifics, and they suggest, following Brisbin's (1968) observations on a common kingsnake (*Lampropeltis getulus*), that these organs release alarm pheromones. Even so, whether scent gland chemicals function primarily to alert conspecifics is uncertain since alarm properties often are derived secondarily from compounds released during predatory attack (Weldon, 1983).

Acknowledgments—B. Beaver helped with preliminary observations on dogs' reactions to scent gland chemicals. L. MacDonald and M. Phi Dao lent valuable help in testing domestic dogs. R.S. Gray, H.B. Harper, and C. Toth kindly allowed us to test their Staffordshire terriers and

assisted in the process. G. Drew, D. Martin, and C. Roberts offered expert field assistance in tests with coyotes. P. Freed, C. Roberts, J.T. Simpson, G. Wills, and T. Wilson helped collect scent gland secretions. D. Synatske and the staff at the Chaparral Wildlife Management Area, Texas Parks and Wildlife Department, allowed us to conduct our studies at their facilities. R.W. Bullard and H.W. Greene commented on earlier drafts of the manuscript. This study was supported by grants from the Whitehall Foundation (to P.J.W.), the Texas Agricultural Experiment Station (through D.B.F.; contribution #23293), and a Texas A&M minigrant (to D.B.F.). To all we are grateful.

(Received March 30, 1988; accepted August 1, 1988)

Abstract—Late-instar larval *Tenebrio molitor* L. were found to be attracted to aqueous extracts of conspecific larval frass. The attraction was evident at both the individual and group level. The attraction of larval groups to frass indicated the possibility of an aggregation pheromone that would be chemically distinct in the mealworm environment. Chemical analysis of short carbon chain acids present in both the mealworm frass and the diet indicated that lactic acid was present in the mealworm frass only. Acetic acid was identified in both the diet and the larval frass. Larvae aggregated on filter papers treated with aqueous frass extracts that had been dried and also on those freshly wetted. The larvae also aggregated on dried or freshly wetted papers treated with lactic acid, but failed to aggregate on freshly wetted papers or dried papers treated with acetic acid. The role of excreted lactic acid as a discriminant of already infested and, therefore, safer environmental regions is discussed.

Key Words—Aggregation, lactic acid, yellow mealworm, *Tenebrio molitor*, frass, acetic acid, Coleoptera, Tenebrionidae, attraction.

INTRODUCTION

The yellow mealworm, *Tenebrio molitor* L. is a cosmopolitan stored-products pest of economic importance with infestations generally originating in damp, dark places where cereals may be decaying (Cotton, 1963). The presence of the

conspicuous larvae in a stored-products mass is an indication of poor storage sanitation (Sinha and Watters, 1985). Pheromone communication among *Tenebrio* adults has been studied (Tschinkel et al., 1967; Happ, 1969; Tanaka et al., 1986). McFarlane and Alli (1986) have shown DL-lactic acid to be an excreted aggregant of larval *Blattella germanica*. In this article, aggregation of larval *Tenebrio molitor* on frass-treated substrates is evaluated. Chemical analysis of diet and frass for short carbon chain acids indicated candidate chemicals that may be used by yellow mealworms to analyze substrates for suitability for aggregate formation. These were tested in a behavioral bioassay. The interaction between water and pheromone found in lactic acid-induced larval aggregation in the German cockroach (McFarlane and Alli, 1986) was also evaluated for *Tenebrio*. This article is the first report of a larval aggregation pheromone in *Tenebrio*. This pheromone was also evaluated for epideictic activity (Wynn-Edwards, 1962; Prokopy, 1981).

The objectives of the following experiments were to evaluate a broad range of concentrations of pheromone for behavioral activity and to observe the nature of the response of the insect to these chemicals during a limited period of presentation in a behavioral bioassay. The possible role of this pheromone in population orientation is discussed.

METHODS AND MATERIALS

Rearing. Yellow mealworms, *Tenebrio molitor* L., were raised on a diet of wheat bran, whole wheat flour, and brewer's yeast (50:45:5 w/w) at $25 \pm 1^\circ\text{C}$ and $55 \pm 5\%$ relative humidity and a photoperiodic regime of 14:10 light-dark. The density of all stages per filled 4.55 liter glass culture jar was not allowed to exceed 250 individuals.

Collection of Frass and Diet. Larvae (> 100 mg) were removed from the culture and individually placed in 20-ml glass jars for 24 hr. Insects were then removed and the collected frass was immediately frozen at -40°C . Frass from any molting larvae was discarded to avoid contamination by the cuticle. Freshly prepared diet was also frozen at $-40 \approx \text{C}$.

Methods of Acid Determination in Frass and Diet. Frass (380 mg) was ground with a mortar and pestle and placed in a 40-ml centrifuge tube. A quantity (20 ml) of deionized distilled water was added to the test tube and the mixture was agitated (1 min) with a vortex mixer and allowed to stand 2 min. This agitation procedure was repeated three times. The resulting mixture was centrifuged (200 g, 10 min), and the supernatant was filtered into a volumetric flask (25 ml). The same procedure was followed for the diet sample (500 mg).

For acid determination by gas chromatographic analysis, the acids were

converted to benzyl ester derivatives (Jones and Kay, 1976). Method II of McFarlane and Alli (1986) indicates column specifications and conditions of gas chromatographic analysis and mass spectrometric confirmation. The method of frass analysis for D- and L-lactic acid was that of McFarlane and Alli (1986).

Bioassay Arena. The arena used was similar to that of McFarlane *et al.* (1983). Experiments were conducted at room temperature and in arenas kept in darkness. Two 14×3.8 -cm strips of Whatman No. 1 filter paper folded three times were placed on edge and evenly spaced in a 19.2-cm-diam. glass culture dish. Test papers were maintained upright by clamping the upper edges of the test paper with two clamp-style hairpins suspended from a copper wire extending across the arena and attached to either side by clothespins.

Testing for Frass Attraction. Frozen frass was ground with a mortar and pestle and added to 5 ml of deionized, distilled water. The resulting mixture was agitated in a vortex mixer for 2 min and immediately subjected to Buchner filtration through a Whatman No. 1 filter disk. An aliquot (0.68 ml) of the filtered liquid was immediately applied to a test strip. A control strip was wetted with deionized, distilled water. Other frass test strips were similarly prepared and allowed to air dry 1.5 hr prior to testing. A yellow mealworm (140–160 mg) was introduced into the center of the arena to test for individual attraction; 20 such larvae were used to test group responses. The filter papers were examined at 0.5-hr intervals after the initiation of the trial. The criteria for aggregation/attraction included larvae in full contact with the test strip or those insects contacting the test strip with their antennae, mouthparts or legs, but not actually upon the paper. Wandering, inactive, or clustering larvae not touching the test paper were considered a covariable for analysis comparing mean numbers of larvae on treatment papers in separate group trials. The dominant response of tested mealworms was to come to rest on or in contact with a test strip. Each trial was terminated after 5 hr. All group trials were replicated 18 times.

Testing for Lactic, Acetic, and Selected Acid Attraction. DL-Lactic acid (Fisher Scientific Company, Montreal, Canada) and acetic acid (Anachemia Limited, Montreal, Canada) were tested by making serial dilutions in deionized distilled water and treating a filter paper strip with 0.68 ml of solution. Dried and wetted test papers were prepared and tested using the method described in the frass aggregation bioassay. Grouped response trials using citric and phosphoric acids (Anachemia), with pK_a s similar to lactic acid, also followed this protocol.

Trials to Evaluate Larval Exploration and Arrest. To determine if either lactic acid or frass were responsible for either larval attraction or full arrest, groups of larvae and individual larvae were subjected to the described bioassay and directly observed. Data collected were the choice of the first two insects in each group trial and whether these first two responding larvae remained on the

test strip for at least 300 sec. Replication was conducted as soon as possible after the previous trial was completed ($\leq 12/\text{day}$), 36 trials in total. Individual larvae were observed to determine the significance of their initial choice and tendency to remain on the chosen substrate for at least 300 sec. This was undertaken to avoid bias possible by scrutinizing data collected at preset times only and also to determine if, in the grouped trials, later larval response is biased by the presence of those first responding individuals.

Statistical Analysis. Aggregation bioassay data were subject to analysis of covariance. Comparisons between distributions on the two papers used the mean number in each location through the period from apparent stabilization (90 min) to the end of the experiment (300 min) (Ross and Tignor, 1986) using Tukey's studentized range (HSD) test on the means with $\alpha = 0.05$. Comparisons between test chemical types were based on a *posteriori* analysis of mean larval response to the treated chemical strips (SAS, 1982). Chi-square analyses were used to test for significant differences in control vs. control trials (groups and individuals) and all treatment vs. control individual trials. Chi-square analyses were also used to determine if the choices of the first two responding larvae were significantly different in group treatment vs. control tests and to determine if there was a difference in the tendency to arrest of insects responding to either treatment or control papers during their initial exploration of the arena.

RESULTS

Analyses of frass indicated lactic acid at 0.24 ± 0.01 g/100 g frass and acetic acid at 0.25 ± 0.01 g/100 g frass. However, analyses of the diet indicated that although acetic acid was present (0.023 ± 0.004 g/100 g diet), lactic acid is not present in the mealworm diet. The lactic acid isomeric analysis gave the following results: 0.098% D-lactic acid and 0.087% L-lactic acid per frass sample (frass was 0.185% lactic acid). Dry weight determination indicates fresh frass has a 10.2% moisture content and freshly prepared diet has a 9.8% moisture content.

All tested concentrations of frass resulted in aggregation of the larvae, with the highest numbers responding to the highest concentration. Aggregation always occurred on papers treated with frass extracts whether they were presented wet or dry (Table 1). Papers treated with 0.68 ml (the minimum amount of liquid required to fully wet the filter paper) of 10^{-1} M lactic acid, both freshly wetted and dried, were found to be repellent. Papers treated with 0.68 ml of 10^{-2} – 10^{-4} M lactic acid and dried were most attractive, with 10^{-2} M freshly wetted being slightly less attractive. Aliquots of lactic acid at concentrations below 10^{-4} M showed no effect (Table 2).

TABLE 1. RESULTS OF AGGREGATION TRIALS USING FRASS EXTRACTS^a

Chemical	Concentration (mg/ml H ₂ O)	Treated ^b	Control ^c
Frass (dry)	50	13.08 ± 0.32a	2.17 ± 0.36*
Frass (wet)	40	12.55 ± 0.37a	4.53 ± 0.41*
Frass (dry)	30	10.92 ± 0.54ab	4.95 ± 0.54*
Frass (wet)	20	10.67 ± 0.58ab	6.28 ± 0.34**

^aBased on 18 replicates of 20 larvae each. Raw data based on counts from time of approximate stabilization to trial end (1.5–5.0 hr).

^bMeans followed by the same letter not significantly different ($P \leq 0.05$). Units are mean number of larvae.

^c*Treated significantly greater than control at $P \leq 0.001$. **Treated significantly greater than control at $P \leq 0.005$.

Acetic acid was found to have no effect on the larvae at any concentration, regardless of the method of presentation (Table 3).

All control vs. control trials indicated no significant differences in preference for substrate (data not shown). Geomagnetic bias is unlikely, therefore.

of the highest concentration of aqueous frass during the aggregation bioassay. Figure 2 illustrates the insect response to dried papers treated with 0.68 ml of 10⁻² M lactic acid during the bioassay. The two graphs show similar overall responses (mean number of larvae on treated paper from 1.5 to 5.0 hr), but early in the frass extract trials there were significantly fewer insects at rest on the control papers. The concentration of lactic acid on the frass-treated paper (Figure 1) is equivalent to that on filter paper treated with a 0.68-ml aliquot containing lactic acid between 10⁻² M and 10⁻³ M. The time required for stabilization in trials which indicated successful aggregation (Figures 1 and 2),

FIG. 1. Mean number of mealworm larvae (±SE) on papers treated with 50 mg frass/ml H₂O and dried. Based on 18 replicates of 20 larvae each. Wandering indicates insects not on filter papers.

FIG. 2. Mean number of mealworm larvae (\pm SE) on papers treated with 10^{-2} M lactic acid and dried. Based on 18 replicates of 20 larvae each. Wandering indicates insects not on filter papers.

was approximately 1.5 hr, at which point no further large increases in numbers on either treated or control test strips occurred. Variations occurring after stabilization generally resulted from insects falling from the filter paper into the arena or larvae that were initially inactive becoming active and responding to the filter papers at a later trial interval. In trials where repellency or an indifferent response was indicated, stabilization occurred more gradually, but trends towards the final response can be seen at 1.5 hr. Figure 3 illustrates the insect response to repellent 10^{-1} M lactic acid (wet). There was a significantly higher number of larvae on the control paper at 1.5 hr but the difference became more obvious at 2 hr. The response of the larvae to an indifferent chemical stimulus (10^{-3} M acetic acid) is illustrated in Figure 4. In this case, stabilization is gradual, with an increase in wandering insects occurring between 3.0 and 4.5 hr. This indicates that prolonged grouped stability was less likely in trials where no chemical message was perceived.

Aggregation bioassays using inorganic and organic acids with pK_a s similar to DL-lactic acid indicated that both citric and phosphoric acid were repellent to groups of larvae when presented wetted on filter paper in aqueous solution at concentrations of 10^{-1} M and 10^{-2} M. Lower concentrations produced no effect (data not shown).

Tests indicated individual larvae were attracted to frass and lactic acid in the same manner as grouped larvae with counts taken at predetermined intervals. Table 4 gives the chi-square values for a selected frass solution and 10^{-3} M lactic acid at 2- and 4-hr intervals.

FIG. 3. Mean number of mealworm larvae (\pm SE) on papers wetted with 10^{-1} M lactic acid. Based on 18 replicates of 20 larvae each. Wandering indicates insects not on filter papers.

Evaluation of first responding individuals (group tested) indicated that overall response of the larvae to treatment or control was not determined by the presence of other larvae (choice of first larvae reaching either test or control strips indicated no significant difference in preference), nor did first responding

larvae remain on either treatment or control filter paper for the 300-sec interval in significantly different numbers. In fact, fewer than 60% of the first-responding treatment or control larvae remained for this amount of time. Individual larvae did not show any significant differences in their first choice, but those selecting frass or lactic acid tended to remain longer on the paper; however, 31% of the observed individuals initially selecting test chemical stimuli left the papers only to return subsequently (data not shown).

DISCUSSION

Both dried and wetted lactic acid test strips are the preferred substrates for the larvae of *T. molitor* at 10⁻²-10⁻⁴ M concentrations. This range approximates the amount found in the fresh larval frass. Other chemicals present in the frass exert different behavioral effects when tested in isolation, but their efficacy is completely masked by lactic acid when tested along with lactic acid at the biological concentration (Weaver *et al.*, 1990). The frass in entirety seems to be exclusively attractive, therefore.

The larval frass has a water content of 10.2%. This indicates that the lactic acid in the frass is unlikely to be in solution, but more correctly, is substrate-associated. This may, in part, account for the fact that the required interaction between pheromone and water (larvae only responding to papers wetted with aqueous acid solution) found in other studies (McFarlane *et al.*, 1983; McFarlane and Alli, 1986; 1987) is not required for *Tenebrio*. The surrounding diet has a 9.8% water content, so environmental stimuli are unlikely to require water as a necessary component. Mealworms are also hygrotaxic in the stored product environment when a water source is available; ecologically they prefer damp surroundings. It is possible that they display two similar patterns of response to frass stimuli. In one case they will aggregate in response to frass in

the appropriate concentration in a dry but species-marked environmental region. In the other case they may respond to moisture in a damp region and may use the presence of lactic acid for the same purpose, to cluster. Group hygrotaxis is a form of aggregation in any case; the important distinction is that damp regions also containing frass could provide information on earlier infestation.

The trials utilizing acids with pK^a 's similar to lactic acid indicate the degree of dissociation of the acid is not responsible for aggregation by these larvae (data not shown). This is unlikely to be a factor in an environment lacking free liquid to act as a solvent.

These components of the aggregation behavior bring to light an important issue. It is necessary to carefully consider all data provided by a particular bioassay. In the case of these trials, it appears that these insects show classical attraction to lactic acid. However, the length of time required for response to occur and the relatively consistent variation of insects that do not respond to acetic acid indicates that these larvae respond to their substrate by contact sampling it in a relatively regular manner (Weaver and McFarlane, 1989). The response may be similar to that described by Burk and Bell (1973), for contact arrest of cockroaches. In this case we see no evidence of consistent arrest for the majority of individuals, perhaps because the stimulus is uniformly distributed on the test substrate, rather than being localized. The *T. molitor* larvae wander over the surface of the papers in a random manner with the rate of activity decreasing through time (Weaver and McFarlane, 1989). As this rate of activity decreases, localized clusters of higher density form, particularly on DL-lactic acid-treated substrates but also, with time, on control substrates (Weaver and McFarlane, 1989). We suspect that yellow mealworm aggregations may involve mechanical interaction between individuals as well as other chemical messages. There can be little doubt that the overall response is acted out in concert with others behaving in the same manner. This complexity makes it difficult to view such chemicals as having a single effect. Their classification must depend, therefore, upon the relative effects upon both individuals and populations, not upon one or the other exclusively, as previously defined.

The response to lactic acid, a component of the frass only, may serve to indicate regions where infestations have been previously located. The long developmental time and conspicuous size of the larvae may make it advantageous for *T. molitor* to aggregate in these regions to avoid mechanical cleaning apparatus or cleaning procedures. This survival advantage may also be augmented by dispersion of the larvae when frass accumulates in amounts large enough to increase the lactic acid concentration into the repellent range. Such concentration increases could be spurred by further decomposition in the damp, dark regions *Tenebrio* inhabits. It is also of interest that acetic acid, which is present in both frass and food, induces no behavioral effects. This may be due to its environmental ubiquity precluding any directional advantage, but the lack

of response to a volatile major component of both food and frass is unexpected, given the fact that both are favorable materials for these larvae to inhabit.

Abstract—Evaluation of the lactic acid attraction of individual and grouped larval *Tenebrio molitor* L. in an olfactometer indicated that olfaction is unlikely to be the chemoreceptive mode governing substrate choice or aggregation of these insects. High-magnification videotaped sequences of mealworms on treated and control filter papers indicated that larvae sample the substrate by rapidly probing with mouthpart palpi in a manner similar to the leaf sampling of certain caterpillars. The reception of lactic acid stimuli may therefore involve contact chemoreceptors. The larvae frequently touch each other in a similar manner. Bioassays comparing the cumulative frequencies of distributions of mealworms on control and lactic acid-treated filter papers indicated significant differences, with higher density clusters being found on the treated papers. Comparison of the control distribution with the expected distribution revealed an innate tendency to aggregate. The implications of these results are discussed with regard to the formation of mealworm clusters in the environment.

INTRODUCTION

Weaver et al. (1988) have shown that DL-lactic acid is an excreted aggregation pheromone found in larval *Tenebrio* frass. It may also act as an epideictic pheromone (Wynn-Edwards, 1962; Prokopy, 1981) if one considers the dispersal

ability of concentrations higher than those naturally occurring in the frass. McFarlane and Alli (1986) found lactic acid to be an excreted aggregant of *Blattella germanica*. L-Lactic acid is an olfactory host attractant for *Aedes aegypti* (Acree et al., 1968; Davis and Sokolove, 1976). Finger et al. (1965) found olfactory attraction was displayed between larvae of *Trogoderma granarium*, another stored products insect. The present study was undertaken to determine the chemoreceptive mode of yellow mealworms, with observations being conducted to determine whether olfaction or contact chemoreception was involved.

Experiments were also conducted to evaluate the density of distributions on lactic acid papers and on control papers using comparative bioassays. The possibility of multichemical stimuli being involved in mealworm aggregations is discussed.

METHODS AND MATERIALS

The larvae were reared as previously described (Weaver et al., 1989).

Olfactometric Analysis. A diagram of the olfactometer is shown in Figure 1. A Tygon T-type connector divided the purified airstream. Each branch was fitted with a 25-ml suction flask (H) to deliver test chemical stimuli (airflow rate 1.2 liter/min). The treatment flask contained 10 ml of test solution; the control flask contained 10 ml of deionized, glass-distilled water. In the case of dried test stimuli, six dried test strips (4 × 4 cm) were cut into 0.5-cm² pieces and placed in the test flask. Six dried distilled water test strips, prepared similarly, were placed in the control flask (flask positions were randomized). Beyond this, in each branch a 30-ml plastic vial was mounted horizontally (I) with a 0.5-cm airstream hole on the the stimulus delivery side and a 1.5-cm hole on the opposing side for insertion of the bioassay tube. These vials functioned as traps for insects committed to a given airstream. The traps were connected to opposing sides of a common starting arena (K) by 15 cm of 1.5-cm-diam. Tygon tubing (J) lined with fine mesh screening to facilitate larval movement. The starting arena vial was mounted vertically with two 1.5-cm-diam. holes opposing each other at the base. The cap of the arena vial was fitted with an airstream outlet to avoid subjecting future experimental animals to test odors. Individual larvae or 14 larval *T. molitor* were simultaneously introduced into the starting arena and their behavior was observed. Counts of mealworms in trap vials were taken at 2 and 4 hr. A solid CO₂ "smoke test" showed no evidence of airstream back-mixing. Ambient air temperature varied between 23°C and 25°C. The apparatus was disassembled after each usage and cleaned thoroughly using dilute acid, detergent, and serial distilled water rinses.

Videotaping Procedure. To determine how the larvae interact with each

FIG. 1. Schematic diagram of olfactometer. other and the test substrate, the aggregation bioassay was set up as previously described (Weaver et al., 1989). Larvae were observed at 0.5-hr intervals and filmed through a Javelin JE 3010 color camera equipped with an EVA/Zoom lens (Javelin, Torrance, California). Taping was performed on a General Electric ICV 5025 videocassette recorder (Canadian General Electric, Montreal, Canada) at SP mode. Individual insects were observed for 1 min, if wandering, and 2 min, if arrested. Tapes were played back at 0.5 and 0.25 speed (real time) on a Hitachi CM-1481 monitor to quantify complex motions, particularly during wandering.

Bioassays for Comparing Population Distributions. A 5×45.5 -cm Whatman No. 1 filter paper strip was treated along its length with 3.5 ml of 5×10^{-3} M lactic acid and fixed into a cylindrical shape using a paper clip. This cylinder was introduced into a 19.2-cm-diam. glass specimen dish. The paper had been previously marked into nine equal 5×5 -cm grids using a carbon pencil. The cylinder was allowed to dry for 2 hr and then 30 mealworms were simultaneously introduced into the center of the cylinder. Counts of the number of larvae per grid were taken at 2, 4, and 6 hr; eight replicates were conducted, with arena positions randomized. Eight replicates of a similarly prepared distilled water control were conducted.

Statistical Analysis. The olfactometer data were subjected to the *t* test procedure, as were comparisons between mean numbers of insects/grid on treated and control papers in the population distribution bioassay (SAS Institute, 1982). Treated versus control population distributions were compared using the Kolmogorov-Smirnov two-sample test; control versus expected Poisson distributions were analyzed using the Kolmogorov-Smirnov one-sample test (Sokal and Rohlf, 1981).

RESULTS

The olfactometer bioassay indicates that larval *Tenebrio molitor* are unlikely to respond to airborne lactic acid molecules. Table 1 shows that yellow mealworms respond to both dried papers and solution-evolved stimuli in a manner not significantly different from the response to the control. This is true for both individual insects and groups of larvae. Table 2 illustrates the types of behavior displayed by *Tenebrio* larvae in the olfactometer bioassay. These data indicate that these larvae do show positive anemotaxis, with a total of 84.8% of the tested larvae reaching the trap vials. It is unlikely, therefore, that any behavioral bias against olfactometric analysis was overlooked.

Videotaping the larvae under high magnification revealed two predominant responses to the test chemical. Initially, mealworms wander over the filter paper surface with the following motion of the principal receptor organs: (1) antennae are rotated arbitrarily in all directions, making occasional contact with the papers; (2) maxillary palpi in a synchronous coordinated tapping activity which

generally contacts the paper two or three times per second, with occasional rates of up to five times per second; and (3) labial palpi are moved in either synchronous or asynchronous fashion, with contact occurring several times per second. Both maxillary and labial palpi contact the substrate for approximately 100 msec with a 100 to 500-msec lapse prior to the next contact. Occasionally, labial palpi may be moved in a similar fashion to the antennae with occasional paper contact rather than the above-described "probing." These occasional contacts occur when the head capsule is turned for a directional change. The other major response is that of larval arrest, in which the head capsule is curled forward so that antennae, maxillary, and labial palpi are generally all in constant contact with the test substrate. Aggregating larvae may not remain totally arrested but show occasional slow gregarious relocation. During wandering, the larvae generally display bursts of "probing" activity rather than doing so continuously. Larvae frequently come into contact with each other. This contact also involves much "probing" with palpi and antennae but is usually lacking the rapid synchronous maxillary tapping described above.

The results of the bioassay used to analyze distributions of *Tenebrio molitor* larvae are given in Figure 2. First, there were significant differences between control trials and those containing 5×10^{-3} M lactic acid test strips at each 2-hr interval. Secondly, these differences occurred at more than one larval density for each time interval. Differences become more pronounced with time. For example, at 2 hr, 100% (cumulative frequency = 1.0) of the larvae on the control were at grid densities of seven larvae per grid or less, whereas only 83.3% of the larvae on the treatment papers were found at this density or less. At 6 hr, 100% of the larvae on the control were located on grids containing seven yellow mealworms or less, whereas only 71.8% of the larvae on the treatment were found in grids containing ≤ 7 larvae. Finally, at both 4 and 6 hr, there are treatment clusters up to 13 or 14 larvae per grid, whereas on the control at 4 hr the highest density of larvae is eight per grid; at 6 hr the highest density on the control paper is six larvae per grid.

FIG. 2. Histogram comparing the cumulative frequency distributions of *Tenebrio molitor* larvae on control filter papers and those on filter papers treated with 5×10^{-3} M lactic acid at 2, 4, and 6 hr. Cumulative frequency at each abscissal point is the sum of all individuals at that density plus those at all preceding (lower) densities. *Cumulative frequency of treatment significantly less than control at $P \leq 0.001$. 2 hr: $n_1 = 174$, $N = 240$; $n_2 = 198$, $N = 240$; $D_{0.001} = 0.20257$. 4 hr: $n_1 = 172$, $N = 240$; $n_2 = 219$, $N = 240$; $D_{0.001} = 0.19862$. 6 hr: $n_1 = 155$, $N = 240$; $n_2 = 220$, $N = 240$; $D_{0.001} = 0.20767$.

There also is a tendency for a higher percentage of larvae to actually contact test substrates as opposed to control substrates, even when they are only presented one or the other. Two hundred forty insects were used in total in all treatment and also in all control trials. In the control trials, 174, 172, and 155 larval *Tenebrio* were found on the papers at 2, 4, and 6 hr, respectively. In the lactic acid trials, 198, 219, and 220 larvae were located on the papers at 2, 4, and 6 hr. The reduction in number of larvae at 6 hr in the control arenas is correlated with clusters that form at the base of the papers. These larvae (unstarved) defecate while on the papers. The fecal pellets accumulate to a substantial amount, and it is in these collections of frass droppings that the mealworms group.

Figure 3 displays the differences in mean numbers of larvae on 5×10^{-3} M lactic acid grids and control grids for occupied grids (excluding those without insects) and for all grids (including those that were empty).

A comparison of the control distribution with the expected Poisson fre-

FIG. 3. Comparison of the mean number of larvae per occupied grid (top) and per all grids (bottom) on treatment or control papers at 2, 4, and 6 hr. For occupied grids treatment (5×10^{-3} M lactic acid) is significantly greater than control at $P \leq 0.001$ at 4 and 6 hr. For total grids treatment is significantly greater than control at $P \leq 0.01$ at 4 and 6 hr.

quency is shown in Figure 4. The frequency of larvae at lower densities is less than expected for certain values at the recorded time intervals. The cumulative frequency reaches or exceeds the expected value only for grids containing a higher number of larvae (at the highest density of 6 larvae/grid for 2 and 6 hr and at 8 larvae/grid at 4 hr). This indicates that the larvae tend to group in higher densities than theoretically expected. The cumulative frequency of larvae at lower densities also decreases with time on the control papers relative to the expected cumulative frequency. The larvae interact with each other in a similar manner, forming higher, as opposed to lower, density clusters, although with much lower density maximal clusters, than they do on treatment papers.

DISCUSSION

Olfactometric analyses indicate yellow mealworms do not respond to air-streams containing lactic acid in concentrations that successfully aggregate the larvae in the aggregation arena. Thus, olfaction is unlikely to be the chemoreceptive mode of *Tenebrio* larvae. This is to be expected, since the dispersion

FIG. 4. Comparison of a histogram of the cumulative frequency distributions of *T. molitor* larvae on control filter with a plot of the cumulative frequency of the expected Poisson distribution at 2, 4, and 6 hr. Cumulative frequency at each abscissal point is the sum of all individuals at that density plus those at all preceding (lower) densities. *Cumulative frequency of the expected distribution (Poisson) of larvae significantly greater than the cumulative frequency of the larvae on control papers at the preceding larval density per grid; $P \leq 0.001$. 2 hr: $n = 174$, $D_{0.001} = 0.14779$. 4 hr: $n = 172$, $D_{0.001} = 0.14865$. 6 hr: $n = 155$, $D_{0.001} = 0.15659$.

of odor through the stored product mass would be uneven due to deflection away from unequal sized particles and collection in unevenly distributed air spaces. This would not provide a conventional concentration gradient for animal orientation. The lack of available water (Weaver et al., 1988) also would not provide for much aqueous evaporation to aid in the volatilization of the relatively low-volatility lactic acid.

The "probing" behavior viewed through videotaping suggests that mouthpart palpi are utilized to test the substrate for chemical information. The rapid maxillary tapping is similar to that described for larval *Choristoneura fumiferana* by Albert and Parisella (1988). This may be a behavior characteristic of feral *Tenebrio molitor* larvae (not those associated with stored products) that could be preadaptive for substrate sampling in stored foodstuffs. This does not suggest that purely mechanical stimuli are not also involved in such behavior.

After these animals arrive on the stimulus substrate they tend to wander rapidly across it, occasionally sampling it by "probing" in the predescribed

manner. This wandering brings the larvae into occasional contact. The individuals then tend to associate in a gregarious manner, with a conspicuous reduction in the rate of wandering, which may lead to group arrest. More often, however, individuals of these groups wander in a relatively random manner in an area in close association with the others; this wandering activity is much less rapid than that displayed after initial contact with the paper. This may involve an effect similar to that described by Burk and Bell (1973) for inhibition of cockroach locomotion by aggregation pheromone. Yellow mealworms may remain active because the bioassay does not provide localized regions of concentration. Frass accumulates to a very high density in *T. molitor* cultures, so stimuli can be continuously contacted by moving larvae.

These data suggest that: (1) mealworms show an innate tendency to aggregate, and (2) since they prefer lactic acid substrates, they might also prefer to aggregate (possibly in a different manner) on such substrates. The analysis of cumulative frequency distributions (Figures 2 and 4) indicates both are true. In addition, the movement of larvae into frass accumulated at the base of the control papers, but not from the treated papers, is convincing. The larvae on the treated paper may not do so because the lactic acid on the papers already delivers a "frass message." Both treatment and control responding larvae encounter this accumulated frass during slow wandering; only the control larvae show any pronounced preference for it.

These data allow for the suggestion of a possible scheme for the formation of mealworm clusters in these bioassays: (1) initially, larvae wander through the arena in a random manner and select a substrate for exploration; (2) next, they decide to remain upon this substrate or leave it after a period of rapid sampling; (3) if they leave, they may or may not return, via future random wandering, depending on the nature of the information further sampling provides (Weaver et al., 1989); (4) if groups of individuals select a substrate, they will encounter each other and tend to form loosely cohesive groups; (5) The chemical nature of the substrate may affect the density per unit area that individuals will tolerate, particularly if DL-lactic acid, a component of larval conspecific frass, is present. A second alternative would be that the presence of lactic acid initiates "conspecific-seeking" behavior after positively reinforcing the quality of substrate for these animals.

However, clusters are also formed on control strips in a similar manner, but at lower densities per grid. This innate tendency may also involve chemical messages related to the close proximity or contact between individuals. This may be similar to the chemotactile/mechanical aggregations among ovipositing locusts described by Norris (1970). This would mean that mealworm aggregation involves multichemical stimuli, with the unknown factor being a possible conspecific "recognition" or "interaction" factor. We are currently investigating this possibility.

It may be that the tendency for yellow mealworms to aggregate is related to an attraction to DL-lactic acid as an indicator of decomposing organic material suitable for these darkling beetles to feed upon in their feral state. The recent tendency of man to store harvested material may have provided abundant foodstuffs for an existing behavior to lead to enhanced survival by inhabiting those cryptic locations where deteriorating foodstuffs and frass may abound. Atkins (1966) states it is beneficial for aggregation to be selected for in cases where a resource is located at low frequency or sparsely distributed.

Alternatively, a mechanism may have evolved during the last 5000–20,000 generations (*T. molitor* development time 3–12 months, 5000 years of postharvest storage) whereby massive selection pressure occurred for attraction to a frass “marker.” Those individuals present in the main stored-products mass contributed little to the gene pool if they were constantly removed along with the food material or by cleaning procedures, whereas those present in cryptic locations remained to breed in these areas where fecal material, exuviae, and decomposing foodstuffs comprise nearly the entirety of the surrounding environment.

Abstract—Growth inhibitors that can be leached from excised leaves of tall fescue grass (*Festuca arundinacea*) were investigated as allelochemicals. Leachates of desiccated Rebel and Kentucky 31 grass cultivars contained three principal inhibitory compounds, abscisic acid (ABA), caffeic acid, and *p*-coumaric acid. After quantitative analysis, abscisic acid was determined to be the predominant inhibitor. A 10-fold increase in ABA levels in leachates occurred after one day of desiccation. The concentration of ABA was 40% greater in Kentucky 31 leachate than in Rebel. This difference was also found in subsequent analyses of leachates of grasses that had been allowed to dry up to 30 days; however, the ABA concentration was reduced by 60% from the 10-fold increased levels.

Key Words—*Festuca arundinacea*, Gramineae, tall fescue, growth inhibition, allelopathy, abscisic acid, caffeic acid, *p*-coumaric acid.

INTRODUCTION

Several instances of apparent allelopathic interactions involving tall fescue have been described in the literature. Fields of tall fescue (*Festuca arundinacea* Schreb) were observed by Peters and Lun (1985) to have no other plant species growing in proximity, and this was considered to be the result of allelopathy. Mixed plantings of Kentucky 31 tall fescue and sweetgum [*Liquidambar styraciflua* (L.)] resulted in a diminution of growth of the sweetgum, which was attributed to interference (competition and allelopathy) by the fescue (Walters and Gilmore, 1976). An apparent allelopathic effect of tall fescue cultivars was

also found where differences in large crabgrass [*Digitaria sanguinalis* (L.) Scop.] infestation could be related to the cultivar of fescue previously grown in the soil. Aqueous leachates of tall fescue leaves and roots were shown to inhibit seedling growth of rape (*Brassica nigra* L.), birdsfoot trefoil (*Lotus corniculatus* L.), and red clover (*Trifolium pratense* L. (Peters and Lun, 1985).

Fractionation of these leachates into anionic, cationic, and neutral fractions was followed by bioassays. Inhibition of growth was found mainly with the anionic fraction. A number of organic acids present in this fraction, including lactic, succinic, malic, citric, shikimic, glyceric, fumaric, quinic, and some unknowns, were identified as inhibitory at a combined concentration of 37.5 mM. No mention was made of the presence of phenolic acids, which have been identified as a major group of allelopathic compounds present in similar concentrations in numerous other plants (Rice, 1984; Tang and Young, 1982). This study was begun to investigate whether tall fescue might be allelopathic when present in a mixture of turf grasses since many turf grass seed mixtures contain one or more cultivars of tall fescue. In this study, phenolic inhibitors were found to be present in leachates from tall fescue, and their level was high enough to cause growth inhibition. The major growth inhibitor, however, was found to be abscisic acid (ABA). In addition, an attempt was made to assess the importance of these compounds as growth inhibitory substances involved in this allelopathic system.

METHODS AND MATERIALS

Leaching. Rebel and Kentucky 31 tall fescue were grown in a greenhouse for 30 days in June and September, 1986, and leaves, after excision, were dried in the same location. Leachates were prepared by immersion of 150 g of fresh grass, or its equivalent after desiccation, in 1 liter of H₂O at 5°C for 24 hr.

Bioassay. The seedling growth assays were done using seeds of lettuce (*Lactuca sativa* Grand Rapids), annual ryegrass (*Lolium multiflorum* Lam.), creeping red fescue (*Festuca rubra* L., Ensylva), Kentucky bluegrass (*Poa pratensis* L., Kenblue), perennial ryegrass (*Lolium perenne* L., Manhattan), and Rebel tall fescue. The preliminary lettuce seed assay was performed in Petri dishes using 10 seeds and 1 ml of test solution with 3 replicates in a growth chamber set at 14 hr day and 10 hr night at 22 ± 1°C. The grass seed assays were done using 10 randomized replicates of 10 seeds with 1 ml of test leachate solution. The concentrations of leachate used were full strength and 1, 10, and 50% dilutions. Leaf and root lengths were measured after 7–14 days depending upon the grass species.

Isolation. The fescue leachate was adjusted to pH 8 and extracted with EtOAc. After adjustment to pH 3, the leachate was extracted twice with EtOAc,

resulting in an organic acid fraction. The original EtOAc fraction was extracted two times with 1 N HCl. The EtOAc layer was considered the neutral fraction. The acidic aqueous layer was made basic (pH 9) and extracted two times with EtOAc giving the basic fraction. The organic acid fraction was further fractionated for subsequent bioassay by HPLC using a semi-prep PRP-1 10 μm polystyrene 10 \times 250-mm column and solvent gradient system of MeCN and 0.006 N HCl (Buta and Lusby, 1986). Fractions found to be inhibitory were methylated with diazomethane in ether and analyzed by GC-MS. The GC-MS analysis was done on a HP5992A instrument equipped with a J&W DB-1701 15-m capillary column, 0.32 mm ID with 0.25 μm film thickness. The GC-EC analysis of ABA was done on a HP 5840A instrument equipped with an EC detector using a J&W SE54 30-m capillary column, 0.32 mm ID with 0.25 μm film thickness. The phenolic acids were quantified by HPLC with a UV detector at 280 nm and comparison with standard compounds. The quantitative determination of ABA in leachates was done by GC-MS isotope dilution analysis using an internal standard, the hexadeuterated analog of ABA (Rivier et al., 1977). At the start of the leaching period, 200 ng of the d_6 -ABA was added to the H_2O . The organic acid fraction was further separated by HPLC, and fractions containing ABA based on retention times were methylated with diazomethane and analyzed by GC-MS as above, except using selected ion current monitoring. Ions at m/z 190 and 194, corresponding to the base peak of the natural ABA and of its deuterated analog, were monitored. Dwell time was 50 msec for each ion.

Statistical Analysis The results of the grass seedling inhibition assays were analyzed by Dr. Marla McIntosh of the Statistical Consulting Group, USDA-ARS, Beltsville, Maryland. Fisher's LSD test for differences between treatment means was done.

RESULTS AND DISCUSSION

Excised leaves of Rebel and Kentucky 31 tall fescue grass grown in the greenhouse did not contain sufficient inhibitory substances to be detected in a lettuce seedling bioassay of the aqueous leachate. The only activity found was a stimulation of growth when the leachate was used at concentrations high enough that the levels of inorganic salts, potassium (19 $\mu\text{g}/\text{ml}$) and phosphorus (3 $\mu\text{g}/\text{ml}$), are comparable to those found in nutrient solutions (Buta et al., 1987). When the excised leaves of these two grasses were allowed to dry in air in the greenhouse for 30 days, high levels of inhibitory activity on the seedling growth of five turf grasses were found in aqueous leachates of both cultivars of tall fescue. These five turf grasses, which often occur in mixed plantings, were annual ryegrass, creeping red fescue *Ensylva*, Kentucky bluegrass *Kenblue*,

perennial ryegrass Manhattan, and tall fescue Rebel. Different levels of seedling growth inhibition or stimulation of the five grasses were found to be dependent on the concentrations of the leachates of the two fescue grasses tested (Table 1). The root and leaf growth of the grass seedlings was inhibited by high concentrations of two fescue leachates and stimulated by low concentrations. No major differences in inhibitory activity of the two fescue leachates were found on root lengths of the five grasses; however, the Rebel leachate was somewhat more inhibitory in its effect on leaf lengths. No effect on grass seed germination was found for treatments with the two leachates.

A partitioning of the leachate of Rebel was done to separate the components into acidic, basic, and neutral fractions. Inhibitory activity in the lettuce seedling bioassay was found in the organic acid fraction. This acidic fraction was chromatographed by reverse-phase HPLC, and three subfractions were found to contain inhibitory compounds, which reduced root growth to 50% of the control. The first inhibitory fraction contained a compound (No. 1) identi-

fied as 3,4-dihydroxycinnamic (caffeic) acid, and the second inhibitory fraction contained a compound (No. 2) identified as 4-hydroxycinnamic (*p*-coumaric) acid, by UV and GC-MS. The third inhibitory fraction contained a compound (No. 3) causing both root and hypocotyl growth inhibition, and this compound was identified as the plant hormone abscisic acid (ABA) by GC-EC and GC-MS (Table 2). The same three compounds were also found in the inhibitory fractions of the partitioned Kentucky 31 leachates.

The concentrations of caffeic acid in the Rebel and Kentucky 31 grass (150 g/liter) leachates were 9 and 11 μ M, while those of *p*-coumaric acid were 14 and 23 μ M. These findings prompted an investigation of the concentrations of phenolic acids that were leached from fresh grass cuttings and grass dried for one day. The concentration of caffeic acid in both leachates for the two cultivars was less than 1 μ M. The concentration of *p*-coumaric acid was less than 1 μ M in the fresh grass leachate for both cultivars. The Rebel leachate of one-day-dried grass contained 1 μ M *p*-coumaric and the Kentucky 31 leachate contained 5 μ M. These concentrations, alone or in combination, were not sufficiently large to cause inhibition of seedling growth in a bioassay using Rebel seeds instead of lettuce seeds.

Since abscisic acid is involved in plant growth inhibition, senescence, and abscission (Takahashi, 1986), nanogram quantities of ABA found in the dried grass leachates by GC-EC analysis were sufficiently large, based on the bioassay results, to warrant further investigation. Experiments were designed to examine the time course of appearance of ABA after the leaves were excised and after they were allowed to dry in a greenhouse for a period of 30 days. In the first experiment, samples were collected for the first two days, after one week, and at the end of the experiment (data not shown). In the second experiment, two additional days of collection were added, and the results of the analyses for the *cis* and *trans* isomers of ABA are presented (Figure 1). These agreed with the findings in the first experiment. Concentrations of the *cis* isomer of ABA that were readily leached in 24 hr from leaves of fresh grass cuttings

FIG. 1. Concentration of ABA in leachate from excised tall fescue leaves: *cis*-ABA (—) and *trans*-ABA (---) with cultivar Rebel (○) and Kentucky 31 (●); 150 g leaves/liter H₂O for 24 hr (means and ranges of duplicate samples).

were essentially the same for both Rebel and Kentucky 31. When 150 g of leaves were leached with 1 liter of water, the resulting concentration of the *cis* isomer was about 10 nM. The concentrations of *trans*-ABA found in the same leachate were 3.9 nM for Rebel and 2.8 nM for Kentucky 31. After one day of desiccation of grass (fresh weight 150 g), the concentrations of the *cis*-ABA found in the leachate of the desiccating grass increased to 97.9 nM for Rebel and 141.4 nM for Kentucky 31, while concentrations of *trans*-ABA were 15.7 nM for Rebel and 11.0 nM for Kentucky 31. Levels of both ABA isomers remained high in leachates obtained from grass dried for several days and diminished somewhat in the leachate of the grass dried for one week. After one month of desiccation, the leachate prepared from Rebel contained 42.8 nM of *cis*-ABA and 23.2 nM *trans*-ABA, while in Kentucky 31 leachate, 51.8 nM of *cis*-ABA and 28.5 nM of *trans*-ABA were found.

Observations have been made on the regrowth of frost-damaged grasses where exudates from these reduced the rate of plant growth, leaf elongation, and tiller production. These exudates inhibited seed germination, and this was not due to pH or osmotic potential. Similar effects were found by leaching dead grasses, but the levels of the inhibitory compounds were less. The bulk of the inhibition was thought to be due to tannins and phenolic compounds (Habeshaw, 1980).

The phenolic acids (*p*-coumaric and caffeic) found in the leachates of the dried tall fescue may not be as significant as ABA in turf grass growth inhibition

considering the concentrations of these compounds found in the leachates from the grasses desiccated for 30 days. Approximately 1 mM concentrations of phenolic acids, such as *p*-coumaric, were found to be necessary to retard barley root growth (Lynch, 1980), and this concentration is approximately 100 times the phenolic acid concentration found in the 30-day desiccated fescue grass leachates. Inhibition of radicle growth of cotton and wheat seedlings by mM concentrations of phenolic acids such as *p*-coumaric in bioassays were also reported in a study of the allelopathic effects of wheat mulch (Lodhi et al., 1987). Aqueous extracts of the ground mulch containing a number of phenolic acids, including *p*-coumaric, functioned as allelochemicals in inhibiting wheat and cotton seedling growth. Similar inhibitory activity was found with extracts of soil from a wheat field. The quantity of mulch used was three to five times greater than the quantity of dried fescue grass used in preparation of the leachates described in Methods and Materials. The concentration of phenolic acids found in the fescue leachates is certainly less than in the wheat mulch leachates described. Another study examining wheat straw leachates using other analytical methods concluded that the concentrations of phenolic acids were insufficient to cause the growth inhibition observed (Hall et al., 1986). Analysis of *p*-coumaric acid levels in the soil beneath California chapparal (*Adenostema fasciculatum*) indicated that there were 2 $\mu\text{g/g}$ of soil, or less than 1% of the quantity of this acid present in leaves on the plant, and it was concluded that the amounts of phenolic acids in the soil seemed to be too small to explain allelopathic effects (Proksch et al., 1985). Similar microgram per gram soil quantities of phenolic acids were found in soil containing decomposed ryegrass residue (Chou and Patrick, 1976).

The concentrations of ABA found in the desiccated tall fescue grass leachates are in the same concentration range as those from straw leachates [100 nM derived from 100-g samples of plant material leached with 1 liter of H_2O (Hall et al., 1986)]. The 100–140 nM ABA found in leachates from fescue after one day of desiccation are sufficiently high to be phytotoxic to barley roots within a few hours of application (Lynch, 1980). The approximately 100 nM concentrations of ABA found in fescue leachates have been found to be among the lowest concentrations of ABA causing root growth inhibition of maize (Pilet and Chanson, 1981). More recent studies have shown an inhibitory effect of exogenous 10 nM ABA on maize root elongation of a portion of a plant population (Pilet and Saugy, 1987). The concentrations of ABA resulting from leaching of desiccated fescue plant material in the field would be higher than the concentrations produced through the leaching process described in Methods and Materials, where sufficient water was used to completely cover the grass leaves. The likelihood that growth-regulating quantities of abscisic acid would be leached out of senescent or dehydrated plant parts, such as leaves, appears reasonable based on the quantities of ABA found upon leaching after the

extended desiccation of 30 days. Recent studies of wheat straw residues have shown nanomolar ABA concentrations in leachates of straw that had been left on the soil surface. When straw was incorporated into the soil after harvest, no ABA was detected nine weeks later (Hall et al., 1986). A similar fate for ABA leached from the tall fescue leaves would be expected.

Acknowledgments—We thank Dr. A.N. Reed for the hexadeuterated ABA and Mr. B.A. Francis for GC-MS analysis.

(Received May 9, 1988; accepted August 1, 1988)

Abstract—Field studies were conducted to determine the effect of (Z)-11-hexadecen-1-ol (Z11-16:OH) on capture of tobacco budworm (TBW), *Heliothis virescens* (F.), males when added to two-component (HV-2) and six-component (HV-6) pheromone blends dispensed from a polyvinyl chloride (PVC) substrate. Numbers of males caught in traps baited with PVC dispensers containing 0.25% Z11-16:OH, relative to total pheromone content, were significantly higher than numbers caught with dispensers containing no Z11-16:OH. Catches of TBW were also increased significantly in some tests when Z11-16:OH was formulated in the bait at a 1% concentration. Catches were significantly reduced with dispensers containing 5.95% Z11-16:OH compared with those containing no Z11-16:OH. There were no differences in catch between traps baited with HV-2 vs. HV-6 or HV-2 + 0.25% Z11-16:OH vs. HV-6 + 0.25% Z11-16:OH when formulated in PVC substrate.

Key Words—Tobacco budworm, *Heliothis virescens*, Lepidoptera, Noctuidae, polyvinyl chloride, pheromone dispensers, pheromone blends, (Z)-11-hexadecen-1-ol.

INTRODUCTION

Two components of the tobacco budworm (TBW), *Heliothis virescens* (F.), sex pheromone complex were identified in independent studies by Roelofs et al. (1974) and by Tumlinson et al. (1975) and were reported by these two groups to be (Z)-11-hexadecenal (Z11-16:Al) and (Z)-9-tetradecenal (Z9-14:Al) in the approximate ratio of 16:1. This blend of the two chemicals was attractive to males, although Tumlinson et al. (1975) speculated that the actual pheromone blend also contained other components based on behavioral data. Klun et al. (1980) subsequently identified five additional components from pheromone gland rinses including (Z)-9-hexadecenal (Z9-16:Al), (Z)-7-hexadecenal (Z7-16:Al), (Z)-11-hexadecen-1-ol (Z11-16:OH), hexadecanal (16:Al), and tetradecanal (14:Al). Some reports concerning the relative biological effectiveness of various blends of the components seem to conflict. Blends previously tested by several workers have contained only Z11-16:Al and Z9-14:Al, while other blends contained the full complement of seven components. Generally, however, these tests have been performed with blends formulated in different substrates. For example, Sparks et al. (1979) reported that the seven-component blend was significantly better in field trapping studies than the two-component blend when dispensed from newly prepared cotton wick dispensers that were placed in traps each night.

Hartstack et al. (1980) observed no significant differences in captures of male TBW in traps baited with either the two-component or the seven-component blends. Both blends were formulated in rubber septa and laminated plastic dispensers. Hendricks (1982) also found that the two-component blend and seven-component blend caught about equal numbers of moths when each mixture was dispensed from polyvinyl chloride (PVC) capsules. Hendricks et al. (1987) showed that the two-component blend incorporated into black molded PVC performed as well as a six-component blend (Z11-16:OH omitted) formulated in the PVC. Ramaswamy et al. (1985) reported that a four-component blend of Z11-16:Al, Z9-14:Al, 16:Al, and Z11-16:OH at a ratio of 65.1:1.6:32.6:0.7 dispensed from rubber septa was an optimal sex pheromone blend for attracting male TBW and that blends containing no Z11-16:OH or those containing more than 1% Z11-16:OH in relation to Z11-16:Al were generally found to be suboptimal.

Tumlinson et al. (1982), Pope et al. (1982), and Teal et al. (1986) found no Z11-16:OH in the volatile pheromone components released from the pheromone gland or in volatiles trapped from actively calling females. Vetter and Baker (1983) evaluated blends of pheromone components with and without Z11-16:OH in studies utilizing a flight tunnel and could find no evidence that the alcohol was involved in behavioral functions under those conditions.

The purpose of our experiments was to determine if addition of Z11-16:OH

to various blends of the six other pheromone components, dispensed from PVC, would affect trap catch of TBW males.

METHODS AND MATERIALS

Pheromone Dispensers. Liquid vinyl chloride (VC) homopolymer (black, S-51-F89) was supplied by Sinclair & Rush, Inc. Pheromone components (95.7–98.5% purity) were supplied by Zoecon Corp., Palo Alto, California; Chem Samp Co., Columbus, Ohio; and Shin Etsu, Japan. Purity was verified by capillary gas chromatography on 50-m OV-1701 and 50-m SP-2330 columns. Liquid VC-pheromone mixtures were molded according to the procedure of Hendricks et al. (1987) to give molded polyvinyl chloride (PVC) dispensers. Individual dispensers were cut from both rods and sheets to give pieces that weighed 0.65 ± 0.2 g and a pheromone dosage per bait of approximately 6 mg active ingredient (AI). Table 1 shows the relative proportions of chemicals in each formulation tested.

Field Test. Inverted 75–50 cone traps (Hartstack et al. 1979) were used in all bioassays conducted in these experiments. These traps were installed so that the access hole (cone bottom) was at a height near the top of surrounding host plants. Host plants were irrigated cotton in Burleson County, Texas, and either irrigated cotton or wild sunflowers in Cameron County, Texas. Traps were positioned at least 20 m apart in tests conducted in Cameron County and at least 50 m apart in tests conducted in Burleson County. The test pheromone dispensers (baits) were suspended 3 cm below the trap at the center of the open cone.

Field tests were conducted to determine the effect of adding varying amounts of Z11–16:OH to a blend of HV-2 or of HV-6 (Table 1). Z11–16:OH

TABLE 1. PERCENTAGES OF CHEMICALS BLENDED IN 2-COMPONENT AND 6-COMPONENT MIXTURES OF *H. virescens* SEX PHEROMONE IN PVC SUBSTRATE

Chemical	Percentage (proportion)/ formulation	
	HV-2	HV-6
(Z)-11-Hexadecenal (Z11–16:AI)	93.7 (14.8)	78.4 (14.8)
(Z)-9-Tetradecenal (Z9–14:AI)	6.3 (1.0)	5.3 (1.0)
(Z)-9-Hexadecenal (Z9–16:AI)		1.8 (0.3)
(Z)-7-Hexadecenal (Z7–16:AI)		1.8 (0.3)
Hexadecanal (16:AI)		9.2 (1.7)
Tetradecanal (14:AI)		3.5 (0.7)

^aProportions were calculated using the amount of Z9–14:AI as (1.0) part.

was added to the blends at concentrations of 0.25%, 1.0%, and 5.95% of the total pheromone content of the individual dispensers. In one test, HV-2 and HV-2 + Z11-16:OH formulated in PVC were compared with a blend of Z11-16:Al (1000 μg), 16:Al (500 μg), Z9-14:Al (25 μg) and Z11-16:OH (10 μg) formulated in rubber septa according to the method of Ramaswamy et al. (1985). Since previous work has indicated that this formulation is very effective in trapping TBW males during the first four nights of use but that efficacy falls off rapidly on subsequent nights (Lopez et al., 1987); rubber septa containing pheromone were replaced every four days. PVC lures were not replaced during the 16-day duration of the test. All other tests were conducted for 10- to 14-day periods with five replicates per dispenser category. The position of each dispenser was initially randomized within each replicate, and then positions were rotated within the replicate daily to reduce bias caused by trap location. Traps were set in lines perpendicular to prevailing winds (SE).

Data were analyzed by a nonparametric *t* test (Ostle, 1969).

RESULTS AND DISCUSSION

Field experiments in which traps were baited with molded PVC dispensers containing Z11-16:Al and Z9-14:Al (14.8:1 ratio) plus varying quantities of Z11-16:OH indicated that small quantities of Z11-16:OH enhanced the performance of the dispenser as indicated by trap catch (Table 2). In tests in Burle-

HV-2	21.3 b	38.1 b	7.6 b
HV-6	— ^c	36.1 b	9.2 b
HV-2 + 5.95% Z11-16:OH	13.2 c	16.5 c	4.5 c

^aHV-2 and HV-6 formulations are described in Table 1. Percentage Z11-16:OH was calculated on the basis of total pheromone content.

^bMeans in the same column followed by same letters were not significantly different ($P \leq 0.05$, $df = 54$, $t \leq 2.01$ for Burleson County, 1986; $P \leq 0.05$, $df = 82$, $t \leq 1.99$ Cameron County, 1986; $P \leq 0.05$, $df = 58$, $t \leq 2.0$ for Burleson County, 1984).

^cNot tested.

son County and Cameron County, Texas, in 1986, those lures containing the lowest quantity of Z11-16:OH (0.25% of the total pheromone content) caught significantly more male TBW moths than dispensers with no Z11-16:OH or those containing high levels of Z11-16:OH (5.95%). Also, traps baited with dispensers containing high levels of Z11-16:OH caught significantly fewer male TBW moths than those without Z11-16:OH. There were no significant differences between mean catches in traps baited with PVC dispensers containing HV-2 and HV-6. In a test in Burleson County in 1984, the same pattern was observed except that moth catches were greater in traps baited with dispensers containing HV-2 plus 1.0% Z11-16:OH than in traps baited with HV-2 alone. Dispensers containing 5.95% Z11-16:OH caught fewer moths than traps baited with dispensers containing no Z11-16:OH.

The effect of Z11-16:OH was tested in June, July, and August 1987, when captures of TBW in pheromone traps were low, medium, and high, respectively, to determine if the number of TBW being captured influenced the effect of Z11-16:OH on field performances of the pheromone in PVC dispensers containing HV-6. Traps baited with dispensers containing 0.25% and 1.0% Z11-16:OH caught more male TBW than traps baited with dispensers containing no Z11-16:OH at all three capture levels except in the July test, where the number caught by dispensers containing 1.0% Z11-16:OH was numerically greater. However, the difference was not significant at $P < 0.05$ (Table 3). Traps baited with dispensers containing 5.95% alcohol caught significantly fewer TBW moths than traps baited with dispensers containing no Z11-16:OH or 0.25% or 1.00% Z11-16:OH.

In 1986, a comparison was made using PVC formulations of HV-2 and HV-6 alone or with 0.25% Z11-16:OH. In this comparison, dispensers con-

^aHV-6 formulation is described in Table 1. Percentage Z11-16:OH was calculated based on total pheromone content.

^bMeans followed by same letters were not significantly different, ($P \leq 0.05$, $df = 190$, $t \leq 1.97$ for June; $P \leq 0.05$, $df = 190$, $t \leq 1.97$ for July; $P \leq 0.05$, $df = 130$, $t \leq 1.98$ for August).

TABLE 4. COMPARISON OF NUMBERS OF *H. virescens* MALES CAUGHT IN TRAPS BAITED WITH HV-2 AND HV-6 ALONE AND WITH 0.25% Z11-16:OH IMPREGNATED IN PVC SHEETS, 6 mg/lure, BURLESON COUNTY, TEXAS, 1986

Formulation ^a	Mean no. of <i>H. virescens</i> males caught/trap/night ^b
HV-6 + 0.25% Z11-16:OH	88.6 a
HV-2 + 0.25% Z11-16:OH	88.5 a
HV-6	54.5 b
HV-2	48.1 b

^aHV-2 and HV-6 formulations are described in Table 1. Percentage Z11-16:OH was added at a rate of 0.25% of the total pheromone.

^bMeans followed by same letters were not significantly different ($P \leq 0.05$, $df = 138$, $t \leq 1.98$).

taining HV-2 and HV-6 plus 0.25% alcohol caught significantly more male *H. virescens* than dispensers containing HV-2 and HV-6 without alcohol (Table 4). No differences were observed in comparisons of HV-2 and HV-6 or between HV-2 + Z11-16:OH and HV-6 + Z11-16:OH.

In the test comparing the rubber septum formulation proposed by Ramaswamy et al. (1985) and the PVC formulations of HV-2 and HV-2 + 0.25% Z11-16:OH, the Ramaswamy dispenser replaced every fourth day caught significantly more male TBW moths than either of the HV-2 PVC formulations. Also, the HV-2 PVC formulation supplemented with 0.25% Z11-16:OH caught significantly more moths than the HV-2 PVC formulation containing no Z11-16:OH. However, the latter two dispenser types (PVC) were not replaced during the 16-day test period (Table 5).

TABLE 5. COMPARISON OF NUMBERS OF *H. virescens* MALES CAUGHT IN TRAPS BAITED WITH HV-2 AND HV-2 + Z11-16:OH FORMULATED IN PVC RODS OR 4-COMPONENT BLEND FORMULATED IN RUBBER SEPTA, BURLESON COUNTY, TEXAS, 1986

Formulation and substrate	Mean no. of <i>H. virescens</i> males caught/trap/night ^a
4-component blend, septa ^b	88.8a
HV-2 + 0.25% Z11-16:OH, PVC	68.7b
HV-2, PVC	39.6c

^aMeans followed by same letters were not significantly different ($P \leq 0.05$, $df = 82$, $t \leq 1.99$).

^bLure was replaced every four days; rubber septa was formulated according to Ramaswamy et al. (1985). PVC lures were not replaced during the 16-day test. Four-component blend was Z11-16:Al, Z9-14:Al, 16:Al, and Z11-16:OH at a ratio of 65.1:1.6:32.6:07.

These tests have demonstrated that the addition of 0.25 or 1.00% of Z11-16:OH to PVC formulations containing either HV-2 or HV-6 enhanced the performance of the dispensers in field trapping studies using inverted cone traps. However, addition of 5.95% of the alcohol to the formulation reduced the effectiveness of the lure. The 5.95% Z11-16:OH used in this study was equivalent to the proportion of Z11-16:OH used by Klun et al. (1980) in field bioassays of attraction of TBW males to mixtures of compounds identified from TBW females. Our results agree with the findings of Ramaswamy et al. (1985), who reported a similar response when pheromone was formulated in rubber septa.

Acknowledgments—This research was conducted in cooperation with the Texas Agricultural Experiment Station, Texas A&M University, College Station, Texas, 77843.

(Received April 28, 1988; accepted August 2, 1988)

Abstract—*Matsucoccus resinosae* in the United States, *M. matsumurae* in China, and *M. thunbergianae* in Korea use (2*E*, 4*E*)-4,6,10,12-tetramethyl-2,4-tridecadien-7-one (**1**) (matsuone) as the primary component of their sex attractant pheromones. The structure was postulated from mass and NMR spectra and confirmed by synthesis of analogs **3**, (2*E*, 4*E*)-4,6,11,12-tetramethyl-2,4-tridecadien-7-one, and **4**, (2*E*, 4*Z*)-4,6,11,12-tetramethyl-2,4-tridecadien-7-one. Both analogs were attractive to the males of *M. resinosae* in laboratory bioassays and to *M. matsumurae* in laboratory and field tests, but the 4*Z* analog (**4**) was much less so than the 4*E* analog (**3**) and had inhibitory effects at high concentrations. Dodecanol, isolated from aeration and solvent extracts of female *M. resinosae*, evoked characteristic wing-raising by pedestrian males, but the role of this response was not determined.

Key Words—*Matsucoccus resinosae*, *M. thunbergianae*, *M. matsumurae*, sex pheromone, analog, dodecanol, Homoptera, Coccoidea, Margarodidae, (2*E*, 4*E*)-4,6,10,12-tetramethyl-2,4-tridecadien-7-one, matsuone.

INTRODUCTION

Despite their great economic significance and diversity, research on semi-chemical-mediated sexual behavior of scale insects and mealybugs (Coccoidea) has been relatively recent and limited. The first report of a sex attractant

in the superfamily was for the red pine scale, *Matsucoccus resinosae* Bean & Godwin (Doane, 1966). Warthen et al. (1970) isolated the sex pheromone of the California red scale, *Aonidiella aurantii* (Maskell), and the chemical structures of the active compounds were described seven years later (Roelofs et al., 1977). To the present date, sex pheromone structures for three additional armored scales (Diaspididae) and two mealybugs (Pseudococcidae) have been reported. Three sex pheromone components have been identified from the San Jose scale, *Quadraspidiotus perniciosus* (Comstock), (Gieselmann et al., 1979b; Anderson et al., 1981), and two from the California red scale (Roelofs et al., 1977). Single component attractants were identified for the yellow scale, *Aonidiella citrina* (Coquillett), (Gieselmann et al., 1979a); the white peach scale, *Pseudaulascaspis pentagona* (Targioni-Tozzetti), (Heath et al., 1979); the Comstock mealybug, *Pseudococcus comstocki* (Kuwana), (Bierl-Leonhardt et al., 1980); and the citrus mealybug, *Planococcus citri* (Risso), (Bierl-Leonhardt et al., 1981). The multiple components of the San Jose scale and the California red scale are individually attractive and apparently not synergistic. The alcohol corresponding to the propanoate sex attractant of the white peach scale acts as a short-range sex stimulant but is not an attractant (Einhorn et al., 1983). Thus, for the purpose of bringing the sexes together, the multiple components are apparently redundant; effectively, all Coccoidea investigated to date respond to single components.

Analogues of California red scale pheromones and the closely related yellow scale were not active (Roelofs et al., 1977, 1978, 1982; Anderson and Henrick, 1979; Gieselmann et al., 1980) while pheromone analogues of the white peach scale (Heath et al., 1979), the citrus mealybug (Bierl-Leonhardt et al., 1981), and the Comstock mealybug (Mori and Ueda, 1981; Uchida et al., 1981; Bierl-Leonhardt et al., 1982) showed somewhat inferior activity.

Sex pheromones were structurally different (Roelofs et al., 1982) and not cross-attractive between *Aonidiella* species (Moreno et al., 1972) or *Planococcus* species (Tremblay and Rotundo, 1976). In contrast, cross-attraction was complete among *M. resinosae*, *M. matsumurae* (Kuwana)⁴ (Young et al., 1984), and *M. thunbergianae* Miller and Park (Park et al., 1986), partial between *M. matsumurae* and *M. massoniana* Young and Hu (Young and Qi, 1983), and slight between *M. massoniana* and *M. resinosae* (Young et al. 1984). Pheromones of *M. matsumurae* (Qi et al., 1983), *M. josephi* (Sternlicht et al., 1983), and *M. resinosae* (Park et al., 1986) have been isolated. We report the chemical structure of the primary component of the sex attractant pheromone isolated from *M. resinosae* in the United States, *M. matsumurae* in China, and *M. thunbergianae* in Korea. We also report identification of a compound from female

⁴McClure (1983) and Young et al. (1984) suggested that *M. resinosae* might be a junior synonym of *M. matsumurae*, but the names have yet to be formally proposed.

M. resinosa that evokes a wing-raising response, but not taxis, by males of that species. Lastly, we present a comparison of laboratory bioassays of male *M. resinosa* response to analogs of its pheromone and to a crude extract of pheromone from *M. thunbergiana* females.

METHODS AND MATERIALS

Chemistry of Pheromone and Analogs. In August 1982, 1984, and 1985, respectively, extracts of 3500, 17,000, and 26,500 female *M. resinosa* were fractionated as previously described (Park et al., 1986). A component that elicited attraction was in subfraction 3-5-4 and a component that evoked wing-raising was in fraction 2. A unit-resolution, EI mass spectrum (70 eV) was obtained for the attractant on a Finnigan 4000 instrument fitted with a DB-1, 30-m capillary column, and for the wing-raising component on a Finnigan 3000 fitted with a 1-m OV-101 packed column.

The tentative identification of the compound that elicited wing-raising was confirmed as dodecanol by coinjection with an authentic sample on a 6.1-m \times 3-mm-ID glass column, 6% Carbowax 20 M and on a 3-m \times 3-mm-ID glass column, 4% FFAP, and also by congruence of the mass spectrum with that of an authentic sample. A high-resolution mass spectrum on the sex attractant component was obtained on a Kratos MS 50TC spectrometer fitted with a 30-m DB-1 column. The same components were also identified in the volatiles obtained by aerating the female *M. resinosa* for five days prior to extracting them; purified air (charcoal) was passed over the insects on crumpled filter paper in a flask, and the volatiles were collected on Porapak Q, from which they were extracted with pentane.

An extract in 1 ml hexane of 400 female *M. thunbergiana* collected from infested *Pinus thunbergiana* in the southwestern extremity of Korea was used for cross-attraction bioassays against *M. resinosa* males (Park et al., 1986) and for coinjection with extracts of *M. resinosa* and *M. matsumurae* on a 30-m DB-1 capillary column programmed, after 40 sec at 35°C, to 200°C at 4°/min; a single sharp peak at 34.8 min represented the attractant component common to the three samples. *M. resinosa* and *M. thunbergiana* extracts were also coinjected on a 50-m FFAP capillary column under the same conditions.

In the spring of 1983, approximately 30,000 female *M. matsumurae* were collected from *Pinus tabulaeformis* in the suburbs of Wuxi, Jiangsu Province and in Haiyang County, Shandong Province. Purified air (molecular sieves) was passed over these insects for seven days, and the volatiles were trapped on Tenax (see Qi and Burkholder, 1982, for general procedure), which was then extracted with hexane. The active fraction was eluted from a silica gel column (35 \times 0.6 cm, 200–320 mesh) with 2% ether in hexane, and the active subfrac-

tion was eluted from a Florisil column impregnated with 15% silver nitrate (35×0.6 cm, 120–150 mesh) with 10% ether in hexane. This active subfraction was concentrated, and aliquots were repeatedly injected on a 40-m \times 0.3-mm-ID PEG capillary column at 158°C, N₂ 2 cc/min. The collected active peak (retention time 33 min) in 3.5 ml hexane gave a unit-resolution mass spectrum that was congruent with that obtained by GC-MS on subfraction 3-5-4 from *M. resinosa* (above). A GC-FTIR (vapor phase) was obtained on an IBM IR98 fitted with a DB-1 capillary. To obtain an NMR spectrum, the *M. matsumurae* sample was injected on a 1.5-m \times 9-mm-ID glass column, 3% OV-101 on Chromosorb G 50/80, 140°C, He 80 cc/min. The peak at 18–22 min was collected in a 25-cm \times 1.7-mm-OD glass capillary under thermal gradient (Brownlee and Silverstein, 1968) and rinsed with 0.4 ml 100% C₆D₆ into a 5-mm-OD NMR tube. The NMR spectrum was obtained on a General Electric GN 500 spectrometer.

Unit resolution mass spectra were obtained on two synthesized analogs (**3** and **4**) under the same conditions above for the primary attractant component. Compounds **3** and **4** were separated on a 2.4-m \times 6-mm-ID glass column, 4% TCEP on Chromosorb G 60/80, 140°C, N₂ 60 cc/min. 500-MHz NMR spectra on **3** and **4** were obtained under the same conditions used for the isolated primary sex attractant component.

Preparing Dilutions of Synthetic Pheromone Analogs and Crude Female Extract. Two pheromone analogs were synthesized: a positional isomer of the *M. resinosa* pheromone component, **3**, and its geometric isomer, **4**. These compounds were prepared at concentrations of 5 ng in 1 μ l hexane and 1 μ g in 1 μ l hexane, respectively. The original dilution of compound **3** was further serially diluted so that each 1 μ l hexane dilution contained 0.5 ng, 0.05 ng, 5 pg, and 0.5 pg; the original dilution of compound **4** was also serially diluted to 0.1 μ g, 0.01 μ g, 1 ng, 0.1 ng, and 0.01 ng in 1 μ l hexane.

A crude pheromone extract was made by immersing in 1 ml of hexane 200 newly emerged *M. thunbergiana* females collected from a laboratory colony at Seoul on March 18, 1986. After three days of storage at room temperature, the crude extract was serially diluted to 10%, 1%, 0.1%, and 0.01%. The amount of extracted pheromone in 1 μ l of each dilution was 2×10^{-2} , 2×10^{-3} , 2×10^{-4} , and 2×10^{-5} female equivalents (FE), respectively. The original crude extract and its hexane dilutions were stored at -10 ± 5 °C.

Preparation of Males for Testing. Branches of red pine (*Pinus resinosa*) containing cocoons of *M. resinosa* were collected from Dutchess County, New York, in September 1987 and put in emergence cages made of cardboard boxes with three Petri dishes attached at one side of each cage. The cages were stored at 20 ± 4 °C under natural day light. Because the males show strong positive phototaxis, newly emerging males could be collected from inside the Petri dishes.

Bioassays with Medicine Droppers. The bioassay procedures using medicine droppers were those of Park et al. (1986). Each test male was kept under a numbered, inverted, transparent plastic cup (ca. 20 ml) until tested. After each test, the male was covered with the same cup and kept for the next test. The stimulus was delivered to walking males, on a sheet of white paper, in puffs from a medicine dropper that had been charged with 1 μ l of solution placed with a micropipet about 1 cm inside the tip. The dropper tip was positioned to one side of a walking male, about 8 mm from the antennae. Puffs of air were then forced from the medicine dropper by gently pressing the bulb at 1.5-sec intervals. The attraction was measured as degree of following towards the retreating dropper tip. Males that followed for one or more sides of a 4-cm-sided equilateral triangle were given scores from 1 to 3, according to the number of triangle sides completed; males responding to the attractant but following less than one side were given a score of 0.5, and those who did not follow were given a score of 0.

On each day of this experiment, between five and eight males were used at 5-min intervals in successive tests of each dilution. A 1% dilution of the crude female extract (2×10^{-3} FE) was used as a standard. Only actively walking males that had a response score of 3 to the standard were used. Males that became sluggish were replaced as needed to complete the test series.

The bioassays were done at $22 \pm 1^\circ\text{C}$, $68 \pm 7\%$ relative humidity, and 500–700 lux of fluorescent light between 8:00 AM and 12:30 PM from September 6 to 27, 1987. The number of stimuli varied among the days. Bioassays always proceeded from the lowest concentration to the highest, and the order for the tests with dilutions of crude extract, **3**, and **4** was alternated each day. The data were analyzed in a completely randomized design and subjected to Duncan's multiple-range test.

Dummy Female Experiments. Dummy females were made by rolling a 4×10 -mm filter paper coated with rice paste to form a cylinder 4 mm long and 1.5 mm in diameter, similar in shape and size to a female. Each dummy female was treated with 1 μ l of test solution, and held for 2 min to allow the hexane to evaporate before the test. The dummy female was placed perpendicular to the path of the walking male, ca. 1 cm away, and the male behavior was observed. Bioassays were done at $22 \pm 1^\circ\text{C}$, $65 \pm 3\%$ relative humidity, and 700 lux of fluorescent light between 10 AM and 3 PM from September 25 to October 8, 1987. Males were selected and replaced as in the medicine dropper bioassays, and allowed a rest of about 10 min between tests.

Laboratory and Field Bioassays of Compounds 3 and 4 Using M. matsurae in China. The laboratory bioassay used was the Petri dish method described by Qi et al. (1983). The assay was conducted by placing two 1-cm pieces of filter paper, one containing the material to be tested, the other, an appropriate solvent blank, into a 7-cm-diameter Petri dish. After the solvent

had evaporated, 10 males were admitted and the Petri dish was immediately covered. After a 2-min adaptation period, the number of males on the sample disk versus the number of males on the blank disk was counted every 2 min over a period of 20 min.

The field experiments were conducted in the suburbs of Wuxi, PRC, from April 26 to 29, 1988. The trap consisted of a piece of cardboard (22 × 26 cm) that was folded so that the 26-cm side was bisected; the angle of the fold was 60°. Both sides of the trap were coated with Vaseline and a hole was cut (1 cm) in each flap. For these tests, a rolled piece of filter paper was utilized as the release device, and it was hung from the inside of the trap.

RESULTS AND DISCUSSION

Isolation and Identification of Active Compounds. *M. resinosa* pedestrian males demonstrated positive klinotaxis upon exposure to an air puff from a medicine dropper charged with solvent-or-aeration extracts of females (Park et al., 1986). While following the plume, males often raised their wings and antennae in a characteristic fashion. Bioassays of extract fractions showed that wing-raising and taxis were elicited by different compounds. Dodecanol was confirmed to be the principal component of the fraction that stimulated wing-raising, and, in bioassays, synthetic dodecanol (1 μg in 1 μl hexane) repeatedly elicited the typical wing-raising behavior.

Bioassays of fractions after three successive GC fractionations placed the principal component of the sex attractant in subfraction 3-5-4 (Park et al., 1986). Spectral data suggested most aspects of the chemical structure but did not permit discrimination among possible structures 1-4. Synthesis of analogs 3 and 4 and comparison of their NMR spectra with that of the isolated attractant resulted in the assignment of structure 1 for the attractant.

Identification of Pheromone Components. Unit-resolution GC-EI MS of the isolated attractant gave the following significant peaks (%): m/z 250 (M, 0.9), 141 (4.4), 123 (24), 109 (100), 81 (20), 67 (35), 57 (21), 55 (26), 43 (57), 41 (48). A GC-CI MS (methane) gave a base peak of m/z 251, thus confirming m/z 250 as the molecular ion. The high-resolution GC-MS gave a molecular ion at 250.2268 m/z ($C_{17}H_{30}O$, index of hydrogen deficiency of three). The molecule split into two fragments: 141.1275 m/z (10%, $C_9H_{17}O$) and 109.0993 m/z (base, C_8H_{13}), the former containing a nonconjugated C=O group (GC-FTIR intense peak at 1747 cm^{-1}), the latter containing two elements of unsaturation in the form of multiple bonds or rings, and possibly branching, so disposed as to stabilize the charge.

A 500-MHz [1H]NMR spectrum, in deuterated benzene, and associated single-frequency decouplings provided the bulk of the data used in elucidating the structure(s). Although there were some impurities present in the isolated

sample, the following peaks were easily discerned: δ 0.76 (d, 3H), 0.81 (d, 3H), 0.85 (d, 3H), 1.14 (d, 3H), 1.60 (d, 3H), 1.68 (s, 3H), 2.40 (t, 2H), 3.29 (m, 1H), 5.25 (d, 1H), 5.50 (m, 1H), and 6.01 (d, 1H). These absorptions account for 24 of the 30 protons and allow us to make certain tentative assumptions. The molecule contains six methyl groups, three of which are quite far upfield and are probably associated with purely aliphatic surroundings; two of them at δ 1.60 and 1.68 are probably olefinic methyls, and one of them has an intermediate chemical shift. The compound contains three olefinic protons that are probably associated with two different double bonds. Furthermore, to account for the downfield doublet at δ 6.01, the two double bonds are assumed to be conjugated.

Most of the structure can be assembled on the basis of the decoupling experiments. Irradiation of the methyl doublet at δ 1.14 collapsed the multiplet at δ 3.29 to a doublet. Irradiation of the multiplet at δ 3.29 collapsed the doublets at δ 1.14 and δ 5.25 to singlets. Since this spin system is closed (no other proton couplings), and since the downfield chemical shift of the methine multiplet at δ 3.29 cannot be explained solely on the basis of being allylic, the proton is probably next to the C=O group; thus we draw the fragment shown in Scheme 1, which contains a trisubstituted olefin.

SCHEME 1.

Irradiation of the doublet at δ 6.01 collapsed the multiplet at δ 5.50 to a quartet. Termination of this end of the chain was deduced by irradiating at δ 5.50; the doublet at δ 1.60 collapsed to a singlet. Since the two double bonds, one of which is trisubstituted while the other is disubstituted, are conjugated, the other olefinic methyl group at δ 1.68 must be on C-4. This information allowed us to piece together completely one end of the molecule, including the carbonyl group (Scheme 2). The terminal double bond can be assigned the *trans* configuration on the basis of the large (17 Hz) coupling constant between the two olefinic protons. The stereochemistry of the trisubstituted double bond cannot be determined from this information.

SCHEME 2.

FIG. 1. Cleavage in the mass spectrum to give base peak.

The mass spectrum indicated that the main cleavage was adjacent to the carbonyl group to give, as the base peak, a hydrocarbon fragment containing a highly stabilized tertiary carbocation (m/z 109, C_8H_{13} , Figure 1). The remainder of the molecule is represented by the peak at m/z 141 ($\text{C}_9\text{H}_{17}\text{O}$, Figure 1). The β,γ -unsaturated carbonyl system accounts for all of the "functional groups" because subtraction of the formula for this fragment, $\text{C}_9\text{H}_{13}\text{O}$, from the molecular formula, $\text{C}_{17}\text{H}_{30}\text{O}$, gives C_8H_{17} —a saturated hydrocarbon chain. This chain, R in Figure 1, contains three methyl groups, each of which is adjacent to a single proton since each shows a doublet in the NMR spectrum. Individual irradiation of the methyl doublet at δ 0.81 and at δ 0.85 caused a partial collapse of the multiplet at δ 1.58, indicating that the hydrocarbon chain terminates with an isopropyl group. Only placement of the methyl group represented by the doublet at δ 0.76 remains. Unfortunately, the important methine proton adjacent to this methyl group is obscured by impurities. Therefore, the evidence can only reduce the number of possible structures to four, if one ignores the stereochemistry of the two chiral centers. The four structures are shown in Figure 2.

FIG. 2. The four structures permitted by the spectral data.

To complete the structure assignment, a synthetic scheme was devised, the essential features of which (1) utilize either of the two primary bromides (**5** and **6**, Scheme 3) thus enabling us to pinpoint the uncertain position of the final methyl group; and (2) provide both geometric isomers during the formation of the trisubstituted double bond.

SCHEME 3.

We now have enough information to identify the isolated attractant, having synthesized **3** and **4**. Although the methyl group is in the wrong position, the synthesis did allow us to assign the correct methyl position and the stereochemistry of the trisubstituted double bond as *trans* by NOE NMR experiments with both analogs **3** and **4**. Irradiation of the methyl group connected to the trisubstituted olefin in **3** gave no NOE enhancement while irradiation of the corresponding methyl group in **4** gave an expected NOE enhancement. The same type of enhancement was noted in a similar olefinic system by Takeda et al. (1982). A similar β,γ -unsaturated ketone system in the antibiotic 9-methylstreptimidone **7** also assisted in assigning the stereochemistry (Scheme 4) (Becker and Rickards, 1979). The greater biological activity of the *E* analog **3** over that of the *Z* analog **4** may be an additional, albeit nonrigorous, argument for the *4E* configuration of the isolated attractant (see below).

SCHEME 4.

The hydrocarbon portion of the pheromone molecule has been synthesized and analyzed. A 500-MHz ^1H NMR spectrum of the ketone/benzyl ether, **8**, closely matches the upfield portion of the ^1H NMR spectrum of the pheromone. We are now converting compound **8** into the racemic pheromone, **1**, whose systematic name is (*2E*, *4E*)-4,6,10,12-tetramethyl-2,4-tridecadien-7-one and to which we assign the trivial name matsuone. Details of the synthesis of racemic compounds **1-4** will be reported elsewhere, and elucidation of the stereochemistry at C-6 and C-10 will be undertaken for compounds **1** and **2**.

Bioassays of Sex Pheromone Analogs 3 and 4. Males of *M. resinosa* were attracted by 2×10^{-4} FE of the *M. thunbergiana* female crude extract in the medicine dropper bioassay. The mean response score approximates those of *M. resinosa* and *M. thunbergiana* to 3×10^{-4} FE of *M. resinosa* female crude extract (Park et al., 1986).

At concentrations of 0.05 ng and higher, compound **3** elicited response by male *M. resinosa* equivalent to that of 2×10^{-4} FE of extract of *M. thunbergiana* females, while the index of response to **4** at a concentration 200 times higher (0.01 μ g) was, at most, 50% of that of **3** (Table 1). The threshold concentration was 5 pg for **3** and about 0.1 ng for **4**, although the mean value of response scores at this concentration was not significantly greater than that of the hexane control. A decrease in the attractiveness of **4** at concentrations higher than 0.01 μ g (Table 1) was associated with apparent irritation (movement sideways from the dropper tip or momentary cessation of walking, lowering the body and/or raising wings).

In the dummy female experiments, male behavior was classified into four categories: (1) males that showed no interest, by passing by or walking less

^dFemale equivalent.

than two female body lengths on the dummy females, (2) those that lingered on dummy females by walking on them for more than two female body lengths, (3) those that showed obvious copulation attempts, and (4) those that, upon contact with a dummy female, showed apparent irritation by retreating a short distance sideways or backwards. A male that avoided contact with dummy females often lowered its body or raised its wings. All males or those that showed avoidance reaction either walked away or returned to the dummy females and repeated the avoidance behavior.

Actively walking males, both in the presence and absence of pheromone, held their antennae parallel to the long axis of the body in lateral view and about 90° from each other in dorsal view. Wings were usually positioned flat, and the tips were dragged when walking; the costal margins of the wings made about a 90° angle with each other. The posture of the antennae or wings did not change until the male contacted the female or other substances bearing sufficient pheromone. This was in contrast with the behavior of the citrus mealybug (Gravitz and Willson, 1968) and the yellow scale (Moreno et al., 1972), where the posture of male antennae was changed before touching the females. When a male contacted and climbed on the female, the antennae closed to an angle of $0-30^\circ$ and were lifted $30-80^\circ$. The wings also were often lifted $30-60^\circ$. The male attempted a copulation thrust by bending the aedeagus downward, either immediately or after orienting his body to that of the female. This posture was maintained until copulation was completed.

Table 2 shows the results of the dummy female tests. Most males made copulatory attempts or lingered on dummy females treated with 2×10^{-3} FE of crude extract. Some males avoided dummy females bearing 2×10^{-2} FE—a concentration 100 times stronger than that which elicited strong response in the medicine dropper assay (Table 1). On the contrary, avoidance behavior was not observed when males were presented with dummy females treated with 5 ng of **3**, which is also 100 times stronger than what is required for a strong response in the medicine dropper assay. Males presented with dummy females treated with **4** did not attempt copulation and either showed no response or even avoided them. Although our female extract was made at 10 AM, some of the newly emerged females probably copulated before they were collected and immersed in hexane. Males of *M. thunbergianae* that showed avoidance behavior to the same crude extract dilutions used in this experiment, did not avoid dummy females bearing 5×10^{-2} FE of extract made from newly emerged virgin females (Park, 1988). This suggests that mated females produce a chemical that inhibits male copulatory behavior (perhaps this is the role of dodecanol). Equal parts of compounds **3** and **4** on dummy females evoked lingering and copulatory attempts by males. However, when **4** was increased relative to **3**, most males avoided the dummy females. Although the number of males tested was too small for statistical significance, and since male physiology

affecting copulatory behavior should be studied further, it is apparent that pheromone analogs may elicit inhibitory as well attractive behaviors.

In laboratory bioassays with *M. matsumuræ* in China, compound 3 was significantly more attractive than compound 4 at all doses (Table 3). Qi et al.

^aMeans followed by the same letters are not significantly different as determined by the Wilcoxon-Mann-Whitney rank-sum test.

(1983) found that 16 μg of compound 3 elicited a response comparable to 5 FE in laboratory bioassays. In field tests in China, only the 56- μg dose of compound 3 attracted significantly more males than the controls; both 32 μg of compound 4 and 16 μg of compound 3 were equivalent in attractiveness to the controls (Table 4).

Analogs have not been found previously to reduce catches of flying male scales on traps (Roelofs et al., 1977; Gieselmann et al., 1980) or close range attraction by walking males (Heath et al., 1979). It is not known whether some of these coccoid pheromone analogs previously reported have inhibitory effects on close range attraction or copulatory behavior.

Based on our results and previous reports of partial activity of coccoid pheromone analogs, we expect the synthetic pheromone (1) of *M. resinosa* to show much higher activity than its analogues; these studies are in progress.

Acknowledgments—We are greatly indebted to the following: Ellen Gallagher, Michael Griggs, Alan Jones, Lorene Lanier, Juan Pajares, Carl Palm, Stephen Teale, Alison Teale, Shaofu Xu, Wen-jun Fu, and Fang-gui Zhao (the latter three at the Shanghai Institute of Entomology) for scale collections, extraction, and aerations; Timothy Wachs (Cornell University) for the GC-FTIR and GC-MS, and Hazel Jennison for GC-MS; Dr. Michael Kolor and Donald Rizzo (both from General Foods Inc.) for high-resolution mass spectra; Gregory Hefron for high-resolution NMR spectra; and Sang kyu Park for his contribution to the synthesis of the analogs. C. Palm and S. Teale assisted with manuscript preparation and data analysis. We are grateful to the New York Department of Environmental Conservation for use of facilities at Ninjin Mountain and assistance in locating *M. resinosa* infestations.

MECHANISM OF DAMAGE-INDUCED ALKALOID PRODUCTION IN WILD TOBACCO

IAN T. BALDWIN

*Section of Neurobiology and Behavior
Cornell University
Ithaca, New York*

(Received August 3, 1987; accepted August 5, 1988)

Abstract—Greenhouse-grown tobacco plants of the species *Nicotiana sylvestris* (Solanaceae) subjected to leaf damage show a fourfold increase in the alkaloid content of their undamaged leaves. This increase in nicotine and normicotine concentrations begins 19 hr after the end of the damage regime, reaches a maximum at nine days, and wanes to control levels 14 days after the start of leaf damage. The increase in leaf alkaloid content in damaged plants is largely due to a 10-fold increase in the alkaloid concentration of the xylem fluid entering leaves, which, in turn, suggests that increased synthesis of alkaloids is occurring in the roots. This research distinguishes between positive and negative cues affecting the change in xylem fluid alkaloid concentrations. A negative cue, such as auxin, when lost or diminished as a result of leaf damage could signal the alkaloidal response. Indeed, exogenous applications of auxin to damaged leaves inhibit the alkaloidal response. However, attempts to block endogenous auxin transport by steam girdling or applying an auxin transport inhibitor fail to mimic the effect of leaf damage on leaf alkaloid concentrations. The damage cue appears to be a positive cue that is related to the timing and the amount of leaf damage rather than to the amount of leaf mass lost. Moreover, when performed proximally to leaf damage, steam girdling truncates the alkaloidal response. This induced alkaloidal response appears to be triggered by a phloem-borne cue that allows the plant to distinguish between different types of leaf damage. The physiological and ecological consequences of the mechanism of this damage-induced alkaloidal response are further explored.

Key Words—Mechanism of induced defense, alkaloids, *Nicotiana sylvestris*, auxins, damage cue, nicotine, normicotine.

INTRODUCTION

Leaf damage increases the alkaloid content of undamaged leaves of *Nicotiana sylvestris* (Baldwin, 1988a–c), and this increase in leaf alkaloids reduces the growth of a tobacco herbivore (Baldwin, 1988b). Although damage-induced defenses have received much attention in the ecological literature (Rhoades, 1979; Schultz and Baldwin, 1982; Haukioja, 1982; Karban et al., 1987; Chiang et al., 1987), these responses have received little attention from plant physiologists. The mechanisms of only two herbivore-induced responses are understood in any detail: the induction of proteinase inhibitors in tomato leaves (Ryan, 1983) and the induction of quinolizidine alkaloids in lupine leaves (Wink, 1983). Ecologists have numerous hypotheses to explain why plants have inducible defenses, yet we understand little about the mechanism responsible for induction. Moreover, only by understanding the mechanism responsible for a particular trait can one assess its responsiveness to selection.

The alkaloids of tobacco—particularly nicotine—are among the best-studied secondary metabolites of plants (Tso, 1972; Leete, 1977; Waller and Nowacki, 1978). Removal of flowering heads at the onset of flowering, a standard practice in the cultivation of tobacco (*N. tabacum*), increases the size, mass, and alkaloid content of leaves (Woetz, 1955). This increase in leaf alkaloid content after removal of the flowering top is largely a result of increased nicotine synthesis in the roots (Mizusaki et al., 1973). The alkaloids are then carried to the leaves by the xylem stream (Dawson, 1942). However, decreased rates of leaf nicotine degradation in the leaves (Yoshida, 1962) and leaf nicotine synthesis (Bose et al., 1956) may also play a role in the topping-induced increase in leaf alkaloid levels. Most nicotine synthesis in cultivated tobacco is thought to occur in young dividing root tips (Dewey et al., 1955). The literature on cultivated tobacco suggests four reasonable mechanisms for the dramatic damage-induced increase in levels of leaf alkaloids in wild tobacco: (1) lower alkaloid degradation rates in leaves; (2) higher rates of alkaloid synthesis in the leaves; (3) higher transpiration rates, resulting in greater transport of alkaloids from roots to leaves; and/or (4) increased amounts of alkaloid entering the leaf in the xylem stream. The latter mechanism could be a result of higher alkaloid synthesis in those roots with xylem traces leading to undamaged leaves and/or the efficient reloading of alkaloids into these xylem traces. This, in turn, would require the extraction of alkaloid from the acidic xylem sap by transfer cells in the stem or roots and would undoubtedly be an energy-demanding process. Knowing which mechanism(s) is correct should be of great interest to ecologists, for two of these (1 and 3) could conceivably operate at little or no cost to the plant, which means the induced defense could represent merely a passive reorganization of a constitutive defense.

This research demonstrates that hypothesis 4 is the most probable expla-

nation for how the increase in alkaloids comes about. Leaf damage results in a dramatic increase in the alkaloid concentration of the xylem stream entering undamaged leaves on damaged plants. Repeated measures of alkaloid concentrations of excised leaves indicate that rates of alkaloid degradation and/or leaf alkaloid synthesis do not differ significantly between damaged and undamaged plants. Moreover, transpiration rates are not different between same-aged leaves of damaged and undamaged plants.

A distinction is drawn between a positive cue, which stimulates root alkaloid synthesis and is produced by or correlated with leaf damage, and a negative cue, which is continuously produced by leaves and when lost or diminished during leaf damage signals the induced response. A candidate for a negative cue is the plant hormone auxin, which is produced by flowering tops as by well as young leaves in *N. sylvestris* (Avery, 1935) and has demonstrated effects on nicotine synthesis (Solt, 1957; Yasumatsu, 1967; Tabata et al., 1971; Mizusaki et al., 1973; Tiburcio et al., 1985). Indeed, the alkaloidal response is completely inhibited by an application of auxins on the damaged leaf edge. However, although exogenously applied auxins clearly affect the alkaloidal response, a change in endogenous auxin transported from shoot to root is not likely to be the damage cue. Both application of an auxin transport inhibitor (TIBA) and steam-girdling, which halts the transport of endogenous auxins from leaf to root (the site of damage to the probable site of alkaloid synthesis), fail to mimic the alkaloidal response to leaf damage.

METHODS AND MATERIALS

Alkaloid Analysis and Plant Growth. The two principal alkaloids of *N. sylvestris* Spegazzini and Comes—nicotine and normicotine—were separated and quantified by high-pressure liquid chromatography with an internal standard technique (Baldwin, 1988a) for all samples except those of the time-course experiment, where an external standard technique was used. Values are expressed (mean \pm SD) as percent dry leaf weight or millimolar xylem exudate. All plants were destructively sampled. Leaf samples for alkaloid analysis were removed from the midsection of the lamina (Rosa, 1973) with a razor in a 1-cm-wide band across the leaf but excluding the midrib, and immediately extracted (Baldwin, 1988a). All leaf alkaloid analyses were performed on undamaged leaves in positions 4, 5, or 6 (from the top). Leaves in these positions on rosette-stage plants were known to exhibit large induced alkaloidal responses. A comparable band adjacent to the sample band was removed, weighed, dried at 50°C for 48 hr, and reweighed for percent dry mass calculations. In the time-course experiment, two 1-cm² circular leaf disks, one from each side of the midrib, were extracted for alkaloid analysis. The remaining

shoot mass and all leaf cuttings were placed individually in labeled bags, dried for 48 hr at 50°C, and weighed.

All plants except those used for the steam-girdling and within-plant experiments were greenhouse-grown in 8-oz. food cups with 3.5 g of Osmocote 14-14-14 fertilizer and transplanted into 18-cm fiber pots five to seven days before the start of the damage regime to avoid inhibition of the induced response as a result of hindered root growth (Baldwin, 1988a). All plants for each experiment were inbred full sibs, of the same age (by germination date), size (by length \pm 5 cm of alkaloid sample leaf, or height to developing flower bud), and clockwise phyllotaxy, and were randomly assigned to treatment groups. Moreover, plants were randomly assigned positions on the greenhouse bench. Plants used in the steam-girdling experiment were 89 days old and had developed flower buds and commenced stalk elongation. All others were in the rosette stage of growth and were 57–71 days old, depending on the experiment.

Leaf Diffusive Resistance and Water-Loss Measurements. Abaxial transpiration rates were estimated with a LiCor LI-700 transient porometer on the portions of the leaf lamina from which the alkaloid sample was later removed. The porometer was calibrated in R values ($\text{sec}/\text{cm}^{-1}$) with a porous plate technique (van Bavel et al., 1965) immediately before and after measurements. Such diffusive resistance measures are valuable for estimating leaf water-loss rates over short time intervals.

Water-loss rates from three age classes of fully expanded leaves were determined gravimetrically over four 24-hr time periods. Forty-five plants growing in 18-cm fiber pots with 505 ± 15 g of artificial soil mix were assigned to four treatment groups. All leaves in each group were removed from the plant with a razor, except those in positions 3–9 (group 1), leaves 7–9 (group 2), leaves 5 and 6 (group 3), and leaves 3 and 4 (group 4). Cut petioles were sealed with lanolin. Remaining leaves were traced at the start and end of the experiment. Leaf areas of each plant were determined by weighing the cut-out tracings, converting these masses into areas (cm^2), and calculating a mass–area regression from known areas of the remaindered tracings. A fifth treatment group consisted of nine pots with 505 ± 2 g soil, but instead of plants, it contained an 18-cm-diameter circular cardboard disk suspended 10 cm above the soil level on a dowel in each pot. This group was used to estimate the amount of water lost from the shaded soil surface. Pots were watered with 400 ml of tap water, left to drain for 30 min, weighed, and reweighed 24 hr later to 0.5 g. Values were corrected for water loss from the shaded soil surface and expressed as milligrams of water lost per square centimeter fresh leaf area per hour.

Alkaloid Sampling of Xylem Stream. Alkaloid concentration of the xylem stream of sample leaves was determined by placing the entire plant (root, soil, and shoot) into a Scholander pressure bomb (Scholander et al., 1965). Three centimeters of petiole from the sample leaf protruded from the top of the bomb.

Xylem fluid was collected at low pressures (up to 0.12 MPa) into a tared microcapillary inserted (Waldron, 1976) into the visibly distinct (Avery, 1933) xylem bundles of the petiole. Collected xylem fluid (7.6 ± 3.2 mg) was extracted into an aqueous methanol solution (0.962 ± 0.056 g) containing the internal standard and analyzed by HPLC.

Time Course of Induction Response. This experiment was designed to ascertain the time course of the plants' alkaloidal response to damage and to examine its physiological basis. Sixty plants were transplanted on February 15, and leaves in positions 5 and 6 were labeled with twist-ties around the petiole. Plants were assigned to 10 sampling groups containing six plants each. The plants in each sampling group were assigned to one of two treatment groups: control and damaged treatments. On February 21, sampling and leaf cutting commenced. Plants in the damaged treatment group had their leaves in positions 3–9 (excluding sample leaf positions 5 and 6) cut with scissors during six cuttings over a 60-hr period. Sample groups were randomly selected for analysis. Analysis of the six (three control, three treatment) plants in each sample group proceeded as follows: leaf transpiration rates were measured, and alkaloid and percent dry mass samples were removed from leaf position 5; plants from sample groups analyzed 127.5, 177.5, and 266.5 hr after the start of the experiment were placed in the pressure bomb to collect xylem fluid samples from the severed xylem bundles leading to leaf position 5; a leaf disk alkaloid sample from position 6 was removed and the leaf was cut from the stem with a razor, placed in 25 ml tap water in a controlled environmental chamber (26°C; 12:12 hr day-night cycle) for 48 hr, after which a second leaf disk alkaloid sample and percent dry mass sample were removed; the remaining shoot was placed in a labeled bag, air-dried at 50°C, and weighed; roots were irrigated over 0.2 cm² plastic mesh to remove soil, dried with paper towels, and a sample of roots was subjected to extraction of alkaloids; the remaining root mass was weighed, air-dried at 50°C, and reweighed.

Steam-Girdling Experiment. This experiment was performed to kill the phloem vascular connections between leaves and roots and to elucidate the nature of the damage cue. Steam was generated in a glass flask on a portable hot plate and directed toward the stem via foil-covered tubing that terminated in a Pasteur pipette. Tissues surrounding the girdle, which was typically 0.5 cm wide, were protected with foil. Leaf transpiration measurements on alkaloid-sample leaves located distal to the girdle were used to diagnose damage to the xylem vasculature, both before and 24 hr after girdling.

On July 15, 30 plants that had developed flower buds and commenced stalk elongation and that had their fifth leaf labeled as a sample leaf were transplanted into 30-cm pots and assigned to the five following treatment groups: untouched control plants (group 1); plants with steam-girdled stems immediately below the ninth leaf (group 2); plants girdled as in group 2 and with leaves in positions

4–9 (excluding sample position 5), i.e., those above the girdle, cut with scissors over a 60-hr period (group 3); plants damaged as in group 3 but not steam girdled (group 4); and plants girdled as in group 2 and with leaves in positions 10–14, i.e., those below the girdle, cut with scissors over a 60-hr period. The position 5 leaf was sampled for alkaloids 100 hr after the start of the leaf damage.

Timing of Leaf Damage. This experiment was designed to determine the effect of the timing of leaf damage on the induction response when the number and age of leaves removed were held constant. Forty-five plants were transplanted on January 7. Plants were assigned to three treatment groups: a control group, to be sampled only for leaf alkaloids; a sudden-damage group, in which leaves in positions 3–9 (excluding sample leaves in position 4) were cut at each leaf's attachment to the stem with scissors on January 10 (defining the start of the experiment); and a gradual-damage group, in which leaves in the same positions were cut in quarters (by leaf length) at times 0, 31, 48, and 52 hr after the start of the experiment, so that by 52 hr the same amount of leaf area from the same leaf positions had been removed from both damage groups. Three plants from each treatment group were randomly chosen for alkaloid analysis at 69, 76, 93, 117, and 142 hr after the start of the experiment.

Auxin Inhibition of Induction Response. This experiment was designed to determine: (1) the effects of auxins—indole-3-acetic acid (IAA) and naphthalene-1-acetic acid (NAA)—applied to the damaged leaf edge on the induction response, and (2) the ability of an inhibitor of polar auxin transport (Nieder-gang-Kamlen and Skoug, 1956)—2, 3, 5-triiodobenzoic acid (TIBA)—to mimic the effect of leaf damage. NAA, IAA, and TIBA were made up fresh daily in lanolin (0.1% by mass). Leaf cutting followed the format of the time-course experiment. Thirty-six plants were transplanted on June 7. After having their alkaloid sample leaves labeled, they were assigned to six treatment groups with six plants per group as follows: (1) control plants sampled for alkaloids only; (2) auxin-control plants with leaves at positions 5–9 (excluding sample leaf 6), which were cut with scissors and the cut edges then thinly coated with a layer of lanolin; (3) undamaged TIBA-control plants that had a thin band of lanolin spread on the base of their leaves at positions 5–9 (except position 6, the alkaloid sample position) after each leaf cutting; (4) NAA-treated plants that were damaged as in group 2, and the cut edges were thinly coated with a layer of NAA-containing lanolin; (5) IAA-treated plants that were treated like those in group 4 but had IAA-containing lanolin spread on cut leaf edges; and (6) TIBA-treated plants that were treated like those in group 3 but had TIBA-containing lanolin spread on the base of the leaves. All plants were harvested for alkaloid analysis and dry mass determinations 120 hr after the start of leaf cuttings.

Transpiration Inhibition of Alkaloid Transport. Previous experiments with plants in gas-tight Plexiglas chambers growing in CO₂-free (0–10 ppm) air and

330 ppm CO₂ air for 10 days demonstrated that plant growth conditions below the CO₂ compensation point had little effect on leaf alkaloid content, measured as percent of leaf dry mass (Baldwin, unpublished). This result allowed the development of an experiment that reduced the transpiration rates of leaves and hence the transport rates of alkaloids into sample leaves by enclosing sample leaves in clear polyethylene bags. Twenty-four plants were transplanted on August 1. On August 6, sample leaves at positions 5 and 6 were labeled; all plants were cut with scissors at positions 3–9, excluding sample leaf positions 5 and 6, over a 50-hr period and were subsequently assigned to four treatment groups: (1) plants without bags; (2) plants with bags on leaf position 5; (3) plants with bags on leaf position 6; (4) plants with bags on leaf positions 5 and 6. Bags were removed at dusk and replaced at dawn. All sample leaf positions were removed for alkaloid analysis 96 hr after the start of the damage regime.

Within-Plant Distribution of Alkaloids. Twelve plants were grown in 2.5-cm × 8-cm sections of plastic pipe and transplanted June 30 to 6.4-cm wide × 14-cm sections of pipe to facilitate placement of plants into the Scholander bomb without removing plants from the pots. Leaves at positions 3, 4, 8, and 9 were labeled as sample leaves, and plants were assigned to two treatments: (1) control plants that were undamaged, and (2) damaged plants that had leaves at positions 2–12 (excluding the alkaloid sample positions) cut over a 48-hr period. Leaf transpiration measures and leaf and xylem fluid alkaloid samples were taken from the four sample leaf positions on all plants 105 hr after the start of leaf damage.

Statistical Analysis. Alkaloid values and plant masses from each experiment were *N* scored (Ryan et al., 1982) and tested for statistical normality. If the data were normally distributed, treatments were tested with a one-way ANOVA; if not, they were compared with the Mann-Whitney U test (Sokal and Rohlf, 1981). Percentages were arcsine transformed for parametric statistical analysis.

RESULTS

Time Course of Induction Response. Plants subjected to the damage regime had high total leaf alkaloids 19 hr after the end of leaf damage regime and lost $38.6 \pm 9.9\%$ of their total shoot dry mass. This leaf alkaloid increase continued nine days (218 hr) into the experiment, reaching a maximum at 4.9 times the alkaloid content of undamaged plants; thereafter the response waned (Figure 1). Leaf alkaloid contents of undamaged plants did not change significantly ($F_{9,20} = 0.3$, $P > 0.75$), but those of damaged plants clearly did change ($F_{9,20} = 9.3$, $P < 0.0001$) over the experimental period. Nicotine represented about 95% of the total alkaloid content, and nornicotine made up the majority of the

FIG. 1. Total alkaloid contents (mean % dry mass \pm SD) from leaves at stalk position 5 of 30 damaged (\square) and 30 undamaged (\blacklozenge) *N. sylvestris* plants randomly sampled, six plants per sampling time, over 338 hr from the start of leaf damage. Leaves were cut from 0 to 60 hr and their removal accounted for $38.6 \pm 9.9\%$ of the shoot mass.

remainder. Nicotine contents generally mirrored the nicotine content. The ratio of leaf nicotine to nicotine increased slightly, from 0.01 to 0.09 over the 14 days of the experiment, but this ratio did not differ significantly in damaged and undamaged plants over the duration of the experiment ($F_{9,20} = 0.6$, $P > 0.70$).

Alkaloid contents of roots, which consisted entirely of nicotine, were substantially lower (mean of all samples = $0.27 \pm 0.19\%$ dry mass) than leaf alkaloid contents and did not differ significantly between damaged and undamaged plants ($F_{6,14} = 1.2$, $P > 0.25$).

The change in leaf alkaloid contents over a 48-hr period in excised and water stem-fed leaves did not differ between leaves from damaged and undamaged plants throughout the course of the experiment ($F_{6,14} = 1.1$, $P > 0.4$). Hence, there was no evidence for differences in rates of either alkaloid synthesis or degradation in the excised leaves of damaged compared to undamaged plants. The average change in leaf alkaloids of excised leaves from both damaged and undamaged plants during the period of alkaloid accumulation (from 0 to 218 hr; Figure 1) was a decrease of $1.57 \times 10^{-3}\%$ dry mass alkaloids/hr, indicating that alkaloid degradation predominates in these leaves. If degradation were the only process responsible for changes in leaf alkaloids, damaged and undamaged plants would have the same alkaloid concentrations. Moreover, the maximum change in alkaloid levels over the experimental period would have been a decrease of about $\frac{1}{2}$ rather than the observed $4\times$ increase.

No evidence was found for compensatory growth in damaged plants; the total shoot biomass (removed plus remaining) of damaged and undamaged plants was not significantly different ($F_{7,16} = 1.4$, $P > 0.25$).

The concentration of nicotine, the only alkaloid found, in the xylem fluid of damaged plants was about 10 times higher ($F_{1,15} = 24.4$, $P < 0.0001$) than that in undamaged plants (Figure 2) and tended to wane as leaf alkaloid levels waned (Figure 1). These concentrations are slightly lower than measures of xylem fluid exuding from cultivated tobacco stumps (Dawson, 1941).

Leaf Diffusive Resistance and Water-Loss Rates. Leaf diffusive resistance was not different among treatment groups in all experiments as long as leaves occupying similar stalk positions were compared. Transpiration rates between leaves on a plant, particularly on sunny days, were different and followed the pattern established (Begg and Turner, 1970; Sasaki and Hirala, 1971) for *N. tabacum*, where diffusive resistance was lower in younger leaves.

Leaf water-loss rates measured over 24-hr periods corroborated the leaf resistance measures. Loss rates were significantly different ($F_{3,129} = 23.7$, $P < 0.0001$) between days, ranging from 3.8 ± 1.9 to 6.7 ± 1.0 mg/cm²/hr for all treatment groups. On days of low water use (3.8 ± 1.9 mg/cm²/hr) no significant difference was found between treatment groups ($F_{3,32} = 1.7$, $P = 0.20$), but on high water-use days (6.7 ± 1.0 mg/cm²/hr), treatment groups (Table 1) differed significantly ($F_{3,32} = 10.9$, $P < 0.001$); younger leaves had greater loss rates than older leaves. Not unexpectedly, daytime loss rates were higher (reaching as high as 30 mg/cm²/hr) than nighttime water loss rates.

Steam-Girdling Experiment. Plants in the different treatment groups of the steam-girdling experiment had significantly different ($F_{4,25} = 40.5$, $P < 0.0001$) alkaloid contents (Figure 3). Steam-girdled plants had leaf alkaloid contents higher than those of control ungirdled plants, indicating that girdling itself elic-

FIG. 2. Concentration (mean mM \pm SD) of nicotine in the expressed xylem fluid from xylem bundles entering sample leaves at stalk position 5 of the plants sampled in Figure 1 at 127.5, 177, and 266.5 hr after start of leaf damage.

TABLE 1. WATER-LOSS RATES FROM PLANTS WITH LEAVES OCCUPYING SPECIFIED STALK POSITIONS (LABELED TOP TO BOTTOM) ON HIGH WATER-LOSS 24-hr DAY ($6.7 \pm 1.0 \text{ mg/cm}^2/\text{hr}$)

Plants with leaves at stalk positions	Water ($\text{mg/cm}^2/\text{hr}$)	
	Mean	SD
3-9	5.8	1.0
7-9	6.0	0.8
5-6	7.0	0.6
3-4	7.7	0.6

its a small alkaloidal response; however, plants girdled and suffering leaf damage above the girdle had alkaloid contents ($F_{1,10} = 0.6$) similar to those plants only girdled. Moreover, nongirdled plants suffering similar amounts of leaf damage had significantly ($F_{1,10} = 25.2$) elevated alkaloid levels, and girdled plants that were damaged below the girdle also had elevated alkaloid levels. Steam-girdling apparently blocks the alkaloidal response to damage.

Timing of Leaf Damage. Plants in the sudden-damage group, which had their leaf material removed in a single cutting ($0.315 \pm 0.076 \text{ g}$), had the same absolute amount ($F_{1,18} = 0.8$, $P > 0.75$) and percentage of shoot mass ($F_{1,18} = 1.9$, $P > 0.5$) removed as did those plants suffering gradual damage to the same leaf positions over 52 hr ($0.349 \pm 0.088 \text{ g}$).

FIG. 3. Total alkaloid content (mean % dry mass \pm SD) of sample leaves occupying stalk position 5 of 30 plants (six per treatment) in the following leaf damage and steam-girdling treatments: control, undamaged, and ungirdled plants; plants girdled below the ninth leaf; girdled plants with leaves at positions 4 and 6-9 cut; ungirdled plants with leaves at positions 4 and 6-9 cut; girdled plants with leaves at positions 10-14 cut.

Although the plants in the two damage groups had the same amount of leaf mass removed from the same leaf positions, the alkaloid contents of their respective undamaged sample leaves were remarkably different (Figure 4) in all but the first sampling. Plants subjected to gradual leaf damage had an alkaloid profile that continued to rise throughout the 142-hr experiment, reaching 2.6 times that of control undamaged plants. In contrast, plants subjected to a single damage event had a significantly more attenuated response: 76 hr after damage the leaf alkaloid contents reached a maximum (at 1.4 times that of control plants) that then waned, reaching control levels by the 117-hr sampling. Plants damaged in four cuttings incurred at least four times the amount of cellular damage as those plants cut once; hence this experiment demonstrates that the alkaloidal response is influenced by the timing and the amount of cellular damage, rather than the amount of leaf area lost.

Auxin Inhibition of Induction Response. The amount of leaf mass (3.15 ± 0.58 g) or the percentage of shoot mass ($55.7 \pm 4.9\%$) removed from the plants in the three damaged-plant groups was not significantly different ($F_{2,15} = 0.4$ and $F_{2,15} = 0.1$, respectively). However, the sample leaf alkaloid contents among the six treatment groups did differ significantly ($F_{5,30} = 16.7$, $P < 0.0001$). Plants subjected to leaf damage and pure lanolin treatments had approximately four times the leaf alkaloid content of undamaged control plants and two to three times the alkaloid contents of both groups of damaged plants that had their damaged leaf edges treated with either auxin (Figure 5). Clearly,

FIG. 4. Total alkaloid contents (mean % dry mass \pm SD) from stalk position 4 leaves of 45 plants in three treatment groups (three plants per treatment per sampling): control undamaged plants (Δ), suddenly damaged plants (\blacksquare) suffering leaf damage in a single cutting at time 0, and gradually damaged plants (\square) that were damaged in four cuttings from 0 to 52 hr. Plants from the two damage treatments had the same amount of leaf area removed from the same leaf positions.

FIG. 5. Total alkaloid contents (mean % dry mass \pm SD) from leaves in stalk position 6 of 24 plants (six per treatment) in the following four treatments 120 hr after the start of leaf damage: control undamaged plants, and three damage treatments where four leaf positions were cut six times over a 60-hr period and after each cutting either pure lanolin, or lanolin with 0.1% (by mass) NAA or IAA was coated on the cut leaf edges.

the application of both synthetic (NAA) and natural (IAA) auxins to damaged leaves effectively terminates the damage-induced alkaloidal response. The application of an auxin transport inhibitor had no significant effect ($F_{1,10} = 1.7$) on sample leaf alkaloid contents (0.17 ± 0.05) compared with the alkaloid contents of plants girdled with pure lanolin (0.26 ± 0.16).

Transpiration Inhibition of Alkaloid Transport. Plastic bags on the undamaged leaves of damaged plants quickly saturated the air surrounding these leaves with water vapor and likely slowed the xylem transport rates of the bagged leaves. Leaves were not visibly affected by bagging but likely experienced higher daytime temperatures than unbagged leaves. The average alkaloid concentrations of leaves in positions 5 and 6 (1.25 ± 0.38) from damaged plants without bags were significantly ($P < 0.005$) higher ($F_{1,10} = 16.6$) than those of leaves in positions 5 and 6 (0.58 ± 0.16) of damaged plants where both sample leaves were bagged. Moreover, plants with either, but not both, leaves in positions 5 or 6 in bags, had significantly ($P < 0.0001$) higher ($F_{1,21} = 32.9$) alkaloid contents in the leaves without bags (1.13 ± 0.27) than in those with bags (0.61 ± 0.13). These results are consistent with the hypothesis that leaf transpiration rates will affect the induction response.

Within-Plant Distribution of Alkaloids. Leaf alkaloid concentrations from damaged plants were significantly higher (all $F_{1,10}$ s > 13.6 , P s < 0.005) than those from undamaged plants for all leaf positions (Figure 6). Similarly, the concentrations of nicotine—again the only alkaloid found—were approximately 10 times as high (all $F_{1,10}$ s > 11.1 , P s < 0.01) in the expressed xylem fluid

FIG. 6. Total leaf alkaloid contents (mean % dry mass \pm SD) (top) and concentration (mean mM \pm SD) of nicotine in expressed xylem fluid (bottom) from leaves in stalk position 3, 4, 8, and 9 (numbered top to bottom) from six damaged and six undamaged plants.

of damaged plants than in that of undamaged plants for all leaf positions. Interestingly, the concentrations of nicotine in the fluid expressed from the xylem bundles of the different leaf positions did not differ significantly in either damaged ($F_{3,17} = 1.9, P > 0.10$) or undamaged plants ($F_{3,19} = 1.7, P > 0.10$). The process responsible for the varying alkaloid concentrations between leaves in tobacco plants (Srivastava, 1983) (Figure 6) appears not to be the process that increases alkaloid levels after damage.

DISCUSSION

Leaf damage dramatically increases the nicotine concentration of the xylem fluid entering undamaged leaves (Figures 2 and 6). Because I have measured the rate of water loss by plants, the concentrations of alkaloids in the xylem stream entering leaves on damaged and control plants, and the rate of change in leaf alkaloids after damage, I can calculate the amount of alkaloid entering the leaf and compare this with the observed change in leaf alkaloid concentra-

tion. A damaged plant can increase its leaf alkaloid concentration from approximately 0.7 to 3.4% in 200 hr, while undamaged plants remain approximately unchanged (Figure 1). For a 1-cm² leaf disk, this represents an addition of approximately 95 μ g of nicotine in the damaged plant. A leaf in stalk position 5 uses approximately 5.5 mg H₂O/cm²/hr and thus in 200 hr will have transpired 1.1 ml of xylem fluid per square centimeter. The concentration of nicotine in the xylem fluid is likely to be 0.53 mM; thus over the 200-hr time period after the start of leaf damage, approximately 94 μ g of nicotine will have been transported to a 1-cm² area of leaf. These calculations should be viewed as rough approximations for two reasons: (1) average values were used and substantial variability in the parameters exists both through time and between plants, and (2) all the parameters were not all measured in the same experiment. Given these caveats, the calculations suggest that the amount of alkaloid entering leaves is sufficient, assuming no alkaloid turnover, to account for the dramatic change in alkaloid concentration in damaged plants.

This research demonstrates that neither alkaloid synthesis nor degradation rates in excised leaves differ between damaged and undamaged plants. However, observations from numerous tracer studies have demonstrated that nicotine is metabolically very active, with a half-life of approximately 20 hr (Leete and Bell, 1959; Yoshida, 1962) in cultivated tobacco. If nicotine is as metabolically labile in *N. sylvestris* as it is in cultivated tobacco, then either the above calculations underestimate the amount of nicotine imported into a leaf and/or the changes in alkaloid concentrations in excised leaves measured in this study do not accurately reflect the changes in intact plants—as is the case in other alkaloid-containing plants (Daddona et al., 1976).

At least two mechanisms are potentially responsible for the dramatic increase in alkaloid concentrations of the xylem fluid in damaged plants: (1) increased root alkaloid synthesis, and/or (2) altered loading of alkaloids into those xylem conduits that lead to undamaged leaves without a corresponding increase in root alkaloid synthesis. Four types of evidence indicate that increased root alkaloid synthesis contributes to the increase in xylem alkaloids. First, the administration of dye to selected root bundles of hydroponically grown plants results in dye transport to specific portions of the shoot, indicating that specific leaves have low-resistance xylem connections to specific roots. Leaf damage does not alter the pattern of dye transport (Baldwin, unpublished results). Second, no significant correlation was found in any of the experiments in this study between the amount or percent of leaf mass removed or remaining and leaf alkaloid concentration, as would be expected if roots were producing unaltered amounts of alkaloid and simply distributing this alkaloid to fewer leaves of damaged plants. Third, decapitation of cultivated tobacco dramatically increases root alkaloid synthesis (Mizusaki et al., 1973; Saunders and Bush, 1979), and it is plausible that the alkaloidal responses that result from topping and leaf

damage share a similar physiological basis. Last, the results of experiments elucidating the nature of the damage cue (Figures 3–5) are difficult to reconcile with mechanisms that do not involve increases in root alkaloid synthesis with damage.

Two lines of evidence suggest that a positive cue is the best candidate for the damage cue(s) effecting the observed change in alkaloid concentrations: the observations that (1) the alkaloidal response is clearly proportional to the timing and amount of leaf damage rather than to the amount of leaf mass removed (Figure 4), and (2) killing the phloem by steam-girdling proximally to leaf damage attenuates the alkaloidal response to damage (Figure 3).

Auxin, a likely candidate for a negative cue, has a pronounced effect on the induced response when applied exogenously (Figure 5), but attempts to block endogenous auxin movement from root to shoot failed to mimic the alkaloidal response to damage. Ethylene is known to be produced after leaf damage (Abeles, 1973) and is a potent inhibitor of auxin transport (Audus, 1972); however, foliar application of 2-chloroethylphosphonic acid—which releases ethylene into plant cells—to cultivated tobacco (Cutler and Gaines, 1971; Kasperbauer and Hamilton, 1978) or *N. sylvestris* (Baldwin, unpublished results) has little or no effect on leaf alkaloid contents. Moreover, the steam-girdling experiment (Figure 3) strongly suggests that the damage cue is phloem-borne rather than gaseous. These results do not deny that auxin may induce the enzymes involved in nicotine biosynthesis: they merely demonstrate that auxin is not functioning as a negative cue for the activation of these enzymes.

In the time-course experiments, the rise in alkaloid content of undamaged leaves after damage is rather slow (Figure 1), compared to that of other damage-induced phytochemical responses (Carroll and Hoffman, 1980). This time delay, possibly a result of the large spatial separation of the sites of damage and alkaloid synthesis, can be divided into three components: (1) delays due to transport of cue from damaged leaves to roots; (2) delays due to the activation of enzymes involved in nicotine synthesis; and (3) delays due to the loading of alkaloids into the xylem stream and their transport to the leaves.

Nicotine biosynthesis in the roots of cultivated tobacco involves the condensation of a pyridine and a *N*-methylpyrrolidine ring. The principal regulatory enzymes in the biosynthesis of these two rings are quinolinic acid phosphoribosyltransferase (EC 2.4.2.19) and putrescine methyltransferase (EC 2.1.1.53), respectively (Wagner et al., 1986a, b; Feth et al., 1986). Both of these key enzymes are substantially induced in the roots of cultivated tobacco within 24–40 hr of decapitation (Mizusaki et al., 1973; Saunders and Bush, 1979; Wagner et al., 1986a). In so far as alkaloid induction by leaf damage and decapitation comes about by a similar mechanism, these results suggest that delays that are the result of components 1 and 2 are less than 24 hr for small plants.

This research demonstrates that altered transport rates of alkaloid due to

increases in leaf transpiration are not responsible for the increase in leaf alkaloid concentrations in damaged plants. However, transpiration rates nevertheless may play an important role in how the physical environment influences this induced response. Conditions of low evapotranspiration (high humidity and low temperatures) will greatly slow both the water loss from plants and the transport of alkaloids to the leaves. The results from the transpiration-inhibition experiment are consistent with this hypothesis. Since any inhibition of transpiration will also increase leaf temperature, the results of this experiment may be confounded by temperature effects. Moreover, because nicotine concentrations of 0.5 mM—the concentration found in xylem fluid of damaged plants—in the roots will repress putrescine methyltransferase activity by at least 50% (Mizusaki et al., 1973), conditions of low evapotranspiration may actually truncate the induced defense by slowing the export of alkaloids from the sites of synthesis. An ecological prediction from this hypothesis is that this response will be most pronounced and hence more effective defensively for plants growing under conditions of high evapotranspiration. Indeed, most members of the genus *Nicotiana* are native to xeric habitats (Kostoff, 1941).

Alkaloid contents in the younger leaves occupying higher stalk positions are higher than those in older, lower leaves (Figure 6) (Srivastava, 1983), although the opposite pattern was also reported (Vickery, 1961). This within-plant distribution of alkaloids is consistent with the predictions of optimal defense theory (McKey, 1974, 1979; Rhoades, 1979; Krischik and Denno, 1983), according to which younger, photosynthetically more valuable tissues receive a greater defense allocation. The process by which this apparently optimal distribution of alkaloids comes about differs from the one responsible for the damage-induced pattern, in that leaf transpiration rate influences the within-plant distribution of alkaloid. The concentration of nicotine in xylem fluid expressed from lower-leaf xylem traces resembles that from upper leaf traces (Figure 6), but the amount of water lost per leaf area from upper leaves is significantly greater than that from lower leaf positions (Table 1). Thus the pattern of higher alkaloid contents in younger leaves is preserved in damaged plants even though the concentration of alkaloids entering the leaf is increased 10-fold. Tobacco plants appear to have two systems for affecting the optimal distribution of defense: a damage-inducible system that triggers an increase in root alkaloid synthesis and a “plumbing system” that ensures greater transport of alkaloid-containing xylem fluid to younger leaves.

Clearly, the induced defense is an active response rather than a passive deterioration of foliage quality after herbivore attack (Myers and Williams, 1984). Its mechanistic basis enables a plant to differentiate between leaf damage resulting from biotic agents, which inflict damage over a sustained period of time, and abiotic agents (leaf and branch fall or hailstorms), which inflict dam-

age that, although it may be significant, is momentary, and to which a defensive response would be inappropriate. Moreover, since the chemical changes were observed also in undamaged leaves, they are not likely to be solely a product of wound metabolism or directed only at potential microbial or viral invasion at wound sites. However, this alkaloidal response should not be viewed as purely a defensive response.

As the metabolic tracer experiments underscore, alkaloidal defense in plants must be considered an integral part of a plant's primary metabolism. Nicotine, when degraded in a cultivated tobacco plant, is metabolized to amino acids, pigments, sugars, and organic acids (Tso and Jeffery, 1959, 1961), and serves as a methyl donor to choline (Leete and Bell, 1959). The amount of nicotine (which is 17% nitrogen) transported to a leaf after damage represents a substantial fraction of the total leaf nitrogen and can be made available for other metabolic demands. Damaged plants undoubtedly have higher leaf nitrogen demands in order to support the rise in photosynthetic rates and other compensatory metabolic changes typically observed after topping in tobacco (Darkanbaev et al., 1962; Yoshinori et al., 1967) and after leaf damage in other species (Crawley, 1983). In addition, damaged plants may have other defenses, such as proteinase inhibitors (Wong et al., 1976) induced by leaf damage. All biochemical and photobiological processes of photosynthesis require nitrogenous compounds, and leaf photosynthetic rates are generally positively correlated with leaf nitrogen contents (Field and Mooney, 1986). Thus nicotine, in addition to playing an important role in leaf defense, may serve as a well-defended vehicle for nitrogen transport from roots to leaves, a transport route vulnerable to attack by the guild of sap-sucking herbivores.

In summary, the mechanistic details of the increase in leaf alkaloid concentrations after damage support the conclusion that the response is an integral part of a plant's primary metabolism and is under both strong environmental constraints (including soil nitrogen availability, water, and depth and climatic factors affecting evapotranspiration) and plant architectural constraints (including the distance between sites of damage and alkaloid synthesis, as well as the number and distribution of reproductive buds or other rich sources of auxin). These considerations will profoundly influence the evolution of the defensive role of this damage-induced change in alkaloid concentration.

VOLATILE COMPONENTS OF ANAL GLAND
SECRETION OF AARDWOLF
(*Proteles cristatus*)

P.J. APPS,¹ H.W. VILJOEN,¹ P.R.K. RICHARDSON,² and

(Received February 11, 1988; accepted August 5, 1988)

Abstract—Volatile constituents of the anal gland secretion and of scent marks of the aardwolf were identified using dynamic solvent effect sampling, capillary gas-liquid chromatography, and mass spectrometry. Both scent marks and gland contents consisted mainly of short- to medium-chain fatty acids, a complex series of medium- and long-chain esters, indole, and hexanol. There were marked individual differences in the relative concentrations of the various components.

Key Words—Aardwolf, *Proteles cristatus*, anal gland, fatty acids, esters, territory, dynamic solvent effect.

INTRODUCTION

The aardwolf (*Proteles cristatus*) is the only member of the family Proteleidae (Meester et al., 1986). Although it shares many features with the Hyaenidae and has often been classified in that family, it is much smaller (9–11 kg) than the hyaenas and is entirely insectivorous, specializing on termites, especially *Trinervitermes* spp. (Kruuk and Sands, 1972; Cooper and Skinner, 1979; Smithers, 1983; Richardson, 1987a). Its range is divided into two main areas, one in eastern and northeastern Africa and the other in the southern African subregion. Aardwolves live in monogamous pairs, which defend territories of

1–3 km², whose size appears to be determined by the density of termite nests (Richardson, 1987b). Territories are demarcated by scent marks produced by wiping the secretion of the well-developed anal gland onto grass stems and other vegetation (Smithers, 1983; Richardson, 1985). It has been suggested by Richardson (1987b) that pastings may also be used by both sexes to attract mates and by males to intimidate other males in competition for mating opportunities.

We report here on the identities of the major volatile constituents of the anal gland secretion of male and female aardwolves.

METHODS AND MATERIALS

Adult aardwolves were captured at Benfontein game farm in the northern Cape Province, South Africa. The animals were anesthetized with ketamine hydrochloride and, by careful pressure, their anal glands were everted and the contents expressed directly into clean glass vials with polytetrafluoroethylene caps. Fresh scent marks were collected into similar vials by clipping the grass stems on which they had been deposited. All material was stored at -10°C until analysis.

Volatiles were sampled from approximately 5-mg blobs of anal gland contents of about the same volume as the real scent marks, which were sampled whole. Palladium-cell-purified hydrogen was passed over the specimens at a flow rate of 15 cm³/min and a temperature of 22–23°C. Volatiles were accumulated by dynamic solvent effect (Apps et al., 1987) using alumina-purified *n*-hexane as solvent. Sampling periods of 5–20 min were used for gas chromatography–flame ionization detector (GC-FID) analyses and 30 min for GC–mass spectrometer (GC-MS) analyses.

GC-FID analyses were carried out on a Varian 3700 gas chromatograph fitted with a dynamic solvent effect inlet (Apps et al., 1987) with a 25-m \times 0.3-mm \times 0.4- μm methyl silicone capillary column. The carrier gas was hydrogen with a linear velocity of 55 cm/sec. The starting temperature of both inlet and column was 40°C. The inlet was heated ballistically to 220°C after 2.2 min, and the column temperature was programmed at 4°C/min after 7 min. The detector sensitivity was 4×10^{-11} A/mV full scale deflection. GC-MS analyses were carried out under equivalent conditions on a modified Varian 1400, using helium as carrier gas, with an open split interface to a VG Micromass 16F spectrometer operating in the electron impact mode. The source temperature was 220°C, and the electron energy was 70 eV.

Compounds were identified by comparison of their mass spectra with those in libraries or the literature. Where necessary, identities were confirmed by retention indices and syntheses of authentic compounds.

RESULTS

The anal gland of the aardwolf contains a bright or pale orange paste, which at room temperature has the consistency of soft butter. The scent marks are blobs or smears of waxy material about 1.0 cm long varying in color from yellow to dark brown. Pale scent marks, but not anal gland contents, darken after one to three days of exposure to air. When fresh, the odor of the anal gland contents is dominated by a penetrating metallic scent. Cheesy and faint, sweet, musky odors are just distinguishable. After 10–20 min of exposure to air, the smell changes to one in which the cheesy and musky scents are dominant; after an hour the original smell returns and persists for at least six months. The odor of scent marks resembled that of fresh and/or aged gland contents. To the human nose, there were only minor differences in odor between material from males and females. The volatiles emitted in the largest quantities by both gland contents and scent marks were fatty acids (Figure 1, Table 1). In addition, there was a fairly complex mixture of minor components dominated by series of esters of the fatty acids. The only other identified compounds were hexanol and indole.

Even within the small number of specimens analyzed, there were marked differences in the occurrence and relative areas of various peaks (e.g., Figure 1). Whether these differences reflect individual identity or are related to, e.g., sex or reproductive condition, is uncertain at this stage. The role of scent marking in reproductive competition among males (Richardson, 1987b) suggests that male scent marks are systematically different to those of females.

DISCUSSION

The color of aardwolf anal gland secretion has been variously reported as dark brown, yellowish ochre, and orange (Smithers, 1983, p. 349), a variability that may be accounted for by the marked differences in color, noted here, between anal gland contents and scent marks. Although there was no systematic difference in volatile components between scent marks and gland contents, the spontaneous darkening of scent marks suggests that some chemical changes are undergone by the gland secretion shortly before its deposition as a scent mark.

The rather rapid changes in the odor of the anal gland contents, and presumably in that of very fresh scent marks, have the potential of acting as short-term indicators of an animal's movements, while the extreme persistence of the odor might be expected to enhance its effectiveness in demarcating territories.

Volatile fatty acids have a widespread, if somewhat sporadic, occurrence in mammalian secretions (Albone, 1984). Whether or not they occur generally

FIG. 1. Chromatograms of volatiles from anal gland contents of two aardwolves (*Proteles cristatus*). The differences between the two chromatograms give an impression of the type of variability encountered within a small set of specimens. Column: 25 m \times 0.3 mm \times 0.4 μ m, methyl silicone, 40°C for 6 min then 5°C/min to 220°C. Sampling by dynamic solvent effect, 15 ml/min for: (A) 20 min, (B) 10 min, 22–23°C, *n*-hexane as solvent. Detection by FID, sensitivity 4×10^{-11} A/mV, full-scale deflection. Peak numbers correspond to identities in Table 1.

^aPeak numbers correspond to Figure 1.

in the anal gland secretions of hyenids is uncertain; Wheeler et al. (1975) reported only 5-thiomethylpentane-2,3-dione and one unidentified volatile component from *Hyaena hyaena*, to which Wheeler (1977) added a macrocyclic lactone. Examination of chromatograms from extracts of brown hyena (*H. brunnea*) pastings (Mills et al., 1980) reveals no peaks with the shape expected

for free fatty acids on an apolar phase, although fatty acids have been found in the headspace of brown hyena pastings (Apps, unpublished)

The occurrence of a complex series of short- and medium-chain esters is unusual in mammalian scent secretions. C₁₆ and C₁₈ acetates have been reported from bank vole (*Clethrionomys glareolus*) urine (Brinck and Hoffmeyer, 1984), and long-chain esters and squalene make up 96% of the scent mark of the saddle back tamarin (*Saquinus fuscicollis*) (Yarger et al., 1977). Esters similar to those from the aardwolf have been reported only from rabbit (*Oryctolagus cuniculus*) feces (Goodrich et al., 1981) and the anal sac of the wolf (*Canis lupus*) (Raymer et al., 1985). Esters may well be more widespread; sample pretreatments involving acidic or basic extractions (e.g., Maurer et al., 1979) are likely to lead to their loss by hydrolysis. No sulfur compounds were identified, although the metallic component of the odor suggests that they may be present. They certainly do not occur in the high concentration (1%) reported for 5-thio-methylpentane-2,3-dione in the anal gland secretion of *H. hyaena* (Wheeler et al., 1975). Indole occurs in the anal gland secretion of *Mustela* spp., but not in other Mustelidae (Brinck et al., 1983), and is a minor component in the anal sac of the wolf (*Canis lupus*) (Raymer et al., 1985). It has also been found in the anal gland secretions of the porcupine (*Hystrix africae australis*) (Apps et al., unpublished) and the guinea pig (*Cavia aperea* and *C. porcellus*) (Wellington et al., 1979).

Gosling (1982) has suggested that scent marks demarcating a territory should have an odor unique to their producer. Individual differences in mammalian odors are possibly based on differences in the relative concentrations of components of complex mixtures (Gorman, 1980). If both these hypotheses are true in the case of the aardwolf, the series of esters in its anal gland secretion appears to have the properties that would be expected to be appropriate to this role.

(Received April 11, 1988; accepted August 8, 1988)

Abstract—The defensive secretion of the carabid beetle *Pasimachus subsulcatus* is a concentrated solution (up to 90%) of carboxylic acids, amounting to about 1% of body mass. It contains three major components (methacrylic, tiglic, and angelic acids) and four minor components (isobutyric, 2-methylbutyric, isovaleric, and senecioic acids). In the single population of this large flightless beetle that was examined, the relative ratio of acidic components was remarkably constant from individual to individual.

Key Words—Defensive secretion, aliphatic acids, beetle, Coleoptera, Carabidae, *Pasimachus subsulcatus*, carboxylic acids.

INTRODUCTION

The beetles of the family Carabidae possess a pair of dischargeable defensive glands, so-called pygidial glands, that open near the tip of the abdomen. Much is known about the chemistry of the secretion of these glands (Blum, 1981). The genus *Pasimachus* has itself been the subject of earlier work, which led to characterization of methacrylic acid as major component in the glands of one species (*P. elongatus*) and tentative characterization of this compound in the glands of two others (*P. duplicatus*, *P. californicus*) (McCollough, 1969, 1972).

¹Report No. 87 of the series Defense Mechanisms of Arthropods; No. 86 is Dussourd, D., et al., *Proc. Natl. Acad. Sci.* **85**, 5992 (1988).

We report here on the secretory chemistry of *P. subsulcatus*, a large flightless species from the southeastern United States. We studied individuals from a single population of this beetle. Our purpose was to characterize as fully as possible the composition of the secretion and to determine the extent of its chemical variability within the population.

METHODS AND MATERIALS

Biological Procedures. The beetles were taken in pit traps in a 50-hectare plot (upland sandhill habitat) of the ecological research area of the University of South Florida (Tampa, Hillsborough County). To test for the beetle's responsiveness to disturbance, individuals were manipulated or held by hand while one or more of their legs were pinched in forceps. Others were stimulated while being held on indicator paper (filter paper soaked in alkaline phenolphthalein solution). Ejections became visible on such paper by the change in indicator color from red to white.

A total of 29 beetles (17 males, 12 females) were individually killed by slow freezing (which fails to induce them to discharge) and dissected under saline. The two glands of each were excised and ruptured in a small vial under dichloromethane. In 11 of these individuals (nine males, two females), the glands were weighed before and after rupturing, thus providing a measure of total mass of secretion per beetle. Two additional beetles, both males, were similarly dissected, but their two glands were extracted separately.

Chemical Analysis. In an exploratory procedure, portions of the dichloromethane extracts were subjected to gas chromatographic (GC) analysis both before and after treatment with diazomethane. Diazomethane was generated by the treatment of Diazald (*N*-methyl-*N*-nitroso-*p*-toluene sulfonamide; Aldrich Chemical Co.) in diethoxyethane with a 1:1 mixture of aqueous potassium hydroxide (10.7 M) and ethanol (95%).

Both the acids and the methyl esters produced by diazomethane treatment were analyzed by gas chromatography, gas chromatography-mass spectrometry (GC-MS), and proton nuclear magnetic resonance spectroscopy ($[^1\text{H}]\text{NMR}$).

GC was performed on a Varian series 2100 Aerograph instrument equipped with glass columns and a flame ionization detector using nitrogen as the carrier gas. A column of 5% Carbowax 20 M on 100/200 Supelcoport, 3.8 m \times 4 mm (50–150°C at 10°/min) served for separation of free acids and methyl esters; a column of GP 10% SP-1200/1% H₃PO₄ on 80/100 Chromsorb W AW, 3.5 m \times 4 mm (isothermal at 150°C) was also used for separating free acids. Capillary GC was carried out on a Shimadzu Mini-2 gas chromatograph equipped with a flame ionization detector, split injector, a 0.25- μm coated Carbowax 20 M fused silica column, 15 m \times 0.25 mm (100–150°C at 6°/min) and a Shi-

FIG. 1. Gas chromatogram of *P. subsulcatus* defensive secretion. Unlettered peak is internal standard (heptanoic acid). Details in text.

madzu C-R1A integrator. Helium was used as the carrier gas. Since two acids overlapped with this system, later studies used a Hewlett Packard 5890A gas chromatograph equipped with a flame ionization detector, a splitless on-column injector, and a 5.0- μm coated methyl silicone fused silica column, 15 m \times 0.53 mm (35°C for 0.5 min, 25°/min from 35°C to 50°C, and 6°/min from 50°C to 100°C). A Hewlett Packard 3392A integrator was used. Hydrogen was used as carrier gas with nitrogen as the makeup gas.

Quantification was done using heptanoic acid as internal standard. For each determination an average was taken, based on two replicate runs (replicate values usually differed by less than 2%). Detector responses were calibrated using authentic methacrylic acid as a standard for peaks A, B, and C, while tiglic acid was used as a standard for peaks D, E, and F (Figure 1).

Packed column GC-MS was performed on a Finnigan 3300 instrument interfaced with a Systems Industries 150 data system. Capillary GC-MS was performed on a Hewlett Packard 5987A mass spectrometer and a Finnigan 4500 instrument.

For preparative GC purposes, a 9:1 effluent splitter was attached to the Varian 2100 gas chromatograph. The effluent was collected in a 2-mm-ID tube cooled by a Dry Ice-acetone bath. The tubes were rinsed with the appropriate solvent for NMR analysis.

Proton NMR spectra were obtained on a Bruker WM-300 spectrometer using deuteriochloroform as the solvent.

Authentic samples of methacrylic, tiglic, isobutyric, isovaleric, and sene-

coic acids were obtained from commercial sources; angelic acid was prepared through isomerization of tiglic acid (Buckels and Mock, 1950); 2-methylbutyric acid was prepared by Jones oxidation of 2-methylbutanol.

RESULTS

Defensive Behavior and Gland Structure. When first taken from the pit traps, the beetles tended to discharge readily in response to manipulation, ejecting their secretion forcibly as a spray, often to a distance of several centimeters. After laboratory confinement they could usually be handled gently without being caused to discharge, although pinching of legs or persistent rough handling of the body almost invariably elicited ejections. Discharges were always accompanied by a pungent odor. Vapor from the secretion was irritating to the eyes, and the fluid itself, if it contacted abraded skin, induced immediate pain.

As evidenced by the patterns left on indicator paper, glandular discharges were sometimes unilateral: if stimulation was restricted to one side, the beetles usually discharged from that side only. Glandular emissions sometimes took the form of liquid outflowings rather than forcible ejections. Following stimulation, fluid would suddenly emanate from the gland openings and spread over the beetle's rear and forward along its flanks. In beetles placed on indicator paper, such discharges manifested themselves by the appearance of a zone of gradual discoloration around the beetle's periphery, as vapors emanated from its body (Figure 2, left).

FIG. 2. (Left) *Pasimachus subsulcatus* being held by right foreleg with forceps on sheet of red indicator paper (filter paper soaked in alkaline phenolphthalein solution). The beetle has discharged secretion, which has oozed from the glands and spread forward over parts of its body. Vapor emanating from the acidic secretion has induced a zone of discoloration on the paper. (Right) Defensive glands of *P. subsulcatus*. Each consists of a cluster of glandular tissue, joined to the saclike reservoir by a narrow efferent tube. The two reservoirs (here shown in partly replete condition) lead to the outside (bottom of photo) by two narrowed ducts. (Reference bars: left, 1 cm; right, 1 mm).

P. subsulcatus has an exceedingly tough integument and a powerful set of mandibles, attributes that must themselves contribute to defense. Beetles that we handled frequently tried to inflict bites.

The glands (Figure 2, right) conform closely in gross structure to those described for *P. elongatus* by Forsyth (1972). Each consists of a racemose cluster of glandular tissue, with an efferent duct leading to a capacious reservoir. From the weighings of glands before and after rupturing, the following values were obtained for mass of secretion per pair of glands of beetle: males ($N = 9$), 4.5 ± 0.6 mg ($X \pm SE$) (range: 2.4–8.9 mg); females ($N = 2$), 1.0 and 6.1. Mass of whole beetles ($X \pm SE$) was as follows: males ($N = 15$), 391 ± 13 mg (range: 318–499 mg); females ($N = 11$), 446 ± 20 mg (range: 356–574 mg). The secretion therefore amounted, on average, to about 1% of body mass.

Composition of Secretion. GC comparison of defensive secretion before and after treatment with diazomethane showed all components to be methylated by this reagent, indicating that they are carboxylic acids.

Packed column GC separated two major acidic components and two minor ones. Subsequent analysis of extracts by capillary GC and GC-MS showed the presence of three additional minor components, giving a total of seven acidic compounds (Figure 1), two of which were unresolved under peak B.

By matching GC peak retention times with retention times of authentic samples, after consideration of the GC-MS and [^1H]NMR data, the following components were identified.

Isobutyric Acid. Peak A cochromatographed with authentic isobutyric acid (1, Scheme 1). Electron impact (EI) GC-MS showed the molecular ion to be at $m/z = 88$ (CI-MS: 89) and gave a fragmentation pattern close to that reported in the literature (Heller and Milne, 1978) and identical to that of authentic isobutyric acid. The [^1H]NMR spectrum of peak A matched the spectrum of an authentic sample of isobutyric acid, as well as that previously reported (Pouchert and Campbell, 1974).

2-Methylbutyric acid and Isovaleric Acid. Peak B cochromatographed with both 2-methylbutyric (2) and isovaleric acid (3). The EI GC-MS spectrum was consistent with that expected for the superposition of the reported spectra of these acids (Heller and Milne, 1978). Subsequent analysis on another capillary GC system resolved the two acids and the retention times were matched to the appropriate authentic samples. The ratio of 2-methylbutyric to isovaleric acid is approximately 4:1.

Methacrylic Acid. Peak C cochromatographed with authentic methacrylic acid (4). EI GC-MS showed a molecular ion of $m/z = 86$ (CI-MS: 87) and gave a fragmentation pattern similar to that reported in the literature (Heller and Milne, 1978) and identical to an authentic sample. The [^1H]NMR spectrum matched that previously reported (Pouchert and Campbell, 1974).

Angelic Acid and Senecioic Acid. Peaks D and E cochromatographed with authentic samples of angelic (5) and senecioic (6) acids, respectively. Due to

SCHEME 1.

incomplete resolution of compounds **5** and **6** during preparative GC, a $[^1\text{H}]$ NMR spectrum of the mixture of acids was obtained. Nevertheless, the peaks observed could be matched with peaks in the individual $[^1\text{H}]$ NMR spectra of authentic samples of angelic and senecioic acids. Peak integration indicated the ratio of angelic to senecioic acid to be approximately 3:1. Capillary GC-MS gave molecular ions of $m/z = 100$ for both acids. The fragmentation patterns of peaks D and E matched those of authentic samples of angelic acid and senecioic acid respectively.

Tiglic acid. Peak F cochromatographed with authentic tiglic acid (**7**). EI GC-MS gave a molecular ion at $m/z = 100$ (CI-MS: 101), and a fragmentation pattern similar to that reported for 2-methyl-2-butenoic acid (of unspecified stereochemistry, Heller and Milne, 1978) and identical to that of authentic tiglic acid. The $[^1\text{H}]$ NMR spectrum matched that reported in the literature (Pouchert and Campbell, 1974).

Relative and absolute amounts of these components, as obtained from paired-gland extracts of individual beetles, were calculated from the capillary column GC analytical data, as described under Methods and Materials. The results are summarized in Figure 3, in which analyses for males (17), females (11), and one unique female are plotted separately.

Based on the values for total mass of secretion per beetle and total fatty acid per beetle, the following values were calculated for percent total fatty acid in secretion: males ($N = 9$), $67 \pm 4\%$ ($X \pm \text{SE}$) (range 46–87%); females ($N = 2$), 57 and 68%. The data for the two males whose four glands were individually extracted are shown in Figure 4. Ratio of components was in line with

FIG. 3. Relative concentration of fatty acids in defensive secretion of male and female *P. subulcatus*. The one female whose composition was discrepant is plotted separately. Letters and numbers refer respectively to chromatographic peaks (Figure 1) and chemical structures figured in text. Mean \pm SE, and ranges are shown.

Gland	% Total Fatty Acid in Secretion	Relative % of Fatty Acids					
		1	2 + 3	4	5	6	7
1A	80.0	0.6	0.7	65.1	1.8	0.2	31.5
1B	90.1	0.4	0.7	59.1	3.1	0.3	36.4
2A	79.8	0.8	0.9	63.6	3.6	0.2	30.9

the norm for the beetles (Figure 3) and comparable for the two glands of each pair.

DISCUSSION

The first isolation of a chemical component from the defensive secretion of an arthropod was that of formic acid from ants (Wray, 1670). Carboxylic acids have since been isolated in substantial diversity from defensive glands of other arthropods, including whip scorpions, millipedes, hemipterans, lepidopterans, and beetles (Blum, 1981). Within the family Carabidae itself, carboxylic acids have been reported from a diversity of genera. All components from *P. subsulcatus* are known from other carabids (Blum, 1981; Kanehisa and Kawazu, 1982), and the combination of methacrylic and tiglic acid as major constituents, first reported by Schildknecht and Weis (1962), is not uncommon (Kanehisa and Kawazu, 1982).

The constancy in composition of the secretion from individual to individual in our *P. subsulcatus* population was striking. Only one of 31 individuals showed a ratio of components notably different from the norm. Ratios were comparable for males and females, and for the two glands of a pair.

One wonders what to make of the one female whose secretory composition was discrepant. In the absence of data on geographical variability of the secretion, it is impossible to tell whether the aberrant female is a local variant or an immigrant from another site. Given the flightlessness of *Pasimachus*, and its consequent potential tendency toward regional genetic stabilization, it might be interesting to see whether secretory composition could serve as an indicator for study of the population dynamics of the species. We cannot categorically rule out the possibility that the aberrant female was taxonomically misidentified. It seems unlikely, however, that the specimen belonged to the congeneric *P. strenuus*, which also occurs in the area, since in several Florida populations of this species that we examined the secretion consistently contained only minimal amounts (<0.5%) of tiglic acid (S. Schultze, M. Deyrup, J. Meinwald, T. Eisner, unpublished).

Acknowledgments—Study supported in part by grants (AI-02908 and AI-12020) from NIH, and an NIH traineeship to B.S.D. We thank the staff of the Archbold Biological Station, Lake Placid, Florida, where some of our work was done, for professional kindnesses, and Dr. Robert Woodruff, Division of Plant Industry, University of Florida, Gainesville, for the beetle identification.

DISRUPTION OF WEB STRUCTURE AND PREDATORY BEHAVIOR OF A SPIDER BY PLANT-DERIVED CHEMICAL DEFENSES OF AN APOSEMATIC APHID

STEPHEN B. MALCOLM¹

(Received March 21, 1988; accepted August 8, 1988)

Abstract—Two toxic and bitter-tasting cardenolides (cardiac-active steroids) were sequestered by the brightly colored oleander aphid, *Aphis nerii* B. de F., from the neotropical milkweed host plant *Asclepias curassavica* L. After feeding on milkweed-reared aphids, the orb-web spider *Zygiella x-notata* (Clerck) built severely disrupted webs and attacked fewer nontoxic, control aphids, whereas the webs of spiders fed only nontoxic aphids remained intact. The regularity and size of the prey-trapping area of webs were reduced significantly in proportion to the amount of toxic aphids eaten. The effects of toxic aphids on spider web structure were mimicked by feeding spiders the bitter-tasting cardenolide digitoxin, a cardenolide with similar steroidal structure and pharmacological activity to the two aphid cardenolides. These results show that the well-known effects of psychoactive drugs on spider web structure are more than interesting behavioral assays of drug activity. Similar effects, produced by plant-derived chemicals in the spider's aphid prey, are relevant to the ecology and evolution of interactions between prey defense and predator foraging.

Key Words—Spider web structure, *Zygiella x-notata*, Araneae, predator foraging, aposematic aphid prey, *Aphis nerii*, Homoptera, Aphididae, chemical defense, cardenolides, *Asclepias*, milkweed.

INTRODUCTION

Intriguing experiments with the effects of psychoactive drugs on spider web structure have shown that amphetamines, mescaline, psilocybin, LSD, and caffeine fed to spiders can induce dramatic changes in their webs (Witt and Reed, 1965; Witt et al., 1968; Jackson, 1974). However, such imaginative assays of drug activity have little relevance to the primary use of webs in prey capture by spiders, since the drugs do not occur in the predominantly insect prey of spiders (Blum, 1981).

At the time that drugs were first found to affect spider webs, plant-derived chemical toxins were also identified in some brightly colored insect herbivores feeding on milkweeds (Parsons, 1965; Reichstein, 1967; Reichstein et al., 1968; Brower et al., 1968; Brower, 1969; Rothschild et al., 1970). These toxins proved to be bitter-tasting cardiac-active steroids, or cardenolides, that caused bird predators to reject the insects on sight, thus confirming the hypothesized aposematism of their bright coloration. Many insect species are now known either to sequester or synthesize a wide range of toxic defensive chemicals (Blum, 1981).

Chemical disruption of spider web structure and the demonstration of chemical defenses in insects suggest that chemically defended prey of spiders could disrupt spider web structure much like some psychoactive drugs. Thus I wished to determine whether known insect toxins, such as cardenolides, in aposematic spider prey could disrupt the web structure of an orb-web spider and whether spider predatory behavior might be influenced by chemically defended prey.

Orb spiders site their webs in areas of high prey density (Turnbull, 1964; Gillespie, 1981; Janetos, 1982, 1986; Olive, 1982; Riechert and Luczak, 1982; Riechert and Gillespie, 1986) to intercept a wide diversity of different kinds of mobile prey. Some of these prey will have defensive chemicals that may make the spider release them unharmed (Brown, 1984; Vasconcellos-Neto and Lewinsohn, 1984) or, if the spider eats them, may disrupt its web-building physiology and behavior, much like the psychoactive drugs. Consequently, spiders should include prey defenses, such as toxic chemicals, when assessing prey profitability (Stephens and Krebs, 1986).

Since aphids make up a significant proportion of the diet of the araneid spider *Zygiella x-notata* (Nyffeler and Benz, 1981; personal observations), and the bright yellow and black, aposematic oleander aphid *Aphis nerii* B. de F. sequesters toxic cardenolides from the milkweed food plant *Asclepias curassavica* L. (Rothschild et al., 1970; Malcolm, 1981, 1986), I investigated the influence of *A. nerii* on the web structure and predatory behavior of *Z. x-notata*. The three trophic level interaction among *A. curassavica*, *A. nerii*, and *Z. x-notata* is often associated with houses and gardens, and as such has been dis-

tributed throughout the warmer parts of the world, from the Mediterranean to Caribbean islands, Chile, Uruguay, Argentina and on both the west and east coasts of North America (Woodson, 1954; Gertsch, 1964; Levi, 1974).

METHODS AND MATERIALS

Spiders were collected in late March from a single egg sac on a stone wall near Oxford. At first, as is normal, each *Z. x-notata* spiderling built an entire orb web without the spiral-free sector that is characteristic of the species (Witt et al., 1968). When the spiders began to build their characteristic webs, after the second or third molt, 13 female spiderlings were induced to build webs in 120 × 120 mm balsa wood frames (Figure 1), each suspended in a 23 × 23 × 10 cm clear plastic box at 15°C, in a constant environment room with 12 hr light.

Web structure was compared for spiders fed toxic *A. nerii*, palatable green pea aphids, *Acyrtosiphon pisum* (Harris), and two commercially available cardenolide standards. For these experiments *A. nerii* was reared on cardenolide-rich *A. curassavica*, and *A. pisum* was reared from broad beans, *Vicia faba* L.

FIG. 1. The web of a *Z. x-notata* spiderling in its balsa frame and the coordinates used to calculate the sticky spirals area (stippled, sum of $VXYZ$), the length of the sticky spiral thread that makes this area, and the average mesh size of the sticky net.

cv *aquadulce*. The *A. curassavica* host plants were grown from plants of unknown origin, via the botanical gardens at Kew and Oxford (the same strain of plants described by Rothschild et al., 1975), and *A. nerii* was collected originally by Miriam Rothschild on *Nerium oleander* in Israel.

There were four feeding treatments involving the 13 spiders: (1) Four experimental spiders were fed once a week with one *A. nerii* followed after 30 min by one green pea aphid, plus a constant supply of 50% sucrose solution; (2) three control spiders were fed one pea aphid weekly, plus a constant supply of 50% sucrose solution; (3) three spiders were fed one pea aphid weekly plus the cardenolide digitoxin, constantly available in 50% sucrose solution (0.014 mg/ml, the maximum solubility of digitoxin in aqueous solution, Wright, 1960); and (4) three spiders were fed one pea aphid weekly plus the polar cardenolide ouabain, constantly available in 50% sucrose solution (1.0 mg/ml). Thus treatments 1 and 2 examined the influence of aphid prey on spider predation and treatments 3 and 4 examined the influence of cardenolide standards on spider predation.

Throughout the experiments, sucrose solution, with or without added cardenolide, was held in a 10 μ l capillary tube by each spider's retreat. Aphids were placed with forceps on the web within 1 cm of the hub and left until discarded by the spider. Spiders were allowed to build repeated webs unmolested and webs were not artificially damaged or destroyed to induce new web construction. These feeding treatments were run for 70 days, during which time spiders were always in their retreat, with one leg on the signal thread (Figure 1) before they were fed.

The presence or absence of a spider response to an aphid (moving from the retreat to touch an aphid) during the first 30 min of a prey presentation was recorded. The time to attack a presented aphid and the time spent on the web in response to an aphid presentation were measured in seconds during this period. Ultimate aphid acceptance (aphid partially or completely eaten) or rejection (intact aphid discarded), which took from hours to days, was also recorded.

The feeding regimes controlled for possible developmental responses of the spiders to their prey (Murdoch, 1971) since the spiders weighed a mean of 1.01 mg (± 0.19 SE) at the start of the experiment and only increased to a mean weight of 1.37 mg (± 0.17 SE), 70 days later. Only one control spider molted during the experiment. Aphids given to spiders were matched for size, *A. nerii* weighing a mean of 0.61 mg (± 0.03 SE) and *A. pisum* 0.65 mg (± 0.09 SE). The wet weights of aphid prey were determined immediately before being fed to a spider and after they were discarded by the spider. Prey weights were approximately 50% of spider weight since this prey size is in the size range most acceptable to spiders (Nentwig and Wissel, 1986).

Experimental Design. In these experiments the replicated experimental units were, (1) direct behavioral responses, and (2) indirect web structure

responses, of spiders to each food treatment. This design precluded temporal pseudoreplication (Hurlbert, 1984) because each replicate (both direct and indirect responses) was an independent response to each feeding treatment. Treatments were interspersed among spiders but not within spiders. Each replicate also had controls for both temporal (the control treatment) and response variation (the web of each spider before treatment commenced). An experimental design with individual spiders as once-used replicates would not have included responses of successive web structure with time, web construction frequencies, dose dependency, or web structure recovery—all aspects considered important to the experiment. Furthermore, the experimental design minimized disturbance to the spiders and eliminated desertion of their balsa web frame.

Cardenolide Analysis. Since Rothschild et al. (1970) found two cardenolides in *A. nerii* from *A. curassavica*, both aphid prey species were assayed for the presence of cardenolides to ensure that spiders received cardenolide in *A. nerii* but not in *A. pisum*. Freeze-dried aphids were homogenized under nitrogen with chloroform-methanol (2:1, v/v) and centrifuged. Concentrated filtrates were eluted with the cardenolide standard digitoxin on 0.2 mm silica gel-60 thin-layer chromatograms at 15°C in the solvent system dichloromethane-methanol-formamide (80:10:1). Cardenolides were detected as blue spots on the developed TLC plates sprayed with alkaline 2,2', 4,4'-tetranitrodiphenyl. The spectrophotometric method of Brower et al. (1975) was used to estimate the cardenolide concentrations of aphids.

The host plants *A. curassavica* and *V. faba* were also assayed qualitatively for the presence of cardenolides. Freeze-dried leaves were macerated and extracted in 65% aqueous methanol and partitioned with hexane. The methanol fraction was extracted three times with chloroform and then extracted three times with chloroform-ethanol (3:2 v/v). The chloroform and chloroform-ethanol extracts were washed with Na₂SO₄ solution and dried over anhydrous Na₂SO₄ and then filtered through Whatman No. 1 filter paper and reduced under vacuum to approximately 1 ml. These concentrated extracts were then eluted in the same TLC system as the aphid extracts.

Web Structure Measurement. Web coordinates were measured (Figure 1) from projected 35-mm negatives, photographed in a light box (after Witt et al., 1968), to give: (1) the sticky spiral area as the sum of the triangles bounded by all radii and the outer sticky spiral, minus the triangle from the hub to the inner sticky spiral. Thus the sticky area = sum of $VXZY$ except the free sector a , where $VXZY = VXH - YZH$ when $VXH = (X'H/m \times VX/m)/2$ and $YZH = (Y'H/m \times YX/m)/2$, and m = magnification of the projected image. (2) Length of the sticky thread, $L = b[n\pi(h + o)]$, where $b = (360 - a)/360$, a = free sector angle, n = mean spiral number, h = lengths of radii at hub ($Y'H$) summed/number of radii - 1, and o = lengths of radii at outer spiral ($X'H$) summed/number of radii - 1. (3) Mesh size = sticky area/number of radii \times

mean spiral number, where mean spiral number = sum of spiral number in each sector/number of radii - 1. These calculations were made using SPSS (Nie et al., 1975).

RESULTS

Aphid and Plant Cardenolides. Two cardenolides were found in prey *A. nerii* but not in *A. pisum*. The solvent mobilities of these cardenolides, relative to digitoxin, were 1.31 (mean \pm 0.08 SD, $N = 7$) and 1.73 (mean \pm 0.21 SD, $N = 7$), which suggests that they are the cardenolides proceroside and calotropin, respectively, found previously in *A. nerii* by Rothschild et al. (1970). The concentration of cardenolides in *A. nerii* from *A. curassavica* was 246 $\mu\text{g}/0.1$ g dry aphid, with an average of 0.5 μg cardenolide in each aphid.

No cardenolides were found in extracts of *V. faba*, the host plant of *A. pisum*. However, 20 cardenolides were identified in TLC separations of *A. curassavica* extracts. Two of these spots had mean mobilities relative to digitoxin of 1.21 (\pm 0.05 SD, $N = 5$) and 1.66 (\pm 0.02 SD, $N = 5$) and did not differ significantly from the two aphid mean spot mobilities of 1.31 and 1.73 ($\chi^2 = 0.08$ and 0.14, respectively; both $df = 4$, and both $P = \text{NS}$ at 5%). Thus, although the mean mobilities of the two plant cardenolides were slightly less than those of the aphid, perhaps because the plant has more cardenolide material, the insignificance of this difference indicates that the aphid cardenolides were plant-derived.

Spider Predatory Behavior. Spiders attacked aphids by moving from their retreat rapidly down the signal thread to the hub and then along the radius on which an aphid was trapped. The aphid was usually bitten immediately and then either cut from the web and taken back to the retreat or left to die while the spider returned rapidly to its retreat. From 79 timed observations of the two aphid species (Table 1), there were no significant differences in the numbers of spider responses to aphids among the treatments ($\chi^2 = 5.76$, $df = 4$, $P = 0.22$). However, only 20% of *A. nerii* were ultimately accepted (killed and at least partially eaten) by experimental spiders, significantly fewer than the 85% of *A. pisum* accepted by all spiders ($\chi^2 = 35.37$, $df = 4$, $P = 0.001$).

The spiders in experimental treatment 1 attacked 76% of the *A. nerii* offered and 47% of the *A. pisum*, and spiders in groups 2, 3, and 4 (the control, digitoxin, and ouabain treatments) attacked 60%, 58%, and 83%, respectively, of their *A. pisum* (Table 1). Only 52% of attacked *A. nerii* were actually killed because 56% of attacks resulted in the spider withdrawing immediately after biting the aphid. These withdrawals may have been caused by cardenolides in *A. nerii* or by the fact that 64% of attacked *A. nerii* produced drops of strongly repellent supercooling cornicle secretion on attack (see Brown et al., 1969),

^aUltimate acceptance of aphids by the spiders, no time limit.

whereas only 6% of *A. pisum* in the same treatment did so. In contrast, 90% of attacked *A. pisum* were killed by spiders in the control, digitoxin, and ouabain groups because 47%, 64%, and 83%, respectively, of these aphids were held by the spiders after they were bitten.

A. nerii also appeared to inhibit attacks by the spiders on *A. pisum* in the experimental treatment because these spiders took twice as long to attack than control spiders and only responded to 47% of their palatable aphids, whereas they responded to 76% of the toxic *A. nerii* presented 30 min earlier (Table 1).

Although experimental and digitoxin spiders seemed to take longer to attack their aphid prey than ouabain and control spiders (Table 1), there were no significant differences among the feeding treatments (Kruskal-Wallis ranked ANOVA, $H_4 = 2.36$, $0.7 > P > 0.5$), since the times taken to attack aphids were highly variable (Table 1). However, at the 10% significance level, experimental and digitoxin spiders spent longer away from their retreats and on their webs in response to presentations of *A. nerii* and *A. pisum*, respectively (Table 1), than spiders responding to *A. pisum* in the experimental, control and ouabain treatments (Kruskal-Wallis ranked ANOVA, $H_4 = 8.53$, $0.10 > P > 0.05$). The experimental and digitoxin spiders often appeared disoriented after attacking an aphid and either wandered around the outer frame, or cleaned their legs and palps, or remained motionless with legs poised near an aphid, before returning to the retreat.

Prey Consumption. Overall prey consumption was examined by comparing the weight changes with time of prey aphids against the weight changes of similar-sized, intact, nonprey aphids. These nonprey aphids were held in similar containers to the prey aphids without access to host plants and hence controlled for weight loss by evaporation. A *t* test comparison between the regression slopes of *A. nerii* weight change with time showed no significant difference between prey and nonprey aphids ($t_{194} = -0.70$, $0.5 > P > 0.4$) because 80% of the prey aphids were intact and uneaten. Thus, although 52% of the *A. nerii* given to spiders were killed, only 20% were at least partially eaten.

In contrast, the spiders ate all of the body contents of the *A. pisum* they killed in each treatment, always discarding a crumpled, sucked-dry or chewed exoskeleton as the remains of their prey. The *t* test comparisons between regression slopes of prey and nonprey *A. pisum* wet weight loss with time in each treatment showed highly significant changes in prey aphids (digitoxin $t_{79} = -4.70$, $P < 0.001$; ouabain $t_{102} = -13.39$, $P < 0.001$; control $t_{90} = -10.57$, $P < 0.001$).

Changes in Web Structure with Time. Although the overall pattern of prey attack by experimental spiders showed rejection of most bitter-tasting *A. nerii* that they killed, each spider ate sufficient amounts of 20% of these aphids to produce dramatic changes in web structure.

An example of such a change is illustrated in Figure 2. The spider ate 68% of a 0.79 mg *A. nerii* placed in its web (Figure 2a) and built a seriously disrupted web two days later (Figure 2b). The next web built by the spider after a further four days showed some recovery, with an increase in trap area and thread regularity, although the web structure remained clearly disrupted (Figure 2c). These highly irregular webs are not the result of food limitation since at each prey presentation the spider completely consumed the palatable *A. pisum* presented, and hence had as much food as the group 2 control spiders which built no irregular webs.

The sticky area, length of the sticky thread that makes up the sticky area, and mesh size (see Figures 1 and 2) determine the web's trapping effectiveness (Rypstra, 1982; Murakami, 1983; Nentwig, 1983; Eberhard, 1986). Hence their changes with time were measured from photographs of the webs. Throughout the 70-day experiment the 13 spiders built 134 webs, distributed among the four treatments as shown in Table 2. Table 2 also shows the means, standard errors, and ranges of the calculated sticky areas, thread lengths, and mesh sizes of webs in each treatment.

The first webs built by spiders after being given an *A. nerii* had reduced sticky areas, reduced sticky thread lengths, and increased mesh sizes (Figure 3, Table 3). Each of these three measures of subsequently constructed webs showed a significant recovery with time following an encounter with *A. nerii*.

FIG. 2. Photographs of three consecutive webs built by a spider given the aphid *A. nerii*. (a) is "typical" of this spider individual and acts as a control for comparison with subsequently disrupted webs. Webs b and c were built two and six days, respectively, after the same spider ate 68% of an *A. nerii* placed in web a. Each web has the same outer frame thread, but the number of radii and the area of spiral sticky thread of webs b and c are much reduced. Accordingly, the length of sticky thread is much shorter and web mesh sizes are larger and more irregular. Web c shows some recovery of web structure with time since feeding on the toxic aphid. The number of radii have increased and the sticky thread area with smaller mesh sizes.

TABLE 2. SAMPLE SIZES, WEB FREQUENCIES, STICKY AREAS, STICKY THREAD LENGTHS, AND MESH SIZES OF WEBS CONSTRUCTED BY SPIDERS IN FOUR FEEDING TREATMENTS WITH *A. nerii*, *A. pisum* CONTROL, DIGITOXIN, AND OUABAIN

In contrast, the web structure of control spiders, fed only *A. pisum*, showed no significant changes (Figure 3, Table 3). Hence feeding encounters with *A. nerii* at first resulted in disrupted webs, but spiders recovered with time, and successive webs increased in regularity and size.

Reductions in the sticky areas and sticky thread lengths of webs, similar to those produced in the *A. nerii* treatment, were mimicked by giving spiders the cardenolide digitoxin, although mesh sizes were not significantly affected (Figure 3, Table 3). Where significant, these regressions have negative slopes because sticky web areas and thread lengths decreased significantly as the time exposed to digitoxin increased throughout the 70-day experiment. Like control spiders, the web structures of spiders in group 4, given the cardenolide ouabain, did not change significantly during the experiment.

Dose-Dependent Changes in Web Structure. Since 64% of *A. nerii* produced supercooling cornicle secretions in response to spider attacks, it is possible that web disruption may have been caused by the physical effects of this

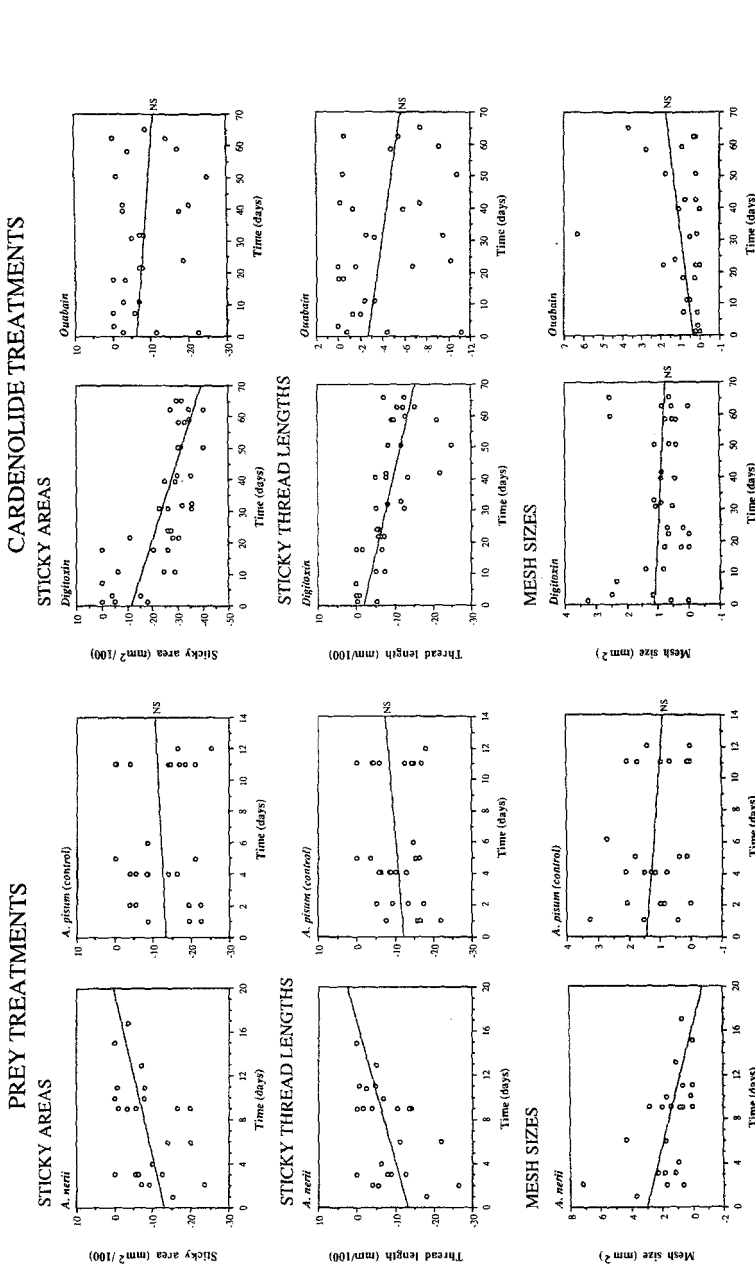

FIG. 3. Linear regressions of web measurements (sticky areas, sticky thread lengths, and mesh sizes) against time for spiders in the *A. neri*, control, digitoxin, and ouabain treatments. The regression data and their significance are given in Table 3 (NS = nonsignificant regression line). Significant regression slopes of sticky areas and sticky thread lengths increase with recovery in the *A. neri* treatment because webs return to their pretreatment size at the zero intercept with recovery in size since an aphid was given. The digitoxin treatment has negative slopes because webs were reduced in size with exposure to digitoxin during the entire 70-day experiment. Mesh sizes decreased with recovery in the *A. neri* treatment because unaffected mesh sizes are smaller and reflect the more effective trap of normal spider webs (see Figure 2).

cardenolide-free fluid (Malcolm, 1981) on the external leg receptors used by the spiders in web construction (Foelix, 1982). Thus in order to demonstrate that web structure is disrupted by the effects of aphid body contents containing cardenolides, the influence of the weight of *A. nerii* eaten with time (dose) on web structure was also examined.

The amount and rate of *A. nerii* eaten significantly reduced the sticky area of webs in a dose-dependent manner (Table 4), since the most *A. nerii* eaten in the shortest time produced the greatest reductions in web sticky area (Figure 4). The interaction was reversible, with less of an aphid eaten per unit time producing a smaller reduction in sticky area. In contrast, the rates of palatable aphid consumption in the control experiment had no effect on the sticky area of webs (Figure 4, Table 4).

Thus it is most likely that this dose-dependent web disruption was caused by aphid body contents containing cardenolides, rather than by the physical effects of hardened cornicle secretion.

^aTime is measured in days since an aphid was given for spiders fed *A. nerii* and control spiders fed *A. pisum* and against days in the 70-day treatment for spiders given the cardenolides digitoxin, and ouabain. Web reduction is calculated by subtraction from the unaffected control webs built by each spider before its feeding treatment. The zero intercept represents this control web size (see Figure 3).

^bSignificant at < 0.05.

FIG. 4. Percent reduction in the sticky web areas of spiders fed either *A. nerii* or *A. pisum* versus the rate of aphid eaten. The data are transformed and analyzed in Table 4 and show that sticky web areas of spiders fed *A. pisum* do not change with rate of prey consumption but that the webs of spiders fed *A. nerii* show greater reductions in sticky areas with higher rates of aphid consumption.

TABLE 4. LINEAR REGRESSIONS OF FIGURE 4 DATA FOR PERCENT REDUCTION IN STICKY AREAS^a OF WEBS BUILT BY SPIDERS GIVEN EITHER DISTASTEFUL *A. nerii* OR PALATABLE *A. pisum* AS APHID PREY, AGAINST RATE OF APHID EATEN^b

DISCUSSION

Webs of spiders fed either *A. nerii* or the cardenolide digitoxin showed significant and similar kinds of disruption. This suggests that one or both of the two plant-derived aphid cardenolides caused the physiological and behavioral disruption of web structure. The highly polar ouabain produced no measurable

changes in web structure, and it is interesting that the aphid does not store any of the high-polarity cardenolides present in the host plant (Rothschild et al., 1970; Roeske et al., 1976; Malcolm, 1981). Ouabain is not a bitter-tasting cardenolide like digitoxin (Malcolm, 1981) and, owing to its high polarity, it is very slow to cross membranes (Wright, 1960; Duffey, 1977). Hence, ouabain may be excreted by the spider before any physiological effects are manifested. Ouabain has also been shown to have no effect on an ATP hydrolyzing enzyme in the central nervous system of *Z. x-notata* (Meyer, 1979), although in crustaceans it inhibits the stimulation of ATP (Lehninger, 1975). In contrast, bitter-tasting digitoxin is much less polar, like the cardenolides in *A. nerii*, and is readily absorbed across tissue and cell membranes (Wright, 1960; Duffey, 1977). Thus, orally administered digitoxin is expected to be considerably more toxic than ouabain to both invertebrate and vertebrate predators.

Construction of spider webs incurs time and energetic costs, associated with foraging for prey, that are balanced by the rewards of prey capture (Ford, 1977; Janetos, 1982; Olive, 1982; Rypstra, 1982; Eberhard, 1986). For these rewards to be maximized, prey capture efficiency is likely to be influenced by web structure. For example, Rypstra (1982) found the number of captured prey was maximized at a particular thread density, above which webs became increasingly visible and caught fewer prey (Craig, 1986). Prey size may be correlated with mesh size (Uetz et al., 1978), or mesh sizes may determine only the lower limit of captured prey size, because small insects can pass through the web mesh (Murakami, 1983). However, Nentwig (1983) found no correlation between prey size and mesh width. Instead, like Rypstra, he found that spiders with narrow-meshed webs caught more prey, but those with wide-meshed webs saved more web construction material. Hence the construction of webs by *Z. x-notata* with increased mesh sizes after feeding on *A. nerii* will decrease the capture efficiency of webs for small-sized prey. Feeding on *A. nerii* also resulted in fewer, smaller, and more irregular webs being built by *Z. x-notata*.

Changes in the web structure of *Z. x-notata*, induced by the chemical defense of an aphid prey, suggest that prey profitability and web site profitability for spiders is influenced by more than prey density or prey size (Janetos, 1982, 1986; Olive, 1982; Nentwig and Wissel, 1986; Riechert and Gillespie, 1986). The cardenolide-based chemical defenses of *A. nerii* clearly influence both the behavior and physiology of prey capture by *Z. x-notata*. The toxic aphid not only influenced predatory behavior indirectly, through altered web construction behavior, but also directly influenced predatory behavior, because spiders attacked fewer palatable *A. pisum* and took longer to attack them immediately after an encounter with toxic *A. nerii* than control spiders given only *A.*

pisum (Table 1). As Suter (1978) found with the orb spider *Cyclosa turbinata*, the spiders appeared unable to discriminate between the aphid prey species on the basis of web-borne vibrations alone.

The lengthened behavioral responses of *Z. x-notata* to aposematic *A. nerii* also meant that spiders were exposed for longer periods on their webs, displaying some evidence of disorientation, than spiders attacking only palatable prey. Thus, an additional cost of feeding on toxic prey may be increased exposure to natural enemies and abiotic mortality.

Web construction physiology was also influenced since spiders fed *A. nerii* built fewer webs (Table 2) than control spiders fed palatable aphids (Mann-Whitney $U_{3,4} = 1$, $P = 0.057$). Thus the mean web duration of spiders given *A. nerii* was also longer (8.95 days \pm 1.02 SE) than that of control spiders given *A. pisum* (6.33 days \pm 0.60 SE).

In order to maximize its foraging effectiveness, a spider must either move its web site, or stay and eat profitable prey, but not toxic prey, like *A. nerii*, trapped in its web. The first option has been documented for some web-building spiders, which remained longer at more profitable than less profitable trapping sites (Janetos, 1982; Olive, 1982; Riechert and Luczak, 1982); the probability of relocating a web and the distance moved both increased with decreasing site profitability. The alternative option, of staying at a web site and releasing trapped, unprofitable prey, has been recorded recently for a neotropical web-building spider that freed distasteful butterflies from their webs according to chemical cues (Brown, 1984; Vasconcellos-Neto and Lewinsohn, 1984). However, *Z. x-notata* was unable to inhibit completely its feeding response to *A. nerii*, which it continued to kill, and occasionally eat, throughout the experiment. Such feeding on chemically defended prey could reduce the numbers of subsequent prey caught, both indirectly by changing the trapping effectiveness of webs, and directly by inhibiting the predatory behavior of spiders. Prey-induced inhibition of spider predatory behavior is similar to the sedative effect of millipede chemical defenses against a wolf spider that Carrel and Eisner (1984) describe, but differs in that aphids are unlikely to escape a spider's web. Since *Z. x-notata* appears to attack automatically and kill both toxic and palatable prey (also, Malcolm, 1986), perhaps in response to similar frequencies of web-borne vibrations (Suter, 1978; Barth, 1982; Klärner and Barth, 1982; Masters, 1984a, b), prey choice may be determined primarily by web location within energetic and site availability constraints, rather than by discrimination among trapped prey items.

Acknowledgments—I am especially grateful to the late Professor George Varley and to Dr. Miriam Rothschild for their interest, and to Dr. Barbara Cockrell for help with measuring spider

webs. Drs. Lincoln Brower, Barbara Cockrell, Craig Hieber, John Reiskind, Thomas Schoener, Mark Stowe, Fritz Vollrath, and Peter Witt gave helpful comments and discussion. Professor John Webster and Dr. Jo Anderson kindly provided facilities at Exeter University to use the South Western Universities Regional Computer network. The research was funded by a NERC research assistantship at Oxford University.

(Received March 21, 1988; accepted August 11, 1988)

Abstract—Racemic 6,10,13-trimethyl-1-tetradecanol has been synthesized. Successive elaboration of the molecule using 5-methyl-2-hexanone as the carbon-terminal fragment gave the desired alcohol in a 4% overall yield over 13 steps. Neglecting stereochemistry, the product was shown to be identical to the alcohol previously identified from the sternal glands of male *Stiretrus anchorago*. It attracts both adult sexes and larvae of this insect in the field, confirming its postulated identity as an aggregation pheromone. The corresponding aldehyde is more than 10 times more concentrated in airborne-trapped samples (5–7% by gas chromatography) than in extracts of glandular setae (0.4–0.5%). This alcohol or its isovalerate ester has been found in other predaceous pentatomids, providing further evidence for pheromones in these species.

Key Words—Pheromone, attractant, *Perillus bioculatus*, *Oplomus severus*, *Mineus strigipes*, *Oplomus dichrous*, stink bugs, Heteroptera, Pentatomidae, 6,10,13-trimethyl-1-tetradecanol.

INTRODUCTION

For some years we have been engaged in exploration of the chemical communication of Heteroptera, particularly with respect to aggregation and/or sex pheromones. This subject has been reviewed recently (Aldrich, 1988).

Examination of five species of predatory asopine stink bugs (Aldrich et al.,

1986; Aldrich and Lusby, 1986) has shown the presence of 6,10,13-trimethyl-1-tetradecanol (in *Stiretrus anchorago* and *Mineus strigipes*), 6,10,13-trimethyl-1-tetradecyl isovalerate (in *Perillus bioculatus* and *Oplomus severus*), or a mixture of the two (in *Oplomus dichrous*) on setae associated with sternal glands present only in males. Identification was by spectrometric and degradative means (Aldrich et al., 1986) but the material was not synthesized.

Because of the potential use of a pheromone for population management of these beneficial insects, we undertook a synthesis of this alcohol. Since there are two asymmetric carbons in the molecule, there are four possible enantiomers. Optically pure materials are often not required, however, so we initially prepared the racemate by a sequential elaboration of 5-methyl-2-hexanone as summarized in Figure 1. The synthesis, comparison to the natural material, and field testing results are described here.

FIG. 1. Synthetic scheme for preparation of 6,10,13-trimethyl-1-tetradecanol.

METHODS AND MATERIALS

All potentially asymmetric compounds reported here are racemic. Solvents were of good technical grade, redistilled in glass. "Ether" was technical anhydrous ether redistilled from sodium, "dry" ether and THF were freshly distilled from LAH. Reactions requiring an inert atmosphere were carried out under nitrogen. Solutions of crude products were dried with $MgSO_4$. Temperatures are uncorrected. Structural confirmations were generally via GLC-MS since NMR and IR spectrometry are not very helpful with saturated aliphatic derivatives.

Chromatography and Instrumentation. Gas-liquid chromatographic (GLC) analysis of synthetic intermediates was carried out on a Packard-Becker model 421 fitted with a 30-m \times 0.53-mm DB-1 column (J&W Scientific, Folsom, California), using helium as carrier gas, and a Perkin-Elmer LCI-100 integrator. Temperature was programmed from 100 to 300°C at 10°/min. Comparisons with natural products were run on a Varian 3700 instrument with 14-m \times 0.25-mm DB-1 or DB-5 columns, helium carrier, and a Shimadzu C-R3A integrator. Integrations were not corrected for differences in detector response.

Mass spectrometry was carried out on a Finnigan MAT 4510 fitted with a 30-m \times 0.32-mm DB-1 column (J&W Scientific) and an INCOS data system.

The preparative HPLC system was based on a PULSAfeeder model 7120-SE diaphragm metering pump (Interpace Corp., Rochester, New York), rated 5.6 liters/hr at 210 kg/cm². All wetted parts were of stainless steel, and the discharge line from the pump to the injector valve had a T fitting leading to a stainless-steel pulse dampener (series 100, Kemlon Products and Development Co., Houston, Texas). The injector valve was a Whitey SS-43Y6 fitted with a 10-ml injector loop made from 2.75 m of $\frac{1}{8}$ in. OD \times 0.085 in. ID (3.175 \times 2.16 mm) stainless tubing.

Columns were fabricated from 3-ft (917-mm) sections of seamless type 304 stainless pipe, 2 in. \times schedule 40 (52.4 mm ID, 60.2 mm OD) with welded-on flanges. Heads were prepared from blind flanges by machining a recess for a stainless frit (Mott Metallurgical Corp., Farmington, Connecticut), a $\frac{1}{16}$ in. deep mixing chamber behind the frit, and a $\frac{1}{8}$ -in. NPT socket for a Swagelok® adapter. Packing was ca. 1500 g of Davison grade 922 silica gel, dry packed and tamped. Pressure drop with 1:1 hexane-ether at 125 ml/min was approximately 18 atm.

The UV detector (fixed wavelength = 254 nm) was salvaged from a DuPont model 830 instrument and fitted with a preparative cell. Further information is available from the first author.

2-Bromo-5-methylhexane (3). To 500 ml of 95% EtOH in a 1-liter three-neck flask fitted with a mechanical stirrer, reflux condenser, and addition funnel was added 23 g (0.6 mol) of $NaBH_4$; then 150 ml (1.17 mol) of 5-methyl-2-

hexanone (Aldrich Chemical Co.) was added over 45 min. The solution boiled spontaneously and the addition rate was adjusted to maintain gentle reflux. After 2 hr additional heating under reflux, the solution was cooled, poured into water, and extracted three times with ether. The combined extracts were washed with water (2×), 5% NaOH, water, and bicarbonate, and then dried. The solvent was removed on a rotary evaporator to give a colorless oil, which was used directly for the next step (bp 144–152°C/762 mm, Aldrich Catalog says 148–150°C).

The oil was dissolved in 500 ml ether in the same apparatus except that the condenser was replaced with a thermometer dipping into the solution. The mixture was cooled in ice to <10°C, then 100 g PBr₃ (0.37 mol, 1.11 eq) was added dropwise over 1.5 hr, keeping the solution temperature between 5 and 10°C. The solution was stirred for one additional hour in the ice bath, and then at room temperature overnight (ca. 22 hr total). The product was isolated by pouring the solution onto ice and extracting twice with ether after separation of the original ether layer. The combined extracts were washed with water and saturated sodium bicarbonate (twice), dried, and distilled to give 128.7 g of the bromide **3** as a colorless oil, bp 55–59°C/25 mm (61% from the ketone). Bergmann et al. (1966) report 58°C/18 mm.

4,7-Dimethyl-1-octene (4). A 2-liter three-neck flask, Friedrich condenser, and dropping funnel were dried at 130°C, cooled under N₂, and fitted with a paddle stirrer. Magnesium turnings (24.3 g, 1 mol) were added, followed by 179 g (1 mol) of 2-bromo-5-methylhexane in ether totaling 600 ml. The addition of bromide took 45 min, and the mixture was heated under reflux for an additional 45 min. Freshly distilled allyl bromide (86.5 ml, 1 mol) was added dropwise at a rate to maintain good refluxing over 1¼ hr. The resulting solution was heated under reflux for 1¼ hr and stirred overnight at room temperature. The two-phase mixture (a heavy gray oil had separated overnight) was hydrolyzed with saturated NH₄Cl solution (150 ml) to the separation of a dense granular precipitate and filtered. The filtrate was distilled to a vapor temperature of 125°C to remove solvent and excess allyl bromide (odor), diluted to 500 ml with pentane, and percolated through a 25 × 300-mm silica gel column with pentane to remove polar impurities. The eluate was distilled bp 148–156°C/763 mm to give a colorless oil (39.8 g, 28%, major component 89% by GLC). A further 5.3 g of slightly less pure material was taken off from 156–170°C and treated with KOH to remove a trace of HBr. Total yield 45.1 g. MS (EI) 140 (0.3% M⁺), 125 (0.4%), 112 (0.4%), 98 (5%), 84, 69, 57 (100%) MS(CI, CH₄), 141 (30%, M+H), 139 (15%), 125 (22%), 99 (45%), 97 (20%), 85 (100%), 83 (88%), 71 (98%).

4,7-Dimethyl-1-octanol (5). A 1-liter three-neck flask, addition funnel, and condenser were dried at 130°C, assembled hot, and cooled under N₂. Dry THF (200 ml) was transferred to the dry flask using a double-tipped needle, followed

by 4,7-dimethyl-1-octene (45 g, 286 mmol of contained olefin). To the magnetically stirred solution was added 1 M BH_3/THF (160 ml, 68% excess, Alfa) over ca. 1 hr at room temperature, and the mixture was stirred for a further 3 hr at room temperature. After cooling in ice to $<10^\circ\text{C}$, 10 ml of water was added slowly (gas evolution), followed by 75 ml of 3 M NaOH. Hydrogen peroxide (30%, 75 ml) was then added at such a rate as to keep the temperature $<40^\circ\text{C}$; then the mixture was heated to $50\text{--}55^\circ\text{C}$ (some reflux) for 1 hr and stirred overnight. Extractive work-up with ether, removal of the solvent on a rotary evaporator, and rotary evaporation with 2×100 ml of *n*-heptane (to remove some *n*-BuOH from the decomposition of the BH_3/THF during storage) gave 44.5 g of a colorless, fragrant (rose-fatty) oil containing 84% of the desired product and 5.3% of the 2-isomer by GLC, along with other minor impurities which were not identified.¹

The reaction of the crude alcohol in pyridine with freshly prepared (acid and SOCl_2) 3,5-dinitrobenzoyl chloride gave a crude ester (87% pure by GC), which was crystallized twice from pentane at -20°C to give 65 g of purified ester, mp $37.5\text{--}39.5^\circ\text{C}$ (98.6% pure by GC). NMR: 0.8–0.9 (9H) CH_3 complex multiplet, 1.0–2.0 complex multiplet (CH , CH_2) 4.42 (2H) triplet (CH_2O), 9.15 (3H) ArH, complex multiplet. Considerable product remained in the mother liquor by GLC, but it could not be induced to crystallize. A comparison sample of 3,7-dimethyl-1-octyl 3,5-dinitrobenzoate was prepared from 3,7-dimethyl-1-octanol (Givaudan) and crystallized from pentane, mp $37\text{--}39^\circ\text{C}$, mixture mp $<25^\circ\text{C}$ (liquefied on trituration). The NMR was indistinguishable from that of the 4,7 compound.

Saponification of 60.4 g of this ester with 2 eq NaOH/MeOH, and aqueous work-up gave 26.5 g purified 4,7-dimethyl-1-octanol as a colorless oil, which was 97.8% pure by GC. This represents a 56% yield from the olefin, allowing for the sample of ester not saponified. The compound has been previously reported (Crombie et al., 1957).

4,7-Dimethyloctyl bromide (6). Triphenylphosphine dibromide was prepared from 53 g (0.2 mol) Ph_3P and 10.3 ml Br_2 in CH_2Cl_2 (250 ml), adding enough additional Br_2 to give a faint yellow color, keeping the temperature between 10 and 15°C . The purified 4,7-dimethyl-1-octanol (5), in 100 ml CH_2Cl_2 , was then added over 25 min below 10°C , and the solution was allowed to warm up to room temperature with stirring overnight. Water (200 ml) was added, followed by solid NaHCO_3 to neutralize the HBr. Extraction of the separated aqueous phase with CH_2Cl_2 and evaporation of the organic layers gave a sticky mixture of Ph_3PO and product, which was partitioned between 90%

¹ A reviewer has pointed out that the quantities of NaOH and H_2O_4 were inadvertently less than stoichiometric. It is probable that the yield would improve by use of sufficient reagents to complete oxidation/hydrolysis.

aqueous DMSO and petroleum ether. The DMSO layer was extracted twice more with petroleum ether; then the extracts were washed twice with 90% DMSO to remove Ph_3PO and once with water, and dried. Removal of solvent gave 42.1 g of almost colorless oil, which was passed through a column (2 × 30 cm) of silica gel with petroleum ether to remove polar impurities, then distilled; bp 112–114°C/26 mm, 34.7 g (93.7% yield) 97.5% pure by GLC. MS (EI, 70 V) 220, 222 (M^+ , trace), 205, 207 (trace) 177, 179 (trace) 163, 165 (trace), 149, 151 (28%), 69 (50%), 57 (100%).

4,8,11-Trimethyl-3-dodecen-1-yl Bromide (Mixed Isomers) (7). To a 250-ml three-neck flask with a magnetic stirrer, addition funnel, and Friedrich condenser, dried at 140°C and cooled under N_2 , was added 4.8 g Mg and, over ca. 30 min, the bromide (6) (34.2 g) in dry ether (ca. 150 ml). After heating under reflux for 1 hr further, methyl cyclopropyl ketone (17 ml, 0.17 mol) was added over $\frac{1}{2}$ hr and the solution refluxed for a further $\frac{1}{2}$ hr. The alkoxide solution was then transferred (double-ended needle) to a dropping funnel fitted to a magnetically stirred 500-ml three-neck flask containing 100 ml 48% HBr and cooled in an ice bath. The alkoxide was added over about 45 min, keeping the pot temperature < 10°C. After a further 30 min, 400 ml H_2O was added. Extractive work-up with ether, followed by washing with water and NaHCO_3 , then passage through a 2.5 × 30 cm silica gel column with petroleum ether gave 38.9 g of a colorless oil that was distilled, bp 175–178°C/26 mm, to give 28.6 g of a colorless oil (GLC: 31.7% *Z*, 56.4% *E*, and 7.8% of the hydrocarbon dimer from the Grignard preparation). The mixed bromides contained represent a 55% yield.

6,10,13-Trimethyl-1-tetradecanoic Acid (10). Sodiomalonic ester was prepared in 200 ml of absolute ethanol (stored over 3A molecular sieves) from 3.4 g sodium (0.15 mol) and subsequent addition of 24 g (0.15 mol, 22.8 ml) freshly distilled diethyl malonate. After stirring for $\frac{1}{2}$ hr, the 28.6 g of crude bromide **7** above was added over 15 min and the funnel was rinsed with 30 ml absolute alcohol. After $1\frac{1}{4}$ hr reflux (GLC analysis of an aliquot taken after 55 min indicated the absence of starting material), the slurry (NaBr) was cooled, hydrolyzed with 500 ml of iced $\frac{1}{3}$ -saturated NaHCO_3 (to buffer the NaOH from hydrolysis of excess sodiomalonic ester), and extracted with three portions of ether, which were washed with water (twice), then brine, dried and concentrated to give 47.9 g of a pale yellow liquid with the odor of the excess malonic ester.

This crude ester (**8**) was dissolved in 95% EtOH (about 150 ml total volume) and hydrogenated over Pd/C at an initial pressure of 50 psi in a Parr apparatus overnight. Filtration and rotary evaporation gave 41 g of a colorless oil.

The saturated ester (**9**) was dissolved in ca. 200 ml 95% EtOH, and a solution of 30 g KOH (2 equivalents)/30 ml H_2O was added. After 45 min heating under reflux, the starting ester was absent by GLC. Most of the ethanol

was removed on a rotary evaporator, and the solution was diluted with water and extracted three times, with petroleum ether with addition of enough EtOH to break the emulsion. Acidification of the alkaline solution with dilute H_2SO_4 and extractive work-up with ether gave 33.7 g of an almost colorless oil, which did not crystallize from pentane at $-100^\circ C$ overnight. GLC of the methyl esters showed almost exclusively the substituted malonic acid with ca. 3% of the decarboxylated product.

The crude acid (33.2g) was heated in an oil bath under N_2 at $175^\circ C$ until effervescence ceased, then distilled (Kugelrohr), bp $135-155^\circ C$ (bath temperature)/1.3 mm, to give 18.5 g (75% from the bromide mixture) of 6,10,13-trimethyl-1-tetradecanoic acid (**10**) as a colorless liquid 97.3% pure by GLC of the methyl ester. We could find no mention of this compound in the literature, but the 5,9,13 isomer boils at $128-130^\circ C/0.05$ min (Weichet et al., 1957) or $150-160^\circ C/1-2$ mm (Lukes and Zobáčová, 1957). A few grams of undistilled residue on methylation (CH_2N_2) consisted essentially of one compound having MS characteristics indicative of bis(4,7-dimethyloctyl)acetic acid derived originally from dialkylated malonic ester, which presumably had a retention time too long to show up in the GLC runs of **8** or **9**. MS of methyl ester (CH_2N_2) 284 (0.4, M^+), 269 (0.3), 252, 253 (0.9,0.6), 208 (30), 143 (10), 115 (15), 111 (15), 97 (15), 97 (15), 87 (40), 74 (100).

6,10,13-Trimethyl-1-tetradecanol (**11**). Distilled 6,10,13-trimethyl-1-tetradecanoic acid (15.5 g, 57 mmol) was reduced in ether with 3 g of LAH (79 mmol, 85% excess). Filtration of the hydrolyzed (3 ml H_2O , 3 ml 15% NaOH, 9 ml H_2O) reaction mixture and evaporation of the filtered solution gave 16 g of an almost colorless liquid, which was distilled (Kugelrohr) to give 13.3 g of a colorless oil, bp $120-127^\circ C/1.8$ mm. This represents a 90% yield from the acid and a 4% overall yield from 5-methyl-2-hexanone. Purity was 96.2% by GLC. NMR: 0.85 (12H, broad doublet, CH_3), 1.0-2.0 (complex multiplet, CH , CH_2), 3.63 (2H, triplet, CH_2O).

In the initial preparation, which provided the material for the field tests, the crude alcohol (1.1 g) showed several spots by TLC on silica gel (Et_2O -hexane 1:1). The 3,5-dinitrobenzoate was prepared (acid chloride + alcohol + pyridine) and purified by preparative HPLC on silica gel with 15-20% ether in hexane to give 1.1 g of purified ester, which showed only one spot on TLC. The pale yellow oil could not be crystallized at $-20^\circ C$ but was saponified with $KOH-H_2O-EtOH$ at reflux for 15 min followed by extractive work-up with ether to give 419 mg of an oil (96.6% pure by GLC).

The products from both preparations were identical to each other and to the natural product by GLC coinjection on DB-1 and DB-5 columns, and the mass spectra were identical to those in Aldrich et al. (1986).

6,10,13-Trimethyl-1-tetradecanal. Alcohol (**11**, 1 μ l) was oxidized with a slurry of ca. 10 mg pyridinium chlorochromate in 1.5 ml CH_2Cl_2 . After 15 min, the solution was diluted with 1:1 Et_2O -hexane to 4 ml and percolated

through a 2.5-cm layer of silica gel in a disposable pipet with 2 ml more of the same solvent. GLC showed a 3:1 mixture of aldehyde and starting alcohol. The retention time (coeluted with natural material from 15-m DB-1 and DB-5 capillaries) and GLC-MS (see under airborne trapping in Results, below) were identical to those of the natural material.

Behavior. Field testing was conducted from July 4 through July 23, 1987, in a 0.94-hectare fallow field surrounded by mixed coniferous/deciduous forest at the Beltsville Agricultural Research Center. Goldenrod (*Solidago* spp.), bush-clover (*Lespedeza* spp.), and smartweed (*Polygonum* spp.), were especially abundant. Traps were made from 20 × 20-cm transparent cylindrical containers (Tri-State Molded Plastics, Dixon, Kentucky) (Aldrich et al., 1984) and suspended in contact with foliage from stakes (ca. 1 m above ground). Six pheromone-baited and six unbaited control traps were deployed in a randomized complete block design. Pheromone traps were rebaited daily with 0.5 mg of 6,10,13-trimethyl-1-tetradecanol (100 µg/µl CH₂Cl₂) on a rubber septum (5 × 9 mm, Thomas Scientific, Philadelphia, Pennsylvania).

Airborne Pheromone Trapping. Groups of 20 field-collected male or female *S. anchorago* were coaxed into a 785-ml glass column for trapping of volatiles. Air was drawn by vacuum for 24 hr through a charcoal prefilter, over the bugs, and through 30 mg of activated charcoal sandwiched inside a Swinney filter holder (13-mm stainless steel, Thomas Scientific). Trapped volatiles were washed from the filter in 200 µl CH₂Cl₂.

A similar procedure was used for determination of release rate and gland contents. Five laboratory-reared males whose sternal gland setae were visibly wet with secretion were used. The males were coaxed into a 10-ml, Luer-tip, disposable, glass syringe (Becton, Dickinson; HYPAK; Ace Scientific Supply Co., East Brunswick, New Jersey) with a cotton-stoppered water bottle, a meal-worm pupa for food, and charcoal prefilter (3 mm ID × 8 cm) in place of the plunger. Air was drawn by vacuum (30 ml/min) through ca. 30 mg of activated charcoal in a Swinney filter holder (as above) inserted onto the tip of the syringe. The males were aerated for 7.5 hr at 23°C during mid-photophase, and volatiles were washed from the filter in 345 µl of CH₂Cl₂. Release rate was determined by GLC external standard comparison to the synthetic material. Subsequent extraction of secretion directly from the sternal gland setae with heptane (Aldrich et al., 1986) and similar GLC analysis was used to measure residual alcohol.

RESULTS

Attraction Data and Observations. Since *Stiretrus* adults and larvae were reluctant to enter traps, individuals within 1 m of traps were collected and counted. A total of 116 bugs were captured at baited traps; three were caught

at unbaited traps. Sixteen of the 116 *S. anchorago* at baited traps were larvae (Figure 2), including second, third, fourth, and fifth instars. Thirty-two bugs were collected on or inside pheromone-baited traps; the remainder were on nearby foliage, often feeding and/or mating. Significantly ($P < 0.05$) more males were caught per day than females ($X = 0.435/\text{trap}/\text{day}$ for males and $X = 0.201$ for females). Analysis of three-day means by date (Table 1) revealed that, except for the fourth three-day period, more adults were caught toward the end of the test period. The low number of adults collected during the fourth three-day interval (July 14–16) was weather related, as it was cool and/or rained on these days. The trend of increasing adult captures with date was significant for males (Table 1) and was accompanied by a decline in the capture of larvae (Figure 2), presumably caused by larval/adult molts during this period.

Airborne Trapping. These experiments showed that 6,10,13-trimethyl-1-tetradecanol is emitted by males, presumably by evaporation from the sternal setae, whereas in airborne extracts of females this alcohol is absent. In addition, GLC analysis of male-derived extracts revealed that there is about 10 times more of a minor component eluting prior to the alcohol in airborne samples ($X \pm \text{SEM} = 5.03 \pm 1.56\%$ of total aldehyde + alcohol, $N = 2$) than in extracts prepared by directly extracting the sternal gland setae of single males with heptane or CH_2Cl_2 as previously described ($X \pm \text{SEM} = 0.53 \pm 0.12\%$, $N = 3$) (Aldrich et al., 1986). A second analysis of effluvia from five males showed the aldehyde to comprise 6.77% of the mixture (average of four determinations

FIG. 2. Cumulative catch of *Stiretrus anchorago* adults and larvae at field traps baited with 0.5 mg 6,10,13-trimethyl-1-tetradecanol (traps rebaited daily).

TABLE 1. *Stiretrus anchorago* ADULTS CAUGHT AT FIELD TRAPS BAITED WITH 6,10,13-TRIMETHYL-1-TETRADECANOL

Interval ^a	X Adults/trap ^b	
	Male	Female
1	0.161 ab	0.042 a
2	0.176 ab	0.085 a
3	0.362 ab	0.309 a
4	0.085 b	0.176 a
5	0.607 a	0.224 a
6	1.515 c	0.399 a

^aIntervals are three-day summations beginning July 5, 1987.

^bCounts were square-root transformed for analysis by an *F*-least significant difference test ($P \leq 0.05$). Means within a column followed by a common letter are not significantly different. No adults were caught at control traps. Traps were baited with 0.5 mg trimethyl-1-tetradecanol and rebaited daily.

on the same sample) and the release rate to be 50 ng/male/hr, assuming continuous calling. Extraction of the sternal gland setae of the same five males gave 11.8 μg /male of an aldehyde/alcohol mixture containing 0.41% aldehyde. Methane CI-MS of the minor component showed an $[\text{M}-\text{H}]^+$ ion at m/z 255, suggesting that the compound is the corresponding aldehyde of the major alcoholic component. This supposition was verified by the identity of the EI-MS of the natural product [m/z (%): 55(33), 57(100), 69(27), 71(25), 82(16), 85(14), 95(30), 96(43), 109(16), 112(12), 123(4), 124(4), 126(5), 137(1), 165(1), and 168(1)] to that of the synthetic aldehyde and by the GC coelution of the synthetic aldehyde with the natural product ($RT = 5.27$ min, 135°C , 15 m DB-1).

Stiretrus adults frequently flew upwind toward traps while they were being rebaited, and flight activity was greatest on very hot days ($>35^\circ\text{C}$). The diet of *S. anchorago* appears to be more varied than previously suspected (Aldrich et al., 1986), as individuals were observed preying upon various caterpillars, a pentatomid larva, and a flatid, and both adults and larvae were seen probing flowers for nectar. Larvae of *S. anchorago* are decidedly beetle-like in appearance, an impression reinforced by the shiny black cuticle of most individuals. However, four fifth-stage larvae were collected whose abdomens were predominantly white. White *S. anchorago* morphs also occasionally occur in our laboratory colony.

DISCUSSION

The synthesis represents a straightforward elaboration of the molecule from the end remote from the functional group. 5-Methyl-2-hexanone is inexpensive and has the proper relationship of methyl groups. Reduction (NaBH_4) and con-

version to the bromide (PBr_3) proceeded in good yield. Preparation of the Grignard reagent and reaction with allyl bromide gave 4,7-dimethyl-1-octene, albeit in only 34% yield. In the initial preparation, this olefin was converted to the iodide by reaction with disiamylborane, then treatment with iodine and NaOH/MeOH by analogy with Brown (1975). The product after distillation was a colorless oil about 90% pure by GC, but the impurities caused subsequent problems. In the second run, hydroboration/oxidation of the olefin gave the alcohol (contaminated with the expected 6% 2-ol), whose 3,5-dinitrobenzoate could be purified by crystallization from pentane. Saponification and treatment with $\text{Ph}_3\text{PBr}_2/\text{CH}_2\text{Cl}_2$ gave 4,7-dimethyloctyl bromide of 97.5% purity (GLC) in excellent yield.

Initial attempts at 5-carbon homologation of this system involved the proposed reaction of 4,7-dimethyloctyl magnesium iodide with 5-chloro-2-pentanone to give a tertiary chloroalcohol, which could be employed directly in a malonic ester synthesis. Unfortunately, none of the desired product was obtained. Instead, a product more volatile than expected formed, whose GLC-MS properties were consistent with 2-methyl-2-(4,7-dimethyloctyl)tetrahydropyran. This can be rationalized by supposing that the Grignard reagent adds to the ketone to give a 3° alkoxide that displaces chloride to give the THP compound. This was not investigated further.

The Julia reaction proved satisfactory. Reaction of 4,7-dimethyloctyl Grignard with cyclopropylmethyl ketone and then with HBr , either by the two-step procedure (Julia et al., 1960) or the improved single step method (Biernacki and Gdula, 1979) gave a 55% yield of a 2-3:1 mixture of (*E*)- and (*Z*)-4,8,11-trimethyl-3-dodecen-1-yl bromide after distillation, whose major impurity was 8% of 2,5,12,15-tetramethylhexadecane from dimerization of the halide during the Grignard reaction (identification was by comparison of retention time with an authentic sample prepared from 4,7-dimethyloctyl iodide and sodium).

The rest of the synthesis was straightforward. Alkylation of sodiomalonic ester, hydrogenation, and saponification gave 4,8,11-trimethyldodecylmalonic acid. Decarboxylation and LiAlH_4 reduction gave the desired alcohol in an overall yield of 4%.

Attraction of *S. anchorago* to 6,10,13-trimethyl-1-tetradecanol in the field demonstrates that the male sternal gland secretion is an attractant pheromone and suggests that the same is true for other asopines with homologous glands (Aldrich and Lusby, 1986; Aldrich et al., 1986). Attraction of larvae to male-produced pheromones has been reported for other predaceous and phytophagous pentatomids (Aldrich et al., 1984; Harris and Todd, 1980), but the response of *S. anchorago* larvae to the pheromone released by males seems exceptionally pronounced. It is likely that *Stiretrus* males produce only one or some of the stereoisomers of the alcoholic pheromone (Silverstein, 1979), but unnatural isomers are apparently not inhibitory. Whether or not inclusion of the minor aldehydic component will increase trapping efficiency remains to be determined. Improvement of trap design is also probable. Because *S. anchorago* is a bene-

ficial insect, the difficulty in trapping them may not prevent the utilization of synthetic pheromone for augmentation and conservation of this predator in agroecosystems.

Acknowledgments—We thank Mr. Tom Harris (USDA-ARS, Beltsville, Maryland) for statistical analysis, and Dawn Harrison and Susan Wilzer for technical assistance.

(Received October 29, 1987; accepted August 15, 1988)

Abstract—Field experiments using baited sticky stovepipe traps and Lindgren multiple funnel traps were done near Chalk River, Ontario, Canada, to determine the effects of conifer monoterpenes (α -pinene, β -pinene, myrcene, limonene, camphene and carene) and ethanol on the number of beetles captured. Several species of conifer-feeding beetles were attracted to the monoterpenes or to monoterpenes and ethanol, including species in the families Cerambycidae (*Asemum striatum*, *Acmaeops proteus*, *Xylotrechus undulatus*, *Monochamus scutellatus*), Curculionidae (*Pissodes strobi*, *Hylobius pales*), and Scolytidae (*Dryocetes autographus*, *Ips grandicollis*). Species of Buprestidae generally did not respond to the monoterpenes or to ethanol. Species of Cleridae (*Thanasimus dubius*, *Enoclerus nigripes rufiventris*, *Enoclerus nigrifrons gerhardi*) which are predators of conifer bark beetles were attracted to the monoterpenes. Synergism between monoterpenes and ethanol was evident for *M. scutellatus*, *H. pales*, and *D. autographus*. While α -pinene was the most potent attractant for most beetle species, monoterpenes other than α -pinene synergized attraction to ethanol for *D. autographus*. Attraction of beetles to commercial turpentine and ethanol did not differ significantly from attraction to a pure monoterpene blend and ethanol.

Key Words—Kairomones, host attraction, monoterpenes, ethanol synergism, turpentine, trapping, Cerambycidae, Scolytidae, Curculionidae, Cleridae, Buprestidae, *Dryocetes autographus*, *Monochamus scutellatus*, *Hylobius pales*, Coleoptera.

INTRODUCTION

With a few exceptions, such as certain species of *Dendroctonus* bark beetles, bark and wood-boring beetles associated with conifers attack weakened or dead trees. This fact generally is attributed to the monoterpenes and other terpenoid chemicals in the bark and foliage of conifers, which act as effective deterrents against feeding by beetles and other herbivores (Hanover, 1975; Cates and Alexander, 1982). For beetle species that are adapted to feeding on conifers, these same chemicals may act as kairomones, attracting beetles to their hosts.

While many species of conifer-feeding Scolytidae do not orient to host-produced chemicals, others are attracted to susceptible host material and to host resin or phloem (see Moeck et al., 1981; Wood, 1972, 1982). Pure conifer terpenes also have been found to attract scolytids, including *Hylastes ater* Paykull (Perttunen, 1957), *Ips grandicollis* (Eichhoff) (Werner, 1972a), *Tomicus (Blastophagus) minor* (Hartig) (Kangas et al., 1970), *Tomicus (Blastophagus) piniperda* (L.) (Perttunen et al., 1970; Byers et al., 1985; Schroeder and Eidmann, 1987), and other scolytids (Rudinsky, 1966; Chararas, 1979). Ethanol, produced by fermentation in moribund trees (Graham, 1968), may attract conifer-feeding species such as *Gnathotrichus sulcatus* (LeConte) (Cade et al., 1970; Moeck, 1971), *Trypodendron (Xyloterus) domesticus* (L.) (Kerck, 1972; Nijholt and Schönherr, 1976), *Trypodendron lineatum* (Olivier) (Graham, 1968; Moeck, 1970, 1971; Nijholt and Schönherr, 1976), and *Xyleborus saxeseni* Ratzeburg (Moeck, 1971). Ethanol may synergize attraction to host terpenes such as α -pinene, as seen with *T. lineatum* (Bauer and Vité, 1975; Nijholt and Schönherr, 1976), *Hylastes nigrinus* (Mannerheim), and *Pseudohylesinus nebulosus* (LeConte) (Nijholt and Schönherr, 1976), or to pine turpentine, as seen with *Dendroctonus terebrans* (Olivier) (Fatzinger, 1985). Monoterpenes, including α -pinene, myrcene and camphene, as well as ethanol can synergize attraction to pheromones in several species of Scolytidae (see Borden, 1982; Wood, 1982).

Monoterpenes and ethanol also may affect the orientation of beetles in families other than Scolytidae. In noncontrolled experiments, turpentine appeared to attract many species of Cerambycidae, Scolytidae, Curculionidae, and Cleridae (Gardiner, 1957) and species of Buprestidae, Cleridae, and Trogositidae (Wickman, 1969). Sawyers (*Monochamus* spp.) and pine reproduction weevils were attracted to turpentine in the field, and attraction was synergized by ethanol (Fatzinger, 1985). The weevil *Hylobius pales* (Herbst) was attracted to the host terpenes (+)- α -pinene and α -phellandrene in olfactometer tests (Thomas and Hertel, 1969) and to various monoterpenes released with ethanol in the field (Siegfried, 1987). Monoterpenes and ethanol acted synergistically to attract *Hylobius abietis* (L.) to traps (Tilles et al., 1986). Among the cerambycids, *Hylotrupes bajulus* (L.) was attracted to α -pinene in the laboratory (Becker,

1962), and *Monochamus alternatus* Hope was attracted to traps baited with monoterpenes alone and with monoterpenes and ethanol (Ikeda et al., 1980, 1981). Upwind flights in laboratory olfactometers indicated responses of the clerid *Thanasimus dubius* (Fabricius) to α - and β -pinene (Mizell et al., 1984). Ethanol might also be involved in the attraction of cerambycids and other beetles. Certain species of Cerambycidae, Cleridae, and Scolytidae were captured by traps baited with ethanol in an oak forest (Montgomery and Wargo, 1983).

Because of the many factors affecting beetle attraction, behavioral responses to semiochemicals recorded in the laboratory may vary from the responses to the same compounds in the field (e.g., Werner, 1972b). As is evident from the discussion above, few field experiments have been done to verify the responses to host volatiles for beetles other than scolytids and weevils. In the case of species thought to be attracted to turpentine, the monoterpenes responsible for the attraction have not been identified. Trapping experiments were therefore done to determine the effects of monoterpenes and ethanol on the attraction of forest Coleoptera in the field.

METHODS AND MATERIALS

Trapping was done on the grounds of the Petawawa National Forestry Institute near Chalk River, Ontario, Canada. The forests in the area are part of the Central Ottawa District of the Great Lakes-Saint Lawrence Forest Region (Rowe, 1972), and are locally dominated by natural stands of eastern white pine (*Pinus strobus* L.), red pine (*Pinus resinosa* Aiton), and jack pine (*Pinus banksiana* Lambert), and plantations of red pine and of larch (*Larix* spp.) and spruce (*Picea* spp.) hybrids. No major insect or disease problems were observed in the area.

Sticky stovepipe traps (pipe traps) (Chénier and Philogène, 1989) and eight-funnel Lindgren multiple funnel traps (funnel traps) (Lindgren, 1983) were used. Candidate monoterpenes were selected to obtain a terpene blend similar to that occurring in most eastern Canadian species of the Pinaceae, based on published identities of the terpenes of these trees (Guenther, 1949; Drew and Pylant, 1966; and many others). The monoterpenes used in the baits were (\pm)- α -pinene (97% pure), (-)- β -pinene (98%), (\pm)-camphene (95%), (\pm)-limonene (95%), and myrcene (89%) (Aldrich Chemical Co., Milwaukee, Wisconsin) and (+)-3-carene (90%) (ICN Biomedicals Inc., Plainview, New York).

Experiment 1: Effects of Monoterpenes and Ethanol. Trapping was done with baited pipe traps to compare the following four treatments: (1) unbaited control, (2) 95% ethanol, (3) monoterpenes, and (4) monoterpenes and ethanol.

Ethanol baits consisted of two 20-ml scintillation vials filled with 95% ethanol; vials were capped with inverted specimen vial caps with four 2-mm

holes in the sides of each cap. Two similarly capped vials were used as dispensers for the monoterpene blend, which consisted of 65% α -pinene, 20% β -pinene, 5% limonene, 5% myrcene, and 5% camphene. A 10 \times 75-mm lamp wick was placed inside each monoterpene vial to provide a greater and more constant rate of vaporization. For traps baited with both monoterpenes and ethanol, two monoterpene vials and two ethanol vials were used.

The four treatments were replicated in four blocks in a randomized block design. The four traps in a given block were at the corners of a square measuring 20 m per side. Traps were at least 30 m from the forest-field boundary. Two blocks were in the forest and two were in open fields, thereby sampling species restricted to any one of the habitat types as well as those species common to both areas (Chénier and Philogène, 1989). Site did not affect the nature of the responses to the baits (unpublished data).

Trapping was done from June 12 to August 5, 1986. Every two weeks (12- to 15-day intervals), large insects were collected from the traps. The positions of the four treatments in each block were randomly changed, moving the entire traps to their new positions. Weighed vials of freshly prepared baits were attached to the top of the traps, and the vials from the previous trapping period were reweighed to determine the quantity of chemicals released during the trapping period. After four weeks and at the end of the experiment, the Stikem Special (Seabright Enterprises, Emeryville, California) and all captured insects were removed from the traps; a fresh layer of Stikem was applied to the traps after the fourth week of trapping. Insects were cleaned and identified to species (conifer-feeding beetles and their associates) or family (other Coleoptera).

For each species, the number of individuals captured per treatment in each block was pooled over all trapping periods to minimize trap position effects. Since data in this and in the following experiments did not satisfy the requirements for parametric testing, nonparametric tests were used to evaluate results. Data were analyzed using Friedman tests corrected for ties (Zar, 1984, equation 13.38), verifying significance for $\alpha = 0.10$, $\alpha = 0.05$, and $\alpha = 0.01$. Significance of the differences between the rank sums of the four treatments was verified using Scheffé-type multiple contrasts with $\alpha = 0.10$, $\alpha = 0.05$, and $\alpha = 0.01$ [using standard error terms corrected for ties (Zar, 1984, equation 13.48)] and nonparametric analogs of Newman-Keuls multiple comparisons with $\alpha = 0.05$ [using standard error terms corrected for ties (Zar, 1984, equations 13.42 and 13.48)].

Experiment 2: Effects of α -Pinene, Minor Monoterpenes, and Ethanol. In order to distinguish between the attraction due to α -pinene and that due to other (minor) monoterpenes, an experiment was done with eight treatments: (1) unbaited control, (2) 95% ethanol, (3) minor monoterpenes, (4) ethanol and minor monoterpenes, (5) α -pinene, (6) α -pinene and minor monoterpenes, (7)

ethanol and α -pinene, and (8) ethanol, α -pinene, and minor monoterpenes. The minor monoterpene blend consisted of 45% β -pinene, 15% 3-carene, 15% limonene, 15% myrcene, and 10% camphene.

Ethanol baits consisted of two 11-ml vials each containing 10 ml of 95% ethanol; each vial cap had one 3-mm hole in the top. Two 4-ml vials with a 7-mm hole in each of the caps were used as dispensers for the α -pinene (4 ml/vial). Minor monoterpene baits consisted of 4 ml of the minor monoterpene blend in one 4-ml vial with a pierced cap (7-mm hole). Traps baited with the ternary treatment (treatment 8) were therefore baited with two ethanol vials, two α -pinene vials, and one minor monoterpenes vial.

The experiment was done in open fields. A randomized block design was used, with the eight treatments replicated in 10 blocks, using pipe traps in five of the blocks and funnel traps in the other five blocks. Trap type did not affect the nature of the responses to the baits, as indicated by data obtained in preliminary experiments and analyzed by the group concordance method of Schucany and Frawley (Zar, 1984). The eight traps in a given block were placed in two parallel lines with 20 m between the lines and 20 m between traps in a line. Traps were placed at least 40 m from the forest-field boundary.

The experiment ran from June 15 to August 16, 1984. Traps were serviced weekly (5- to 11-day intervals, depending on the weather). The positions of the eight treatments in each block were randomly changed, moving the entire traps to their new positions in the block. Bait vials were replaced weekly. On July 29, August 9, and August 16, the volumes of chemical baits remaining from the previous trapping period were measured to determine elution rates. All insects were collected weekly from the funnel traps. Large insects were collected weekly from the pipe traps, and a fresh layer of Stikem was applied to the pipes after the fourth week. All insects were collected from the pipe traps after the fourth week and at the end of the experiment. Conifer-feeding beetles and their associates were identified to species and counted.

The number of individuals captured per treatment was pooled within each block over all trapping periods. Data were analyzed as in Experiment 1.

Experiment 3: Effects of Commercial Turpentine and Pure Monoterpene Blend. A small-scale study was done to compare attraction to commercial turpentine with attraction to the monoterpene blend used in Experiment 1. Pipe traps were baited with: (1) 95% ethanol and the monoterpene blend, or (2) 95% ethanol and commercial turpentine (Record Chemical Company Inc., Montréal, Québec). Bait dispensers and trapping procedure were as in experiment 1. The two treatments were replicated in four blocks. Traps in a block were 20 m apart and were at least 60 m from traps in adjacent blocks. The experiment extended over three trapping periods, from July 7 to August 5, 1986. Since trap position effects were unlikely in this two-treatment test, data from each trapping period

were treated as replicates for each of the four blocks, giving a total of 12 replicates. Data were analyzed by Wilcoxon signed-ranks tests for paired-samples experiments (Zar, 1984, section 10.4).

RESULTS

Rates of vaporization of the chemical baits for all three experiments are given in Table 1. In experiment 2, given the composition of the minor monoterpene blend and the elution rates for the α -pinene and for the minor monoterpenes, terpenes were released from traps baited with both α -pinene and minor monoterpenes at an average rate of 0.59 g/day/trap and in a ratio of about 73% α -pinene, 12% β -pinene, 4% each of carene, limonene, and myrcene, and 3% camphene.

Experiments 1 and 2. Results are shown in Table 2 for experiment 1 and in Table 3 for experiment 2. Species of Buprestidae generally did not respond to the chemicals tested. Experiment 1 did not yield significant results for *Buprestis maculativentris* Say, but data from experiment 2 indicated treatment effects. However, the ranks of neither ethanol-baited traps (lowest rank) nor traps baited with α -pinene and ethanol (highest rank) were significantly different from control traps, and it appears unlikely that the treatment effects were of biological significance. For the melandryid *Serropalpus* sp., traps baited with the complete monoterpene blend (α -pinene and minor monoterpenes) and

3. July 7–August 5, 1986 ^b	blend	1.59	0.61	8	2.57	0.53	16
	turpentine	1.36	0.49	8			

^aMean, standard deviation (SD) and sample size (N).

^bDispensers (per trap): terpenes, two 20-ml vials with wicks; ethanol, two 20-ml vials.

^cDispensers (per trap): α -pinene, two 7-ml vials; minor terpenes, one 7-ml vial; ethanol, two 11-ml vials.

ethanol ranked highest in both experiments, with these compounds possibly acting synergistically as indicated by the Scheffé contrasts in experiment 1.

Four species of Cerambycidae showed definite responses to the treatments. In experiment 2, *Asemum striatum* (L.) was attracted by α -pinene, with minor monoterpenes exerting no apparent effect on attraction; while contrasts indicate a possible synergism between the α -pinene and ethanol ($P < 0.05$ for treatments with both compounds vs. other treatments), an examination of rank sums and multiple comparisons shows that the attraction was probably due simply to the presence of α -pinene ($P < 0.01$ for the contrast between treatments with α -pinene vs. treatments without). Both experiments indicated significant treatment effects for *Acmaeops proteus proteus* (Kirby), due largely to the presence of monoterpenes (experiment 1); rank sums and multiple comparisons indicate that the α -pinene may account for much of the attraction to the monoterpenes (experiment 2). *Xylotrechus undulatus* (Say) was attracted to monoterpenes in both experiments; in experiment 2, maximum attraction was obtained with traps baited with both α -pinene and the minor monoterpenes, and contrasts indicate a possible effect of the minor monoterpenes on attraction. Ethanol and α -pinene acted synergistically to attract *Monochamus scutellatus scutellatus* (Say), with the minor monoterpenes having little effect on this attraction (experiment 2); in the absence of ethanol, attraction to monoterpenes was significant only at $P < 0.10$.

Pissodes strobi (Peck) responded to the treatments in both experiments. In experiment 2, *H. pales* was attracted to traps baited with both α -pinene and ethanol, which acted synergistically.

Among the scolytids, almost all *Dryocetes autographus* (Ratzeburg) in experiment 1 were captured in traps baited with the combination of monoterpenes and ethanol. Experiment 2 demonstrated further that while α -pinene, minor monoterpenes, and ethanol alone did not attract this beetle, the combinations of α -pinene and ethanol and of minor monoterpenes and ethanol were very attractive ($P < 0.01$ for each of the relevant contrasts).

Treatment effects were detected for three species of clerid predators. *T. dubius* was captured in greatest numbers in traps baited with both monoterpenes and ethanol in experiment 1. Experiment 2 demonstrated further that the minor monoterpenes had no apparent effect on attraction, with most beetles being captured in traps baited with both α -pinene and ethanol. Both *Enoclerus nigripes rufiventris* (Spinola) and *Enoclerus nigrifrons gerhardi* Wolcott were attracted by α -pinene.

Experiment 3. None of the beetles showed significantly greater attraction to either the pure monoterpene blend and ethanol or to commercial turpentine and ethanol (Table 4).

Two treatments replicated 12 times.

^cWilcoxon N too low to determine significance probability.

DISCUSSION

The general lack of response of Buprestidae to the various baits indicates that ethanol and the monoterpenes tested in these experiments probably do not play a major role in the orientation of these beetles. Buprestidae have also been shown not to respond to ethanol-baited traps in an oak forest (Montgomery and Wargo, 1983). Since most of the species of Buprestidae identified in this study were captured in greater numbers in traps with dark vertical silhouettes rather

than in clear flight interception traps (Chénier and Philogène, 1989), visual cues may be more important than chemical cues for the orientation of the species involved.

Results for *M. scutellatus* were similar to those obtained in Japan for *M. alternatus*. That species was attracted to a blend of 10 monoterpenes, with ethanol synergizing attraction (Ikeda et al., 1980). Among the monoterpenes, α -pinene proved the most attractive, with some activity being detected for β -pinene and β -phellandrene (Ikeda et al., 1981). In Florida, the sawyers *Monochamus carolinensis* (Olivier) and *Monochamus titillator* (Fabricius) were captured in greatest numbers in traps baited with both turpentine and ethanol, followed by traps baited with turpentine alone and with ethanol alone (Fatzinger, 1985).

The attraction of *H. pales* was greatest for traps baited with both α -pinene and ethanol. Siegfried (1987) reported attraction of *H. pales* to traps baited with α -pinene and ethanol, as well as attraction to β -phellandrene, limonene, and ethanol and to β -pinene and ethanol. Although Anderson and Fisher (1960) reported repellency of *P. strobi* by α -pinene and other terpenes, Wilkinson (1972) found that the weevil was attracted to white pine oleoresin. Experiment 1 clearly demonstrated attraction of *P. strobi* to monoterpenes.

Upwind flights in a laboratory olfactometer have shown that *T. dubius* responds to both α -pinene and β -pinene (Mizell et al., 1984). The greatest number of *T. dubius* in this study was captured in traps baited with both monoterpenes and ethanol.

Billings and Cameron (1984) found no attraction of *T. dubius*, *M. titillator*, or *I. grandicollis* to traps baited with loblolly pine turpentine, but the elution rates of the turpentine in their study ranged from 25 to 40 mg/day/trap, or about 25–40 times lower than the rates obtained in experiments 1 and 2. When turpentine was released from traps at rates of about 3.6 g/day, *T. dubius* was attracted to traps baited with frontalure and turpentine, but not to traps baited with turpentine alone; *M. titillator* was attracted to *Ips* pheromones and turpentine, but not to the pheromones or turpentine alone (Billings, 1985). The strong attraction to the pheromone–turpentine combinations possibly may have masked attraction of these two species to the turpentine. In the present study, both *T. dubius* and *M. scutellatus* were captured in greatest numbers in traps baited with both monoterpenes and ethanol. The effects of ethanol were not verified by Billings (1985). It is not known whether *M. scutellatus* is attracted to scolytid pheromones as is *M. titillator*. For beetles responding both to host odors and to scolytid pheromones, the strong responses to scolytid pheromones reported by Billings (1985) would permit efficient location of hosts; in the absence of pheromones, the weaker response to the host volatiles would still permit host finding. While Billings and Cameron (1984) and Billings (1985) used flight interception traps in their experiments, *T. dubius*, *M. scutellatus*, and other

beetles were captured in much greater numbers in vertical sticky stovepipe traps baited with monoterpenes and ethanol than in clear flight interception traps baited with the same chemicals (Chénier and Philogène, 1989), and it appears that visual cues may be of major importance for the orientation of these beetles to the tree volatiles.

Although results from experiment 3 indicate that attraction to the monoterpene blend and ethanol does not differ significantly from attraction to the chemically complex turpentine and ethanol, the small sample size should preclude definite conclusions. This is certainly the case with *T. dubius* and *M. scutellatus*, with Wilcoxon *T* values of zero for the monoterpene blend and ethanol (Table 4). Considering results from all three experiments, the use of commercial turpentine and ethanol as attractant baits could prove useful for sampling a wide variety of conifer forest Coleoptera.

While the responses of insects observed in these experiments are being heuristically referred to as "attraction", the true nature of the behavioral mechanisms involved is not known. The terpenes may be acting as arrestants, as was demonstrated with *Dendroctonus pseudotsugae* Hopkins exposed to phloem tissue of *Pseudotsuga menziesii* (Mirbel) Franco (Bennett and Borden, 1971). Most of the species that were found to respond to the test chemicals in these studies have been shown to land in greatest numbers on traps with distinct vertical silhouettes (Chénier and Philogène, 1989). Thus, while insects responding to the baits in these experiments may well be attracted from a distance, the chemicals may also be acting as arrestants for insects flying within sight of the traps.

Acknowledgments—We thank the staff of the Agriculture Canada Biosystematics Research Centre for verifying or carrying out species identifications, and the management and staff of the Petawawa National Forestry Institute for permission to carry out the experiments on their land and for discussions regarding selection of sites. J.T. Arnason, University of Ottawa, provided useful suggestions and comments.

(Received May 1, 1988; accepted August 15, 1988)

Abstract—Of 12 alarm pheromones assayed in European and Africanized honeybees, nine were found in larger quantities in the Africanized population. Isopentyl and 2-heptanone levels were similar in both; 2-methylbutanol-1 was greater in European workers. These differences were not due to age or geographical location. Significant positive correlations between alarm pheromone levels and defensive behavior, especially numbers of stings, were observed.

Key Words—Honeybee, *Apis mellifera*, alarm pheromone, Hymenoptera, Apidae, isopentyl acetate, 2-heptanone, sting, mandibular gland.

INTRODUCTION

A vital part of honeybee colony defense is the communication of alarm through the use of pheromones (Maschwitz, 1964; Collins et al., 1980). Various investigators have identified alarm pheromones by chemical analysis and assay of biological activity. Boch et al. (1962) identified isopentyl acetate (IPA) (previously called isoamyl acetate) as a biologically active alarm pheromone associated with the sting, and Shearer and Boch (1965) reported on the alarm activity of 2-heptanone (2HPT) isolated from mandibular glands in the head. Blum and colleagues (Blum et al., 1978; Blum and Fales, 1988) identified over 80 compounds from the sting apparatus, of which 15 were shown to elicit alarm responses from caged workers (Collins and Blum, 1982, 1983). Pickett et al.

(1982) reported that (Z)-11-eicosen-1-ol was also an important component of the sting pheromone complex.

These initial identifications were made on samples of worker honeybees collected in North America (*Apis mellifera*, European subspecies). Two other subspecies, *A. m. scutellata* (formerly *adansonii*) and *A. m. capensis*, were assayed for IPA and 2HPT by Crewe and Hastings (1976). *A. m. scutellata* exhibits more intense colony defense than the European subspecies. The range of pheromone levels found, however, was within that seen in the European populations and did not prove to be an easily obtained predictor of defensive behavior.

Two other studies (Kerr et al., 1974; Boch and Rothenbuhler, 1974) investigated the relationship of IPA and 2HPT levels with several measures of defensiveness in the same colony of European bees. Levels of IPA did not show a significant correlation with the behavioral assay in either study, even though the more defensive line of Boch and Rothenbuhler had higher levels of IPA assayed. However, Kerr et al. (1974), using Africanized bees, reported that levels of 2HPT were positively correlated with three measures of defensive behavior: time to first sting, time to visible worker response, and number of stings.

The work reported here is from two studies measuring levels of IPA, 2HPT, and the more recently identified components of sting alarm pheromone (Blum et al., 1978; Collins and Blum, 1982, 1983) in two geographical types, European and Africanized bees.³ These geographical types display quite different levels of defensive behavior (Collins et al., 1982). One study involved sampling from a large number of representative colonies in Louisiana, U.S.A., and Monagas, Venezuela. The second was an experiment controlling for location and age in a smaller number of colonies. Correlations of the pheromone levels with aspects of defensive behavior as measured by a sequenced standardized test (Collins and Kubasek, 1982) were also calculated for the larger study.

METHODS AND MATERIALS

Survey. This experiment used 150 large colonies near Baton Rouge, Louisiana (30°30'N, 91°W), and 147 similar-sized colonies near Maturin, Monagas, Venezuela, (10°N, 63°W). The Louisiana colonies had been established

³The European honeybees in this study were from North America. Such bees have in their ancestry representatives of mixed subspecies. Africanized bees are descendants of *A. m. scutellata* bees imported from Africa and their hybrids with various subspecies previously imported into Brazil. Neither the European nor the Africanized bees can correctly be called race, subspecies, stock, or line representatives. We use the term "geographical type" to indicate that the bees we studied showed major characteristics typical of descriptions for temperately or tropically (*A. m. scutellata*) adapted bees.

from various U.S. commercial honeybee stocks. Some of the Venezuelan colonies had originally been headed by European queens but were chosen on the basis that they had not been requeened within at least the past year. This would have been sufficient time for several supersedures with the new queens mating with Africanized drones or for invasion of colonies by Africanized queens. The rest of the Venezuelan colonies had been established from caught swarms.

Ten bees from each colony were collected in alcohol and identified using an updated version of the Daly et al. (1982) morphometric identification procedure. Twenty-five characters were measured and the colonies classified as European, Africanized, or hybrid.

Samples of 30 worker bees of mixed ages per colony were collected from the entrance in a plastic bag and killed by freezing. The sting apparatus and head of each bee were removed from the body by forceps, immersed in 1 ml pesticide-grade methylene chloride with sodium sulfate as a drying agent, and sealed in a crimp-top vial. Three samples of 10 bees each were prepared per colony and stored in a freezer prior to analysis.

One-microliter aliquots of solvent from each vial were injected into a Perkin Elmer Sigma 3 gas chromatograph fitted with two glass columns (6 ft \times $\frac{1}{4}$ in. OD, 2 mm ID, packed with SP1000 on 80–100 mesh Chromasorb W with 10% loading) run as dual compensation. The heat cycle started at 70°C for 3 min and increased 5°C/min up to 120°C. Quantities of butyl acetate, IPA, 2-methylbutanol-1, hexyl acetate, 1-hexanol, 2-heptyl acetate, 2-heptanol, octyl acetate, 1-octanol, 2-nonyl acetate, 2-nonanol, and 2HPT were calculated by electronic integration using a Varian CDS III.

The data were analyzed with an analysis of variance for bee type using the mean value per colony. Colony means were also used for the correlations of pheromone and behavior measures. Data for each chemical were transformed by square root. Differences between means were determined by Tukey's test.

The colonies were also tested using a standardized procedure for measuring colony defense (Collins and Kubasek, 1982). These results were reported in Collins et al. (1982). For the defense test, a picture of the bees around the entrance was taken before testing. Timing of the test began when 0.8 ml of an artificial alarm pheromone (isopentyl acetate in paraffin oil, 1 : 100 by volume) was sprayed over the entrance. The other compounds from the sting had not been identified at the time of development of this test and were not used. At 30 sec, the second photograph was made, and the colony was given a physical jolt by shooting it with a glass marble (19 g, 2.3 cm in diameter) propelled by a slingshot. The third photograph was taken at 60 sec, and the suede targets were moved into place, one 2–6 cm in front of the entrance and a second 25 cm farther away. These two blue suede targets (5 \times 5 cm) were clipped to the arms of a battery-operated device that swung them vertically 20 cm about 120 times per minute during the 60- to 90-sec interval. At 90 sec, the targets were removed

and the final photograph was taken. New targets were used for each test sequence. At a later time, the number of bees in each photograph and the number of stings in the two targets were counted. Each colony was tested twice, on different days, and colony means were calculated.

Controlled Location and Age. Because samples from the extensive survey of the two populations were collected in separate geographic locations (Louisiana and Venezuela), the possibility existed that differences seen were due to environmental differences. Such factors as temperature, food sources, and previous disturbance might influence alarm pheromone levels or components produced. Also, both IPA and 2HPT levels vary with age, as reported by Boch and Shearer (1966, 1967), reaching a peak at ca. two weeks and then decreasing somewhat to a stable level. Whiffler et al. (1988) reported age variation for a number of the other alarm pheromones and associated changes in responsiveness to alarm pheromones.

To control for location and age in these pheromone assays, newly emerged bees from 10 Africanized and 10 European (various sources) colonies from the same apiary in Sarare, Lara, Venezuela (10°N, 69°W) were color-coded for eclosion date by being marked on the thorax with paint and released in the parent colony. Four weeks after emergence, marked bees were collected, held for 24 hr in a small cage in an incubator with sugar syrup and water available, and then killed by freezing. Stings were collected as above, except that only 0.5 ml of solvent was used and an internal standard, methyl octanoate, was added. Three additional sting alarm pheromones were measured, 1-acetoxy-2-octene, 1-acetoxy-2-nonene, and benzyl acetate. Data were analyzed by analysis of variance for bee type using the mean value per colony. Data were transformed by square root.

RESULTS AND DISCUSSION

Survey. All of the colonies in Louisiana were identified as European, but the population in Venezuela included 70 European colonies, 37 Africanized colonies, and six hybrid colonies. This allowed for additional comparisons of differences due to location (Europeans in Louisiana and Venezuela). Three Louisiana colonies and 29 Venezuela colonies were not precisely identified at the 0.90 threshold and were deleted from the data set.

The mean values of micrograms per bee produced for each of the 12 alarm pheromones are shown in Table 1. The sum of all the pheromones measured except 2HPT, which is not part of the sting pheromone complex, and 1-hexanol, for which there were too few observations, is also included. The four classes of bees were not significantly different for levels of IPA, the major sting alarm pheromone component. 2-Heptanone levels are probably not different in

ⁱ Means within pheromone followed by the same letter are not significantly different.

the European and Africanized types, although the statistical relationships seen here are difficult to decipher. 2-Methylbutanol-1 is produced in greater quantity by European bees, but all the rest of the pheromones and their sum are at higher levels in the Africanized population. The intermediate values of the few hybrids indicate the likelihood of a simple additive genetic control for the production of most of these compounds.

Correlations of the levels of pheromones with the measures of colony defense for all colonies are presented in Table 2. The components of the sting alarm pheromone which occurred at higher levels in the Africanized group were consistently significantly correlated with a more defensive behavior. Levels of

^aSum is the total quantity of all sting alarm pheromones assayed except 1-hexanol. $P < 0.01$, except * = $P < 0.05$.

2HPT, the mandibular gland pheromone, do not correlate well with behavioral measures. IPA, which was not significantly different between bee types, shows only a low correlation with the number of bees responding to the test stimuli and with the number of stings. The corresponding alcohol, 2-methylbutanol-1, had no significant correlation with the behavior. Levels of 1-hexanol were not correlated with the number of bees responding but were correlated to the speed of the responses and to number of stings. The low correlations to number of bees on the entrance at 00 sec are expected since stimuli for defensive behavior have not been presented at this time.

Controlled Location and Age. From an examination of the data in Table 1, there are differences between the European groups from Louisiana and Venezuela. Nine of the compounds are at higher levels in the Venezuelan group. This difference can be easily explained by the presence of Africanized drifters in the Venezuela European colonies. Morphometric identifications support this, as only 12% of the Louisiana European colonies had one or two bees classed as Africanized, while 42% of the Venezuela European colonies had one to three Africanized individuals.

The levels of alarm pheromones found in worker bees of the two types when geographic location was identical and the age of the collected bees was controlled are shown in Table 3. The results are similar to those found for the initial survey. The major difference is that in the controlled group, IPA occurs in greater quantity in the Europeans. In comparing the actual quantities of IPA found per bee, the bees in the second study have less than half of what was found previously. IPA increases to a peak in bees that are of guarding and beginning-foraging age (ca. 2 weeks) and decreases thereafter (Boch and Shearer, 1966). In the age-controlled collection, the younger bees of guarding age with higher IPA levels were excluded and the 4-week-old bees collected would expectably show decreasing IPA levels.

The two values for 2-heptyl acetate and 2-nonyl acetate are not statistically different in the second study. However, the direction of the difference that is there (Africanized greater than European) is the same as that previously found. Of the three new pheromone components analyzed, 1-acetoxy-2-octene, 1-acetoxy-2-nonene, and benzyl acetate, only the last shows a significant difference with Africanized levels greater than European.

^c* $P < 0.05$; ** $P < 0.01$; NS, not significant.

Therefore, it appears that with the exception of IPA (the major sting alarm pheromone component) and its alcohol, 2-methylbutanol-1, and, possibly, 2HPT (a mandibular gland alarm pheromone), Africanized bees produce greater quantities of nine alarm pheromones. Furthermore, within the species *Apis mellifera*, these higher concentrations of alarm pheromones are associated with more intense levels of colony defense. The correlation of 0.554 (Table 2) between the total amount of alarm pheromone and the total number of stings indicates that 0.31 (r^2) of the variance of numbers of stings is determined in linear fashion with the variance in quantities of alarm pheromone (Snedecor and Cochran, 1967). A higher concentration of pheromone released from the first bee alerted could alert more recruits. Because alarm pheromones mediate the first step in honeybee colony defense (Collins et al., 1980), the influence of a higher concentration of pheromone on the intensity of the defensive response is easily seen and has been documented by Collins et al. (1987b). As the recruited bees also release pheromone through extrusion of the sting and loss of the sting in an intruder, a higher concentration of alarm pheromone would accumulate around Africanized colonies than around equivalent European colonies. This higher level of pheromone would also require a longer time to disperse. Both of these phenomena would account for at least part of the difference in defensive behavior between the two honeybee types. At this time, it does not seem necessary to invoke synergistic effects of differing proportions of the components in the two bee types to account for behavioral differences.

The correlations found between the pheromone produced and the behavior induced suggest that the genes controlling the variation of both of these characters are coadapted, that is, jointly selected for their effects on fitness (Falconer, 1981). It has been further hypothesized that coadapted genes form supergenes by being closely associated on a chromosome (linked) (Dobzhansky, 1970). Such supergene complexes would tend to stay together and could account for the persistence of the intensive African defense phenotype in the Africanized populations.

We have reason to believe that the number of genes involved could be small for each character. Both the behavior (Collins et al., 1984) and the pheromones (Collins et al., 1987a) show genetic correlations. A few genes could determine structure or biochemistry of the central nervous system, resulting in variable behavior. Likewise, very few genes might be needed for the synthesis of the array of very similar compounds that are the alarm pheromones studied.

Acknowledgments—We thank the Venezuelan Ministerio de Agricultura y Cria for laboratory and living quarters and equipment; and O. Taylor, University of Kansas; D. Pulido, Universidade de Oriente; and several Venezuelan beekeepers for access to Africanized colonies. We also thank A.B. Bolten and V. Lancaster for assistance with sample collection in Venezuela; R.T. Daniel, USDA-ARS, Baton Rouge, Louisiana, for chromatographic work; and Kim Hoelmer, University of California, Berkeley, for all the morphometric identifications. Special appreciation is given to

Dr. M.A. Brown, Mathematical Statistician, ARS, USDA, and to Dr. S.M. Buco, Statistical Resources, for assistance with the statistical analysis. This research was done in cooperation with the Louisiana Agricultural Experiment Station and the Universidad de Centro Occidental "Lisandro Alvarado." Mention of a proprietary product does not constitute an endorsement by the USDA.

BIOCHEMICAL AND BEHAVIORAL EVIDENCE FOR
HYBRIDIZATION BETWEEN FIRE ANTS, *Solenopsis*
invicta AND *Solenopsis richteri* (HYMENOPTERA:
FORMICIDAE)

ROBERT K. VANDER MEER and CLIFFORD S. LOFGREN

U.S. Department of Agriculture
Agricultural Research Service

Gainesville, Florida 32604

(Received April 27, 1988; accepted August 15, 1988)

Abstract—Behavioral and biochemical evidence is presented for hybridization between the fire ants, *Solenopsis richteri* and *S. invicta*. The response of the two species to extracts of their trail pheromones presented as a point source is clearly species-specific; however, hybrid workers responded to parental Dufour's gland extracts and parental workers responded to Dufour's gland extracts of the hybrid. The behavioral evidence for hybridization was confirmed by gas chromatograph comparison of the Dufour's gland extracts of the three fire ant forms, which showed a pattern for the hybrid that was intermediate to the two parental species.

Key Words—Fire ants, *Solenopsis invicta*, *Solenopsis richteri*, Hymenoptera, Formicidae, trail pheromone, hybridization.

INTRODUCTION

The discovery of hybridization between two imported fire ant species, *Solenopsis invicta* and *S. richteri*, in the United States has raised questions regarding the validity of their species status and the mechanism by which the extensive hybrid population is being maintained (Vander Meer et al., 1985; Ross et al., 1987; Vander Meer and Lofgren, 1988). Based on the earliest known records of imported fire ants in the United States (see Lofgren, 1986), it was deduced that a black form entered the Mobile, Alabama, area around 1918. A red form was also discovered in the Mobile area and was thought to have been introduced

in the 1930s. Both forms were identified as *S. saevissima* var. *richteri* until Buren (1972) elevated the black form to species status (*S. richteri*) and described the red form as a new species (*S. invicta*). These assignments were based on their lack of hybridization and the consistency of phenetic characters in the United States populations. However, hybridization between the two species has been recently discovered on the basis of biochemical characters (Vander Meer et al., 1985). Morphologically the hybrid is difficult to distinguish from *S. richteri* (Vander Meer et al., 1985; Ross et al., 1987). Biochemical analysis of museum specimens collected in the United States (Vander Meer and Lofgren, in preparation) indicates that hybridization has occurred wherever the range of the two forms has overlapped. Although this indicates that the criteria for differentiating them as species may no longer be valid, we will continue to use the species designations of Buren (1972).

The rapid spread of imported fire ants after their introduction was due primarily to their transportation by man in nursery stock and sod. The speed and mode of this spread resulted in an early disjunct distribution in Alabama, Louisiana, and Mississippi (see Bruce et al., 1949; Culpepper, 1953), which could not be explained by dispersion after natural mating flights. Currently the gaps have been filled, except at the western and northern frontiers of their range. At the present time, imported fire ants occupy 100,000,000 hectares in 11 states of the south and southeast and in Puerto Rico. Unfortunately, previous surveys of fire ant infestations did not distinguish between the red and black forms, so we know very little of the population dynamics of the two forms that have taken place since the 1940s.

Species-specific pheromones in social insects often play an important role in maintaining species isolation, both sexually and in foraging situations (Hölldobler and Carlin, 1987). In addition, the competitiveness of a colony or ant population is mediated to a large extent by its ability to discriminate the chemical cues associated with territory, recruitment, and competitor/enemy recognition (reviewed in Hölldobler and Carlin, 1987). In this paper we compare the behavioral species specificity of the recruitment pheromones produced by *S. invicta*, *S. richteri* and their hybrid, as well as the biochemical composition of these pheromones.

METHODS AND MATERIALS

Source of Ant Colonies. All individuals used as sources of Dufour's glands and for bioassays were taken from mature (producing sexuals) queenright, monogynous colonies. *Solenopsis invicta* colonies were collected from the field or reared from newly mated queens collected in Alachua County, Florida (see Banks et al., 1981, for methodology). Queenright *Solenopsis richteri* colonies

were collected along the Natchez Trace in Lee County, Mississippi. Hybrid colonies were collected from Lowndes County, Mississippi. The identification of the *S. richteri* and hybrid colonies was verified by gas chromatographic analyses of venom alkaloids and cuticular hydrocarbons (Vander Meer et al., 1985).

Source of Glandular Trail Pheromone Extracts. Dufour's glands from randomly chosen worker ants from each of the *Solenopsis* forms were extirpated in water, then transferred to, and macerated in a vial containing hexane (Burdick and Jackson, HPLC grade, Muskegan, Michigan). Pooled Dufour's gland extracts were used for both gas chromatographic (GC) analysis and bioassays. For bioassays, the concentration of the Dufour's gland extract was adjusted to give the desired number of worker equivalents (WE) per microliter by dilution with hexane or evaporation under a stream of nitrogen.

Gas Chromatograph Analysis. Hexane extracts or soaks were analyzed by GC on a Varian 3700 gas chromatograph (Sunnyvale, California), equipped with a flame ionization detector. Analysis of hexane soaks (1–24 hr) for venom alkaloids and cuticular hydrocarbons was performed with a 30-m DB-1 fused silica column (J&W Scientific, Inc., Folsom, California) and oven program of 150°C to 285°C at 5°/min (Vander Meer et al., 1985; Ross et al., 1987). Separation of the volatile components of the Dufour's gland extracts was achieved with a 15-m DB-1 fused silica column (J&W Scientific), operated isothermal at 88°C. Peak areas were integrated and the separation visualized on a Varian Vista 401 data processor.

Recruitment Pheromone Point Source Bioassay. One to three rearing cells from queenright laboratory-reared colonies were placed on top of each other in the center of a clean colony tray (7 × 44 × 56 cm). Ten positions were marked in a circle, 15 cm from the edge of the cells and equidistant from each other around the cells. Workers in the foraging arena of the donor colony tray were also transferred to the clean bioassay tray. The ants were given a minimum of 1 hr to habituate to their new surroundings. Squares of blotter paper (2 × 2 cm) on which a 1.5-cm-diameter circle had been drawn in the center were placed on larger squares of aluminum foil. The circular area was treated with a Dufour's gland extract (5 µl of hexane) containing one worker equivalent of one of the following: Dufour's gland extracts from *S. invicta*, *S. richteri*, or the hybrid (as defined by GC analysis; see Vander Meer et al., 1985; Ross et al., 1987), or a hexane control. The samples were randomly placed on the numbered locations around the colony cells. The number of ants within the 1.5-cm circle on the blotter paper squares were counted at 5-min intervals for 30 min. The sum of the six counts was regarded as the result for each position. Each bioassay was replicated using 10 different *S. invicta*, *S. richteri*, and hybrid colonies. Colony-to-colony variation was leveled out by setting the response of test colony workers to their own Dufour's gland extract at 100 and their response to the hexane control at 0 (see also Vander Meer et al., 1988).

RESULTS

Point-Source Bioassay. The response of foraging worker ants in the point-source bioassay to Dufour's gland extracts from *S. invicta*, *S. richteri*, and the hybrid are shown in Table 1. *S. invicta* responded poorly to the Dufour's gland extract of *S. richteri* and, similarly, *S. richteri* responded minimally to the Dufour's gland extract of *S. invicta*, demonstrating distinct behavioral differences for the two fire ant species in this bioassay. The response of workers from both parental species to hybrid Dufour's gland extracts was indistinguishable from the response of hybrid workers to their own Dufour's gland extract. Likewise, hybrid workers did not discriminate between the Dufour's gland extracts of the parental species or extracts of their own Dufour's glands.

Chemical Analysis of Dufour's Gland Extracts. The results of gas chromatographic analysis of Dufour's gland extracts from *S. invicta*, *S. richteri*, and hybrid are shown in Figure 1. The chromatographic trace of *S. invicta* has the characteristic profile previously reported (Vander Meer et al., 1981). (*Z,E*)-alpha-farnesene (A) is the major peak followed by an as yet unidentified mono-unsaturated tricyclic homosesquiterpene (B) (Vander Meer et al., 1988) and two known acyclic homosesquiterpenes (C and D) (Alvarez et al., 1987). The *S. richteri* profile is characterized by a single major component that has been shown to be identical to component B in *S. invicta*. However, none of the minor components in the *S. richteri* GC trace correspond to the identified biologically active components observed for *S. invicta*. The Dufour's gland GC trace of the hybrid shows a combination of all four known biologically active recruitment pheromones (A, B, C, and D) in proportions indicative of a blend of the two parental species. Components A, C, and D, absent from the Dufour's glands of *S. richteri*, are present in the hybrid, and component B, which is found in only trace amounts from Dufour's glands of *S. invicta*, is conspicuously present in the GC trace of the Dufour's gland of the hybrid.

TABLE 1. PERCENT RESPONSE OF FIRE ANT WORKERS IN POINT-SOURCE BIOASSAY OF DUFOUR'S GLAND EXTRACTS^a

Test species	Dufour's gland extract ^b		
	<i>S. invicta</i>	<i>S. richteri</i>	Hybrid
<i>S. invicta</i>	100.0	32.1 ± 7.7	123.3 ± 16.2
<i>S. richteri</i>	16.1 ± 1.8	100.0	103.2 ± 7.3
Hybrid	109.1 ± 18.9	147.3 ± 17.2	100.0

^aResults are expressed as the mean and standard error of 10 replicates.

^bTest samples were applied at a concentration of 1 WE/5 µl solution.

FIG. 1. Gas chromatograms of the volatile region from Dufour's gland extracts that have recruitment pheromone activity. See Methods and Materials section for details of the GC conditions.

DISCUSSION

Species-specific semiochemicals play an important role in many facets of social insect behavior, for example, reproductive isolation in bumblebees (van Honk et al., 1978) and recruitment of worker ants to food resources (Morgan, 1984; Attygale and Morgan, 1985). In some ant species, colony-specific cues (*Lasius*

neoniger) (Traniello, 1980) and even individual-specific orientation trails (*Pachycondyla tesserinoda*) (Jessen and Maschwitz, 1986) have been discovered. Although nonsemiochemical factors also affect species separation, the partitioning of resources in complex ant communities is largely dependent on chemical communication employed in territorial and recruitment behavior (Hölldobler and Carlin, 1987).

Fire ants have a complex food foraging and recruitment mechanism. Following food discovery, the foragers use light as a visual orientation cue to guide them to the entrance to their foraging tunnel. On the return trip, the forager leaves a trail by touching its stinger to the substrate and simultaneously releasing pheromone that originates in the Dufour's gland (Wilson 1959, 1962; Vander Meer, 1986). At the nest, additional pheromone is released, which induces other workers to follow the trail (Vander Meer, 1986; Vander Meer et al., unpublished). Depending on the size and quality of the food source, the returning workers reinforce the trail, thus providing a feedback mechanism regulating the number of workers recruited (Wilson, 1962).

The fire ant recruitment process has been reduced to three measurable and sequential behaviors: (A) attraction, (B) orientation induction, and (C) orientation (Vander Meer, 1986). Orientation has been demonstrated to be nonspecific for the two species (Barlin et al., 1976; Jouvenaz et al., 1978). Orientation induction shows an asymmetric specificity (Vander Meer, 1986; Vander Meer and Lofgren, unpublished). However, worker response to a point source of Dufour's gland extract is species-specific (Vander Meer, 1986). The latter bioassay measured attraction and aggregation to Dufour's gland extracts (Vander Meer et al., 1988). Quantitative differences in active components present in the Dufour's glands of the two species (Figure 1), coupled with differential worker sensitivity to those components, could account for the observed non-specificity of the orientation and attraction bioassays (Barlin et al., 1976; Jouvenaz et al., 1978), as well as the species specificity of the point-source bioassay (Vander Meer, 1986).

Our results using the species-specific point-source bioassay mentioned above (Table 1) clearly provides the first behavioral evidence for hybridization between *S. invicta* and *S. richteri*. Although the chemistry associated with the three recruitment behavioral subcategories is not fully known, it is clear from a visual comparison of the gas chromatograph traces (Figure 1) of the hybrid and its parents that the hybrid combines the chemical features of its parents. This is analogous to the gas chromatograph profiles of the hybrid and parent venom alkaloids and hydrocarbons that were first used to describe the hybrid (Vander Meer et al., 1985; Ross et al., 1987).

Recent surveys in Mississippi, Alabama, and Georgia indicate that the range of the hybrid population is extensive throughout the northern portions of

these states (Vander Meer and Lofgren, 1988; Diffie et al., 1988). The only place that the hybrid is sandwiched between its two parental types is in northeastern Mississippi. At the present time competition for territory is taking place between (1) hybrid and *S. invicta*; (2) hybrid and *S. richteri*; and (3) hybrid and hybrid, but not between the two parental types.

Chemical analyses of fire ant samples from the Meridian, Mississippi, area over a 24-year period of time indicates that the hybrid and *S. invicta* have reached a point of equilibrium, with neither form capable of displacing the other (Vander Meer and Lofgren, unpublished). In contrast, chemical analyses at the hybrid-*S. richteri* interface indicate that the hybrid is displacing *S. richteri*. It is probably only a matter of time before *S. richteri* is eliminated from the United States.

Analysis of alcohol-preserved fire ant specimens for their venom alkaloid patterns demonstrated that hybridization between *S. invicta* and *S. richteri* was taking place wherever and whenever the two species have met (Vander Meer and Lofgren, in preparation). Consequently, all three forms have been vying for territory over the last 50 years. It could be argued that the lack of recruitment specificity of the hybrid would give it a homospecific versus a heterospecific advantage in resource competition with either of the parent species. However, the current distribution suggests that other factors, such as environmental and ecological adaptability, have probably played an important role in the observed population dynamics of *S. invicta*, *S. richteri*, and their hybrid. In South America, *S. invicta* occupies the northern tropical and subtropical areas, whereas *S. richteri* occupies the southern, more temperate climatic zone (Buren, 1972). The same climatic distribution is currently seen for the two parental types in the United States. The hybrid occupies a climatic niche in between their parents. To arrive at the present hybrid distribution requires: (1) a fitness advantage of *S. invicta* over hybrid in the southern parts of their United States distribution; (2) a fitness advantage of the hybrid over *S. invicta* in the northern parts of their distribution; (3) fitness factors being equal, no competitive advantage for *S. invicta* or the hybrid; and (4) environmental factors being equal, a possible competitive advantage of hybrid over *S. richteri*.

Our behavioral studies demonstrate for the first time hybridization between *S. invicta* and *S. richteri* through a behavioral bioassay and again through a species-specific biochemical character (Vander Meer et al., 1985). This work brings us closer to an understanding of possible mechanisms by which the two fire ant species and their hybrid reached their present distribution in the United States.

RELEASE KINETICS OF LIQUID FLOWABLE
FORMULATIONS OF GOSSYPLURE, SEX PHEROMONE
OF THE PINK BOLLWORM MOTH *Pectinophora*
gossypiella SAUNDERS (LEPIDOPTERA: GELECHIIDAE)

IAIN WEATHERSTON¹ and DAVID MILLER²

(Received April 11, 1988; accepted August 15, 1988)

Abstract—The kinetics of the release of gossyplure, measured in the laboratory at $34.5 \pm 0.5^\circ\text{C}$, from two liquid flowable formulations are presented and discussed. The data indicate that liquid flowable formulations, defined as those formulations where the active ingredient (in this case gossyplure) is attached to a particulate material, which in turn is suspended in a liquid medium, probably can be successfully used to disseminate pheromones and other behavior-modifying chemicals, although much work remains to be done in the development of these and other liquid flowable formulations.

Key Words—Pheromone formulations, controlled release, release rate determination, release kinetics, liquid flowables, *Pectinophora gossypiella*, Lepidoptera, Gelechiidae.

INTRODUCTION

Despite the fact that sex pheromones have been researched for more than 25 years, their successful commercialization and widespread use in plant protection strategies have not yet been realized. One of the major reasons for this is the fact that the development of efficacious and cost-effective controlled release formulations for behavior-modifying chemicals can be a slow and costly undertaking. The question of the principles of the design of such controlled release

¹Present address: 628, Placid Avenue, Sault Ste. Marie, Ontario, P6B 3M7, Canada.

²Present address: Forintek (Canada) Corp., 800 Montreal Road, Ottawa, K1G 3Z5, Canada.

formulations and their use strategies has recently been reviewed (Weatherston, 1988). Currently there are five basic types of commercial formulation available, namely, micro- and macrocapsules, trilaminates, capillaries, ropes, and liquid flowables. Of these five, the liquid flowables are the most recent development, and interest in this type appears to be wide-ranging, research currently being pursued by Montedison (Italy), Dexter Chem. Intl. (Israel), Monterey Chemical [Mitsubishi] (California), Spray Control Systems (Georgia), and Fermone Inc. (Arizona). A liquid flowable formulation is one in which the pheromone is attached to a particulate material that in turn is suspended in a liquid medium.

Liquid flowable formulations of insect sex pheromones can be used in pest management as disruptants or in the bioirritant strategy. This strategy involves the use, usually as a tank-mix, of a pheromone in conjunction with a compatible registered insecticide. Certain adult female lepidopteran insects (Priesner, 1979), including the pink bollworm (Cook and Shelton, 1978), have been shown to detect their own pheromone, and in some cases (Palanaswamy and Seabrook, 1978; Mitchell et al., 1972; Birch, 1977) behavioral responses have been demonstrated. Taking the pink bollworm *Pectinophora gossypiella* as an example, it is envisaged that increased control over either the insecticide alone or the pheromone alone can be achieved by causing increased in-field movement of adults of both sexes, resulting in increased probability of contacting the insecticide.

The intended use of a pheromone in this manner changes some of the design parameters from those of a disruptant formulation; although it will still be desired to utilize all the pheromone within the field use period, it should be possible to utilize a lesser amount of gossyplure and have a shorter longevity period. It is not intended that the longevity of the pheromone should be much different from the concurrently used pesticide.

At this time, we wish to report preliminary laboratory studies carried out on two liquid flowable formulations of gossyplure obtained in 1984 from Rainbow Chemical Inc., Litchfield, Arizona. The two formulations studied were identical in that both contained the same amount of gossyplure (0.632% active ingredient) [(Z,Z)- and (Z,E)-7,11-hexadecadien-1-yl acetate] impregnated onto a particulate material, which, by the use of emulsifiers and surfactants, was suspended in an aqueous medium. The only difference in the formulations was in the choice of particulate material: one formulation utilized Hi-Sil, an amorphous silica (formulation H), while the other contained perlite, a silicate (formulation P).

METHODS AND MATERIALS

Gas chromatography (GLC) was carried out on a Hewlett-Packard 5790 capillary gas chromatograph fitted with flame ionization detectors and coupled to a Hewlett-Packard 3390A programmable integrator. The column used was 11.5

m × 0.20 mm fused silica, with a stationary phase of methyl silicone gum, operated isothermally at 200°C. The carrier gas was hydrogen, used at a linear velocity of 42 cm/sec. The injector, operated in the split mode (split ratio 100: 1), was held at 240°C with a detector temperature of 300°C. Under these conditions, the isomers are not resolved and gossyplure is seen as one peak with a retention time of 3.50 min.

Determination of the amount of gossyplure in the formulations was carried out by introducing approximately 300 mg of the formulations directly into a tared 5-ml volumetric flask, which was reweighed. About 0.5 ml of a hexane solution of the internal standard (methyl heptadecanoate, 3.77 mg/ml) was then added, and the flask was filled to the 5-ml mark with hexane. A small stirring bar was carefully introduced into the flask, the stopper was inserted, and the contents of the flask were continuously stirred on a magnetic stirrer. At various time intervals, 2- μ l samples were analyzed by GLC.

The determination of the release rate of the gossyplure was carried out by residue analysis. For each formulation, the bottle was well shaken, a sample was drawn up into a Pasteur pipet, and approximately 200 mg was weighed onto a Teflon disk 2 cm in diameter. In this manner, 24 disks were prepared from formulation H (three replicates for eight time periods) and 15 disks from formulation P (three replicates for five time periods). Each disk was placed on a small aluminum foil pan and incubated at $34.5 \pm 0.5^\circ\text{C}$. Three samples from each formulation were analyzed immediately to yield the time-zero amounts of gossyplure. At various time intervals over 10 days, the residues from three randomly chosen disks of each formulation were each washed into a scintillation vial with 2 ml of hexane; 1 ml of the hexane solution of the methyl heptadecanoate was then added, followed a stirring flea and the mixture stirred for 24 hr. After the first day, the formulations had dried and the residual "cake" was eased off the disk into the vial, the disk and the point of the spatula washed with 2 ml of hexane, and the extraction carried out as indicated above. For the GLC analyses, five or six injections were carried out for each disk extract.

Hexane, distilled in glass, was purchased from Burdick and Jackson, Muskegon, Michigan, and used without further purification. Methyl heptadecanoate (99.9%) was obtained from Chromatographic Specialities Ltd., Brockville, Ontario.

RESULTS AND DISCUSSION

Initially it was determined by extraction and subsequent GLC analysis that formulations without the active ingredient yielded no volatile materials and that there was no interference in the area of interest on the chromatograms. The retention times, on methyl silicone, of the technical gossyplure used to prepare the formulations and the material extracted from the formulations were identical.

In order to determine the release rate of the gossypure by residue analysis, the time required to extract all of the gossypure from the formulations had to be ascertained. The results are presented in Figure 1; as can be seen clearly, the gossypure can be extracted from formulation H in a shorter time than from formulation P. Virtually all of the gossypure (95%) has been extracted after 2 hr, whereas only about 65% has been extracted from the perlite formulation. Although there do not appear to any significant differences between the values obtained after 4- and 5-hr extractions and the 24-hr extraction with both formulations, it was determined that for the release rate studies a 24-hr extraction period would be used.

The data presented below are given in micrograms per hour per gram of formulation because liquid flowables are diluted with water or emulsifiable vegetable oil and tank mixed with a compatible registered pesticide when used in the bioirritant strategy.

FIG. 1. Residue analysis for gossypure from formulation H [---] and formulation P [—] extracted at ambient temperature for various periods of time. The 24-hr values are the means of five replicated extractions; all other data points are from a representative extraction. The line [- · - · -] represents the stated active ingredient percentage.

Data from the residue analysis of the formulations after various periods of aging at $34.5 \pm 0.5^\circ\text{C}$ are presented in Table 1 and Figure 2. From the table it can be calculated that the mean release rate over 10 days is $19.9 \mu\text{g/hr/g}$ for formulation H and $15.8 \mu\text{g/hr/g}$ for formulation P. Linear regression analysis of these data indicate a correlation coefficient $r^2 = 0.0980$ for both formulations, a mean release rate of $21.1 \mu\text{g/hr/g}$ over 13.6 days for formulation H, and $17.3 \mu\text{g/hr/g}$ over 17 days for Formulation P. Although the regression analyses indicate longevitys of 13.6 and 17.0 days, after 9.5 days in the case of H and 10 days in the case of P there is actually 35.5% and 43.5% of the gossyplure still remaining in the formulation. These results are presented graphically in Figure 2.

Considering formulation H, 64.5% of the gossyplure is emitted in 10 days. As can be seen from the data (Table 1 and Figure 2A), after the first 24 hr, during which the average release is 18.3 mg/hr/g , the rate then remains relatively constant over the next five days at $26.1 \mu\text{g/hr/g}$ ($r^2 = 0.997$) before slowing during the remainder of the 10 days, although there is an unexplained anomalous increase during day 9. The best-fit curve and the regression line (Figure 2A) are diverging at day 10, indicating that the pheromone release from the formulation is slowing significantly. With regard to formulation P, 56.5% of the active ingredient is emitted during 10 days. The data (Table 1 and Figure 2B) indicate that after the first 49 hr, during which there is a low mean release of $6 \mu\text{g/hr/g}$, the release kinetics are zero order over the next six days ($r^2 = 0.999$) at a release of $21.2 \mu\text{g/hr/g}$. During the ninth and tenth days, the rate has slowed to less than $10 \mu\text{g/hr/g}$; the best-fit curve and regression line (Figure 2B) are beginning to diverge at this time.

Both formulations exhibit a latency period, which we believe to be due to a slower release of gossyplure until all of the water has evaporated. This period

^aLinear regression: Formulation H— $r^2 = 0.980$; $a = 6.836$; $b = -0.0211$. Formulation P— $r^2 = 0.980$; $a = 6.947$; $b = -0.0173$.

FIG. 2. Residue analyses for gossyplure from (A) formulation H and (B) formulation P, aged at $34.5 \pm 0.5^\circ\text{C}$ for up to 10 days. [---] best-fit curve from observed data; [—] linear regression.

is probably only a few hours in duration, but the design of the experimental protocol precluded confirmation. It is important to know the distribution of the gossyplure throughout the formulation, especially in regard to whether it migrates to and/or is released from the liquid phase. Studies have indicated (Weatherston and Miller, unpublished) that, of the gossyplure recovered from formulation H, 81% was associated with the Hi-Sil, while 19% was associated with the oils and emulsifiers. No pheromone was found in the aqueous phase.

The above data indicate that the formulations tested could be used as a basis for a development program involving both laboratory and field studies to define the effects on rate release and efficacy of solid-phase loading, gossyplure loading, various emulsifiers, nonreversible adsorption of the active ingredient onto the particle, temperature, etc. Preliminary indications are that formulations such as those tested could possibly, in the future, become commercial products used in a bioirritant strategy of plant protection.

Acknowledgments—Many valuable discussions with Mr. John Person, Vice President for Research, Cumberland Chemical Corp., Houston, Texas, concerning the preparation of the formulations are gratefully acknowledged. The formulations and samples of Hi-Sil, perlite, and technical gossyplure were supplied by Rainbow Chemical. This project was supported by a research development grant from NSERC (I.W.). Financial support was also provided by Rainbow Chemical Inc., Litchfield, Arizona.

(Received May 2, 1988; accepted August 18, 1988)

Abstract—Three pheromone traps were evaluated in paired field trials for effectiveness in capturing wild male velvetbean caterpillar moths (VBC), *Anticarsia gemmatalis* Hübner, and fall armyworm moths (FAW), *Spodoptera frugiperda* (J.E. Smith), using a wind-oriented trapping device. The traps were: (1) the standard multicolored bucket trap consisting of a forest green canopy, yellow funnel, white bucket and open (i.e., single wire) pheromone holder; (2) a forest green monocolored bucket trap; and (3) the Multi-Pher-1 trap consisting of a blue-green canopy, white funnel, white bucket, and white, multislotting pheromone holder. The Multi-Pher-1 trap differs primarily from the other two in that its entrance is smaller in diameter and is partially obstructed by the pheromone holder. Significantly fewer VBC and FAW males were captured in pheromone-baited monocolored (forest green) bucket traps than standard multicolored bucket traps. The Multi-Pher-1 trap also caught significantly fewer VBC moths than the standard multicolored bucket trap, but there was no significant difference in numbers of FAW moths caught in the two traps. The results further demonstrate the importance of considering visual cues, in this case color, in the design of pheromone traps for nocturnal insects.

Key Words—Trap color, trap design, velvetbean caterpillar, *Anticarsia gemmatalis*, fall armyworm moth, *Spodoptera frugiperda*, Lepidoptera, Noctuidae, electroretinogram.

INTRODUCTION

International Pheromones Moth Traps (bucket trap; International Pheromone Systems, Merseyside, England) baited with pheromone are used widely to survey adult populations of the fall armyworm (FAW), *Spodoptera frugiperda* (J.E. Smith) (Mitchell et al., 1985). Mitchell and Heath (1986) also demonstrated the utility of bucket traps for surveying adult populations of the velvetbean caterpillar (VBC), *Anticarsia gemmatalis* Hübner, with sex pheromone. In the course of these and subsequent investigations involving pheromones of the FAW, VBC, and *Heliothis* spp., we observed a propensity for bumblebees, *Bombus* sp., to be captured in bucket traps along with the target species. Captures of bumblebees were most common in late summer and fall when the traps were deployed in weedy areas with plants having large conspicuous blooms. We attributed the apparent attraction of bumblebees to the bucket trap's colorful appearance—a protective canopy of forest green, an entrance funnel of bright yellow, and a white bucket receptacle. Bucket traps of identical dimensions also are available with one color throughout—forest green. The present study was designed to determine if the forest green bucket trap could be used in place of the multicolored bucket trap without sustaining significant reductions in captures of male FAW or VBC moths. We also evaluated the Multi-Pher-1 (Bio-Controle Services, Ste-Foy, Canada), a trap somewhat similar in design to the bucket trap but costing approximately 30% less. This trap has a blue-green canopy, white funnel, white bucket, and white, multislotting pheromone holder. The design of the Multi-Pher-1 trap differs from the standard multicolored bucket trap in that the entrance is smaller, the funnel is abbreviated, and the funnel opening is partially obstructed by the pheromone holder.

METHODS AND MATERIALS

Field Trials. All tests were conducted in northwest Alachua County, Florida, in fall 1987. Pheromone baits for the FAW were prepared by Terochem Laboratories, Ltd. (Alberta, Canada). The four-component pheromone blend formulated on rubber septa at 2.0 mg/dispenser consisted of (percentage by weight): (*Z*)-7-dodecen-1-ol acetate, 0.45%; (*Z*)-9-dodecen-1-ol acetate, 0.25%; (*Z*)-9-tetradecen-1-ol acetate, 81.61%; and (*Z*)-11-hexadecen-1-ol acetate, 17.69%.

The pheromone used in tests with the VBC was prepared in our laboratory. The pheromone was purified by AgNO₃ high-performance liquid chromatography (Heath and Sonnet, 1980). Analysis of the purified pheromone was obtained on a capillary gas chromatograph (Varian 3700), and the columns used for analysis were 50 m × 0.25 mm ID methyl silicone (OV-1); 50 m × 0.25 mm ID Carbowax 20 M; and 42 m × 0.27 mm ID cholesteryl-*p*-chlorocinna-

mate, a liquid crystal phase described by Heath et al. (1979). Analysis of the pheromone with these columns showed the material to be at least 99% pure. Before loading, the rubber septa (5 × 9 mm; No. 8753-D22, A.H. Thomas, Philadelphia, Pennsylvania) were extracted with CH₂Cl₂ for 24 hr and air dried. A septum was loaded by depositing 0.5 mg of a blend consisting of (Z,Z,Z)-3,6,9-eicosatriene and (Z,Z,Z)-3,6,9-heneicosatriene (40 and 60%, respectively) dissolved in 100 μl hexane into the end with the largest reservoir.

Wind-oriented traps (WORT) (Mitchell et al., 1988) were used to make simultaneous comparisons of the bucket trap combinations (standard multicolored vs. forest green, Figure 1a) or the standard multicolored bucket trap and the Multi-Pher 1 trap (Figure 1b). The WORT consists of three major compo-

FIG. 1. Wind-oriented trapping device (WORT) used to determine the effect of color (a) and design (b) on capture of male velvetbean caterpillar and fall armyworm moths in traps baited with sex pheromone. (a) International Pheromones bucket traps (BT) mounted on WORT (left, standard BT, with forest green top, yellow funnel, and white bucket; BT on right is forest green throughout). (b) Standard BT on right and Multi-Pher-1 trap on left.

nents: tail and nose assembly, pivot, and support arms arranged perpendicularly to the tail and nose sections. The design of the WORT is such that treatments are always aligned in the same relationship relative to the prevailing wind, thereby minimizing the possibility of interactions among closely spaced pheromone traps caused by shifts in surface winds. The test traps were positioned 1 m apart opposite each other on the WORT support arms. WORTs were positioned so that the bottom of each trap bucket was ca. 1 m from the soil surface. The bucket receptacle of each trap contained a small piece of dichlorovos (Vapona) insecticide strip that served as a killing agent for trapped moths.

Three WORTs baited with VBC pheromone and three WORTs baited with FAW pheromone were operated simultaneously in a soybean field (> 35 hectares) that also had a high population of young (pretassel) volunteer corn plants. The WORTs were spaced 300–500 m apart throughout the field. In the first test with the VBC, the standard multicolored bucket trap (forest green canopy, yellow funnel, white bucket, Figure 2a) was compared to the monocolored forest green bucket trap (not shown). The first trial with the FAW involved the same trap color combinations on different WORTs and was carried out simulta-

FIG. 2. Trap components: (a) multicolored bucket trap with forest green canopy, yellow funnel, white bucket; (b) Multi-Pher-1 trap with blue-green canopy, white pheromone holder, white funnel and bucket.

neously with the first VBC trap test. The second test for both the VBC and FAW compared the standard bucket trap with the Multi-Pher-1 trap (blue-green canopy, white multislotted pheromone holder, white funnel, white bucket) (Figure 2b). These trials also were carried out simultaneously. In all cases, the trap colors were an integral part of each molded component, i.e., the colors were not simply painted onto the component's exterior surfaces. Moth catches were recorded daily, and the treatments (i.e., traps) were rotated between positions on each WORT. Pheromone baits were replaced every two weeks. Each collection was considered a replicate. Differences between means were separated using the *t* test for paired treatments (Steel and Torrie, 1960).

Spectral Analysis of Compound Eye. Spectral sensitivity of the compound eye of male VBC and FAW moths (six of each) to monochromatic light at wavelengths from 350 to 675 nm was measured electrophysiologically. The moths were from cultures reared in our laboratory on a modified pinto bean diet (Guy et al., 1985). The moths were 2–3 days old when tested. The moths were immobilized on a wax base to facilitate the insertion of microelectrodes into their compound eyes. A recording stainless-steel microelectrode was inserted 20–30 μm into the mid-dorsal region of one eye that was positioned with the mid-lateral center directed toward the stimulating light. The indifferent electrode was positioned in a similar position in the unilluminated eye. A light beam from a monochromator was focused directly on the lateral surface of the eye and head of the moth. The moths were dark-adapted for 45–60 min until they were at maximum sensitivity in a light-proof electrically shielded cage.

The electroretinogram techniques were similar to those described by Agee (1973) and Agee and Patterson (1983). Light pulses of 200 msec were delivered at a rate of one per 2 sec and intensity adjusted to produce a "criterion" electrical response of 200 μV in the eye per stimulus. The light pulse duration was controlled by an electrically driven solenoid shutter. Monochromatic light was produced by a quartz-halogen lamp with intensity adjusted to the criterion response by quartz-icnel neutral density wedge and filters. The intensity of light stimuli was determined at all test wavelengths with a calibrated thermopile (accuracy traceable to National Bureau of Standards) and a nanovolt meter in microwatts per square centimeter. Test wavelengths from 350 to 675 nm were selected with a grating monochromator. The electrical responses generated by the photoreceptors in the eye were amplified with a biological amplifier and displayed on an oscilloscope for analysis.

Spectral Reflectance of Trap Colors. The spectral reflectance of samples (2.5 cm \times 2.5 cm) of the various colored trap components were determined using a Varian 634S recording reflectance spectrophotometer. The surfaces were scanned at wavelengths from 330 to 850 nm with the monochromator slit width set at 1 mm and operated at a scan rate of 50 nm/min to obtain maximum accuracy. Eastman Kodak white (No. 6091) was the 100% standard.

RESULTS AND DISCUSSION

Color had a profound effect on pheromone trap effectiveness in capturing male VBC moths (Figure 3A). The standard multicolored bucket trap captured 6.7 times more VBC moths than the forest green bucket trap (difference significant at $P < 0.01$, paired t test). The standard multicolored bucket trap also captured significantly more male FAW moths than the forest green bucket trap (Figure 4A; $P < 0.01$), although the magnitude of increase was not as great as for the VBC.

The standard multicolored bucket trap captured significantly more ($P < 0.01$; Figure 3B) male VBC moths than the Multi-Pher-1 trap. However, there was no significant difference in the numbers of FAW males captured in the standard multicolored bucket trap and the Multi-Pher-1 trap (Figure 4B).

The spectral reflectance of the standard multicolored bucket trap parts showed that white had 91–100% reflection at wavelengths from 420 to 680 nm. The yellow reflected 55% of the incident light at wavelengths from 530 to 680 nm. The forest green had a reflectance peak at 510–530 nm of only 16% of the incident light. By contrast the blue–green canopy of the Multi-Pher-1 trap reflected 43% of the incident light at wavelengths of 480–510 nm (Figure 5).

The eyes of both the VBC and FAW were most sensitive at two similar peaks: a broad major peak in the green–yellow range from 480 to 570 nm (Fig-

FIG. 3. Capture of male velvetbean caterpillar moths in: (A) standard bucket trap (BT) versus the all-green BT trap (33 replications); (B) standard BT versus the Multi-Pher-1 trap (21 replications). Difference between means within A and B were significant, $P < 0.01$, paired t test. Thin black bars represent standard error of the mean.

FIG. 4. Capture of male fall armyworm moths in: (A) standard bucket trap (BT) versus the all-green BT (43 replications); (B) standard BT versus Multi-Pher-1 trap (22 replications). Difference in mean moth captured within A was significant, $P < 0.01$, paired t test; difference in mean moth captured within B was not significant. Thin black bars represent standard error of the mean.

FIG. 5. Spectral reflectance of components of the multicolored bucket trap (BT), forest green BT, and Multi-Pher-1 trap (M-P 1) at wavelengths from 350 to 680 nm.

ure 6). The FAW was most sensitive at 530 nm while the VBC was most sensitive at 520 nm. Both species had smaller second peaks centered in the ultraviolet at 365 nm. The spectral sensitivity curve for both species were quite similar to sensitivity curves reported for the corn earworm moth, *H. zea* (Boddie), and the tobacco budworm moth, *H. virescens* (F.) (Agee, 1973).

No attempt was made to quantify the effect of individual colors, except forest green, and then only in the case of the monocolored forest green trap. The impact of the standard multicolored trap's forest green canopy on trap catch is unknown. However, because of the canopy's small surface area—relative to the surface area of the funnel and bucket—and horizontal orientation, it is considered unlikely that the standard multicolored trap's forest green canopy had much, if any, impact on moth catch.

Mitchell et al. (1985, 1988) reported that standard multicolored bucket traps baited with pheromone captured significant numbers of male VBC and FAW moths, whereas unbaited control traps caught few or no moths. Thus, it does not appear that the multicolored bucket trap per se is attractive to either the VBC or FAW. Based upon the spectral reflectance of the various colored trap components and the spectral sensitivity of the compound eyes of the two species, it appears that the factor responsible for the decreased capture of VBC moths—and to a lesser extent FAW moths—was the forest green color of the monocolored bucket trap, which showed the lowest light reflectance. Thus, it

FIG. 6. Mean spectral sensitivity of the compound eyes of six laboratory-reared velvetbean caterpillar moths and six fall armyworm moths at wavelengths from 350 to 675 nm.

appears that visual stimuli tended to overcome a normally strong attraction response to a powerful olfactory stimulant—sex pheromone.

Failure of the Multi-Pher-1 trap to catch significant numbers of VBC also may have been due to visual stimuli associated with the white trap (Figure 2B), which had a reflectance in the range of 91–100%. However, the reduced catch of VBC moths with the Multi-Pher-1 trap probably was due more to the physical design of the trap itself rather than light reflectance. The Multi-Pher trap's funnel entrance was partially obstructed by the pheromone holder protruding downward from the canopy. Previous observations in field situations on the response of both the VBC and FAW to synthetic pheromone dispensed from rubber septa in multicolored bucket traps revealed that attracted moths generally flew rapidly around, above, and below the septa in uneven arcs; they were captured after striking the side of the funnel and tumbling into the bucket. The VBC is a much larger moth than the FAW. Presumably then, the pheromone holder for the Multi-Pher-1 trap kept the larger VBC moths from falling into the trap receptacle.

The results reported here contrast sharply with those of McLaughlin et al. (1975), which showed that pheromone traps with low spectral reflectance in the 360- and 550-nm regions (e.g., black) were more effective in capturing the nocturnal cabbage looper, *Trichoplusia ni* (Hübner), and soybean looper, *Pseudoplusia includens* (Walker), than brightly colored traps (e.g., daylight fluorescent yellow). Nevertheless, both studies demonstrate the importance of considering the visual response of night-flying insects in the design of pheromone traps. While the correct choice of color probably will not overcome a trap design that fails to address adequately basic parameters that in themselves may limit effectiveness (e.g., too small an entrance), the wrong choice of color could render an otherwise well-designed trap virtually useless. Furthermore, the results reported here support previous studies that showed the standard multicolored bucket trap to be an effective tool for surveying adult populations of the velvetbean caterpillar (Mitchell and Heath, 1986) and fall armyworm (Mitchell et al., 1985) using synthetic sex pheromone.

Acknowledgments—We thank B. Dueben for preparation of the pheromone lures, W. Copeland for collecting the field trap data, and R. Hines and S. Yocum for their assistance in analyzing the data and preparation of the graphic materials.

(Received June 7, 1988; accepted August 29, 1988)

Abstract—The sesquiterpene lactones, burrodin, confertiflorin, desacetylconfertiflorin, dihydroparthenolide, parthenin, and 7 α -hydroxy-3-desoxyzaluzanin C, and the sesquiterpene ester guayulin A were assayed at concentrations of 1, 10, and 100 μ M for effects on seed germination of 16 dicot and nine monocot species. Six of the dicot and two of the monocot species were affected by one or more of these compounds. Germination was both inhibited and promoted, depending on the compound and the specific species or cultivars, at concentrations as low as 1 μ M. For example, guayulin A, which promoted the germination of lettuce at all concentrations tested, inhibited the germination of tomato. Confertiflorin stimulated germination of the lettuce cultivar Grand Rapids at 1 μ M, but inhibited germination of a light-sensitive cultivar at all concentrations tested.

Key Words—Burrodin, confertiflorin, desacetylconfertiflorin, dihydroparthenolide, parthenin, 7 α -hydroxy-3-desoxyzaluzanin C, guayulin A, sesquiterpene lactone, allelopathy, seed germination.

INTRODUCTION

Over 3000 sesquiterpene lactones have been chemically characterized (Vasquez and Fischer, unpublished), but relatively little work has been done on the biological activity and ecological significance of these compounds (Picman, 1986; Duke, 1986). Several studies have suggested that sesquiterpene lactones may function as plant growth regulators. Reported allelopathic effects include both

stimulation and inhibition of radical growth and inhibition of germination (McCahon et al., 1973; Spencer et al., 1984; Stevens and Merrill, 1985). Sesquiterpene lactones have also been implicated as allelopathic agents of *Parthenium hysterophorus* L. (Kanchan and Jayachandra, 1980) and *Ambrosia cumanensis* H.B.K. (del Amo and Anaya, 1978). However, in preliminary studies of 10 sesquiterpene lactones, including four of those examined in the present study, Fischer and Quijano (1985) found only minor effects when these compounds were screened at single concentrations (50–100 μM) on the germination of 12 cultivated and weedy species.

The objective of this study was to examine the effect of the six sesquiterpene lactones, burrodin, confertiflorin, desacetylconfertiflorin, dihydroparthenolide, parthenin, and 7α -hydroxy-3-desoxyzyluzanin C, and the sesquiterpene ester, guayulin A, (Figure 1) on the germination of 25 plant species at concentrations of 1, 10, and 100 μM .

METHODS AND MATERIALS

Isolation of Sesquiterpene Lactones. The isolation of the sesquiterpene lactones used in these experiments has previously been described. Burrodin was isolated from *Ambrosia dumosa* (Gray) Payne (Seaman, 1976), confertiflorin and desacetylconfertiflorin from *Ambrosia confertiflora* DC. (Fischer and Mabry, 1967), 11,13-dihydroparthenolide from *Ambrosia artemisiifolia* L. (Fischer et al., 1981), and 7α -hydroxy-3-desoxyzyluzanin C from *Podochaenium eminens* (Lagasca) Schultz-Bip. (Fronczek et al., 1984). Parthenin was isolated from *Parthenium hysterophorus* L. and guayulin A from *Parthenium argentatum* Gray by normal procedures for sesquiterpenes (Fischer et al., 1975).

Multiseed Germination Bioassay. The assay seeds, common names, seed sources, and number of seeds per replicate are shown in Table 1. All undersized and damaged seeds were discarded, and the assay seeds were preselected for uniformity of size and seed coat color in the case of weed species. Assays were performed using 9-cm plastic Petri dishes lined with filter paper. The multiseed assay protocol was the same 25°C, 72 hr, dark assay with eight replicates described by Bradow (1985), including the presence of 0.1% dimethylsulfoxide (DMSO) added as an initial solubilizing agent to all test solutions and parallel deionized water controls. Test solutions (3 ml) contained 1, 10, or 100 μM of the appropriate sesquiterpene. Where necessary, test solution pH was adjusted to 6.8 with 0.1 N KOH, and the osmolarities of all test solutions (0–5 mosm) were below levels (≥ 18 mosm) inhibitory to the most sensitive test seeds, i.e., tomato, lettuce, and carrot (data not shown).

Statistical Analyses. Using a completely random design with eight replications, the count data were normalized by the transformation $(x + 0.5)^{0.5}$. Data

FIG. 1. Structures of the sesquiterpenes used in this study.

for each seed species were analyzed separately, and significant differences between compound effects were determined using one-way analyses of variance and the Waller-Duncan Bayesian k ratio t test (significance level, $P = 0.01$) (Steel and Torrie, 1980). Concentration effects were examined via two-way analyses of variance (significance level, $P = 0.01$) (Sokal and Rohlf, 1981).

RESULTS AND DISCUSSION

The germination of the six dicot species listed in Table 2 was affected by one or more of the six sesquiterpene lactones, burrodin, confertiflorin, desacetylconfertiflorin, dihydroparthenolide, parthenin, and 7 α -hydroxy-3-desoxyzaluzanin C, and the ester, guayulin A. The seeds of the 10 dicot species listed in Table 1, but not in Table 2, were not significantly affected. Compound differences and the compound \times concentration interactions were significant ($P = 0.01$) in each of the two-way analyses of variance for the individual sensitive seed species.

^a 1: Baxter's, Weslaco, Texas 78596; 2: Burpee, Warminster, Pennsylvania 18974; 3: Carolina Biological Supply, North Carolina 27215; 4: R. Menges, USDA, Weslaco, Texas 78596; 5: Valley Seed Service, Fresno, California 93791.

All of the sesquiterpenes affected seed germination in more than one of the listed species, both promoting and inhibiting (or delaying) germination. Desacetylconferitiflorin, parthenin, and 7 α -hydroxy-3-desoxyzaluzanin C each affected five of the eight sensitive species, and the three lettuce cultivars were sensitive to all seven sesquiterpenes. The effects of the sesquiterpenes on lettuce

germination varied with concentration and cultivar. All three guayulin A concentrations tested increased germination of all three lettuce cultivars. Confer-tiflorin stimulated germination of lettuce cultivar Grand Rapids at 1 μM , but inhibited germination of the light-sensitive cultivar at all concentrations tested. Tomato seed germination was increased by 1, 10, and 100 μM burrodin and parthenin and by 1 and 10 μM desacetylconfer-tiflorin, dihydroparthenolide, and 7 α -hydroxy-3-desoxyzaluzanin C. All levels of guayulin A tested and 100 μM 7 α -hydroxy-3-desoxyzaluzanin C inhibited tomato germination.

The seeds of *Amaranthus palmeri* and *A. retroflexus* germinated minimally under the bioassay conditions used. Under more permissive conditions, i.e., alternating 20/30°C for three days, control samples from the same seed lots germinated 89.6% (*A. palmeri*) and 70.5% (*A. retroflexus*), respectively (Bradow et al., 1988). Several seed lots of these weedy amaranth species exhibited an environmentally induced dormancy that fluctuated in degree over time (5–31% germination), while during the same time period germination under promotive environmental conditions remained in the range of $90 \pm 2\%$ for *A. palmeri* and $70 \pm 3\%$ for *A. retroflexus* (data not shown). This environmentally induced dormancy was alleviated by several synthetic analogs of the sesquiterpene lactone strigol (Bradow et al., 1988), but not by strigol itself or any of the sesquiterpenes considered in this paper.

Only two monocot species were significantly affected by one or more of these sesquiterpenes (Table 3). Again, the seven monocot species listed in Table 1 and not appearing in Table 3 were insensitive to the test compounds. Barnyard-grass was inhibited only by 100 μM parthenin. In the two-way analyses of variance of the sorghum data, compound, concentration, and the compound \times concentration interaction were all significant ($P = 0.001$). Sorghum germination was inhibited by 1, 10, and 100 μM burrodin, parthenin, and desacetyl-confer-tiflorin, and by 10 and 100 μM confer-tiflorin. Sorghum germination was increased by 1, 10, and 100 μM dihydroparthenolide and 7 α -hydroxy-3-desoxy-zaluzanin C.

In a few cases, apparently aberrant results were noted; for example, parthenin did not affect *Sida spinosa* germination at 100 and 10 μM , but a significant reduction was observed at 1 μM (Table 2). This study involved 594 individual treatments (7 compounds \times 3 concentrations \times 27 species and cultivars plus controls) and, at the 0.01 level of probability used for statistical significance, a few instances in which a value is falsely found significantly different from the control are expected (type I errors).

In summary, the data demonstrate that sesquiterpenes can selectively promote or inhibit germination at concentrations as low as 1 μM . The activity of these compounds is considerably higher than the activity of many allelochemicals reported to affect seed germination (cf. Duke, 1986). A direct extrapolation of these results to field situations cannot be made. However, it is not

unreasonable to hypothesize that localized concentrations of sesquiterpenes in soil might reach the low concentrations used in this study as a result of root exudation or litter decomposition. Thus, these results support the hypothesis (Muller, 1969) that allelochemicals can play a significant role in vegetation patterning and that microscale variations in the soil chemical environment, such as those caused by breakdown of plant litter and release of secondary metabolites, are important in the germination and establishment of individual seeds.

Abstract—Tannins are chemically diverse polyphenolics that have multiple biological activities. Attempts to establish the ecological significance of tannins have been hindered by the complexities of tannin analysis. A multitude of analytical procedures for tannins has been described, but it is difficult for the nonspecialist to select appropriate methods. We have classified the most common procedures for determining tannin as either chemical assays, appropriate for determining the amount and the chemical nature of the tannin in a sample, or as protein-binding assays, suitable for determining the potential biological activity of the tannin in a sample. We have recommended procedures that are particularly reliable and straightforward for general use. We have also considered the problems encountered in selecting appropriate standards for tannin analysis and have recommended standards that are readily available.

Key Words—Tannin, proanthocyanidin, gallotannin, ellagitannin, protein precipitation, Folin assay, phenolic analysis.

INTRODUCTION

Investigations of the ecological or nutritional significance of tannins are often flawed by inappropriate choices of tannin assays and standards, leading to erroneous conclusions (Mole et al., 1989; Wisdom et al., 1987; Mole and Waterman, 1987a,b). A more complete understanding of the chemical structure of tannins and their chemistry will improve the quality of these studies. We present here a brief summary of the major considerations involved in choosing and interpreting methods of tannin analysis.

FIG. 1. Representative structures of tannins and tannin subunits: **1** is the condensed tannin (proanthocyanidin) from *Sorghum*, with polymer length of 6-7 (Butler et al., 1982); **2** is cyanidin, the anthocyanidin produced from *Sorghum* condensed tannin during the acid butanol assay; **3** is Chinese gallotannin, from one to three galloyl groups are linked as depsides (phenol-carboxylic acid esters) to the gallic acid ester on carbon 2 of the glucose in this tannin (Haslam, 1981); **4** is a simple ellagitannin, pendunculagin; **5** is gallic acid; **6** is hexahydroxydiphenic acid; and **7** is the lactone ellagic acid, which spontaneously forms from **6**.

Tannins are water-soluble polymers, rich in phenolic groups, capable of binding and/or precipitating water-soluble proteins (Bate-Smith and Swain, 1962). The two major types of tannin are chemically quite different (Figure 1). Condensed tannins (proanthocyanidins) (**1**) are flavonoid polymers, with car-

FIG. 1. Continued

bon-carbon bonds joining the individual flavonoid monomers. Condensed tannins are not susceptible to hydrolysis but can be oxidatively degraded in strong acid to yield anthocyanidins (2) (Porter et al., 1986). Hydrolyzable tannins (3, 4) are gallic or hexahydroxydiphenic acid esters of glucose or other polyols (Haslam, 1979). The ester bonds are acid, base, and enzyme labile (Haslam, 1979), and the hydrolyzable tannins are easily broken down to gallic acid (5) or hexahydroxydiphenic acid (6) subunits and the core polyol. Free hexahydroxydiphenic acid spontaneously forms the internal ester ellagic acid (7). A few examples of more complex materials, chemically related to condensed and/or hydrolyzable tannins, have been described but remain poorly characterized (Swain, 1965, 1979). Water-insoluble resins that may bind protein have been

detected (Bryant, 1981), but the structures of these materials have not been elucidated. At the present time, it is not appropriate to classify these water-insoluble materials as tannins.

Bate-Smith surveyed a large number of plants for condensed and hydrolyzable tannins and found that fungi, algae, mosses, and liverworts do not contain tannin (Haslam, 1979). More recently, tannins have been reported in some algae (Nishizawa et al., 1985). The presence of condensed or hydrolyzable tannins has been correlated with the woodiness of the plant (Swain, 1965) or with the phylogenetic rank of the plant (Haslam, 1979; Haddock et al., 1982). Results of other surveys do not suggest any taxonomic or morphological correlation with the presence of tannin (Jung et al., 1979). Conflicting conclusions in taxonomic studies of tannins are due, at least in part, to differences in assay choice and interpretation of results.

Tannins are present in the leaves, wood, flowers, or seeds of plants. Often tannins are found in only a single tissue of a plant; for example, the vegetative tissue of grasses does not contain tannin (Haslam, 1979; Watterson and Butler, 1983), but the seeds of several grasses including *Sorghum* and barley may be tannin-rich (Eggum and Christensen, 1975; Strumeyer and Malin, 1975).

Both condensed and hydrolyzable tannins interact with proteins to form soluble or insoluble complexes (Haslam, 1979). Under mild conditions, the interaction with proteins is based on noncovalent, hydrogen and hydrophobic bonds (Hagerman and Butler, 1978, 1981; McManus et al., 1981). The complexes formed can be dissociated by detergents, which disrupt hydrophobic interactions, or by high pH, which ionizes the phenolic hydroxyl and thus destroys its hydrogen-bonding ability (Hagerman and Butler, 1978, 1981). Both condensed and hydrolyzable tannins are susceptible to oxidation at high pH. The oxidation products can form covalent bonds with nucleophiles including the amino or sulfhydryl groups of proteins (Pierpoint, 1969; Leathan et al., 1980; Beart et al., 1985).

The chemical reactivity and protein-binding capacity of the tannins, their oxidation products, and, in some cases, the nontannin phenolics associated with tannins are responsible for the broad range of biological systems affected by tannins. Ecologists are interested in the role of tannins in diet selection by herbivores (Feeny, 1968; Schultz and Baldwin, 1982; Batzli, 1983; Waterman et al., 1984) and in range management (Provenza and Malechek, 1984; Owen Smith and Cooper, 1987; Robbins et al., 1987). Nutritionists need to know the effect of tannin on feed consumption, rate of weight gain, and efficiency of feed utilization by livestock (Glick and Joslyn, 1970a,b; Jambunathan and Mertz, 1973; Schaffert et al., 1974; Kumar and Singh, 1984; Mitaru et al., 1984). Agronomists investigate the effect of tannins on crop resistance to pathogens,

molds, birds, and preharvest germination (Tipton et al., 1970; Harris and Burns, 1970; Mishra et al., 1980).

In all of these fields, the major question is usually whether a particular biological characteristic is significantly correlated with the amount of tannin present. There are a variety of published methods available for analyzing tannins, and new methods appear in the literature regularly (Wisdom et al., 1987; Armory and Schubert, 1987; Makkar et al., 1987; Inoue and Hagerman, 1988). Choosing an appropriate method may seem overwhelming to the nonspecialist. None of the available methods are universally useful; for example, measurements of total phenolics correlate with biological data in some studies (e.g., McKey et al., 1978), but measurements based on protein precipitation correlate with biological value in other studies (e.g., Robbins et al., 1987). However, understanding the fundamental principles of tannin analysis will enable the investigator to select an appropriate method from a small group of well-established methods. One critical parameter to consider is whether a chemical assay or a protein-binding assay is more appropriate. Chemical assays are particularly useful for determining the amount of tannin in a sample and for elucidating the structure of the tannin. Protein-binding assays are more useful for determining the potential biological activity of tannin in a sample. The analyst must also decide whether a commercial or a noncommercial tannin standard is appropriate. Methods of tissue preservation and tannin extraction have been compared in an earlier paper (Hagerman, 1988).

Specific instructions for performing the methods discussed below, including directions for preparing the reagents and for ensuring that the methods are giving reliable data, are available in IBM-compatible form from A.E. Hagerman.

CHEMICAL ASSAYS FOR TANNIN
