

IMPORTANT ANNOUNCEMENT

Due to the increased flow of excellent papers from research workers throughout the world, *Journal of Chemical Ecology* will be expanding in 1989, with the number of pages published *increased by about 25%*. Thus, the subscription price for Volume 15, 1989 (12 issues) is \$345.00 (outside the U.S., \$405.00). The price for individuals certifying that the journal is for their personal use is \$72.50 (outside the U.S., \$89.00).

OLFACTORY ORIENTATION RESPONSES BY WALKING FEMALE *Ips paraconfusus* BARK BEETLES I. Chemotaxis Assay

R. PATRICK AKERS¹ and DAVID L. WOOD

Department of Entomological Sciences
University of California
Berkeley, California

(Received May 12, 1987; accepted October 19, 1987)

Abstract—Gas-liquid chromatography of the air within the arena developed for this assay showed that a concentration gradient was established within 1–2 min of applying the pheromone (ipsenol, ipsdienol, *cis*-verbenol), and that this gradient was nearly constant for 20–95 min after application. The concentration fell rapidly and approximately exponentially between the source and the center of the arena. Turning rate and the number of beetles that reached the source increased, and heading with respect to the source decreased, in the presence of pheromone. Responses of beetles that did and did not reach the source were significantly different, but within each group there were no significant differences among dosages. Turning rate and heading varied little with distance from the source, while walking rate decreased as distance from the release point of the beetles increased. We hypothesize that dosage exerts its major effect on source location by altering the probability that a beetle will enter into orientation behavior and that beetles orienting to sources have similar behaviors even when orienting to a wide range of dosages.

Key Words—*Ips paraconfusus*, Coleoptera, Scolytidae, bark beetles, taxis, chemotaxis, orientation, olfaction, pheromones.

INTRODUCTION

These experiments were undertaken while developing assays for a study of quality discrimination among the components of a multicomponent pheromone

¹ Present address: Worcester Foundation for Experimental Biology, 222 Maple Ave., Shrewsbury, Massachusetts 01545.

(Akers and Wood, 1989). An assay had to provide clear, differential responses to olfactory stimuli, which could serve as a behavioral basis for defining different odor qualities. The extent to which an assay met this requirement was tested by exposing beetles to a dosage series of a standard pheromone blend. *Ips paraconfusus* females readily found pheromone sources 16–18 cm away in still air, and we became curious as to the mechanisms involved. A complete knowledge of the behavioral mechanism was not necessary to use the assay as an indicator of olfactory significance, but the more complete the behavioral description, the better we can visualize possible neural mechanisms. This, in turn, should assist in interpreting neurophysiological recordings and in deriving models from them (Kein 1974ab, 1975).

Several other studies of orientation in still air suggested that the paths of insects become more linear as they near a source of odor (Klingler, 1958; Bell and Tobin, 1981; Fraenkel and Gunn, 1961, Chap. 18). Since higher dosages should produce steeper concentration gradients (Crank, 1956), the inference might be drawn from these previous studies that as dosage increased all the insects in a population would shift their overall directional vectors (Bell and Tobin, 1982) towards the source and then approach it in a more linear or direct manner. The proportion of beetles that reached the source would increase as the intersections of their paths with the arena wall became more narrowly distributed around the source. Alternatively, the group that reaches the source might be comprised of beetles that enter into orientation behavior while the group that does not reach the source might be comprised of beetles that do not enter into orientation. Dosage would then change the proportion of orienting beetles, while the behavior of orienting beetles in different dosages might be similar. In our first analyses the beetles appeared to head more directly to the source as dosage increased, which seemed to support the first hypothesis. However, when the second hypothesis occurred to us, a more extensive analysis indicated that it was probably the more correct of the two. The initiation of orientation therefore appears to have a strong all-or-none component. A second paper (Akers, 1989) examines the mechanisms by which an orienting beetle may reach the source.

METHODS AND MATERIALS

Compounds. The attractant pheromone of *I. paraconfusus* is a blend of ipsenol (Ip), ipsdienol (Id), and *cis*-verbenol (cV) (Silverstein et al., 1966; Wood et al., 1967, 1968). The compounds were obtained from Booregard Industries, Ltd., Sarpsborg, Norway. Gas-liquid chromatography (GLC) showed the following purities: ipsenol 95%, ipsdienol 98%, and *cis*-verbenol >99%. None of the compounds had any contamination of the other compounds. A small

sample of the ipsenol was purified by GLC to >99% purity. This sample was tested in the chemotaxis assay and was found to have full activity.

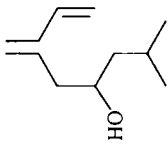

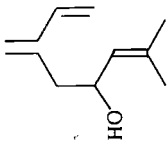

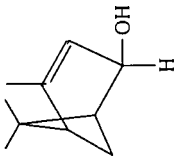

The Chemotaxis Assay. The design of the assay followed discussions in Fraenkel and Gunn (1961, pp. 271–284) and was intended to create a concentration gradient across an arena. The top and bottom of the arena were each a pane of double-strength glass, 40.6 cm square and sealed along the edges. The top had a 1-cm hole in the center, cut with a diamond-dust core drill (Equamat Distribution, Santa Clara, California). The wall of an arena was a ring of polyvinyl chloride plastic, 1 cm high, 40 cm OD, 39 cm ID, with silicon rubber gaskets permanently bonded to the edges of the wall. To assemble an arena, a wall was centered between an upper and lower pane of glass, and the edges were bound with heavy rubber bands. The hole in the upper pane was sealed with a stopper except when access to the interior was needed. A treatment was placed on a 22-mm-square cover slip. Once the solvent evaporated within a fume hood, the cover slip was slipped under the wall of an assembled arena, and placed in a standardized location just inside the wall.

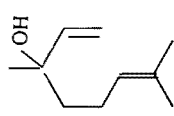

The spatial and temporal variation of the pheromone within the arena were estimated by taking samples of air directly from an arena with a gas-tight syringe and injecting them onto a gas-liquid chromatograph (GLC) fitted with flame ionization detectors. Peak areas were converted to quantity by comparing them to peaks produced by known amounts of linalool. The amount of compound remaining behind in the syringe after injection was not estimated. Therefore, only the amount recovered and not the actual concentration in the air is reported. Linalool, an isomer of ipsenol, was used in these studies to conserve pheromonal compounds. The molecular weight, structure, and adjusted boiling points of ipsenol, ipsdienol, and linalool are very similar (Table 1). In addition, linalool and ipsenol are indistinguishable on many GLC columns (Young et al., 1973). One milligram of linalool applied to an arena gave a concentration in the air similar to 1 mg of ipsdienol, ipsenol, or *cis*-verbenol. Accordingly, linalool appeared to be a reasonable substitute for the pheromonal compounds.

The first experiment evaluated the behavior of the concentration gradient within the arena through time. One milligram of linalool was applied to the dispenser, and 1-ml samples of air were taken periodically (Figure 1) over the dispenser and at the center of the arena. A difference in concentration appeared almost immediately between the center and the dispenser. The concentration difference was nearly constant between 20 min and 95 min after charging the arena. Diffusion periods of 30 or 60 min were thereafter used in all experiments, and all beetles in a single arena were run by 15 min after the diffusion period.

The spatial variation within the arena was further characterized at the 60-min diffusion time by taking 1-ml samples of air at four points along the line between the dispenser and the center of the arena (Figure 2), by fitting the

TABLE I. PHYSICAL PROPERTIES OF PHEROMONAL COMPOUNDS AND THEIR BEHAVIOR IN ASSAYS

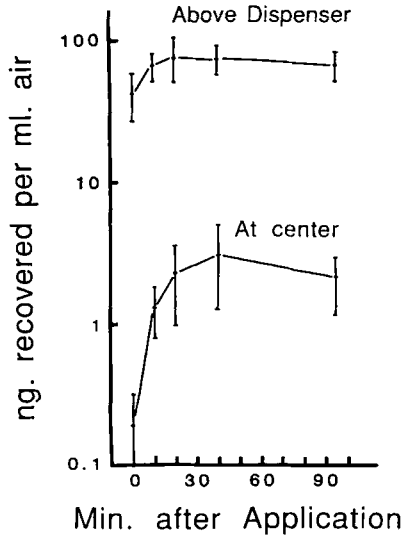

FIG. 1. The concentration of linalool in the air above the pheromone dispenser and at the center of the arena, near the release point of the beetles. One milligram was applied approx. 1 min before the first sample was taken at time 0. Distance between the center and the dispenser was approx. 17 cm. Error bars show standard deviations.

FIG. 2. The concentration of linalool in the air at various distances between the dispenser and the center of the arena. One milligram was applied to the dispenser 60 min before taking the samples. Error bars show standard deviations.

syringe with a long needle. The dispenser contained 1 mg of linalool. All samples from a single arena were taken within a 5-min period. Five arenas were sampled. The theory of diffusion indicates that, if a material diffuses freely in two dimensions without any constraints, its concentration should fall off exponentially with the square of the distance from the source (Crank, 1956). In this experiment, the relationship was estimated as falling off exponentially with the distance, not its square. When both forms of relationships were fitted to the data using the nonlinear regression (NLIN) procedure available in the Statistical Analysis System (Goodnight and Sall, 1982), the relationship based on the distance produced the lower sums of squares.

Observation and Recording Procedures. Preliminary experiments in the open laboratory indicated that the beetles were not orienting at random within untreated arenas (Akers, 1985). Accordingly, an observation chamber was developed that isolated the insects from these possibly confounding cues (Figure 3). The beetles oriented at random within the chamber when no odor cues were available. All experiments were performed using the chamber in the darkened laboratory.

The movements of a beetle were recorded by marking its position by hand at 1-sec intervals, with reference to an electronic metronome. The beetle's path was usually traced at the same time with the free hand. If an animal stopped walking, recording of its position ceased until it began moving again. However, the beetles are highly thigmotactic, and most did not stop moving until they contacted the wall of the arena or the pheromone source, at which time tracking ceased. Tracks were later entered into a computer via a digitizing table. The observation procedure was able to separate trails differing in average linear speeds by 0.02–0.04 cm/sec and in turning rates by about 2–5°/sec (Akers, 1985).

Handling of Experimental Animals. Naturally infested ponderosa pine was collected as logging debris, mostly from the vicinity of Blodgett Research Forest near Georgetown, Eldorado County, California. Infested logs were held at 5°C until needed. At such time, the logs were moved to a rearing chamber in a greenhouse, where the emerging beetles were attracted into a refrigerator at 2–5° C (Browne, 1972). Beetles were stored for periods up to three weeks before use, with no signs of adverse effects (Borden, 1967).

One day before they were to be used, the beetles were tested for their ability to perform in the assay. They were placed on a flat piece of glass and were accepted for assays if they had both their antennae and could walk more than 5–6 cm upon the glass. The sex of the selected beetles was then determined. If the beetles were kept uncrowded after emergence from the log, they did not damage one another, and a high proportion of the females were usable. Selected females were stored in individual glass tubes. They were removed from the cold 5–20 min before use. Recovery from the cold took a minute or

FIG. 3. The observation chamber used in all experiments to isolate the beetles from extraneous cues for orientation.

two at room temperature, which was $22 \pm 1^\circ\text{C}$. They were kept cool until a few minutes before use, since their struggles within the storage tubes seemed to decrease their vigor after an hour or so. A beetle was brought out of the cold directly onto the observation platform of the observation chamber, where it could recover in the same light and temperature conditions under which it would be tested. A beetle was used only once.

When a beetle was to be released, the tape was removed from the storage tube and the beetle was slid gently but immediately into an L-shaped, glass release tube inserted through the hole in the arena. The outlet of the tube was oriented at approx. 90° with respect to the source.

Dosage Series. The experimental design was a dosage series of a 1:1:1 blend of the three pheromonal compounds, as used in earlier behavioral tests (Byers and Wood, 1981). Dosages differed by powers of 10, had a range of 10^{-4} –1 mg of each compound, and were dissolved in 0.1 ml of pentane. The series was run with diffusion periods of both 30 and 60 min. Solutions were stored at -60°C or over Dry Ice until a few minutes before use.

In order to minimize contamination between treatments, each treatment had its own arena. An arena was rinsed after each use in hot (approx. 70°C) water, since the pheromone compounds are moderately soluble in water. The water flowed at a rate that provided an exchange of water approximately every 4 min. The rinse lasted about an hour. The parts of an arena were then aired for two to five days before the next use.

A preliminary experiment indicated that the beetles did not exhibit any trail-following behavior or otherwise interact significantly with one another when more than one beetle was released within an arena (Akers, 1985). In this experiment, the relationships between the tracks of two beetles that had run together within a single arena were compared to the relationships between the tracks of a pair of beetles that had run in separate arenas. The average distance that the second beetle of a pair maintained with respect to the trail of the first beetle was measured, as were the walking and turning rates of the second beetle. There were no significant differences in these measurements between the beetles that had the opportunity to follow a trail and those that did not. Observations made on different beetles moving within a single arena could therefore be considered as independent for statistical purposes, and running more than one beetle within a single arena greatly reduced the time required per replicate. Five beetles were usually run successively in each arena, with an interval of approx. 2–3 min between runs. A randomized block design was used as a precaution, in case the supply of beetles was lost during an experiment, but the effects of blocks were slight and are not reported. The experimenter did not know the identity of the treatments, either during the experiment or during the manipulation of the data.

Analysis of Orientation Data. The kinetic responses measured were orthokinesis, or linear rate of motion, and klinokinesis, or rate of turning. The estimate of the rate of motion was the mean distance between each point on a beetle's track. Two related measures were used to summarize the turning rate. Both depended on measuring the turn angle at each point on a track. The turn angle at a point was defined as the angle between the direction from the previous to the current point on the track and the direction from the current to the next point. Zero degrees was defined as straight ahead from the current point on the track. For the net turning rate, the "handedness" of a turn was taken into consideration, with left-hand turns defined as positive. In the gross turning rate, the absolute value of each turn was used. The estimates of the rates were the mean turn angles over all the points on the track. A heading was also determined

at each point on an insect's track by finding the angle between the direction towards the source and the direction from the present point to the next point on the track. Zero degrees was defined as straight towards the source. Both a mean net and a mean gross heading were defined.

The statistical analyses available for circular variables are more complex and much more limited than those available for linear variables (Batschalet, 1965, 1981). However, the gross angles used here are defined on only half the circle and thus are actually angular distances. As such they may be treated as linear variables (Batschalet, 1981, p. 231). On the other hand, the net angles are defined on the full circle and thus are true circular variables. The mean angle and its angular (=standard) deviation may be estimated from the mean vector (Batschalet, 1981, Chap. 1). This provides an unbiased estimate of the mean, but a fairly biased estimate of the angular deviation (Batschalet, 1981, p. 46). However, once the mean net angle of a track is obtained, the major point of interest in comparing means of beetles and treatments is the magnitude of the mean, which is again an angular distance. The summaries made then were: walking rate and its variation within a track, net turning rate, gross turning rate and its variation within a track, mean net heading, and mean gross heading and its variation within a track.

RESULTS

A logistic regression showed that dosage had a significant effect on the number of beetles that reached the source (Figure 4) (30-min diffusion period: $a = 1.42$, $B = 0.58$; 60-min diffusion period: $a = 2.22$, $B = 0.86$. All parameters are significantly different from 0 at $P < 0.001$). Increasing dosage decreased the net and gross headings (Table 2, all beetles; Figures 5F, G; 6F, G), implying that beetles headed more directly towards sources of higher dosage. Increasing dosage also increased the gross turning rate (Figures 5C, 6C). It decreased the walking rate in the 60-min diffusion period (Table 2: dosage, all beetles; Figure 6A), but the effect was not significant in the 30-min diffusion period (Table 2: dosage). There was no significant effect on the magnitude of the net turning rates.

Since turning rate increased with dosage while walking rate either decreased or remained constant, turning radius therefore decreased with increasing dosage, meaning that the animals made tighter turns in the higher dosages. Such behavior was difficult to reconcile with the notion that the tracks of the beetles were more linear in the higher dosages. Further, a comparison of trails of beetles that did (Figure 7: A_1 , B_1) and did not (Figure 7: A_2 , B_2) reach the source

FIG. 4. The effect of pheromone dosage on the proportion of beetles that reached the pheromone source. Solid line represents experiment with 60-min diffusion period and dotted line represents experiment with 30-min diffusion period. suggested that the behavior of the beetles differed fairly strongly between the two groups. Samples of trails of beetles that reached the source looked similar, even though the beetles were exposed to different dosages (Figure 7: A_1 , B_1). Therefore, the behavior of beetles that did and did not reach the source was compared.

The mean gross headings were significantly different between the two groups (Table 2: *rs* vs. *nrs*; Figures 5G, 6G). Beetles that did not reach the source had mean gross headings that did not differ among dosages (Table 2: dosage, *nrs*; Figures 5G, 6G). Beetles that reached the source also had mean gross headings that did not differ among dosages (Table 2: dosage, *rs*; Figures 5G, 6G), even though these beetles might have been expected to approach higher dosages more directly.

Similar results were apparent from other behavioral responses. Walking

rate was lower among beetles that reached the source than among beetles that did not (Table 2: rs vs. nrs; Figures 5A, 6A). There were no significant differences among dosages in either group (Table 2: dosage, nrs, and dosage, rs; Figures 5A, 6A). The results for gross turning rate were somewhat less clear. In either diffusion period, beetles that reached the source had higher turning rates than beetles that did not (Table 2: nrs vs. rs; Figures 5C, 6C). In the

increased with dosage among those beetles that reached the source (Table 2: dosage, rs; Figure 6C). The threshold for these effects appeared to be at about 10^{-3} – 10^{-1} mg (Figures 5 and 6), while the proportion of beetles reaching the source seemed to have a lower threshold, at most 10^{-4} mg (Figure 4).

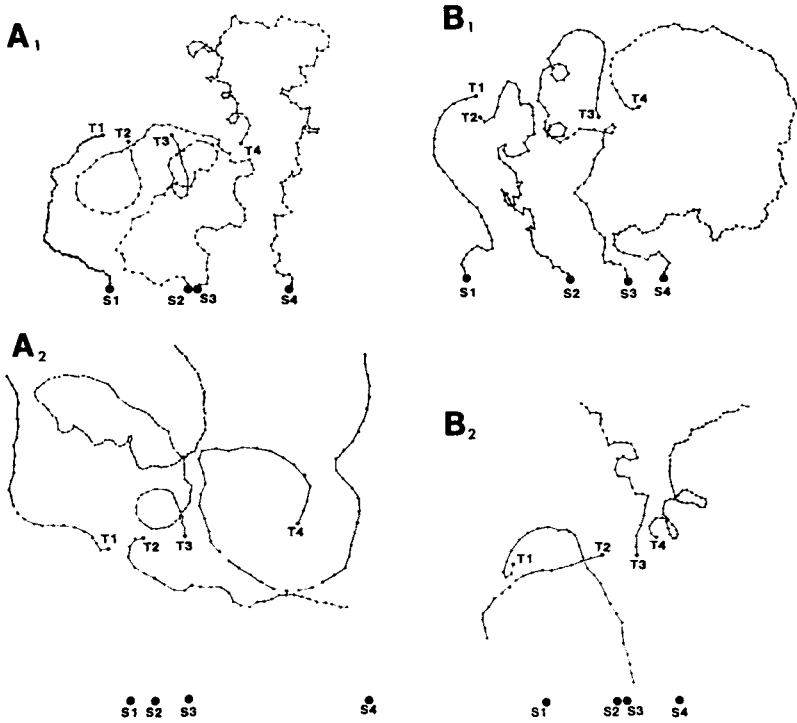

FIG. 7. Randomly selected examples of trails from two treatments in the dosage series experiment with the 60-min diffusion period, illustrating the dissimilarity between the behavior of beetles that did and did not reach the source, and the similarity between the behavior of beetles that reached sources of dissimilar dosage. A = 10^{-1} mg treatment; B = 10^{-4} mg treatment; A₁, B₁ = beetles that reached the source of pheromone; A₂, B₂ = beetles that did not reach the source of pheromone; T_x = start of trail x; S_x = location of source for trail x. Points on tracks show location of beetles at 1-sec intervals and are enlarged for clarity. Distance between release points of beetles and source was 16–18 cm.

DISCUSSION

Since more than one beetle could be tested in a single arena, the chemotaxis assay allowed the testing of large numbers of insects, which was important to later experiments. It also created environmental conditions appropriate for eliciting the desired orientation response. Without a source of pheromone, the beetles oriented at random within the observation chamber. Orientation was definitely nonrandom when pheromone was present in the assay (Figure 7). A

beetle, wandering in a random straight line away from its point of release, had a probability of approximately 0.021 of contacting the pheromone source by chance, given the dimensions of the pheromone dispenser and arena. As dosage increased, the proportion of beetles reaching the source increased well above the levels expected by chance (Figure 4).

This change in the proportion of beetles reaching the source could have been brought about by a change in the directional vector (Bell and Tobin, 1982) of orientation of every beetle in a treatment, or a change in the proportion of beetles entering into orientation, or a combination of the two. At first glance the summaries of heading made over entire treatments made the first hypothesis appear adequate. When the second hypothesis occurred to us, the problems with the hypothesis of increasing accuracy became apparent. The decrease in turn radius as dosage increased meant that beetles in higher dosages had trails that were less linear than those of beetles in lower dosages, although earlier studies had suggested that they might have been expected to be more linear. Then an examination of samples of trails suggested that the behavior of beetles that did and did not reach the source differed from one another (Figure 7). This was confirmed by the analysis of beetles that did and did not reach the source, which showed that not only was the behavior of responding beetles qualitatively different from that of nonresponding beetles, but also that dosage had small effects on the behavior of beetles within either of the two groups (Table 2, Figures 5 and 6). In particular, increasing dosage did not decrease the mean heading of beetles that reached the source. Beetles within this group all seemed to be about equally accurate in approaching the source, despite differences in dosage. These results indicated that the major factor in pheromone source location was whether or not a dosage elicited orientation behavior. A beetle's reaching the source was a good indication that it was responding to the pheromone and entering into such behavior. In addition, since the behavior of beetles that did not reach the source was so dissimilar to that of beetles that reached the source, not only in heading but in walking and turning rate as well, most of this group was probably not responding to the pheromone at all.

There are two main exceptions to this pattern. Dosage had a significant, although small, effect on the gross turning rate of beetles that reached the source, at least in the experiment with the 60-min diffusion period (Table 2: dosage, rs, 60 min; Figure 6C). Second, neither dose nor group had any significant effect on the magnitude of the net turning rate (Table 2, Figures 5E, 6E). In other words, the paths of all beetles tended to be about equally straight overall. On the other hand, not only their directional vector (Bell and Tobin, 1982) but their walking and turning rates depended strongly on whether they reached the source.

Since the behavior of a female nearing a source was similar at all dosages, and since higher dosages should produce steeper gradients, the behavior of a

beetle nearing a source of pheromone also might not vary much with distance from the source, even if the concentration changed rapidly and perhaps nonlinearly. A direct test of this hypothesis is possible in the 60-min experiment in the treatment with a 1-mg dose of pheromone, in which the concentration of pheromone in the air had been quantified. The concentration changed rapidly with distance from the source (Figure 2). In contrast, the gross turning rate changed slightly between the source and the release point of the beetles (Figure 8). The mean gross heading also changed very little as the beetles neared the source, except for an apparent decrease within the last few centimeters of the source (Figure 9).

On the other hand, the beetles walked distinctly more slowly as they moved farther from their release point (Figure 10). This result had not been expected, since dosage had little effect on the walking rate. A similar response might have been expected if the beetles were tiring, recovering from an escape response, or otherwise acclimating to their surroundings. However, the walking rate did not appear to depend on distance from the source or from the release point of

FIG. 8. The relationship between the gross turning rate and the distance to the source of pheromone, in the experiment with the 60-min diffusion period. The curve for the 1-mg treatment is based on data from only those beetles ($N = 23$) that reached the source, while the curve for the control treatment is based on data from all the beetles in the treatment ($N = 24$). Arrow marks the approximate release point of the beetles.

FIG. 9. The relationship between the mean gross heading and the distance to the source of pheromone, in the experiment with the 60-min diffusion period. The curve for the 1-mg treatment is based on data from only those beetles ($N = 23$) that reached the source, while the curve for the control treatment is based on data from all the beetles in the treatment ($N = 24$). Arrow marks the approximate release point of the beetles.

the beetles in the control treatment, although such a decline has been noted in other instances in blank arenas. Thus, the decrease in walking rate may be an effect of the pheromone, but perhaps only in part.

Similar analyses of responses vs. distance to the source at other dosages and of the 30-min diffusion period showed similar results, but (1) the variability of the mean gross headings was often larger at lower dosages; (2) the decrease in gross heading was often more gradual and less steplike, especially in the 30-min experiment; and (3) the gross turning rate was more variable, especially in the 30-min experiment (Akers, 1985). These results suggest that concentration or change in concentration modulated the behavioral responses to a small extent, once a beetle responded to the pheromone. Higher concentration and/or ascending a gradient caused a slight increase in the gross turning rate (Figure 8) (Akers, 1985), a possible decrease in the walking rate (Figure 10) (Akers, 1985), and

FIG. 10. The relationship between the walking rate and the distance to the source of pheromone, in the experiment with the 60-min diffusion period. The curve for the 1-mg treatment is based on data from only those beetles ($N = 23$) that reached the source, while the curve for the control treatment is based on data from all the beetles in the treatment ($N = 24$). Arrow marks the approximate release point of the beetles.

the heading decreased gradually as the source was neared, except for a more abrupt decrease that usually occurred within 0–5 cm of the source (Akers, 1985, 1989). However, dosage exerted its major effect by altering the probability that orientation behavior was elicited, rather than affecting the linearity and heading of every beetle exposed to the source.

(Received August 10, 1987; accepted October 19, 1987)

Abstract—An olfactometer bioassay was used to follow attractant for screwworm flies, *Cochliomyia hominivorax*, in steam distillates of bovine blood under different distillation and storage conditions and after HPLC separation of components in a water-methanol gradient. In addition, fly responsiveness was examined in relation to sex and ovarian stage. Gravid and vitellogenic nullipars were attracted to the blood, although the former predominated four to one. Males did not respond at a dose that attracted 76% of gravid females. Maximum attractiveness occurred when distillate was stored in sealed glass ampoules. An argon atmosphere made storage at ambient temperatures feasible, but offered no advantage during storage at ca. -60°C or during distillation. The HPLC separation produced four fractions that duplicated the attractiveness of the distillate when recombined but showed little activity when presented as two-fraction, and most three-fraction, mixtures. Availability of the HPLC fractions for combination with other samples will facilitate location via bioassay of attractant components in samples obtained from subsequent or alternate isolations that preserve only one or two elements of the multicomponent mixture.

Key Words—Screwworm fly, *Cochliomyia hominivorax*, Diptera, Calliphoridae, attractant, host finding.

INTRODUCTION

The screwworm fly, *Cochliomyia hominivorax* (Coquerel), is a pest of livestock throughout the tropical and subtropical Americas, although populations have been eradicated north of the Isthmus of Tehuantepec in Mexico via sterile insect releases (Krafsur et al., 1987). Females oviposit on newborn or wounded animals (Knipling, 1979) and can use wound-derived olfactory cues in host seeking (Hammack and Holt, 1983). They are attracted by odors from a variety of materials simulating hosts, including decomposing meat and liver (Bishopp, 1937; Jones et al., 1976), incubated blood (DeVaney et al., 1973), and spent artificial diet from larval rearing (Adams et al., 1979). Gram-negative bacteria associated with screwworms also produce attractive odors, and microbial contamination of the above hostlike materials is probably necessary for their activity because neither sterile blood nor fresh wounds are attractive (DeVaney et al., 1973; Eddy et al., 1975; Bromel et al., 1983; Hammack and Holt, 1983; Hammack et al., 1987). These attractants are of value to monitor and perhaps suppress screwworm populations (Knipling, 1979; Snow et al., 1982), but little headway has been made in their chemical isolation and identification. Progress has been hampered by a number of factors including variable effectiveness of different batches of attractant (DeVaney et al., 1973), batch variation in dose-response patterns (Hammack, unpublished data), and loss of biological activity with attractant fractionation (Grabbe and Turner, 1973).

Difficulties due to batch variation can be minimized by isolation of attractant from a dried bovine blood that is available in quantity and stable when crude to heat treatment and frozen storage (Hammack and Holt, 1983). In this paper, we (1) report on the responsiveness of screwworm flies to the dried-blood attractant in relation to sex and ovarian status, (2) describe methods to conserve attractiveness of a steam distillate of the blood during storage, (3) describe a distillate fractionation procedure that yielded nearly full recovery of biological activity after recombination of four fractions that individually showed little attractiveness, and (4) illustrate how availability of these four fractions will facilitate bioassay of samples that preserve only one or two components of the total attractive mixture.

METHODS AND MATERIALS

Insects. Screwworms of the V-81 strain derived from multiple egg masses collected in Veracruz, Mexico, were used in generations 28-51, except that sex comparisons were done in generation 91. Larvae were reared on a beef-based diet, and adults maintained on a 12 : 12 light-dark photoperiod at $25 \pm 1^\circ\text{C}$

and $50 \pm 10\%$ relative humidity with access to corn syrup and water (Hammack, 1984). Anesthesia (CO_2) was used only to separate the sexes.

Chromatographic fractions and stored distillates were bioassayed with 10- to 15-day-old nulliparous females that had been held with males through 6 days of age. Such females should be gravid and more than 90% inseminated (Hammack et al., 1987); this was confirmed by dissecting 25 females per rearing group when each group was first sampled for bioassay. We used the ovarian scoring scheme of Adams and Reinecke (1979) in which egg stage 10 indicates the presence of mature eggs and stages 4-8 the presence of vitellogenic terminal oocytes. Females with sperm in their spermathecae were considered mated.

Similar procedures were used to obtain flies for the sex and ovarian status tests, except that cages of males were also set up following sexing at six days and females with vitellogenic-stage ovaries were assayed three to four days after emergence. The latter females had been held with males from emergence and sexed on the day of testing without anesthesia. Their ovarian stage and mating status were determined by dissection after assay.

Attractant. A single batch of spray-dried bovine blood (Rath Packing Co.), which had been stored dry for up to eight years at ca. -20°C , was used in all experiments. A crude 10% by weight mixture of the dried blood in water (concentration ca. 50% that of whole blood) was assayed in tests done to examine fly responsiveness in relation to sex and ovarian status, as well as in the distillate stability tests where it served as a bioassay standard. Some aliquots were stored at ca. -20°C up to 96 days after reconstitution, which does not affect attractiveness (Hammack and Holt, 1983).

A steam distillate to be fractionated chromatographically was prepared in air from 200 g of the dried blood in 1 liter of distilled water. Steam was passed through the stirred mixture at $\leq 100^\circ\text{C}$, and then condensed and frozen in a flask cooled by dry ice. The first 500 ml were thawed and divided into 10-ml aliquots that were stored in glass screwtop vials at $\leq -60^\circ\text{C}$ in the dark.

Two additional batches of steam distillate, one prepared in air and the other in argon, were used to examine the cause of rapid activity losses encountered when distillate was handled at room temperature and to determine the effect of oxygen exclusion during distillation and sample storage. In both air and argon runs, 135 ml of distillate were collected over a 60- to 75-min period in an ice-chilled receiver from a mixture of 45 g of the dried blood, 600 ml of distilled water, and three drops of methyl silicone oil (to reduce foaming). Portions (8-ml) of each distillate, held ice-cold, were sealed in glass ampoules or placed in glass screwtop vials. The ampoules holding distillate prepared under argon were filled and sealed in an argon atmosphere. The samples were stored one to two months in the dark at $\leq -60^\circ\text{C}$ or ambient temperature (ca. $20-25^\circ\text{C}$) and then tested for attractiveness.

Distillate aliquots (4-ml) were chromatographed by preparative high-pressure liquid chromatography (HPLC) on a C₈ Radial Pak Cartridge (10.0 × 0.8 cm, Waters Associates, Inc.) employing a water-methanol solvent at a flow rate of 1.5 ml/min. The water-methanol ratio was changed during the first 25 min from 98 : 2 to 10 : 90 via a linear program and then held constant. Five major fractions eluting over a 36-min period were initially collected for use in bioassays; three of these were subdivided in subsequent separations (Figure 1). Controls for each fraction consisted of solvent blanks collected after water was injected onto the column.

A 10-ml aliquot of distillate was applied to a column (8.0 × 0.8 cm) that had been packed with C₁₈ Bondapak (10- μ l, Waters Associates, Inc.) and equilibrated with distilled water. The column was eluted with methanol (MeOH), and the first 1.0 ml after the void volume, hereafter referred to as the MeOH eluate, collected for bioassay.

Behavioral Bioassays. Bioassays were conducted at $25 \pm 1^\circ\text{C}$ as previously detailed (Hammack and Holt, 1983) in olfactometers that each consisted of a vertical tube with four choice ports located upwind (Adams et al., 1979). Samples were placed in two diagonally positioned ports (treated ports), while the other two held only water and served as controls. The fluid volume per port was adjusted with water to 1.0 ml, except for several instances when sample volumes exceeded 1.0 ml. Twenty-five females were routinely tested per olfactometer; they were discarded after one use.

In tracing attractant in the HPLC fractions of the blood distillate, we first established that the recombined mixture of all fractions was attractive and then determined which fractions could be eliminated from the mixture without loss of activity. This approach was used to avoid discarding fractions that might contribute to attractiveness of the mixture but show little activity when bioassayed individually. The isolated fractions were recombined for bioassay in the proportions in which they were originally present in the steam distillate, except when otherwise indicated.

The MeOH eluate was bioassayed alone and in combination with HPLC fraction 1, which contained the more water-soluble constituents of the blood distillate.

Calculations and Statistics. Test doses are given as sample volumes and as relative strengths (RS), the latter to facilitate comparisons among different combinations of fractions of varying volume. The attractant activity in a 75- μ l dose of steam distillate was arbitrarily assigned an RS of 1, and the other dosages expressed accordingly after assuming 100% recovery of attractant activity after fractionation.

The equation for the percentage of females attracted was: $[(T - C)/N] \times 100$, where T is the total number of flies trapped in treated ports, C is the total number trapped in control ports, and N is the total number tested. Because

of variation in responsiveness to the attractant (Hammack, 1984), statistical comparisons were limited to treatments tested simultaneously with matched insects, except for one case involving the MeOH eluate in which the response to an internal standard remained constant between assays done at different times and another in which gravid and vitellogenic females were assayed but not reared simultaneously. Treatments within tests were compared with respect to the total number of flies in treated ports, control ports, and the rest of the olfactometer using χ^2 calculated from contingency tables. Further comparisons within tests of more than two treatments were made only when overall χ^2 values were significant ($P \leq 0.05$). Independence of these comparisons was maintained when applicable by successive pooling of similar data sets as described by Steel and Torrie (1960).

RESULTS AND DISCUSSION

Gravid and vitellogenic nullipars both responded to the dried-blood attractant; however, the gravid ones predominated nearly four to one (Table 1). The vitellogenic flies were 70% inseminated and ranged in ovarian stage from 4–8, with a mean of 6.8 ± 1.1 (\pm SD). Too few males reacted to demonstrate significant attraction, although the test dose was sufficient to attract 76% of similarly aged gravid females (Table 1).

Wounded host animals likewise attract both gravid and vitellogenic nullipars, which feed and oviposit at the wound, but few males (Guillot et al., 1977, 1978). Females also predominate in response to steam distillate prepared from cultures of the bacterium, *Providencia rettgeri* (Hammack et al., 1987), although attraction of vitellogenic nullipars was only just detectable. Thus, with

respect to the three population segments examined here, the dried blood showed a response profile similar to that characterizing hosts and bacterial attractants.

The following results with the steam distillates of blood prepared and stored under various conditions implicated both volatility and oxidative degradation in distillate lability at ambient temperatures, but showed no advantage to air exclusion during distillation or low-temperature storage. Distillate prepared in air or argon attracted significantly more females by 23% (Table 2, test 1) or 36% (data not shown), respectively, when it was stored at $\leq -60^{\circ}\text{C}$ in a sealed ampoule as compared with a screwtop vial. Samples stored in ampoules at ambient temperature were less attractive than those held frozen only when ampoules contained air, not when they contained argon (Table 2, tests 2-5). However, when held frozen in ampoules, distillate prepared and stored in air did not differ in attractiveness from that similarly handled in an argon atmosphere (Table 2, test 6).

of blood are summarized in Table 3. The recombined mixture of all HPLC fractions (fractions 1–5, Figure 1) attracted fewer gravid females than the original distillate, but this was due to interference from the MeOH solvent rather than any loss of attractant activity during fractionation (Table 3, tests 1–3). Fractions 2, 4G, and 5 could be eliminated from the mixture without affecting fly responses (Table 3, test 4). Fractions 3A, 3E, 3F and 4D, 4E, 4F were also deleted on the basis of preliminary data; their failure to contribute to attractancy was confirmed only later (Table 3, tests 10, 11, and 15). Their elimination along with fractions 2, 4G, and 5 reduced the amount of MeOH in test samples to levels unlikely to interfere with attraction (Table 3, test 5).

The deletion of fraction 1, eluting between 3 and 9 min and containing the more polar components, or the removal of portions of fraction 1 consisting of either 1A or 1B resulted in a significant decline in attractancy of the mixture (Table 3, tests 5 and 6). The magnitude of the decline ranged from 50% to 60% of females attracted when either 1A or 1B was deleted, and this was higher than the 20–25% reduction expected even if doses of the crude distillate were halved (Table 3, test 1). This discrepancy suggests that at least some of the active fractions acted synergistically or else affected different behaviors contributing to the overall attraction response.

Neither fractions 3B–D nor 4A–C could be deleted from the mixture without a significant loss of attractiveness (Table 3, test 6). Activity in fraction 4A–C was traced to the 4A area (Table 3, test 7), but not 4B (test 8) or 4C (test 16). Activity in fraction 3B–D was associated with 3C (Table 3, tests 12 and 13), but not 3B or 3D (tests 14 and 15).

Mixtures of the HPLC fractions that contained fractions 1A, 1B, 3C, and 4A were generally as attractive as the original steam distillate (Table 3, tests 10, 11, 12, and 13); any discrepancies were usually slight (test 9) or attributable to the methanol solvent (test 3). Therefore, we concluded that attractiveness of the steam distillate could be accounted for by components present in these four fractions.

The percentage of females attracted to the MeOH eluate alone failed to exceed 17% and showed little dose dependence over a 50-fold range from 1.5 to 75 μ l (Table 4, test 1). However, responses as high as 55% and dose dependence were demonstrable when 1.5–3 μ l were tested in combination with HPLC fraction 1, which also showed little or no attractancy when tested by itself (Table 4, tests 2 and 3). The MeOH eluate was able to substitute for HPLC fractions 3 and 4 and did so at doses consistent with concentration of the less polar attractant components by as much as 10 times in the MeOH eluate as compared with the steam distillate (Table 4, test 4).

Although some of the HPLC fractions may prove unsuitable for further isolation, their availability for mixing with samples generated in subsequent or

alternate steps (e.g., the MeOH elution of the Bondapak column) can facilitate identification via bioassay of samples containing only one or two components of the attractant mixture. Because the four fractions recombined were about as attractive as the original steam distillate, the relative volumes of the fractions provide a guideline for mixing the attractant constituents in proportions expected to yield strong and dose-dependent responses.

Odors from screwworm-infested wounds were attractive to gravid screwworm flies in earlier olfactometer tests (Hammack and Holt, 1983), but a plateau occurred with increasing dose at a response level well below the maximum obtainable with the dried-blood attractant. These differing dose-response patterns could indicate that attractants from the blood and wound are chemically and functionally distinct; however, many batches of *P. retzgeri* attractant also elicit a dose-response plateau at 20–40% of females attracted (Hammack and

Bromel, unpublished data), even though some produced by the same bacterial isolate consistently evoke strong and dose-dependent responses (Bromel et al., 1983; Hammack et al., 1987). Such variation in dose-response patterns could alternatively arise simply from quantitative or qualitative variation among components of one multicomponent system; for example, peak responses to sex pheromones of the lightbrown apple moth are limited at ratios of components that deviate significantly from those released by the female (Bellas and Bartell, 1983).

Results of the present study, including demonstration of the multicomponent nature of the blood attractant, the apparent synergism among active fractions, and the similarity in the segments of the population responding to dried-blood and host attractants, are consistent with the hypothesis that blood and hosts share a common multicomponent attractant. That attractiveness of host-associated materials apparently depends upon microbial contamination provides even stronger support (DeVaney et al., 1973; Eddy et al., 1975; Bromel et al., 1983). Thus, procedures developed for chemical isolation of the blood attractant may prove applicable to host and defined bacterial sources that have been difficult to examine because of limited quantities or variable compositions.

Acknowledgments—We thank Patsy L. Evenson and Carlee A. O'Dell for insect rearing; Frances A. Baglia (Zabel) and Heidi L. Close for assistance with the bioassays; and Harold E. Brown, Richard D. Peterson II, and Donald B. Thomas, Jr., for manuscript reviews.

(Received July 16, 1987; accepted October 20, 1987)

Abstract—Combined gas chromatography–electroantennogram (GC-EAG) recording of *Campoletis sonorensis* (Cameron) responses to cotton plant volatile chemicals was performed. *C. sonorensis* antennal olfactory receptors respond differentially to green leaf, mono-, and sesquiterpene chemicals that have been identified previously in cotton. EAG depolarizations to green leaf chemicals were greater than to terpenes.

Key Words—*Campoletis sonorensis*, parasitoid, Hymenoptera, Ichneumonidae, cotton, *Gossypium hirsutum*, host habitat location, green leaf chemical, monoterpene, sesquiterpene, electroantennogram, olfaction, volatile.

INTRODUCTION

Parasitoid host-finding behavior includes the steps of habitat preference, potential host community location, and host location (Vinson, 1984). While proceeding through this hierarchy of behavioral events, parasitoid sensory systems are bombarded by environmental stimuli, some of which are more important in eliciting behavioral responses than others.

Plants and their chemicals are important in parasitoid habitat location (Vinson, 1981). *Diaeretiella rapae* responds to allyl isothiocyanate as a cue to locate its host on crucifers (Read et al., 1970). Similarly, *Heydenia unica* uses α -pinene as a cue to locate its host on pine trees (Camors and Payne, 1972). Elzen et al. (1983, 1984) described short-range orientation and attraction of *Campoletis sonorensis* to host-free cotton and to some volatile cotton chemicals

and subsequently (1986) demonstrated the long-range orientation and attraction of *C. sonorensis* to host-free cotton in a wind tunnel bioassay.

Parasitoid host habitat location in these cases involves perception of volatile chemicals. The sensory cells that detect volatile, low molecular weight organic molecules are olfactory receptor neurons usually located on the antennae (Schneider, 1964). The electroantennogram (EAG) (Schneider, 1957) records cumulative antennal olfactory receptor responses to volatile chemicals. Visser (1983) suggested that herbivores show differential olfactory sensitivities depending on the volatile chemistry of their host plant. It would be adaptively advantageous for parasitoids to evolve similar receptors for plant chemicals and utilize them in host habitat location. While Visser (1983) stressed the importance of green leaf chemicals (short-chain alcohols and aldehydes that smell like grass; Visser et al., 1979) in habitat location by herbivores, he realized that there are many other volatile plant chemicals that influence leaf odor and perhaps insect behavior. A similar approach must be taken to decipher host habitat location by insect parasitoids. The objective of this study was to use combined gas chromatography-electroantennogram (GC-EAG) studies (Arm et al., 1975) to record cumulative olfactory receptor responses of *C. sonorensis* to volatile chemicals that have been previously identified in cotton plants.

METHODS AND MATERIALS

Insects. *C. sonorensis* were reared on a culture of *Heliothis virescens* larvae, which were fed an artificial diet described by Vanderzant et al. (1962). Adult parasitoids were mated and maintained in 300-ml screened cages and fed honey-distilled water (1:2) on cotton pads. Cages were held in an environmental chamber at $26 \pm 2^\circ\text{C}$ with a photoperiod of 16:8 hr (light-dark).

Chemical Stimuli. Chemicals used for olfactory stimuli are listed in Table 1. These chemicals were chosen based on their presence in cotton essential oil (Minyard et al., 1967; Hedin et al., 1971; Elzen et al., 1984), their volatility as defined by Amoore (1982), their attraction to insects of various species (Camors and Payne, 1972; Visser and Ave, 1978), and their behavioral effects described for *C. sonorensis* (Elzen et al., 1984). All chemicals were diluted to desired concentration with hexane (pesticide grade, Fisher Scientific).

Combined Gas Chromatography-Electroantennogram Methodology. The GC-EAG technique used was similar to that previously described by Struble and Arm (1984). Chemicals were injected in 1.0- μl aliquots via an on-column injector (Scientific Glass Engineering, Inc.) to a 0.22-mm ID \times 25-m vitreous silica BP1 capillary column in a Varian 3700 GC equipped with a flame ionization detector (FID). Upstream from the FID, makeup gas was added at 20 ml/min and effluent was then split 5:1 (EAG-FID) by a fixed outlet splitter

TABLE 1. SOURCE AND PURITY OF ODOROUS STIMULI USED IN EAG STUDIES.

system (Williams and Vinson, 1980). EAG routed effluent passed through a 200°C exit port into a modified water cooled (24°C) condenser (1 cm ID). The distance between effluent introduction into the condenser and antenna preparation was 20 cm. Purified air, humidified by bubbling through distilled water at 300 ml/min, swept the effluent over the antenna preparation.

EAGs were recorded using Ag-AgCl electrodes encased in glass capillaries filled with 0.75% NaCl. Heads of mated 6-day postemergent female *C. sonorensis* were excised, and the antenna tip was inserted into the recording electrode. The indifferent electrode was inserted into the mandibles. EAG signal was amplified 100-fold by a DC preamplifier (George Johnson Electronics) and viewed on a Tektronix 561B oscilloscope. EAG and FID signals were simultaneously recorded for later analysis on Hewlett Packard 3390A integrators.

Dilutions of heptanal (10^1 - 10^{-2} μg) were administered to a series of antenna preparations. All EAG responses were measured relative to a 1.0- μg heptanal standard. Each presentation of stimuli was performed as an individual GC injection and was followed by the application of a standard. Green leaf chemicals were presented in 1.0- μg doses while the mono- and sesquiterpenes were tested at 1.0- and 10.0- μg doses. Test chemicals were applied in a sequence within each of the three chemical groups with each sequence being applied to a different antenna preparation. Prior to testing data for significance, a regression of mean and variance was performed to determine if a pattern in the data was present that required a data transformation (Ott, 1984). The mean percent

response relative to the standard was tested for all chemicals at all doses using Duncan's multiple range test ($P < 0.05$) (Duncan, 1955).

RESULTS AND DISCUSSION

A typical GC-EAG response is shown in Figure 1. The mean response of female *C. sonorensis* to the 1.0- μg heptanal standard was -1.02 mV (SE ± 0.14 , $N = 10$). Precision of flame ionization and antenna detection time is evident. The reliability of the EAG was tested by dose response (Figure 2). EAG responses to each dose of heptanal were significantly different by Duncan's multiple range test ($P < 0.05$).

Response to Green Leaf Chemicals. Green leaf volatile chemicals elicited larger *C. sonorensis* EAG responses than the mono- and sesquiterpenes tested, with heptanal producing the strongest response (Figure 3A). Six-carbon alcohols and aldehydes elicited EAG responses that were significantly smaller than heptanal.

Differing olfactory responses to green leaf volatile chemicals are not surprising. Similar results have been shown for several orders of insect (Dickens, 1984; Dickens and Boldt, 1985; Dickens et al., 1986; Guerin and Visser, 1980;

FIG. 1. Typical combined GC-EAG responses of female *C. sonorensis* to 1.0 μg of heptanal.

FIG. 2. Mean EAG response of female *C. sonorensis* to dilutions of heptanal.

Van der Pers, 1981; Visser, 1979). Although Dickens et al. (1986) have demonstrated this phenomenon in Hymenoptera, and Lecomte and Pouzat (1985) have recorded parasitic Hymenoptera EAG responses to plant chemicals, this is the first suggestion of different olfactory response to similar green leaf chemicals in parasitic Hymenoptera.

Response to Monoterpenes. Monoterpenes elicited significantly smaller EAG responses than most green leaf chemicals and smaller, but not significantly smaller, responses than sesquiterpenes. α -Pinene was the only monoterpene that stimulated *C. sonorensis* at a 1.0- μ g dose (Figure 3B). *C. sonorensis* responded electrophysiologically to 10.0 μ g of α -pinene, myrcene, and limonene, while β -pinene never elicited any response at either dose. Responses to 10.0 μ g of α -pinene and limonene were significantly greater than to the other monoterpenes tested. These data suggest that *C. sonorensis* is capable of discriminating differences not only in green leaf molecular structure but also in monoterpene structure, based on differences in EAG response to α -pinene and β -pinene.

Response to Sesquiterpenes. *C. sonorensis* EAG responses to sesquiterpenes were similar to responses elicited by monoterpenes in that doses of 10.0 μ g were needed to approach parity of responses elicited by 1.0 μ g of green leaf chemicals (Figure 3C). All the sesquiterpenes tested except gossonorol produced small EAG responses at a 1.0- μ g dose. *C. sonorensis* responded to all the sesquiterpenes tested at 10.0 μ g. β -Caryophellene oxide elicited the strongest responses at both 1.0 and 10.0 μ g.

While it is important that EAG data and data from behavioral studies are compared, it must be stressed that EAG responses do not necessarily reflect

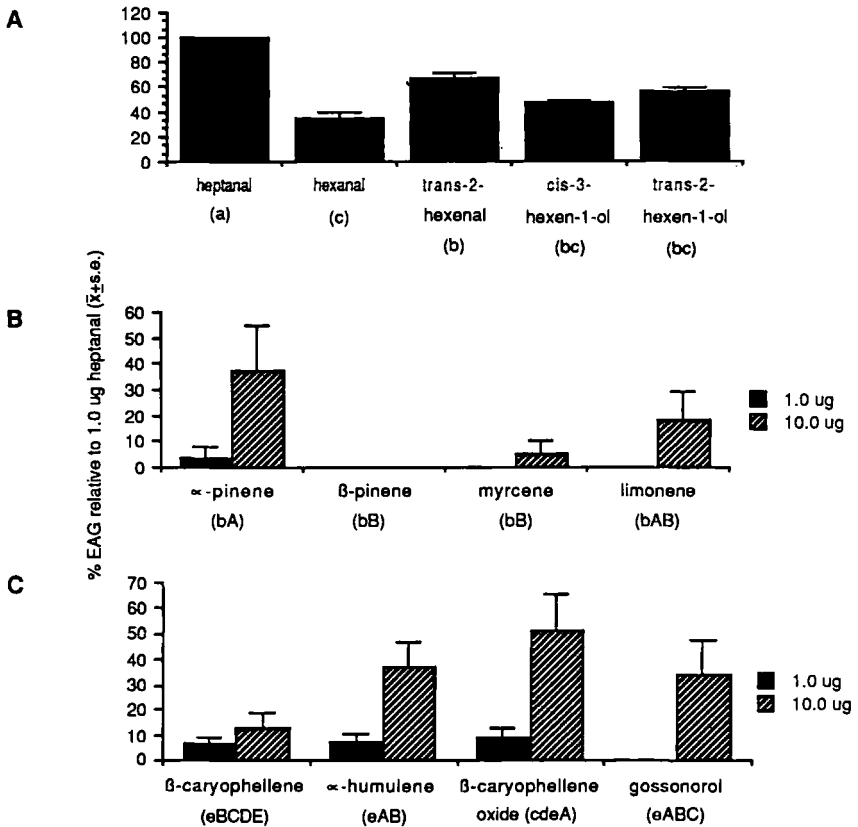

FIG. 3. Mean EAG response of female *C. sonorensis* to 1.0- μ g doses of green leaf chemicals (A), 1.0- and 10.0- μ g doses of monoterpenes (B), and 1.0- and 10.0- μ g doses of sesquiterpenes (C). Chemicals followed by the same letter are not significantly different with capital letters representing 10.0- μ g doses, Duncan's multiple range test ($P < 0.05$, $N = 10$).

central integration of peripheral stimuli and therefore do not indicate the resulting behavioral response. When electrophysiology data described here are compared to *C. sonorensis* behavioral Y-tube bioassay data of Elzen et al. (1984), minor differences are evident. The strongest EAG response to sesquiterpenes was toward β -caryophellene oxide, while behavioral data indicate a greater attraction to gossonorol. Behaviorally *C. sonorensis* did not respond to β -caryophellene, which was the least responsive sesquiterpene tested electrophysiologically. Behavior and EAG data appear to agree well with respect to α -humulene and β -caryophellene oxide responses.

CONCLUSION

Little research has been conducted on insect parasitoid attraction to specific plant chemicals and chemical blends other than those previously mentioned of Camors and Payne (1972), Elzen et al. (1984), and Read et al. (1970). While electrophysiological techniques have been utilized as tools in insect herbivore olfactory-mediated behavior studies, to date few electrophysiological studies have been conducted on parasitoids. Such research may elucidate the mechanisms involved in perception of behavioral stimuli by organisms used for biological control of insects.

The most striking similarity between our data and those of EAG studies with insect herbivores (Guerin and Visser, 1980; Kozłowski and Visser, 1981; Visser, 1979) is that substantially larger doses of terpenes than of green leaf chemicals are required to elicit responses near parity. While such data may be a function of volatility or chemical plating in the odor delivery tube, it may also suggest that molecules with smaller dose olfactory sensitivities (green leaf chemicals) could be more important in longer distance orientation to an odor source while chemicals with larger dose olfactory sensitivities (terpenes) may be more important at shorter ranges. Evidence supporting this supposition has been provided by studies comparing glanded and glandless cotton varieties, which differ mainly in production of terpenes (Elzen et al., 1985). *C. sonorensis* preferentially landed on glanded (high terpene) cotton if a choice were allowed, but landed on glandless (low terpene) cotton in no-choice wind tunnel studies (Elzen et al., 1986). Future behavioral studies may clarify such questions.

Acknowledgments—This paper is approved as TA No. 22849 by the Director of the Texas Agricultural Experiment Station. Funding for this project was provided by the USDA Competitive Grants Program, grant 85-CRRC-1-1601. This work was conducted by E.H.B. as part of the requirement for the MS degree. We gratefully acknowledge the equipment and technical advice supplied by Dr. T.L. Payne and helpful discussions with Heather McAuslane.

Abstract—Adults of three species of arctiid moths (*Cisseps fulvicollis*, *Ctenucha virginica*, and *Halysidota tessellaris*) are attracted to plants that contain pyrrolizidine alkaloids (PAs). The moths use olfactory cues to locate these plants, then feed on leaves, flowers, and roots with the proboscis. To investigate the chemical basis of attraction, sticky traps were baited with roots of a PA-containing plant, *Eupatorium maculatum*, alkaloids of *E. maculatum*, and several derivatives of these alkaloids. Volatile derivatives of the bicyclic pyrrolizidine skeleton attracted all three arctiid species. The dihydropyrrolizines, (*S*)-(+)-hydroxydanaidal and (*R*)-(–)-hydroxydanaidal, proved to be the most attractive compounds tested, accounting for over 70% of the moths captured. Different alkaloid derivatives attracted different proportions of male and female *Cisseps*. Both (*S*)-(+)-hydroxydanaidal (52% male) and (*R*)-(–)-hydroxydanaidal (71% male) attracted a significantly lower percentage of *Cisseps* males than *E. maculatum* roots (87% male). *Cisseps* males possess eversible scent organs (coremata) that are displayed during courtship. Analysis of coremata extracts revealed the presence of hydroxydanaidal. *Cisseps* moths thus resemble danaine and ithomiine butterflies, both in their attraction to PA sources and in the presence of PA derivatives in the male scent organs.

Key Words—*Cisseps fulvicollis*, *Ctenucha virginica*, *Halysidota tessellaris*, hydroxydanaidal, pyrrolizidine alkaloids, *Eupatorium maculatum*, Lepidoptera, Arctiidae, Ctenuchinae, coremata, male pheromones, attractants.

INTRODUCTION

Adults of many species of butterflies and moths visit damaged or decaying plants that contain pyrrolizidine alkaloids (PAs) (Edgar et al., 1973, and references cited; Pliske, 1975a; Goss, 1979; Boppré, 1981, 1986; Brown, 1984b). These Lepidoptera feed on the surface of the plants, often by regurgitating fluid, then reimbibing the presumably enriched solution. Visitation is restricted largely to members of four subfamilies: Danainae and Ithomiinae of the Nymphalidae, and Arctiinae and Ctenuchinae of the Arctiidae. Within each species, visitation may be further limited to one sex. While males typically predominate at baits of PA-containing plants, female biased and unbiased visitation patterns occur in some species.

Studies of both nymphalids and arctiids have documented that adults imbibe and store alkaloids while feeding at PA sources (Edgar et al., 1976a, 1979; Edgar, 1982; Brown 1984a, b; Dussourd, 1986). These alkaloids may be subsequently used as a defense against predators (Eisner, 1980; Brown, 1984a, b), as precursors for male courtship pheromones (references cited in Ackery and Vane-Wright, 1984, and in Boppré, 1984), and/or as a "nuptial gift" whereby the male contributes alkaloids to the female during mating (Brown, 1984a, b; Dussourd, 1986; Dussourd et al., 1988).

In this report we consider the chemical basis of attraction of Lepidoptera to PA-containing plants. Previous studies documented that attraction is mediated by olfactory cues (Beebe, 1955; Edgar et al., 1973), and specifically by volatile derivatives of plant alkaloids (Pliske, 1975a; Pliske et al., 1976). Ithomiine butterflies locate PA sources by detecting "esterifying acids" (such as viridifloric acid, Figure 1F) or breakdown products of these acids (Pliske, 1975a; Pliske et al., 1976). Esterifying acids presumably dissociate from the amino-alcohol nucleus of pyrrolizidine alkaloids when plant tissues decay. Unlike ithomiine butterflies, arctiid moths appear to respond to derivatives of the amino-alcohol nucleus. Pliske (1975a) and Pliske et al. (1976) were able to attract a small number of moths with amino-alcohol derivatives (such as retronecine, Figure 1D), but failed to attract any moths with esterifying acids.

Our study arose from the serendipitous discovery that volatiles from the scent organs (coremata) of male *Pyrrharctia isabella* (J.E. Smith) (Arctiidae) attract adults of three other arctiid species. Sticky traps baited with excised coremata or coremata extracts of *P. isabella* males captured the following moths: *Cisseps fulvicollis* Hubner (five males, one female), *Ctenucha virginica*

FIG. 1. Structures of pyrrolizidine alkaloids and derivatives.

Esp. (20 females, one male), and *Halysidota tessellaris* J.E. Smith (three females). Moreover, we observed a *Cisseps fulvicollis* male feeding upon excised *P. isabella* coremata, and a *Halysidota tessellaris* female feeding on a filter paper disk impregnated with an extract of *P. isabella* coremata (Figure 2).

Dussourd (1986) had collected over 800 individuals of the same three arctiid species at baits of two PA-containing plants, *Eupatorium maculatum* L. and *E. capillifolium* Lam. (Asteraceae). The proportion of males and females attracted to the *Eupatorium* baits and *Pyrrharctia* coremata was similar for each arctiid species. These results suggested that *Eupatorium* and *Pyrrharctia* might contain similar attractants. A dihydropyrrolizine, hydroxydanaidal (Figure 1G, H), had been identified previously from the coremata of several other arctiid species that feed on alkaloid-containing plants as larvae (Culvenor and Edgar, 1972; Conner et al., 1981; Schneider et al., 1982). We hypothesized that hydroxydanaidal might also be present in *P. isabella* coremata (subsequently documented by Krasnoff et al., 1987); that it was responsible for attracting *Cisseps fulvicollis*, *Ctenucha virginica*, and *Halysidota tessellaris* to the core-matal extracts; and that this compound, or some closely related amino-alcohol derivative(s), mediated the attraction of these species to *Eupatorium* plants.

Herein we describe a trapping study in which we compare the attraction of arctiid moths to a natural plant lure, *E. maculatum*, alkaloids from *E. macu-*

FIG. 2. *Halysidota tessellaris* female feeding in the field on a filter paper disk impregnated with a hexane extract of *Pyrrharctia isabella* coremata.

latum, and several derivatives of these alkaloids including hydroxydanaidal. We also document the presence of hydroxydanaidal in *Cisseps fulvicollis* coremata. While dihydropyrrolizines such as hydroxydanaidal have been identified from the male scent organs of numerous danaine visitors to PA plants (references in Ackery and Vane-Wright, 1984), there has been no parallel evidence for the presence of pyrrolizidine derivatives in the scent organs of male arctiid visitors.

METHODS AND MATERIALS

Attractancy of Pyrrolizidine Alkaloids and Derivatives. Pherocon 1C sticky traps were baited with the following treatments: (1) 10 g (fresh weight) *Eupatorium maculatum* roots; (2a) two diastereomeric alkaloids from *E. maculatum*, lycopsamine (Figure 1A) and echinatine (Figure 1B), tested in 1982 in the same

3:2 ratio as they occur in *E. maculatum* roots (J. Resch, S. Goldstein, and J. Meinwald, unpublished); (2b) monocrotaline (Figure 1C) (tested in 1983); (3) retronecine (Figure 1D), a hydrolysis product of lycopsamine; (4) heliotridine (Figure 1E), a hydrolysis product of echinatine; (5) (*R*)-(-)-hydroxydanaidal (Figure 1G), an oxidation product of retronecine; (6) (*S*)-(+)-hydroxydanaidal (Figure 1H), an oxidation product of heliotridine; (7) (2*S*, 3*S*)-(-)-viridifloric acid (Figure 1F), the acid produced by hydrolysis of either echinatine or lycopsamine; and (8) a control consisting of 25 μ l dichloromethane. Compounds were dissolved in either dichloromethane (treatments 2a, 5, 6) or methanol (2b, 3, 4, 7) at a concentration of 50 μ g/25 μ l, and tested at a dosage of 50 μ g/trap. The *E. maculatum* roots served as a standard for determining the activity of synthetic compounds relative to this natural attractant. We tested excised roots since arctiids primarily visit the roots of uprooted *E. maculatum* plants in preference to other plant parts (Dussourd, 1986).

Fresh *E. maculatum* roots were bundled with thread and placed on the sticky surface in the center of traps. Each of the other treatments and the control were prepared by pipetting 25 μ l solution into the open end of a rubber septum (5 \times 9 mm) similarly placed in the center of the traps. Traps were suspended ca. 2 m off the ground, approximately 15 m apart, along a fence in a grassy field in Tompkins County, New York. Treatments and trap liners were replaced and the trap positions rerandomized every seven days.

Daily counts were taken of the number of arctiid moths in each trap from August 17 to September 17, 1982, and from June 24 to July 30, 1983. Moths were removed and sexed every other day in 1982 and daily in 1983. Weekly totals were transformed to $\log_{10}(x + 1)$ and submitted to analysis of variance. Differences between treatment means were determined using Waller and Duncan's (1969, 1972) BSD rule. For the 1982 test, differences in the sex ratio of moths captured were determined by a *z* test using the normal approximation of the binomial (Snedecor and Cochran, 1967) with Sidak's inequality to adjust alpha levels for > 1 pairwise comparison (Sidak, 1967).

Chemistry of Cisseps Coremata Secretion. *Cisseps fulvicollis* males were collected at lights in Manatee County, Florida, during April 1984, and in Ontario County, New York, during August and September 1985. The males were either frozen and stored at -20°C for later use or were dissected alive within two days of capture. Coremata were extruded by gently squeezing the abdomen. They were then gripped with forceps, excised with a razor blade, and placed in redistilled dichloromethane (ca. 150 μ l/male) to which hexadecane had been added as an internal standard. The coremata were allowed to soak in solvent for at least 1 hr at 20°C before the extract was analyzed by GLC.

Capillary GLC was conducted with either a 25-m cross-linked methyl silicone column (ID 0.31 mm) or a 5% phenylmethyl silicone column (ID 0.20 mm), programmed from 80 to 200°C at $10^{\circ}/\text{min}$ after an initial hold of 1 min,

or with a 30-m Supelcowax 10 column (ID 0.25 mm) programmed from 80 to 230° at 15°/min after an initial hold of 1 min. Quantification of hydroxydanaidal was achieved on the 5% phenylmethyl silicone column by comparing the electronically integrated peak areas of hydroxydanaidal and its degradation products (Krasnoff et al., 1987) with the peak area of a known amount of internal standard (hexadecane). Electron impact (EI) mass spectra were obtained with a Hewlett-Packard 5985 GC-MS system using a methyl silicone capillary column.

A bioassay used in the identification of the male pheromones of *Phragmatobia fuliginosa* L. and *Pyrrharctia isabella* (Krasnoff et al., 1987) was also utilized as a probe for small amounts of dihydropyrrolizines. This assay, hereinafter referred to as the *Pyrrharctia* bioassay, employs the wing-fluttering and clicking response of *Pyrrharctia* females to courting males (or pheromone samples) as evidence for the presence of hydroxydanaidal (the male pheromone) or related compounds.

RESULTS

Attractancy of Alkaloids and Derivatives. In the 1982 tests, only a single arctiid species, *Cisseps fulvicollis*, was captured in the sticky traps. The dihydropyrrolizine, hydroxydanaidal, proved to be a potent attractant for *Cisseps* adults. Of the 977 *Cisseps* collected, 53% were captured in the (*S*)-(+)-hydroxydanaidal traps (Table 1), with an additional 19% in the (*R*)-(-)-hydroxydanaidal traps. The remaining test compounds were either moderately active (heliotridine), weakly active (retronecine), or inactive (viridifloric acid, lycopsamine, and echinatine). The relative attractancy of compounds [(*S*)-(+)-

TABLE 1. ATTRACTION OF *Cisseps fulvicollis* TO PYRROLIZIDINE ALKALOIDS AND RELATED COMPOUNDS

Treatment	Moths/week ^a
(<i>S</i>)-(+)-hydroxydanaidal	129.75 a
(<i>R</i>)-(-)-hydroxydanaidal	46.75 b
<i>Eupatorium maculatum</i> roots	43.50 bc
Heliotridine	19.25 c
Retronecine	4.25 d
Dichloromethane	0.50 e
(-)-Viridifloric acid	0.25 e
Lycopsamine/echinatine	0.25 e

^aMean number of *Cisseps* captured per week (*N* = 4 weeks). Means followed by the same letter are not significantly different at the 0.05 level (Waller and Duncan's BSD rule).

hydroxydanaidal > (*R*)-(-)-hydroxydanaidal > heliotridine > retronecine] remained constant from week to week. Analysis of the daily capture totals indicated that all attractive compounds remained active for the duration of each week, and none of the unattractive compounds became activated with time.

The sex ratios of *Cisseps* in traps differed greatly among treatments (Figure 3). The strong male bias (87% male) of the roots treatment agreed with the 89% male bias reported by Dussourd (1986) for moths collected at uprooted *Eupatorium* plants, but differed significantly from both the (*S*)-(+)-hydroxydanaidal (52% male) and (*R*)-(-)-hydroxydanaidal (71% male) treatments. The per-

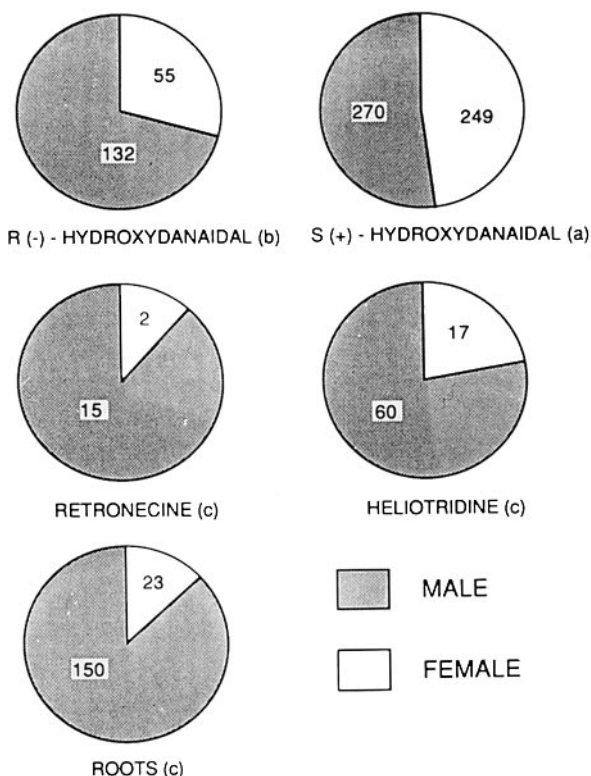

FIG. 3. Sex of *Cisseps fulvicollis* adults captured in sticky traps baited with either pyrrolizidine alkaloids, related compounds, or roots of an alkaloid-containing plant, *Eupatorium maculatum*. Numbers represent the total capture of each sex in the 1982 test. Treatments followed by the same letter do not differ in sex ratio of captured moths at the 0.05 level by a z test using the normal approximation of the binomial (Snedecor and Cochran, 1967) with Sidak's inequality to adjust alpha levels for > 1 pairwise comparison (Sidak, 1967).

centage of *Cisseps* males captured in the (*S*)-(+)-hydroxydanaidal traps varied between weeks (range 31–64%); nevertheless, (*S*)-(+)-hydroxydanaidal consistently attracted a lower proportion of males than any of the other treatments.

The 1983 test, conducted during the flight periods of *Cisseps*, *Ctenucha*, and *Halysidota*, documented the general attractancy of hydroxydanaidal to arctiids that visit plants containing pyrrolizidine alkaloids (Table 2). Of the 172 moths captured, 69% were found in the (*S*)-(+)-hydroxydanaidal traps, with an additional 20% in the (*R*)-(–)-hydroxydanaidal traps. As previously noted for the 1982 tests, moths attracted to the (*S*)-(+)-hydroxydanaidal traps exhibited less skewed sex ratios (*Cisseps*, 66% male; *Ctenucha*, 28%; *Halysidota*, 31%) in comparison with the strong sex biases reported by Dussourd (1986) for arctiids visiting *Eupatorium* baits (*Cisseps*, 89% male; *Ctenucha*, 19%; and *Halysidota*, 4%).

Corematal Chemistry. Artificially extruded coremata of *Cisseps fulvicollis* males elicited a positive response in the *Pyrrharctia* bioassay, indicating the presence of hydroxydanaidal or related compounds. A compound present in *Cisseps* corematal extracts was identified as hydroxydanaidal by comparing its retention times on polar and nonpolar GLC columns and its EI mass spectrum with retention times and spectra of an authentic sample of hydroxydanaidal. Individual *Cisseps* males were found to contain small, but variable, amounts of hydroxydanaidal in their coremata (mean = 31 ng/male; range: 2–122 ng) (Figure 4).

DISCUSSION

Attractancy of Alkaloids and Derivatives. Our results suggest that arctiid moths locate plants containing pyrrolizidine alkaloids by detecting volatile derivatives of the amino-alcohol nucleus. We captured a total of 959 moths in traps containing amino-alcohols [retronecine, heliotridine, (*S*)-(+)- and (*R*)-(-)-hydroxydanaidal], but collected only two moths in traps baited with monoesters (lycopsamine/echinatine), a macrocyclic diester (monocrotaline), and an esterifying acid (viridifloric acid).

Pliske (1975a) also attracted arctiid moths with amino alcohols and related compounds (one moth each at retronecine, laburnine, isoretronecinol, and 1-methylene-pyrrolizidine). Another amino alcohol (heliotridine), a dihydropyrrolizine (1-formyl-6,7-dihydro-5H-pyrrolizine = "danaidal"), and seven esterifying acids were not observed to attract any moths. A small number of moths visited monoesters (10 moths) and diesters (two moths); however, breakdown products in these samples may have been responsible for their activity (Pliske, 1975a; also see Pliske et al., 1976).

To determine the attractiveness of chemicals, Pliske (1975a) impregnated

blotter pads with 1–10 mg of synthetic compounds (20–200 times the amount that we used). It is surprising that he did not collect more moths, especially with heliotridine and retronecine, which we found to be moderately attractive, and with danaidal, which resembles the highly attractive enantiomers of hydroxydanaidal.

While our results suggest that volatile amino-alcohol derivatives attract arctiid moths, other insects evidently respond to different compounds. Edgar et al. (1973) tested a series of dihydropyrrolizines (including hydroxydanaidal) for attractiveness to danaines, but failed to attract any butterflies. Ithomiine butterflies likewise failed to visit amino-alcohol baits (Pliske, 1975a) but were attracted to 50-mg samples of esterifying acids (Pliske et al., 1976). Impure samples appeared to be more active than pure samples, suggesting that breakdown products of the acids mediated attraction. Boppré et al. (1984) tested the attractiveness of 50- and 100-mg samples of a monoester, heliotridine, and a mixture of a diester, senecionine, and a monoester, fuchsisenecionine. Both treatments attracted large numbers of a pyrgomorphid grasshopper, *Zonocerus elegans*.

Whether any of these attractants actually occur in the natural habitats of the attracted insects remains to be demonstrated. Edgar et al. (1973) identified hydroxydanaidal in chloroform rinses of moistened *Heliotropium amplexicaule* Vahl (Boraginaceae) from the New Hebrides. In light of our demonstration of the potent attractancy of hydroxydanaidal, it seems quite likely that dihydropyrrolizines, such as hydroxydanaidal, account for the documented attractiveness of several species of *Heliotropium* to arctiids (Pliske, 1975a, and references cited; Goss, 1979; Boppré, 1981). However, we have no evidence that hydroxydanaidal is present in volatiles produced by *Eupatorium maculatum*, the plant employed in our study. On the contrary, preliminary GLC and mass spectral analyses of airborne volatiles and dichloromethane rinses of moistened *E. maculatum* roots did not indicate the presence of either hydroxydanaidal or two related compounds, heliotridine and retronecine. Furthermore, the *Pyrrharctia* assay indicated that hydroxydanaidal was absent from the volatile collections. In addition, our trapping results with *Ciseps* suggest that compounds other than hydroxydanaidal mediate attraction since both (*R*)-(–)- and (*S*)-(+)–hydroxydanaidal attracted significantly different sex ratios of moths than *Eupatorium* roots.

The actual attractant in *E. maculatum* may resemble hydroxydanaidal in structure. Tsuda and Marion (1963) identified an amino alcohol, trachelanthamidine (Figure 1I), in *E. maculatum* roots. This is an unusual PA in that it occurs in the plant as a nonester. As such it is a relatively small molecule (mol wt = 141) that should be volatile enough to be an attractant in this system. While trachelanthamidine was not tested in our trapping study, two stereoisomers, laburnine and isoretronecinol, were screened by Pliske (1975a); each iso-

mer attracted a single female *Halysidota moraniensis* Schaus. In future studies, sticky traps could be used to test the attractancy of trachelanthamidine and to assay volatile collections from *E. maculatum* and other plants for attractive compounds.

A potential problem with sticky traps concerns the effect of trapped insects on trap attractiveness. Hydroxydanaidal released by captured *Cisseps* males, for example, could conceivably attract other moths, and thus affect capture rates and sex ratios. In our study, this effect was probably insignificant since *Cisseps* coremata contain only small amounts of hydroxydanaidal (< 150 ng/male) relative to the quantity of alkaloids tested in our traps (50 µg/trap). In addition, the trapped males did not extrude their coremata and thus probably did not release coremata secretions.

In previous studies, lepidopteran species have been categorized as male-biased, female-biased, or unbiased, based on their visitation patterns to PA-containing plants (e.g., Pliske, 1975a; Goss, 1979). Our data clearly demonstrate that sex ratios depend not only on the species, but also on the chemical composition of the attractant. In addition, the chirality of the attractant can affect overall attractiveness as well as sex ratio. Not only was (*S*)-(+)-hydroxydanaidal more attractive than its antipode, but also heliotridine, the stereospecific reduction product of the (*S*)-(+)-enantiomer, was more attractive than retronecine, the stereospecific reduction product of the (*R*)-(-) form. (*S*)-(+)-hydroxydanaidal also attracted a significantly greater percentage of females than (*R*)-(-)-hydroxydanaidal (48% vs. 29%), as did heliotridine relative to retronecine (22% vs. 12%). Why *Cisseps* sex ratios differ with different attractants remains a mystery; a comparison of the electrophysiological responses of males and females to different attractants may provide insights into the mechanisms involved.

Coremata Chemistry. *Cisseps fulvicollis* adults resemble danaine and ithomiine butterflies, both in their attraction to PA-containing plants and in their release of PA derivatives from male scent organs. Danaine males disseminate hydroxydanaidal and other dihydropyrrolizines from extrusible abdominal hair-pencils (references in Ackery and Vane-Wright, 1984), while ithomiine males release a lactone derived from esterifying acids (Edgar et al., 1976b) from erectile scent scales along the hind wings.

The coremata of several arctiid species that feed on PA-containing plants as larvae also contain dihydropyrrolizines. The quantity of hydroxydanaidal in *Cisseps* coremata (2–122 ng/male) is small in comparison with these species. Substantially larger amounts of dihydropyrrolizines have been isolated from the following arctiids: *Cretonotos* species—up to 400 µg/male (Schneider et al., 1982); *Estigmene acrea* Drury—up to 150 µg/male (Krasnoff, unpublished data); *Phragmatobia fuliginosa*—up to 1.5 µg/male (Krasnoff et al., 1987); and *Pyr-rharcia isabella*—up to 12.3 µg/male (Krasnoff et al., 1987). In addition, large

quantities of dihydropyrrolizines (up to 415 $\mu\text{g}/\text{male}$) have been recorded in danaine hairpencils (Boppré et al., 1978).

Cisseps males presumably synthesize hydroxydanaidal from PAs acquired during adult feeding. However, the presence of PAs in endophytic fungi (references cited in Belesky et al., 1987) that infect grasses that are potential larval food plants suggests that *Cisseps* larvae may also obtain hydroxydanaidal precursors.

During courtship, *Cisseps* males repeatedly evert their paired tubular coremata in the vicinity of calling females (Meyer, 1984). What effect coremata display and the presumed release of hydroxydanaidal have on *Cisseps* females remains unknown. Dihydropyrrolizines released from the coremata of an arctiid moth, *Utetheisa ornatrix* (Conner et al., 1981), and from the hairpencils of a danaine butterfly, *Danaus gilippus* Cram. (Pliske and Eisner, 1969), elicit a receptive posture from females and mediate male courtship success. In other arctiid species, *Pyrrharctia isabella* and *Phragmatobia fuliginosa*, dihydropyrrolizines released during courtship elicit a stereotyped response in females, but do not appear to affect the outcome of courtship (Krasnoff, 1987). *Cisseps* coremata also contain a nonalkaloidal compound, 12-hydroxy-2-tridecanone (Ubik, 1985), the function of which has not been determined.

It is intriguing that the coremata of *Cisseps* males contain hydroxydanaidal, a potent attractant for *Cisseps* adults. Male scent organs in other species also contain attractants. Extracts of danaine hairpencils attract several species of danaines and elicit feeding (Edgar et al., 1973). Similarly, excised scent scales from ithomiine males attract some ithomiines, which feed on the scales for short periods (Pliske, 1975b; Haber, 1978). In addition, females of both *Cisseps fulvicollis* (Krasnoff, personal observation) and *Danaus plexippus* L. (Danainae) (Urquhart, 1960) have been observed to extend the proboscis during courtship, possibly in response to male displays of scent organs.

Thus, in both butterflies and moths, chemicals in male scent organs stimulate attraction and feeding, behaviors also elicited by PA-containing plants. This association, together with the occurrence of volatile PA derivatives in both scent scales (references in Ackery and Vane-Wright, 1984; Edgar et al., 1976b) and plants (Edgar et al., 1973; references in Bull et al., 1968; Culvenor, 1978), suggests that adults may use the same sensory mechanisms in pair-formation and in location of plants containing PAs (as hypothesized for danaine butterflies by Edgar et al., 1974; Boppré, 1978). Further studies of the chemical cues involved in mating and PA visitation may shed light on these relationships and on the evolution of PA visitation and PA courtship pheromones.

Acknowledgments—We thank Jerrold Meinwald and members of his research group (J. Resch, S. Goldstein, T.W. Bell) for supplying all alkaloid samples used in this study. We are also grateful to R. Denno, T. Eisner, J. Meinwald, J. Nyrop, J. Resch, and W. Roelofs for helpful comments and suggestions. This study was partially supported by a grant (to D.E.D.) from the Bache Fund (National Academy of Science).

(Received April 19, 1987; accepted October 23, 1987)

Abstract—The thoracic gland of the ant-lion *Euroleon nostras* was found to contain nerol oxide (**1a**) and (Z)-6-undecen-2-ol (nostrenol, **3**) while the species *Grocus bore* contained 10-homonerol oxide (**1b**) and nostrenol (**3**). Nerol (**2a**) and 10-homonerol (**2b**) were found in a third species, *Myrmeleon formicarius*. 10-Homonerol, racemic 10-homonerol oxide, and racemic as well as (R)- and (S)-nostrenol were synthesized. The nerol oxide of *E. nostras* and the 10-homonerol oxide of *G. bore* were found to be racemic, while both species contained optically pure (R)-nostrenol (**28**).

Key Words—*Euroleon nostras*, *Grocus bore*, *Myrmeleon formicarius*, Neuroptera, Myrmeleontidae, nerol oxide, nostrenol, (R)- and (S)-(Z)-6-undecen-2-ol, 10-homonerol oxide, nerol, 10-homonerol, chiral shift reagent, chiral GC phase.

INTRODUCTION

The three ant-lion species, *Euroleon nostras* (Fourc.), *Grocus bore* Tjed., and *Myrmeleon formicarius* L., are sympatric both in time and space in high populations in limited areas on the northern part of Öland, an island in the Baltic in southern Sweden. Their biology indicates pheromone communication as species-specific isolating mechanisms. A morphological study revealed an unusually big, paired, thoracic gland in the males (Elofsson and Löfqvist, 1974). The gland was present in females only as a tiny remnant, which supports the hypothesis of the gland secretion as a species separating pheromone. Two small brushes, which are present only in males at the basal hind margin of the back wings, fit into small pits on the thorax when the wings are folded. The gland secretion is emptied into the pits and is dispersed in the air by the brushes when the males flutter their wings.

The volatile secretions of the glands in males of *E. nostras*, *G. bore*, and *M. formicarius* were analyzed with capillary gas chromatography and gas chromatography-mass spectrometry (Löfqvist and Bergström, 1980). In each species the secretion consisted of only two major components present in about equal proportions. Only traces of minor components were found. One of the components (MS, $m/e = 170$) was present in *E. nostras* and *G. bore*, but it was not identified. In addition, nerol oxide was identified from males of *E. nostras*. The other component in *G. bore* had a mass spectrum very similar to nerol oxide, and it was suggested to be a homonerol oxide. *M. formicarius* contained nerol and an unknown compound (MS, $m/e = 168$).

The intention with this study was to determine the chemical structures, including the stereochemistry, of significant compounds in *E. nostras*, *G. bore*, and *M. formicarius* as a basis for studies of their biological role. Methods for synthesis of the compounds and their isomers have also been developed.

METHODS AND MATERIALS

Insect Material

Larvae of *E. nostras* and *G. bore* were collected in southern Sweden at Byerum in the northern part of Öland, an island in the Baltic. The larvae were bred in the laboratory up to the time of pupation and emergence of imagines according to the procedure of Löfqvist and Bergström (1980).

Preparation of Extracts

The thoracic glands of 3 to 5-day-old males were dissected and immersed into ca. 200 μ l distilled pentane. After concentration to about 100 μ l the extracts

were run on a preparative capillary gas chromatograph (injected volume: 2 μ l, recovery: 80%) equipped with a revolving fraction collector (Wassgren and Bergström, 1984). The analysis was performed using a fused silica column with stationary phase OV-351, 25 m \times 0.35 mm ID, d_f 1 μ m. Thus, the solvent was removed from the volatile compounds, and a separation of the compounds was simultaneously achieved. The neat compounds were then dissolved in chloroform-*d* for analysis by [1 H]NMR.

Analytical Techniques

Gas Chromatography. Gas chromatographic analyses were performed on a Hewlett Packard (HP) 5880 gas chromatograph equipped with an N/P-detector and a flame ionization detector. Fused silica columns were used with stationary phases as follows: Superox FA, 27 m \times 0.5 mm ID, d_f 0.4 μ m; OV-351, 25 m \times 0.35 mm ID, d_f 1.0 μ m; XE-60-(*S*)-valine-(*S*)-2-phenylethylamide, 50 m \times 0.23 mm ID, d_f 0.12 μ m; Ni(II)-bis[3-heptafluorobutyryl-1(*R*)-camphorate], 25 m \times 0.25 mm ID; Mn(II)-bis[3-heptafluorobutyryl-1(*R*)-camphorate], 35 m \times 0.25 mm ID.

Mass Spectrometry. Finnigan 4021 GC-MS (quadropole) and LKB 2091 GC-MS instruments (magnetic type) were used.

[1 H]NMR Spectrometry. 1 H (200.3 MHz) NMR spectra were measured in CDCl_3 with tetramethylsilane as an internal standard on a Bruker WP200 spectrometer.

Determination of Absolute Configuration.

Lanthanide-Induced Shift (LIS) Studies on Nerol Oxide (*la*). Several chiral shift reagents were investigated in order to resolve nerol oxide. Tris[3-(trifluoromethylhydroxymethylene)-*d*-camphor]europium [$\text{Eu}(\text{TFC})_3$ Stohler Isotope Chemicals] gave no observable shift changes. Tris[*d,d*-dicampholylmethanato]europium [$\text{Eu}(\text{dcm})_3$, Alfa] gave small shift changes but no shift separation of the two enantiomers. However, the third shift reagent tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphor]europium [$\text{Eu}(\text{HFC})_3$] proved to be successful. The quality of the commercial shift reagents varied a lot. Initially Stohler I.C. delivered a sample that gave shift differences of the enantiomers. However, later deliveries proved inactive (and insoluble in chloroform-*d*). Then samples from Ega, Lancaster Synthesis Ltd., and Aldrich were tried with varying success. Sublimation of shift reagent did not improve the result.

The conditions for the LIS studies had to be worked out carefully. In a typical test run $\text{Eu}(\text{HFC})_3$ dissolved in chloroform-*d* was added in portions (0.1 equiv.) to the nerol oxide (7 mg) in chloroform-*d*. The result of each addition was checked by [1 H]NMR, and a lanthanide reagent to substrate ratio (L/S) of 0.5:1 was found to be optimal. Pentane extracts of thoracic glands from 20

males of *E. nostras* were fractionated by preparative capillary gas chromatography to give ca. 200 μg of nerol oxide. A microtube (5/2.5 mm, Wilmad Cat. No 520-1) was used with a sample volume of 100 μl .

Chiral GC Separations. GC separations of the enantiomers of nerol oxide and 10-homonerol oxide were carried out on a fused silica capillary column (35 m \times 0.25 mm ID) coated with Chirametal Mn(II)-bis[3-heptafluorobutyryl-1(*R*)-camphorate] in OV-101 (Schurig and Weber, 1981); conditions: isothermal at 65°C, carrier gas N₂ (9 psi), $\bar{\mu}$ = 16 cm/sec. Retention times: (*S*)-neroloxide, 29.6 min; (*R*)-nerol oxide, 30.6 min; 10-homonerol oxide, 59 min and 61.3 min (tentatively assigned to *S* and *R*, respectively). It is interesting to note that only the enantiomers of nerol oxide could be separated on the closely related phase Ni(II)-bis[3-heptafluorobutyryl-1(*R*)-camphorate] in SE-54, 25 m \times 0.23 mm ID (Schurig and Weber, 1984); conditions: isothermal at 93°C, carrier gas N₂ (7 psi), $\bar{\mu}$ = 15 cm/sec, split 40/1. Retention times: (*S*)-neroloxide, 12.6 min; (*R*)-neroloxide, 12.4 min.

Separations of the *E/Z* isomers as well as the enantiomers of synthetic (*Z*)- and (*E*)-6-undecen-2-ol were carried out by tandem GC of the isopropyl carbamate derivatives. The first fused silica capillary column (12 m \times 0.22 mm ID, d_f 0.1 μm) was coated with chemically bonded SE-54. The second fused silica capillary column (50 m \times 0.23 mm ID, d_f 0.12 μm) was coated with XE-60-(*S*)-valine-(*S*)-2-phenylethylamide (König, 1982; König et al., 1982). Running conditions were as follows: isothermal at 120°C for 60 min and then programmed to 165°C at a rate of 1°C/min, carrier gas N₂ (22 psi), $\bar{\mu}$ = 12 cm/sec, N/P-detector.

The isopropyl carbamate derivatives of synthetic and natural materials were prepared according to the procedure described by König et al. (1982). After evaporation of the solvent, the residue was dissolved in ca. 50 μl methylene chloride. Then 20 μl isopropyl isocyanate was added followed by heating in an aluminium block at 100°C for 20 min. The solvent was then evaporated and the residue was dissolved in 20 μl methylene chloride; 2 μl of the solution was injected for analysis on a gas chromatograph as described above.

Synthetic Compounds

Column chromatography separations were made on a column that had been dry packed with Merck 60 silica gel, 230–400 mesh. Light petroleum, bp 40–60°C, with increased amounts of ethyl acetate (0, 1.25, 2.5, 5, 10, 20, 40, and 80%) was delivered by a metering pump at a rate of 30 ml/min for 12.5 mm ID columns. Analytical GLC of the synthetic compounds was performed on a Pye Unicam 204 instrument with an FID detector connected to a computing integrator; 25-m columns were used coated either with Carbowax 20 M or with SP-1000. A Finnigan model 4021 spectrometer connected to an INCOS data

system was used to record GC-MS spectra. The [^1H]NMR spectra were recorded in CDCl_3 with tetramethylsilane as internal standard using Varian EM360, Jeol PMX60Si, and Bruker WP200 spectrometers. The coupling constants (J) are in Hz. The following abbreviations are used: DMSO = dimethyl sulfoxide, THF = tetrahydrofuran, DIBAL = diisobutylaluminium hydride, PCC = pyridinium chlorochromate.

Syntheses of 10-Homonerol (2b) and 10-Homonerol Oxide (1b)

(Z)-2-Ethyl-6-methyl-1-iodo-1,5-heptadiene (**6**). 1-Bromo-4-methyl-3-pentene (**4**, 2.64 g, 16.2 mmol) in dry ether (30 ml) was slowly added to Mg metal (480 mg) and a small crystal of iodine. After 1.5 hr at reflux, the solution was carefully transferred into a solution of $\text{CuBr}/\text{Me}_2\text{S}$ (3 g, 0.9 equiv) in 10 ml of ether and 20 ml dimethylsulfide at -55°C . This temperature was kept for 2.5 hr. Then 1-butyne (**5**, 1.26 ml, 870 mg) was added via a cooled syringe during 1 min at -45°C . The mixture was warmed to -23°C for 2 hr and then recooled to -40°C . Iodine was added in small portions and the mixture was allowed to warm to -10°C for 0.5 hr. Ammonium chloride (20 ml, 10% aq.) was added and the organic layer was diluted with pentane, separated, filtered and washed ($\text{Na}_2\text{S}_2\text{O}_3$, NH_3 aq., NaCl 10% aq.). This procedure yielded 2.6 g (61%) of the desired product **6**; [^1H]NMR (200 MHz) δ 1.0 (t, 3H), 1.6 (s, 3H), 1.7 (s, 3H), 2.0–2.4 (m, 6H), 5.1 (t, 1H), and 5.9 (bs, 1H).

(Z)-3-Ethyl-7-methyl-2,6-octadienoic Acid (**7**). An ether solution of *n*-butyllithium (1.2 M, 1.14 mmol) was added under stirring at -70°C to the iodoalkene **6** (1 mmol) in ether (10 ml). The mixture was stirred at -60°C for ca. 30 min. The reaction was complete when the Gilman test was negative (Fieser and Fieser, 1967). Then excess carbon dioxide was bubbled through the mixture at -78°C . The reaction mixture was allowed to warm to -20°C . Water (5 ml) was added followed by an aqueous sodium bicarbonate solution until the mixture was alkaline. The aqueous layer was then acidified with hydrochloric acid (1 M) followed by extraction with ethyl ether (3×10 ml). The organic solution was dried (MgSO_4) and the solvent evaporated to give the acid **7**, 62 mg (34%); [^1H]NMR (200 MHz) δ 1.08 (t, 3H, $J = 7.4$), 1.62 (s 3H), 1.69 (s, 3H), 2.10–2.26 (m, 4H), 2.63 (t, 2H, $J = 7.4$), 5.15 (bt, 1H), 5.66 (bs, 1H), and 10.7 (broad, 1H).

(Z)-3-Ethyl-7-methyl-2,6-octadien-1-ol, 10-Homonerol (**2b**). A solution of the acid **7** (62 mg, 0.34 mmol) in anhydrous ethyl ether (5 ml) was added dropwise to lithium aluminium hydride (25.8 mg, 0.68 mmol) in anhydrous ethyl ether (5 ml) to create a gentle reflux. After 2 hr, sodium sulfate decahydrate-celite was added (Baekström, 1978). After another 1.5 hr, the solid was filtered off and washed with ethyl ether. After evaporation of the solvent and flash-chromatography, the combined ether filtrates gave the 10-homonerol (**2b**),

30 mg (45%); MS (*m/e*) 168 (M), 150 (M-18), 135 (M-18-15), 121, 107, 79, 69 and 41; [^1H]NMR (200 MHz) δ 1.03 (t, 3H, $J = 7.4$), 1.60 (s, 4H), 1.69 (s, 3H), 1.9-2.1 (m, 6H), 4.13 (d, 2H, $J = 7.0$), 5.11 (bt, 1H), and 5.42 (t, 1H).

Photooxidation of 10-Homonerol (2b). 10-Homonerol (**2b**, 30 mg, 0.18 mmol) was dissolved in a chloroform solution of Rose Bengal (3 ml). The solution was irradiated in a Rayonet reactor equipped with 16 RPR 350 nm lamps. Oxygen was bubbled through the solution. Tetrabutylammonium borohydride (46 mg, 0.18 mmol) was added in three portions (23, 12, and 11 mg, respectively) after 0, 60, and 80 min of irradiation (Baeckström et al., 1982). After 1.5 hr, the chloroform was removed by evaporation. Potassium iodide (60 mg, 0.36 mmol) in water (1 ml) and ethyl ether (6 ml) was then added to the residue. After stirring for 10 min, the resulting crystals were removed and washed by filtration. The combined red ethereal layer containing the alcohols **8** and **9** was separated from the aqueous phase and dried (MgSO_4).

10-Homonerol Oxide (1b). The obtained ethereal solution of the alcohols **8** and **9** was mixed with 2 drops of perchloric acid in ether (4 ml) and stirred for 30 min. After addition of a small amount of sodium carbonate, the resulting crystals were filtered off and washed with ethyl ether. Silica gel (2 g) was added to the ethyl ether solution and the solvent was evaporated in vacuo. The red powder with the adsorbed reaction products was added to the top of a column for flash-chromatography on basic alumina. 10-Homonerol oxide was obtained in a pure state. The GC-MS and [^1H]NMR spectra were identical with those of the natural compound (cf. Figures 2 and 3). [^1H]NMR (200 MHz) δ 1.01 (t, 3H, $J = 7.5$), 1.69 (d, 3H, $J = 1.2$), 1.73 (d, 3H, $J = 1.2$), 1.85-2.16 (m, 4H), 4.19 (m, 3H), 5.22 (bd, 1H), and 5.39 (bs, 1H).

Syntheses of Nostrenol (3) and Related Alcohols 10 and 11

6-Methyl-6-hexanolide (18). *m*-Chloroperbenzoic acid (11.9 g) in methylene chloride (100 ml) was added to a stirred solution of 2-methylcyclohexanone (5.6 g) in methylene chloride (20 ml). The resulting mixture was refluxed for 2 hr, cooled to 0°C, filtered and the filtrate was concentrated in vacuo. Bulb-to-bulb distillation (10 mm Hg/air bath at 100-120°C) gave an oil (4.70 g, 73%). NMR (60 MHz) δ 1.4 (d, 3H), 1.4-2.1 (m, 6H), 2.5-2.8 (m, 2H), and 4.1-4.8 (m, 1H).

Cyclic Lactols 12, 13, and 14. One of the lactones **18**, **19**, or **20** (0.1 mol) was stirred in dry THF (100 ml) at -50°C under argon. DIBAL (25 ml, 0.21 mol) in THF (100 ml) was added (30 min) and stirring at -50°C was continued for an additional 30 min. A powdered mixture of celite (1 vol), sodium sulfate decahydrate (70 g, 1 vol), and ethyl ether (300 ml, saturated with water) was added at -50°C. The mixture was allowed to warm slowly to room tempera-

ture, after which it was filtered and the solid was thoroughly washed with ethyl ether. The filtrate was dried (MgSO_4) and concentrated to give an oil (9.5–10.1 g, 93–99%), which was used in the next step without further purification.

Wittig Reaction of Cyclic Lactols 12, 13, and 14. Sodium hydride (300 mg, 80% in oil, 20 mmol) was washed free of oil with dry THF in portions under argon. The residual THF was evaporated under vacuum and the flask filled with argon. DMSO (40 ml, freshly distilled from CaH_2) was added, and the mixture was stirred and heated slowly to 60°C until all the hydride had reacted. After cooling to 20°C an alkyltriphenylphosphonium bromide (20 mmol) was added to the stirred solution. The ylide (**15**, **16**, or **17**) was formed rapidly, and the resulting intensely red solution was cooled to 15°C and a solution of the lactol (**12**, **13**, or **14**, 20 mmol) in DMSO (10 ml) was added dropwise. After stirring at 15°C for 1.5 hr, the reaction mixture was poured into water and extracted with pentane. The pentane solution was concentrated to 10 ml and filtered. The solid was washed with a few milliliters of pentane, and the solution was concentrated to give an oil, which was subjected to flash-chromatography to give the (*Z*)-alkenol (**10**, **11**, or **21**) after bulb-to-bulb distillation (air bath at $130^\circ\text{C}/7$ mm Hg, yield 14–16 mmol, 70–80%). The products contained less than 8% of the *E*-isomers (GC). The NMR spectra of **10** and **11** are shown in Figure 5.

(*Z*)-5-Decen-1-ol (**21**). Bp $58\text{--}60^\circ\text{C}/1$ mm Hg. GC showed the ratio (*Z*/*E*) to be 93/7; n_{25}^D 1.4504; IR (film) ν_{max} 3320 cm^{-1} (very broad, H-bonded OH); NMR (60 MHz) δ 0.9 (t, 3H), 1.1–1.8 (m, 8H), 1.8–2.3 (m, 4H), 2.80 (s, 1H disappears on addition of D_2O), 3.60 (t, 2H), and 5.37 (m, 2H).

(*Z*)-5-Decenal (**22**). (*Z*)-5-Decen-1-ol (**21**, 5 g, 32 mmol) was stirred in methylene chloride (20 ml). PCC (16 mg, 50 mmol) in methylene chloride (100 ml) was added. The mixture was stirred at room temperature for 2 hr, poured into ethyl ether (1.5 l), and the organic phase was washed with aqueous HCl (2 M) followed by saturated sodium bicarbonate solution and water. The organic phase was dried (MgSO_4) and concentrated to give an oil, which, after flash-chromatography and distillation (bp $80\text{--}85^\circ\text{C}/7$ mm Hg), furnished the pure aldehyde (4.3 g, yield 87%, 99% pure, *Z*/*E* = 93/7 by GC); n_{25}^D 1.4491; IR (film) ν_{CO} 1725 cm^{-1} (strong); NMR (60 MHz) δ 0.93 (t, 3H), 1.1–2.2 (m, 10H), 2.43 (dt, 2H, $J = 6.8$ and 1.6), 5.40 (m, 2H), and 9.82 (t, 1H, $J = 1.6$).

Nostrenol, rac-(Z)-6-Undecen-2-ol (3). Methyllithium (1.6 M in ethyl ether, 50 ml) was stirred in dry ethyl ether (100 ml) at -80°C under argon. (*Z*)-5-Decenal (**22**, 4.1 g) in ethyl ether (25 ml) was added dropwise. After stirring for 2 hr, the temperature was raised to -50°C and 2 M aqueous HCl was added. After warming to room temperature the reaction mixture was poured into water. The organic phase was washed with water, dried (MgSO_4), and the solvent evaporated to give an oil, which was flash-chromatographed and dis-

tilled (3.2 g, yield 72%, bp 108–109°C, 12 mm Hg, 99% pure, *Z/E* = 95/5 by GC). This compound had identical IR, [¹H]NMR, and MS spectra and GC behavior (achiral columns) as those of natural nostrenol.

Syntheses of (S)- and (R)-Nostrenol (26 and 28, respectively)

(Z)-1-Chloro-3-octene (25). (Z)-3-Octen-1-ol (**23**, 2.62 g, 20.5 mmol; Zhong et al., 1982), triphenylphosphine (6 g, 23 mmol) and carbon tetrachloride (4 ml) were mixed and heated to 120°C (cf. Hooz and Gilani, 1968). A vigorous reaction occurred. Heating was continued for 15 min. Ethanol (0.5 ml) was added and heating was continued for an additional 15 min. After cooling, pentane (25 ml) was added. Precipitated triphenylphosphine oxide was filtered off and the filtrate was carefully concentrated to give an oil, which, on addition of pentane (10 ml), precipitated further oxide that was removed, and the pentane was evaporated to give an oil. This was chromatographed on silica gel. Pentane eluted the desired product, which was distilled to give 2.92 g (88%). Bp 60–61°C/5 mm Hg; n_{25}^D 1.4486; [¹H]NMR (60 MHz) δ 0.93 (t, 3H), 1.2–1.7 (m, 4H), 1.9–2.3 (m, 2H), 2.54 (quint., 2H, *J* = 7.5), and 5.48 (t, 2H, *J* = 7.5).

(S)-Nostrenol, (S)-(Z)-6-Undecen-2-ol (26). (Z)-1-Chloro-3-octene (**25**, 2.94 g, 20 mmol) in dry THF (15 ml) was added to magnesium turnings (0.72 g, 30 mmol), which had been activated by a few drops of 1,2-dibromoethane under argon. The resulting mixture was heated to reflux for 1 hr. After cooling, the solution of the Grignard reagent was decanted from the excess magnesium and added via a syringe to a solution of CuBr/Me₂S (1 mmol) in THF (20 ml) at –30°C under argon (cf. Huynh et al., 1979). (S)-Epoxypropane (**24**, 1.2 g, 21 mmol) was added. After stirring at –30°C for 1 hr, the temperature was raised to 20°C. The reaction mixture was poured into an aqueous solution of ammonium chloride. The resulting mixture was diluted with pentane and the aqueous layer extracted twice with pentane. The combined organic phases were washed with water, dried (MgSO₄), and the solvent was carefully evaporated to give 2.72 g (80%) after flash-chromatography and distillation, bp 108–109°C/12 mm Hg; [α]_D = +6.02° (neat); *Z/E* ratio > 98.5/1.5 by GC (Carbowax 20 M, 135°C). The [¹H]NMR spectrum (200 MHz) was identical with that of natural nostrenol.

(R)-Nostrenyl benzoate, (R)-(Z)-6-Undecen-2-yl benzoate (27). (S)-Nostrenol (**26**, 1.70 g, 10 mmol), triphenylphosphine (6.55 g, 25 mmol), and benzoic acid (3.05 g, 25 mmol) was stirred in dry THF (100 ml) under argon at 0°C. Diethyl azodicarboxylate (4.52 g, 26 mmol) in THF (10 ml) was added during 5 min. After stirring overnight at room temperature, methanol (0.6 ml) was added to destroy excess reagents. After concentration to 25 ml, the mixture was poured into pentane. The precipitate was removed by filtration and the

solvent evaporated. The remaining oil was flash-chromatographed. Ethyl acetate (2–3%) in light petroleum eluted 2.15 g (78%), pure by GC; $[\alpha]_D = -26.4^\circ$ (neat); ^1H NMR (60 MHz) δ 0.9 (t, 3H), 1.0–2.2 (m, 12 H), 1.37 (d, 3H), 5.2 (sextet, 1H), 5.3 (m, 2H), and 7.2–8.2 (m, 5H).

(*R*)-*Nostrenol*, (*R*)-(*Z*)-6-Undecen-2-ol (**28**). (*R*)-*Nostrenyl benzoate* (**27**, 1.67 g, 0.61 mmol) was dissolved in dry ether (25 ml) under argon. A suspension of lithium aluminium hydride in ether (1 M, 20 ml) was added. The mixture was stirred overnight, when aqueous HCl (2 M) was carefully added to pH 1. After extraction twice with pentane, the organic phase was washed with water, dried (MgSO_4), and concentrated to give an oil, which was flash-chromatographed. Ethyl acetate (3–4%) in light petroleum eluted a colorless oil, which was distilled (Kugelrohr 10 mm Hg/air bath 130°C), 0.9 g (87%); $[\alpha] = -6.08^\circ$ (neat).

rac-(*E*)-6-Undecen-2-ol. This compound was prepared via the reaction sequence described for (*S*)-(*Z*)-nostrenol (**26**) except that the starting materials were *rac*-(*E*)-3-octen-2-ol (Zhong et al., 1982) and racemic epoxypropane; colorless oil, ^1H NMR (60 MHz) δ 0.85 (t, 3H), 1.10 (d, 3H) 1.1–2.2 (m, 9H), 3.8 (m, 1H), and 5.3 (m, 2H); IR (film) 970 cm^{-1} [(*E*)-CH = CH-].

RESULTS

Identification

Typical capillary gas chromatograms of the volatile secretions from *E. nostras* and *G. bore* are given in Figure 1. The two major components in each species were nerol oxide (**1a**) and (*Z*)-6-undecen-2-ol (nostrenol, **3**) in *E. nostras*, and 10-homonerol oxide (**1b**) and nostrenol (**3**) in *G. bore* (Scheme 1). In both species these compounds are found in the proportions 3:2 (in the order mentioned above). The small peaks present in the gas chromatograms emanate from the solvent used for extraction (hydrocarbon isomer and phthalates). Similarly, the major components of *M. formicarius* were found to be nerol (**2a**) and 10-homonerol (**2b**).

SCHEME 1.

FIG. 1. Capillary gas chromatographic separation of the volatile compounds from the thoracic glands of *E. nostras* (A) and *G. bore* (B). Column: Superox FA 27 m \times 0.25 mm. Temperature program: isothermal at 60°C for 2 min and then programmed to 200°C at a rate of 5°C/min.

Structure Determinations

10-Homonerol Oxide (1b). This compound, present in the secretion from males of *G. bore*, has a mass spectrum ($m/e = 166$) very similar to that of nerol oxide (1a). Löfqvist and Bergström (1980) suggested that it was a homonerol oxide. This was confirmed by a methyl triplet present in the [^1H]NMR spectrum, which indicates that the structure can be 10-homonerol oxide (1b) with an ethyl substituent instead of the methyl group in the 3-position (Figures 2 and 3). The other possible isomers, 8- and 9-homonerol oxide (Rohjahn and Bruhn,

FIG. 2. Mass spectrum of natural 10-homonerol oxide (**1b**) from *G. bore*.

1978), were not identical with the natural product as shown by comparisons (GC-MS; NMR) with an authentic sample of a mixture of the two isomers.

In order to confirm the structure of 10-homonerol oxide (**1b**) a synthesis was designed according to Scheme 2. The alkyl cuprate of **4**, prepared from the

FIG. 3. ^1H NMR of natural 10-homonerol oxide (**1b**); approx. 50 μg (in CDCl_3) derived from an extract of 45 males of *G. bore*. The large peak at δ 1.54 belongs to water.

corresponding magnesium reagent, was added to 1-butyne (**5**) followed by treatment with iodine to form the vinyl iodide **6**. Lithiation of **6** followed by alkylation with carbon dioxide yielded the acid **7** (Cahiez et al., 1976). Reduction with lithium aluminium hydride (LAH) afforded the 10-homonerol (**2b**). Photooxidation with singlet oxygen of **2b** and simultaneous reduction with tetramethylammonium borohydride (QBH₄; Bäckström et al., 1982) gave the two isomeric alcohols **8** and **9**. Acidic cyclization of the alcohol mixture (Ohloff et al., 1980) gave the 10-homonerol oxide (**1b**), which was separated from the unreacted alcohol by column chromatography. The GC-MS data and the [¹H]NMR spectrum synthetic **1b** were identical with those of the isolated natural product of *G. bore*.

SCHEME 2.

10-Homonerol (2b). From *M. formicarius* we have earlier identified nerol (**2a**) in the male volatile secretion. A second compound gave $m/e = 168$ (Löfqvist and Bergström, 1980). It has now been identified as 10-homonerol (**2b**) by comparison of GC-MS data (magnetic and quadropole instrument) of the natural substance and the synthetic compound produced as an intermediate in the synthesis of 10-homonerol oxide.

(*Z*)-6-Undecen-2-ol (*Nostrenol*, **3**). This compound was found to be present in the secretions of *E. nostras* and *G. bore*, as shown by identical mass spectra (Figure 4) and GC retention times (Figure 1). It was identified by [¹H]NMR as an undecen-2-ol, which was named *nostrenol* (**3**).

The spectral data gathered for *nostrenol* (**3**) were inconclusive regarding the double bond position. However, preliminary inspection of the [¹H]NMR spectrum suggests the most probable isomers to be **3**, **10**, and **11**. The synthetic procedures of those isomers are outlined in Scheme 3. The key step is the Wittig reaction of the lactols **12**, **13**, and **14** with the appropriate alkylidene phosphoranes **15**, **16**, and **17**, respectively. Wittig reactions in dimethylsulfoxide are known to give a high ratio of *Z* to *E* configuration (Goto et al., 1975; Hall et al., 1975), and this was also found in our case (*Z/E* > 10:1). The lactols **12**, **13**, and **14** were prepared in excellent yields by reduction of the corresponding lactones **18**, **19**, and **20** with diisobutylaluminum hydride in tetrahydrofuran. The lactone **18** was obtained from 2-methylcyclohexanone on oxidation with *m*-chloroperbenzoic acid.

Racemic compound **3** was prepared from (*Z*)-5-decenol (**21**) via oxidation to (*Z*)-5-decenal (**22**) by pyridinium chlorochromate. The aldehyde was then reacted with excess methylolithium in ethyl ether at low temperature which furnished (*Z*)-6-undecen-2-ol (**3**).

The [¹H]NMR spectra of the (*Z*)-undecen-2-ols **3**, **10**, and **11** as well as that of the natural product isolated from *E. nostras* are shown in Figure 5. From

FIG. 4. Mass spectrum of natural *nostrenol* (**3**) from *E. nostras*, also present in *G. bore*.

SCHEME 3.

FIG. 5. ^1H NMR spectra of extract from *E. nostras* (top), (*Z*)-6-undecen-2-ol (**3**), (*Z*)-7-undecen-2-ol (**10**), and (*Z*)-5-undecen-2-ol (**11**) (bottom). For comparison the signals from the vinylic protons are expanded.

the comparison of these spectra it is evident that (*Z*)-6-undecen-2-ol (**3**) is identical with the natural nostrenol.

Absolute Configurations

Nerol oxide (1a). It was of interest to investigate whether the identified compounds from the ant-lions were optically active and if there was any difference in chirality between the three species. Samples of nerol oxide with known absolute configurations (Ohloff et al., 1980) were investigated. $\text{Eu}(\text{HFC})_3$ was added to (*S*)-nerol oxide ($L/S = 0.5$), and the ^1H NMR showed that the low-field doublet at δ 5.6–5.8 belonged to H-7 of (*S*)-nerol oxide. When a solution of racemic nerol oxide and $\text{Eu}(\text{HFC})_3$ ($L/S = 0.5$) was added to the sample of (*S*)-nerol oxide and $\text{Eu}(\text{HFC})_3$, the ratio between the two doublets changed according to the ratio between the *S*-enantiomer and the racemate. Thus (*R*)-

nerol oxide gives rise to the upfield doublet in this region. Addition of 0.45 equivalents of $\text{Eu}(\text{HFC})_3$ to naturally occurring nerol oxide (200 μg) from *E. nostras* resulted in two signals from H-7 in a 1 : 1 ratio, showing that this natural nerol oxide is racemic.

The nerol oxide from *E. nostras* was also analyzed using fused silica capillary GC columns coated with either Ni(II)- or Mn(II)-bis[3-heptafluorobutyryl-1(*R*)-camphorate] (Schurig and Weber, 1981, 1984). The results confirmed that the nerol oxide is racemic. (*S*)-Nerol oxide was used as reference. The elution order of the *S*-enantiomer compared to that of the *R*-enantiomer was reversed on the two columns (see Methods and Materials).

10-Homonerol Oxide (1b). The homonerol oxide isolated from *G. bore* was similarly tested and found to be racemic. However, only the Mn(II)-derived chiral phase separated the enantiomers of **1b**. The close relationship between **1a** and **1b** suggests also that (*S*)-10-homonerol oxide has the shorter retention time (see Methods and Materials).

Nostrenol (3). In order to establish the chirality of natural nostrenol an asymmetric synthesis was outlined as shown in Scheme 4. (*Z*)-3-Octen-1-ol (**23**) (Zhong et al., 1982) and commercially available (*S*)-epoxypropane (**24**) were used as starting materials. The alcohol **23** was transformed into the chloride **25** on treatment with triphenylphosphine and tetrachloromethane (Hooz and Gilani, 1968). The chloride was converted to the alkyl cuprate via the corresponding Grignard reagent followed by reaction with (*S*)-epoxypropane (**24**) to furnish (*S*)-nostrenol (**26**). The *R*-enantiomer was prepared from (*S*)-nostrenol (**26**) via a Mitsunobu reaction (Mitsunobu, 1981). Thus, (*S*)-nostrenol (**26**) was reacted with triphenylphosphine, diethyl azodicarboxylate, and benzoic acid, which gave (*R*)-nostrenyl benzoate (**27**). Reduction with lithium aluminium hydride furnished (*R*)-nostrenol (**28**). Gas chromatography of the isopropyl carbamates of the two alcohols on a tandem GC column [SE-54/XE-60-(*S*)-valine-(*S*)-2-phenylethylamide] showed that the synthetic enantiomers were almost optically pure ($\approx 93\%$ ee) and contained less than 2% of the *E*-isomer. The latter was prepared as the racemate as described above but starting from (*E*)-3-octen-1-ol (Zhong et al., 1982) and racemic epoxypropane. Retention times were 118.9 min [(*Z*)-(*R*)-6-undecen-2-ol], 119.2 min [(*Z*)-(*S*)], 119.4 min [(*E*)-(*R*)], and 119.7 min [(*E*)-(*S*)] on the tandem GC column.

Nostrenol from *E. nostras* was analyzed by capillary GC as the isopropyl carbamate derivative. The naturally occurring sample was found to be enantiomerically pure ($>99.9\%$) and of *R*-configuration. The nostrenol isolated from *G. bore* was also found to be of *R*-configuration. The retention times were 66.4 min and 66.9 min for the (*R*)- and (*S*)-nostrenols, respectively, on the column coated with XE-60-(*S*)-valine-(*S*)-2-phenylethylamide.

SCHEME 4.

DISCUSSION

The ant-lion species are old from an evolutionary point of view. Therefore, it is of interest to investigate the pheromone systems of these insects in order to gain knowledge of possible isolating mechanisms between closely related species. The male ant-lion species have large thoracic glands, producing characteristic volatile chemicals which exhibit close structural relationships between the different species. The adults live only for a few days during which they must mate. These observations suggest that the substances may form part of a communication system associated with mating and contributing towards isolating mechanisms between the sympatric species.

Löfqvist and Bergström (1980) reported earlier that the thoracic glands of each of the three ant-lion species contained two major volatile constituents. One of the compounds in *E. nostras* was found to be nerol oxide (**1a**), while nerol (**2a**) was identified from *M. formicarius*. In the present investigation we have used [¹H]NMR and/or MS to identify the three remaining components as 10-homonerol oxide (**1b**) in *G. bore*, 10-homonerol (**2b**) in *M. formicarius*, and (*Z*)-6-undecen-2-ol (nostrenol, **3**) in *E. nostras* and *G. bore*. Four of these compounds are biosynthetically related and of isoprenoid origin, whereas the fifth compound, nostrenol (**3**), is of another biogenetic origin. It seems that the three sympatric ant-lion species make use of a combination of a minimum of two substances for reproductive isolation.

Nerol (**2a**) and nerol oxide (**1a**) are well-known plant constituents while their homologs 10-homonerol (**2b**) and 10-homonerol oxide (**1b**) have not been identified previously. Nostrenol (**3**) has been reported as a minor constituent of cognac (ter Heide et al., 1978), but its synthesis and spectral data have not, to our knowledge, been reported in the literature.

Syntheses were designed for 10-homonerol, 10-homonerol oxide, and nostrenol in order to verify the structural assignments and for EAG measurements and bioassays. The biological role of the compounds is currently under investigation.

Three of the isolated compounds possess an asymmetric center, and we have found that nostrenol from the two ant-lion species *E. nostras* and *G. bore* is enantiomerically pure and of *R*-configuration. The nerol oxide of *E. nostras* as well as the closely related 10-homonerol oxide of *G. bore* are racemic. Nerol oxide has not yet been found to occur in nature in a chiral form (Ohloff et al., 1980).

A GC separation of a mixture of *Z*- and *E*-isomers of racemic 6-undecen-2-ols into their chiral entities was successfully performed by connecting one column for the separation of geometrical isomers to a chiral column for subsequent separation into the two pairs of enantiomers. The corresponding isopropyl carbamates were employed for this separation, and use of a nitrogen-

sensitive flame photometric detector gave a sensitivity 10–20 times greater than that with a flame ionization detector.

The amount of the compounds isolated from *E. nostras* was relatively large compared with amounts of pheromone components typically found in insects. Thus, it was possible to obtain a large enough amount of material to determine the chirality of nerol oxide (200 μg) by [^1H]NMR after addition of a chiral shift reagent. The chirality of nerol oxide was also determined in the nanogram range by GC on a column coated with Ni(II)-bis[3-heptafluorobutyryl-1(*R*)-camphorate]. This chiral phase could not, however, separate the enantiomers of 10-homonerol oxide. On the other hand the corresponding Mn(II)-derived GC phase separated the enantiomers of both nerol oxide and 10-homonerol oxide. Furthermore, the order of elution of the two enantiomers of nerol oxide was reversed on these two chiral GC phases.

The NMR technique for structural and configurational studies has rarely been used on insect pheromones, which are generally produced only in nanogram quantities. Silverstein and coworkers (Plummer et al., 1976; Stewart et al., 1977) have reported the enantiomeric composition of a few pheromones (alcohols and ketals) determined by the addition of shift reagents. The quantity (150–200 μg) of compound used in these and the present investigation is at present the minimum amount for determination of chirality by addition of a chiral shift reagent.

Acknowledgments—The authors thank Dr. G. Ohloff, Firmenich SA, for kindly supplying samples of (*R*)- and (*S*)-nerol oxide. Special thanks are also due to Dr. E. Klein, Dragoco, for showing interest in this work and for the sample of the 8- and 9-homonerol oxides, and to Dr. T. Ohlsson, Department of Organic Chemistry, Chalmers University of Technology, Göteborg, for the synthesis of manganese(II)-bis[3-heptafluorobutyryl-1(*R*)-camphorate]. We also warmly thank Elisabeth Marling for valuable help with collecting and rearing the insect.

HPLC IDENTIFICATION OF ALLELOPATHIC COMPOUNDS FROM *Lantana camara*¹

MEGH SINGH, RAMA V. TAMMA, and HERBERT N. NIGG

University of Florida, Institute of Food and Agricultural Sciences
Citrus Research and Education Center
700 Experiment Station Road
Lake Alfred, Florida 33850

(Received January 26, 1987; accepted October 29, 1987)

Abstract—Aqueous extracts of *Lantana camara* L. leaves inhibited ryegrass (*Lolium multiflorum* Lam.) germination and seedling growth. Phytotoxic compounds were fractionated from crude aqueous extracts and fractions were evaluated for their phytotoxicity. Inhibition was most pronounced with the alkaline and acid hydrolysates. Plant inhibition by the crude extract reflected a complex interaction of numerous individual components of diverse chemical compositions and potencies. Presumptive identification of the individual components was accomplished with high-performance liquid chromatography (HPLC). Thirteen phenolic compounds were identified, and most of these compounds were phytotoxic to ryegrass seedlings. Radicle elongation was more sensitive to the toxins than shoot elongation.

Key Words—Allelopathy, *Lantana camara*, ryegrass, phenolic compounds.

INTRODUCTION

Lantana camara L., a widespread weed in many citrus groves in Florida, is also one of the world's worst weeds (Holm et al., 1977). Its leaves and seeds are toxic to many animals (McSweeney and Pass, 1982; Sharma et al., 1981) and humans (Mortan, 1971). Habeck (1976) suggested that lantana competes with citrus for nutrients, but there is no experimental evidence to substantiate this claim. Pope et al. (1983), Rice (1984), Achhireddy and Singh (1984), Achhireddy et al. (1985), and Mersie and Singh (1987) previously reported the

¹ Florida Agricultural Experiment Station Journal Series No. 7906.

effect of lantana extracts on various weed and crop species. The nature and characteristics of the inhibitory compounds were not determined. This study deals with the isolation and identification of allelochemicals (particularly phenolics) in fractions of lantana extracts and the gross determination of their biological activity on ryegrass (*Lolium multiflorum*).

METHODS AND MATERIALS

Materials. Leaves of lantana were collected in the vicinity of Lake Alfred, Florida. Phenolic standards used in this study were obtained from Sigma Chemical Company (St. Louis, Missouri). Solvents were from Burdick and Jackson Laboratories, (Muskegon, Michigan).

Extraction and Isolation of Phytotoxins. Methanol, methylene chloride, and water extracts (1000 ml each) of 100 g fresh lantana leaves were preliminarily tested on ryegrass seed growth. Concentration equivalents of 5, 10, and 25 mg of fresh leaf tissue/Petri dish were used in the ryegrass bioassay.

Since water is the extraction solvent in nature, the procedures were designed to allow a natural release of toxins. A crude aqueous extract was prepared by soaking 100 g of fresh leaf material in 1000 ml of distilled water for 48 hr. The liquid was decanted, the leaves were reextracted twice by soaking the leaf residue in 100 ml distilled water for 24 hr, and the extracts combined. The aqueous extract was filtered through cheesecloth and the solids discarded. The filtrate was centrifuged for 15 min at 3000 rpm and the supernatant decanted. The residue was washed twice with 50 ml of water, centrifuged, and all supernatants were combined. The final filtrate was concentrated to 1000 ml in vacuo below 40°C.

The aqueous extract (fraction 1) obtained as above was first extracted 3× with 100 ml of hexane to remove lipids (fraction 2). The resulting aqueous solution (fraction 3) was extracted with diethyl ether (fraction 4). The remaining aqueous fraction (fraction 5) was subjected separately to acid and alkaline hydrolyses. Acid hydrolysis was carried out in the dark in a water bath at 40°C for 2 hr in 2 N HCl. The hydrolysate was extracted with diethyl ether (fraction 8). Alkaline hydrolysis was also carried out in the dark with 2 N NaOH for 2 hr under nitrogen at room temperature and the hydrolysate extracted with ethyl ether (fraction 6). All extractions with ethyl ether (100 ml) were repeated three times. The severe acid and alkaline hydrolyses were employed to release the potential allelochemical moieties from water soluble conjugates. Each of these fractions, along with the remaining aqueous fractions from alkaline (fraction 7) and acid (fraction 9) hydrolyses, was used for bioassay as described below (Figure 1).

Tests for Phytotoxicity. Phytotoxicity of the various lantana fractions was

determined through germination assays using ryegrass seeds. Two Whatman No. 1 filter papers in 9-cm glass Petri dishes were initially wetted with 5 ml of treated solution at concentrations equivalent to 5, 10, and 25 mg of leaf fresh weight/Petri dish. After the solvent evaporated, 10 ryegrass seeds were placed in each dish and 5 ml of glass-distilled water were added. The experiment was conducted in the laboratory at 25°C with a 12-hr photoperiod (150 $\mu\text{E}/\text{m}^2/\text{sec}$). Control treatments received 5 ml of glass-distilled water. After seven days, growth was determined by measuring the lengths of roots and shoots. Seeds were considered germinated if the radicle had emerged from the seed coat. The experiment was repeated twice in triplicate sets.

Analytical Method. Gradient separation (Table 1) and identification of the different fractions was accomplished on a high-performance liquid chromatograph (Waters Associates, Milford, Massachusetts), model 6000 A pump, equipped with a U6K injector. Elution was monitored at 280 nm using a variable wavelength Perkin Elmer LC 75 spectrophotometric UV detector. All injections were 10 μl ; samples were filtered through a 0.45- μm filter prior to injection into the chromatograph. Separation by HPLC was done by using a reverse-phase C 18- μ Bondapak column (7.8 mm \times 30 cm). A Waters 730 Data Module and a 721 System Controller were used for retention times and peak areas. Presumptive identification of allelopathic compounds was done by comparison of retention times of unknown peaks with retention times of authentic standards.

Biological Activity of Identified Compounds. Phytotoxicity of each of the identified compounds was further verified with a 100 ppm solution using the bioassay procedure described above.

Data Analyses. The experiment was a randomized design with three replications for each treatment. Data from each experiment were expressed as per-

TABLE 1. GRADIENT HPLC CONDITIONS

cent of the untreated control and then were combined (six replications per compound/fraction per concentration). The statistical model was a one-way analysis of variance, which allowed the means for fraction/standards and concentration to be pooled.

RESULTS AND DISCUSSION

Preliminary results showed inhibitory activity of methanol, methylene chloride, and water extracts on the growth of ryegrass roots and shoots by all three concentrations (5, 10, and 25 mg fresh weight/petri dish) of leaf extracts (Table 2). Water extracts were slightly less inhibitory than the extracts by the organic solvents. The inhibitory effect was more pronounced on root growth.

The aqueous leaf extract exhibited phytotoxic effects on ryegrass growth and seed germination (Table 3). A stepwise separation of the crude extract (Figure 1) and the various fractions resulted in a diminishing activity with some fractions. Fraction 3 (crude extract minus lipids) was as effective as the crude extract. The phenolic acids (fractions 6 and 8) and aglycones (fraction 4) all reduced germination of the test species, but the effect was slightly greater with fraction 6 (alkaline hydrolysate). This may be because more phenolic acids were liberated with alkaline hydrolysis of the water extract than with acid hydrolysis. The 2 N HCl will cleave most of the glycosidic linkages and 2 N NaOH at room temperature will cleave esters. The aqueous fractions from acid (fraction 9) and alkaline (fraction 7) hydrolyses inhibited ryegrass root growth slightly. The different leaf fractions varied in their ability to affect germination and growth of ryegrass. The basic (fraction 6) and acidic (fraction 8) organic fractions were the most active (Table 3; Figure 1).

TABLE 2. INHIBITION OF ROOT AND SHOOT LENGTHS OF RYEGRASS BY METHANOL, METHYLENE CHLORIDE, AND AQUEOUS EXTRACTS OF LANTANA LEAVES

^aSee Figure 1 for fractions 1-9.

^bThe average lengths of roots and shoots for control were 6.4 and 5.2 mm, respectively.

^cDifferences between fractions.

All fractions except fraction 2 (lipids) were toxic, to some extent, to ryegrass root and shoot growth. Toxicity depended upon concentration. Most extracts did not inhibit germination. Root growth was inhibited (69.5% of control) even at a low concentration of 5 mg fresh weight/Petri dish of the crude aqueous extract. Shoot growth was generally less affected. Previous studies (Achhireddy et al., 1985) indicated a greater sensitivity of root growth than shoot growth to inhibitors.

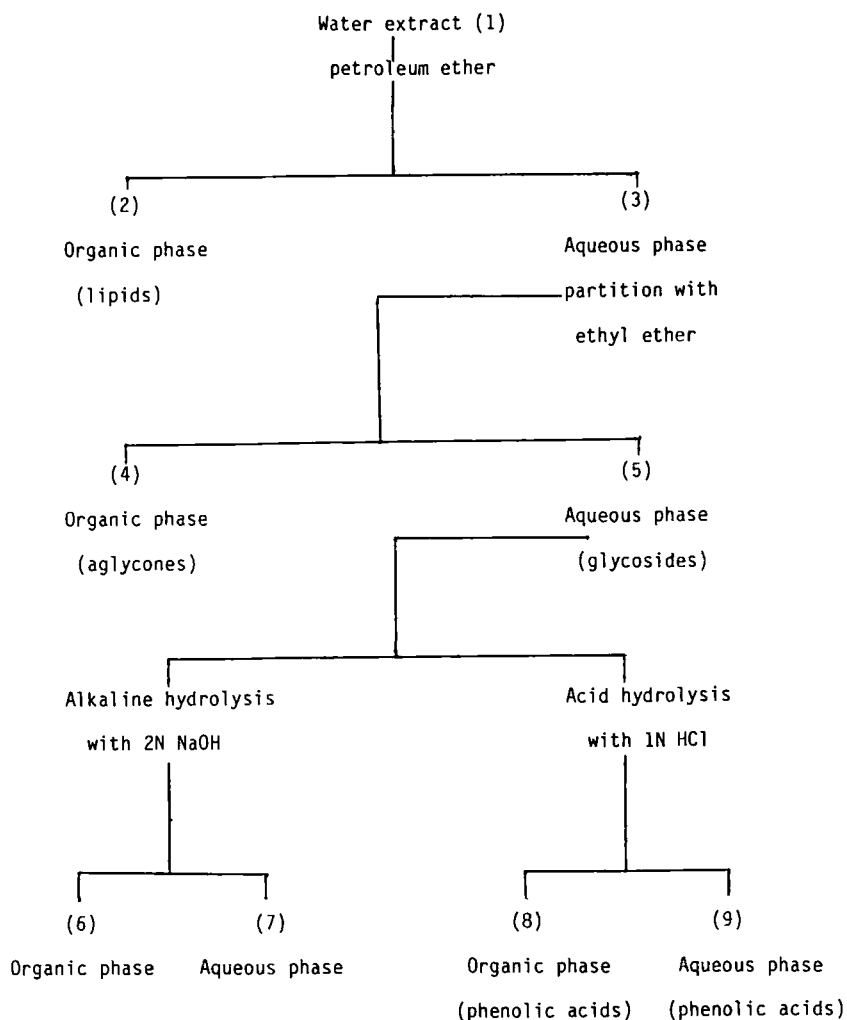

FIG. 1. Flow diagram for the separation of inhibitory compounds from the aqueous extract of *Lantana camara*.

The inhibitory basis of fractions 1 and 3 is probably the result of the combined expression of numerous components of diverse potencies, a phenomenon reported by several workers (Wilson and Rice, 1968; Muller and Chou, 1972; Lodhi, 1975). Phytotoxic effects on seed germination and seedling growth of ryegrass ranged from 58 to 100% inhibition for seed germination; 10–90% for root growth, and 10–50% for shoot growth (Table 3). The degree of inhibition

Ferulic acid	4-hydroxy, 3-methoxycinnamic acid	Alkaline	17.8	194.2	0.52	44.4	68.0
Quercetin	3,3',4',5',7'-pentahydroxyflavone	Organic	21.5	302.2	0.33	72.2	85.1
LSD (0.05)						3.5	4.1

^aSee Figure 1 for fractions 1-9.^bThe average lengths of roots and shoots for control were 5.7 and 4.5 mm, respectively.

could be classified into three levels based on concentration. Dilute concentrations (5 mg fresh weight/Petri dish) did not inhibit seed germination and shoot length but root lengths were reduced. With 10 mg fresh weight/Petri dish, root and shoot lengths were affected more than seed germination. Twenty-five milligrams fresh weight per Petri dish involved complete inhibition of seed germination and resulted in blackening of the seeds.

Phenolics that have been isolated and identified from lantana leaves are umbelliferone, methyl coumarin, gentisic acid, β -resorcylic acid, α -resorcylic acid, *p*-hydroxybenzoic acid, salicylic acid, vanillic acid, caffeic acid, *p*-coumaric acid, vanillin, ferulic acid, and quercetin. These compounds have been reported to be allelopathic (McPherson et al., 1971; Rice, 1984; Fay and Duke, 1977).

Umbelliferone, methyl coumarin, vanillin, quercetin, and a few unknown compounds were found in fraction 5. All other identified compounds were found only after acid or alkaline hydrolyses. Gentisic acid was identified in the acid hydrolysate; and caffeic, *p*-coumaric, and ferulic acids were identified in the alkaline hydrolysate. The other phenolic acids were found in the acidic and basic fractions (Table 4). Overall, more phenolic compounds were found in the alkaline extracts.

To verify the phytotoxic effect of these compounds, 100 ppm solutions of individual authentic compounds were tested on ryegrass growth (Table 4). Of the 13 compounds tested, umbelliferone, methyl coumarin, β -resorcylic, *p*-hydroxybenzoic, salicylic, and ferulic acids reduced ryegrass growth. The aromatic acids were generally more active than the alcohols (Table 4). The activity of phenols decreased as the number of hydroxyl groups increased.

We conclude from these studies that several phenolic compounds found in lantana inhibit ryegrass seed germination and seedling growth. The severity of growth inhibition depended on the concentration and compound. Roots were affected more than shoots. Information on naturally occurring plant growth inhibitors may provide leads for the development of new, more efficient and selective herbicides.

Acknowledgments—We wish to thank Ms. Kathy M. Dedlow and Mr. H. Kevin Hostler for technical assistance during this study.

Abstract— ω -Fluorinated (*E*)-11-tetradecenal (14F-E11-14:Al) was synthesized using 1,10-decanediol as a starting compound. Male and female western spruce budworm, *Choristoneura occidentalis* Freeman, moths exposed to 14F-E11-14:Al had LC_{50s} (CI) of 12.0 (7.4–19.5) μ g and 41.7 (22.7–76.2) μ g, respectively. Antennectomized moths had lower mortality rates than normal moths. 14F-E11-14:Al elicited slightly lower amplitudes than 97:3 (*E/Z*)-11-tetradecenal (*E/Z*11-14:Al) in electroantennogram studies, but the lag or recovery period following excitation by 14F-E11-14:Al was much lower than for *E/Z*11-14:Al at the same concentrations. 14F-E11-14:Al and *E*11-14:Al evoked similar responses from male moths in wind-tunnel evaluations but neither compound was as effective as a virgin female in stimulating moths to fly upwind to contact the lure.

Key Words—Fluorinated pheromone analog, western spruce budworm, *Choristoneura occidentalis*, Lepidoptera, Tortricidae, electroantennogram, wind tunnel, toxicity, (*E*)-14-fluorotetradec-11-en-1-ol.

INTRODUCTION

Fluorine is used as an isosteric replacement for hydrogen in organic molecules, and several fluorinated insect pheromones have been synthesized that show biological activity similar to the natural pheromones (Camps et al., 1984a, b; Briggs et al., 1986). An ω -fluorinated analog of the trail pheromone of the eastern subterranean termite, *Reticulitermes flavipes* (Kollar), displayed latent toxicity (Carvalho and Prestwich, 1984) possibly by a mechanism similar to the in vivo β -oxidation of long-chain ω -fluorinated fatty acids to fluoroacetate (Pattison, 1959). Thus the fluorinated analog acted as a proinsecticide, and the oxidative enzymes of the insects were recruited to generate the potent toxin fluoroacetate (Prestwich, 1986; Prestwich et al., 1984), which would block the citric acid cycle by the formation of fluorocitrate (Peters, 1957).

We synthesized the ω -fluorinated analog of the major component of the western spruce budworm, *Choristoneura occidentalis* Freeman, a major defoliator of Douglas-fir in western North America (Furniss and Carolin, 1977), and evaluated its biological activities by toxicity determinations, wind-tunnel studies, and the electroantennogram technique.

METHODS AND MATERIALS

Synthesis

All reagents were obtained from commercial suppliers and were used without further purification. Tetrahydrofuran (THF) was distilled from sodium benzophenone ketyl, and dichloromethane (CH_2Cl_2) and triethylamine were distilled from CaH_2 . [^1H]NMR spectra were recorded at 270 MHz on a modified Nicolet-Oxford H-270 spectrometer, and at 400 MHz on a Bruker WH-400 spectrometer in deuteriochloroform with tetramethylsilane as the internal standard. EI mass spectra were recorded on a Kratos AEI MS-902 or MS-50 spectrometer at 70 eV. Infrared spectra of the neat liquids were obtained on a Perkin-Elmer 710B instrument. Thin-layer chromatography was performed using Merck (Kieselgel 60F₂₅₄, 0.2 mm) precoated TLC plates. Flash chromatography (Still et al., 1978) was performed on Merck silica gel G (400–230 mesh) using ethyl acetate–petroleum ether, bp 60–80, mixtures (v/v). Elemental analysis was carried out by Mr. P. Borda of the UBC Microanalytical Laboratory. GC analyses were carried out on a Hewlett-Packard 5880A gas chromatograph using an OV-101 glass capillary column (12 m) with a He flow rate of 1.0 ml/min, and a temperature program of 50–260°C at 20°C/min. Structures of compounds numbered below are shown in Figure 1.

2-(9-Bromononyl)-1,3-dioxane (**3**). Dimethyl sulfoxide (35.5 g, 0.5 mol) was added slowly dropwise over a period of 30 min to a cold (Dry Ice–acetone)

FIG. 1. Scheme for synthesis of (*E*)-14-fluorotetradec-11-en-1-al (**11**). Reagents: (i) 48% HBr, H₂O, heptane, 80°C; (ii) DMSO, (COCl)₂, Et₃N, -78°C; (iii) HO(CH₂)₃ OH, PPTS, PhCH₃, reflux; (iv) LiNH₂, NH₃ liq; (v) PPTS, MeOH; (vi) LiAlH₄, diglyme, 140°C; (vii) CH₃SO₂Cl, Et₃N, CH₂Cl₂, 0°C; (viii) nBu₄NF, THF; (ix) AcOH, H₂O, reflux.

solution of oxalyl chloride (22.1 ml, 0.25 mol) in CH₂Cl₂ (750 ml) stirring under N₂. The solution was stirred for a further 20 min, and then a solution of 10-bromodecanol (50.0 g, 0.21 mol) in CH₂Cl₂ (90 ml) was added slowly dropwise over a period of 45 min. After a further 15 min, triethylamine (100 ml, 0.72 mol) was added dropwise and the mixture was allowed to warm to room temperature over a 3-hr period. The reaction was quenched by addition of water, and the reaction mixture was washed with water, 2 M HCl, and satd NaCl soln. After drying and removing the solvent, the crude product was obtained as a yellow oil (53.7 g). The crude aldehyde, 1,3-propanediol (22.8 ml, 0.32 mol)

and PPTS (1.6 g, 6.4 mmol) were dissolved in toluene (500 ml) in a Dean-Stark apparatus and refluxed for 5.5 hr. The reaction was cooled, washed with water, satd NaHCO_3 soln, and NaCl soln. After drying and removing the solvent, the crude product was subjected to vacuum distillation. A colorless oil distilling at 120–140°C at 0.25 mm Hg was collected (51.8 g, 84%): IR (neat) cm^{-1} 1140 (C—O), 2750, 2657 (—O—CHR—O—); MS m/z (%) 293, 291 ($\text{M}^+ - 1$, 12.52, 13.36), 211 (4.14), 137, 135 (14.67, 14.83), 123, 121 (3.12, 4.70), 115 (10.70), 102 (26.24), 97 (15.75), 95 (18.93), 86 (100); [^1H]NMR δ 1.19–1.44 (m, 13H), 1.44–1.59 (m, 2H), 1.95 (quin, 2H), 2.02 (m, 1H), 3.36 (t, 2H), 3.70 (t, 2H), 4.04 (dd, 2H), 4.45 (t, 1H).

2-{13-[(2'-Tetrahydropyranyl)oxy]tridec-10-ynyl}-1,3-dioxane (5). A solution of lithium amide was prepared by adding lithium metal (0.31 g, 19 mmol) to dry liquid ammonia (100 ml, distilled from sodium) under N_2 , and adding a small quantity (1 mg) of ferric nitrate. A solution of 4 (1.50 g, 9.7 mmol), prepared from but-3-yn-1-ol, in THF (10 ml) was added and the mixture left stirring for 1.25 hr. A solution of 3 (2.78 g, 9.5 mmol) in THF (20 ml) was added dropwise over a period of 10 min. The mixture was allowed to warm to room temperature, and the ammonia was evaporated over a period of 21 hr. The residue was dissolved in EtOAc and washed with water, 0.2 M HCl, satd NaHCO_3 soln, and satd NaCl soln. After drying and removing the solvent, the crude product was placed on a silica gel column (80 g) and eluted with 10% EtOAc–petroleum ether, collecting fractions of 20–25 ml. Fractions 17–28 were shown by GC and TLC to contain the product and were combined and evaporated to obtain a yellowish oil (1.74 g, 50%): IR (neat) cm^{-1} 2750, 2680 (—O—CHR—O—), 1145, 1080, 1035 (C—O); MS m/z (%) 366 (M^+ , 0.13), 87 (84.4), 85 (100); [^1H]NMR δ 1.16–1.57 (m, 21H), 1.64 (tt, 1H), 1.72–1.84 (m, 1H), 1.99–2.10 (m, 1H), 2.05 (m, 2H), 2.38 (m, 2H), 3.40–3.50 (m, 2H), 3.65–3.76 (m, 3H), 3.82 (m, 1H), 4.03 (dd, 2H), 4.44 (t, 1H), 4.58 (t, 1H).

(E)-2-(13-Hydroxytridec-10-enyl)-1,3-dioxane (7). A solution of 5 (5.88 g, 16 mmol) and PPTS (0.44 g, 1.7 mmol) in methanol (50 ml) was stirred under N_2 for 22 hr. The reaction mixture was poured into water, extracted with EtOAc, and the organic layer washed with water, satd NaHCO_3 soln, and satd NaCl soln. After drying and removing the solvent, a yellow oil 6 was obtained (4.74 g). A suspension of lithium aluminum hydride (2.1 g, 55 mmol) in diglyme (50 ml) and THF (10 ml) was heated under N_2 at 110°C for 30 min, during which time a small amount of liquid was distilled from the reaction vessel. The solution was cooled to 0°C and a solution of 6 in diglyme (12 ml) was added via syringe. The solution was then maintained at 140°C for 93 hr. The reaction mixture was then slowly poured into a mixture of ice and satd Rochelle salt soln which was then extracted with EtOAc. The organic layer was washed with water, and satd NaCl soln, dried, and the solvent removed. The crude product was placed on a silica gel column (200 g) and was eluted with 30% EtOAc–

petroleum ether, collecting fractions of 25 ml. Fractions containing the product were combined and evaporated to obtain a yellowish oil (3.32 g, 69.6%): IR (neat) cm^{-1} 3450 (—OH), 1150, 1060 (C—O), 980 (CH=CH); MS m/z (%) 284 (M^+ , 0.17), 283 (1.00), 254 (0.94), 209 (1.55), 87 (100); [^1H]NMR δ 1.20–1.47 (m, 15H), 1.53–1.64 (m, 2H), 2.01 (q, 2H), 1.87–2.18 (m, 1H), 2.26 (q, 2H), 3.63 (t, 2H), 3.76 (td, 2H), 4.11 (dd, 2H), 4.53 (t, 1H), 5.41 (dt, 1H), 5.56 (dt, 1H).

(*E*)-2-(13-Fluorotridec-10-enyl)-1,3-dioxane (**9**). A solution of **7** (1.80 g, 6.3 mmol) in CH_2Cl_2 (50 ml) was cooled to 0°C and triethylamine (1.30 ml, 9.50 mmol) was added, followed 5 min later by methanesulfonyl chloride (0.59 ml, 7.60 mmol). The mixture was stirred for 3 hr, then diluted with dichloromethane and washed with water, 0.3 M HCl, satd NaHCO_3 soln, and satd NaCl soln. After drying and removing the solvent, a yellowish oil was obtained. This crude product was dissolved in THF (50 ml), 4 Å molecular sieves (3.0 g) and Bu_4NF (1 M in THF, 10.0 ml) were added, and the mixture stirred at room temperature under N_2 overnight (19 hr). More Bu_4NF (2.0 ml) was added and the mixture refluxed for 2 hr. The reaction was filtered through a short silica gel plug, which was washed with Et_2O and EtOAc. The filtrate was evaporated, and the residue dissolved in EtOAc and washed with water and satd NaCl soln. After drying and removing the solvent, the crude product was placed on a silica gel column (40 g) and eluted with 5% EtOAc–petroleum ether. Fractions containing the second slower-moving product were combined and evaporated. This crude product and maleic anhydride (0.5 g, 5 mmol) were dissolved in toluene (50 ml) and heated to reflux for 5 hr. The reaction mixture was diluted with EtOAc and washed with water, satd NaHCO_3 soln, and satd NaCl soln. After drying and removing the solvent, the crude product was placed on a silica gel column (40 g) and eluted with 5% EtOAc–petroleum ether, collecting fractions of 10 ml. Those fractions containing the product were combined and evaporated to obtain a yellowish oil (0.76 g, 42%): IR (neat) cm^{-1} 2750, 2690 (—O—CHR—O—), 1150 (C—O), 1000 (C—F), 970 (CH=CH); MS m/z (%) 286 (M^+ , 0.93), 285 (4.15), 266 (1.40), 87 (100); [^1H]NMR δ 1.23–1.42 (m, 15H), 1.53–1.61 (m, 2H), 1.99 (q, 2H), 1.95–2.12 (m, 1H), 2.38 (dq, 2H, $J_{\text{HF}} = 24$ Hz), 3.74 (td, 2H), 4.08 (dd, 2H), 4.34, 4.46 (dt, 2H, $J_{\text{HF}} = 46$ Hz), 4.49 (t, 1H), 5.38 (dt, 1H), 5.54 (quin, 1H). Anal. Calcd. for $\text{C}_{17}\text{H}_{31}\text{FO}_2$: C, 71.28; H, 10.91. Found: C, 70.98; H, 11.04.

(*E*)-14-Fluorotetradec-11-en-1-ol (**11**). A solution of **9** (0.67 g, 2.3 mmol) in acetic acid (9 ml) and water (1.5 ml) was heated at reflux under N_2 for 5 hr. The reaction mixture was diluted with Et_2O and washed with water, satd NaHCO_3 soln, and satd NaCl soln. After drying and removing the solvent, the crude product was placed on a silica gel column (40 g) and eluted with 5% EtOAc–petroleum ether, collecting fractions of 10 ml. The purest fractions were combined and evaporated to yield a colorless oil (0.27 g, 50%), which was

shown to be 97.6% pure by GC. (The only other peak on the GC trace was assigned to the corresponding chloro compound). Combination of the other fractions yielded less pure product (0.14 g, 26%): IR (neat) cm^{-1} 2750 ($-\text{CHO}$), 1730 ($\text{C}=\text{O}$), 1010 ($\text{C}-\text{F}$); MS m/z (%) 210 ($\text{M}^+ - \text{H}_2\text{O}$, 1.51), 209 ($\text{M}^+ - \text{F}$, 0.45), 208 ($\text{M}^+ - \text{HF}$, 2.13), 200 ($\text{M}^+ - \text{C}_2\text{H}_4$, 0.32), 122 (22.04), 121 (24.06), 98 (34.21), 94 (78.84), 55 (100); [^1H]NMR δ 1.20–1.42 (m, 12H), 1.64 (m, 2H), 2.03 (q, 2H), 2.43 (td, 2H), 2.31–2.49 (m, 2H), 4.35, 4.53 (dt, 2H, $J_{\text{HF}} = 48\text{Hz}$), 5.44 (dt, 1H), 5.54 (dt, 1H), 9.93 (t, 1H, $-\text{CHO}$). Anal. Calcd. for $\text{C}_{14}\text{H}_{25}\text{FO}$: C, 73.64; H, 11.04. Found: C, 73.49; H, 11.09. Mol. Wt. Bioassay

Budworms were reared on artificial diet in 180-ml plastic cups in the laboratory at 24–26°C and 30–50% relative humidity. The moths were maintained in individual 180-ml cups at 16:8 light–dark with scotophase at 1500 hr (PST). Adult emergence was checked daily, except on weekends, and males were used in wind-tunnel experiments when two to six days posteclosion.

Toxicity Tests. LC_{50}s of (*E*)-14-fluorotetradec-11-en-1-al (14F-E11-14:Al) were determined for both male and female western spruce budworm moths. 14F-E11-14:Al was diluted in *n*-heptane at concentrations ranging from 0.03 to 3.0 mg/ml. One drop (approx. 14 μl) of a given concentration was added to a circle of filter paper (Whatman 42; 2.00 cm^2). After allowing the solvent to evaporate, the filter paper was placed inside a 180-ml plastic specimen cup containing four or five moths 2–5 days old (mean age = 3.4 days). Each concentration was tested with 8–10 moths. Moths were kept in a fume hood at 23–26°C and 10:14 light–dark and observed after 24 hr. Both 97:3 (*E/Z*)-11-tetradecenal (*E/Z*11-14:Al) and *n*-heptane were used as controls. Mortality was corrected by Abbott's formula and mortalities of 0% and 100% were excluded from computation of the LC_{50} . The LC_{50}s and 95% confidence intervals (CI) were determined for 24-hr exposure and the log-dosage probit line was tested for goodness of fit by chi-square.

To test the hypothesis that toxicity was acting primarily through adsorption and reaction with antennal receptors, we compared the mortality between antennectomized and normal moths exposed to 14F-E11-14:Al. The antennae were severed as near as possible to the head and the moths exposed to one drop on filter paper of either 2.5 mg/ml 14F-E11-14:Al or *n*-heptane for 24 hr.

Antennal Sensitivity to 14F-E11-14:Al. 14F-E11-14:Al and *E/Z*11-14:Al were formulated in polyvinyl chloride (PVC) (Daterman, 1974) in concentrations of 0.0005 to 0.5% (w/w). Antennal responses were recorded using the electroantennogram technique (EAG) described by Roelofs (1977) with modi-

fications described in Sweeney and McLean (1987). Each of 15 male moths was tested for its response to four concentrations of both 14F-E11-14:Al and E/Z11-14:Al. The concentrations were tested in order of increasing strength; at each concentration the treatment order was decided by the toss of a coin. Each replicate was the mean of five treatment responses corrected by subtracting the mean of three control (blank PVC) responses both preceding and following the treatment. Two variables from the EAG were used to quantify the budworm's response: (1) peak amplitude of antennal depolarization; and (2) the time from initial depolarization to the return to the baseline signal (=lag), i.e., the total width of the signal deflection.

Wind-Tunnel Observations. The wind tunnel was as described by Angerilli and McLean (1984) but was modified by removing the baffles from the intake end, adding activated charcoal filters, and reducing its length by 1.2 m. Male moths were released in groups of four to six on a platform 2 m downwind (windspeed = 40 cm/sec) from a lure consisting of either 14F-E11-14:Al, E11-14:Al, or a virgin female, and were observed for 3 min. All lures were held within fiberglass screen cages about 5 × 5 × 3 cm. The moths were scored for wing-fanning, taking off, locking-on (flying a zigzag course upwind towards the pheromone source), landing at the pheromone source, and displays of copulatory behavior on the lure cage (curling their abdomen to the side while wing fanning).

RESULTS AND DISCUSSION

The ω -fluorinated pheromone was prepared by the sequence of reactions shown in Figure 1. 10-Bromodecanal (**2**) was obtained in two steps from 1,10-decanediol (**1**), protected as its cyclic acetal **3**, and coupled with the protected acetylenic alcohol **4** in moderate yield. Acidic hydrolysis of **5** removed the tetrahydropyranloxy group, leaving the acetal intact, and the resultant β -hydroxyacetylene **6** was reduced stereoselectively (LAH/150°C) (Rossi and Carpita, 1977) to the (*E*)-homoallylic alcohol **7**. Preparation of the mesylate **8**, followed by treatment with tetra-*n*-butylammonium fluoride (Foster et al., 1967) yielded a mixture of the desired β -fluoroalkene **9**, and the diene **10**. The latter could be removed by performing a Diels-Alder reaction on the crude reaction product using maleic anhydride in refluxing toluene, and isolating the unreacted β -fluoroalkene **9** by chromatography. An attempt to introduce fluorine directly by the reaction of diethylaminosulfur trifluoride (Middleton, 1975) with a related homoallylic alcohol yielded exclusively the rearranged α -fluorocyclopropane derivative. Acidic hydrolysis of the acetal protecting group of **9** furnished the fluorinated pheromone **11** in good yield.

Toxicity

No males were killed by exposure to 0.03 mg/ml 14F-E11-14:Al so this treatment, rather than the *n*-heptane control, was used to calculate corrected mortalities (Swaroop et al., 1966). No mortality occurred in the E/Z11-14:Al controls. The log-dosage probit regression of percentage mortality vs. concentration of 14F-E11-14:Al was significant for males ($r^2 = 0.89$) and females ($r^2 = 0.80$) and both fitted a straight line (chi-square, $\alpha = 0.05$). The LC₅₀ (95% CI) was 0.62 (0.39-1.01) mg/ml for males and 2.17 (1.18-3.96) mg/ml for females. By using a mean of 52 drops/ml of *n*-heptane from a Pasteur pipet, these LC₅₀ values (95% CI) translate to 12.0 (7.4-19.5) μg and 41.7 (22.7-76.2) μg of 14F-E11-14:Al on filter paper for males and females, respectively.

When we removed the moths' antennae, the respective mortalities of male and female moths that were exposed to 2.5 mg/ml 14F-E11-14:Al were only 55% and 50%, compared to 90% and 70% for normal moths. The drop in mortality was significant for the antennectomized males but not the females (Fisher's exact probability test, $P \leq 0.05$). There was no mortality of antennectomized moths exposed only to *n*-heptane.

These results demonstrate that 14F-E11-14:Al is lethal to western spruce budworm moths and that its toxicity is greater for males than females. The LC₅₀ of 14F-E11-14:Al was more than three times lower for male moths than for female moths. The difference in toxicity between sexes may have been due to differences in body weights, antennal sensitivity, or both. Male budworm pupae weigh about 40% less than female pupae (unpublished data). Although we do not rule out the possible effect of body weight, we suspect that the greater toxicity in the male moths was associated with greater antennal sensitivity to the analog. According to EAG recordings, the female moth is much less sensitive to E/Z11-14:Al than is the male moth (unpublished data). Adult female spruce budworm, *C. fumiferana* (Clemens), have one third to one half the number of pheromone-sensitive sensilla trichodea as males (Albert and Seabrook, 1973) and are correspondingly less sensitive to E/Z11-14:Al in EAG comparisons (Palaniswamy and Seabrook, 1978; Ross et al., 1979).

Removal of the moths' antennae significantly reduced the percentage mortality of the males but mortality still occurred. This suggests that 14F-E11-14:Al enters the moth not only through the antennae but also via other body surfaces. Lonergan (1986) found a cuticular enzyme in male and female spruce budworm moths that degraded adsorbed aldehyde pheromone to its corresponding acid. Esterases that degrade pheromone adsorbed to body scales and which probably serve to clean the insect of uncontrolled pheromone sources have been found in the giant silk moth, *Antheraea polyphemus* (Cramer) (Vogt and Rid-diford, 1986a), and the cabbage looper, *Trichoplusia ni* (Hübner) (Ferkovich et al., 1982). From our results we hypothesize that a cuticular enzyme similar

to or the same as that described by Loneragan (1986) is also present in the western spruce budworm moth and that it probably transforms adsorbed 14F-E11-14:Al to (*E*)-14-fluoro-11-tetradecenoic acid. The fluorotetradecenoic acid, due to its even number of carbons, would likely be broken down via β -oxidation to yield the latent toxin fluoroacetate (Peters, 1957; Pattison, 1959).

EAG Response

At the same concentration, 14F-E11-14:Al elicited significantly reduced amplitude and lag than did *E/Z*11-14:Al (Table 1). However, the most notable difference in response was the much shorter recovery period or lag following stimulation with 14F-E11-14:Al. The lag after response to 0.5% *E/Z*11-14:Al was about 14 times longer than the lag after response to 0.5% 14F-E11-14:Al in spite of a difference of only 0.33 mV in amplitude (Table 1).

These data show that the budworm antenna is sensitive to 14F-E11-14:Al, but that the EAG shape is quite different from that of *E/Z*11-14:Al. The difference in amplitude might have been due to different release rates of *E/Z*11-14:Al and 14F-E11-14:Al from PVC but this is unlikely, due to the similarity of molecular size and volatility. The presence of 3% *Z*11-14:Al in the *E/Z*11-14:Al lure may also have contributed to the difference in amplitude; future EAG experiments with 14F-E11-14:Al should include an *E*11-14:Al control. Other possibilities include a difference in the binding affinity at the putative acceptor site and/or fewer of these sites that are sensitive to F-ALD.

TABLE 1. ELECTROANTENNOMETER RESPONSES OF WESTERN SPRUCE BUDWORM MALE MOTHS TO FOUR CONCENTRATIONS OF 14F-E11-14:Al AND *E/Z*11-14:Al FORMULATED IN PVC^a

Concentration in PVC (% w/w)	AMP (mV) ^b		LAG (sec) ^b	
	<i>E/Z</i> 11-14:Al	14F-E11-14:Al	<i>E/Z</i> 11-14:Al	14F-E11-14:Al
0.5	1.34a	1.03b	5.71a	0.41b
0.05	1.06a	0.92b	1.91a	0.13b
0.005	0.65a	0.49b	0.68a	0.10b
0.0005	0.25a	0.16a	0.16a	0.05b

^aEach of 15 male moths was tested for its response to all concentrations of 14F-E11-14:Al and *E/Z*11-14:Al. The concentrations were tested in order of increasing strength; at each concentration the treatment order was decided by the toss of a coin. For each replicate, amplitude (AMP) and LAG responses are the mean of five responses corrected by subtracting the mean of three control responses both preceding and following the treatment.

^bMeans within variable and within row followed by different letter are significantly different; Wilcoxon's matched-pair rank-sum test ($\alpha = 0.05$).

The short recovery period after response to 14F-*E*11-14:Al is very interesting, but we can only speculate on its cause. Roelofs and Comeau (1971) hypothesized that EAG shape and recovery period were related to the affinity of the pheromone component with the putative receptor site, whereas Baker and Roelofs (1976) suggested that differences in EAG recovery rate in response to various compounds might be due to the activation of olfactory neurons with different intrinsic recovery rates. Kaissling (1986) suggested that a long recovery period following a receptor potential might be due to active pheromone molecules remaining at the receptor sites after stimulation and may reflect processes of odor inactivation. The very short recovery period following stimulation by 14F-*E*11-14:Al might be due to an increased affinity for the enzyme(s) responsible for pheromone inactivation, possibly resulting from the substitution of the more electronegative ω -fluorine for the hydrogen. It may also be related to an increased rate of adsorption and transport due to enhanced lipid solubility of fluorinated analogs (Filler and Naqvi, 1982). Experiments using radiolabels, like those of Prestwich et al. (1986) and Vogt and Riddiford (1986b), are required to further elucidate the olfactory biochemistry of the western spruce budworm moth in response to 14F-*E*11-14:Al and *E/Z*11-14:Al.

Behavioral Response to 14F-E11-14:Al

The proportion of budworm that took off, locked-on, reached the lure, and displayed copulatory behavior was not significantly different in response to either 14F-*E*11-14:Al or *E*11-14:Al. However, neither synthetic lure was as effective as a virgin female in eliciting locking-on and upwind flight to the lure (Table 2). This was probably due to the absence of components in the 14F-*E*11-14:Al and *E*11-14:Al lures that are normally present in the virgin female effluvia, chiefly *Z*11-14:Ald. The effluvia of western spruce budworm female moths is composed of a blend of 92:8 *E/Z*11-14:Al + 89:11 (*E/Z*)-11-tetradecenyl acetate + 85:15 (*E/Z*)-11-tetradecenol in about a 10:3:6 ratio (Silk et al., 1982; Cory et al., 1982). Trap catch of western spruce budworm male moths was four times higher in traps baited with 92:8 *E/Z*11-14:Al than in traps baited with the same concentration of *E*11-14:Al alone (Cory et al., 1982). In wind-tunnel experiments with spruce budworm moths, Sanders (1984) found that 95:5 *E/Z*11-14:Al (0.05% in PVC) induced 75% of males to lock-on and sustain flight for greater than 1 min compared to only 10% in response to *E*11-14:Al. We suggest that the addition of *Z*11-14:Al to the 14F-*E*11-14:Al, at the natural ratio (92:8 *E/Z*), would increase the lure's attraction without significantly affecting its toxicity. This remains to be tested however.

Prestwich (1987) described the use of fluorinated pheromone analogs in which the aldehyde moiety has been altered in order to cause sensory disruption. By ω -fluorination, in contrast, we have left the aldehyde functional group intact

TABLE 2. RESPONSES OF WESTERN SPRUCE BUDWORM ADULT MALES TO 0.05% 14F-E11-14:Al (IN PVC), 0.05% E11-14:Al (IN PVC), OR VIRGIN FEMALE IN WIND TUNNEL

Treatment	n (N) ^a	Percentage Response ^b

^an = number of moths able to fly. All moths (N) were used to calculate the percentage of moths wing-fanning and displaying preflight copulatory behavior but only fliers (n) were used to calculate the percentage taking off, locking-on, and landing at the source, and the percentage displaying postflight copulatory behavior.

^bPercentages within each column followed by different letters are significantly different. Fischer exact probability test ($\alpha \leq 0.05$ except where * denotes $\alpha \leq 0.10$).

^cCop = copulatory behavior.

and we have produced an analog that retains considerable biological activity as well as being toxic to budworm moths. Sanders (1982) suggested that mating disruption of spruce budworm would be more effective using a few potent pheromone sources rather than numerous low-potency sources and that disruption would be enhanced by adding an insecticide or sterilant to the pheromone. Our results indicate that 14F-E11-14:Al is toxic to the western spruce budworm and is equivalent to E11-14:Al in terms of long-range attraction of males and that it therefore shows potential as a mating disruptant. However, the practical testing of 14F-E11-14:Al as a mating disruptant must await testing of its toxicity to vertebrates and other nontarget organisms. Other even-numbered ω -fluorinated aldehydes have been shown to be highly toxic to vertebrates (Pattison, 1959). Nonetheless, we are optimistic that these hazards may be reduced significantly by the use of low concentrations, low release rates, and by the containment of lures in traps.

Abstract—Calling behavior and pheromone emission by virgin female *E. loftini* moths were investigated in laboratory experiments. Calling peaked during the last three hours of the night. Three-day-old moths called more than older or younger moths and began calling earlier in the night than younger moths. Female emissions were collected in flasks without airflow and cylinders with airflow. Control tests indicated that the pheromone components (Z)-11-hexadecenyl acetate (HDA) and (Z)-13-octadecenylacetate (ODA) were 69 and 54% adsorbed on moths, respectively, and the component (Z)-13-octadecenal (ODL) was 92–99% adsorbed depending on its concentration, when put into flasks with noncalling females for 4 hr. Pheromone exposed to moths for less than 4 hr was adsorbed less. After correction for adsorption, the pheromone blend from females calling in flasks was 9:42:49% of HDA/ODL/ODA with an overall emission rate of 58 ng/female/4 hr. Three-day-old females emitted more pheromone than 0- to 2- or 4- to 5-day-old moths, in flasks. Little or no pheromone put into cylinders either downwind or upwind from a male moth was adsorbed by the moth. The pheromone blends from females calling in cylinders, corrected using downwind and upwind control test results, respectively, were 15:35:50 and 13:40:48% of HDA/ODL/ODA with overall emission rates of 32 and 35 ng/female/night.

Key Words—Sex pheromones, pheromone adsorption, age, pheromone emission, Lepidoptera, Pyralidae, Crambinae, *Eoreuma loftini*, calling behavior, (Z)-11-hexadecenyl acetate, (Z)-13-octadecenyl acetate, (Z)-13-octadecenal.

INTRODUCTION

Three components of the sex pheromone of *Eoreuma loftini* (Dyar) have been identified by Shaver et al. (1988). The three chemicals, (Z)-11-hexadecenyl acetate (HDA), (Z)-13-octadecenal (ODL), and (Z)-13-octadecenyl acetate (ODA), proved active as sexual stimulants and attractants in laboratory and field experiments when tested in ratios found in abdomens of calling females. However, amounts in abdomens do not necessarily reflect blends emitted by the moths (Tumlinson et al., 1982). In particular, aldehydes are frequently emitted in greater blend percentages than are present in glands (Baker et al., 1980; Ramaswamy and Cardé, 1984). Our work reports when female *E. loftini* of various ages call and how much of each component they emit, as determined by two methods.

METHODS AND MATERIALS

General. Pupae were from cultures that originated in the Lower Rio Grande Valley (LRGV) of Texas. Insects were maintained on a 14:10 light-dark cycle similar to natural summer conditions in the LRGV. Laboratory temperatures ranged between 20 and 27°C and relative humidity between 40 and 75%. Ecdysis began after three to five days under these conditions. Female moths of each age were held in separate wood-frame, screened cages (20 cm/side). Cages were sprayed with water each day during the light period.

Calling Behavior Observations. The numbers of "calling" virgin females of various ages were recorded every half hour during the last 7 hr of the night using night-vision goggles. Calling behavior was described by Brown et al. (1988). Ages were 0, 1, 2, 3, and 4-5 days posteclosion. Since most moths eclosed at night, 0 days posteclosion indicates moths that emerged earlier on the test night. Between 62 and 122 moths of each age were observed over three test nights.

Pheromone Emission in Closed Flasks without Airflow. We collected pheromone emitted by females of various ages in flasks with no airflow using a method similar to that of Baker et al. (1980). Ages were 0, 1, 2, 3, 4, and 5 days posteclosion. For each replication, 25 virgin females of one age were put into a 500-ml round-bottom flask with a glass stopper during the last 4 hr of the night ($N = 10$ replications/age). At the onset of the light period, the flask was chilled at 0°C for 1 h to freeze the pheromone onto the sides of the flask. The dead moths were then discarded from the cold flask. The flask was extracted by shaking for 5 min with each of two 20-ml portions of pentane. The portions were combined, filtered, and concentrated to 100 μ l under a stream of nitrogen with low heat.

To control for sample-handling losses, 100 ng of each component were added to empty 500-ml flasks 4 hr before extraction ($N = 40$). To control for pheromone losses due to adsorption on moths, three additional experiments were conducted. In the first experiment, 0.4, 0.6, and 0.6 μg of HDA, ODL, and ODA, respectively, and 25 males were put into 500-ml flasks 4 hr before extraction ($N = 6$). In the second experiment, various amounts of the three pheromone components and 25 noncalling females were put into flasks 4 hr before extraction. Noncalling females were virgin females used during the photophase. Since these moths moved little compared to calling females, flasks were shaken slightly each hour to stimulate activity. Amounts of HDA, ODL, and ODA, respectively, added to flasks were: 0, 0, and 0 μg ($N = 2$); 0.1, 0.15, and 0.15 μg ($N = 3$); 0.4, 0.6, and 0.6 μg ($N = 8$); 0.7, 1.0, and 1.0 μg ($N = 5$); 1.0, 1.5, and 1.5 μg ($N = 3$); 1.3, 2.0, and 2.0 μg ($N = 6$); and 2.0, 3.0, and 3.0 μg ($N = 3$). In the third experiment, 25 noncalling females were put into flasks and 0.4, 0.6, and 0.6 μg of the three components were introduced in four equal increments at 4, 3, 2, and 1 hr before extraction ($N = 8$). This experiment was to measure adsorption when pheromone was introduced in a way more like calling females would emit it. Extractions of flasks in control experiments were performed exactly as in tests with calling females.

Pheromone Emission in Cylinders with Airflow. This method was used to minimize adsorption of pheromone on calling females. Females of ages 0, 1, 2, 3, 4, and 5 days posteclosion were tested ($N = 2/\text{age}$). For each replication, one virgin female was put into a vertical cylinder (20 cm long \times 0.85 cm ID) with its abdomen oriented downward. The tapered bottom of the cylinder contained glass wool covered with 20 mg of Porapak Q (Supelco, Inc., Bellefonte, Pennsylvania) (50/80 mesh). A 5-cm section containing the moth was located 10 cm above the Porapak Q and was delineated above and below by plugs of glass wool. Another 50 mg of Porapak Q covered the glass wool over the moth section. A humidified airflow of ca. 2–5 cm/sec was directed downward through the cylinder. Moths remained in the cylinders for the entire 10-hr scotophase, except 0-day-old moths, which were put into the cylinders for the last 4 hr of the night.

Cylinders containing the bottom 20 mg of Porapak Q were cleaned with successive rinses of 100 ml of acetone, 100 ml of 10% acetone in pentane, and 50 ml of pentane before testing. To extract pheromone, the cylinder, the bottom 20 mg of Porapak Q, and all glass wool downwind from the moth were rinsed with 20 ml of 5% acetone in pentane. The extract was concentrated to ca. 200 μl under nitrogen at low heat.

Several control experiments were conducted. First, 40, 60, and 60 ng of HDA, ODL, and ODA, respectively, were introduced onto the walls of a cylinder 1 cm downwind of a male moth 4 hr before extraction ($N = 2$). Second, 40, 60, and 60 ng were introduced on the glass wool upwind from a male moth

4 hr before extraction ($N = 9$). The second experiment was also conducted with no moth in the cylinder to control for adsorption onto the upwind glass wool ($N = 2$). Finally, the experiment was conducted with a male moth present but no pheromone introduced to the cylinder ($N = 4$). Extractions were performed exactly as with cylinders containing calling females.

Chemical Analyses. Extracts were prepared for gas chromatography (GLC) using a Waters liquid chromatograph (HPLC) (Waters Associates, Milford, Massachusetts) to remove hydrocarbons that interfere with detection of the pheromones. Two methods were used, as dictated by availability of materials. For flasks with calling females and flask controls without moths, the extract was injected onto a NOVA-PAK C18 Radial-PAK HPLC cartridge (4 μm particle size) in an RCM-100 module using a mobile phase of acetonitrile at 2 ml/min. Detection was at 205 nm (model 490 Programmable Multiwavelength Detector). Eluent fractions were collected from 2 ml of elution volume before the retention volumes of the three pheromones until 2 ml of elution volume after the pheromone retention volumes, as determined by standards. The k' values were ca. 4, 4, and 7 for ODL, HDA, and ODA, respectively. The fractions were combined and reduced to 5–10 μl under a stream of nitrogen at low heat. Gas chromatography was conducted using a Shimadzu GC-9A instrument (Shimadzu Scientific Instruments Inc., Columbia, Maryland) with a flame ionization detector. Analyses were on an SPB-5 capillary column (Supelco) (60 m, fused silica, 0.32 mm ID, 1 μm film). Helium carrier gas linear velocity was 25 cm/sec. A splitless injection (0.5 min split valve closed) of 1–2 μl was used. The column oven conditions were: 50°C for 5 min; 10°C/min increase until 250°C; 250°C isothermal.

For all other pheromone emission and control experiments, extracts were injected onto a Resolve silica Radial-PAK HPLC cartridge (5 μm particle size) in an RCM-100 module. The mobile phase was 2 ml/min of the following: hexane for 2 min; 0.5% isopropyl alcohol in hexane for 4 min; and 1% isopropyl alcohol in hexane for 14 min. Eluent was collected from 18–30 ml of elution volume since ODL eluted between 20–24 ml and HDA and ODA eluted between 26–28 ml. The fraction was concentrated to 5–7 μl , all of which was injected onto a DB-225 Megabore column (J & W Scientific, Rancho Cordova, California) (30 m, fused silica, 0.53 mm ID, 1 μm film). Helium carrier gas linear velocity was 60 cm/sec. A splitless injection was used as before. The column oven conditions were: 50°C for 5 min; 10°C/min increase until 170°C; 2°C/min increase until 190°C; 190°C isothermal. The two chemistry methods proved identical by tests with standards.

Pheromone amounts were quantitated by comparing peak heights to those of standards. Standard HDA and ODL (Sigma Chemical Company, St. Louis Missouri) were greater than 95% pure. Standard ODA (Bedoukian Research, Danbury, Connecticut) was 99% pure. Known amounts of (*Z*)-11-tetradecenyl

acetate and methyl arachidonate were added to the syringe and coinjected with pheromone standards and extracts. Elution of (*Z*)-11-tetradecenyl acetate preceded the earliest-eluting pheromone component, and elution of methyl arachidonate followed the latest-eluting pheromone. The two purposes for these chemicals were to correct for retention-time shifts and response-factor changes over the course of numerous analyses with varying injection volumes.

Statistical Analyses. The calling experiment was a randomized complete block design with three replications of a two-way classification of five age and 15 time treatments. Proportions of calling moths were transformed to arcsins of the square roots for analysis of variance. Age, time, and age/time interactions were included in the model. Means and groups of means were compared by *t* tests and single-degree-of-freedom *F* contrasts, respectively, using the error term from the analysis of variance.

The flask pheromone-collection experiment was completely randomized. Analyses of variance tested effects of age on total emission (HDA + ODL + ODA) and on blend percentages, both uncorrected for adsorption on moths.

Flask control experiments were completely randomized. For tests with noncalling females in which pheromone was introduced 4 hr before extraction, analyses of variance tested effects of amounts added to flasks on the percent recoveries of the three components. The treatment effect was partitioned into linear regression and deviations. Effects were tested using the experimental error term.

Estimations of variances of derived results calculated by multiplication and/or division of two or more means were conducted by addition of relative variances (Skoog and West, 1969).

RESULTS AND DISCUSSION

Calling Behavior. Few females called during the first half of the 10-hr night according to preliminary observations. Most calling occurred during the last 3 hr of the night (Figure 1). In general, older moths began calling earlier. This was demonstrated by a large age/time interaction ($P < 0.001$) resulting from earlier rises in the curves of the older moths. Kanno (1979) and Das and Islam (1982) also found that older *Pyralidae* females called earlier than younger moths.

More older moths called at most times during the peak calling period. More 1-day-old than 0-day-old moths, more 2-day-old than 1-day-old moths, and more 3- and 4- to 5-day-old than 2-day-old moths called ($P < 0.01$). An exception was that fewer 4- to 5-day-old moths than 3-day-old moths called during the peak hours ($P < 0.01$), possibly due to senescence (Tamaki, 1985). Similar effects of age on maximum calling rate have been observed in other

FIG. 1. Calling behavior of virgin female *Eoreuma loftini* moths of different ages.

Pyralidae (Kanno and Sato, 1978; Kanno, 1979; Das and Islam, 1982; Hirai, 1982).

Calling behavior declined just before the beginning of the light period (0 hr = 2-3 min before the lights came on) (Figure 1). Significant decreases occurred during the last hour for 0-, 1-, 3-, and 4- to 5-day-old moths ($P < 0.05$). This suggests that cessation, as well as onset, of calling behavior is a circadian rhythm rather than simply a direct response to light.

Pheromone Recovery in Flask Control Experiments. Percent recoveries of pheromone components from flasks without moths were: HDA, 49.9%; ODL, 42.1%; and ODA, 49.5% (Table 1). Nearly all losses occurred during the final concentrating procedure and syringe loading before GLC analysis.

Pheromone amounts extracted from flasks with noncalling females to which no pheromone was added were: HDA, 0.4 ng/25 females; ODL, 0.3 ng; and ODA, 5.0 ng. It is important that the amount of ODL extracted from these flasks was low since experiments discussed below showed that ODL recovery

TABLE 1. PERCENT RECOVERIES OF PHEROMONE FROM FLASK CONTROL EXPERIMENTS COMPARING PRESENCE OF MOTHS, SEX, AND TIMING OF PHEROMONE INTRODUCTION

	Percent recoveries (SE) ^a

Noncalling females, increments ^d	20.0 (2.0) c	1.56 (0.51) b	29.2 (3.0) b

^aHDA = (Z)-11-hexadecenyl acetate; ODL = (Z)-13-octadecenal; ODA = (Z)-13-octadecenyl acetate. Means in the same vertical column followed by the same letter are not significantly different at the 5% level by *t* tests.

^b0.1 μg each of HDA, ODL, ODA introduced 4 hr before extraction.

^c0.4 μg HDA, 0.6 μg ODL, 0.6 μg ODA, introduced 4 hr before extraction.

^d0.4 μg HDA, 0.6 μg ODL, 0.6 μg ODA, introduced in four increments at 4, 3, 2, and 1 hr before extraction.

rates depend on amounts in flasks. The extracted 0.3 ng ODL translates into 0.016 μg in the flask before losses, according to methods discussed in a later section. This amount is small relative to amounts of ODL introduced to flasks (0.15–3.0 μg) and probably little affected recovery rates.

Unknown compounds with retention times within 0.1–0.3 min of the pheromone peaks were also found in flasks with noncalling females to which no pheromone was added. These unknowns interfered with pheromone quantitation. Therefore, to correct data from tests in which pheromone was added to flasks containing noncalling females, we subtracted the following amounts from those recovered: HDA, 1.4 ng/25 females; ODL, 1.8 ng; and ODA, 8.1 ng. These amounts include pheromone from noncalling females and the unknown peaks.

Recoveries from flasks containing 0.4 μg HDA, 0.6 μg ODL, 0.6 μg ODA and moths were lower than recoveries from flasks without moths (*P* < 0.05) (Table 1), indicating adsorption onto moths that were discarded before flask extraction. Pheromone recoveries from flasks containing males, to which pheromone was introduced 4 hr before extraction, were: HDA, 9.6%; ODL, 0.33%; and ODA, 15.8%. Recoveries from flasks containing noncalling females, to which pheromone was also introduced 4 hr before extraction, were: HDA, 14.9%; ODL, 0.56%; and ODA, 24.4%. Male/female differences in recoveries (HDA, ODA: *P* < 0.05; ODL: *P* = 0.10) may be related to behavior as males were more active during tests. Recoveries from flasks containing noncalling

females to which pheromone was introduced in four increments were: HDA, 20.0%; ODL, 1.56%; and ODA, 29.2%. These recoveries were higher than from flasks with noncalling females to which all pheromone was added 4 hr before extraction (HDA, $P < 0.05$; ODL, $P = 0.08$; ODA, $P = 0.21$). Pheromone introduced at 1, 2, and 3 hr before extraction apparently did not have as much time to adsorb on moths as that added 4 hr before extraction. The greater the adsorption affinity, the more the incremental technique increased recovery rate. Thus, recovery of ODL increased more (178%) than recoveries of HDA (34%) and ODA (20%). Since the incremental technique is similar to pheromone emission by females, these results suggest recoveries from flasks with calling females should also be 20.0%, 1.56%, and 29.2% for HDA, ODL, and ODA, respectively. Note, however, that these values are accurate only for HDA and ODA. Recovery of ODL depends on the amount of ODL in flasks ($0.6 \mu\text{g}$ in this test) as reported below.

Flask experiments with noncalling females and various amounts of pheromone added 4 hr before extraction indicated that percent recovery was independent of amount added for HDA and ODA (regression coefficients were not significant) but not for ODL. Mean recoveries of HDA and ODA, over all amounts added to flasks, were ca. 16 and 23%, respectively. Regression of percent recovery of ODL on amounts added to flasks gave the equation:

$$\text{Recovery (\%)} = 1.38 (\text{amount added to flask}) - 0.17$$

The coefficient, 1.38, was significant ($P < 0.05$). The correlation coefficient, r , was 0.46. Linear regression (1 df) accounted for 84% of the treatment effect (5 df), indicating a good fit to linearity. The low r was due to variability associated with the greater amounts of ODL introduced to flasks (1.5, 2.0, 3.0 μg). Recovery rates ranged from 0.2 to 10.1% for these treatments compared to 0.1–1.8% for the three lower treatments.

Estimation of Percent Adsorption on Moths. Percent adsorptions were estimated for flask control experiments with noncalling females in which various amounts of pheromone were added 4 hr before extraction (Table 2). Percent adsorption was calculated by dividing the percent recovery from flasks with moths by the percent recovery from flasks without moths, subtracting the quotient from 1, and multiplying by 100. This calculation assumed that handling losses from flasks without moths does not depend on amounts added to flasks. Table 2 shows that HDA and ODA adsorption rates on moths did not vary with amounts of HDA and ODA added, but ODL adsorption increased with decreasing amounts of ODL added to flasks ($P < 0.05$ by regression). Mean adsorptions were: HDA, 69.0%; ODL, 96.2%; and ODA, 54.1%. Similar adsorption trends were reported for *Grapholitha molesta* (Lepidoptera: Tortricidae) with two components of its pheromone (Baker et al., 1980).

Effects of Age on Pheromone Emission by Females in Closed Flasks. Blend

percentages of the three components, corrected for handling losses but not for adsorption on moths, changed with moth age (Table 3). Apparent blends became richer in ODA and poorer in HDA and ODL each day as females aged from 0 to 3 days ($P < 0.05$), then remained constant with further aging. We believe

the change in blend with age is an experimental artifact. Figure 1 showed that most calling by 0-day-old females occurred during the last 2 hr of the night, whereas calling by 3- to 5-day-old females was evenly spread over the last 3 hr. Calling by 1- to 2-day-old females was intermediate. Applying the results from the incremental pheromone introduction test, pheromone from younger moths had less time to adsorb than that from older moths. Therefore, percent recoveries of HDA and ODL from younger moths should be higher than their recoveries from older moths. Recovery of ODA should follow a similar trend, but to a lesser extent since it adsorbs less on moths. Thus, it was adsorptions that changed with age; blend percentages only appeared to change as a result of changes in recoveries.

Table 3 also shows total pheromone (HDA + ODL + ODA), per female, extracted from flasks with calling females. The data were corrected for handling losses but not for adsorption. Three-day-old females emitted the most pheromone ($P < 0.05$) and newly emerged females the least ($P < 0.05$). However, females either did not call continuously or not all females called during the last 4 hr of the night (Figure 1). Dividing pheromone per female per 4 hr in Table 3 by the mean percentages of females calling during the last 4 hr of the night as estimated from Figure 1 gives an approximate correction for noncalling time or noncalling females. Thus, pheromone emissions per calling female per 4 hr, uncorrected for adsorption, were: 0 days old, 36 ng; 1 day old, 50 ng; 2 days old, 55 ng; 3 days old, 56 ng; and 4 to 5 days old, 36 ng. Correction for adsorption at each age would require data that we do not have concerning adsorption per unit time.

Calculation of Pheromone Blend in Closed Flasks with Calling Females.

Assuming that effects of age on pheromone emission were averageable, corrected blend percentages and emission rates were calculated from extracted amounts of HDA, ODL, and ODA without regard to age. Mean amounts extracted per female were: HDA, 1.08 ng (SE = 0.005 ng); ODL, 0.46 ng (0.002 ng); and ODA, 8.25 ng (0.051 ng).

To correct the HDA and ODA emission data for adsorption and handling losses, the mean extracted amounts were divided by their respective recovery rates from the incremental-introduction tests (Table 1). Thus the amount of HDA emitted per female per 4 hr was $1.08/0.200 = 5.4$ ng. The amount of ODA per female per 4 hr was $8.25/0.292 = 28.3$ ng.

For the ODL emission data, corrections were made for incremental introduction and for regression. First, the recovery rate for 0.6 μg of ODL introduced in increments was divided by the recovery rate for 0.6 μg of ODL introduced 4 hr before extraction (Table 1). The ratio was $1.56\%/0.56\% = 2.79$. This ratio was used to correct the regression equation assuming that the

effect of introducing ODL in increments is constant over all amounts of ODL tested:

$$\text{Recovery (\%)} = 2.79 [1.38 (\text{amount in flask}) - 0.17]$$

Since percent recovery equals the amount extracted (amt. ext.) divided by the amount in the flask (amt. flask), times 100, the equation was rewritten as:

$$\text{amt. ext.} = 2.79 [1.38 (\text{amt. flask})^2 - 0.17 (\text{amt. flask})]/100$$

This equation was used to correct the extracted amount of ODL for changes in percent recovery as amounts of ODL in flasks changed. For 11.5 ng extracted per flask (0.46 ng/female × 25 females/flask), the mean amount in the flasks was 612 ng/flask or 24.5 ng per female. Since 612 ng is close to the 0.6 μg used in determination of the ratio 2.79, error due to nonconstancy of the ratio with changing amounts of ODL is minimal.

Adding amounts of HDA, ODL, and ODA yields total pheromone emission, corrected for adsorption and handling losses, of ca. 58 ng per female in flasks per 4 hr (Table 4). Correcting for the mean percentage of females calling for all ages over the last 4 hr of the night yields an emission rate of 126 ng per calling female per 4 hr. Note, however, that females that do not appear to be calling may be emitting some pheromone. Blend percentages were ca.: HDA, 9%; ODL, 42%; and ODA, 49% (Table 4).

Pheromone Recovery in Cylinder Control Experiments. No peaks were found at pheromone retention times when no pheromone was added to cylinders

with male moths. However, unknown peaks were found within 0.1–0.3 min of pheromone retention times. To correct data from tests in which pheromone was added to cylinders and tests with calling females, we subtracted the following amounts from those recovered: HDA, 0.15 ng; ODL, 0.80 ng; and ODA, 1.25 ng.

When pheromone was introduced in the cylinder downwind from a male moth, recoveries were: HDA, 41.1%; ODL, 36.8%; and ODA, 38.6% (Table 5). Losses may have been caused by inability to extract all pheromone from cylinders, trap breakthrough, postextraction sample handling, and oxidative breakdown. Since recoveries were only about 5–11% less than those in flasks without moths (Table 1), most losses from cylinders were probably due to postextraction sample handling.

When pheromone was introduced on the glass wool upwind from a male moth, recoveries were: HDA, 20.6%; ODL, 10.6%; and ODA, 13.0%. These recoveries do not take into account adsorption to the upwind glass wool which was not solvent-extracted.

Adsorbances to the upwind glass wool were estimated as: HDA, 52.6%; ODL, 63.3%; and ODA, 64.5%. These were calculated as follows: Recoveries from cylinders in which pheromone was introduced on the upwind glass wool with no moth present (HDA, 19.5%, ODL, 13.5%, ODA, 13.7%) were divided by recoveries from cylinders in which pheromone was introduced downwind from a male moth (41.1%, 36.8%, 38.6%) to correct for losses due to sample handling, etc. Quotients were: HDA, 47.4%; ODL, 36.7%; and ODA, 35.5%. These are estimates of pheromone evaporation from the upwind glass wool. Adsorptions were found by subtracting these percentages from 100%.

TABLE 5. PERCENT RECOVERIES OF PHEROMONE FROM CYLINDER CONTROL EXPERIMENTS IN WHICH PHEROMONE WAS INTRODUCED DOWNWIND OR UPWIND FROM MALE MOTH

	Percent recoveries (SE) ^a		
	HDA	ODL	ODA
Downwind	41.1 (2.8) a	36.8 (2.2) a	38.6 (6.5) a
Upwind ^b	43.5 (4.6) a	28.9 (5.3) a	36.6 (7.1) a
Difference	-2.4 (5.4)	7.9 (5.7)	2.0 (9.6)

^aHDA = (Z)-11-hexadecenyl acetate; ODL = (Z)-13-octadecenal; ODA = (Z)-13-octadecenyl acetate. Means in the same vertical column followed by the same letter are not significantly different at the 5% level by t-tests.

^bOnly pheromone not adsorbed to the upwind glass wool was used in the calculations.

Recoveries from cylinders in which pheromone was introduced on the glass wool upwind from a male moth, corrected for adsorption to the glass wool, were: HDA, 43.5%; ODL, 28.9%; and ODA, 36.6% (Table 5). These were calculated by dividing the uncorrected recoveries (20.6%, 10.6%, 13.0%) by percentages evaporated from the glass wool (47.4%, 36.7%, 35.5%).

Subtracting "upwind" recoveries from "downwind" recoveries (Table 5) yields estimates of pheromone adsorptions on the male moth in the "upwind" experiment: HDA, -2.4%; ODL, 7.9%; and ODA, 2.0%. None of these differences is statistically significant. However, the larger difference for ODL is consistent with its strong adsorption on moths in flask experiments (Table 2). Possibly, some ODL adsorbed on the male as it passed over his body and/or adsorbed on scales that had fallen onto the downwind glass wool.

Pheromone Emission by Females in Cylinders. Although not statistically significant, 3-day-old females again appeared to emit the most pheromone. Age did not affect blend percentages of the uncorrected data.

To correct for adsorption and handling losses, data from all ages were combined. Mean amounts extracted per female, uncorrected for losses, were: HDA, 1.96 ng (SE = 0.20 ng); ODL, 4.04 ng (0.76); and ODA, 6.16 ng (0.90). The data were corrected using the results of both cylinder control experiments. In each case, the mean extracted amounts were divided by their respective recovery rates from Table 5. For the downwind control test, the corrected emission data per female per night were: HDA, 4.8 ng; ODL, 11.0 ng; and ODA, 16.0 ng. Total pheromone emission (HDA + ODL + ODA) per female per night was 32 ng (Table 4). Blend percentages were: HDA, 15%; ODL, 35%; and ODA, 50% (Table 4). For the upwind control test, the corrected emission data per female per night were: HDA, 4.5 ng; ODL, 14.0 ng; and ODA, 16.8 ng. Total pheromone per female per night was 35 ng (Table 4). Blend percentages were: HDA, 13%; ODL, 40%; and ODA, 48% (Table 4).

How much emitted pheromone that blew back over the bodies of females calling in cylinders is not known. Therefore, we do not know which control test is most applicable. Most likely, turbulence caused some emitted pheromone to blow back over the females. Also scales that had fallen from the female onto the downwind glass wool may have adsorbed some pheromone. Thus the most applicable correction factors may lie between those from the two control tests.

Pheromone Emission vs. Gland Extracts. Amounts of pheromone in glands are not necessarily the same as the amounts and blend percentages females emit (Tumlinson et al., 1982; Mayer and Mankin, 1985). In particular, aldehydes are often more prevalent in emissions than in gland extracts (Baker et al., 1980; Ramaswamy and Cardé, 1984). Our work shows that the sex pheromone of *E. loftini* fits this trend. We report a blend of ca. 9–15%, 35–42%, and 48–50% for HDA, ODL, and ODA, respectively, from calling females. Shaver et al.

(1988) reported a blend of ca. 10:13:78 for these three components extracted from glands of females of this species. Further, we found total pheromone emission (HDA + ODL + ODA) of ca. 32–58 ng per female per night, while Shaver et al. (1988) found only ca. 30 ng in glands. This latter result suggests that pheromone biosynthesis is concurrent with emission (Nordlund and Brady, 1974) such that the amount in the gland at any time is only a portion of what is produced during a day.

Comparison of Methods. This work used two methods for collecting pheromone emitted by calling moths. The cylinder method with airflow proved the simpler, more direct method. Its principal advantage was that there was little or no adsorption on moths, resulting in higher recoveries and less reliance on control test correction factors. Another advantage was that pheromone was emitted in moving air, a more natural situation (Kaae and Shorey, 1972). However, the flask method may have advantages over cylinders when pheromone emission is low and many emitters are needed to trap a quantifiable amount of pheromone.

Females in flasks without airflow produced more pheromone than females in cylinders with airflow ($P < 0.05$ by t test) (Table 4). This is the opposite result from that obtained by Ramaswamy and Cardé (1984) with *Chloristoneura fumiferana* (Lepidoptera: Tortricidae). We have no explanation for the discrepancy, although a group stimulation effect in flasks is possible.

Because of differential adsorption of pheromone components as demonstrated here and by Baker et al. (1980), it now seems critical that collection methods do not allow pheromone emitted by one female to pass over other females, even in moving air. It would be difficult indeed to control for this effect in a chamber containing 100 calling females.

Baker et al. (1981) reported efficient trapping of pheromone on glass wool without the need for chemical adsorbents. Their method eliminates the contamination that accompanies use of chemical trapping agents. Recoveries from their apparatus were 90–100%. Recoveries from our cylinders, after adjusting for postextraction losses of 50–60%, were also about 90–100%. The method of Baker et al. (1981) also employed forced extrusion of the female's pheromone gland, so that adsorption onto scales was minimized, thus minimizing correction for adsorption. Our cylinder method allows females to call naturally and also requires little correction for adsorption onto scales (Table 5). By trapping with glass wool, as reported by Baker et al. (1981), our cylinder method would have been substantially improved to allow clean, efficient collection of pheromone emitted by naturally calling females. Unfortunately, we were unaware of the work of Baker et al. (1981) until after our work was completed.

Finally, an intriguing question with regard to adsorption is: How much pheromone emitted by a female moth is adsorbed on her body and on her immediate environment in nature? Perhaps optimal blends for male response are the

result not only of what the female emits but also of differential adsorption of components by nearby leaves and by the female oriented in a characteristic way in an airstream.

Acknowledgments—We thank Bianca Chapa for an authorship's worth of excellent technical assistance in all phases of the work but especially for conducting the GC and LC analyses. We thank Soledad Alvarez, Reyes Garcia, and Noe Martinez for technical assistance; Karen Robacker and H. Del Var Petersen for statistics and computer assistance; and USDA-APHIS (Mission, Texas) and H. Browning (Texas Agricultural Experiment Station, Weslaco, Texas) for insects. We thank T.N. EFFECT OF MELIACEOUS SEED EXTRACTS ON GROWTH AND SURVIVAL OF *Spodoptera frugiperda* (J.E. SMITH)¹

K.L. MIKOLAJCZAK, B.W. ZILKOWSKI, and R.J. BARTELT

Northern Regional Research Center, USDA, ARS

(Received June 25, 1987; accepted October 29, 1987)

Abstract—Hexane and ethanol extracts of seeds from 10 plant species (including neem—*Azadirachta indica* A. Juss.) of the family Meliaceae were incorporated into artificial diet at various doses and fed to fall armyworm [*Spodoptera frugiperda* (J. E. Smith) (Lepidoptera: Noctuidae)] larvae in no-choice tests. All produced significant mortality, reduced larval growth rate, increased time to pupation, or all three, at some concentration. The two highest doses of all of the ethanol extracts caused 100% mortality before pupation, but the hexane extracts tended to be less effective. *Aglai cordata* Hiern. ethanol extract was as potent as the comparable neem seed extract at virtually all levels, and its hexane extract was active at much lower concentrations than the neem extract was. The sublethal effects (slower growth and increased time to pupation) were usually detectable at lower doses of extract than mortality was.

Key Words—*Spodoptera frugiperda*, Lepidoptera, Noctuidae, Meliaceae, neem, insecticides, limonoids, seed extracts.

INTRODUCTION

Interest in the possible application of natural products to insect pest management continues at a high level. Numerous research programs are engaged in searching for and developing plant-derived products that produce deleterious effects in insects. Although this research encompasses many plant families and classes of compounds (Abivardi and Benz, 1984; Lane et al., 1985; Saxena et

¹ Mention of firm or product names does not imply recommendation or endorsement by USDA over others not mentioned.

al., 1986; Villani et al., 1985), the most widespread effort is currently being applied to limonoids, primarily from meliaceous plants (Chiu, 1985; Hassanali et al., 1986; Prabhaker et al., 1986; Siddiqui et al., 1986).

The complexity of many limonoids may preclude economically feasible syntheses; this complexity is exemplified by the structure of azadirachtin (the insecticidal compound from neem), which has recently been revised (Kraus et al., 1985; Broughton et al., 1986) 10 years after it was proposed by Zanno et al. (1975). Because synthesis of azadirachtin is unlikely, and its isolation in pure form is difficult and tedious, most agricultural applications will probably utilize extracts that have undergone some degree of fractionation to concentrate the active components.

Plants of the family Meliaceae are widely distributed in tropical and subtropical areas where they might be available for pest control in local agriculture. We previously investigated the feeding deterrence and mortality produced by seed extracts from 22 meliaceous species on fall armyworm (FAW) larvae [*Spodoptera frugiperda* (J.E. Smith)] and on striped cucumber beetle adults [*Acalymma vittatum* (F.)] (Mikolajczak and Reed, 1987). These mortality data were obtained at a single dose level (10,000 ppm) in artificial diet, and, at this level, a number of the extracts were as active as comparable neem seed extracts. We therefore conducted this study (an expansion of our earlier work) of the growth-regulating properties of some of these extracts on FAW larvae using doses of 10,000 ppm and lower.

METHODS AND MATERIALS

Extracts. The names of plant species investigated appear in Table 1. Seeds were identified and collected by USDA botanists, Beltsville, Maryland. Hexane and ethanol extracts were prepared as previously described (Mikolajczak and Reed, 1987).

FAW Bioassay. Pinto bean diet as described by Shorey and Hale (1965) was used for rearing FAW larvae and also for the bioassays. Seed extracts were incorporated into the artificial diet in appropriate quantities and the bioassays were set up according to the procedure presented earlier (Mikolajczak and Reed, 1987); the concentrations used were 10,000, 2000, 400, 80, and 16 ppm. All concentrations of each seed's extracts were assayed simultaneously along with a hexane and an ethanol solvent control and a diet blank. Neonate larvae were caged individually in 1-oz plastic cups; 10 replicates were done. The larvae were maintained in darkness at 26–28°C and 55–65% relative humidity. The larvae were weighed on days 7 and 13, and a record was made of those that died prior to pupation. In addition, the number of days required for pupation was also recorded.

TABLE 1. FALL ARMYWORM BIOASSAY RESULTS FOR MELIACEAE SEED EXTRACTS.

ⁱEthanol control used for comparison.

Treatment of Data. The larval mortality data were analyzed as contingency tables, using chi-square tests. For each experiment, the diet blank and solvent controls were first tested for consistency. Significant differences among controls could indicate incomplete removal of solvents during diet preparation, which would confound conclusions about the effectiveness of extracts. No differences among controls were detected, however (the probability levels for the chi-square statistics were >0.05 in all cases), and the data for diet blank, hexane, and ethanol controls were pooled. Each experimental treatment was then tested against the combined controls. Extracts were considered active when the probability level for the chi-square statistic was <0.05 .

Sublethal effects, as evidenced by lower larval weights at 7 and 13 days, and increased times to pupation, were detected by one-way analysis of variance. Time to pupation was analyzed in the original scale, but a variance-stabilizing transformation was required for the larval weight data. Conversion to the logarithmic scale was satisfactory. Upon finding a significant overall F statistic in an analysis, each extract treatment was then compared to the combined controls (diet blank and solvent controls) using a t test. As with the mortality data, consistency of controls was checked before pooling the control data. In the few cases where differences among controls were detected, treatments were compared to the appropriate solvent control only.

RESULTS AND DISCUSSION

Table 1 presents the test data for concentrations of extracts from 10,000 ppm to 16 ppm in the artificial diet. To conserve test materials during this early stage of the project, tests were limited to 10 replications. *A. cordata* and *Lansium domesticum* hexane extracts were not tested at the highest concentration due to scarcity of material. In some cases, the mortality figure was 100% prior to pupation, but a value is also listed for larval weight; in these cases the larvae that were weighed on day 13 subsequently died before pupation. This effect can be seen (Table 1) in the higher ethanol extract concentrations for the *Dysoxylum* species, *Sandoricum koetjape*, and others, and also for three of the *A. cordata* hexane concentrations. Otherwise, a dash in the larval weight row indicates all larvae died before day 13.

Overall, the effects produced by the ethanol extracts were more pronounced than those resulting from the hexane extracts. The ethanol extracts of all species caused 100% larval mortality at doses of 2000 ppm and above. Extracts of two species, neem and *A. cordata*, had considerably lower activity thresholds, the former causing 100% mortality at 16 ppm, and the latter at 80 ppm. The ethanol extract of *Trichilia roka* was intermediate in activity, with 400 ppm causing 100% mortality. Although the ethanol extracts of all the spe-

cies were active, only that of *A. cordata* produced activity approaching that of neem ethanol extract, which contains most of the azadirachtin found in the seed. Differences in the activities of these extracts could be due to the presence of different deleterious compounds, quantitative differences in these compounds, or both. Further chemical purification would be required to resolve qualitative and quantitative effects. It is likely that inert compounds account for much of the extracts' weights.

Ethanol extracts of *L. domesticum* and *Melia azedarach* produced 100% mortality at 10,000 ppm (Table 1), but in our earlier work (Mikolajczak and Reed, 1987), neither caused any mortality at the same dose. We feel that this difference may be due, in large part, to the age difference between the two groups of test insects—6-day-old larvae in the previous experiments as opposed to neonate larvae in the current experiments.

The hexane extract of *A. cordata* was considerably more active than those of the other species, including neem, causing 100% mortality at only 16 ppm. Only three other hexane extracts caused 100% mortality, and then only at the highest concentration tested (Table 1). The ability of hexane to extract appreciable activity from *A. cordata*, but not from neem, suggests that the active compound(s) in *A. cordata* are less polar than azadirachtin.

The 7- and 13-day larval weights, and time before pupation were examined for evidence of sublethal effects. There were highly significant differences among the 13-day weights (Table 1). Larval weight was a more sensitive indicator of extract activity than mortality. In 13 cases, a significantly slower weight gain was detected in the absence of significant mortality. This usually occurred one dose level below where mortality became significant. However, significant mortality always corresponded to significantly smaller larvae at day 13, with one marginal exception (the hexane extract of *Melia azedarach* at 10,000 ppm). The significantly lower weights for larvae fed the *Dysoxylum malabaricum* and *Sandoricum koetjape* ethanol extracts at 16 ppm were unusual, since effects were seen at three dose levels below where mortality became significant.

The 7- and 13-day larval weights led to the same conclusions about these extracts; for the sake of clarity we present only the 13-day data in the table. In 78 of 80 treatments in which larvae remained alive through day 13, weights differed significantly from controls at day 13 but only when they also differed at day 7. When expressed as a percentage of control weights, the 7-day and 13-day mean weights were strongly correlated ($r = 0.86$).

Time to pupation showed highly significant differences among extracts (Table 1). It was negatively correlated with the 13-day larval weights: the smaller the larvae at day 13, the longer it took them to pupate. A linear regression model was fitted using the 18 treatments in which both time to pupation and 13-day larval weight were significantly different from control levels. For

larval weights between 75% and 5% of the control value, mean time to pupation increased by ca. 1.3 days for each decrease in weight of 10 percentage points (slope significant, $P \ll 0.001$, $r^2 = 0.67$). For larval weights above ca. 75% of the control value, neither the larval weight nor time to pupation tended to differ significantly from the control. Mean larval weights that were less than 5% of the control weights on day 13 usually led to 100% mortality before pupation.

In cases where an extract caused lower larval weights at day 13, surviving larvae required a longer development time, but pupae tended to be of normal weight (data not shown). Thus, although the larvae seemingly overcame the adverse effects of the diet treatments, their longer development time might benefit IPM strategy by reducing the number of generations per season.

SUMMARY

The mortality-producing capabilities of ethanol extracts of the seeds from nine species of meliaceous plants at 10,000 and 2000 ppm are equivalent to neem ethanol extract, which contains the insecticidal compound, azadirachtin. Hexane extracts of three species, *A. cordata*, *Chickrassia tabularis*, and *T. roka*, caused the same amount of mortality as neem seed hexane extract did at 10,000 ppm; however, *A. cordata* hexane extract proved superior to neem hexane extract at all other doses.

These data, plus our earlier antifeedant results (Mikolajczak and Reed, 1987), clearly demonstrate that extracts of many meliaceous plants could be used for pest control in much the same way neem extracts are. Additionally, we have demonstrated the existence of specific activities different from those displayed by neem extracts. Some examples are the high activity of *A. cordata* hexane extract at very low levels, described here, and the minimal feeding deterrence of *C. tabularis* hexane extract coupled with high mortality and the potent feeding deterrence of *Swietenia mahogani* hexane extract coupled with virtually no mortality, described earlier. Perhaps certain of these plants will find utility in areas where they are native as simple pest-control formulations requiring little expense or equipment to prepare.

Although limonoids may be responsible for much of the observed activities, some cases of non-azadirachtin-like activity could be due to other classes of simpler compounds, which might be more amenable to synthesis. We will continue to pursue the identification of active components from selected meliaceous species as additional plant material is obtained.

(Received May 13, 1987; accepted October 30, 1987)

Abstract—Survival of *Reticulitermes hesperus* workers was assessed in *Pseudotsuga menziesii*, *Lysiloma seemanii*, and *Tabebuia ochracea* sawdusts; and on heartwood solvent extracts of *P. menziesii*, *L. seemanii*, *T. ochracea*, *Pinus ponderosa*, *Tabebuia guayacan*, and a *Centrolobium* species. Survival in *P. menziesii* sawdust was 100% at 5 days and 81–87% at 15 days. Survival in *L. seemanii* and *T. ochracea* sawdusts was significantly less over both 5 and 15 days than in the starvation control, indicating toxicity. Survival on filter papers treated with solvent extracts of *T. ochracea* and *P. ponderosa* was significantly less than that on control papers, but only *P. ponderosa* differed significantly from the starvation control. In behavioral assays with groups and with individual *R. hesperus* workers, extracts of *P. menziesii* and *P. ponderosa* were preferred. In the individual behavioral assays, extracts of *T. guayacan* and *T. ochracea* were repellent. Results of toxicity assays were not predictable from preference assays.

Key Words—*Reticulitermes hesperus*, Isoptera, Rhinotermitidae, termite feeding behavior, termite bioassay, tropical hardwoods, wood extractives.

INTRODUCTION

Subterranean termites in the genus *Reticulitermes* (Isoptera: Rhinotermitidae) are important structural pests throughout North America. Along the Pacific coast, *Reticulitermes hesperus* Banks is the most destructive species (Weesner, 1965; Ebeling, 1975). Currently, use of preservative-treated wood and soil treatment with insecticides are the principal methods used to prevent or control subterranean termite damage.

Naturally occurring toxicants and semiochemicals (e.g., attractants, arrestants, repellents, feeding deterrents, and feeding stimulants) may offer safer alternatives to the current reliance upon insecticidal treatments. Extractives from termite-resistant woods have been under investigation for many years (Wolcott, 1924) and offer some promise as protective treatments for nonresistant woods (Carter and Beal, 1982). However, Smythe and Carter (1970) demonstrated that different termite species may respond differently to sawdust from the same tree species, requiring that all target termite species be investigated. Despite the economic importance of *R. hesperus*, the feeding responses of this species to different woods have not previously been studied. In addition, there has been little evaluation of behavioral (as opposed to toxic) effects associated with termite-resistant woods. As with feeding responses, chemical stimuli may elicit quite different behavioral responses in different termite species (Becker et al., 1972).

In the present study, investigations were conducted on the survival and behavior of *R. hesperus* workers on wood of a North American conifer readily fed upon by termites, and wood of five tree species thought likely to possess some resistance to termite feeding. Bioassays were designed to examine the relative importance of behavioral and toxicological factors in termite feeding and survival on these species. The behavioral responses of both groups and individual *R. hesperus* workers were determined.

Woods of six tree species were evaluated. Two of these, *Pseudotsuga menziesii* (Mirb.) Franco and *Pinus ponderosa* Dougl. ex Laws., are softwoods (Family Pinaceae) of North American origin. The other four species are Central American hardwoods: *Centrolobium* sp. (Leguminosae), *Lysiloma seemanii* Britt. & Rose (Leguminosae, subfamily Mimosaceae), *Tabebuia guayacan* (Seem.) Hemsl. (Bignoniaceae), and *Tabebuia ochracea* (Cham.) Standl.

P. menziesii and *P. ponderosa* are, respectively, the first and second most important timber-producing tree species in North America (Harlow et al., 1979). *P. menziesii* is used extensively for house construction in California, and the three termite colonies used in our experiments were collected from Douglas-fir lumber. In studies with other termite species (Carter, 1976; Carter and Smythe, 1974; Smythe and Carter, 1970), *P. menziesii* heartwood and sapwood have been found to promote termite feeding and survival. These same studies have shown *P. ponderosa* heartwood to be detrimental to termite feeding and survival.

One of the four tropical hardwood species, *T. guayacan*, resists subterranean termite attack in field tests with heartwood stakes (Bultman and Southwell, 1976) and has been found to reduce survival of the termites *Coptotermes formosanus* Shiraki and *Reticulitermes flavipes* (Kollar) (Beal et al., 1974), as have congeners of the other hardwood species (Beal et al., 1974; Wolcott, 1950). Selection of these four particular tropical hardwoods from the great number of

possibly termite-resistant species was due in part to convenience. The heartwoods of *T. guayacan* and *Centrolobium* sp. were already under chemical investigation (Jurd and Wong, 1984), and solvent extracts were available for biological assays. The other two tree species, *L. seemanii* and *T. ochracea*, are abundant in Guanacaste Province, Costa Rica, and were collected there in conjunction with other studies (Frankie et al., 1983). These species were selected before their collection by correlating an extensive study of Costa Rican tree phenology (Frankie et al., 1974) with the available literature on termite resistance, especially Beal et al. (1974), Carter (1976), and Wolcott (1950). Their abundance in Guanacaste Province suggests resistance to the structural damage caused by termites feeding on the heartwood of living trees, a common occurrence in the tropics (Sen-Sarma, 1986). Although not harvested commercially, these woods are locally reputed to be termite and decay resistant (GWF, unpublished observation).

In termite-infested buildings, differential feeding by termites on apparently identical timbers is frequently observed by researchers and pest-control personnel (Kofoid and Bove, 1934). To examine whether *R. hesperus* workers responded differently to adjacent structural timbers exhibiting different amounts of feeding, we included sawdust from field-collected *P. menziesii* timbers in the survival assays.

METHODS AND MATERIALS

Source of Insects. Western subterranean termites, *R. hesperus*, were collected from three sites in Alameda County, California. One colony (Berkeley) was removed from a Douglas-fir, *P. menziesii*, form board embedded in the soil beside a residential driveway in the city of Berkeley, the second (Gilman) from infested Douglas-fir wall framing in a residence in Berkeley, and the third (Oakland) from infested Douglas-fir floor joists in a residence in the city of Oakland. Termites were removed from the wood and kept in separate groups in plastic trays at room temperature (21–25°C) in a humidity chamber (94 ± 5% relative humidity) (Grace, 1986). Only workers (pseudergates, or undifferentiated individuals older than the third instar as determined by size), were used in assays due to their predominance in foraging activities.

Preparation of Sawdusts and Wood Extracts. Solvent extracts of the heartwood of *P. menziesii*, *P. ponderosa*, *T. guayacan*, and *Centrolobium* sp. were provided by L. Jurd and G.D. Manners (Western Regional Research Center, USDA, ARS, Albany, California). These woods were purchased from local merchants in California, and the *Centrolobium* species could not be identified to species by the United States Forest Products Laboratory in Madison, Wisconsin (L. Jurd, personal communication). Dried concentrates from five-day

continuous acetone extraction in a Soxhlet apparatus were diluted 1 g/10 ml acetone. Due to crystalline insolubility, *P. menziesii* extract was diluted in equal parts CH₃OH:CHCl₃.

L. seemanii and *T. ochracea* heartwoods, collected in Costa Rica, were ground in a Wiley mill (40-mesh screen), and 200 g of each sawdust was extracted by soaking in methanol at room temperature (21–25°C) for seven days. The resulting filtrates were concentrated by rotary evaporation and desiccation under vacuum, yielding ca. 10 g *L. seemanii* and 17 g *T. ochracea* dry extracts, which were diluted 1 g/10 ml methanol.

Survival in Douglas-Fir Sawdust. Samples of the timbers from which the *P. menziesii* solvent extracts were prepared were not available, and a separate experiment was designed with two field-collected *P. menziesii* samples. These samples were from two adjacent floor joists in a severely infested house where the Oakland colony was collected. One of these timbers had been extensively tunneled by termites, while the other exhibited only minor tunneling. Excluding the tunneled areas, such sample (heartwood plus sapwood) was reduced to sawdust in a Wiley mill (40-mesh screen).

The assay consisted of an open, 40-mm × 27-mm bottom diam. × 37-mm top diam., ca. 30-ml (1 US fluid oz., Anchor Hocking No. 5175) plastic cup containing 2 g of sawdust, 2 ml steam-distilled water, and 40 *R. hesperus* workers from the Oakland colony. These cups were placed in a humidity chamber, and termite mortality recorded by gently removing and replacing the contents of each cup at 5 and 45 days. This assay was replicated six times with each of the two *P. menziesii* samples.

Survival in Hardwood Sawdusts. Of the six woods used in this study, only samples of the unextracted heartwood of *L. seemanii* and *T. ochracea* were available, since the others were provided in the form of solvent extracts. These two species were reduced to sawdust and assayed as described above for *P. menziesii* sawdust, except that mortality of Oakland workers was recorded at 5, 15, and 45 days. Each substrate was tested with three groups of 40 termites. Alpha-cellulose (Alphacel, Nutritional Biochemicals Corp., Cleveland, Ohio) was included as a feeding control. A starvation control with 2 g white sand in lieu of sawdust was performed under the same experimental conditions, although not simultaneously with the other substrates.

Survival on Wood Extracts. Survival on filter papers treated with solvent extracts of the six woods was assayed in a manner comparable to that used with sawdusts. A 25-mm-diam. Whatman No. 1 filter paper disk was saturated with 100 μl of wood extract (diluted 1 g/10 ml solvent). Each feeding substrate thus consisted of ca. 18% wood extractives by weight. Treated disks were air-dried ca. 20 min, and placed in an open 30-ml plastic cup with 40 Oakland workers. The cups were placed in a humidity chamber and termite mortality recorded at 5, 15, and 45 days. Each wood extract was tested with three groups of termites.

Starvation (no filter paper) and feeding (filter papers treated with methanol only) controls were included in the experiment.

Group Behavioral Responses. Preference (either attraction or arrestment) or repulsion of groups of 10 *R. hesperus* workers (Berkeley and Gilman colonies) in response to wood extracts was measured in an assay similar to that used by Amburgey and Smythe (1977) to assess termite responses to solvent extracts of fungus-decayed wood. A 9-cm-diam. Whatman No. 1 filter paper disk treated with 1 ml wood extract (sufficient to saturate the disk), equivalent to ca. 15% extractives by weight, and air-dried ca. 20 min was cut in half and each half taped to one half of a solvent-treated paper disk. Each reconstituted two-choice disk was placed in an open glass Petri dish, uniformly illuminated by overhead fluorescent lighting (13.5–19.5 foot-candles) at room temperature (21–24°C). Five *R. hesperus* workers were gently deposited onto each half of the disk. The number of termites (in the group of 10) on the extract-treated half of the disk was recorded every 30 sec for 20 min.

The behavioral response of the group was calculated as the number of times more than five insects were recorded on the extract-treated half-disk, divided by the number of times more than five insects were recorded on either half-disk. This index of preference thus indicated the proportion of time spent on the extract-treated half-disk by the majority of each group of 10 termite workers. Each assay was replicated eight times, and the mean proportional response computed for each wood extract. Control assays using half-disks treated only with methanol were also performed.

Individual Behavioral Responses. Behavior of individual workers (Gilman and Oakland colonies) was measured similarly to group behavior. An 18-mm-diam. Whatman No. 1 filter paper disk was saturated with 40 μ l wood extract (ca. 15% extractives by weight), air-dried ca. 20 min, and paired with a solvent-treated disk in an open 5-cm-diam. glass Petri dish under uniform overhead lighting. A single *R. hesperus* worker was placed on the glass between the two disks, and its position on either (or neither) disk recorded every 30 sec for 20 min.

The behavioral response of each individual was calculated as the number of times it was recorded on the extract-treated disk divided by the number of times it was recorded on either disk. Again, this index of preference indicated the proportion of time spent on the extract-treated disk by the worker. A mean proportional response was computed from 50 individual assays with each wood extract. As in the group assays, control assays with two disks treated only with solvent (methanol) were also performed.

Statistical Analyses. Termite survivorship was analyzed with standard *t* test and analysis of variance (ANOVA) techniques, and means were compared with the Ryan-Einot-Gabriel-Welsch (REGW) multiple *F* Test ($\alpha \leq 0.05$) (SAS Institute, 1982). In the behavioral assays, the mean proportional responses of

groups and of individual termites to wood extracts were tested against the mean response of 0.50 expected under the null hypothesis of no effect (two-tail t test, $\alpha \leq 0.05$) (Dixon and Massey, 1983).

RESULTS AND DISCUSSION

Survival in Douglas-Fir Sawdust. Termite survivorship over 45 days was uniformly high and not significantly different (t test, $P = 0.06$) in sawdust from *P. menziesii* samples exhibiting either minor ($81 \pm 6\%$ surviving) or extensive ($87 \pm 4\%$ surviving) prior tunneling by the same *R. hesperus* colony. Survivorship at five days was 100% for workers in both treatments. These data do not support the hypothesis that the pattern of selective termite infestation observed in the field can be attributed to differential survival in the two timbers. Smythe and Carter (1970), however, demonstrated that differences do exist within tree species of different geographic origin that influence feeding by *R. flavipes*.

The overall high survivorship (range = 73–90%) of *R. hesperus* in *P. menziesii* sawdust is comparable to the high survivorship previously reported for *R. flavipes* (Carter, 1976; Carter and Smythe, 1974; Smythe and Carter, 1970) and *Incisitermes minor* (Hagen) (Kofoid and Bowe, 1934; Rust and Reiersen, 1977) on blocks and sawdusts of this tree species. In contrast, Smythe and Carter (1970) reported poor survival (0–8%) in groups of *Reticulitermes virginicus* Banks on *P. menziesii* heartwood blocks.

Survival in Hardwood Sawdusts. Very few of the workers fed sawdust from either of the two Costa Rican hardwoods *L. seemanii* or *T. ochracea* survived 15 days, and none survived 45 days (Table 1). Mortality in *T. ochracea* sawdust at five days was significantly different from and greater than that in

TABLE 1. PERCENT SURVIVAL OF *Reticulitermes hesperus* WORKERS IN HEARTWOOD SAWDUST OF TWO COSTA RICAN TREE SPECIES

Substrate	Mean survival (% \pm SEM) ^a		
	5 days	15 days	45 days
<i>Lysiloma seemanii</i>	35 \pm 11b	2 \pm 2b	0b
<i>Tabebuia ochracea</i>	5 \pm 4c	0b	0b
α -Cellulose	100 \pm 0a	100 \pm 0a	74 \pm 3a
Starvation Control	99 \pm 1a	97 \pm 3a	0b

^aMean of three groups of 40 *R. hesperus* workers. Means in the same column followed by different letters are significantly different (ANOVA, REGW multiple F test, $\alpha \leq 0.05$).

L. seemanii sawdust, and mortality in both sawdusts differed significantly from that observed in the starvation control. Mortality can thus be attributed to toxicity of the woods rather than feeding deterrence alone, since 15-day survivorship in the sand starvation control was very high ($97 \pm 3\%$) and did not differ significantly from the α -cellulose feeding control ($100 \pm 0\%$).

Survival on Wood Extracts. Survivorship after five days on filter papers treated with each of the six wood extracts (Table 2) was 96–100% and did not differ significantly from survivorship in either the solvent ($99 \pm 1\%$) or starvation ($100 \pm 0\%$) controls. At 15 days, only survivorship on papers treated with extracts of *T. ochracea* ($55 \pm 11\%$) and *P. ponderosa* ($27 \pm 19\%$) heartwoods differed significantly from the solvent control ($98 \pm 2\%$), and only *P. ponderosa* differed from the starvation control ($78 \pm 12\%$). Thus, toxic materials in *P. ponderosa* were extracted in acetone, and toxicants and/or feeding deterrents in *T. ochracea* were extracted in methanol. Compounds extracted from *P. ponderosa* sawdust with a mixture of acetone, hexane, and water have also been found to reduce the survival of *R. flavipes* (Carter, 1976).

The poor survivorship of *R. hesperus* on *T. ochracea* extracts corresponds with the toxicity of the *T. ochracea* sawdust, although the much greater mortality observed in the sawdust assays (Table 1) suggests incomplete extraction of toxicants from both *T. ochracea* and *L. seemanii*. Mortality was virtually complete in all treatments but the solvent control at 45 days (Table 2), and extraction of feeding deterrents from all six woods is supported by the observation that only the control disks had been extensively fed upon. In two-choice feeding assays with the drywood termite *I. minor*, Rust and Reiersen (1977) observed that filter papers treated with methanol extracts of various woods,

including *P. menziesii* and *P. ponderosa*, were not fed upon in favor of untreated or solvent-treated papers.

Group Behavioral Responses. In behavioral assays with groups of ten *R. hesperus* workers (Table 3), only the responses to extracts of *P. menziesii* and *P. ponderosa* differed significantly from the 50% response expected under the null hypothesis of no effect (*t* test, $\alpha \leq 0.05$). In both cases, these were positive responses, suggesting a behavioral preference for filter papers treated with these extracts. Although not differentiated in this assay, such a preference could result either from attraction to the extract-treated papers (orientation to airborne volatiles) or from arrestment after contact (cessation of locomotion), or from a combination of the two behaviors.

Individual Behavioral Responses. The responses of individual workers (Table 3) to extracts of *P. menziesii* and *P. ponderosa* also differed significantly and positively from the no-effect null hypothesis. In these individual assays, the behavioral responses to extracts of *T. guayacan* and *T. ochracea* were also significant, but in a negative direction. Methanol extracts of *T. ochracea* thus appear to contain repellents, in addition to toxic and/or antifeedant materials. The response of *R. hesperus* workers to *P. ponderosa* extract, on the other hand, suggests the presence of positive allelochemical stimuli in addition to toxicants.

Lapachol is considered to be an antitermitic agent in *T. guayacan* (Bultman

and Southwell, 1976; Kukachka, 1970). Becker et al. (1972) found that this compound was repellent to *Microcerotermes crassus* Snyder, and possibly repellent to *Kaloterms flavicollis* (Fabr.), but did not repel the other 12 termite species tested, including three species of *Reticulitermes*. Lapachonone, however, isolated from other *Tabebuia* species, was repellent to 10 termite species, including *R. flavipes*, *Reticulitermes lucifigus* (Rossi), and *Reticulitermes santonensis* Feytaud (Becker et al., 1972).

Several studies have indicated that termites from different colonies may respond differently in bioassays (Carter et al., 1972; Lenz, 1985; Su and LaFage, 1984). Since different *R. hesperus* colonies were used in our behavioral assays with groups and with individual termites, we can make no inferences from these experiments on individual versus group behavior. Problems are apparent, however, with both types of behavioral assays. Rather than averaging individual responses in a single measure of group behavior, or measuring the responses of single termites within the artificial context of an individual assay, an alternative approach of current interest to us is to record the responses of individual termites within the context of a group assay.

CONCLUSIONS

The chemical nature and biological activity of wood extractives have been investigated with respect to termites for over 60 years. Most of this work has utilized tropical hardwoods, with the aim of identifying more resistant building materials (Bultman et al., 1979; Su and Tamashiro, 1986) or isolating toxins or antifeedants that could be applied to susceptible lumber to increase termite resistance (Carter and Beal, 1982).

Only a few researchers (e.g., Carter and Mauldin, 1981; Carter et al., 1983) have investigated behavioral responses to wood extractives in conjunction with feeding assays. Varma et al. (1984) also investigated the attractiveness of extracts of plant materials to *Odontotermes guptai*. It is hoped that the extraction, and subsequent isolation and identification, of behaviorally active compounds from susceptible and resistant woods will contribute to the development of new techniques of behavioral termite control, such as the use of baits (Esenther and Beal, 1979), rather than simply replacing current wood preservatives and insecticides with naturally occurring toxicants.

Acknowledgments—We are grateful to L. Jurd and G.D. Manners (Western Regional Research Laboratory, USDA, ARS, Albany, California) for providing several wood extracts, and to I. Kubo (Department of Entomological Sciences, UCB) for providing facilities for other wood extractions. K.Q. Lindahl, Jr., made valuable suggestions on statistical analyses. R.F. Chapman, L. Jurd, I. Kubo, R.H. Scheffrahn, and W.W. Wilcox reviewed early drafts of the manuscript. Funding was provided by the Division of Entomology and Parasitology (UCB), and NSF grant BNS-8518195 to D.L. Wood and I. Kubo.

(Received June 2, 1987; accepted November 2, 1987)

Abstract—Odor-mediated host-searching by female *Microplitis croceipes*, a braconid endoparasitoid of larval *Heliothis* species, was studied in a flight tunnel. Volatiles emitted by third-instar *H. zea* feeding on cowpea seedling leaves were released and carried with the wind, resulting either in an irregularly shaped plume, or injected with high velocity, resulting in a conically shaped jet plume. Flight maneuvers of *M. croceipes* had a higher stereotype in jet plumes compared to irregularly shaped plumes. Variation in odor concentration in jet plumes due to intermittent feeding of the host larvae did not affect the number of flights. At the levels employed, odor concentration did not alter the rate of upwind progress in jet plumes. Because air velocity inside a jet increases in the upwind direction, *M. croceipes* regulates its ground-speed during its approach to the odor source.

Key Words—Hymenoptera, Braconidae, *Microplitis croceipes*, *Heliothis zea*, Lepidoptera, Noctuidae, anemotaxis, parasitoid, jet plumes, optomotor response, semiochemicals.

INTRODUCTION

The question of how flying insects orient to volatiles has been studied most extensively in the response of moths to pheromones (Baker, 1986; Cardé, 1984; Kennedy, 1983). However, little is known about behavioral mechanisms that are used by parasitoids during in-flight orientation to host-related odors (Jones, 1986; Waage, 1978). In contrast to sex pheromone communication, in which efficiency in signal emission and response is favored, a larval parasitoid responding to kairomone is confronted with an emitter that benefits by minimizing its detectability.

Microplitis croceipes (Cresson), a parasitoid of *Heliothis* spp., oviposits predominantly in third-instar larvae of *H. zea* (Boddie) (Hopper and King, 1984; Lewis, 1970). These larvae are often concealed inside flower buds and blooms of cotton and prevalent at the lower levels of the canopy (Farrar and Bradley, 1985; Schmidt, 1985), where even a slight breeze will generate abundant turbulence due to the dense vegetation. Powell and King (1984) observed no difference in parasitization rates for host larvae collected from different parts of the plant. This might be due to larval mobility, but it is also possible that *M. croceipes* is equally successful in detecting *H. zea* throughout the plant. The semiochemicals involved in in-flight host-searching of *M. croceipes* are emitted during feeding of *H. zea* larvae on foliage (Drost et al., 1986). Eller et al. (1988) noted that volatile trappings from third instars on cowpeas presented on filter paper were never behaviorally active for more than 10 min.

A question arises whether *M. croceipes* is adapted to shorter detection distances than male moths responding to sex pheromone because turbulence in the habitat disintegrates odor plumes and the host benefits by minimizing its detectability. Of parallel interest is whether flight maneuvers used by *M. croceipes* differ from pheromone-evoked orientation in moths.

Semiochemical-mediated flight of *M. croceipes* was demonstrated in a flight tunnel by Drost et al. (1986). The odor sources used in that study, a cowpea seedling with a feeding third-instar *H. zea*, did not permit systematic manipulation of the odor stimulus. Odors emanating from a plant form an irregularly shaped odor plume, which makes it difficult to determine at which instant the insect is enveloped by the chemical stimulus. The effect of variation in the odor production, due to changes in host feeding, on the flight maneuvers of *M. croceipes* also is unknown. A controlled presentation of stimuli is one of the steps necessary to facilitate the interpretation of flight behavior.

Several systems that allow the use of irregularly shaped odor sources and generate odor plumes with a predictable shape have been developed. These units comprise an enclosed flow system through which clean air is blown over the odor source and discharged into the center of the flight tunnel (Baker and Cardé, 1979; Cardé et al., 1984; Rauscher et al., 1984). In previous studies

these devices have been used to inject the odor-laden air with a velocity equal to or lower than the air velocity in the flight tunnel.

In the present study the odor-laden air is injected with velocities at least 10 times ambient. The difference between ambient and injected flow creates a turbulent jet with a conical shape and sharp but irregularly formed boundaries. A more homogeneous distribution of odor occurs inside a jet plume due to the high level of turbulence, as compared to plumes from an odor source in ambient flow. The term "irregularly shaped," as used in this paper, pertains to odor plumes whose instantaneous dimensions suggest that an insect heading straight upwind towards the odor source will be enveloped intermittently by the chemical stimulus. In contrast, an insect that flies a similar track in a jet plume will be continuously enveloped by the chemical stimulus.

High-velocity injection of odor causes an increase in odor concentration toward the source, similar to other techniques, but is dissimilar in that an insect must increase its flight speed to maintain a fixed ground speed during its approach to the source. Therefore, this odor presentation technique is suited to demonstrate whether insects actively regulate their upwind progress and whether they can maintain this response when approaching the source when odor concentrations are increasing.

The objectives of this paper are to describe in *M. croceipes* the effects on flight maneuvers of: (1) irregularly shaped and jet plumes; (2) intermittent host feeding; and (3) controlled dilution of odors in jet plumes of varying dimensions.

METHODS AND MATERIALS

Insects. *H. zea* larvae were reared on artificial diet using the method of Burton (1969). A colony of *M. croceipes* was obtained in March 1984 from the Southern Field Crop Insect Management Laboratory, Stoneville, Mississippi. This colony had been in culture at Stoneville since September 1982 and reared on *H. zea* (Lewis and Burton, 1970) in the Insect Biology and Population Management Research Laboratory, Tifton, Georgia. Parasitoids of both sexes were kept in Plexiglas cages (30 × 30 × 17 cm) at 28°C, 50–70% relative humidity, a 8:16 dark–light photocycle, and provided daily with fresh water and honey. Mating occurred as soon as both sexes were present (Bryan et al., 1969). The age of the females used in our experiments varied between 3 and 7 days. All experiments were done on at least three different days, and we used parasitoids from different collections each day.

Odor Sources. Greenhouse-reared cowpea seedlings (*Vigna unguiculata* L.), 5–10 cm in height, were used in all experiments. Either third- or fifth-instar *H. zea* feeding on cowpea seedling leaves were used as odor sources.

Both instars are attacked in the field (Hopper and King, 1984) and host viable progeny. To ensure feeding activity during the experiments, we starved the *H. zea* larvae during the 20 hr preceding the test: the third and fifth instars were provided with only one third or one half of a cowpea seedling leaf, respectively.

The average feeding rate for starved third- and fifth-instar *H. zea* larvae was obtained by timing the cumulative feeding duration and associated weight loss of cowpea seedling leaves. We observed individuals of each instar for 2 min. Third-instar *H. zea* consumed 4.1 ± 0.6 mg/min (mean \pm SE, $N = 14$) and fifth instars 23.5 ± 10.8 mg/min (mean \pm SE, $N = 24$) cowpea foliage. An odor source with 16 third instars will contain feeding activity approximately equivalent to three fifth instars, but presumably with lower variation over time.

To study the effect of intermittent feeding, we used individual fifth instars as an odor source because feeding was more visible on video recordings. To study in-flight navigation with a constant odor source, we used a group of 16 third instars.

The effect of daily variation in average feeding rates on the percentage of sustained flights was tested using a maximum likelihood estimate for a standard response function as provided by SAS (1982).

Flight Tunnel. An open-circuit, closed-throat flight tunnel with a $50 \times 50 \times 100$ -cm working section, described previously by Drost et al. (1986), was modified as follows: a 10×10 -cm grid of black lines (4 mm width) on white posterboard was placed underneath the Plexiglas floor; also the motor that drives the fan was held with rubber blocks to reduce vibrations of the flight tunnel floor. The air velocity was 50 ± 2 cm/sec (mean \pm SE, $N = 25$), the temperature was 26°C and relative humidity was 40–70%. Overhead lighting was provided by two fluorescent bulbs. The light intensity varied between 2260 and 3010 lux, depending on the position on the flight tunnel floor.

Contamination of the air circulating in the flight tunnel was minimized by releasing semiochemicals only when a parasitoid was to be tested. Between tests the air velocity in the flight tunnel was set at maximum speed to enhance ventilation of the test section. During experiments, the air of the room that housed the flight tunnel was continuously exhausted outside the building. The flight tunnel was cleaned using the procedures described by Drost et al. (1986).

Odor Supply System. An enclosed flow system (Figure 1) holds an odor source and injects emitted semiochemicals with the wind in the flight tunnel. Air, pressurized with a membrane pump (model 7530-40, Cole Parmer), was filtered through activated charcoal, kept at ambient temperature, and humidified with distilled water. Air in the supply system was heated by the membrane pump, and to prevent condensation of warm humidified air in the nozzles, the air was cooled to ambient levels. Connections up to the odor source were made of Tygon (B-44-3) tubing. Beyond the odor source we used 3-mm ID glass tubing. The main valve of the system, a three-way stopcock, allowed simulta-

FIG. 1. Schematic of the odor supply system.

neous disconnection of the air supply and depressurization of the flow system. Because the air was pulled through the flight tunnel causing an inside pressure lower than ambient, the odor supply system was depressurized through a vacuum trap to prevent leakage of odor when the main valve was closed. Flow rates were monitored and adjusted separately for the branch containing the odor source and the diluting branch with two flowmeters (model 7530-40, Cole Parmer). All experiments were done with a set flow rate of 244 ml/min in the branch containing the odor source. The odor concentration in the jet plume could be lowered by adding clean air to the odor-laden air in the mixing section. During dilution a pressure relief valve made of an adjustable air bubbler (model 7506-06, Ace Glass) kept the pressure in the system at a preset level. This method of dilution allowed us to manipulate shape and odor concentration of the jet plume independently.

The odor collection container designed to monitor larval behavior was constructed as follows. Three No. 8 rubber stoppers were connected in series with 3-mm ID glass tubing and could be covered with plastic Petri dishes (model 1008, Falcon). Each Petri dish could hold a cowpea seedling leaf and a fifth-instar *H. zea*. The space between the Petri dish and the stopper restricted the larva in one plane and thereby minimized the possibility of concealment during feeding. The total capacity of this container was 13 ± 0.5 ml.

The odor collection section used for navigation studies consisted of two units. Each unit held four 1-dram vials (6 cm height, 1.5 cm diam.) in two parallel groups of two vials connected in series. To reduce cannibalism and fighting, we used two larvae per unit of the odor collection container. In pilot

tests we found that the frequency of landings decreased on odor sources that contained fighting or cannibalizing larvae. The total capacity of the collection section with a set of eight units, containing eight cowpea seedling leaves and 16 third-instar *H. zea*, was 82 ± 0.5 ml.

Connected to the mixing section was a nozzle made of a Pasteur pipet, which injected odors in the main wind direction of the flight tunnel, 10 cm above the floor. To provide a landing site, a cardboard target was attached to the nozzle and positioned inside the plume but outside the high-speed flow region (Figure 2). *M. croceipes* lands on any object that is provided with host-related volatiles (Drost et al., 1986).

Odor Presentation. The shape and average velocity distribution in a turbulent jet are determined by the difference in velocity of injected and ambient air and the diameter of the nozzle. We obtained a narrow, low-velocity jet with a low-pressure nozzle and a wide, high-velocity jet with a high-pressure nozzle. A high-pressure nozzle was made by heating and simultaneously pulling the tip of a Pasteur pipet (model P5200-2, diSPo pipets, Scientific Products). High-pressure nozzles had an over pressure of 6 ± 0.5 cm water above atmospheric pressure, at a flow rate of 244 ml/min. The tip of a Pasteur pipet was left unaltered for a low-pressure nozzle. The average air velocities in the turbulent

FIG. 2. Wide jet plume visualized with titanium chloride smoke and position of landing site attached to the nozzle.

jets were measured on the center line of the jet at 10 cm intervals with a hotwire anemometer (model AB-27, Hastings Raydist, Hampton, Virginia).

The time-averaged dimension of a cross section of a jet plume was obtained using a method similar to the ones described by Miller and Roelofs (1978) and by Sanders (1985). A frame covered with cheesecloth, with dimensions that fitted exactly inside the tunnel, was positioned at appropriate distances from the nozzle. The air-pull of the fan of the flight tunnel was adjusted so that drag losses caused by the screen were corrected to an air velocity of 50 cm/sec upwind of the screen. Cheesecloth impregnated with crystal violet was placed downwind from the nozzles at the upwind side of the screen. Acid "smoke," resulting from titanium tetrachloride reacting with humidified air, was injected and the acid component stained the purple cheesecloth yellow according to the size of the jet plume. After a 3-min exposure to the acid smoke, a print of the cross section of a jet plume was immediately photographed. The dimensions of the turbulent jets were sampled at the same 10-cm intervals used in the air velocity measurements.

Event Recorder. An event recorder program in BASIC for a Tandy model 100 computer allowed the sequential recording of behavioral components and their duration in seconds, the "complete" record (Colgan and Smith, 1978) and the experimental conditions. To describe each experiment, we used the variables of date, time of day, parasitoid age, ambient temperature, type of odor source, type of flight response, individual number, and trial number. The following behavioral components applicable in a flight tunnel, modified from Drost et al. (1986), were recorded: (1) preflight behavior—all behavior between first contact with the odor plume and take-off; (2) initial zigzagging—lateral excursions, mainly in the horizontal plane and perpendicular to the wind direction soon after take-off; (3) straight flight—straight upwind flights; (4) recurrent zigzagging—lateral excursions after straight flight; (5) downwind loop—a downwind looping maneuver; (6) hovering—stationary flight at approximately 10 cm downwind from the target; and (7) standing still on the target—standing still on the target.

After analysis of our raw data, we found that during sustained flights initial zigzagging was always followed by straight flight. Therefore, in behavioral descriptions the term *initial flight stage* is used instead of the sequence initial zigzagging; straight flight.

Each observation was terminated after a landing occurred on a wall of the flight tunnel or on the target and given a response category according to the types of behavioral components performed.

The following response categories were used: (1) sustained flight—nonstop flights resulting in standing still on the target; (2) temporary-oriented flight—flights that included at least initial zigzagging and straight flight but were subsequently terminated; (3) non-target-oriented flight—flights terminated imme-

diately after or before initial zigzagging; and (4) no take-off—preflight behavior lasting longer than 2 min. Behavioral sequences of females performing the response category sustained flight to the same type of odor source were used to construct contingency tables of transition frequencies between behavioral components.

Statistical Analysis of Behavioral Sequences. Conditional probabilities of transitions between behavioral components were calculated to depict the main behavioral pathway. We tested whether transitions occurred at a frequency significantly different from chance expectation assuming independence between behavioral components. For behavioral components preceded or followed by more than two other types of components, we calculated standardized residuals based on estimated expected frequencies obtained by iterative proportional fitting (Bishop et al., 1975; Goodman, 1968), as provided by SAS (1982). Because certain behavioral components cannot follow each other, as a consequence of their definition (see Figure 2 in Drost et al., 1986), and not themselves as a result of our sampling procedure, the contingency tables were incomplete due to “logical zeros” (Bishop et al., 1975). In this case the iterative procedure provides row and column sums of estimated expected frequencies that converge to the corresponding sums of the observed frequencies, a requirement for the use of chi-square. Because initial flight stage was only preceded by preflight behavior, following its definition, this transition was not eligible for the chosen analysis and omitting this transition resulted in a similar situation for preflight behavior. Therefore behavioral components following preflight behavior were analyzed using a binomial test.

When the absolute value of the standardized residual, $(\text{observed} - \text{expected})/[\text{SQRT}(\text{expected})]$, of a transition frequency exceeded 3, then that transition occurred at a frequency significantly different from chance expectation assuming independence between behavioral components (Colgan and Smith, 1978). Because we performed multiple comparisons, the 1.96 standard can serve only explorative means, and standardized residuals with values greater than 3 are a more reasonable guide for significance. We used contingency tables with more than five times the possible transitions (19) observed. This amount (95) is a recommended minimum required for the use of the standardized residuals method (Colgan and Smith, 1978).

Statistical Analysis of Durations of Behavioral Components. The precision of the stopwatch of the event recorder is 1 sec. We chose to use only those durations whose range was 30 sec or more or had a median of at least 5 sec.

To test whether durations of behavioral components were independent from following components, durations were plotted semilogarithmically in a log-survivor plot. If, for each given behavioral component, the probability to occur is constant through time (a Poisson process), then the duration of components will have an exponential distribution and the log-survivor curve will be a straight

line. The Kolmogorov goodness-of-fit test was used to test whether log-survivor curves differed significantly from a straight line (Colgan and Smith, 1978; Conover, 1971).

The mean duration of each occurring behavioral component was calculated for each sustained flight. The effect of treatments on the mean duration of behavioral components was tested using the Wilcoxon test in case of a two-level comparison or the Kruskal-Wallis test when more levels were to be tested.

Video Recording. A video camera (model TC 2055/UBC, RCA), connected to a video recorder (model NV-8950, Panasonic), with a 8 mm f1.4 lens (model TC 1810C, RCA) was mounted in front of the larval container or on top of the flight tunnel. The video recorded an area of 40×90 cm of the flight tunnel floor. A time generator (model WJ-810, Panasonic) was used to superimpose hundredths of a second onto the video signal. Flight tracks of sustained flights, performed by first-time flyers, were traced on acrylic sheets. Subsequently these tracings were measured with a digitizer (model HP-9874A, Hewlett-Packard) interfaced to a computer (model HP-9915A, Hewlett-Packard) using software written in BASIC.

Flight track measurements were made relative to the 10×10 -cm grid on the floor of the flight tunnel. Because we wanted to determine the relationship between position in the plume and flight behavior, measurements were allocated to squares enclosed by the grid, numbered one (10 cm downwind from the odor source) through seven (near the release point, below the jet plume). The time and position of an insect's exit from a square were used to allocate tracks to the squares. Flight tracks that included downwind loops extending beyond one square were not used in the analysis. Distortion of the grid in the area of flight activity was of the same order of magnitude as the body length of the insect and was therefore ignored.

The average ground speed, the distance traveled, and the maximal flight deviation from the center line of the odor plume were measured for each square (Figure 3). Average ground speed in a square was calculated as the quotient of the track length and time elapsed to travel that distance. The maximal flight deviation from the center line of the plume gives the envelope within which the parasitoid flew. Distance traveled increases the more the insect deviates from a straight flight path and is thus related to the frequency and amplitude of zig-zagging. When the insect flies in a straight line from the release point to the target, distance traveled is the minimum of 70 cm.

We found the variation of log $(x + 1)$ -transformed data for ground speed and maximal flight deviation to be normally distributed using the Shapiro-Wilks (1965) statistic as provided by SAS (1982). This was not the case for distance traveled. Consequently, we used an ANOVA for ground speed and maximal flight deviation after testing for homoscedasticity and the Kruskal-Wallis test for distance traveled to test for homogeneity among days for each square of

FIG. 3. Schematic of the flight track measurements made in each square.

each treatment. Further analysis was performed on data for which homogeneity among days was obtained. Significance of differences among treatments, among squares within a treatment, and among treatments for each square for ground speed and maximal flight deviation was tested using an ANOVA and the Duncan's multiple-range test on $\log(x + 1)$ -transformed data, whereas the Friedman test was used in the case of distance traveled.

General Experimental Procedure. All experiments took place between the 4th and 8th hour of the photophase. Odor sources were prepared as follows. Shortly before adding the larvae, cowpea seedling leaves were picked and weighed. The period that larvae and cowpea foliage were together in the odor collection container was timed in minutes. Immediately after the completion of the experiments, the leaves were weighed again and the weight loss of the leaves was calculated. The average feeding rate was used to compare odor production during different experiments.

Prior to testing, the odor supply system was left open for 30 min to allow the equilibration between release and adsorption of semiochemicals on the glass walls of the supply system. Pasteur pipets were rinsed with acetone after use.

About 30 min prior to the experiments, a cage with untested parasitoids was transferred from the rearing room to the flight tunnel room. Prior to release in the flight tunnel, female parasitoids were exposed for 2 min to a third-instar *H. zea* and frass as described by Drost et al. (1986). These third-instar larvae had fed on cowpea seedling leaves overnight. Females were discarded if they were injured by the host larva during their stay in the exposure cup or performed prolonged supination of the wings. The latter is a response to being doused by fluids of a larva when it regurgitates in response to being stung. A 1-dram vial

(8 × 1 cm), containing a parasitoid with preflight exposure, was placed with its opening 80 cm downwind from the odor source. As soon as the parasitoid reached the opening of the vial, the video recorder was started, the main valve of the odor supply system was opened, and the recording of the behavior with the event recorder commenced. When a parasitoid landed, recording was stopped, the main valve of the odor supply system was closed, and the parasitoid was caught with the release vial and returned to the initial release point for a next trial.

RESULTS

Experiment 1: Flight in Irregularly Shaped Odor Plumes. Thirty female parasitoids were released individually in odor plumes generated from third- or fifth-instar larvae on a cowpea seedling placed at the center of the flight tunnel at the upwind side. Air velocity was 50 cm/sec. Each female was given four trials, and flight behavior was recorded with the event recorder.

We observed no significant (binomial test, $P < 0.05$) differences in percentages of sustained flights in irregularly shaped plumes emitted by either third (69%, $N = 120$) or fifth (63%, $N = 120$) instars feeding on cowpea seedling leaves.

Flight behavior during sustained flights remained similar among trials in terms of frequencies of transitions between behavioral components and were not significantly different for flights toward both third and fifth instars ($\chi^2_{54} = 40.8$ and 31.5 , respectively). The duration of the initial flight stage of sustained flights to third instars declined significantly ($P < 0.0004$) over the first, second, and third trials, which matches the observations of Drost et al. (1986). The durations of all behavioral components during sustained flights to fifth instars did not differ among trials.

From the conditional probabilities shown in Figure 4A, it follows that sustained flights in irregularly shaped plumes, permeated with semiochemicals from third-instar larvae feeding on a cowpea seedling, were most frequently performed in the following behavioral sequence: preflight behavior, initial flight stage, recurrent zigzagging, straight flight, standing still on the target. Behavioral components that did not occur independently are summarized in Table 1. Transitions from downwind loop to recurrent zigzagging and from hovering to standing still on the target had standardized residuals larger than 3. Transitions between preflight behavior and initial flight stage occurred more often than can be expected by chance (binomial test, $P < 0.05$).

Experiment 2: Effect of Intermittent Host Feeding on Flight. Flight tunnel responses of female *M. croceipes* and the behavior of the larvae used for the

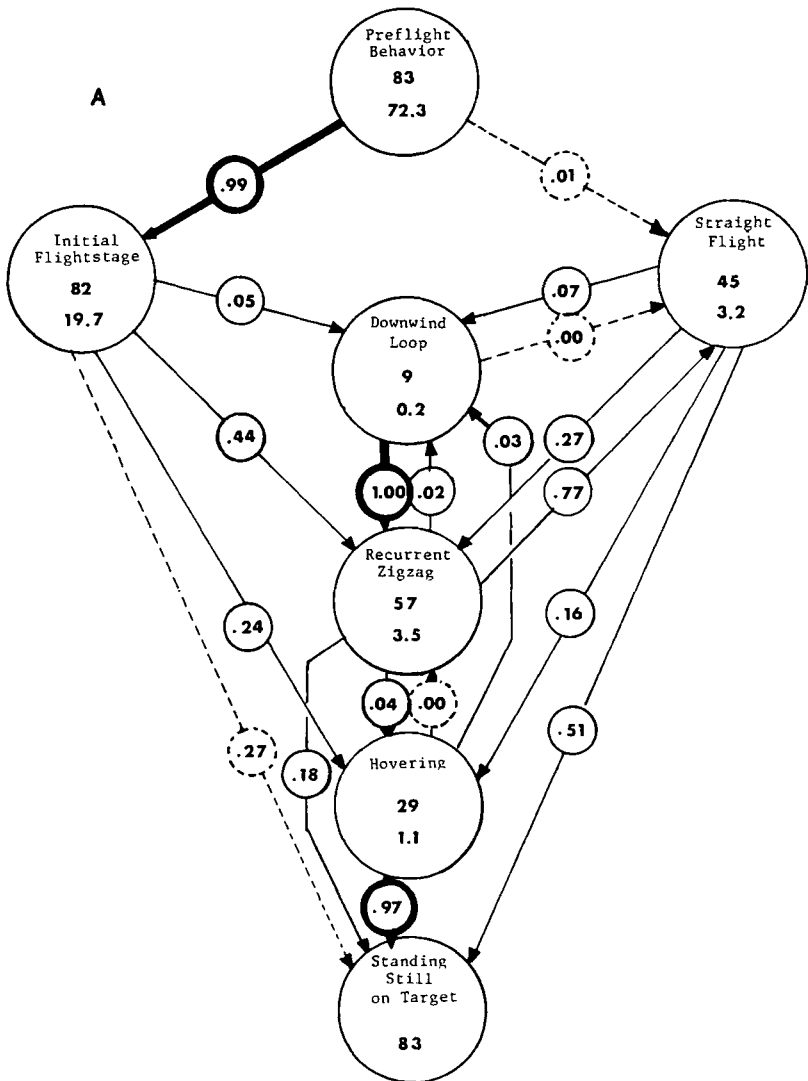

FIG. 4. Kinematic graphs of transitions between behavioral components performed during sustained flights toward semiochemicals emitted by third-instar *H. zea* feeding on cowpea seedling leaves when presented an irregularly shaped plume (A, $N = 83$) and a jet plume (B, $N = 83$). Information provided inside large circles is: behavioral component, number of tokens, and percent of total time spent to that behavioral component. Numbers in small circles associated with arrows are conditional probabilities. Boldface arrows and circles refer to transitions that occur more often than random, whereas dotted arrows refer to transitions that occur less often than random.

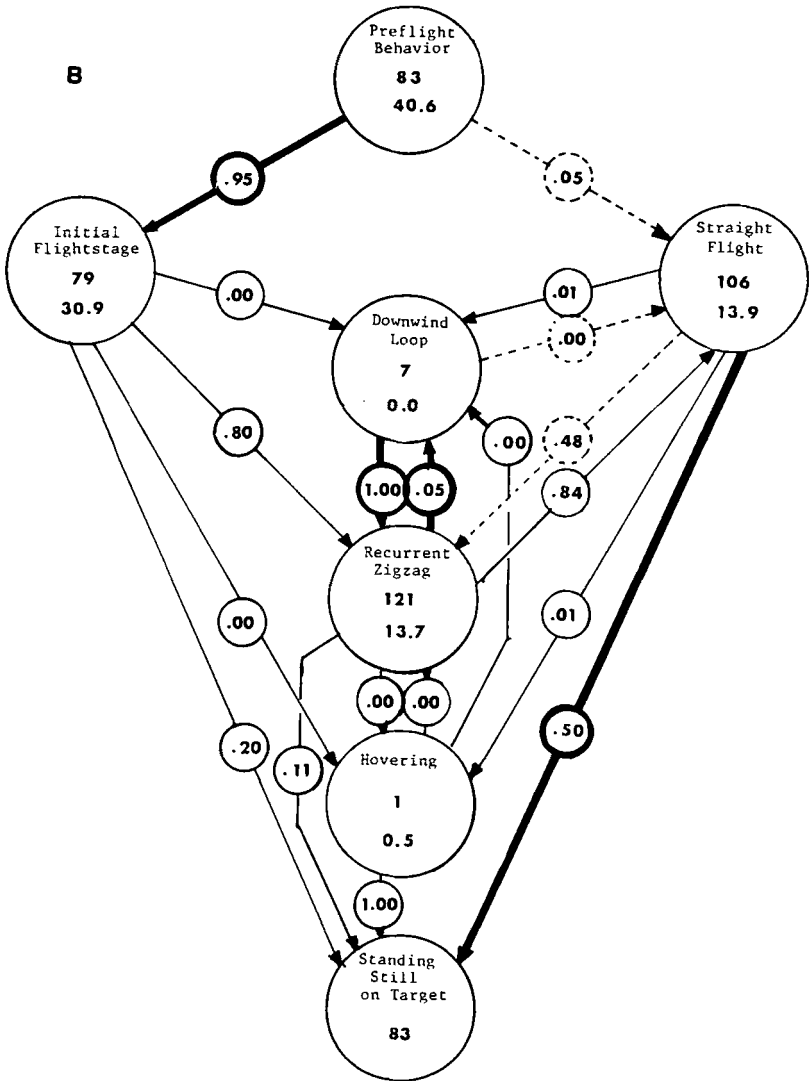

Fig. 4. Continued.

odor source were recorded simultaneously. The onset and duration of feeding movements by the fifth-instar larvae were determined by frame-by-frame analysis of the video recordings.

Of the 80 tested parasitoids, three were released when two larvae were feeding at the same moment, one when three larvae were feeding simulta-

^bVII: Standing still on the target.

neously, and the remaining 76 when no feeding or feeding by a single larva was observed. The median duration of feeding bouts for an individual larva was 2 min (range 1-19 min) and the median duration between feeding bouts was 5 min (range 1-15 min). Between feeding, larvae were defecating, sitting motionless, walking, and making jabbing movements of the head.

Apparently in our experimental set-up there was no decay of attractancy between feeding. Sustained flights were performed by 49% ($N = 76$) of the wasps evaluated. There were no significant differences in the percentage of sustained flights during feeding bouts (50%, $N = 29$) compared to periods between feeding bouts (48%, $N = 47$); between percentages of sustained flights during feeding bouts longer than 2 min (upper 50% percentile) and shorter than 2 min; and between the upper and lower 50% percentile of periods between feeding bouts (median 5 min).

Flight behavior was not different for periods with and without host feeding, because no significant difference was found for transition frequencies between behavioral components ($\chi^2_{18} = 9.829$).

The log-survivor curves of durations of preflight behavior and the cumulative duration of all other behavior during sustained flights did not significantly differ from a straight line, which means that the durations of these behavioral components are independent from preceding or following components (Hooff, 1982). More parasitoids performed shorter preflight behavior when responding during host feeding bouts compared to those that responded between feeding bouts, as expressed in the different slopes of the log-survivor curves (Figure 5). However, we found no significant differences for the average durations of pre-flight or flight-behavior components for sustained flights either during or between feeding bouts.

Experiment 3: Effect on Flight of Varying Olfactory Conditions in Jet Plumes. Six types of odor plumes were presented in a randomized order, and five parasitoids were released twice into each plume. The experiment was replicated six times. Odor sources used for jet plumes were: humidified air as a control; semiochemicals emitted by 16 third-instar *H. zea* feeding on cowpea seedling leaves (two larvae per leaf); and the same amount of odors diluted by adding an equal amount of clean air, as described earlier. Odors were presented either by a "wide" or a "narrow" conical-shaped turbulent jet. When an odor plume had a lower odor concentration than one previously presented, the branch of the odor supply system containing the odor source was closed and clean air provided by the diluting branch was ducted through the nozzle for 15 min prior to testing.

FIG. 5. Log-survivor curve of preflight behavior prior to sustained flights by *M. croceipes* during feeding bouts and feeding intervals of the "odor-source larvae."

The daily variation in feeding activity for a group of 16 third instars did not significantly affect the percentage of sustained flights to each treatment. The percentage of sustained flights, however, did vary for the six types of jet plumes (Figure 6A). No sustained flights were observed with either control plume (low- or high-pressure nozzles injecting humidified air). A significantly lower percentage of sustained flights was found for a narrow jet plume with a half odor load when compared to a wide jet plume with a full odor load. Of all unsuccessful responses the category "nonoriented" was the most frequent, whereas temporary-oriented flights seldom occurred (Figure 6B).

Behavioral components performed during sustained flights in the four odor-containing types of jets were compared. Although jets with half odor loads evoked significant lower percentages of sustained flights, when those flights occurred, no significant difference was found in frequencies of transitions between behavioral components as compared to those performed in jets with full odor loads ($\chi^2_{54} = 31.85$).

From the conditional probabilities shown in Figure 4B, it follows that sustained flights in all four types of jet plumes, permeated with semiochemicals from third-instar larvae feeding on cowpea seedling leaves, were performed with less variation in the behavioral sequences than in irregularly shaped plumes of the same odor source. More behavioral components during sustained flights in jet plumes did not occur independently as compared to sustained flights in irregularly shaped plumes. Table 2 shows that the transitions between downwind loop and recurrent zigzagging and straight flight into standing still on the

^aobs = observed frequency; exp = expected frequency; StdR = standardized residual.

^bVII: Standing still on the target.

target had standardized residuals larger than 3. The transitions from preflight behavior into initial flight stage occurred more often than can be expected by chance (binomial test, $P < 0.05$).

The log-survivor plot of durations of behavioral components performed in the four odor jet plumes did not differ from a straight line, so apparently there was no dependency of durations between behavioral components. The average durations of behavioral components were compared and found not to differ significantly among the four treatments.

A Comparison of Flight in Irregularly Shaped Plumes and Conically Shaped Jet Plumes. We obtained percentages of sustained flights in irregularly shaped plumes generated with third instars (69%, $N = 120$) or fifth instars (63%, $N = 120$) on cowpea seedlings similar to those of Drost et al. (1986) (58%, $N = 24$). The percentage of sustained flights was lower when odors from similar sources (third: 40%, $N = 83$; fifth: 49%, $N = 76$) were released in jet plumes. *M. croceipes* is confronted in the field with odor plumes typical for point sources, which resemble irregularly shaped plumes. However, jet plumes

provide a continuous odor stimulus, which may have caused a lower percentage of sustained flights.

Contingency tables of behavioral components performed during sustained flights in irregularly shaped plumes and jet plumes (Figure 4A and B), both permeated with semiochemicals from feeding third-instar larvae on cowpea seedling leaves, differed significantly ($\chi^2_{18} = 123.7$). During sustained flights in jet plumes the initial flight stage was more often followed by the behavioral sequence of recurrent zigzagging, straight flight than during sustained flights in irregularly shaped odor plumes. In irregularly shaped odor plumes the initial flight stage was more often followed by hovering, whereas straight flight was more often followed by downwind loops. The duration of preflight behavior lasted significantly longer for parasitoids responding with sustained flights in irregularly shaped plumes as compared to jet plumes ($P < 0.0001$).

Flight Track Analysis of Video Recordings. To compare responses of the parasitoids in different portions of the jets, it is necessary to take into account the different levels of olfactory stimuli. However, because no prediction of actual odor emission rates of the odor sources used are available, we calculated relative expected odor fluxes. We used the position in the jet 10 cm downwind from the nozzle with the highest expected odor flux as a reference, i.e., vertically above the first square inside a narrow jet plume permeated with a full odor load. Local odor flux in a jet plume varies with the inverse of the local cross-sectional area of the jet times the local air velocity. To calculate local cross-sectional area, we used the time-averaged dimensions of the jet plumes obtained with the titanium tetrachloride staining method (Figure 7). The average air velocity in a jet plume varies from ambient at the boundaries to a maximum at the center line of the jet. The center line odor flux is encountered by an insect when sitting on a release vial at the center line of the jet. For the release point, in the four jet plumes, these odor fluxes were, respectively, 1.5, 0.75, 0.50, and 0.25% of the reference odor flux for a narrow plume full load, a narrow plume half load, a wide plume full load, and a wide plume half load. When an insect starts flying, odor fluxes perceived instantaneously are difficult to estimate, because in a jet plume the air velocity drops from the local maximum at the center line to ambient at the boundaries. However, an insect flying upwind with a fixed average flight speed relative to the ground will perceive, on average, increasing odor fluxes of 32- to 67-fold close to the center line of the jet plume, as depicted in Figure 8. In the case of boundary following, the average increase of the perceived odor flux will be at least 20-fold, because turbulent mixing causes a homogeneous distribution of odors inside the jet plume and air velocity will average equal to ambient.

The plume width and maximal flight deviation from the center line of the plume is plotted against square number in Figure 9A. No significant differences

FIG. 7. Dimensions (cm) of wide and narrow jet plumes. Numbers at center line of each jet plume refer to measured air velocities (cm/sec), S = source, R = release point.

FIG. 8. Estimates of olfactory stimulus conditions occurring in wide and narrow jet plumes with full (upper symbols) and half (lower symbols) odor loads expressed in relative odor fluxes above each square.

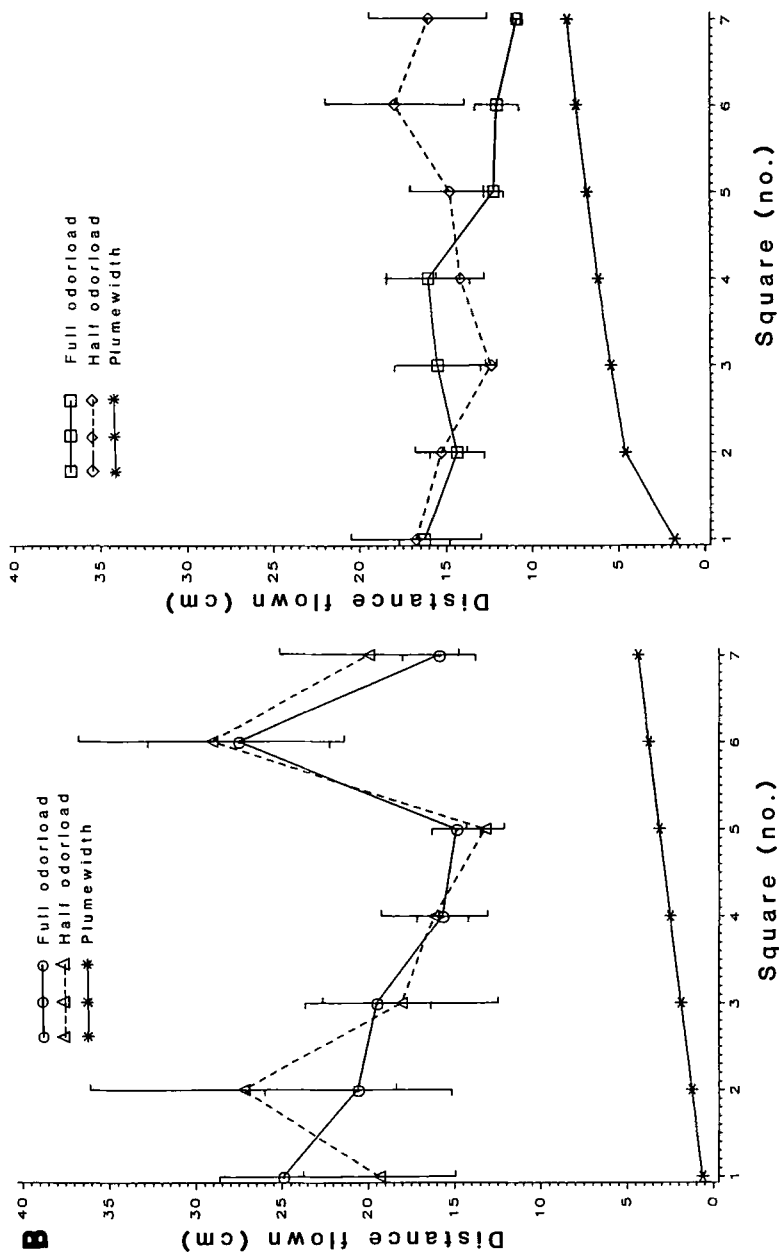

FIG. 9. Measurements from videotaped flight tracks in a narrow jet plume (left graph) and wide plume (right graph). (A) Maximal flight deviation from center line plume and plume width. (B) Distance traveled and plume width. (C) Average ground speed and air velocity at center line plume.

Fig. 9. Continued.

for maximal flight deviation between treatments were found. Unfortunately, part of the flight behavior in wide plumes was not recorded. In contrast to initial zigzagging performed in narrow plumes, *M. croceipes* tended to drift quickly downwind from the release point during initial zigzagging in wide plumes and out of the viewing area of the video camera. Apparently, straight flight and recurrent zigzagging were performed similarly in narrow and wide plumes, whereas initial zigzagging in a narrow plume did not differ in its amplitude from recurrent zigzagging.

From these findings it remains questionable whether *M. croceipes* uses information on the position of the boundaries of a jet plume in its flight maneuvers. A comparison of initial zigzagging in narrow and wide jet plumes may show a relationship between plume width and counterturn position. At this point we must assume that straight flight and recurrent zigzagging are more or less fixed and not affected by plume width, because no difference between treatments was demonstrated.

Distance traveled in each square together with the plume width is plotted in Figure 9B. Wasps flew significantly greater distances in narrow plumes as compared to wide plumes ($P < 0.0003$). This might be due to more frequent counterturning because the maximum flight deviation from the center line did not differ among treatments. Dilution of the odor load in each size jet plume, wide or narrow, did not significantly affect the distance traveled. When differences between narrow and wide plumes were tested for each square separately, the differences were significant for squares 5, 6, and 7 ($P < 0.0278, 0.0447, 0.0122$). The differences in maneuvers above squares 5, 6, and 7 of wide and narrow jet plumes are due to the fact that in narrow plumes initial zigzagging was performed upwind from the release point, whereas in wide plumes parasitoids more often performed straight flight. Above the more upwind squares 1, 2, 3, and 4, straight flight and recurrent zigzagging were of similar frequency for both jet plumes.

The center line air velocity of jet plumes was plotted with the ground speeds of the wasps for each square (Figure 9C). In a wide jet plume, the ground speed decreased toward the source from 30 to 23 cm/sec; however, this decline was not significant. Consequently the airspeed varied between 80 and 85 cm/sec close to the release point and between 73 and 113 cm/sec 10 cm downwind from the target. Although not significant, the average ground speed in narrow low-velocity plumes decreased from around 23 to 18 cm/sec. This decrease could not result from exceeding demands on airspeed by the jet plume, because *M. croceipes* can fly at least 113 cm/sec as was observed in the wide high-velocity plume, and the maximum demand in a narrow plume was 71 cm/sec 10 cm downwind from the target. Females flew at significantly lower ground speeds in narrow jet plumes compared to wide jet plumes ($P < 0.0001$). This

can partly be explained by the assumption that the initial flight stage is at slower ground speed.

DISCUSSION

The orientation mechanisms used during in-flight host searching by parasitoid wasps of herbivorous larval insects are not well understood. Traditionally the first two steps of host searching in parasitoids are called host habitat location and host location. *Heliothis* has a polyphagous feeding pattern and switches among host plants during the season. Several host-related olfactory cues might be used during habitat and host location. The relative importance of each of these cues for host location depends on how closely it is associated with the presence of the host. From this perspective, cues that persist in attracting *M. croceipes* after the larva moved elsewhere may be less important for immediate host detection, whereas semiochemicals exclusively emitted by larvae are more valuable. Odors emitted by the larva itself or odors with little persistence and emitted during feeding fall into this class. The odors used by *M. croceipes* for detection of hosts come from sources that may differ in strength. In our set-up, only the strongest sources associated with the host-plant complex might have been active. The use of an extensive odor supply system was intended to stabilize odor emission, shape of odor plume, and visual stimuli at the source. The experiments presented in this paper use an indirect indicator for emission rates of semiochemicals: feeding activity of the host larvae.

Female *M. croceipes* respond to semiochemical sources that are similar to those evoking pheromone-guided responses by male moths. In both cases the semiochemicals emanate from point sources, although the location of the sources on the foliage may differ. In both cases the insects involved are fast and strong flyers that are able to approach the source from downwind. The olfactory cues are emitted by the objects that evoke the consummatory act, which are, respectively, egg deposition into the host larva and copulation with a "calling" female moth. In both cases intraspecific competition might have led to optimization of flight maneuvers to enhance searching success.

However, in larval parasitoids interspecific interaction might have increased the intensity of competition. *M. croceipes*, for example, competes with other entomophagous insects for *H. zea* larvae. Another factor that cannot be ignored is the possibility of defensive actions by the attacked host. Our experiments excluded interference of defensive behavior of the host with orientation behavior of the parasitoids.

The question arises as to what caused oriented flights between feeding bouts of the host. Sustained flights were not observed by Drost et al. (1986) to undamaged cowpea seedling leaves in a flight tunnel or by Eller et al. (1988)

to volatiles emitted by isolated *H. zea* larvae in an airflow olfactometer as described by Vet et al. (1983). Fecal pellets and artificially damaged cowpea seedling leaves attract female parasitoids in an airflow olfactometer (Eller et al., 1988). The emission of volatiles from plant damage and possibly host secretions associated with feeding is probably short-lasting, because Eller et al. (1988) found that collected odors from hosts feeding on cowpeas were behaviorally inactive after 10 min. In our experiment, the median period between feeding bouts for a group of three starved fifth-instar *H. zea* was 5 min, and therefore we probably did not measure the effect of fading of the source. In addition, volatiles rereleased from the glass walls might have caused sustained flights between feeding bouts.

It is surprising that the percentage of sustained flights in narrow plumes with a half odor load was less than in a wide plume with a full odor load (Figure 6A). Response would not be expected to differ when odor concentrations are of the same order of magnitude (Figure 8). Because only a minority of all non-successful responses were temporary-oriented flights, *M. croceipes* evidently will not interrupt its flight due to increasing odor concentrations. In moths, increasing pheromone concentrations typically decrease net upwind speed (e.g., Cardé and Hagaman, 1979; Sanders, 1985).

In moths attracted to pheromone, an internal program of counterturns (zig-zags) is thought to be evoked by pheromones (Cardé, 1984; Kennedy, 1983; but see also Preiss and Kramer 1986). The rate of upwind displacement is modulated by odor concentration, causing a decrease of net upwind speed close to the source, resulting from a combination of an increased frequency of zigzagging and a decrease in flight speed. Fluctuations in the odor concentration are needed to maintain counterturn responses in *Grapholitha molesta* (Baker et al., 1985). Wind experienced prior to take-off or while in flight establishes polarity of the counterturns, so that displacement toward the source will occur. Thus odor concentration modifies the anemotactically polarized optomotor responses performed by moths.

One experimental method to study concentration effects on oriented flights is the use of moving floor patterns in a flight tunnel. The effect of the floor pattern being moved in the downwind direction by the experimenter will be that the responding insect will lower its flight speed. Once the floor movement is at a level equal to the "preferred" retinal velocity, the insect will have lowered its flight speed to a level where it remains at a relatively fixed position in the flight tunnel. One can thus determine how odor concentration alters the optical feedback needed to arrest upwind progress of a flying insect (Sanders, 1985). The advantage of this method over using a jet plume is that substantially less wind shear can be expected as compared to jet plumes. In jet plumes air velocity gradients are accompanied by odor concentration gradients.

An insect able to perceive its acceleration can determine wind direction in a jet plume without using optical information, following principles proposed by Gillett (1979). When flying upwind with a fixed airspeed, an insect will decelerate at the center of the jet plume, whereas it will accelerate when shifting its course away from the center of the jet plume. In a downwind heading, similar maneuvers will have opposite effects on flight velocity. Therefore one cannot determine if insects flying in jet odor plumes use either optical or inertial input to maintain an upwind course. Another important difference between jet plumes and a regular point source is their distribution of odors. Murlis and Jones (1981) concluded that odor plumes emerging from point sources do not contain information that enables insects to determine their distance relative to the source. For this reason, previous studies of concentration effects have been possible only by using point sources with different odor emission rates. In a jet plume one can manipulate upwind odor gradients by changing the dimensions of the jet using the same source. In moths, upwind progress decreases around three-fold with a 10-fold increase of odor load of the test sources (Cardé and Hagam, 1979; Sanders, 1985). In contrast, *M. croceipes* does not respond to odor concentration in this manner. Ground speed was not affected by increasing odor concentrations over a 20- to 67-fold range as the wasp progressed upwind in jet plumes. The fact that *M. croceipes* responds with increasing flight speeds to increasing odor concentrations is the opposite of the response found to date with moths.

The stereotypic shift from initial zigzagging to straight flight and the evidently minor importance of odor concentrations or odor fluxes in modulating the upwind progress may be explained as an adaptation to short communication distances and unstable odor sources. *M. croceipes* interrupted straight upwind flight with two types of maneuvers: recurrent zigzagging and downwind loops. Downwind loops were predominant in irregularly shaped plumes. In jet plumes, recurrent zigzagging was most often performed. Loss of contact with the odor stimulus can result from windshifts and interruption of odor emission. *M. croceipes* hunting for third-instar larvae can expect larval feeding activity only 50% of the time, as was found by Schmidt (1985). David et al. (1983) describe how wide lateral zigzags aid the gypsy moth in reentering a plume "lost" because of shift in wind direction. His model is applicable when windshifts are the main cause of scent loss and interruption of odor emission is unlikely. When interruptions of odor emission occur, which may be the case in *M. croceipes*, a strategy other than casting may be more effective in enhancing the likelihood of recontacting the plume. All course angles that are crosswind but have no upwind component are more effective in finding another source, because for a given amount of flight, the area searched is greater than for course angles with an upwind component. Both casting and downwind loops thus may serve as a

strategy for recontacting a lost scent over the distances of host detection used by *M. croceipes*.

Acknowledgments—We thank Y.C. Drost, D.W. Whitman, M.A. Willis, and two anonymous reviewers for a critical reading of the manuscript; M. Sutherland for his advice on statistics; and L.J.H. Hill for rearing *M. croceipes*. The research was supported in part by a grant from the International Research Division of the USDA, OICD, and a USDA Competitive Research Grant to R.T.C. and W.J.L.

EFFECT OF ERGOT ALKALOIDS FROM FUNGAL ENDOPHYTE-INFECTED GRASSES ON FALL ARMYWORM (*Spodoptera frugiperda*)

KEITH CLAY and GREGORY P. CHEPLICK¹

(Received August 5, 1987; accepted November 3, 1987)

Abstract—Ergot alkaloids produced by endophytic fungi in the tribe Balansiae (Clavicipitaceae, Ascomycetes), which infect grasses, may provide plant defense against herbivores. This study examined the effects of six ergot alkaloids on survivorship, feeding, and growth of larvae of the fall armyworm (*Spodoptera frugiperda*, Lepidoptera: Noctuidae), a generalist herbivore of grasses. Corn leaf disks were soaked in solutions of individual ergot alkaloids at different concentrations and presented to neonate larvae. At the highest concentrations (77–100 mg/liter) of ergonovine, ergotamine, ergocryptine, agroclavine, and elymoclavine, larval weights and/or leaf area consumed after eight days were reduced relative to controls. Lysergol had no effect on larval weights and leaf consumption at any concentration. Although active concentrations were higher than those reported from two host grasses, *in vivo* levels of ergot alkaloids have not been quantified for most endophyte-infected grasses. The detrimental effects on fall armyworm observed in this study suggest that ergot alkaloids could be responsible, at least in part, for the greater insect resistance of endophyte-infected grasses.

Key Words—Balansiae, Clavicipitaceae, ergot alkaloids, fall armyworm, feeding deterrents, acquired chemical defense, fungal endophytes, grasses, Lepidoptera, Noctuidae, *Spodoptera frugiperda*.

INTRODUCTION

Recently the role of clavicipitaceous fungal endophytes infecting grasses as insect feeding deterrents has been demonstrated (Funk et al., 1983; Clay et al., 1985; Latch et al., 1985). Systemic fungi in the tribe Balansiae, family clavi-

¹Present address: Department of Botany, Miami University, Oxford, Ohio 45056.

cupitaceae (Ascomycetes), and their anamorphs, are known to infect hundreds of species of grasses and sedges (Diehl, 1950; Clay, 1987; White, 1987). Livestock toxicity problems of unknown etiology historically have been associated with certain pasture grasses (e.g., tall fescue, perennial ryegrass). The presence of fungal endophytes in these grasses has been correlated with livestock toxicity (Bacon et al., 1986). Perennial ryegrass pastures in New Zealand toxic to sheep were shown also to be more resistant to damage by the Argentine stem weevil, *Listronotus bonariensis* (Prestidge et al., 1982). The association between fungal endophyte infection and resistance to insect herbivores has now been demonstrated in a number of grasses and sedges (Clay, 1987).

Increased insect resistance of infected grasses may result from the production of alkaloids by the fungi present within the tissues of its host. The Balansiae, like their close relatives in the genus *Claviceps*, produce a variety of ergot alkaloids. However, unlike *Claviceps*, which is a localized ovarian parasite of grass flowers, Balansiae species are systemic, and both the fungi and the alkaloids can be found throughout the above-ground host-plant tissues (Clay, 1986; Siegel et al., 1987). The anamorphic endophytes of tall fescue and ryegrass and several Balansiae species are also known to produce other types of alkaloids (Porter et al., 1977; Bush et al., 1982; Gallagher et al., 1984; Rowan and Gaynor, 1986).

While the association among fungal endophytes, ergot alkaloids, and insect resistance in grasses strongly suggests a functional relationship, to our knowledge there have been no previous published studies of the effect of ergot alkaloids on insect feeding. The purpose of this study is to determine the effect of several ergot alkaloids on feeding by larvae of the fall armyworm (*Spodoptera frugiperda* J.E. Smith, Lepidoptera: Noctuidae), a generalist herbivore of grasses. The fall armyworm has been shown previously to be sensitive to the presence of fungal endophytes in grasses (Clay et al., 1985; Hardy et al., 1985, 1986), and it has been widely utilized as a bioassay for grass feeding studies (Pencoe and Martin, 1981). In particular, we ask whether the alkaloids function as antifeedants and/or antibiotics and whether specific alkaloids representing the major classes of ergot alkaloids differ in their toxicity.

METHODS AND MATERIALS

The Alkaloids. A large number of ergot alkaloids have been isolated from Balansiae fungi-infected grasses or extracted from fungal cultures (Bacon et al., 1979; Porter et al., 1979; Lyons et al., 1986). In general, ergot alkaloids are characterized by the ergoline nucleus (Cordell, 1981) (Figure 1) and can be divided into three general groups: clavine alkaloids, lysergic acid alkaloids, and ergopeptide alkaloids (Cordell, 1981). Clavine alkaloids have a $-\text{CH}_2\text{OH}$ or

FIG. 1. Structure of the six ergot alkaloids utilized in this study. An 8 denotes the C-8 position of the ergoline nucleus.

—CH₃ group at the C-8 position while lysergic acid alkaloids have a carboxyl or carboxamide group at that position; ergopeptide alkaloids are amides of lysergic acid with dipeptide or tripeptide structures (see Figure 1) (Waller and Dermer, 1981). The alkaloids utilized in this study included members of each of these types (agroclavine, elymoclavine, and lysergol—clavine types; ergonovine—lysergic acid type; ergotamine and ergocryptine—ergopeptide type) (Cordell, 1981). The structures of these compounds are illustrated in Figure 1. Agroclavine and elymoclavine were supplied by Eli Lilly and Co., Indianapolis, Indiana while the remaining alkaloids were obtained commercially from Sigma Chemical Co., St. Louis, Missouri. Agroclavine, elymoclavine, and ergonovine have been reported from *Balansia* and *Epichloë* species (Bacon et al., 1979; Porter et al., 1981), and ergotamine has been isolated from pure cultures of *Atkinsonella hypoxylon* (unpublished), all members of the Balansiae.

Bioassay. Aqueous solutions of ergonovine and ergotamine were prepared at the following concentrations: 0, 0.077, 0.77, 7.7, and 77 mg/liter. A few drops of 0.0001% Tween 80 were added to each to facilitate adherence of the solution to fresh plant material. This provided an evenly distributed layer of

solution across the disk surface: the weight of water deposited onto a single 1-cm-diameter disk using this method was 16.8 ± 1.3 mg ($\bar{X} \pm \text{SE}$; $N = 10$). Corn (*Zea mays* L., variety Illini-Xtra Sweet) leaves were used in all feeding trials because corn is known to be a preferred food of the fall armyworm, the tissues do not contain ergot alkaloids, and the wide leaves are suitable for obtaining leaf disks of known area. Leaf disks were soaked in each alkaloid solution for 3 min and then put onto pins until all water had evaporated (ca. 10 min). Leaf disks then were placed individually into plastic Petri plates lined with moistened filter paper and newly emerged larvae of the fall armyworm were immediately added, one larva per disk per Petri plate. There were 30 Petri plates per alkaloid solution. Petri plates were kept in transparent plastic bags to maintain high humidity and stored in an incubator with a 16 hr light-8 hr dark, 25°C-20°C diurnal cycle.

The alkaloid concentrations chosen were based on data from endophyte-infected tall fescue presented in Lyons et al. (1986), where ergot alkaloid concentrations ranged from less than 0.1 mg/kg plant tissue to over 10 mg/kg with an average of about 1 mg/kg. Based on the mean dry weight per 1 cm corn leaf disk (1.3 mg) and the mean weight of water deposited onto each disk (16.8 mg) by our methods, the intermediate concentration we used (0.77 mg/liter) approximated mean field levels of ergot alkaloids in tall fescue. The other concentration levels provided a convenient range in 10-fold increments to encompass and exceed the variability in ergot alkaloid content found in endophyte-infected plants (Lyons et al., 1986). Because most of the effects of ergonovine and ergotamine, the first alkaloids screened in this study, were detected at the highest concentrations, for the remaining four alkaloids an expanded range of concentrations was used: 0, 1, 10, and 100 mg/liter.

Every three days, the leaf disks were removed and the unconsumed leaf area remaining was determined with a LI-3100 leaf area meter (Li-Cor, Inc., Lincoln, Nebraska). Fresh leaf disks were added to each plate at this time. The experiment was terminated after eight days. Fall armyworm larval weights were then obtained, and total leaf area consumed was determined by subtracting the unconsumed leaf area from the total leaf area originally presented to the larvae.

Determination of Alkaloid Deposition. To quantify the rate and variation in alkaloid deposition onto the corn leaf disks, an experiment was performed using ergonovine. Ten corn leaf disks were soaked in an ergonovine solution (1 g/liter) as described above. After the disks had dried, they were cut into quarters and the alkaloid deposited onto each piece was quantified colorimetrically following Michelin and Kelleher (1963). Each leaf piece was agitated in 2 ml of a 2% tartaric acid solution. After removing the leaf piece, 2 ml of 0.1% PDAB (paradimethylaminobenzaldehyde) in sulfuric acid-water (1:1 v/v) was added to the 2 ml tartaric acid containing dissolved alkaloid. The solution was mixed well: after 10 min, 0.1 ml of 0.1% aqueous sodium nitrite was added to each solution. Following color change, absorbance was measured with

a spectrophotometer (Turner model 350) at 590 nm. Alkaloid content was calculated from a regression equation based on absorbances known from a prior calibration using a range of concentrations of ergonovine solutions. The high concentration of ergonovine used was necessitated by the sensitivity of this technique.

Analyses. For each alkaloid, *G* tests of independence were used to test differences in larval survival between the control (0 mg alkaloid) and the other concentrations (Sokal and Rohlf, 1981). One-way analysis of variance was used to determine whether leaf area consumed and larval weights differed among concentration levels within an alkaloid, and if so, least significant differences were used to compare means (SAS Institute, 1985). Log transformations were used to improve normality when necessary. To examine the relationship between leaf area consumed and larval weight, and specifically whether alkaloid concentration affected this relationship, linear regressions were performed using weight as the dependent variable. Regression coefficients (slopes) for each alkaloid concentration level were compared to the control by the Tukey-Kramer method for comparing regression lines (Sokal and Rohlf, 1981).

RESULTS

Bioassay. For ergonovine and ergotamine, larval survival was uniformly high across all alkaloid concentration levels (Table 1), ranging from 83% to 97%. Larval survival tended to be slightly lower at high concentrations for the other alkaloids, but was only significantly lower than the control for ergocryptine at 100 mg/liter and elymoclavine at 10 mg/liter (Table 1).

Although total leaf disk consumption did not vary significantly among different concentrations of ergonovine (Table 2), larval weights were significantly

^aLog-transformed data.

lower than the control at the highest concentration (Figure 2A). This suggests that ergonovine acted as an antibiotic rather than as an antifeedant. Further evidence is presented in Figure 3, where larval weight is plotted against leaf area consumed. The slopes of these regression lines are significantly lower than the control at 0.77 and 77 mg/liter ($P < 0.05$), although not at 7.7 mg/liter, indicating that for any particular level of consumption, larvae gained less weight at these concentrations of ergonovine when compared to the control which contained no alkaloid.

In contrast to ergonovine, leaf disk consumption was significantly reduced at the highest concentration of ergotamine (Table 2, Figure 2B). In addition, the slope of the regression line for larval weight vs. consumption at this concentration (77 mg/liter) was significantly lower than the control ($\bar{X} \pm SE = 2.85 \pm 0.18$ and 3.60 ± 0.15 , respectively; $P < 0.05$). Larval weights were also lowest at this concentration; however, at intermediate alkaloid levels, weights were higher than those of the control (Figure 2B), even though leaf consumption was not significantly greater than the control at the 0.077 and 0.77 mg/liter concentrations.

The pattern of heavier larval weights despite no significant increase in consumption at intermediate alkaloid levels was also evident for ergocryptine (Figure 4A). Again, both larval weight and leaf consumption were reduced at the highest concentration. Slopes of the regression lines for larval weight vs. con-

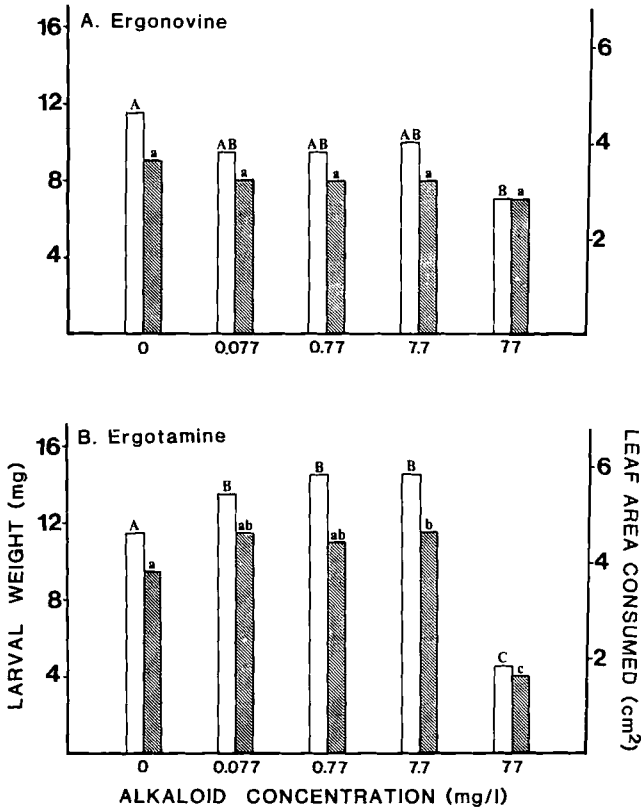

FIG. 2. Effect of various concentrations of two ergot alkaloids, (A) ergonovine and (B) ergotamine, on eight-day larval weight (open bars) and leaf area consumed (hatched bars). Means with the same capital letter (open bars) or with the same lower case letter (hatched bars) are not significantly different ($P > 0.05$).

sumption at all concentrations did not differ from that of the control, suggesting that ergocryptine acts as an antifeedant to fall armyworm larvae.

The three clavine alkaloids differed greatly in their effects on the fall armyworm. Lysergol had no effect on larval consumption or weight at any concentration, and resulted in the heaviest larvae of any of the alkaloid feeding trials (Table 2, Figure 4B). However, highly significant effects were detected for agroclavine and elymoclavine (Table 2). For both alkaloids, leaf consumption and larval weight were lowest at the highest alkaloid concentration (Figures 4C and D). In addition, the slopes of the regression lines for larval weight vs. consumption were significantly lower than the control (3.67 ± 0.19) at 1 (2.99

FIG. 3. Relationship between leaf area consumed and larval weight at various concentrations of ergonovine. Asterisks indicate lines with slopes significantly lower than the control ($P < 0.05$).

± 0.17) and 100 mg/liter (3.16 ± 0.17) concentrations of agroclavine ($P < 0.05$). Like ergocryptine, elymoclavine did not show these differences among slopes; it presumably acts primarily as an antifeedant at high concentration (Figure 4D).

Alkaloid Deposition. Ergonovine was detected on every piece from each leaf disk. Based on leaf area, amount of solution absorbed, and alkaloid concentration, 7.17 μg ergonovine was expected from each quarter leaf piece. A mean of 6.78 μg was determined (± 0.58 SE), a recovery rate of 95%. Although there was variation among pieces in deposition rate (range 1.47–14.79 μg), 30 of 40 leaf disk quarters had values between 3 and 10 μg . Moreover, there were no significant differences among leaf disks in total alkaloid deposition. Thus, these results indicate that the technique of soaking leaf disks in alkaloid solutions resulted in a fairly uniform delivery of alkaloid to the insect larvae.

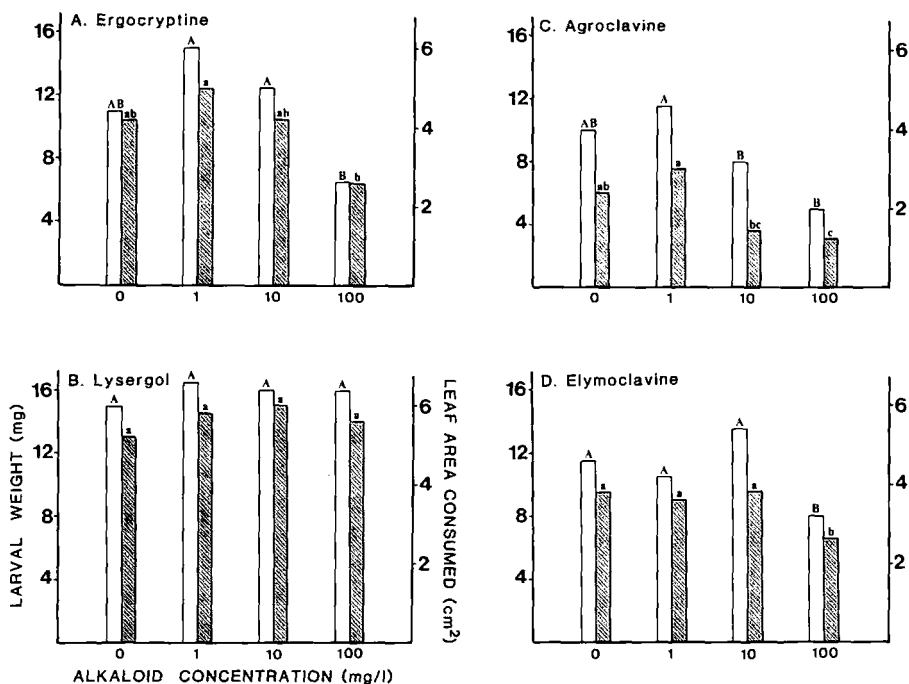

FIG. 4. Effect of various concentrations of four ergot alkaloids: (A) ergocryptine, (B) lysergol, (C) agroclavine, and (D) elymoclavine, on eight-day larval weight (open bars) and leaf area consumed (hatched bars). Means with the same capital letter (open bars) or with the same lower case letter (hatched bars) are not significantly different ($P > 0.05$).

DISCUSSION

With the exception of lysergol, the ergot alkaloids examined in this study affected fall armyworm larvae feeding on corn leaf disks. In contrast, the alkaloids had little effect on larval survival; only two of 20 comparisons were significantly lower than the control. At the highest alkaloid concentrations, there were significant and dramatic declines in both larval weights and leaf consumption. At these concentrations the alkaloids appeared to function as antibiotics (ergonovine), antifeedants (ergocryptine and elymoclavine), or both (ergotamine and agroclavine) in relation to their effects on the fall armyworm.

There appeared to be little relationship between the structural features of the different alkaloids and their effects on fall armyworm larvae. For example,

there were highly significant differences among concentrations of agroclavine and elymoclavine on both larval weights and leaf consumption, while lysergol, also a clavine alkaloid with a similar structure (Figure 1), had no effect on fall armyworm (Table 2). There was no evidence that ergopeptide alkaloids were any more toxic than the clavine alkaloids in this study, although they are suspected to be more toxic to mammalian herbivores (Bacon et al., 1986).

Somewhat surprisingly, at lower concentrations, several of the alkaloids resulted in increased larval weights and leaf area consumption compared to the control, although the differences were significant only for ergotamine (Figure 2B). While alkaloids are nitrogen-rich compounds, it is unlikely that they contributed significantly to the nitrogen budget of the larvae. For example, a 1-cm corn leaf disk (1.3 mg mean dry weight) contains approximately 52 μg N [Schrader et al. (1972) indicated that corn leaves contain on average about 4% N on a dry weight basis.] At the highest concentration of ergonovine, with our technique approximately 1.3 μg alkaloid would be deposited containing 0.17 μg N. Although the reason for the initial increase in larval weights at low alkaloid concentrations is unclear, similar phenomena have been documented in other insects. Reese (1979) discussed several cases where insecticides at low concentrations actually stimulated insect growth. Similarly, Maxwell et al. (1967) reported that low levels of gossypol from cotton stimulated feeding and oviposition of the boll weevil but inhibited them at high concentrations.

The effect of ergot alkaloids on herbivores has been well documented for mammalian herbivores grazing *Claviceps*-infected grasses (Mantle, 1969) and for human populations consuming ergot-infested grain products (Bové, 1970; Groger, 1972). However, in *Claviceps* spp. the alkaloids are concentrated in the sclerotium, upon which few insects feed. Grasses systematically infected by Balansiae species contain fungal alkaloids within plant tissues and can be toxic to both mammalian and insect herbivores (Bacon et al., 1986; Clay, 1986). Mammalian toxicity resulting from the consumption of Balansiae-infected grasses resembles ergotism, suggesting that the causal agent is the same, i.e., ergot alkaloids (Bacon et al., 1975; Porter et al., 1981). The chemical basis for insect feeding deterrence and antibiosis has not been shown definitively for Balansiae-infected grasses, although in perennial ryegrass and tall fescue infected by anamorphic *Acremonium* spp., peramine and pyrrolizidine alkaloids, respectively, are known to be feeding deterrents for some insects (Johnson et al., 1985; Rowan and Gaynor, 1986). The presence or absence of these compounds in grasses infected by *Balansia* and other related fungi has not been reported in the literature. In contrast, ergot alkaloids occur in Balansiae-infected grasses and are produced by fungal cultures, and a number of infected grasses have been shown to be resistant to fall armyworm (Bacon et al., 1979; Clay et al., 1985). Here we have shown that fall armyworm larval weights and/or feed-

ing on corn leaf disks is reduced at high concentrations of several ergot alkaloids.

Some of the variability observed in this study may have resulted from differential deposition of alkaloids onto the leaf disks. In the deposition experiment with ergonovine, there were no significant differences among leaf disks in overall alkaloid level, although there was some variability in deposition on different parts of the disk. Larvae may have preferentially fed upon areas of the disk with slightly lower concentrations; nevertheless, minor variations among leaf disks at the same concentrations should have no effect on the pattern of mean response because leaf disks used at all alkaloid levels and controls were treated in the same manner. However, in light of the variability in deposition, the statistically significant differences detected in this study are conservative.

The greatest antifeedant and antibiosis effects were achieved in this study at alkaloid concentrations of 77–100 mg/liter. These concentrations correspond to values of between 1 and 1.3 g/kg plant tissue, which is approximately two orders of magnitude higher than the concentrations of ergot alkaloids reported for endophyte-infected tall fescue and *Balansia epichloë*-infected smutgrass (Bacon et al., 1979; Lyons et al., 1986). It is possible that the ergot alkaloids, at the levels reported in tall fescue, play only a minor role in the observed resistance of endophyte-infected plants to insect herbivores (Clay et al., 1985; Hardy et al., 1986). Although the endophyte of tall fescue also produces pyrrolizidine alkaloids, Hardy et al. (1986) found that the youngest leaves contained the highest concentration of nearly 1000 mg/kg dry weight leaf tissue but the greatest growth of armyworm larvae occurred on the youngest leaves, suggesting that these alkaloids are not the primary feeding deterrent. In feeding studies of fall armyworm larvae there were significant decreases in larval weight gain and rate of development when reared on infected tall fescue compared to uninfected tall fescue (Clay et al., 1985; Hardy et al., 1986). However, other endophyte-infected grasses elicited much more dramatic responses in the same insect, suggesting that they were more toxic, perhaps containing higher levels of ergot alkaloids (Clay et al., 1985; Cheplick and Clay, 1988). With the exception of smutgrass, which has not been subject to insect feeding studies, ergot alkaloid levels in other endophyte-infected grasses have not been quantified.

The role of alkaloids in plants has been subject to debate, but many researchers agree that alkaloids often play a defensive role, protecting plants against herbivores (Fraenkel, 1959; Freeland and Janzen, 1974; Levin, 1976; Robinson, 1979). There is a vast literature on the effects of plant secondary compounds from various plants on different insects. Patterns of host specificity of particular groups of insects indicate that secondary compounds have been an important selective force in the coevolution of plants with their insect herbivores. The widespread relationship between grasses and endophytic fungi, and

their effect on herbivores, suggests that ergot alkaloids may be playing a similar role to alkaloids found in other plant families by providing protection against herbivores. Our data are in agreement with the hypothesis that ergot alkaloids can act as insect feeding deterrents. In contrast with the direct biosynthesis of defensive compounds by plant tissues in many plant taxa, endophyte-infected grasses represent a special case of acquired chemical defense against herbivores (Cheplick and Clay, 1988). The secondary products of endophyte metabolism could partially compensate for the general lack of insect-detering compounds in the grass family.

Acknowledgments—We thank Dr. Herbert Kirst of Eli Lilly and Co. for making several ergot alkaloids available to us. This research was supported by NSF grants BSR-8400163 and BSR-8614972, and NIH grant BRSO PHS S07 RR 7031J to K.C.

COUNTERTURNS INITIATED BY DECREASE IN RATE OF INCREASE OF CONCENTRATION

Possible Mechanism of Chemotaxis by Walking Female *Ips paraconfusus* Bark Beetles

R. PATRICK AKERS¹

Department of Entomological Sciences, University of California, Berkeley, California.

(Received June 8, 1987; accepted November 5, 1987)

Abstract—The position of beetles were marked at 1-sec intervals after they were released in still air 16–18 cm from point sources of pheromone. Characteristics of the tracks were quantified and compared to those that might be produced by counterturning schemakinesis, tropotaxis, klinotaxis, zigzagging, look-and-leap, or steepest-ascent schemakinesis mechanisms. The beetles' movements were highly irregular, but they turned almost continually and never fixed on a heading near 0° (=straight towards the source). Turn angle sizes increased slightly with absolute size of heading but had the opposite sign, thus compensating slightly for heading. Their distribution was centered about 0° and was unimodal. Heading decreased gradually as the source was neared, but the decrease became steeper within 1–5 cm of the source. Histograms showed that the maximum headings between occurrences when the beetle was headed directly towards the source (0°) were centered around 0° and most of them were less than 90°. However, maximum headings between 90° and 180° were not uncommon. Turn radius decreased as the source was neared. The counterturning mechanism was the most consistent with these observations. An analysis of rate of change of concentration with respect to heading and distance to the source further demonstrated that the counterturning mechanism could explain the form of the decrease in heading as the source was neared, if the major cue used to initiate counterturns was a decrease in the rate of increase of concentration. The tropotaxis could not recreate the form of the decrease, under any form of stimulus processing.

Key Words—*Ips paraconfusus*, Coleoptera, Scolytidae, bark beetles, olfaction, orientation, counterturning, chemotaxis, taxis, pheromones, tropotaxis, schemakinesis.

INTRODUCTION

Ips paraconfusus Lanier (Coleoptera: Scolytidae) has three compounds in its pheromone, which it uses to orient with respect to mates, competitors, and hosts (Silverstein et al., 1966; Wood et al., 1967). The analyses described here arose from experiments undertaken to develop a behavioral assay for olfactory quality discrimination among the components of the pheromone (Akers, 1985; Akers and Wood, 1987b). Chemotaxis was one behavior used as the basis for an assay. The responses in this assay were striking (Akers, 1985; Akers and Wood, 1987a). From a distance of 16–18 cm, approximately 80–90% of all beetles located sources of 0.1–1.0 mg of pheromone, guided by odor alone. I became interested in the mechanisms underlying the taxis, because of its apparent efficiency. A more complete description of the mechanism was not necessary to use the assay as an indicator of olfactory quality, but it would aid in limiting the possible neural mechanisms that could be involved in orientation.

Previous work established the hypothesis that the initiation of chemotaxis was essentially an all-or-none phenomenon (Akers, 1985; Akers and Wood, 1987a). The behavior of beetles that did and did not reach the source was qualitatively different, while the behavior of beetles within either of these groups was very similar, even though the beetles were exposed to dosages differing by several orders of magnitude. Thus, the major influence of increasing pheromone dosage was to increase the probability that a beetle would initiate orientation.

The mechanisms by which an orienting beetle reaches the odor source are explored in this paper. Its premise is that orientation based on different sources of information will produce tracks that differ in form. Quantitative analyses were designed to describe various aspects of track form. The predicted effect of several possible orientation mechanisms on each analysis was then compared to the observed results to identify any particular mechanism that might be consistent with the observations. The analysis indicated two major hypotheses concerning the mechanism of orientation. First, an orienting beetle locates the source by turning in one direction until it detects a critical sensory cue, at which time it initiates a turn in the opposite direction. This mechanism is termed a counterturning schemakinesis (Kennedy, 1986), or counterturning, for short. Second, if counterturning is the mechanism, the major cue used to initiate a counterturn appears to be a decrease in the rate of increase of concentration.

METHODS AND MATERIALS

The compounds used as stimuli, the observation chamber, the recording procedures, the handling of the experimental animals, the experimental design, and some of the analytical methods for orientation data have all been described

previously (Akers and Wood, 1989a). The basic experimental design was a dosage series of a 1 : 1 : 1 blend of the three pheromonal compounds, ipsenol (Ip), ipsdienol (Id), and *cis*-verbenol (cV). The dosages differed by powers of ten, running from 10^{-4} to 1 mg, and were dissolved in 0.1 ml pentane. The series was run with diffusion periods of 30 and 60 min in separate experiments.

The position of each beetle was marked at 1-sec intervals after it was released in still air 16–18 cm from a point source of pheromone. The angle the beetle turned at each point on its track was measured. The turn angle was defined as the angle between the direction from the current point had the beetle continued walking straight ahead along the line from the previous to the current point on the track, and the direction from the current to the next point. Zero degrees was defined as straight ahead. A heading was also measured at each point on a track. The heading is the direction an animal takes with respect to the pheromone source, at any given point on its track. It was defined as the angle between the direction towards the source from the current point on the track and the direction from the current point to the next point on the track. Zero degrees was defined as straight towards the source. For “net” angle summaries, left-hand angles were defined as positive. For “gross” angle summaries, the absolute values of the angles were used (Akers and Wood, 1989a). Summaries of walking rate and its variation within a track, net turning rate, gross turning rate and its variation within a track, mean net heading, and gross heading and its variation within a track have been reported elsewhere (Akers, 1985; Akers and Wood, 1989a). Further analyses were needed to identify the probable mechanism of chemotactic orientation. Unless otherwise noted, the following analyses were made on only those beetles in a treatment that reached the source and on control beetles when comparisons with nonorienting beetles seemed appropriate.

Histograms were made of the size of the turn angles, to determine whether their distribution was unimodal or bimodal. A bimodal distribution would have indicated that the beetles had two distinct rates of turning, such as might occur if linear sections of track were interspersed with more rapid turning. A bin size of 10° was chosen for this analysis. The recording procedures were accurate to only 2–5°, and even beetles in control situations had standard deviations of 8–15° in their turn angles (Akers and Wood, 1989a). Any much smaller bin size seemed inappropriate. The results for both the 30- and 60-min diffusion periods were extremely similar. Only the results from the 60-min period experiment are shown for illustration.

The beetles' movements were very irregular or noisy (Figure 7 in Akers and Wood, 1989a). Some orientation mechanisms might be expected to produce noisy tracks, while others would more likely produce more regular oscillatory or patterned movements. Therefore an analysis of the variation of the “overall turn” or “arc” sizes of the swings on a beetle's track was made. A “turn”

could mean the turn angle at a particular point on a beetle's track. However, a track is more usually perceived, not as a series of points, but as a series of "arcs" or "swings" or "turns." An arc is usually recognized when a series of turn angles all have the same sign, or at least mostly so, and their signs are opposite to those of the series of turn angles just preceding and following the arc in question. To avoid confusion, the use of "turn" will be avoided, and "turn angle" and "arc" will be used in the above sense.

A program was developed to analyze the number of degrees turned in an arc. It was based upon the following set of criteria, which was intended to filter out variation due to recording procedures and very small turn angles made by the beetles: (1) Each point was considered sequentially and, if its turn angle was of the same sign as the immediately preceding points, it was summed with those points. (2) If the turn angle was of the opposite sign from the preceding points, several different possibilities were evaluated. (2a) If its absolute angle was greater than 10° , it was accepted as initiating a new arc. Ten degrees was chosen because it was about twice the measuring error for a single turn angle (Akers, 1985; Akers and Wood, 1989a) but still less than half the average turn angle even for control beetles. (2b) If the turn angle was less than 10° , the next point on the path was checked. (3a) If the sum of the points was more than 15° and if both points were of the same sign, they were accepted as a new arc. (3b) If a turn angle was not accepted as a new arc, it was summed into the previous arc.

The above algorithm filtered out the very noisy arcs, and its determinations of arcs were generally in accordance with subjective judgments in the sense that, where the program indicated an arc, an arc would be recognized. The standard deviation of the arc sizes within each track was used to probe for regular movements. There was no a priori reason to suppose that every beetle should have a similar mean arc size, i.e., the size of arcs made by a beetle might well have a strong component due to the individual beetle. However, if regular oscillatory or patterned movements were occurring, the arcs of a given beetle should all be of a similar size, and the variation of the arc size should be low for every beetle, regardless of each beetle's particular mean arc size. A consideration of the general heading of the beetle during an arc was also important. Several of the mechanisms might conceivably produce a track that would oscillate regularly back and forth about a heading of 0° . However, only in those in which the basic turn pattern was centrally generated should the regular, oscillatory movements continue regardless of the heading with respect to the source. Mechanisms based on a balance of sensory input ought not generate regular, uniform turns at headings away from 0° . Accordingly, the program also calculated the net heading of each arc. Forty-five degrees was chosen as an arbitrary cutoff for arcs with a heading near 0° , for the purpose of pooling the data.

The maximum absolute heading with respect to the source was determined

between occurrences where the heading was 0° . This measured how far away a beetle turned from the source before turning back towards it, and thus gave a measure of the heading at which a beetle initiated its turns back towards the source. If an insect turned beyond 180° or went in a circle, this heading was defined as 180° .

The effects of distance from the source on gross heading were explored graphically and by linear regressions. Similar analyses were done for walking and turning rates (Akers, 1985), but are not shown here. Turn (=arc) radii were not measured directly but were estimated from walking and gross turning rates using the relationship:

$$r_c = (360 \times WR)/(2 \times \pi \times GTR),$$

where r_c = turn radius, WR = walking rate, and GTR = gross turning rate.

The relationship between the gross (absolute) heading of a beetle at a point and the gross turn angle that was subsequently made at that point was estimated by linear regression, to reveal any tendency of the beetle to stabilize on a heading of 0° . Similar regressions were made between the net (actual) heading of a beetle at a point and the net turn angle that was subsequently made at that point (Bell and Tobin, 1981, 1982), to reveal any mechanism where the insect was able to more or less efficiently estimate the direction towards the source.

RESULTS

Frequency histograms of turn angle size showed that the distribution was centered about 0° and that it fell off smoothly and without any intermediate peaks at higher turn angles (Figure 1). The distributions were unimodal, indicating that the beetles apparently did not have two distinct turn angle sizes within the track, such as might occur if tight arcs were interspersed with relatively straight sections.

No consistent pattern in the analysis of overall arc size appeared among the dosages (Table 1), except that the beetles responding to a source consistently turned through more degrees of arc than beetles in blank arenas. The overall coefficients of variation were in the range of 60–90% (calculated from Table 1). This does not seem to be a very low amount of variation, since it would produce an error confidence interval for the arc size at least as large as the mean itself. Coefficients of variation for moths zigzagging in an odor plume appear to be 20–30% (Kuenen and Baker, 1983; Cardé et al., 1984). By contrast, the beetles' movements are highly irregular (examples of trails may be found in Figure 7 of Akers and Wood, 1989a). The variation was similar both when the heading was less than and greater than 45° , although the variation was possibly a bit smaller at headings less than 45° . Low variation at both low

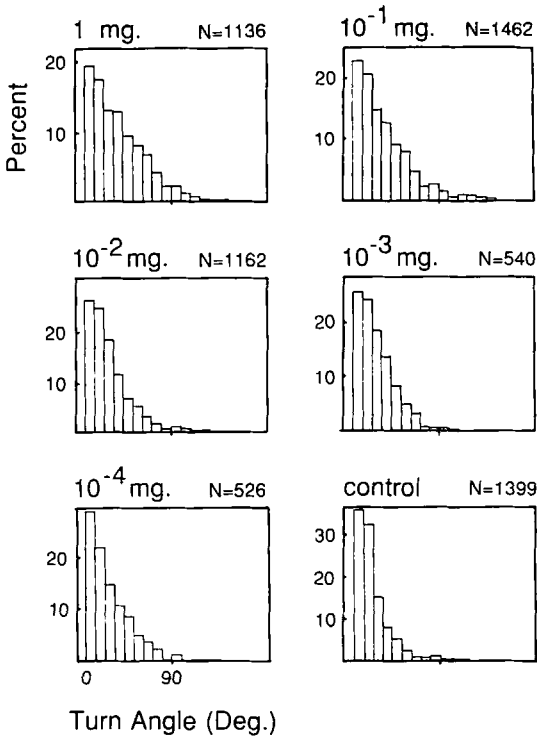

FIG. 1. The number of occurrences of turn angle sizes within each 10° interval in each treatment of the experiment with the 60-min diffusion period. The unimodal distribution suggests there were not two classes of turn angles sizes, such as might have been expected if straight sections were interspersed with bouts of turning. N = total number of turn angles in treatment.

and high headings would have been consistent with regular movements driven by a central pattern generator, while low variation at low headings and high variation at headings farther from the source would have been consistent with regular movements driven by a highly efficient mechanism based on sensory input. High variation at both low and high headings would seem more consistent with mechanisms where the movements are derived from chemosensory input.

In comparing the gross (absolute) heading of a beetle at a point to the absolute turn angle that was subsequently made at that point, the most important result was that the intercepts of the regression lines were always significant and in the range of $20\text{--}30^\circ$ (Table 2). Thus, the beetles continued to have moderate rates of turning even when they were headed almost directly towards the source.

The slopes of the regressions were often significant and always positive, although they were low (Table 2). Thus, the beetles tended to have slightly larger turn angles at higher headings.

In the analysis of the net (actual) heading of a beetle at a point as compared to the net turn angle that was subsequently made at that point, the regressions showed the slopes were highly significant (Table 3), but they were in the range of -0.1 to -0.2 , and the correlation coefficients were in the range of -0.15 to -0.30 . The sign of a turn angle therefore had a weak tendency to be opposite to the sign of the heading at that point.

Frequency histograms of the maximum absolute heading between occurrences of headings of 0° suggested that the distributions on the full circle were centered about 0° and fell off gradually towards the higher angles, with a small peak at 180° (Figures 2 and 3). There was no consistent sign of any peak at intermediate angles, although there was a suggestion of peaks at 50 – 70° and 90 – 110° . Most of the maximum headings were less than 90° . However, headings between 90 and 180° were not uncommon. Calculations from the regressions of maximum heading versus distance to the source further showed that, on average, turns back towards the source were initiated at about 70° , even at the release point of the beetles (Table 4).

The heading decreased gradually as the source was neared, becoming steeper within 1 – 5 cm of the source (Figures 4 and 5). Turn radius decreased as the source was neared (Figure 6) (Akers, 1985).

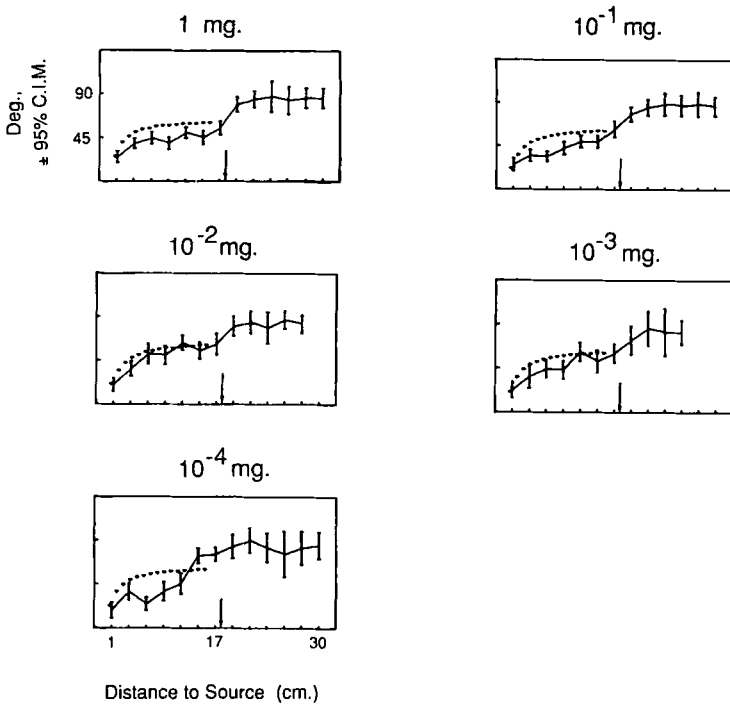

FIG. 4. The effect of distance from the source on the mean gross heading in the experiment with the 30-min diffusion period. Error bars show the 95% confidence interval of the mean. Dotted lines show headings predicted by a model based on counterturns initiated by a decrease in the rate of increase of concentration. Arrow marks the approximate release point of the beetles.

DISCUSSION

Since Fraenkel and Gunn (1961) published their benchmark work on orientation, the many mechanisms that are potentially available to an animal for orientation have gradually become more evident (e.g., Mittelstadt-Burger, 1972; Jander, 1975; Kennedy, 1977a,b, 1978, 1983, 1986; Bell and Tobin, 1982). The mechanisms the beetles used to orient to a point source in still air were inferred from a set of hypotheses about the characteristics of track form produced by each of several possible mechanisms. Measurements were found or devised to describe different characteristics of track form, and then the observed measurements were compared to those that were expected from each of the mechanisms. However, while analyses such as the present one may be strongly

FIG. 5. The effect of distance from the source on the mean gross heading in the experiment with the 60-min diffusion period. Error bars show the 95% confidence interval of the mean. suggestive, they cannot be completely conclusive without further experiments that isolate individual mechanisms (Bell and Tobin, 1982; Kennedy, 1977b). Because of the considerable state of flux in the theory and terminology of orientation, each mechanism will be explicitly defined as it is considered. They will be discussed using the terminology of Fraenkel and Gunn (1961), as extended by Kennedy (1986) and herein. Although Kennedy developed many of his ideas while working with anemotactic situations, with some care they can be extended to a purely chemotactic situation, as will be attempted here.

The counterturning schemakinesis best explained the observed results if the cue used to initiate the counterturns was a decrease in the rate of increase of concentration. It was further necessary to postulate that the beetles have some innate tendency to compensate for the size of a previous arc in the opposite direction (Mittlestadt-Burger, 1972). In a schemakinesis, an animal uses infor-

FIG. 6. An example of the relationship between distance from the source and the mean turn radius, as calculated from the walking and gross turning rates within 2.54-cm increments of radius from the source. Data are from the 1-mg dosage with a 60-min diffusion period. Arrow marks the approximate release point of the beetles.

mation concerning the behavior of stimulus intensity through time, combined with proprioceptive or central information concerning its own movements, to guide its path to the source (Kennedy, 1986). This is unlike many of the more classic mechanisms, where the animal is guided towards the source primarily by information on its position or orientation relative to the geometry of an intensity gradient (Fraenkel and Gunn, 1961). In the counterturning schemakinesis, an animal turns in one direction until it senses a critical sensory cue, at which time it initiates a turn in the opposite direction (Kennedy, 1986).

In a purely tactic situation, the environmental cue used to initiate a counterturn will strongly affect the form of the track. For example, consider an animal moving in a radial gradient, wherein contour lines of equal concentration form a series of concentric circles. If an animal depends upon a decrease in intensity to initiate a counterturn, each arc will have to obtain a heading beyond 90° before the animal can encounter such a decrease, because the animal does not move away from the source at headings less than 90° . On the other hand, an animal could use the rate of increase of intensity to initiate counterturns before a heading of 90° . As heading decreases towards 0° , the rate of increase of concentration increases, while as heading increases away from 0° , the rate decreases. The rate of increase of intensity begins to decrease when a heading of 0° is crossed.

Counterturning is consistent with the unimodal distribution of turn angle sizes (Figure 1). Turning is essentially constant in this mechanism, and there

is nothing to cause two or more classes of turn angle size, such as might occur if straight sections were interspersed with tight arcs.

The beetles' movements were irregular and noisy, as indicated by the analysis of arc size (Table 1) (examples of trails are shown in Figure 7 of Akers and Wood, 1989a). Counterturning is consistent with such noise, because the counterturns are initiated largely or entirely by sensory input and therefore are liable to the full effects of sensory noise.

The comparison of absolute heading at a point with the absolute turn angle made at that point indicated that turning rate remained moderate even at headings near 0° (Table 2), meaning that the beetles had no tendency to fix on a heading directly towards the source. This is entirely consistent with counterturning. However, the beetles also tended to have slightly larger turn angles at higher headings. There is no clear reason why counterturning alone ought to produce larger turn angles at larger headings. However, there are two possible contributing factors. First, the beetles may have some innate tendency to initiate arcs in the direction opposite to the current arc, and this tendency may grow stronger the longer it takes to be released by sensory cues. There is some support for this suggestion. Beetles in control situations do not have gross turning rates low enough to account for their low net turning rates (Akers, 1985; Akers and Wood, 1989a). In other words, control beetles have much straighter paths overall than would be the case if all their turn angles were of one sign. Therefore, the beetles probably have some innate tendency to compensate for the size of a previous arc. Mittelstadt-Burger's work also supports the possibility of an innate counterturning tendency that compensates for the size of a previous arc (Burger, 1971; Mittelstadt-Burger, 1972), and Kramer (1975) found that moths walking in pheromone-free wind periodically reverse their heading with respect to the wind in a manner that produces fairly direct movement overall. The second possible mechanism that could produce larger turn angles at higher headings is a change in the cue used to initiate a counterturn as heading changed, from a decrease in the rate of increase of concentration to a decrease in concentration itself. However, while exploratory graphs showed turn angle increasing as heading increased, no pattern was consistent enough to allow a decision on this second possibility.

Compensated counterturning is consistent with the low slope and correlation coefficient observed in the comparison of the net (actual) heading of a beetle at a point with the net turn angle that was subsequently made at that point (Table 3). In counterturning, turn angles would be away from as well as towards a heading of 0° , which would decrease the correlation, but if there were compensation for the size of a previous arc, the slope would be negative.

The analysis of the maximum absolute heading between occurrences of headings of 0° (Figures 2 and 3) gave the first indication that, if counterturning were in operation, a cue for counterturn initiation was likely to be a decrease

in the rate of increase of concentration. Most maximum headings occurred before 90° , the heading beyond which a decrease in concentration becomes possible. These counterturns, then, could not have been initiated by a decrease in concentration. Calculations from the regressions of maximum heading versus distance to the source further showed that, even at the release point of the beetles, counterturns were initiated at about 70° , on average (Table 4), consistent with the possible minor peak in maximum headings at $50\text{--}70^\circ$. In addition, counterturning could produce a distribution centered near 0° , if the cue used to initiate counterturns were a decrease in the rate of increase of concentration, because the rate of increase begins to decrease just as a heading of 0° is crossed. Finally, counterturning has no difficulty explaining those maximum headings that occurred between 90 and 180° , because these counterturns could have easily been initiated by a decrease in concentration. A decrease in concentration would begin to occur just beyond 90° , where the second possible minor peak in maximum heading also appears to lie.

Counterturning was also best able to explain the form of the decrease in heading as the source was neared (Figures 4 and 5), but only if the cue used to initiate counterturns was a decrease in the rate of increase of concentration. If a counterturn were initiated by a decrease in concentration, heading would not decrease much, because, at any distance, the animal still must head away from the source, i.e., at a heading of greater than 90° , to encounter a decrease in concentration. If the animal used a decrease in the rate of increase to trigger a counterturn, we need to know how concentration changes with heading as the animal turns, in order to predict how heading would decrease as the source is neared. If we assume that the beetles move along roughly circular arcs, then the rate of change of distance to the source with respect to heading can be determined (Figure 7). The relationship between concentration and distance to the source may then be substituted into the equations. This latter relationship was estimated from gas-liquid chromatography data, under the assumption that the gradient is circular (Akers and Wood, 1989a).

In order to better visualize the behavior of the system, the equations were evaluated at 1° intervals over arcs of 0° to 90° , using a computer to carry out the calculations. If turn radius is held constant, the rate of increase decreases more rapidly with heading the closer an arc is to the source, but decreasing turn radius can strongly offset this effect (Akers, 1985). The effect of changing turn radius can be taken into account by calculating the turn radius from regressions relating the walking and turning rates to distance from the source (see Methods and Materials). For the purposes of exploration (Figure 8), the regression parameters used to estimate the turn radii were the means over all treatments except the control.

The rate of increase is always maximal at a heading of 0° , directly towards the source, and falls to 0 at 90° , where the animal is moving neither away from

$$r^2 = (r_1 - r_c \sin \theta)^2 + (r_c - r_c \cos \theta)^2$$

$$r = (r_1^2 - 2r_c r_1 \sin \theta - 2r_c^2 + 2r_c^2)^{\frac{1}{2}}$$

$$\frac{dr}{d\theta} = \frac{r_c^2 \sin \theta - r_c r_1 \cos \theta}{r}$$

$$h = (90 - (90 - \theta)) + \theta_s$$

$$= \theta + \theta_s$$

$$= \theta + \arctan \left[\frac{r_c - r_c \cos \theta}{r_1 - r_c \sin \theta} \right]$$

$$\frac{dh}{d\theta} = \frac{r_1^2 - r_c r_1 \sin \theta - r_c^2 \cos \theta + r_c^2}{r^2}$$

Where:

- r = distance from beetle to source
- r₁ = distance at which arc was initiated (heading = zero degs.)
- r_c = turn radius of arc
- h = heading angle of beetle
- θ = angle turned by beetle along arc

The relationship between heading and motion along the arc is a one-to-one mapping, at least when r_c < r₁ and h < 90 deg. Therefore the derivative of the function relating arc angle to heading is the inverse of the derivative of the function relating heading to arc angle. that is,

$$\frac{d\theta}{dh} = \frac{1}{\frac{dh}{d\theta}}$$

Then, by the chain rule,

$$\frac{dr}{dh} = \frac{dr}{d\theta} \frac{d\theta}{dh} = \frac{dr}{d\theta} \frac{1}{\frac{dh}{d\theta}}$$

FIG. 7. The geometry and equations needed to analyze the rate of change of distance from the source with respect to heading. The animal is assumed to turn along circular arcs of turn radius r_c.

or towards the source (Figure 8). Any arbitrarily chosen amount of decrease from the maximum is still reached at considerably lower headings as the source is neared, despite the accounting for the decrease in turn radius. For example, if the animal were sensitive to an absolute decrease of 0.01 units, heading would be expected to decrease in a strongly linear manner as the source was neared (Figure 9). The linear relationship and especially the steepness of the decrease

FIG. 8. An example of the effects of heading, turn radius, and distance of arc initiation from the source of pheromone on the rate of change of concentration with respect to heading, under the assumptions of a radial gradient and circular arcs. The y axis units are arbitrary and derive from a gradient decreasing exponentially with distance from the source and with concentration at the source arbitrarily set to one. r_1 and r_c are defined in Figure 7. The r_c for each r_1 was calculated from regressions relating the walking and gross turning rates to distance from the source. The parameters used in the regression equations were the means of the parameters over all treatments but the control.

is different from that seen in the data (Figures 4 and 5). On the other hand, if the animal were, for example, sensitive to a 50% decrease from the maximum rate of increase, heading would decrease gradually farther from the source, becoming steeper as the source was neared (Figure 9).

If the animal indeed initiated a counterturn when it just perceived a change in the stimulus, counterturn initiation would occur at the "just noticeable difference" of psychophysics, and the behavior of the headings might be expected to follow the classic Weber's and Fechner's laws. These laws state that the difference in stimulus intensity needed to obtain a just noticeable difference in sensation magnitude is proportional to the original stimulus intensity (Gescheider, 1976). Therefore, a model based on a proportionate decrease is also physiologically reasonable.

The dotted lines in Figures 4 and 5 show the predicted changes in heading as the source is neared, for a counterturning schemakinesis when the cue is a 50% decrease in the rate of increase. The turn radii were calculated using the respective parameters for the regressions of walking and turning rate in each

FIG. 9. The predicted headings at counterturn initiation derived from Figure 8 and under the assumption that counterturns are initiated by either an absolute decrease of 0.01 units from the maximal rate of increase (lower curve, circles) or a proportional decrease of 50% from the maximal rate of increase of concentration (upper curve, squares). Each point on a curve is derived by finding the curve in Figure 8 that has the same distance from the source as that point, then moving down from the maximum rate of increase on that curve until the chosen critical decrease from the maximum is reached. The heading at which that decrease was reached is then read from the horizontal axis.

treatment. While somewhat arbitrary, a 50% decrease was chosen because it produced critical headings of about 60° at the starting distance of 15 cm from the source. Values of $45\text{--}65^\circ$ are typical for the mean gross headings at that distance. Although the analysis required several simplifying assumptions, the predicted curves often approximate the actual data in form, if not actually lying on the line (Figures 4 and 5). This is particularly true in the 60-min experiment (Figure 5). Perhaps a slight difference in the shape of the gradient in the 30-min experiment was responsible for the slightly steeper decreases in heading observed in that experiment (Figure 4). The relationship between concentration and distance from the source was estimated using data from the 60-min diffusion period (Akers and Wood, 1989a), while no information is available on the exact form of the gradient in the 30-min experiment.

A similar process of comparing expected and observed results was applied to each of the other possible mechanisms of orientation. Each appeared to be inconsistent with at least some observations. The classic tropotaxis is inconsistent with several of the results. In the tropotaxis, symmetrically placed receptor organs permit simultaneous comparisons of intensity in space. If the organism turns towards the receptor with the greater intensity, it will turn towards the source. If it can then balance the stimuli efficiently on its receptors, its path to the source should be very direct (Fraenkel and Gunn, 1961).

The paths of the beetles towards the source were generally far from direct (Figure 7 in Akers and Wood, 1989a), and the beetles were turning almost continuously. The comparison of the gross (absolute) heading of a beetle at a point with the gross turn angle that was subsequently made at that point (Table 2) showed that the beetles continued to have moderate rates of turning even when they were headed almost directly towards the source. Thus, the beetles never appeared to fix on a heading near 0° . In addition, in the regressions of the net (actual) heading of a beetle at a point on the net turn angle that was subsequently made at that point (Table 3), the slopes were in the range of -0.1 to -0.2 , and the correlation coefficients were in the range of -0.15 to -0.30 . If the animal was perfectly tropotactic, and given the conventions by which the signs of angles were defined, the regressions should have had a slope of -1.0 and a correlation coefficient of -1.0 (Bell and Tobin, 1981). These observations, then, are inconsistent with an efficient tropotaxis. However, an inefficient tropotaxis, where the animal cannot accurately balance the intensity on the two receptors, is still a possibility. Such a tropotaxis is consistent with the above results, with a unimodal distribution of turn angle sizes (Figure 1), and with the increase in turn angle size as heading increased away from 0° (Tables 2 and 3).

Nevertheless, a tropotaxis cannot explain those maximum headings of 90° to 180° that occurred between occurrences of headings of 0° (Figures 2 and 3). The difference between the antennae in distance to the source reaches a maximum at a heading of 90° and then begins to decrease again as the animal turns away from the source. If a tropotactic animal does not perceive the difference in concentration by the time it achieves a heading of 90° , that difference will once again begin to decrease and make it even less likely that the animal will initiate a return towards the source. It would more likely continue on until it completes a circle. The possible minor peak in maximum heading, which appears to occur at about 90 – 110° , could be attributed to tropotaxis, but the argument would seem more satisfactory if the peak were centered just before 90° rather than beyond it.

Neither is the tropotaxis consistent with the form of the decrease in heading as the source was neared or with the decrease in turn radius. As distance from the source decreases, smaller separations in space should be needed to obtain the same amount of information concerning the gradient. In a tropotaxis, the difference in intensity between two receptors separated by some fixed distance will increase, thereby improving its possible efficiency. Accordingly, heading should decrease. However, since the animal should then head more linearly to the source as the source is neared (Fraenkel and Gunn, 1961), turn radius should increase. This is opposite to the behavior observed (Figure 6) (Akers, 1985).

Furthermore, although an inefficient tropotaxis might be expected to cause a decrease in heading as the source was neared, the expected form of the decrease

does not fit the data. An analysis similar to that done for the counterturn was done for the tropotaxis (Figure 10) and predictions made as to the heading at which the animal would encounter a concentration difference large enough between its antennae to cause it to turn back towards the source after having once turned away (Figure 11). Again, for Figure 11, the critical concentration difference was taken to be that which occurred at a heading of 60° and a distance of turn initiation of 15 cm, and the parameters of the regressions for the walking and turning rates were the means of the parameters of all treatments but the control. The receptors were treated as point receptors in this analysis, but this is a reasonable estimate given the beetle's club-shaped antenna.

Two points become apparent from this analysis. First, neither curve fits the observed data (Figures 4 and 5). Second, the difference in concentrations between antennae at a distance of 15 cm and a heading of 60° is on the order of 3%. The animal must be able to detect this difference if the tropotaxis is to

FIG. 10. The geometry and equations needed to analyze the difference in distance to the source between two point receptors placed symmetrically about an animal's midline. The animal is assumed to turn along circular arcs.

FIG. 11. The headings at which an animal would turn back towards the source after having once turned away, as predicted by an inefficient tropotaxis which requires either a critical absolute (lower curve, circles) or proportional (upper curve, squares) difference in concentration between the antennae before a return towards 0° can occur.

function. However, this implies a Weber fraction of 0.03, considerably lower than the values of 0.3–1.5 that have been obtained for other animals and modalities (Gescheider 1976). The few direct measurements that have been made on insects indicate that the ability to detect a 3% difference may be an order of magnitude better than any performance previously observed (Martin, 1964; Kramer, 1975; Bell and Tobin, 1982). On the other hand, the 50% decrease for counterturn initiation is within the usual range for Weber fractions.

Both the classic klinotaxis of Fraenkel and Gunn (1961) and a closely related modification of it are also inconsistent with several of the behavioral observations. In the classic klinotaxis, short “wigwags” of the receptor organs are made to either side of the body and information on the stimulus intensity in space is obtained by comparing stimulus intensity through time. The wigwags are herein assumed to be generated within the central nervous system. Oriented maneuvers are made on the basis of information obtained about the symmetry of the gradient during the wigwags. However, unless the wigwags are large enough that the concentrations can be made different enough at the ends of the swings, a classic klinotactic movement will not gain the animal much information regarding the form of the gradient (Kennedy, 1986).

A small modification to the classic klinotaxis overcomes this problem. Since it would generate a pattern that appears analogous to the zigzagging behavior of flying moths (Kennedy, 1983), it shall be referred to as the zigzagging mechanism. The animal still obtains information concerning the symmetry of the gradient as it executes centrally generated arcs, but the two mechanisms

differ in scale. In the classic klinotaxis, the arcs are executed by swinging the anterior portion of the body back and forth, and the size of each wigwag is smaller than the body length of the animal, or certainly very little more. In the modified klinotaxis, the arcs may be many body lengths of the animal and are executed by a regular alteration of the walking pattern. Straight sections between arcs could also occur.

The small wigwag movements that would be expected under a klinotaxis are inconsistent with the size of movements made by the beetles. The beetles are 4–6.5 mm long, and their turn radii were typically in the range 0.7–1.5 cm (Figure 6). The circumferences of the arcs made by the beetles therefore averaged two to five body lengths, clearly much larger than would be expected of the klinotaxis. However, such arcs would easily be consistent with zigzagging. Zigzagging is also consistent with the unimodal distribution of turn angle sizes, if no straight sections occurred between arcs (Figure 1). In addition, zigzagging is consistent with a moderate rate of turning even at headings close to 0° , although there is no clear reason why zigzagging should produce larger turn angles as heading increased, or why these turn angles should compensate in sign for the heading (Tables 2 and 3).

Further, zigzagging is inconsistent with the noise apparent in the movements of the beetles (Figure 7 in Akers and Wood, 1989a). This was also indicated by the analysis of the variation of arc sizes (Table 1), which failed to demonstrate the low level of variation that might be expected from regular, oscillatory movements. The turns in zigzagging are herein postulated to be driven largely by a central pattern generator, and such movements tend to be regular, especially once they have come into balance with environmental requirements (review in Camhi, 1984). Examples of such movements may be found in leg movements in walking, wing movements in flight, swimmeret movements, leech swimming movements, and respiratory movements. Even the zigzagging of moths in a windstream may be driven by a central pattern generator (Kennedy, 1983, 1986), although there is now some renewed controversy on this point (Preiss and Kramer, 1986). Coefficients of variation for moths zigzagging in an odor plume appear to be 20–30% (Kuenen and Baker, 1983; Cardé et al., 1984). By contrast, the beetles' movements are highly irregular, with coefficients of variation in the range of 60–90% (calculated from Table 1). Since variation was always fairly high, rigid zigzagging seems unlikely.

Zigzagging was also inconsistent with the distribution of maximum headings between occurrences of 0° , which was centered about a heading very close to 0° (Figures 2 and 3). Zigzagging might have been expected to produce maximum headings centered some distance from 0° , as the animal turned on its regular, centrally defined arcs. For instance, track headings of the straight sections in zigzagging moth flight are generally in the range of 30–90° with respect

to the wind (Kuenen and Baker, 1983; Cardé et al., 1984; Kennedy et al., 1980; Farkas et al., 1974).

Zigzagging was also inconsistent with the notable decrease in heading as the source was neared (Figures 4 and 5). Since the turns in zigzagging are postulated to be under central control, heading should not change much under this mechanism, despite possible changes in sensory stimulation. However, the path might become narrower as the source was neared, which would be reflected in a decrease in turn radius (Akers, 1985).

Two other possible orientation mechanisms became apparent during the course of this analysis, but they also appeared to be inconsistent with the results. The first is a modification of the zigzagging mechanism and was termed the "look and leap." In zigzagging, oriented movements have to interact with instructions for movements arising from the basic turn-pattern generator, or else the animal would probably never reach a source. In the look and leap, the animal separates movements to gather information from oriented movements, in order to minimize the amount of turning. It first initiates an orientation movement, based on an endogenously generated pattern of turns, during which it obtains information about the symmetry or form of the gradient. Based upon this sensory information and information concerning the form of its own movements, the animal estimates the direction towards the source, and aligns itself with it. It then continues in a more or less linear fashion until an endogenous or sensory cue triggers another orientation maneuver. Apparently, some flies use a similar mechanism to orient with respect to the wind in response to an odor cue (the "aim first, then shoot" mechanism, Bursell, 1984; Hawkes and Coaker, 1979; Miller and Strickler, 1984; Kennedy, 1986).

The second mechanism is termed the "steepest-ascent schemakinesis." If an organism could efficiently measure the rate of change of the stimulus, it might attempt to identify that heading with the steepest rate of increase in intensity, which would be directly towards the source. The path might be expected to consist of relatively straight segments, during which the animal would determine the rate of increase along that heading, punctuated by sharp turns.

In both the above mechanisms, linear sections of track are interspersed with bouts of rapid turning. They might then be expected to generate a bimodal distribution of turn angle sizes (Figure 1), which was not observed. However, the sharp turns in the steepest ascent might be relatively rare, and thus perhaps obscured in a distribution. Furthermore, both mechanisms could conceivably operate without the appearance of a bimodal distribution of turn angles or turn radii. If an animal had relatively regular turn angles at every point on its track, it could create relatively linear sections by alternating the signs of the turn angles and larger arcs by holding the sign constant for a period of time. I have not yet conceived a simple measurement that would reflect such a behavior. Such

behavior is not obvious in samples of tracks (Figure 7 in Akers and Wood, 1989a) and it seems difficult to reconcile with the variation in turn angle size (Figure 1). Nonetheless, the possibility cannot be completely excluded. Otherwise, the steepest ascent schemakinesis is inconsistent with the nearly constant turning executed by the beetles, and the beetles never seemed to head very directly towards the source, which also might have been expected. In the look-and-leap mechanism, the animal is also postulated to fix on a heading towards the source, once it estimates its direction from the orientation maneuver. Accordingly, it should not turn much for a period while on a heading near 0° , while at higher headings its turn angles should generally be considerably larger. However, the comparison of the absolute headings and turn angles at a point on the track showed that the beetles continued to have moderate rates of turning even when they were headed almost directly towards the source (Table 2). Combined with the lack of any regular movements and the unimodal turn angle size distribution, the beetles apparently did not look and leap very well.

In summary, the numerical analysis of the behavioral responses indicated that a compensated counterturning schemakinesis was most consistent with the observations, if the sensory cue used to initiate a counterturn was a decrease in the rate of increase of concentration. However, this raises the question of whether a beetle could detect such a cue at all. Concentration itself increases only about 30% as the animal swings from a heading of -90° to 90° , or vice versa. The detection of this increase itself would imply a Weber fraction of 0.3, relatively low by classic psychophysics. Detection of a rate of increase would require comparing at least two successive increases within this interval. On the other hand, Kramer (1978) has indicated that moths can detect a decrease of as little as 1%/sec, if continued for 5 sec. If this is true of the beetles as well, then they could possibly make the comparisons necessary for the mechanism to function. Finally, the possible effects of habituation have not been addressed in this paper. Because the animal is moving in a gradient, the stimulus is constantly changing, and thus any habituation is very difficult to isolate in the present experiment. However, in a preliminary experiment on the purely kinetic effects of pheromone (Akers, 1985), pheromone was applied as uniformly as possible to the arena, in an attempt to minimize any gradients. In that experiment, walking and turning rates were very similar between early (0–10 sec) and late (45–55 sec) portions of the track, giving at least some indication that pheromone perception habituates only slowly in this species, if at all.

BEHAVIORAL RESPONSE OF SOLITARY FATHEAD MINNOWS, *Pimephales promelas*, TO ALARM SUBSTANCE

B.J. LAWRENCE and R.J.F. SMITH

Department of Biology, University of Saskatchewan

(Received June 29, 1987; accepted November 9, 1987)

Abstract—Single fathead minnows, *Pimephales promelas*, were exposed to a range of concentrations of conspecific skin extract. Their responses were observed qualitatively and quantified by a computer linked to an activity meter. The response of fathead minnows to skin extract is complex, involving at least three separate types of behavior. The minnows responded over a 1000-fold range of extract concentrations with combinations of dashing, freezing, slowing, and exploring. The latency of the response increased at the lowest extract concentrations, suggesting summation of sensory cell responses. At low stimulus concentrations, a period of exploratory behavior sometimes preceded the more typical alarm responses. The active space generated by the alarm substance in 1 cm² of minnow skin may exceed 58,000 liters.

Key Words—Schreckstoff, alarm pheromone, fathead minnow, *Pimephales promelas*, fish behavior, club cells, alarm substance cells.

INTRODUCTION

Alarm substance (Schreckstoff) is released, by mechanical damage, from specialized alarm substance cells (ASCs) in the skin of ostariophysan fishes and initiates a defensive response, or "fright reaction," in the receiver (reviews: Pfeiffer, 1977; Smith, 1986). As with most fish pheromones, the exact chemical nature of the alarm substance is not known. There is developing evidence that hypoxanthine-3(*N*)-oxide is an important component of the alarm signal (Pfeiffer, 1982; Pfeiffer et al., 1985), but a single compound may not account for the species specificity that has been reported in the ostariophysan alarm system (e.g., Schutz, 1956). The response of the receiving fish has been reported to

vary among species in ways that seem generally appropriate to the habits of the species (Pfeiffer, 1977). Pfeiffer et al. (1986) examined the fright reaction of 15 species and found a generalized reaction consisting of rapid swimming (possibly controlled by Mauthner cell discharge), followed by goal-directed avoidance or shelter-seeking behavior.

Research on the effects of acidic pH on the response of fathead minnows to alarm substance (Smith and Lawrence, 1988) required description of the fright reaction as measured by an automatic recording system (Lemly and Smith, 1986). This description and the experiments conducted to find appropriate stimulus levels for the pH experiment provided new information on the characteristics of the fright reaction. A combination of visual observation, using video equipment, and sensitive measurement of times and distances, using a computer-based activity meter, allowed us to distinguish several components in the response of the fish to alarm substance. The constraints of the system limited the study to lone fish confined in shallow water.

In nature, the response of prey animals to predators may vary with the degree of risk or vulnerability. In general, risk and distance from the predator will be inversely related. In a chemical warning system dilution will often indicate distance. We might expect that prey will respond as if predators are close at high alarm substance concentrations, and as if predators are more distant at greater dilutions of alarm substance. Similarly there may be responses that are performed as a first response and others that are more frequently the second or third step in the fright reaction, and the appropriate first response may vary with distance and hence dilution.

Active space, the volume in which concentration of the stimulus exceeds the threshold of the receiver, is a key attribute in a chemical warning system. Active space is presumably an adaptive trait based on selection of sender and receiver for a combination of stimulus concentration and sensory threshold that provides adequate warning without too many unnecessary responses. The findings of this study allow the calculation of a conservative value for the active space, per surface area of skin, of fathead minnow alarm substance.

METHODS AND MATERIALS

Experimental Animals and General Handling Procedures. The majority of the fathead minnows were collected at Zelma Reservoir, approximately 70 km southeast of Saskatoon, Saskatchewan, Canada. Other fish were from Eagle Creek, approximately 100 km southwest of Saskatoon. The fish were held in temperature-controlled outdoor pools until they were used between April and August 1986. The experimental fish were moved from the outdoor pools to glass aquaria (45–60 liters) where they were sorted by size. Fish 5-cm or more in

fork length were retained and held for approximately two weeks at 16°C under a 12:12 light-dark photoperiod. They were fed daily with Tetramin, a commercial fish food.

After this initial adjustment period, the fish were transferred to the experimental room in groups of 10–15 and held up to a week in 45-liter glass aquaria. From this holding facility, fish were transferred in pairs to a series of Plexiglas acclimating tanks and finally to the testing tank (Lemly and Smith, 1985, 1986, 1987). The fish were acclimated and tested under incandescent lighting of 55 lux as measured at the water surface, on a 12:12 light-dark cycle. Testing occurred between 0830 and 1030 hr at a mean water temperature of 23°C.

To ensure that experimental fish would display relatively "undisturbed" behavior, a series of two acclimating tanks was used prior to placing the fish in the testing tank. Acclimating and testing aquaria were identical in size, water quality, and the provision of a centrally moored floating shelter. In the first acclimating tank the water depth was 8–10 cm and two fish were present. After 24 hr both fish were transferred to a second acclimating tank with water depth of 4–5 cm, the same depth as in the testing aquarium. After 24 hr the individual fish that seemed least disturbed were selected as the experimental fish and transferred into the testing tanks for the final 24 hr. The other fish was discarded. This procedure was necessary to allow the fish to adjust to being alone in shallow water. The fish were fed after each transfer.

Testing aquaria, tubing, and filters were drained, thoroughly rinsed, and refilled immediately after each trial to ensure the longest possible adjustment time to the testing tank. The washing and water exchange also minimized exposure of experimental fish to alarm substance from the previous trial. After each trial the experimental fish were measured, weighed, and sexed. For the dilution experiment the overall sex ratio was 23 females (mean wt. 2.16 g) to 47 males (mean wt. 2.69 g).

Activity Tracking System. The system consisted of an Opto-Varimex-Aqua tracking meter (Columbus Instruments) that surrounds a Plexiglas aquarium. This system has been described in detail by Lemly and Smith (1986). Recessed inlet and outlet manifolds on the aquarium were attached to one another by Tygon tubing that ran through a power filter and back into the test aquarium. The activity tracking meter (ATM) was interfaced to a microcomputer that integrated the digitized signal from the grid of light beams in the meter and tabulated data on position and activity of a single fish for a designated time period. At regular intervals, the computer "scans" the light beams for breaks. A minimum time between beam scans of 0.125 sec was chosen after pilot testing showed that this interval was short enough to record accurately the movement of a rapidly swimming fish. Of the eight behavior parameters measured by the meters, six proved useful in assessing fathead minnow alarm responses: total distance traveled, time spent resting, number of stereotypic movements, time

spent in stereotypic activity, time spent in ambulatory movement, and total number of beam breaks. Stereotypic activity is a term used by Columbus Instruments to describe activity in which the fish breaks light beams without moving out of a "box" of beams of preset dimensions, one grid square. Ambulatory movement refers to movement in which the fish progresses steadily from one region of the tank to another. The total number of beam breaks per unit time provided an index of general activity. The variables measured by the ATM are not totally independent nor are they all directly correlated. Together they allow the experimenter to characterize the response of a particular species to a stimulus.

In this study each trial consisted of eight identical time periods of 2.13 min. The alarm substance stimulus was injected into the circulation system at the end of the fourth time period. A loop of the circulation system, between the power filter and the inlet manifold, passed into an adjacent room allowing a hidden observer to inject the stimulus through the tubing. Video equipment allowed the remote observer to see and record the behavioral responses of the fish as well as to simultaneously monitor the quantitative data from the ATM.

Alarm Substance Preparation. Fifteen donor fish were selected, weighed, measured (fork length), and sexed immediately after capture from an outdoor pool. Mature males that might have seasonally reduced numbers of ASCs (Smith, 1973) were not used. The sex ratio of the donor fish was nine females to six males. The mean weight was 1.5 g and the mean length was 5.1 cm. A patch of skin was removed from each side of the caudal peduncle area of each fish. A small subsample was preserved in 10% formalin for histological examination and determination of ASC abundance. These samples were embedded in paraffin and 7- μ m sections were stained with periodic acid-Schiff's reagent and counterstained with hematoxylin. ASCs were counted and measured in representative sections. The relative area of ASCs and epidermis were determined using an image analyzing computer. ASCs were present in 14 of the 15 donors. A damaged sample prevented assessment of the 15th fish. The approximate total area of minnow skin used to prepare the alarm substance was 11.9 cm². This skin was homogenized in 100 ml of glass-distilled water (GDW) using a Polytron homogenizer and then filtered to remove scales and tissue. A portion of the stock solution was immediately frozen (-18°C) in 5-ml quantities, another portion was diluted 1 part stock to 4 parts GDW and frozen in 5-ml portions. After a period of initial testing, four different dilutions were chosen for more intensive testing: (1) stock solution, (2) a 1:10 dilution of the stock, (3) a 1:100 dilution, and (4) a 1:1000 dilution. With the exception of the stock solution that was used as previously prepared, the solutions were made by slowly thawing (the test tube was set in a beaker of cold water and allowed to thaw at room temperature) the original 1:4 dilution, adding appropriate amounts of GDW, and refreezing in 5-ml portions. Immediately prior to use in the exper-

imental apparatus, the prepared alarm substance was slowly thawed, as above, and 1 ml was drawn into a syringe. Fifteen fish were tested at each concentration. Solutions were tested in random order to minimize effects of seasonal changes in behavior and of possible contamination. Control injections of 1 ml of GDW were also tested on 15 fish.

Statistical Analyses. Data from the three time periods immediately preceding the alarm substance injection were pooled and compared with pooled data from the three time periods immediately following the stimulus using Wilcoxon's matched-pairs, signed-ranks test (Sokol and Rohlf, 1981). Data were analyzed separately for each of the six behavioral parameters for each stimulus dilution. Differences were considered to be significant at probabilities less than 0.05.

RESULTS

Description of Alarm Behavior. Video observations indicated that the most common response to the alarm substance stimulus was to become motionless, freezing, for periods ranging from approximately 0.5 min to greater than 8 min (the entire poststimulus time). The next most frequent alarm behavior was slowing, in which the fish would slow its rate of movement, e.g., less circling and nibbling under the shelter and fewer, shorter forays away from the shelter. Nibbling and circling under a shelter are common types of fathead behavior (McMillan and Smith, 1974). Dashing, the least common response, was actually the first part of a biphasic response. Several seconds to approximately 1.5 min of very rapid, apparently disoriented swimming were followed most often by the fish becoming motionless, freezing, or by the fish showing a very low level of movement, slowing. A nonalarm behavior, exploring, typified by slow, open-water swimming towards and along the inlet channel, was observed when alarm substance stimulus levels of <0.01 were injected. Exploratory swimming lasted from slightly under a minute to just over 2 min. In six of seven cases an obvious alarm reaction, either freezing (4/6) or slowing (2/6), was observed to follow the initial exploratory behavior. A portion of the experimental population did not respond to the alarm substance stimulus; human qualitative assessment indicated 21% nonresponders while machine assessment indicated 13% (Smith and Lawrence, 1988).

Effects of Stimulus Dilution on Alarm Behavior. The majority of fathead minnows were still capable of sensing and reacting to the lowest dilution of alarm stimulus tested (Table 1 and Smith and Lawrence, 1988). Exploring was observed only at the two lowest stimulus concentrations (Figure 1) and caused an initial increase in distance traveled in the first poststimulus interval in the 0.001 treatment group (Figure 2). A comparison of the last pre-

^aB = before stimulus introduction. A = after stimulus introduction. Distance was measured in centimeters, time in seconds, and moves and beam breaks were counted. Values are the mean scores of 15 fish over the three intervals (total 6.39 min) preceding stimulus introduction and the three intervals following stimulus introduction. All differences are significant ($P < 0.05$), except those marked "ns," based on a Wilcoxon matched-pairs, signed-ranks test comparing each individual fish's cumulative score before the stimulus with that fish's score after the stimulus.

stimulus interval with the first poststimulus interval indicated that both the stock and 0.1 stimuli initiated significant decreases in distance traveled ($P < 0.05$, Wilcoxon matched-pairs, signed-ranks test), but the difference between these two intervals in the 0.01 and 0.001 stimuli was not significant. The frequency of freezing as the first response was positively correlated with stimulus strength ($P = 0.05$, Spearman rank correlation coefficient; Siegel, 1956). However, freezing often followed exploring so the total frequency of freezing declined only slightly. There was an observable increase in the latency of the response as stimulus concentration was reduced. With stock and 0.1 dilutions, the response was initiated almost immediately after injection, whereas at 0.001 the alarm response was delayed (Figure 2). This delay could be demonstrated by comparing stereotypic activity for the last prestimulus and first poststimulus intervals. The two intervals differed significantly in the three highest dilutions ($P < 0.01$, Wilcoxon matched-pairs, signed-ranks test) but at the 0.001 dilution the difference was not significant ($P > 0.05$). In the 0.001 dilution the second

FIG. 1. Proportional frequencies, as a first response, of behaviors in the post stimulus intervals after introduction of skin extract at four dilutions of the stock solution.

poststimulus interval was significantly different from the last prestimulus interval ($P < 0.05$).

Since we know the area of skin used in preparing the stock solution and the various dilutions performed, we can estimate the active space of alarm substance per cm^2 . The original stock solution contained 11.9 cm^2 of skin diluted in 100 ml of water. That stock solution diluted to 1 : 1000 still produced a significant reaction when 1 ml was added to an ATM containing 7 liters of water. This indicates that 1 cm^2 of fathead minnow skin contains enough alarm substance to reach threshold levels in 58,823.5 liters, equivalent to a cube approximately 3.9 m on a side. Since the 1 : 1000 dilution was still a very effective stimulus, the real active space may considerably exceed our estimate. The initial exploring response occurred in the 0.01 dilution but not in the 0.1 dilution, indicating that the active space at which the transition from an immediate fright reaction to an initial exploration occurs presumably lies between 588 liters/cm^2 and 5882 liters/cm^2 . Our measurements of epidermal thickness (mean = 0.052 mm), cell diameter (mean 0.025 mm), and proportion of epidermis composed of ASCs (11.7%) permit a rough calculation of the amount of ASC material in 1 cm^2 of skin in our sample ($6.1 \times 10^{-3} \text{ mm}^3$) and of the active space generated per average ASC (80 liters). A conservative conclusion, considering the high

FIG. 2. Changes in relative levels of three behavior patterns over time, before and after introduction of skin extract at four dilutions of the stock solution. The stimulus was introduced at the end of the fourth time interval (2.13-min intervals). Average activity of each test fish over the first four intervals has been indicated on the Y axis as 1.0. Arrows indicate alarm substance introduction.

variation among samples and uncertainties such as the proportion of ASCs broken by the tissue disruption process, would be that the contents of a single ASC could generate an active space of the order of 10s of liters.

DISCUSSION

Lone fathead minnows exposed to skin extracts performed four general types of behavior: dashing, reduced activity (slowing and freezing), exploring, and no response. The use of lone fish was necessitated by the limitations of the activity tracking meter. Being alone may be a relatively rare situation for minnows in nature, and the behavioral responses may have been modified by the stress of being alone. Although they are schooling fish, there are some situations in which fathead minnows are alone in nature. Male fatheads are often alone on their territories during the spawning season (Unger, 1983), and females have been observed moving singly into the territories during the spawning season (Smith, personal observation). Males retain their response to alarm substance during their territorial phase (Smith, 1976). Using lone fish had the advantage of yielding a "pure" response to the chemical stimulus. Schooling minnows have been reported to show a fright reaction to the sight of other fish responding (Verheijen, 1956). Any response with more than one fish present may be influenced by visual as well as chemical stimuli.

The dashing component of the multiphase response to alarm substance may be an escape response controlled by the Mauthner neurons, as suggested by Pfeiffer et al. (1986). The behavior we observed was consistent with his descriptions of Mauthner responses in other fishes. Sudden unpredictable dashing may be appropriate as an initial response to imminent danger. The Mauthner response has been hypothesized to be escape behavior (Eaton and Bombardieri, 1978). It can be initiated by mechanical or visual stimuli as well as by alarm substance. Freezing and slowing may follow dashing or may occur as initial responses without a preceding dashing phase. It is not clear whether freezing and slowing are two different responses or different intensities of the same response. Both may make the minnow less conspicuous but freezing is probably more effective in this regard. Similar reductions in activity are components of the fright reaction in other cyprinids such as the pearl dace, *Semotilus margarita*, where they are associated with physiological indicators of stress (Rehnberg et al., 1987).

The exploring behavior that occurred at low stimulus concentrations may be a response to low alarm substance concentrations or to other chemical components of the skin extract. The behavior is generally similar to the response of fathead minnows to feeding stimuli (Lemly and Smith, 1985, 1987) and the skin extract will contain amino acids and other compounds that may elicit food searching. Bardach and Todd (1970) suggested that alarm substance may be attractive in low concentrations but provided no evidence or arguments to sup-

port this idea. Our results leave the question unresolved. The answer may have to await the availability of chemically pure alarm substance. Increased response latency at low stimulus concentration is typical of stimulus summation (Getchell, 1986). In fathead minnows increased response latency was often associated with exploring behavior, which may bring the minnow into contact with more alarm substance, speeding the summation process. Exploring may be similar to the "predator inspection behavior" described by Magurran (1986) in the European minnow, *Phoxinus phoxinus*, behavior thought to provide the prey with information about the predator.

The active space of a semiochemical depends on attributes of both the sender and the receiver. The sender determines the concentration of the semiochemical through the amounts produced and released. In the minnow alarm substance system this is presumably adjusted through control of the density of ASCs in the skin. In fathead minnows ASC density is known to be under endocrine control during the breeding season. Males lose their ASCs during the breeding season in response to increased androgen levels and regain them later as androgen declines (Smith, 1973, 1974). The factors controlling ASC numbers in females and nonbreeding fish are not known. The receiver determines the threshold of the response, either through sensory capabilities or central controlling mechanisms. Virtually nothing is known about the sensitivity of fathead minnows to chemical stimuli. The data reported here suggest that they detect and respond to low concentrations of skin extract. Calculations based on the work of Gandolfi et al. (1968) suggest an active space of $> 10,000$ liters/cm² of skin in the zebra danio, *Brachydanio rerio*, the same order of magnitude as our findings. Such calculations of active space provide an opportunity to compare laboratory findings with subjective impressions of the usefulness of the alarm substance in the wild. Active spaces with dimensions of several meters, containing 10s of thousands of liters seem to be within the range that should be useful to a 5-cm fish. There are a number of uncertainties in applying these findings to natural situations, including lack of knowledge of the amount of skin damage caused by natural predation or of the spatial distribution of alarm substance plumes in natural waters.

Abstract—Mated female *Heliothis subflexa* (Gn.) (HS) moths 1–7 days old responded positively in a Plexiglas flight tunnel to an attractant extracted with methanol from fresh whole-leaf washes of groundcherry, *Physalis angulata* L. Response to the groundcherry extract, as indicated by plume-tracking (i.e., upwind flight toward the odor source) and contact with the chemical dispenser did not change significantly during the first 5 hr of scotophase. Overall, ca. 50% of the responding moths also landed on the chemical dispenser; ca. 50% of the moths that landed also deposited eggs. There were no significant differences in the behavioral responses of females mating only once and those that had mated two or more times. Virgin females and male moths were significantly less responsive to the groundcherry attractant than mated females. The flight tunnel bioassay described provides an excellent system for evaluating plant allelochemicals associated with host-plant selection.

Key Words—*Heliothis subflexa*, Lepidoptera, Noctuidae, attractant, kairomone, groundcherry, *Physalis angulata*, flight tunnel bioassay, plant–insect interaction.

INTRODUCTION

Environmentally controlled systems are needed to study host-finding behaviors of phytophagous insect species. The present study was designed to develop a

¹This article reports the results of research only. Mention of a proprietary product does not constitute an endorsement or the recommendation for its use by USDA.

system that could be used to evaluate host-plant attractants and associated behaviors (e.g., oviposition) in a controlled environment. *Heliothis subflexa* (Gn.) (HS) was selected as the test subject because of its limited host range (*Physalis* spp.) (Brazzel et al., 1953) and also because of potential changes in plant selection behaviors that might occur as a result of hybridization between HS and its sibling species *H. virescens* (F.) (HV) (Laster, 1972). Little is known about the nature of flight responses of *Heliothis* moths to host-plant chemical stimuli.

METHODS AND MATERIALS

A Plexiglass flight tunnel was used to observe the behavior of HS to crude plant extract (Mitchell and Heath, 1987) obtained by washing fresh, whole groundcherry leaves in methanol. Typically, 100 g of groundcherry leaves were extracted for 30 sec in 500 ml of methanol. The extract was filtered and concentrated to 1 g/ml with a rotary evaporator. The 60 × 60 × 185-cm tunnel was located in an environmentally controlled room 3 × 2.6 × 2.1 m. The room was maintained at ca. 26.8°C with a heat pump/air conditioner and ca. 50% relative humidity with a room humidifier. Overhead fluorescent lights (two banks of two 40-W bulbs) connected to an electric timer were used to control the reversed light-dark cycle (14 hr light; 10 hr dark). Three 25-W red light bulbs were spaced equally above the tunnel and remained on continuously. Air was pulled through the tunnel at 0.5 m/sec and was exhausted via a 30-cm-diam. flexible pipe with a fan. An intake vent located in the wall of the environmental chamber allowed a continuous flow of fresh air into the room from the outside.

The HS used in the tests were obtained from our laboratory colony, which was started from ca. 300 larvae collected from groundcherry in the fall of 1983 and has had new genetic material introduced each fall since 1984 (Mitchell et al., unpublished data). The larvae were reared on a modified pinto bean diet (Guy et al., 1985). The insects were sexed in the pupal stage and separated before emergence of adults. Upon emergence, the adults were confined either in 3.8-liter cages as virgins or combined for mating (21 females and 14 males/cage) and held until the desired age for testing. Insects were held under the same environmental conditions as were maintained in the flight tunnel room. On the day of testing, the moths were sexed by gently squeezing the abdomen to extrude the genitalia and the females were placed in a 25 × 25 × 50-cm Plexiglas holding cage, which was placed in the flight tunnel room ca. 1 hr before scotophase.

Each test was begun by introducing 1-g equivalent of groundcherry-methanol extract into the tunnel on the evaporator substrate (white muslin) placed over the end of a glass cylinder dispenser with a 3.5-cm opening. Air was blown

through the cylinder and cloth into the tunnel with an aquarium pump at a rate of 1 liter/min to provide a continuous flow (plume) of the extract odor through the tunnel. The location of the plume through the center of the tunnel was verified previously by observing a smoke trail, produced by introducing smoke into the dispenser system. Each moth was removed individually from the holding cage and placed into a cylindrical 4×6.5 -cm plastic release cage with screened ends. After placement of the release cage into the downwind end of the flight tunnel, the moth was released immediately and observed for 2 min. Behavioral responses were timed and recorded. All female moths were dissected after testing to confirm mating status. Tests with untreated controls were conducted periodically to ensure that response to the dispenser substrate (white muslin) was negligible when treated with solvent (methanol) only and that contamination of the bioassay system had not occurred. Data were analyzed by ANOVA or the unpaired *t* test (Steel and Torrie, 1960).

Experiment 1. Females 1, 2, 3, 4, 5, 6, or 7 days old, which had been confined with males for mating, were tested to determine the effects of moth age on response to the groundcherry extract. Tests were conducted 1–4 hr after the beginning of scotophase. Specific responses, including flight initiation, type of flight (either undirected or plume tracking, i.e., following the plume trail upwind), contact with or without landing on the extract-treated substrate (white muslin), and duration (in sec) of each response were recorded. Three replications of 10 individuals each were completed for each age group.

Experiment 2. A second experiment was conducted to determine if response to the extract changed significantly as the scotophase progressed. Mated female moths 3–6 days old were tested in the flight tunnel as described for the first experiment. The tests began ca. 10 min after the onset of scotophase and continued through the 5th hr of darkness. Data were tabulated from two replications of 37 individuals each for each hour.

Experiment 3. In the third experiment, 3- to 5-day-old mated HS female moths were tested for their response to groundcherry extract in the flight tunnel as described previously. Special attention was focused on detecting any previously unobserved differences in the behavior of insects in the different response groups; i.e., (1) those that flew at random (undirected flight), (2) those that responded by tracking the plume trail from the extract dispenser, (3) those that made very brief contact with the extract-treated substrate but did not land, and (4) those that actually landed on the dispenser substrate. The time (sec) that each moth in each response group remained in the release cage before taking flight, the time spent in undirected flight, the number and duration (sec) of plume trackings, and when contacts and landings occurred also were recorded. Data collected from 3- to 5-day-old moths in experiments 1 and 2 were combined with the experiment 3 data to provide three replications of 150–170 individuals each.

Since all of the HS females used in the various experiments were dissected to determine mating status, the data were tabulated to determine if the number of matings per female had any effect on moth response to the attractant. The number of matings per female was determined by the number of spermatophores counted in each moth upon dissection.

Also, in experiment 3, the response of virgin HS females and males (0, 2, or 4 days old) to the groundcherry extract was determined during the first 3 hr of scotophase (three replications) using the criteria and methods described previously.

RESULTS AND DISCUSSION

Mated female HS moths in all age groups (experiment 1) demonstrated a positive anemotactic response to groundcherry extract (Figure 1). There were no significant differences in total response (59–71%) among the age groups (1–7 days old) (Figure 2). An average of 71% (1 day old), and 79% (7 days old) to 100% (4 days old) of the moths that followed the attractant plume also made contact or landed. Of these, 20% (7 days old) and 25% (1 day old) to 55% (4 days old) and 61% (3 days old) landed on the treated surface. There was a significant correlation ($P < 0.05$, $r = 0.821$, 5 *df*) between moth age and the percentage of moths that contacted the groundcherry extract without landing on the treated substrate. Seven-day-old moths made the most contacts (46%) but had the fewest landings (13%) (Figure 2).

There were no significant differences among the age groups in the mean number of contacts (1–3) per female before landing on the extract-treated substrate or in the number of repeated contacts (1.5–4.8, including initial contact) when making contact without landing (Table 1). Also, moth age had no significant effect on (1) mean number of times a moth flew up the plume before landing, (2) number of times that an individual flew up the plume and made contact without landing, or (3) the number of plume trackings (1–2) by moths that responded without contacting the dispensing substrate (Table 1).

Response to groundcherry extract by mated HS female moths (experiment 2) did not change significantly from 10 min to 5 hr after the initiation of darkness. The percent that either tracked the plume, contacted, or landed on the extract-treated substrate ranged from 84% during the first hour and 75–77% from hours 2–4, to 58% for those flown 4–5 hr after dark.

In experiment 3, 73% of the mated female HS moths responded to groundcherry extract by flying up the plume, contacting the dispenser, or landing (Table 2). There were no significant differences in the seconds before flight initiation (8.3–13.2) among the moths that did not respond to the extract and those that demonstrated a positive response. Although the resting position was sometimes

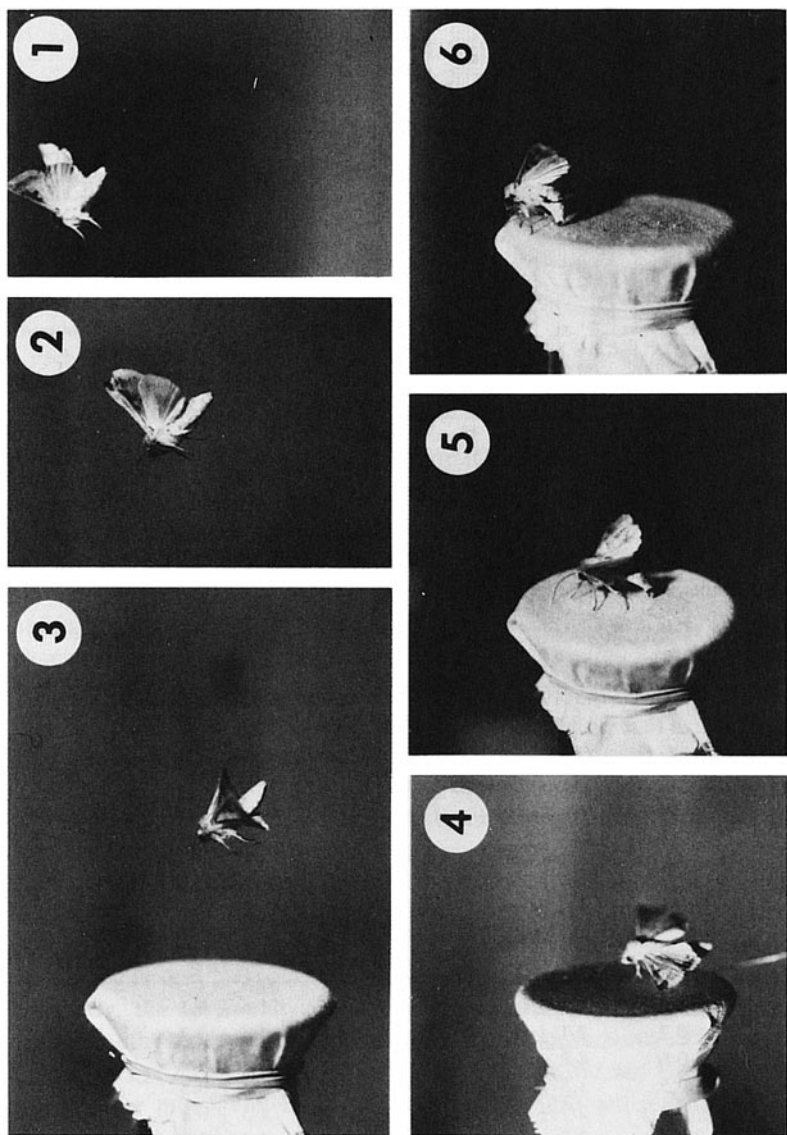

FIG. 1. Flight sequence of *Heliothis subflexa* in a positive anemotactic response to 1-g equivalent of methanol extract from whole-leaf washes of fresh groundcherry leaves in methanol. Response includes plume tracking (1-3), contact with the extract-treated substrate (4), and landing (5-6) with possible oviposition.

FIG. 2. Response in a flight tunnel of mated *Heliothis subflexa* females of indicated age to 1-g equivalent of an attractant extracted by washing fresh groundcherry leaves in methanol. Total response includes flying up the odor plume with no contact with the dispenser, contacts without landing, and landings.

^bMoths were in resting state for balance of 120-sec test.

assumed on the sides of the tunnel during each 120-sec test, the total flying times (80.7–107.1 sec) of females that flew randomly, flew up the plume, or contacted and did not land on the substrate were significantly longer than the 38.5 (\bar{X}) sec flown before landing by those that did land ($F = 36.25$, $df = 8$, $P < 0.0001$, ANOVA). Upon landing, ca. 50% of the moths landing were observed to oviposit on the dispenser before they could be captured and removed from the tunnel (Figure 1). However, detailed ovipositional behavior after landing was not studied in this experiment.

The HS females that landed on the extract-treated substrate in experiment 3 (Table 2) made significantly fewer flights upwind toward the source of the plume before landing than moths that responded to groundcherry extract by contacting or only following the plume ($F = 27.22$, 6 df , $P < 0.001$, ANOVA). However, the mean duration of the plume trackings was statistically equal among moths that landed, contacted, or plume tracked only. The mean number of contacts (1.9) by moths that made contact but did not land was almost the same as the number of contacts (1.8) made before and at time of landing by those that did land.

The data obtained from the 4-day-old moths ($N = 158$) in experiment 3 are presented in Figure 3 to illustrate the typical flight behavior of the mated females in response to groundcherry extract. Most (96%) of the HS females

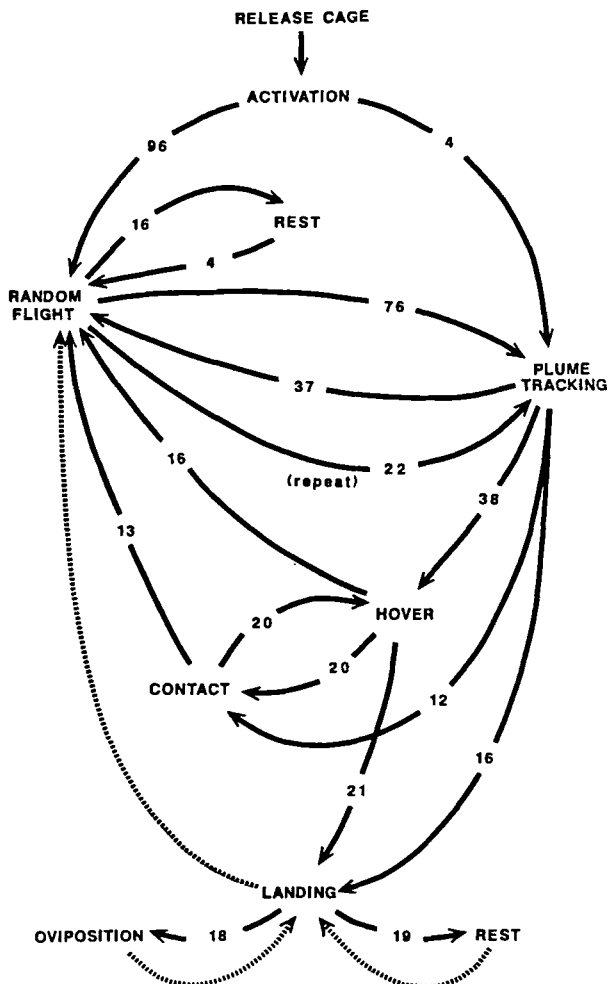

FIG. 3. Behavioral paths of mated female *Heliothis subflexa* females ($N = 158$) responding to 1-g equivalent of a methanol extract from whole-leaf washes of fresh groundcherry leaves. Values indicate percent of total insects responding. Broken lines indicate that observations were discontinued at the time of landing except for noting if oviposition occurred immediately.

began nondirectional (random) flight after emerging from the release cage at the downwind end of the flight tunnel. Random flight usually began in an upwind direction. A few of the moths (4%) began flying up the plume almost immediately upon release. Moths were more likely to begin flying up the plume trail

of the groundcherry extract if they remained in the release cage for a few sec before initiating flight.

During random flight, 76% of the HS moths detected and followed the extract plume (Figure 1), but of these, 37% returned to random flight (Figure 3). About half the moths that resumed random flight made additional flights up the plume. The moths usually began directed flight up the odor plume when they were 40–80 cm downwind from the extract dispenser. After flying up the plume, 38% of the moths began to hover ca. 5 cm from the dispenser. These moths then contacted (20%) or landed (21%) on the treated surface or returned to random flight. After making contact, they either returned to random flight or resumed the hovering position and then made a repeated contact or landed.

Females that followed the plume of the groundcherry extract, but did not hover near the dispenser, either contacted (12%) or landed (16%) without hesitation on the extract-treated substrate. More than one third of the moths flown in this experiment landed and either began to oviposit (18%) on the extract-treated substrate or assumed a resting position (19%). The significant ($P < 0.05$) behavior transitions, as determined by calculating chi-squared values for observed and expected frequency transitions to a behavior from the preceding behavior (Teal et al., 1981), are indicated on the flow diagram (Figure 4). After plume tracking, 32 of the 51 moths that contacted without landing hovered near the dispenser before making contact with the substrate, and 33 of the 58 moths that landed hovered before landing. The total positive response (landing, contacting, or plume tracking without making contact) was 80%.

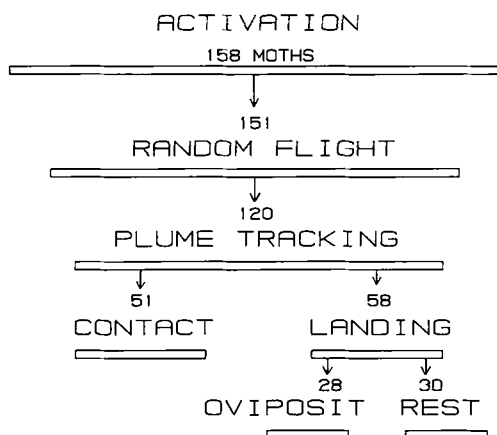

FIG. 4. Significant behavior transitions of mated *Heliothis subflexa* females responding to 1-g equivalent of methanol extract from whole-leaf waxes of fresh groundcherry leaves. Lengths of horizontal lines are decreased as transitions become less frequent.

There were no differences in behavioral responses to groundcherry extract by HS females that mated only once and those that had multiple matings. Of 392 females examined, 35% mated more than once before testing. The mean total positive response to the groundcherry extract was 73% for each group. Similar, but significantly less, positive response was observed when using virgin HS females ($\bar{X} = 41.7\%$) and males ($\bar{X} = 19.6\%$). Also, there were no significant differences among responses by 0-, 2-, and 4-day-old virgin moths with 28, 52, and 46%, respectively, demonstrating a positive response to the extract.

These results are particularly encouraging for future studies of insect-host plant relationships. The flight bioassay described demonstrates conclusively that volatile components attractive to HS can be extracted with a methanol wash of fresh whole groundcherry leaves. To our knowledge, this is the first documented demonstration of a flight response of female *Heliothis* moths to chemicals extracted from their host plant. This extract at dosages of 0.01–10.0 g equivalent elicited significant ovipositional response by HS when tested in an olfactometer as described previously (Mitchell and Heath, 1987). Characterization of the active chemicals and evaluation of the host-finding behaviors to these chemicals by HS \times HV hybrids are underway.

Although HS has a limited host range, there is reason to believe that polyphagous species also may be attracted to odors emanating from plants. A recent report by Rembold and Tabor (1985) showed that *H. armigera* (Hübner) females (a polyphagous species) responded differentially in oviposition trials to odors obtained by pulling air over seedlings of two cultivars of pigeonpea, *Cajanus cajan* L. Millsp. Jackson et al. (1984) reported that whole-leaf cuticular washes from green leaves of flue-cured tobacco stimulated HV oviposition when sprayed onto leaves of a resistant tobacco strain. It appears reasonable that using a flight bioassay of the type described here, alone or in combination with a behavioral oviposition bioassay (Mitchell and Heath, 1987), would add a new dimension to the study of insect-host plant resistance and enable integration of insect behavior and plant chemistry. Once a specific behavior (e.g., directed flight toward an odor source) is identified, the bioassay would permit the isolation of the active components. After the active material is isolated and characterized, the bioassay then could be used to screen other cultivars and even wild plants for germ plasm having none or substantially reduced levels of the active compounds. Programs of this type would reduce the screening time of plants and could be carried out year-round in a laboratory setting. Selected germ plasm could be tested in competitive field trials and then incorporated into commercial lines using classical or perhaps even the newer molecular genetic techniques. Such procedures conceivably would reduce significantly the time and expense of bringing resistant cultivars to market.

Abstract—We determined the chirality of ipsdienol in individual male pine engravers, *Ips pini* (Say), from New York, California, and two localities in British Columbia (BC). Both quantity and chirality of ipsdienol varied significantly between and within populations of *I. pini*. Beetles from California and southeastern BC produced primarily (*R*)-(–)-ipsdienol with mean ratios of (*S*)-(+) : (*R*)-(–) of 9:91 and 11:89, respectively, while beetles from New York produced primarily (*S*)-(+) ipsdienol with a mean (*S*)-(+) : (*R*)-(–) ratio of 57:43. A population from southwestern BC was unlike any other known western population, producing primarily (*S*)-(+) ipsdienol with a mean (*S*)-(+) : (*R*)-(–) ratio of 66:34. In contrast to the unimodal chirality profiles for ipsdienol production in populations from California and southeastern BC, the profiles of the populations from southwestern BC and New York were bimodal, with a common mode at approximately 44:56 (*S*)-(+) : (*R*)-(–). Bimodality in the profiles of ipsdienol chirality in two populations of *I. pini* and remarkably high levels of intrapopulation variation in pheromone chirality in all four populations suggest that evolutionary change in pheromone channels of communication could occur, possibly in response to artificial selection pressures such as mass trapping.

Key Words—*Ips pini*, Coleoptera, Scolytidae, aggregation pheromone, ipsdienol, geographic variation, intrapopulation variation, speciation.

INTRODUCTION

Pine engravers, *Ips pini* (Say) (Scolytidae: Coleoptera), are common and ubiquitous bark beetles found throughout North America. They breed primarily in the phloem tissue of the boles and branches of pines and can be a serious pest in stands of lodgepole, *Pinus contorta* var. *latifolia* Engelmann, and ponderosa pines, *P. ponderosae* Dougl. ex Laws. (Furniss and Carolin, 1980). Male *I. pini* are polygamous with harems of three to four females, on average. Each male excavates a nuptial chamber in the phloem of the host. Females in his harem then construct egg tunnels that radiate from the nuptial chamber, resulting in a characteristic X- or Y-shaped gallery, often engraved in the sapwood. The larvae feed in the surrounding phloem, pupate at the end of their feeding tunnels, and mature adults bore out through the bark and disperse to new hosts (Chamberlin, 1958; Bright and Stark, 1973; Bright, 1976; Furniss and Carolin, 1980; S.L. Wood, 1982).

Like many scolytids, *I. pini* aggregate rapidly and in large numbers to a suitable host (Anderson, 1948). Both sexes of *I. pini* are attracted to a terpene alcohol, ipsdienol (2-methyl-6-methylene-2,7-octadien-4-ol) (Vité et al., 1972; Stewart, 1975). Only male *I. pini* produce ipsdienol, presumably from the host monoterpene, myrcene, as shown for male *I. paraconfusus* (Hughes, 1974; Byers et al., 1979; Hendry et al., 1980; Byers, 1981; Fish et al., 1984). Female *I. pini* are not known to produce any pheromone.

Geographic variation in the use of ipsdienol as a pheromone is known (Lanier, 1972). Ipsdienol exists as two optical isomers or enantiomers (Figure 1), differing only in the absolute configuration around the chiral center. Males from California (Stewart, 1975; Birch et al., 1980) and Idaho (Plummer et al., 1976) produce only (*R*)-(-)-ipsdienol while beetles from New York produce a 65:35 mixture of (*S*)-(+)- and (*R*)-(-) enantiomers (Lanier et al., 1980). California beetles are attracted by (*R*)-(-)-ipsdienol but are repelled by (*S*)-(+)-ipsdienol (Birch et al., 1980), while New York beetles respond best to a racemic mixture (equal quantities of (*S*)-(+)- and (*R*)-(-)-ipsdienol) (Lanier et al., 1980).

Pheromones are important in speciation and community structure in many Coleoptera and Lepidoptera, particularly in the families Scolytidae and Tortricidae, respectively (Lanier and Burkholder, 1974; Roelofs and Cardé, 1974; Cardé and Baker, 1984). In many Tortricidae, specificity in the use of pheromones is based on the ratio of *E* and *Z* isomers (Cardé and Baker, 1984), comparable to the specificity shown by bark beetles for enantiomeric ratios (Birch, 1984).

In order to understand if and how natural selection structures the use of pheromones, estimates of intrapopulation variation and heritability in pheromone traits are first required (Lanier and Burkholder, 1974; Collins and Cardé,

FIG. 1. Stereochemistry of the aggregation pheromone, ipsdienol, produced by male pine engravers, *Ips pini* (Say).

1985). To date, variation within populations of *I. pini* has been masked by the need for pooled samples of 300 or more beetles to obtain a sufficient quantity of ipsdienol for a single determination of chirality. It is now possible to determine the chirality of as little as 25 ng of ipsdienol by splitless gas chromatography following derivatization to acetyl lactate diastereomers (Slessor et al., 1985). By using this procedure we were able to elucidate the variation in quantity and chirality of ipsdienol within and between populations of *I. pini*.

METHODS AND MATERIALS

Collection of Pine Engravers. Populations of pine engravers were collected from four localities in North America. In 1984 we collected bolts of lodgepole pine infested with live broods of *I. pini* from Kimberley in southeastern British Columbia and just east of Manning Park in southwestern BC. Infested bolts were placed in rearing cages in the laboratory and adult beetles were collected after emergence as mature adults. In 1984 and 1985, newly emerged adults were transported by aircraft from Newcomb in New York, and Hat Creek in California. Red pine, *P. resinosa* Ait., was the brood host species for beetles from Newcomb; lodgepole pine was the brood host for beetles from the other three localities.

Procedure for Extracting and Analyzing Ipsdienol. Using the gelatin-pill capsule technique (Borden, 1967), adult males from each of the four populations were restrained on uninfested bolts of lodgepole pine collected near Man-

ning Park, BC. They were allowed to bore into the bark and feed for 24–48 hr. Abdomens from individual males were removed and each was crushed in 150 μl of pentane containing racemic 3-octanol (4.1 ng/ μl) as an internal standard. These extracts were analyzed by splitless capillary gas chromatography (Hewlett Packard HP 5890 using a 30-m \times 0.25-mm ID fused silica column), before and after derivatization to acetyl lactate diastereomers (Slessor et al., 1985). Retention times of ipsdienol and its derivatives were determined with racemic ipsdienol obtained from Borregaard A.S., Sarpsborg, Norway, and chiral assignments were made according to Slessor et al. (1985). The identities and integrities of ipsdienol acetyl lactate diastereomers were verified by mass spectrometry using splitless capillary gas chromatography (Hewlett Packard HP 5985B).

Procedure for Statistical Analyses. Coefficients of variation (Sokal and Rohlf, 1981) were calculated for quantity and chirality of ipsdienol using transformed data to obtain normality in the data sets. In addition to the mean chiral ratio for individuals, a pooled chiral ratio was also determined for each population using the pooled quantities of each enantiomer. The pooled chiral ratio is comparable to the method used in previous studies (Stewart, 1975; Plummer et al., 1976; Birch et al., 1980; Lanier et al., 1980). For each pooled chiral ratio, a root-mean-squared error (RMSE) was calculated using the following expression:

$$\text{RMSE} = (x_i - x_p)^2 + [\text{SE}(x_i)]^2$$

where x_i stands for the mean chirality for population i , x_p is the chiral ratio using pooled data for population i and $\text{SE}(x_i)$ is the standard error for the mean chiral ratio, x_i . Quantities were transformed by $\log(1 + X)$ while the data for chiralities were transformed by $\arcsin \sqrt{X}$. Student-Newman-Keuls test at $P < 0.05$ was used to compare mean quantities of ipsdienol produced by males between the four localities. Coefficients of correlation between quantity and chirality of ipsdienol were determined for each locality and adjusted for degrees of freedom. The Minitab Statistical Package (Statistics Department, The Pennsylvania State University, University Park, Pennsylvania 16802) was used for Student-Newman-Keuls test and the calculations of coefficients of correlation.

RESULTS

Quantity of Ipsdienol. The mean quantities of ipsdienol per male varied between populations of *I. pini* (Table 1), probably due to environmental factors and differences in vigor. Males from southeastern BC were quick to bore into logs and produced copious amounts of frass, while beetles from New York were the least vigorous of all the populations with respect to rates of boring and

TABLE 1. QUANTITIES AND CHIRALITIES OF IPSIDIENOL PRODUCED BY INDIVIDUAL MALE *Ips pini* (SAY) FROM 4 LOCALITIES IN NORTH AMERICA.

Locality	Quantity of ipsdienol (ng)			Chirality of ipsdienol (S)-(+):(R)-(-)			Correlations between quantity and chirality of ipsdienol ^c

feeding. Geographic variation in brood host could have affected the ability of adult males to produce ipsdienol in lodgepole pine. New York beetles were bred in red pine, in contrast to beetles from the other three localities which were bred in lodgepole. Lodgepole used as a brood host could also vary significantly between localities. Beetles from southeastern BC were bred in logs of lodgepole pine with thicker phloem than logs used for beetles from southwestern BC.

Intrapopulation variation in the quantity of ipsdienol produced by individual males was found in all four populations (Figure 2A–D), with coefficients of variation ranging from 26.4 to 80.5% (Table 1). The high coefficient of variation for the New York population may be a consequence of the change from red pine, as a brood host, to lodgepole pine for pheromone production. Most males contained low quantities of pheromone and relatively few contained large amounts. The frequency distributions are similar to those for the production of *trans*-verbenol (*trans*-4,6,6-trimethylbicyclo[3.1.1]hept-3-en-2-ol) by female *Dendroctonus ponderosae* Hopk. (Borden et al., 1986) and *cis*-verbenol and 2-methyl-3-buten-2-ol by male *I. typographus* (L.) (Birgersson et al., 1984; Schlyter et al., 1985).

Chirality of Ipsdienol. Variation in the chirality of ipsdienol was very evident between populations (Figure 2E–H). Males from California and southeastern BC produced primarily (*R*)-(–)-ipsdienol with mean (*S*)-(+) : (*R*)-(–) ratios of 9 : 91 and 11 : 89, respectively (Table 1). As expected, males from New York produced primarily (*S*)-(+) -ipsdienol with a mean (*S*)-(+) : (*R*)-(–) ratio of 57 : 43. However, the mean chiralities for all three of the above populations differ significantly (*t* tests, $P < 0.001$) from the previously published (*S*)-(+) : (*R*)-(–) ratios of 0 : 100 for California (Birch et al., 1980) and Idaho (similar to southwestern BC) (Plummer et al., 1976), and 65 : 35 for New York beetles (Lanier et al., 1980).

When the mean chiralities of ipsdienol in the same three populations were estimated from our pooled data (Table 1), the estimates did agree with the published estimates (*t* tests, $P > 0.05$). The bias in the estimator using pooled data is due to weak but significant correlations between the quantities and chiralities of ipsdienol in individual males (Table 1). However, the correlations are not consistent between the populations and change in magnitude and sign. Although ratio estimates on pooled samples are biased estimates of the true population means, they do reflect the overall chirality of ipsdienol produced by several hundred males on a single tree or log. The possibility exists that individuals attracted by the pooled pheromone from a large group of males may be favored differentially, by natural selection, over individuals attracted to the pheromone produced by an average male. Both methods of estimating chirality are valid but must be clearly stated and interpretation of the data related to the appropriate level of selection.

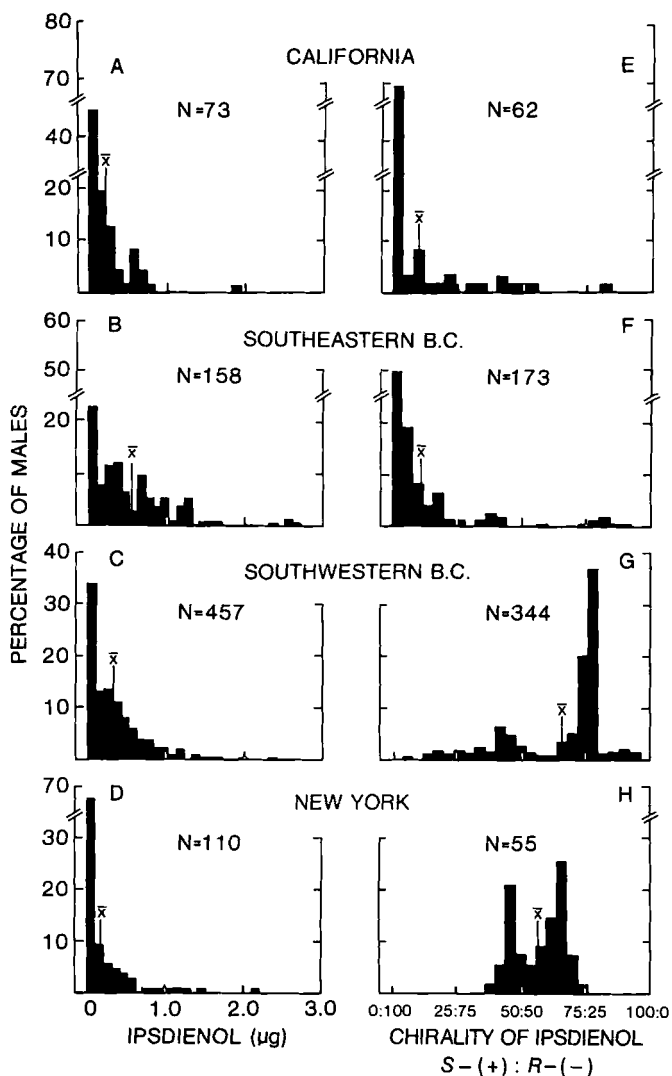

FIG. 2. Frequency distributions of the quantities (A-D) and the chiralities (E-H) of the aggregation pheromone, ipdienol, produced by male pine engravers, *Ips pini* (Say). Means are denoted by \bar{X} .

The population from southwestern BC (Figure 2G) is remarkably different from the other two western populations (Figure 2E, F). Males in this population produced primarily (*S*)-(+)-ipsdienol with a mean (*S*)-(+):(R)-(-) ratio of 66:34 (Table 1). This population negates previous generalizations that western populations of *I. pini* are homogeneous with respect to the chirality of their aggregation pheromone. Of the four populations studied, this is the only population in which there is no correlation between quantities and chiralities of ipsdienol in individual males (Table 1). Both mean and pooled estimators of chirality yielded the same result.

Intrapopulation variation in the chirality of ipsdienol was found in all four populations (Figure 2E-H) with coefficients of variation ranging from 13.2% to 33.2% (Table 1). Variation in the modalities of the four distributions of the chirality of ipsdienol is also apparent. The distributions for the populations from California and southeastern BC have long tails but are strongly centered around an (*S*)-(+):(R)-(-) ratio between 5:95 and 15:85, with only one mode in each. Bimodality is evident in the New York population, with both modes almost equal in size. In the population from southwestern BC, the modes are distinctly different in size with the major mode between 75:25 and 80:20 (*S*)-(+):(R)-(-). Both New York and southwestern BC populations have modes between 40:60 and 45:55 (*S*)-(+):(R)-(-). The earlier estimates from pooled samples (Stewart, 1975; Plummer et al., 1976; Birch et al., 1980; Lanier et al., 1980) failed to disclose these striking differences between individuals in the same population as well as the bimodality in some populations.

DISCUSSION

In bark beetles, a pheromone message should be a reliable indicator of either host quality or the genetic quality of the sender. This message should not be subject to chance variation or noise. In *I. pini*, we found that there is substantial variation in both quantity and chirality of ipsdienol. Most of the variation in quantity can probably be attributed to variation in vigor and environmental factors, such as brood host and levels of precursors in the host tissue. Production of the pheromone, *cis*-verbenol, by male *I. paraconfusus* increased directly with the concentration of vapors of the precursor, (-)- α -pinene (Byers, 1981). In *I. typographus*, over 80% of the variation in quantities of *cis*-verbenol, *trans*-verbenol, and myrtenol were explained by the variation in the amounts of α -pinene in the host (Birgersson et al., 1984). In addition, the quantity of pheromone in the hindgut may vary over time in the same individual. The rates of ingestion and defecation may not be constant.

The major factors responsible for the variation in chirality of ipsdienol are not the same as those responsible for the variation in quantity. No more than

25% of the variation in chirality of ipsdienol in any population was explained by the variation in the quantity of ipsdienol (all $r^2 < 0.25$). In southwestern BC less than 1% of the variation in the chirality of ipsdienol was explained by the variation in quantity of ipsdienol ($r^2 < 0.01$). Since both enantiomers are produced from the same achiral precursor, myrcene (Hughes, 1974; Byers et al., 1979; Renwick and Dickens, 1979; Hendry et al., 1980; Byers, 1981; Fish et al., 1984), it seems unlikely that environmental factors should significantly affect the chirality of ipsdienol, certainly not to the extent seen in the quantity of ipsdienol. Variation in enzymatic composition due to genetic variation is the most probable source of the variation in chirality.

Our data are consistent with the hypothesis that the production of ipsdienol of a specific chirality by an individual male *I. pini* is a quantitative genetic trait. We are currently trying to quantify the variation in behavioral responses associated with ipsdienol. We plan to determine the heritability of both the production of and the responses to chiral ipsdienol in individual beetles. To date, heritability of pheromone quality has been clearly estimated only for the pink bollworm, *Pectinophora gossypiella* (Saunders). Collins and Cardé (1985) found that the heritability of the sex pheromone blend of the *Z,E* and *Z,Z* isomers of 7,11-hexadecadienyl acetate, produced by female *P. gossypiella* from a laboratory strain was 0.34. The variation of the chirality of ipsdienol in *I. pini* (Table 1) is more than that of the *E:Z* ratio of the sex pheromone in *P. gossypiella* ($CV = 5.3\%$). Assuming that there is a large heritable component to the variation in ipsdienol chirality, then such high levels of variation should facilitate microevolutionary changes in relatively short periods of time, possibly giving rise to further geographic variation in *I. pini*.

In addition, bimodality in the populations from New York and southwestern BC suggests that distinct groups exist within populations and that disruptive selection may be occurring in these areas. The modes may separate further and possibly result in behavioral isolation and subsequent speciation. Alternatively, bimodality may be stable in these populations, representing mixed evolutionary stable strategies (Smith, 1982) in which individuals from both modes have equal fitness, on average.

Knowledge of the variation and heritability in the use of pheromones should help predict the consequences of artificial selection pressures such as mass trapping. Bark beetles are major economic pests of forestry (Furniss and Carolin, 1980), and pheromones are gaining acceptance as pest management tools. If pheromones are used to mass trap *I. pini*, would "resistance" to pheromone baits occur? Lanier et al. (1972) suggested that some populations of *I. pini* are already resistant to a single pheromone blend. Since the levels of variation of ipsdienol chirality were high in all four populations of *I. pini* (Table 1), we hypothesize that resistance to a pheromone blend could develop within a population as well. The development of resistance has been shown in laboratory

colonies of the khapra beetle, *Trogoderma granarium* Everts. After 18 generations of selection for nonresponse by males, there was a 74% reduction in mean response by males to the natural pheromone produced by female beetles (Rahalkar et al., 1985). The possibility exists that populations of bark beetles, such as *I. pini*, subjected to repeated use of pheromone-based trapping programs using a fixed pheromone blend, could develop resistance by shifting to another pheromone blend (Lanier et al., 1972; Lanier and Burkholder, 1974).

Competition for Pheromone Channels of Communication. An understanding of the mechanisms of any behavior must go along with an understanding of the functional value of that behavior. With respect to any insect using pheromones, we need to ask why a pheromone blend exists as well as how. Selection should favor individuals that use a communication system, such as pheromones, that minimizes the expenditure of energy and time (Matthews and Matthews, 1978). The pheromone blends used by different insect species can be called pheromone channels of communication (Cardé and Baker, 1984). Each channel is comprised of a cluster of points in an n -dimensional space. Each axis, in this space, is an array of quantities of a single and unique semiochemical. The coordinates of each point represent one possible pheromone blend that has a probability, greater than zero, of successfully communicating the pheromone message. The density of points varies within the cluster. The highest density is located centrally and represents the optimal pheromone blend for communication. In tortricid moths, the dimensions of the pheromone channels consist of a variety of 12- and 14-carbon-chain-length acetates, aldehydes, and alcohols, and their isomers when double bonds are present along the carbon chain (Cardé and Baker, 1984).

Bark beetles use pheromones to transmit information about location to conspecifics, usually to facilitate mating or feeding. In British Columbia, 82 scolytid species have been found either on or in lodgepole pine; at least 56 species breed in lodgepole pine (Bright, 1976; S.L. Wood, 1982; Evans, 1983). Although most of these species have not been investigated for the use of pheromones, the ubiquitousness of pheromone communication in the Scolytidae (Klassen et al., 1982) suggests that such communication should occur in many of the 56 species breeding in lodgepole pine. The number of potential competitors for pheromone channels of communication just among bark beetles is very high. In addition, there are insects in 10 other orders that are known to use pheromone communication (Klassen et al., 1982), many of which have representatives in stands of lodgepole pine (Furniss and Carolin, 1980). If the number of channels, particularly those with the best physiochemical traits for communication, is limited, then competition for pheromone channels should occur, particularly if the channels also differ in quality as a communication system.

If competition does occur, then three major predictions can be made.

Firstly, sympatric species of bark beetles should use separate and distinct pheromone channels in order to minimize competition for a resource or to maintain species specificity in mating (D.L. Wood, 1970; Lanier and Burkholder, 1974; Cardé and Baker, 1984; West-Eberhard, 1984). In California, the pheromone channel for *I. pini* is comprised primarily of (*R*)-(-)-ipsdienol (Birch et al., 1980; Plummer et al., 1976) (Figure 2E). The channel for the sympatric species, *I. paraconfusus*, is a blend of (*S*)-(+)-ipsdienol, (*S*)-*cis*-verbenol and (*S*)-(-)-ipenol (Silverstein et al., 1966a,b; D.L. Wood et al., 1967, 1968).

Secondly, if competition is structuring the use of pheromones, then the channels should not only be distinct, they should also be widely separated (Matthews and Matthews, 1978; Cardé and Baker, 1984). Widely separated signals (i.e., signals with high signal-to-noise ratios) minimize the possibility of making a costly mistake. The cost may involve loss of time or energy or may be a higher risk of predation because of greater exposure time before finding a host or mate.

In California *I. pini* and *I. paraconfusus* seem to have separated their channels almost maximally with respect to the chirality of ipsdienol and with respect to the presence of ipenol (Light and Birch, 1977). *I. pini* produces primarily (*R*)-(-)-ipsdienol (Plummer et al., 1976) (Figure 2E) and response is inhibited by ipsdienol when the percentage of the (*S*)-(+)-enantiomer is greater than 5% (Birch et al., 1980). Most male *I. paraconfusus* produce ipsdienol with a chiral ratio probably between 90:10 (Silverstein and Young, 1976) and 95:5 (*S*)-(+):(*R*)-(-) (Stewart, 1975). Response of *I. paraconfusus* to ipsdienol is inhibited when the chirality is predominantly (*R*)-(-) (Light and Birch, 1977; Birch et al., 1980). *I. paraconfusus* also uses (*S*)-(-)-ipenol as part of its pheromone channel (Silverstein et al., 1966a,b; D.L. Wood et al., 1967, 1968). (*S*)-(-)-Ipsenol inhibits response of *I. pini* to (*R*)-(-)-ipsdienol (Birch and Wood, 1975; Birch and Light, 1977; Birch et al., 1977).

Lastly, one should expect geographic variation in the specificity and separation of pheromone channels due to geographic differences in competition pressures (Cardé and Baker, 1984). Competition pressure should increase with either an increase in the absolute number of scolytid species or an increase in the number of superior competitors. In areas where the pressure is lower, the channels should be either different or broader. In California *I. pini* is sympatric with *I. paraconfusus* and uses primarily (*R*)-(-)-ipsdienol (Birch et al., 1980) (Figure 2E). In New York where *I. paraconfusus* is absent (S.L. Wood, 1982), *I. pini* produces ipsdienol with (*S*)-(+):(*R*)-(-) ratios close to 50:50 (Figure 2H). Furthermore, the variation in chiral ratios is greater in the New York population than in the population from California (Table 1).

These three predictions are fairly straightforward; however, not all of our evidence appears to support them. For example, separation of all channels does not seem maximal. In 15 species of *Ips* studied to date, males in 14 species

produce ipsdienol and males in 10 produce ipsenol (Vité et al., 1972; Lanier and Burkholder, 1974; Francke et al., 1980; Borden, 1982; D.L. Wood, 1982). Three species of *Pityokteines* use ipsenol and two use ipsdienol (Harring, 1978). Ipsdienol is produced by males in four species of *Dendroctonus* following exposure to myrcene vapors (Hughes, 1973; Renwick et al., 1976; Byers, 1982; Hunt et al., 1986). One possibility is that physiochemical constraints limit the dimensions of pheromone channels to very few compounds, such as ipsenol and ipsdienol (Silverstein, 1977; Cardé and Baker, 1984). Another possibility is that parsimony of semiochemicals is beneficial (Blum, 1970, 1977). One compound may serve as a pheromone in various ways, or as an allomone or a kairomone, depending on the context in which it is used. The advantage may be a saving in production or receptor hardware without giving up the potential for a diversity of messages (Matthews and Matthews, 1978).

Another area of uncertainty regarding our predictions is that existing geographic differences are not all easily explained, nor do differences necessarily exist when they should, according to our predictions. *I. pini* is sympatric with *D. brevicomis* and *D. ponderosae* in both southwestern and southeastern BC (S.L. Wood, 1982), yet populations of *I. pini* from these two regions produce ipsdienol with different chiral ratios (Figure 2F, G). *I. paraconfusus* is not found in Canada (Bright, 1976), but the distribution of chiral ratios for *I. pini* is not much different between southeastern BC and California (Figure 2E, F). It is possible that some of the geographic variation may be a product of colonization of *I. pini* from different refugia following the last Ice Age.

Clearly, there is a need for more baseline information on the use of semiochemicals by all competing species in a given habitat before the selection pressures can be elucidated. An understanding of the population genetics in the use of pheromones should facilitate the testing of quantitative predictions about the various selection pressures affecting pheromone production and response and elucidate the importance of competition in structuring communities of bark and ambrosia beetles (Sturgeon and Mitton, 1982). Our data on the variation of pheromone production in *I. pini* constitute only one step towards understanding the mechanism structuring pheromone channels of communication. The hypothesis that competition is the major driving force in the structuring of pheromone channels in communities of bark beetles is still the most supportable, but the effects of competition may be dampened by benefits of parsimony of semiochemicals, in which many species share certain semiochemicals for differing reasons (Blum, 1970, 1977).

Acknowledgments—We thank G.N. Lanier and D.L. Wood for their continual support and encouragement. G.N. Lanier and S. Seybold kindly supplied beetles from New York and California, respectively. E.K. Czyzewska resolved both enantiomers of ipsdienol, and G.G.S. King provided assistance with gas chromatography. The research was supported by an H.R. MacMillan Family Fund Fellowship to the senior author and by the Natural Sciences and Engineering Research Council, Canada, Operating Grants A3881, A3785, and A0851; and Strategic Grant G1039.

FUSARIC ACID
A Secondary Fungal Metabolite that Synergizes Toxicity of
Cooccurring Host Allelochemicals to the Corn Earworm,
Heliothis zea (Lepidoptera)¹

P.F. DOWD

*Northern Regional Research Center
Agricultural Research Service
U.S. Department of Agriculture
Peoria, Illinois 61604*

(Received August 3, 1987; accepted November 13, 1987)

Abstract—The ability of naturally occurring levels of the *Fusarium* spp. fungal metabolite fusaric acid to synergize the toxicity of the allelochemicals gossypol, a saponin, and 6-methoxy-2-benzoxazolinone to larvae of *Heliothis zea* (Boddie) was tested. Levels of fusaric acid comparable to those found near the fungus increased mortality of *H. zea* to gossypol, the saponin, and 6-methoxy-2-benzoxazolinone, and decreased the development rate of surviving larvae exposed to gossypol and 6-methoxy-2-benzoxazolinone. Some effect was also noted for levels of fusaric acid found generally distributed throughout infected plants. The chemical properties of fusaric acid suggest that it synergizes the toxicity of the allelochemicals by inhibiting oxidative enzymes responsible for detoxification. Production of the biosynthetically simple fusaric acid may be a fungal strategy for conserving resources as compared to those fungi that produce biosynthetically complex toxins of their own.

Key Words—Fusaric acid, corn earworm, *Heliothis zea*, Lepidoptera, Noctuidae, saponin, gossypol, 6-methoxy-2-benzoxazolinone, synergism, allelochemical, mycotoxin.

¹The mention of firm names or trade products does not imply that they are endorsed or recommended by the U.S. Department of Agriculture over other firms or similar products not mentioned.

INTRODUCTION

Many secondary plant metabolites are thought to act as defensive chemicals to protect the plant from herbivores. Fungi also produce a variety of toxic chemicals that are thought to play a defensive role (Wicklow, 1984). Plants may contain additional chemicals that are thought to act as synergists of the cooccurring allelochemicals (Berenbaum, 1985); such synergism has been demonstrated in some instances (Berenbaum and Neal, 1985). These synergistic chemicals appear to act by inhibiting the enzymes responsible for detoxification of the allelochemicals by the herbivores (Berenbaum and Neal, 1985). Fungi also appear to possess secondary chemicals that can act as synergists of mycotoxins, again presumably by inhibiting enzymes responsible for detoxification (Dowd, 1988).

The fungal secondary metabolite fusaric acid is produced by many species of *Fusarium*, some of which also produce trichothecene mycotoxins (Marasas et al., 1984), which are toxic to insects (Wright et al., 1982). Other species of *Fusarium* (i.e., *Fusarium moniliforme*) do not produce mycotoxins that are toxic to insects (Marasas et al., 1984). Although fusaric acid is thought to be involved in the pathogenic process (Davis, 1969), this involvement has been disputed (Kuo and Scheffer, 1964). However, fusaric acid is known to inhibit metal-containing oxidative enzymes (Jain, 1982), which are similar in structure to the unspecific monooxygenases (EC 1.14.14.1; I.U.B., 1984) that are thought to be widely involved in the metabolism of xenobiotics by insects (Brattsten, 1979). This information suggests that fusaric acid may be able to act as a synergist of allelochemicals that may already be present in the host. Since both *Fusarium* spp. (Booth, 1971) and *Heliothis zea* (Boddie) (Metcalf et al., 1962) may compete for the same hosts (such as legumes, cotton, and maize), allelochemicals from these hosts were selected for testing in combination with fusaric acid at naturally occurring levels.

METHODS AND MATERIALS

Insects. Neonate larvae of *H. zea* were used for all assays. They were obtained from a laboratory colony reared on pinto bean-based diet (Dowd, 1987) at $27 \pm 1^\circ\text{C}$, $40 \pm 10\%$ relative humidity, and a 14 : 10 light-dark photoperiod.

Chemicals. The three test chemicals, gossypol, a saponin, and 6-methoxy-2-benzoxazolinone (MBOA) were obtained from Sigma Chemical Co., (St. Louis, Missouri), while fusaric acid was obtained from Aldrich Chemical Co. The saponin was from *Gypsophila* root (Sigma Chemical Co., personal communication) and is presumably related to the gypsoside reported from *Gypso-*

phila pacifica root (Kochetkov et al., 1963). All other chemicals were of reagent grade.

Diet Preparation. The pinto bean-based diet was prepared and added in 5-ml quantities to test tubes. The test tubes were held at 60°C until chemicals were incorporated to prevent solidification of the diet. The three allelochemicals were added in 125 μ l of acetone or water to the liquid diet to give a final concentration of 250 ppm, levels which are similar to naturally occurring levels (gossypol, Hedin et al., 1973; MBOA and derivatives, Manuwoto and Scriber, 1982; saponins, Applebaum and Birk, 1979). Fusaric acid was added in 125 μ l of water so that the final concentration approximated that found throughout infected plants (25 ppm, Gaumann, 1957), or a level that would be expected in the proximity of the fungus (250 ppm, J.D. Miller, personal communication). The chemicals were incorporated into the diets by blending vigorously with a vortex mixer for 20 sec. Preliminary observations with colored solutions of both water and acetone indicated uniform incorporation by this method. The diets were dispensed into culture plates and allowed to cool to room temperature. To remove the potentially toxic acetone, the diets were placed in a fume hood for ca. 20 min until slight darkening occurred. All diets were treated in the same way. The diets were cut into approximately equal sections, and each section was placed into a well of a 24-well immunoassay plate. A single neonate *H. zea* larvae was added to each well. To prevent desiccation of the diet, the plate was covered by a sheet of parafilm, a sheet of cardboard, and the plastic cover. The cover was secured by two rubber bands, and groups of plates were placed in two polyethylene bags held closely by rubber bands. The plates were held under the same conditions used to rear the insects. Mortality was checked at two, four, and seven days, and the surviving larvae were weighed after seven days. Each chemical set was tested on a total of 40 larvae. Mortalities were tested for synergistic interactions by log likelihood ratio tests using Yate's correction for small sample sizes, and weights were tested for synergistic interactions by factorial analysis (Sokal and Rohlf, 1969).

RESULTS AND DISCUSSION

The toxicities of all of the allelochemicals were synergized when they cooccurred with fusaric acid at 250 ppm (Table 1). The toxicity of MBOA and gossypol (both mortality and weight reduction) was synergized to the greatest extent, while only the mortality due to saponin was increased by fusaric acid. A slight synergistic reduction in weight of the larvae was noted when gossypol was incorporated with the lower concentration of fusaric acid. Thus, the *Fusarium* species that produce fusaric acid should be able to synergize the toxicity of plant allelochemicals to the insects that feed on plants both organisms

TABLE I. EFFECT OF FUSARIC ACID ON TOXICITY OF PLANT ALLELOCHEMICALS TO *HELIOTHIS ZEA*

Chemical	Mortality (%)			7-day weight		
	-FA	FA1	FA10	-FA	FA-1	FA-10
Control	0.0	0.0	0.0	37.5 ± 1.5	34.2 ± 2.1	31.3 ± 2.3
MBOA	0.0	0.0	18.9*	26.7 ± 2.1	30.5 ± 2.0	14.0 ± 2.4
Gossypol	2.5	0.0	18.4*	33.0 ± 2.1	28.5 ± 2.1	15.7 ± 2.2*
Saponin	2.5	0.0	10.5	28.4 ± 2.1	25.6 ± 1.7	24.2 ± 2.1

"Mortality values are based on two studies of 20 insects each, while 7-day weights are based on the survivors of the mortality studies (means ± standard errors). MBOA = 6-methoxy-2-benzoxazolinone, FA1 = fusaric acid at 25 ppm, FA10 = fusaric acid at 250 ppm. Mortality values followed by * are significantly greater than predicted additive values at $P < 0.05$ when analyzed by the log-likelihood ratio test, with Yate's correction for small sample sizes (Sokal and Rohlf, 1969). Weights followed by * represent a significant interaction between the toxin and fusaric acid at $P < 0.05$ when analyzed by factorial analysis (Sokal and Rohlf, 1969). Some escapes of larvae occurred, and mortality values have been adjusted accordingly.

use as hosts, although the effect would be greater near the fungus, where the concentration of fusaric acid is higher. The enhanced toxicity of the chemical combinations could also deter feeding under field conditions.

Chelators such as fusaric acid bind to metal ions by contributing a free electron pair (Mellor, 1964). Chemicals that inhibit the unspecific monooxygenases by complexing with the iron atom present in these enzymes also must contribute a free electron pair (Ullrich and Duppel, 1975). Thus, the chemical properties of fusaric acid, coupled with its proven ability to inhibit other metalloxygenases (Jain, 1982), suggest that it is able to act as a synergist by inhibiting the unspecific monooxygenases of *H. zea* that are normally responsible for detoxifying the allelochemicals. For example, all three allelochemicals tested contain double bonds and other sites that can be attacked by unspecific monooxygenases from insects (Ahmad et al., 1986). Since plants also contain similar enzymes responsible for xenobiotic metabolism (Cole, 1983), fusaric acid could interact with these enzymes as well as part of the pathogenic process.

Fusaric acid is relatively simple for the *Fusarium* spp. to produce (Hill et al., 1966), in contrast to the highly toxic trichothecenes, which are produced by other species of *Fusarium* (Tamm and Breitenstein, 1980). Thus, the species of *Fusarium* that produce fusaric acid can conserve their resources by enhancing the preexisting defenses of the host plant to protect themselves, and potentially parts of the host plant remote to the infection, from consumption by insects such as *H. zea*. In cases where the infection by these *Fusarium* spp. is asymptomatic, the net protective effect could be similar to the acquired defenses pre-

viously reported for some plants that contain fungal endophytes. Although the ability of fungus-infected plants to deter insect feeding has been attributed to the induction of phytoalexin production in the infected plants (Karban et al., 1987), the toxicity of mycotoxins produced by pathogenic fungi themselves to insects has already been demonstrated in several instances (Wright et al., 1982). The present study indicates that chemicals produced by plant pathogenic fungi can also enhance the toxicity of preexisting plant defenses to insects.

PRESENCE OF LONG-CHAIN DIALKYL ETHERS IN CUTICULAR WAX OF THE AUSTRALIAN CHRYSOMELID BEETLE *Monolepta australis*¹

IAN A. SOUTHWELL and IAN A. STIFF

North Coast Agricultural Institute
Wollongbar, N.S.W. 2480, Australia

(Received August 24, 1987; accepted November 13, 1987)

Abstract—Investigation of the lipid extract of the Australian chrysomelid beetle, *Monolepta australis*, has revealed a novel homologous series of long-chain, unsaturated-saturated dialkyl ethers in the cuticular wax. Gas chromatography-mass spectrometry, proton magnetic resonance, infrared spectroscopy, and chemical degradation have shown that ethers of formula $\text{CH}_3(\text{CH}_2)_9\text{CH}=\text{CH}(\text{CH}_2)_6\text{O}(\text{CH}_2)_{12-16}\text{CH}_3$ predominate.

Key Words—*Monolepta* beetle, red-shouldered leaf beetle, *Monolepta australis*, lipid extract, unsaturated aliphatic ethers, 7-octadecenyl alkyl ethers, gas chromatography-mass spectrometry, Coleoptera, Chrysomelidae.

INTRODUCTION

Long-chain, saturated aliphatic ethers have recently been reported from the cuticular waxes of the locust *Locusta migratoria cinerascens* (Genin et al., 1987). Concurrently we isolated and orally reported a homologous series of long-chain, unsaturated-saturated dialkyl ethers from the indigenous monolepta or red-shouldered leaf beetle, *Monolepta australis* (Jacoby).

M. australis is a chrysomelid beetle approximately 6 mm in length endemic to the subtropical central coast of eastern Australia. Swarms of the beetle now attack the foliage, flowers, and fruit of avocado, macadamia, lychee, mango, stone fruit, citrus, and eucalyptus windbreak species (Murray, 1982). Present methods of monitoring and control could be greatly improved by the use of

¹Presented at the 9th National Conference of the Organic Chemistry Division of the Royal Australian Chemical Institute in Adelaide, South Australia, May 11-15, 1986.

pheromone-based traps. Consequently, the chemical constituents of *M. australis* were extracted and fractionated and are currently being purified and evaluated for pheromone-type activity. This first paper reports the isolation and identification of a novel series of long-chain ethers from the lipid fraction of the beetle.

METHODS AND MATERIALS

Swarms of *M. australis* (1.5 kg, approx. 93,000) were collected from ornamental trees at Wollongbar, New South Wales (28°50'S, 153°25'E) in summer and immediately soaked in doubly distilled petroleum spirit (bp 50–70°C May and Baker). After 20 days, the beetles were filtered, washed (2 × 1 liter, 5 min), soaked (2 liters, 14 hr), filtered, washed (2 × 1 liter) with petroleum spirit and the combined solutions concentrated to give a yellow wax (21.5 g, 1.4%). The washed beetles were then extracted at 25°C with dichloromethane and acetone for the investigation of more polar constituents. The yellow wax (21.5 g) was preabsorbed onto alumina (40 g) and subject to flash liquid chromatography on alumina (160 g).

Elution with aliquots (100 ml) of petroleum spirit (50–70°C) gave first a colorless wax fraction (IR 720 cm⁻¹) (0.62 g) followed by an orange-colored oil (3.10 g) showing some carbonyl (1740 cm⁻¹) and ether (1100–1200 cm⁻¹) infrared absorption. This second fraction was also preabsorbed on alumina (20 g) and subjected to flash chromatography on alumina (100 g). Elution with aliquots (50 ml) of light petroleum gave further wax (0.86 g) from fractions 1 and 2 and then an ether mixture (0.45 g) (IR 1118 cm⁻¹) from fractions 3–5. Thin-layer chromatography on silica gel when run in 4% ethyl acetate in petroleum spirit gave a single spot (R_f 0.47). This mixture distilled at 220°C at 0.5 mm. [¹H]NMR indicated an olefinic triplet at δ 5.35 (J 5.5 Hz, 2H), an oxymethylene triplet at δ 3.39 (J = 8.2 Hz, 4H), a methyl triplet at δ 0.88 (J = 7.0 Hz, 6H), and a prominent methylene signal at δ 1.26 (46–50 H). Signals for β -oxy and allylic methylenes were evident at δ 1.56 (4H) and δ 2.01 (4H), respectively.

Analytical gas chromatography was conducted on a Perkin Elmer Sigma 2B chromatograph using a 10-m × 0.22-mm ID, BP1-coated, fused-silica, open-tubular (FSOT) capillary column using N₂ as carrier gas. Individual runs were temperature programmed from 100°C to 300°C with no initial holding period. Percentage compositions were computed with a Perkin Elmer Sigma 10B data station, and Kovats indices were calculated with respect to straight-chain hydrocarbon standards.

Preliminary mass spectral data were obtained on an AEI MS 12 mass spectrometer at 70 eV ionizing voltage, 8000 V accelerating voltage with ion source at 200°C.

Combined gas chromatography-mass spectrometry was conducted on a Hewlett Packard MSD instrument using on-column injection into a 12-m \times 0.2-mm ID BP1 FSOT capillary column. Temperature was programmed to rise from 30°C to 220°C at 30°C/min and then to 300°C at 4°C/min.

Proton magnetic resonance spectra were recorded at 300 MHz in CDCl_3 on a Bruker CXP 300 spectrometer.

Chemical Degradation. The *M. australis* lipid ether fraction (1) (65.5 mg) in dry diethyl ether (2.0 ml) was treated with 3-chloroperbenzoic acid (46.8 mg, approx. 2 equiv.) at 25°C in the dark. After 64 hr, the solution was diluted with diethyl ether (20 ml), washed with: (1) 5% sodium bisulfite solution (5 ml), (2) 5% sodium bicarbonate solution (2 \times 5 ml), and (3) saturated sodium chloride solution (5 ml). The epoxide (5) solution was dried (Na_2SO_4) and without concentration stirred at 25°C with freshly prepared periodic acid (178 mg) (Willard, 1939). After 1 hr the mixture was diluted with diethyl ether (10 ml), washed with: (1) 10% sodium thiosulfate solution (5 ml), (2) saturated sodium chloride solution (5 ml), and dried (Na_2SO_4). Without concentration, the aldehyde mixture [6 + 7 (see Scheme 2 below)] was treated with lithium aluminium hydride (50.0 mg) and stirred. After 16 hr, excess reagent was decomposed by the dropwise addition of 10% ammonium chloride solution, dried (Na_2SO_4), filtered, and concentrated to give a colorless mixture of alcohols 8 + 9 (45.7 mg). This alcohol mixture was dissolved in dry chloroform (2.0 ml) and refluxed with excess trimethylsilyliodide (0.2 ml, 281 mg). After 1 hr, the mixture was cooled and decolorized by the dropwise addition of 10% sodium thiosulfate solution, diluted with diethyl ether, dried (Na_2SO_4), and concentrated. The resulting iodide mixture, 10 + 11 + 12, in dry diethyl ether (2.0 ml) was added to lithium aluminium hydride (103.6 mg) suspended in dry diethyl ether (1.0 ml) and stirred at 25°C. After 16 hr excess reagent was destroyed by the cautious dropwise addition of saturated ammonium chloride solution. The solution was dried (Na_2SO_4) and concentrated at 25°C to give the hydrocarbon mixture 13 + 14 + 15. All reactions were followed to completion using TLC, GLC, and IR spectroscopy. Hydrocarbon products 13, 14, and 15 were also confirmed by GC coinjection of authentic standards.

RESULTS AND DISCUSSION

The aliphatic ethers in *M. australis* comprise in excess of 2% of the total lipid fraction and in excess of 300 ppm of the entire fresh insect. Their presence in the cuticular wax layer was established by isolating the ether fraction from a brief (10 min), cold (0°C) extraction.

Identification was based on IR and NMR spectroscopy, gas chromatography (GC), and gas chromatography-mass spectrometry (GC-MS). IR absorption at 1118 cm^{-1} , when coupled with retention data from thin-layer, liquid,

and gas chromatography clearly indicated aliphatic ethers. GC indicated a mixture containing nine components, each contributing more than 1% to the total ether fraction (Figure 1). From the retention index data, the major (60%) component (Figure 1, peak 3) seemed to represent the middle member of a five-member homologous series. Traces of members of this series preceding peak 1 (Figure 1) were also evident from the GC and MS data. $[^1\text{H}]\text{NMR}$ indicated $-\text{CH}_2-\text{CH}=\text{CH}-\text{CH}_2$ ($\times 1$), $-\text{CH}_2-\text{CH}_2-\text{O}-\text{CH}_2-\text{CH}_2-$ ($\times 1$), $-\text{CH}_2-$ ($\times 23-25$) and $-\text{CH}_2-\text{CH}_3$ ($\times 2$), suggesting a long-chain ether series with formula:

GC-MS analysis defined each member of the series more specifically (Table 1). Molecular ion peaks were prominent for all except peak 6. All components gave strong fragments at m/z 250 and 281, representing fragment ions 2 and 4, resulting, respectively, from C-O and α -C-C cleavage (Scheme 1). The alternative α -C-C fragmentation was evident from prominent mass spectral peaks at $M-267$ in all members of the series except chromatographic peak 2. The alternative fragmentation in the unsaturated chain was absent. Support for this assignment is seen in the typical $\text{C}_n\text{H}_{2n+1}$, $\text{C}_n\text{H}_{2n-1}$, and $\text{C}_n\text{H}_{2n-2}$ decomposition fragments in the mass spectra. Thus an octadecenyl structure for the unsaturated half of the ether is established. The position of the double bond in the

SCHEME 1.

TABLE 1. MASS SPECTRAL INTENSITIES OF SIGNIFICANT PEAKS (MOL WT IN PARENTHESES) FOR MAIN HOMOLOGOUS SERIES MEMBERS OF ALIPHATIC ETHER LIPIDS OF *Monolepta australis*

m/z	Peak No.				
	1	2	3	6	8
M+	10.7 (450)	4.4 (464)	6.5 (478)	< 1.0 (492)	5.4 (506)
281	5.3	5.2	3.3	10.8	6.8
250	40.6	10.5	16.2	19.5	25.4
M-267	9.9 (183)	< 1.0 (197)	6.6 (211)	6.3 (225)	5.4 (239)

chain was, as anticipated (Hallgren et al., 1959; Ryhage and Stenhagen, 1963; McCloskey and McClelland, 1965), not available from the mass spectral data. The M-267 and subsequent C_nH_{2n+1} fragments indicated that chromatographic peaks 1, 2, 3, 6, and 8 were, respectively, tridecyl ($c = 12$), tetradecyl ($c = 13$), pentadecyl ($c = 14$), hexadecyl ($c = 15$), and heptadecyl ($c = 16$) octadecenyl ether.

Of the numerous methods available for the location of double bonds in unsaturated fatty acid or other alkene derivatives (e.g., McCloskey and McClelland, 1965; Capella and Zorzut, 1968; Niehus and Ryhage, 1968; Abley et al., 1970; Dommès et al., 1976; Blomquist et al., 1980; Suzuki et al., 1981), a chemical degradation method best suited to monoenic series (Privett, 1966) was used. In our method (Scheme 2), the mixture of ethers (**1**) was epoxidized with 3-chloroperbenzoic acid, and the resulting epoxide series (**5**) was cleaved with periodic acid to give aldehydes **6** and **7**. Without separation, this mixture was reduced to the alcohols **8** and **9** and treated with the ether-cleaving agent trimethylsilyliodide (Jung and Lyster, 1977; Olah, 1979) to give iodides **10**, **11**, and **12**. These were reduced to their respective alkanes undecane **13**, heptane **14**, and a tridecane-heptadecane mixture (**15**) fixing the double bond in the 7-position of the octadecenyl chain in contrast with the 9-position as would be expected from an ether derived from the more usual oleyl derivatives. The retention times and indices of the major starting material and products are shown in Table 2. The saturated side of the ether linkage of the homologous series was confirmed by using GC to follow the presence of the five-membered homologous series through the entire reaction sequence (Scheme 2). In each reaction mixture, the presence of C_{13} to C_{17} alkyl chains in an approximate ratio of 13:3:60:2:3 was clearly observed, giving finally tridecane, tetradecane, pentadecane, hexadecane, and heptadecane (**15**). This then confirmed the structure of the homologous series as **1** where $a = 9$, $b = 6$, and $c = 12-16$, and GC peaks 1, 2, 3, 6, and 8 (Figure 1) were assigned, respectively, to tridecyl, tetradecyl, pentadecyl, hexadecyl, and heptadecyl 7-octadecenyl ether. Peaks 4, 5, 7, and 9 and their mass spectra are less definitive and await further identification.

CONCLUSION

This occurrence of long-chain, alkenyl-alkyl ethers in the lipid extract of *Monolepta australis* is, to our knowledge, the first reported occurrence of such compounds in either their natural or synthetic state. Recent reviews of insect lipids have not included any such ethers (Blomquist and Jackson, 1979; Hadley, 1981; Lockey, 1985; Lockey, 1986, personal communication). As far as we know, this then becomes the second formally reported occurrence of long-chain

SCHEME 2.

ethers in a biological environment. Although the isomeric 11-octadecenoxy radical is known in insects (vaccenyl acetate: Brieger and Butterworth, 1970; Meinwald et al., 1966; Jackson et al; 1981), the occurrence of 7-octadecenoxy derivatives in any biological environment is not known to us. On the other hand, the alkyl chain with predominantly odd numbers of carbon atoms is common and similar to half the *Locusta migratoria* lipid ethers, with carbon numbers C₁₃, C₁₅, and C₁₇ predominating (Genin et al., 1987).

Speculation about the taxonomic significance of the occurrence of these

lipid ethers in insects as diverse as *M. australis* and *L. migratoria* would be premature until the lipid fractions of other insects have been investigated. Indeed, the advances in GC-MS technology that have facilitated the identification of these components may show that lipid ethers are widespread among insects. Speculation concerning biogenetic pathways is also awaiting the outcome of further investigation, although the presence of unsaturated chains with an even number of carbon atoms in *M. australis* and saturated chains with an even number of carbon atoms in *L. migratoria* indicates an extra step in the pathway of one species. Although our biological assays showed no pheromone activity for these ethers when tested on *M. australis*, their possible role in the physiology and/or behavior of *M. australis* also awaits the outcome of further investigation.

Acknowledgments—We are indebted to Mr. Noel Davies, Central Science Laboratory, University of Tasmania, for GC-MS analysis, and Dr. J.J. Brophy, Department of Chemistry, University of NSW, for spectral determinations and useful discussion.

(Received August 3, 1987; accepted November 16, 1987)

Abstract—(Z)-11-Eicosenyl acetate (Z11-20:Ac) was identified as the aggregation pheromone in *Drosophila malerkotliana*. The pheromone (200–300 ng/fly) was isolated from hexane extracts of the ejaculatory bulb of sexually mature male flies. Males released very little, if any, Z11-20:Ac to the food at any time. During mating there was a transfer of ca. 100 ng of Z11-20:Ac to the female's reproductive tract. The mated female fly transferred the Z11-20:Ac to the surrounding surfaces in just a few hours after mating. In bioassay in a wind-tunnel olfactometer, Z11-20:Ac was not attractive alone, but was synergistic with fermenting food or with acetone. Although *D. malerkotliana* has no (Z)-11-octadecenyl acetate (Z11-18:Ac), it was as attracted to Z11-18:Ac as to an equal quantity of Z11-20:Ac. *D. melanogaster* and *D. simulans*, however, responded to the Z11-18:Ac that they produced and did not respond to Z11-20:Ac.

Key Words—*Drosophila malerkotliana*, Diptera, Drosophilidae, aggregation pheromone, (Z)-11-eicosenyl acetate.

INTRODUCTION

Aggregation pheromones have been demonstrated in 11 species of *Drosophila*: *D. virilis* (Bartelt and Jackson, 1984; Bartelt et al., 1985a); *D. a. americana*, *D. a. texana*, *D. novamexicana*, and *D. lummei* (Bartelt et al., 1986); *D. borealis* and *D. littoralis* (Bartelt et al., 1988); *D. hydei* (Moats et al., 1987); *D. melanogaster* (Bartelt et al., 1985b), *D. simulans* (Schaner et al., 1987); and *D. mulleri* (Bartelt et al., 1989). In many of the closely related species, the

aggregation pheromones had the same or similar chemical structures, but between some species groups there appeared to be considerable differences in the chemical structures of the aggregation pheromones.

D. melanogaster and *D. simulans* of the *melanogaster* species group and *melanogaster* subgroup both used (*Z*)-11-octadecenyl acetate (Z11-18:Ac, *cis*-vaccenyl acetate, cVA) as their aggregation pheromone (Bartelt et al., 1985b; Schaner et al., 1987). No other fly-derived coattractant was necessary, but food or food-derived odors were synergistic with the Z11-18:Ac. In *D. melanogaster* and *D. simulans* the Z11-18:Ac was stored in the ejaculatory bulb of sexually mature male flies, transferred to females during mating, and released by mated female flies to the food media within hours after mating.

D. malerkotliana was chosen for aggregation pheromone investigation because it was in the *melanogaster* group but in the *ananassae* subgroup, and we could test whether male-derived compound(s) could function as an aggregation pheromone and whether the compound(s) were the same or differed from the Z11-18:Ac used by members of the *melanogaster* subgroup.

METHODS AND MATERIALS

Flies, Extraction, Chromatography, and Bioassay. *D. malerkotliana malerkotliana* (strain 14024-0391.0) was obtained from the National *Drosophila* Species Resource Center at Bowling Green, Ohio. It was originally collected at Mysore, India. *D. melanogaster* (wild type, Canton S strain) and *D. simulans* (strain 14021-0251.0) were as reported previously (Bartelt et al., 1985b; Schaner et al., 1987). Details of rearing, extraction, chromatography, and bioassay of the flies have been described previously (Bartelt and Jackson, 1984, Bartelt et al., 1985b; Schaner et al., 1987). Briefly, flies were separated by sex at 0-6 hr old and extracted at 6-7 days of age by soaking the flies in hexane at room temperature for 24 hr. Fractionation of the hexane extracts was on open columns of silicic acid eluted with hexane, 10% ether in hexane, 50% ether in hexane, and 10% methanol in methylene chloride. The 10% ether in hexane fraction was purified further by preparative gas chromatography (GC).

Bioassays were conducted in a wind-tunnel olfactometer containing ca. 1000 (0- to 2-day-old) flies that had been without food and water for approximately 2 hr. An extract, fraction, synthetic compound, or control solvent was applied to a filter paper strip inserted around the lip of the glass vial. Each bioassay test consisted of placing two differently treated vials, to be compared, into the olfactometer for 3 min. The bioassay data was transformed to the log ($x + 1$) scale before analysis to stabilize variance and analysis was done by the method of Yates' (1940).

Identification. Identification of the pheromone was done by comparing

retention times on GC, by gas chromatography-mass spectrometry (GC-MS) of the pheromone on a VG-MM16 GC-MS and by GC-MS of the dimethyl disulfide reaction product (Nichols et al., 1986). The determination of the isomer of the double-bond was done by comparison of synthetic Z11-20:Ac (Sigma Chemical, St. Louis, Missouri) and the fly-derived 11-20:Ac on a 30-m DB-1 capillary GC column with a temperature program of 140-220°C with a 4-min initial hold and a rate of 4°C/min. With this method the Z and E isomers of 9-18:Ac had previously been separated by a difference in the retention times of 0.11 min. The isomer of the fly-derived 11-20:Ac was determined by a coinjection of this compound with the synthetic Z11-20:Ac.

Production of Z11-20:Ac with Age. Since Z11-18:Ac was found in the ejaculatory bulb in *D. melanogaster* (Brieger and Butterworth, 1970), the ejaculatory bulbs of *D. malerkotliana* were removed, extracted with hexane, and analyzed by GC. To remove ejaculatory bulbs, the males were placed in the freezer for approximately 10 min and then placed, ventral side up, on a cork board with a dissecting pin through the thorax. The genital region was teased loose with forceps and placed in a drop of *Drosophila* Ringer's solution (Ephrussi and Beadle, 1936). Using two dissecting pins, the ejaculatory bulb was removed from the genital region under 45× magnification. Two sets of five bulbs for age groups from 2 hr to 8 days were placed in 1-ml conical vials that contained 500 ng nonadecane as an internal standard in 10 µl of hexane. The bulbs were smashed with the head of a dissecting pin and the hexane extract analyzed by GC. For comparison, we also analyzed hexane extracts of whole flies (3 × 20 flies) at each age. The flies were extracted at room temperature for 24 hr, and the hexane extracts were fractionated on open silicic acid columns described above. Z11-20:Ac was quantified by GC relative to the internal standard, Z11-16:Ac.

Transfer during Mating. The transfer of Z11-20:Ac from males to females and the subsequent release of the ester from the females was investigated. Virgin females (6-7 days old) were mated with virgin males of the same age. Immediately after completion of mating, the females were either extracted or placed into an empty 8-ml vial for 6 hr and then extracted. The vials were rinsed with 1 ml of hexane to recover any Z11-20:Ac that had been released. The mated males were treated in a similar fashion and, as controls, comparable sets of extracts were obtained from males and females that had not been allowed to mate. Each extract represented 10 fly equivalents and there were four replications per extract. The Z11-20:Ac in the extracts was quantitated by GC relative to an internal standard.

Female Reproductive Tract Removal. The female reproductive tract was also removed and the extract analyzed for the presence of Z11-20:Ac. Immediately upon completion of mating, the female was placed in the freezer for approximately 10 min. Viewed through a 10× dissecting scope, the female was

held ventral side up with forceps pressed laterally on the abdomen. The ovipositor was clasped with another pair of forceps and teased until the reproductive tract, without the ovaries, was pulled away from the fly. Two sets of five reproductive tracts were placed in conical vials with an internal standard and the extract analyzed as described previously for the ejaculatory bulbs. The hexane extract of female flies minus the reproductive tracts were analyzed by GC after they were soaked in hexane for 1 hr.

RESULTS AND DISCUSSION

Demonstration, Purification, and Identification of Pheromone. Initial attempts to demonstrate an aggregation pheromone in *D. malerkotliana* were patterned after previous experiments with *D. melanogaster* (Bartelt et al., 1985b) and *D. simulans* (Schaner et al., 1987). The hexane extract of mature males, with a food synergist, was clearly active in bioassay, and the hexane extract of mature females was, with food, also about twice as attractive as the food (Table 1, A). The male fly hexane fraction alone was not attractive. Although food was an effective coattractant, we felt that using a synergist that was less attractive might clarify pheromonal effects and make pheromone identification more rapid. Acetone was the preferred coattractant, which led to the identification of the aggregation pheromone in *D. melanogaster* (Bartelt et al., 1985b). Compounds such as acetone and ethyl acetate are known to be produced by molds and yeasts (Fogleman, 1982) and could well influence the behavior of the flies under natural conditions. When acetone was used as a coattractant in *D. malerkotliana* (Table 1, B), the male fly hexane extract plus acetone was about 10 times more attractive than the female fly hexane extract plus acetone. Acetone alone was not attractive. Both sexes of flies respond nearly equally to the hexane extracts of mature male flies. Since the attractive nature of the male fly extracts was much greater than that of female fly extracts, this paper will concentrate on the male fly-derived pheromone. After fractionation of the hexane extract of male flies on silicic acid, only the 10% ether-hexane fraction was active. The remaining fractions from the extract of male flies were not different in activity from the control solvent. By capillary GC, the male 10% ether-hexane fraction was predominantly one component. GC-MS of the major peak in the male 10% ether-hexane fraction indicated that the component was an acetate ester of a monounsaturated alcohol with 20 carbons. GC-MS of the dimethyl disulfide-treated fraction revealed that the double bond in the 20-carbon alcohol of the ester was at 11. Synthetic (Z)-11-eicosenyl acetate (abbreviated Z11-20:Ac) compared identically with the fly-derived component in GC and GC-MS. GC comparison of the fly-derived compound and the synthetic Z11-20:Ac identified the fly-derived 11-20:Ac as the Z isomer. Z11-20:Ac was present in the

Synthetic Z11-20:Ac + food	73.3c
Fermenting food	5.3b
Z11-20:Ac	1.2a
Hexane control	0.7a

^aAll fly-derived fractions and their synthetic counterparts were used at 1 fly equivalent per test (220 ng of Z11-20:Ac).

^bIn any experiment, means followed by the same letter were not significantly different at the 5% level (LSD).

^cFermenting food is Formula 4-24 Instant *Drosophila* Medium (Carolina Biological Supply, Burlington, North Carolina) to which active yeast has been added at least 24 hr previous to testing.

^dAcetone, 10 μ l, was added to the filter paper with the extracts.

hexane extract of mature male flies at a concentration of ca. 200 ng/fly, and there was no indication of the presence of Z11-18:Ac in the extract. This is the first report of Z11-20:Ac as an aggregation pheromone in *Drosophila*.

The male hexane extract, 10% ether-hexane fraction, synthetic Z11-20:Ac, and male-derived Z11-20:Ac were compared by bioassay (all at 220 ng Z11-20:Ac; Table 1, C). All were significantly greater than the control ($P < 0.001$). In this study, the synthetic Z11-20:Ac was significantly more attractive than the male hexane extract and male-derived Z11-20:Ac ($P < 0.05$). The 10% ether-hexane fraction was intermediate in attraction. However, Z11-20:Ac accounts for all the activity of the male hexane extract.

Synergism of Z11-20:Ac with food. Since Z11-18:Ac was synergistic with food in other *Drosophila* species (Bartelt et al., 1985b; Schaner, et al., 1987), the synthetic Z11-20:Ac was tested for synergism with food. In this bioassay there was a 14-fold synergism of synthetic Z11-20:Ac with food (Table 1, D).

Response of Flies to Z11-Acetates of 16, 18, and 20 Carbons. When synthetic Z11-20:Ac, Z11-18:Ac, and Z11-16:Ac along with acetone were compared in bioassay (Table 2), *D. malerkotliana* not only responded strongly to Z11-20:Ac but also to Z11-18:Ac, the aggregation pheromone of *D. melanogaster* and *D. simulans* (Bartelt et al., 1985b; Schaner et al., 1987). No attraction was detected toward Z11-16:Ac. In contrast, *D. simulans* and *D. melanogaster* were strongly attracted only to their own aggregation pheromone. *D. melanogaster* also preferred Z11-16:Ac significantly over controls. A similar study was conducted with the *virilis* group (Bartelt and Jackson, 1984; Bartelt et al., 1986; 1988), where both the number of carbons in the alkene pheromone, as well as the position and stereochemistry of the double-bond were investigated. In *D. virilis* the aggregation pheromone was (Z)-10-heneicosene, but in *D. a. americana*, *D. a. texana*, and *D. novamexicana* it was (Z)-9-heneicosene. *D. lummei*, *D. borealis*, and *D. littoralis* possessed no heneicosenes, but curiously all three responded well to (Z)-9-heneicosene, and *D. lummei* and *D. littoralis* responded to (Z)-10-heneicosene. Therefore, it is not uncommon for a species to be attracted to the aggregation pheromone of a closely related species even though it does not possess it.

TABLE 2. ESTER SPECIFICITY^a FOR *D. malerkotliana*, *D. melanogaster*, AND *D. simulans*

Ester ^b	Bioassay flies (N = 18) ^c		
	Mal	Mel	Sim
Z11-16:Ac	4a	23b	9a
Z11-18:Ac	157b	100c	100b
Z11-20:Ac	100b	6a	-8a

^aEster specificity is described by an index of activity: $I = (\text{test ester} - \text{control}) / (\text{standard ester} - \text{control}) \times 100$, where the three means were taken from a balanced incomplete block experiment, the "standard ester" is the male-specific ester for that species. The index compares esters on a percent scale, corrected for controls.

^bEsters used at 800 ng for *D. melanogaster* (mel) and *D. simulans* (Sim) and 220 ng for *D. malerkotliana* (Mal) (~1 fly eq), 10 μ l of acetone was used as coattractant.

^cWithin each column, indices of activity followed by the same letter were not significantly different at the 0.05 level and those followed by the letter "a" were not significantly different from the control. Comparisons of means between columns are not meaningful because the experiments were conducted on different days with different species of flies.

Dose Response to Z11-20:Ac. Increasing amounts of Z11-20:Ac lead to greater relative aggregation activity but the dose response was essentially log-linear (Figure 1, $r = 0.9503$, $P < 0.05$). The dose of 200 ng is approximately the hexane extractable amount from the mature male fly, so 200 ng was given the relative value of 100. A 20-ng dose was only 2.8% as attractive as the 200-ng dose and may be near the minimum quantity of Z11-20:Ac that these flies can detect. Between 200 ng and 2000 ng there was a nearly twofold increase in response. The increase in response to 20,000 ng of Z11-20:Ac was slightly over twofold and showed no sign of reaching a plateau.

Location, Production, and Transfer of Z11-20:Ac. The ejaculatory bulbs from mature (6 days old) male *D. malerkotliana* were analyzed and found to contain approximately 270 ng/fly of Z11-20:Ac. The rest of the fly contained 22 ± 5 ng/fly of Z11-20:Ac, so most of the aggregation pheromone is located in the ejaculatory bulb of mature male flies. During the first 24 hr after eclosion the male flies have very little Z11-20:Ac, during the next 48 hr there is a rapid

FIG. 1. Activity of *D. malerkotliana* towards different doses of Z11-20:Ac. Relative activities are 100% for the 200-ng dose of Z11-20:Ac (~ 1 fly eq) and 0% for the controls ($N = 8$). In each case, 10 μ l of acetone was used as a co-attractant. Spacing along the x axis is logarithmic.

increase in Z11-20:Ac. Over the next few days there is a gradual increase to a plateau of about 300 ng/fly (Figure 2). The assays of ejaculatory bulb contents are somewhat higher than the 24-hr hexane extracts of whole flies. The same trend in Z11-20:Ac production is observed from the whole fly and ejaculatory bulb extracts. Although the whole fly extracts are much easier to perform, they do not provide a reliable quantitative estimation.

Virgin females possess no Z11-20:Ac. However, males transferred over half of the Z11-20:Ac they possessed to the female during mating. Immediately after mating about 85% of the male-transferred Z11-20:Ac is in the female's reproductive tract. Within 6 hr after mating, the female transferred approximately one third of the Z11-20:Ac into an empty vial. Males, virgin or mated, emitted no Z11-20:Ac into an empty vial that they occupied for 6 hr. Therefore, as in *D. melanogaster* and *D. simulans* (Bartelt et al., 1985b; Schaner et al., 1987), it is the mated female that emits the pheromone into the environment although it is male-produced.

In summary, sexually mature *D. malerkotliana* males produce Z11-20:Ac,

FIG. 2. Amounts of Z11-20:Ac extracted from virgin males *D. malerkotliana* of various ages. Solid circles indicate the Z11-20:Ac from a 24-hr hexane soak of the whole fly, and open circles indicate the Z11-20:Ac within the hexane extract of ejaculatory bulbs. The bars indicate standard deviation.

which is stored in the ejaculatory bulb, transferred to the reproductive tract of females during mating, and released from the females to the surrounding surfaces after mating. Along with food odors, Z11-20:Ac acts as an aggregation pheromone to attract *D. malerkotliana* of either sex to food and potential mating sites.

PHENOLIC BIOSYNTHESIS, LEAF DAMAGE, AND INSECT HERBIVORY IN BIRCH (*Betula pendula*)

S.E. HARTLEY and R.D. FIRN

Department of Biology
University of York
Heslington, York. YO1 5DD, England

(Received August 5, 1987; accepted November 16, 1987)

Abstract—The effect of both caterpillar herbivory and artificial damage on phenylalanine ammonia lyase (PAL) activity of birch foliage was measured, using an intact cell assay. After artificial damage there was a small increase in PAL activity in damaged leaves but no change in adjacent undamaged ones. Insect grazing produced a larger increase in PAL activity, and the enzyme activity was also increased in adjacent undamaged leaves. Artificial damage increased the phenolic levels of the damaged leaves. Insect grazing caused a larger, longer-lasting increase in phenolic levels and also elevated phenolic levels in undamaged leaves. The possible role of these wound-induced biochemical changes in birch is discussed.

Key Words—Phenolics, PAL activation, insect herbivory, plant resistance, *Betula pendula*, *Apocheima pilosaria*, Lepidoptera, geometridae.

INTRODUCTION

Wound-induced reductions in leaf palatability to insect herbivores have been reported in *Betula pubescens* Ehrh. (Haukioja and Niemela, 1977) and *Betula pendula* Roth (Wratten et al., 1984). Such changes can occur in damaged and adjacent undamaged leaves, and the responses may be part of a wound-induced antiherbivore defense mechanism (Haukioja and Hahnimaki, 1985; Bergelson et al., 1986; Lawton, 1987). It has been suggested that the decrease in palatability is a result of an increase in the concentration of phenolic compounds known to occur in damaged leaves (Niemela et al., 1979; Wratten et al., 1984; Bergelson et al., 1986). However, palatability to insect herbivores does not always correspond well with phenolic levels (Hartley and Lawton, 1987).

Changes in the phenolic metabolism of damaged birch leaves were investigated at a more fundamental level than has hitherto been possible. Simple phenolic compounds are derived from the shikimate pathway (Conn, 1981). Consequently, by studying the activity of enzymes in this pathway in damaged and undamaged leaves, it may be possible to define, in more precise biochemical terms, the way in which plants respond to insect attack. Differences in the chemical changes induced by artificial damage as opposed to insect-grazing can thus be characterized in terms of enzyme activity, which could be important in assessing whether the changes are likely to be involved in defense against herbivores or pathogens, or simply in repair of wounded tissues. For example, an increase in phenolic compounds in undamaged leaves due to increased enzyme activity in these undamaged tissues, rather than due to transport of phenolics from the site of damage, may indicate a mechanism which is not purely tissue repair.

In the present study, the activity of phenylalanine ammonia lyase (PAL) was investigated, together with the concentration of phenolic compounds, in damaged and undamaged leaves from both insect-grazed and artificially damaged trees. Evidence is presented that PAL activity is stimulated by insect attack on birch, even in undamaged leaves, and the response differs from that caused by artificial damage to the leaves.

METHODS AND MATERIALS

PAL Measurements. On July 8, 1986, 12 birch trees, each about 2 m high, were chosen in the University of York tree nursery, where they had been transplanted several years earlier. Twenty-five *Apocheima pilosaria* larvae (Lepidoptera, Geometridae) were caged on three branches on each of four of the trees and allowed to graze overnight, by which time 10–15% of the leaf area of the caged branches had been removed. A further four trees had the same amount and distribution of damage inflicted on three of their branches with a pair of scissors (sterilized in alcohol to reduce the risk of fungal infection). The four remaining trees were left as controls. Fifteen leaves were collected from each tree at the start of the experiment, and from the control trees one, three, five, and seven days later, while 15 damaged, and 15 undamaged leaves immediately adjacent to damaged ones, were removed from the treatment trees on the same days. The undamaged leaves included some at the same node, some above, and some below the damaged leaves, as available.

Enzyme activity was measured immediately after the leaves were collected using a modified version of the intact cell assay of Amrhein et al. (1976). This "in vivo" method for assaying PAL was chosen in preference to an in vitro enzyme assay in order to obviate possible differences in enzyme recovery from the damaged and adjacent leaves.

One half gram (wet weight) of 6-mm leaf disks was incubated with 5 μCi L-phenyl(2,3- ^3H)alanine (Amersham; specific activity 43 Ci/mmol) in 2 ml of 0.15 M potassium phosphate buffer (pH 5.5) for 3 hr. The labeled phenylalanine was absorbed by the cells, equilibrated with the endogenous substrate, and the action of PAL liberated labeled N^3H_2 . This lost ^3H to tissue water to produce ^3HOH , a virtually irreversible process due to the considerable dilution of the tracer, so recycling is very unlikely.

The ^3HOH was recovered from the medium by sublimation by a procedure similar to that of Mitra et al. (1975). Twenty microliters of incubation medium, together with a drop of $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$, was placed on a filter paper disk that was positioned on a pin stuck into the lid of a scintillation vial. Vials were placed in a piece of polystyrene such that the bottom of the vial was in liquid nitrogen while the top was heated with an infrared lamp until the CoCl_2 solution turned blue. The pin and filter paper were then removed, and the ^3H activity of the ice formed was determined using a scintillation counter (LKB), following the addition of 2 ml of Optiphase MP (Fisons) to the vial. The PAL activity was measured as counts per minute (cpm) per 0.5 g fresh weight per 3 hr, after correction for background and control counts. (Control counts are the values recorded from incubations using boiled leaves with no PAL activity.) The results were expressed as mean percentage changes over the activity at the start of the experiment (to reduce the effect of the between-tree variation in initial PAL activities) and were analyzed in a one-way ANOVA, tested separately each day. The specific treatments responsible for producing significant effects in the ANOVA were identified using nominated comparison *t* tests.

The leaf material remaining after the enzyme assay had been carried out was freeze-dried and assayed for total phenolics as described below.

Field Experiment. On May 15, 1985, at Skipwith Common, 10 miles south of York (grid ref. SE 664379), 15 small *Betula pendula* trees (each about 1.5 m high) were selected, sprayed with insecticide (Sprayday, Pan Britannica Industries Ltd.; contains resmethrin and pyrethrum), and all natural damage marked with a small dot of paint on leaf petioles. Three weeks later, the leaves of five of the trees were left undamaged, five were cut with scissors, and five were grazed by *Apocheima pilosaria*, as in the experiment described above.

Twenty leaves were collected from each of the control trees at the start of the experiment, and one, three, five, and eight days subsequently. In the case of the other treatments, 20 leaves were collected before damage, but on days one, three, five, and eight, 20 undamaged leaves from a branch adjacent to a treatment branch were collected, in addition to the 20 damaged leaves. Leaves were placed on ice immediately after collection, returned to the laboratory within 1 hr, and stored at -20°C .

Chemical Analyses. All chemical analysis (except for PAL activity) was carried out on freeze-dried material. Total phenolics were measured using the Folin-Denis method as described in Bergelson et al. (1986), except that 20 mg

of leaf powder was extracted and after centrifugation the volume was adjusted to 10 ml, and then aliquots equivalent to 0.1 and 0.2 mg of leaf-powder were used in the analysis. Protein precipitation was measured using the Bradford method (Bradford, 1976). The procedure was similar to that of Martin and Martin (1982), but slightly modified as described in Hartley and Lawton (1987). The protein-precipitating properties were expressed as the coefficients (slopes) of regression lines fitted to the graphs of milligrams (dry weight) of leaf extracted vs. grams of BSA precipitated (see Martin and Martin 1982 for further details).

RESULTS

PAL activity was measured in control leaves and in damaged and adjacent undamaged leaves from insect and artificially damaged trees (Figure 1). The activity was found to vary somewhat on a daily basis (Figure 1), with large between-tree differences; hence, although there was a significant effect of treatment on activity on both days 1 ($F = 10.64$, $df = 4, 15$, $P = 0.0003$) and 5 ($F = 5.46$, $df = 4, 14$, $P = 0.0084$), there were no significant effects on day 3, or on day 7, by which time activities in all treatments had decreased to near control levels. In the artificially damaged trees, cut leaves had significantly higher PAL activities than leaves from the control trees one day after damage

FIG. 1. The percentage change in PAL activity in damaged and adjacent undamaged birch leaves over the seven days subsequent to damage, and in control trees. Each value is the mean of measurements of four trees (the same four trees for each sample).

($t = 4.03$, $df = 6$, $P < 0.01$), but by day 5 the activity had declined, and there was no longer a significant difference. At no time did the undamaged leaves from these trees show a significant increase in their PAL activity. On the insect-grazed trees, PAL activities were greatly increased, with the damaged leaves having higher activities than both control and cut leaves ($t = 6.64$, $df = 6$, $P < 0.001$, and $t = 5.09$, $df = 6$, $P < 0.02$, respectively). On these trees, the adjacent undamaged leaves had the largest increase in activity of all on day 1 ($t = 3.39$, $df = 3.2$; $P < 0.05$), but this was short-lived; by day 3 there was no significant difference from the controls. However, the elevation of PAL activity in the insect-damaged leaves was more persistent and, unlike the artificially damaged leaves, the level of activity five days after damage was still significantly higher than in control trees ($t = 2.58$, $df = 6$, $P < 0.05$).

Samples of the leaves used for enzyme assays were analyzed for total phenolics, and the phenolic levels were found to be elevated in the leaves with increased PAL activity (Figure 2). However, since the amount of phenolics accumulating depends on factors such as the rate of phenolic degradation (which was not measured), and because of the imprecise method used to estimate phenolics, PAL activity and phenolic levels do not correspond exactly. The control leaves and the undamaged leaves on cut trees showed no significant changes in phenolic content, but the cut leaves, and both the damaged and undamaged leaves on the insect-grazed trees all had increased amounts of phenolic compounds (paired t tests, $t = 6.64$, $df = 3$, $P < 0.01$; $t = 13.6$, $df = 3$, $P < 0.001$; and $t = 5.79$; $df = 3$; $P < 0.02$, respectively). Insect attack produced a larger increase in phenolics than artificial damage (two sample t test, $t = 3.52$, $df = 6$, $P < 0.02$).

FIG. 2. The effect of leaf damage on phenolic levels in birch leaves. The values are the means of measurements made on four trees, and the same trees were used on each sampling day. The percentage change in phenolic content after seven days is also shown.

The results of the 1985 field experiment also show chemical differences between insect and artificially damaged leaves. The level of phenolic compounds in control trees (Figure 3) did not differ significantly over an eight-day experimental period (paired *t* test, $t = 1.36$, $df = 4$; $P > 0.1$). In trees with leaves that were cut with scissors (Figure 3), the phenolic levels increased in the damaged leaves (paired *t* test, $t = 5.91$, $df = 4$, $P < 0.01$), but not in undamaged ones from an adjacent branch (paired *t* test, $t = 1.33$, $df = 4$, $P > 0.1$). Again, in insect-grazed leaves, the phenolics rose to higher levels than in cut leaves (two sample *t* test on eight-day values: $t = 3.14$, $df = 8$, $P < 0.02$), and undamaged leaves on the neighboring branch to the grazing also had slightly increased phenolic levels after eight days (paired *t* test, $t = 2.99$; $df = 4$, $P < 0.05$). However, the change in the undamaged foliage was less than in the 1986 experiment, perhaps because the undamaged leaves in that experiment were immediately adjacent to the insect-damaged ones.

The protein-precipitating abilities of extracts of artificially damaged, insect-grazed, and control trees were also made. However, these measurements failed to reveal any significant increases in protein-precipitating ability resulting from insect grazing, although a slight, but statistically significant, increase was recorded in artificially damaged leaves (data not shown). These results suggested that assays of protein-precipitation ability and Folin-Denis measurements were not equivalent as indicators of insect-induced chemical changes, possibly because they were measures of different kinds of chemicals, and no further protein precipitation measurements were made.

FIG. 3. The effect of leaf damage on the phenolic content of birch leaves. Each value is the mean of measurements of five trees, each tree sampled on the days shown. The percentage change in phenolic content after eight days is also shown.

DISCUSSION

It is clear from previous work (e.g., Wratten et al., 1984), and from the results presented here, that phenolic concentrations are elevated in insect-grazed birch leaves and are also higher in undamaged leaves adjacent to those which were damaged. The finding that PAL activity is also increased in such leaves suggests that these elevated levels of phenolic compounds are the consequence of increased *in situ* biosynthetic activity, rather than mobilization of phenolics from the site of damage. The response to artificial damage was different, however, with smaller changes both in terms of PAL activity and phenolic concentration, and no changes occurring in adjacent undamaged leaves. It has been suggested that such a response, in which insect damage is a more effective inducer of chemical changes than artificial damage and in which synthesis of phenolics occurs at sites remote from damage, represents an active and specific defense, rather than a wound-repair mechanism (e.g., Haukioja and Neuvonen, 1985). However, a number of questions require further investigation before the role of these wound-induced changes is clear.

First, is the increased PAL activity the result of enzyme activation or enzyme synthesis? A number of stimuli, such as light, chemicals, and fungal infection, can increase PAL activity in plants, and it has been shown in some cases that increased synthesis of mRNA coding for PAL is associated with this increase in PAL activity (e.g., Dixon, 1986).

The second question is, what is the nature of the transmitted factor that passes from insect-grazed leaves to adjacent leaves, resulting in elevated PAL activity? Transmittable factors have been reported in plants following damage (Ryan, 1974), and, interestingly, "elicitors" capable of inducing PAL in plant cells are found in some fungal-plant interactions (Hahlbrock et al., 1981).

The fact that increased PAL activity is a common response of plants subject to fungal attack raises a third question: what is the relevance of the increased PAL activity found in the insect-grazed leaves? Although insect grazing had a more marked effect on PAL activity than an equivalent amount of damage inflicted with scissors, this could simply reflect the contamination of caterpillar mouthparts with fungal spores (Shain and Hillis, 1972). A second possibility is that grazing produces a more severe stress on the leaf by a sustained period of physical damage.

The function of the damage-induced increase in phenolic levels is also hard to assess since the responses of leaves to damage might include the induction of many chemicals, some of which may be primarily antifungal and some of which might play a role in defense against insects. Phenolics have certainly been associated with resistance to fungal attack (Werder and Kern, 1985), as well as antiherbivore effects (Bennett, 1965; Todd et al., 1971; Roehrig and

Capinera, 1983), as has leaf damage (Karban et al., 1987). However, the role of phenolics is not entirely clear, as both insects (Bernays, 1981) and fungi (Shaw, 1985) can remain unaffected, and birch-feeding insects often seem indifferent to the chemical changes induced in damaged leaves (Lawton, 1987; Hartley and Lawton, 1987; but see Bergelson et al., 1986; Wratten et al., 1984).

Although the ecological significance of the reported changes in PAL activity remains to be established, this study has clearly shown a differential response of birch trees to insect and artificial damage and that insect attack produces marked changes in phenolic biosynthesis in both grazed and adjacent undamaged leaves. Furthermore, these results suggest that the *in vivo* PAL assay may prove to be a sensitive measure of insect and mechanical damage-induced chemical changes. Further studies are needed on other plant species and on the mechanism of increasing PAL activity to progress towards a better understanding of the way in which plants detect and respond to insect attack.

Abstract—A series of flavones with widely varying degrees of substitution was fed to neonate larvae of the navel orangeworm. Growth of navel orangeworm larvae is inhibited by 5-methoxy flavones and flavone itself; 5-hydroxy flavones do not inhibit growth. Host resistance of citrus fruit to attack by the navel orangeworm might be due to the 5-methoxy flavones that occur in the peels.

Key Words—*Amyelois transitella*, Lepidoptera, Pyralidae, citrus, flavones, growth inhibition, host-plant resistance, navel orangeworm, nobiletin, orange, tangeretin.

INTRODUCTION

The navel orangeworm (NOW), *Amyelois transitella* (Walker), was first described as a pest in the Salt River Valley of Arizona in 1922 where it was found on navel oranges (Mote, 1922). By 1925 the NOW had been found on grapefruit, lemons, many varieties of oranges, figs, pears, and rotting pomegranates. Although fear of spread to the California citrus groves was prevalent, scientific studies indicated that the worm was a secondary pest, occurring mainly on split or damaged fruit (Wade, 1961). It is unlikely that the peels of citrus fruit act as a physical barrier to the NOW since the larvae have mandibles strong enough to bore through nut shells (Michelbacher and Davis, 1961). It is more likely that chemical constituents in the peels act as feeding deterrents or growth inhibitors making the fruit unattractive to NOW larvae.

The peels of citrus fruits are typically rich in pectins, essential oils, caro-

tenoid pigments and flavones, especially flavanone glycosides and highly methoxylated flavone aglycones (Horowitz and Gentili, 1977). Flavones (Figure 1) exhibit a wide range of biological activities on insects, including growth inhibition (Chan et al., 1978; Elliger et al., 1980). The three fully methoxylated flavones, nobiletin (Table 1, 4) tangeretin (Table 1, 6), and heptamethoxyflavone (Table 1, 3), all occur in the peels of tangerines, oranges, and grapefruit. The corresponding 5-hydroxy analogs (Table 1, 10–12) are found in tangerines and oranges (Tatum and Berry, 1972). These six citrus flavones and 14 additional flavones with a wide variety of substitution patterns were tested in an artificial diet for growth inhibiting properties on NOW larvae. The resulting relationship between structure and growth inhibition of NOW larvae is presented here.

METHODS AND MATERIALS

Flavones 1 and 7 (Table 1) were purchased (Sigma Chemical Co., St. Louis, Missouri) and recrystallized. Flavones 13–20 were available from earlier studies of the American desert shrub *Gutierrezia microcephala* (Roitman and James, 1985). Flavones 3, 4, and 6 were isolated from tangerine peel by extraction, solvent partition, and repetitive silicic acid chromatography. Flavones 2 and 9 were kindly provided by Dr. L. Jurd of these laboratories. Flavone 8 was prepared from benzoyl chloride and 2',6'-dihydroxyacetophenone, and flavone 5 was prepared by methylation of 8 with dimethyl sulfate in acetone solution in the presence of potassium carbonate. Flavones 10 and 11 were prepared by demethylation (ethanolic hydrochloric acid) of tangeretin (6) and nobiletin (4), respectively. Flavone 12 was prepared by partial methylation (methyl iodide, acetone, potassium carbonate, reflux 3 hr) of flavone 19. All flavones were chromatographically homogeneous, and their physical and spectroscopic properties agreed well with values reported in the literature.

For each concentration of flavone tested (1, 2, 4, and 8 mmol/kg wet diet),

^cNot active, ED₅₀ greater than 8 mmol flavone/kg diet.

two identical 6-g portions of artificial diet were prepared as described below. Scarcity of material precluded preparation of duplicate diets for flavones 15, 17, 18, and 20. An acetone or methanol solution of the flavone to be tested was stirred into 50 mg of alpha-cellulose. After the solvent had evaporated, 4.6 g of codling moth diet (Bioserve) was added and mixed to homogeneity with 1.4 ml of a 2% aqueous solution of agar. Control diets were prepared in an identical manner including alpha-cellulose but no flavone. Each diet was allowed to solidify, then cut into 10 equal pieces, each of which was placed in a 2-ml disposable conical cup (Markson Science). Two neonate larvae were then placed in each cup. After 14 days at 26°C (day length 14 hr), the largest larva in each cup was weighed, providing a total of 2 × 10 larval weights for each concentration of each flavone. For each flavone concentration a mean larval weight was calculated and compared to the control mean larval weight to give the percent growth inhibition. For flavones that showed growth inhibiting activity, four

additional concentrations bracketing the ED_{50} (the concentration at which larval growth is inhibited by 50%) were tested to confirm its value. Standard deviations of 15–20% from the mean weight were noted for larvae of control weight size; larger standard deviations were noted for the smaller weights of the stunted larvae. Flavones whose ED_{50} was greater than 8 mmol/kg wet weight diet were considered inactive.

RESULTS AND DISCUSSION

Flavones with either no substitution or methoxy substitution at the 5-position are active as growth inhibitors of NOW larvae (Figure 2 and Table 1), whereas flavones with hydroxy substitution at the 5-position are inactive. Since a 5-hydroxy substituent is strongly hydrogen bonded to the 4-carbonyl oxygen, growth inhibition is correlated with the availability of this carbonyl. Flavone (1), with no substituents to form chemical or steric interactions with the 4-carbonyl, proved to be the most potent growth inhibitor of the flavones tested. The presence of a single hydroxy substituent at the 5 position (compound 8) completely destroys growth inhibition, whereas 5-methoxyflavone (5) remains active as a growth inhibitor, albeit less active than flavone.

Quercetin (7) is active as a growth inhibitor for several insects (Chan et al., 1978), but is inactive against the NOW, as expected due to its 5-hydroxy

FIG. 2. Activity of flavones on navel orangeworm.

substitution. Fully methoxylated quercetin (2) is active, whereas the analog with 5-hydroxy substitution (9) is inactive. The same pattern is observed for the citrus flavones. The permethoxylated flavones nobiletin (4), tangeretin (6), and heptamethoxyflavone (3) all show growth-inhibiting activity, whereas their 5-hydroxy analogs (11, 10, and 12, respectively) are inactive. Other 5-hydroxy flavones (13–20) exhibiting diverse hydroxy and methoxy substitution patterns all proved to be inactive as growth inhibitors.

Although this structure–activity relationship does not shed light upon the mechanism of growth inhibition, it is consistent with the theory that secondary plant products are factors in host-plant resistance. Flavones with a 5-methoxy substitution, to which the NOW is sensitive, are relatively rare in nature; permethoxylated flavones are seldom found outside the citrus family. For example, of the 11 flavones found in orange peel, nine are fully methoxylated and only two have a free 5-hydroxyl. The predominant orange peel permethoxylated flavones are nobiletin (4) and sinensetin (5,6,7,3',4'-pentamethoxyflavone), with moderate amounts of tangeretin (6), heptamethoxyflavone (3), tetra-*O*-methylscutellarein (5,6,7,4'-tetramethoxyflavone), and 3,5,6,7,3',4'-hexamethoxyflavone; in addition small amounts of 5,7,8,4'-tetramethoxyflavone, 3,5,7,8,3',4'-hexamethoxyflavone, and 5,7,8,3',4'-pentamethoxyflavone have been found (Tatum and Berry, 1972). As all of these flavones contain a 5-methoxy group, it may be assumed they would be active as growth inhibitors of NOW. Nobiletin, which has an ED_{50} of 440 ppm, has been found in orange peel at levels of 190 ppm (Park et al., 1983) to 800 ppm (Sastry et al., 1964). Orange juice, on the other hand, contains nobiletin at approximately 1 ppm, with the five major permethoxylated flavones present at a total of 4–6 ppm (Veldhuis et al., 1970). It appears that these permethoxylated flavones play a major role in protecting undamaged oranges from NOW attack. The larvae do not penetrate the peel, which contains flavone levels high enough to cause significant growth inhibition, but rather gain access through splits or fungally damaged spots in the peel and then eat the pulp, which contains very much lower levels of the permethoxylated flavones.

Despite its name, the NOW is currently not a citrus pest, having found more suitable hosts, especially walnuts and almonds. The chemical defense provided by the citrus peel appears to be a factor preventing the NOW from becoming a more prominent pest in citrus. Compounds such as the permethoxylated flavones, which play a role in the host-plant resistance of citrus to the NOW, may be useful in protecting more vulnerable crops. The techniques of genetic engineering may allow development of walnut and almond husks containing protective levels of 5-methoxy flavones.

Acknowledgments—We thank Dr. Rodney Fries, USDA Horticultural Crop Research Laboratory, Fresno, California, for providing regular supplies of navel orangeworm eggs.

Abstract—A bioassay of eight synthetic anal sac compounds showed that ferrets were most attracted to a mixture of 2-propylthietane and *trans*- and *cis*-2,3-dimethylthietane. This mixture was used as the basis of an artificial scent lure. Trapping experiments used two traps at each site. In comparing trap success, ferrets chose artificial lure in preference to no odor, and chose both food baits and natural-product anal sac odor over artificial lure. However, the effectiveness of artificial lure was demonstrated by comparison between trap sites with bait-lure pairs and those with lure only. The comparison indicated that scent lures should be as effective as bait in attracting ferrets, and this was confirmed in a field program. We conclude that scent lures are valuable additions to the current techniques used in mustelid control operations, but more work is needed to increase the inherent species specificity of scent lures for mustelids and to develop a simple means of making a lure that will release odor for a long time.

Key Words—Ferret, *Mustela furo*, lure, scent, thietane, sulfur-containing compounds, anal sac secretion, wildlife management, trapping.

INTRODUCTION

Introduced mustelid species (ferrets, *Mustela furo*; stoats, *M. erminea*; weasels, *M. nivalis*) have had a significant impact as predators of native fauna in New Zealand. Native birds in Kowhai Bush, Kaikoura, lost 67% of their nests to predators, with stoats and weasels being responsible for 78% of this predation

(Moors, 1983, and personal communication). Predation has been the main reason for nesting failure of the endangered black stilt (*Himantopus novaeseelandiae*), with ferrets being one of the main predators (Pierce, 1982). Merton (1978) noted that indigenous bird life has been depleted on New Zealand offshore islands inhabited by introduced mustelids. Predation by stoats cannot be excluded from consideration of factors limiting the population of takahe, *Notornis mantelli* (Lavers and Mills, 1978; King, 1984) and North Island kokako, *Callaeas cinerea wilsoni* (King, 1984). Another mustelid problem occurs at Tairoa Head, Otago, where some royal albatross chicks, *Diomedea ephemphora*, may fall prey to ferrets (King and Moors, 1979). This predation has led to a need for effective damage control procedures that require the exploration of new mustelid control measures.

Ferrets use anal sac odors as a means of communicating sexual and individual identity (Clapperton et al., 1988). This knowledge, and the fact that various components of ferret anal sac secretions have been identified and can be synthesized (Crump, 1980a), suggested that compounds from anal sac secretions could be used as the active ingredients of ferret trap lures.

The use of synthetic scents to lure animals to control devices has the potential advantages of increasing the effectiveness, efficiency, and species specificity of a control program. These features are also of value when trapping is part of ecological research rather than a control program. In addition, inedible scent lures are advantageous in studies where the stomach contents or faeces of the captured animals are to be examined and edible bait can be confused with prey. Synthetic scent lures also have consistent chemical properties, an important feature if research is aimed at estimating population densities by monitoring numbers of visits to scent stations.

In this study we investigate the responses of ferrets to components of their anal sac secretions in a laboratory bioassay experiment, and we report field tests of the efficacy and species specificity of scent lures containing the active components.

PART I. LABORATORY BIOASSAY

Methods and Materials

We conducted four bioassay experiments, using a T maze (Clapperton et al., 1988), to determine the relative attractiveness of the components of ferret anal sac secretions. The terms "attractive" and "attractiveness" are used to describe the investigative responses of ferrets and do not imply any subjective like or dislike of the odors. Measures of attractiveness included speed of approach to the odor source, and time spent sniffing at the odor source. The compounds are shown in Figure 1 and the various combinations of compounds

FIG. 1. The eight chemical compounds used in the experiments. (1) 2-propylthietane, (2) 2,3-dimethylthietane, (3) 3-propyl-1,2-dithiolane, (4) indole, (5) quinoline, (6) 2,2-dimethylthietane, (7) 3,4-dimethyl-1,2-dithiolane, and (8) 2-pentylthietane.

tested in each experiment are listed in Table 1. The thietane and dithiolane compounds were synthesized according to Crump (1980a). The indole and quinoline were commercial products. All these pure synthetic compounds were diluted with hexane to a ratio of one part odor compound to five parts hexane. For the combinations of two odor compounds the ratio was 1:1:10. These synthetic odor solutions were kept in 1-ml Teflon-sealed glass vials, and stored at -10°C .

All trials were conducted between 8 AM and 5 PM. Only three trials were run on any one day, and each animal was tested no more than once every four days. The subject was placed in the start-box 5 min before the beginning of a trial. During this time $5\ \mu\text{l}$ of the odor solution was mixed with two drops (ca. $50\ \mu\text{l}$) of diethylene glycol succinate (DEGS), to reduce the rate of evaporation, and spread on a piece of filterpaper. This odor sample was then placed in one arm of the maze, and a blank (filterpaper plus DEGS and hexane) in the other arm. Thirty seconds elapsed before the door was raised and timing began. For each 15-min trial we recorded: (1) the animal's initial choice of odor port, (2) the time the subject took to approach within 10 cm of the odor port, and (3) the

TABLE 1. COMBINATIONS OF SYNTHETIC COMPOUNDS USED IN BIOASSAY EXPERIMENTS

Experiment	Combinations of compounds ^a					
I	1	2	3	1 + 2	1 + 3	2 + 3
II	1 + 2	4	5	1 + 2 + 4	1 + 2 + 5	Blank
III	1 + 2	6	7	1 + 2 + 6	1 + 2 + 7	6 + 7
IV	1 + 2	8	1 + 2 + 8			

^aCompounds numbered as in Figure 1.

total time spent sniffing the odor and the blank. At the end of the trial the animal was removed and the apparatus cleaned using chlorine bleach and water. At least 4 hr separated one trial from the next, allowing time for the apparatus to dry completely.

The anal sac compounds used in the four experiments (Table 1) were chosen to determine the most attractive combinations of compounds. The combination 1 + 2, which was most attractive in experiment I, was used throughout the remaining experiments. This combination served as a comparison for the attractiveness of other compounds and was also used in the thought that it might, in combination with other compounds, form the basis of an even more attractive mixture.

Each subject was tested against all the odor combinations. Experiments I–III were Latin-square designs, balanced to avoid residual effects of order of presentation of the odors. Odor/blank positions were randomized to offset right–left preferences in the maze. In experiments II and III the subjects more often investigated the right odor port first (36 right vs. 11 left in experiment II, 38 right vs. 19 left in experiment III). This did not occur in experiments I and IV (28 right vs. 28 left, 17 right vs. 11 left, respectively). In experiment IV only three odor combinations were tested.

The time data were ranked and then normalized before analysis. Analysis of variance was used to test the effects on response time of the sex of the subjects, the odor that they were tested against, and the order in which the odors were presented. Some animals in the experiments had been bred in captivity and were therefore younger and tamer than the wild-caught individuals. In each of the four experiments, we used two males and two to five females that were captive-bred. A single dummy covariate (0 or 1) was used to account for the possible effect of tameness and/or age. Some animals did not run the maze, and their responses were treated as missing data. Missing data were estimated in the analysis of variance and degrees of freedom adjusted appropriately (Rothamsted Experimental Station, 1980). The Tukey test was used to detect significant differences between levels of a factor.

Results

Experiment I. There were significant differences between the times spent sniffing at the various odors in experiment I ($F_{5,35} = 7.3$, $P < 0.0005$; Figure 2a). Males and females did not respond differently, nor was the interaction between odor and sex a significant factor, but the covariate for tameness explained a significant amount of the variation in the subjects' responses ($F_{1,7} = 13.8$, $P < 0.01$). The combination of compounds 1 and 2 was the most attractive overall and to both males and females separately. It was significantly more attractive than all the other odors except for compound 1 on its own,

FIG. 2. Subjects' responses to odors in bioassay experiment I. Data are untransformed means and standard errors ($N = 10$).

which was significantly different only from compound 3 ($P < 0.005$, Tukey; Figure 2a). In comparisons of the time spent investigating the odor port and the blank port, the ferrets spent significantly longer at the odor port with compounds 1, 2, and 1 + 2 ($P < 0.01$, $P < 0.05$, $P < 0.014$, respectively, Wilcoxon).

There were also significant differences between the subjects' speed of approach to the various odors ($F_{5,35} = 4.2$, $P < 0.005$; Figure 2b). Males and females did not, overall, show differences in speed of responses, even when the differences in tameness and/or age were accounted for, but they did respond differently to different odors ($F_{5,35} = 4.8$, $P < 0.0025$). Overall, it was again compound 1 + 2 that provided the most attractive odor, although the speed of response to this combination differed significantly only from that of compound

3 ($P < 0.025$, Tukey) and 1 + 3 ($P < 0.05$, Tukey). Males and females differed in that males responded relatively faster to compound 3 and slower to 2 + 3 than did females. The order of presentation did not affect the relative attractiveness of the odors.

Experiment II. No simple pattern of responses emerged in experiment II. There was a significant difference in the time spent sniffing the different odors ($F_{5,25} = 6.9$, $P < 0.005$), with 1 + 2 and 4 being significantly more attractive than either no odor ($P < 0.01$, Tukey) or 1 + 2 + 4 ($P < 0.025$, Tukey; Figure 3a). Males and females found different odors more attractive ($F_{5,25} = 6.6$, $P < 0.001$). For females, the addition of 5 to 1 + 2 reduced its attractiveness to less than that of no odor (but not significantly so) and 5 on its own

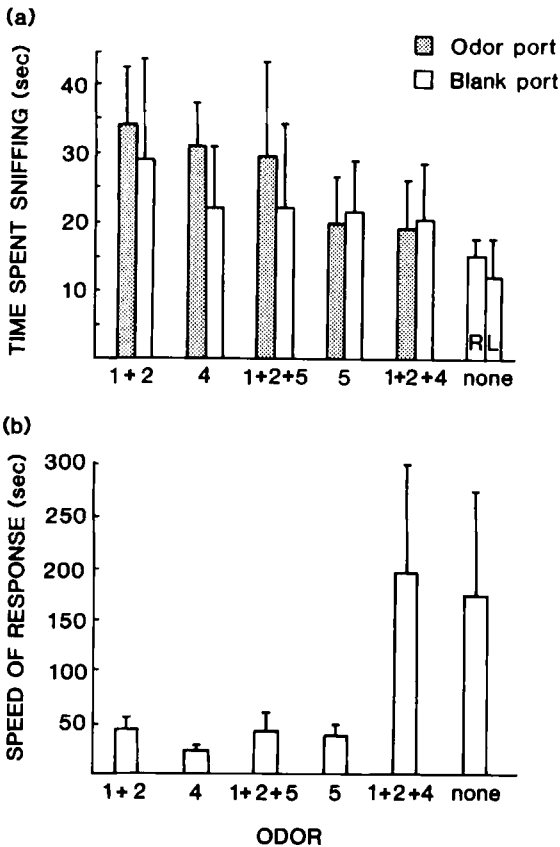

FIG. 3. Subjects' responses to odors in bioassay experiment II. Data are untransformed means and standard errors ($N = 8$). R = right odor port, L = left odor port.

was less attractive still. In males, 1 + 2 + 4 was no more attractive than no odor, and these two were significantly less attractive than 4, 1 + 2, and 5 ($P < 0.01$, $P < 0.01$, $P < 0.025$, Tukey, respectively). There was no difference in the time spent at the odor and blank ports for any of the odors tested (Figure 3a).

In terms of speed of response, females responded significantly faster than males ($F_{1,5} = 11.3$, $P < 0.025$), and there was no significant effect of tameness and/or age of the subjects. Overall, there were significant differences in the subjects' speeds of response to the various odors ($F_{5,25} = 4.7$, $P < 0.005$), due mainly to a rapid response to 4 compared to 1 + 2 + 4 ($P < 0.01$, Tukey) and the blank ($P < 0.025$, Tukey, Figure 3b). Males and females responded at different speeds depending upon the odor being tested ($F_{5,25} = 2.7$, $P < 0.05$), with the males responding relatively faster to 5 than the females did. Order of odor presentation was not an important factor determining either the time spent sniffing the odors or speed of response.

Experiment III. In experiment III the subjects spent significantly different lengths of time sniffing the different odors ($F_{5,35} = 3.2$, $P < 0.025$). The sexes did not differ significantly, nor was there a significant sex-odor interaction, but the young tame animals spent significantly longer at the odors than did the adults ($F_{1,7} = 14.0$, $P < 0.01$). The most attractive odor was again 1 + 2, but this was significantly greater than compound 6 only ($P < 0.025$, Tukey, Figure 4a). The ferrets showed no preferences for sniffing longer at the odor or the blank ports (Figure 4a), nor were there any significant differences in the speeds of response (Figure 4b). Order of presentation had no effect.

Experiment IV. In experiment IV no significant differences in attractiveness were found, either in the time spent sniffing the odors, or in speed of response (Figure 5a,b). There was a tendency for the subjects to be less attracted to compound 8 than compound 1 + 2. The subjects spent longer sniffing at the odor port with 1 + 2 compared to the blank ($P < 0.01$, Wilcoxon), but showed no preferences for odor and/or blank ports when the test odor was 8 or 1 + 2 + 8 (Figure 5a).

PART 2. FIELD TRIALS OF SCENT LURES

Methods and Materials

Live-Trapping Experiment. We carried out trapping experiments at Puke-puke Lagoon Wildlife Management Reserve, Manawatu, New Zealand, between February 1984 and June 1985, to test wild ferrets' preferences for various trap lures and baits. We used 42 Edgar live-traps (King and Edgar, 1977), 650 mm long \times 150 mm wide \times 160 mm high. They were given one coat of polyurethane varnish inside for ease of cleaning and removing odors. Synthetic lures

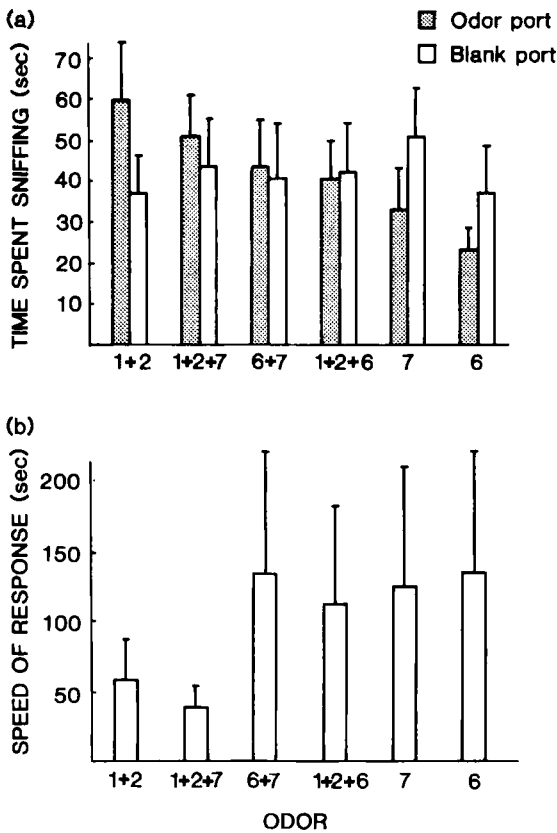

FIG. 4. Subjects' responses to odors in bioassay experiment III. Data are untransformed means and standard errors ($N = 10$).

consisted of one part odor compound to five parts hexane or pentane by volume. The diluted odor compounds were then incorporated in white petroleum jelly which made up 93% by weight of the lure. The odors tested as lures were: lure A was half 2-propylthietane and half *trans*- and *cis*-2,3-dimethylthietane; lure B contained only 2-propylthietane; lure C only indole; and lure D was a "natural" lure prepared from female anal sac extracts mixed with white petroleum jelly to produce a lure of approximately the same strength as the synthetic lures. The blank control lure consisted of 93% white petroleum jelly and 7% hexane. A smelly natural bait was made from dead laboratory mice cut open.

In the late afternoon, bait was placed directly into the traps and lures were smeared onto 40 × 40-mm galvanized iron plates, which were then put in the traps. Care was taken to avoid contaminating the next trap with the previous

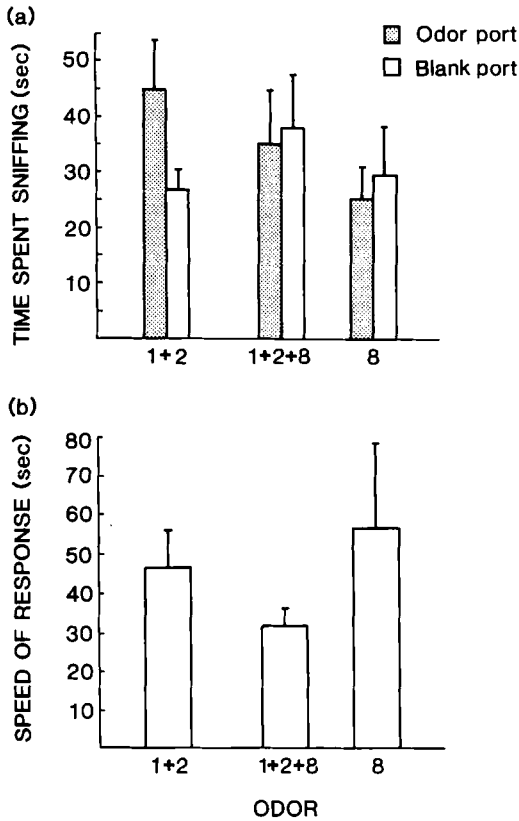

FIG. 5. Subjects' responses to odors in bioassay experiment IV. Data are untransformed means and standard errors ($N = 9$).

treatment. The traps were checked the following morning, cleaned with water and chlorine bleach, and closed. Prior to release at the same site, captured ferrets were ear-tagged, sexed, and their breeding condition noted. The trap position and treatment were also recorded. Other animals caught in the traps were identified and released.

In a preliminary trial in February 1984, 40 traps were set out singly throughout the reserve. The traps were sited on animal runways to maximize the likelihood of catching ferrets at every site. The traps were operated for eight consecutive nights. On each of the first four nights one quarter of the traps had each of the following treatments: bait plus lure A, bait only, lure A only, and clean. The traps were divided into groups of four, and treatments assigned

according to a Latin-square design. At the end of four nights all the traps were moved to new sites and the experiment repeated.

In all subsequent trials 21 trap sites were used. At each site two traps containing different treatments were set side by side. Trap sites were not changed within a trial. A trial consisted of six consecutive nights of trapping. The trap sites were divided into groups of three and the treatment pairs rotated among them. Each pair of treatments had equal exposure at each site, and the experimental design was balanced for order of presentation. From March to May 1984 treatments were renewed every day, while in subsequent trials treatments were renewed every second day, with the treatments being swapped between the traps at each site for the second night. A trap site was closed for one night if it had caught a ferret the night before. The data were analyzed using chi-square goodness-of-fit and independence tests to determine the effect on capture success of treatment, sex of the captured ferrets, time of year, freshness of treatment, and independence of these factors.

Kill-Trapping Experiment. The synthetic lure A was incorporated into the regular predator trapping program of the New Zealand Wildlife Service in the Mackenzie Basin, South Canterbury, from September 4, to October 10, 1984. Ninety-one leghold gin traps were set singly in an irregular pattern. Bait (fresh rabbit or occasionally hare or fish) was hung on a hook and lure put on a metal plate behind the trap in "blind" sets, and the plate camouflaged to prevent removal by magpies (*Gymnorhina tibicen*) and to avoid direct sun. In "walk-through" sets, the bait or lure plate was hidden underneath the trigger platform. Traps were checked and reset each morning or early in the afternoon.

Traps were treated alternately with lure and with bait. Treatments were renewed every third day and swapped between traps every third or sixth day to counterbalance location bias. The variation in numbers of animals caught relating to treatment, freshness of treatment, and species and sex of captured animals were analyzed using chi-square goodness-of-fit and independence tests.

Results

Live-Trapping Experiments. In the preliminary live-trapping experiment at Pukepuke Lagoon in February 1984, 25 ferrets were caught over the eight nights, six on bait plus lure traps, nine on bait only traps, seven on lure only, and three on clean traps. These differences in success rates are not significant.

The paired-trap design experiments yielded capture rates of 4–20 ferrets per six nights of trapping, with the same individuals being regularly caught.

Over the 325 trap nights in which bait vs. lure A trap pairs were operated, significantly more ferrets were caught on bait than on lure A ($P < 0.005$), whereas there was no significant difference between the choice of treatment in the breeding and nonbreeding seasons or between the sexes. The first-night

treatments were not significantly more successful than second-night treatments (for bait $\chi^2_1 = 0.17$, for lure $\chi^2_1 = 2.15$), and choice of treatment was independent of freshness of treatment (Table 2).

The difference in the numbers of captures on bait and lure D were not significant (Table 2). However, when comparing these results with bait vs. lure A, the trend to catching more ferrets on bait than on lure was independent of the type of lure ($\chi^2_1 = 1.60$). Only females were caught on lure D, giving a significant difference between the male and female choices ($P < 0.05$). Captures on these two treatments did not vary with season or with freshness of treatment (Table 2).

Lure D was preferred over lure A ($P < 0.05$), and choice was independent of season, sex, and freshness (Table 2). Significantly more ferrets were caught on lure A than on the blank treatment ($P < 0.025$), and again males and females had similar likelihoods of being caught on the two treatments. All four ferrets captured on the blank treatment were trapped on the second night of treatment,

χ^2_1	0.67, NS	0.22, NS		1.65, NS		0.51, NS	

NS = not significant, * $P < 0.05$, ** $P < 0.025$, *** $P < 0.005$. ? = sex unknown. Statistical comparisons are chi-square goodness-of-fit and independence tests with correction factor for small ($N < 10$) expected values (Pirie and Hamden, 1972).

giving a significant dependence between choice and freshness of treatment ($P < 0.025$). Lure A was preferred over the blank in both the nonbreeding and breeding seasons. Both lure B and lure C were as attractive as lure A, and in neither case was the success of the different lures dependent upon season, sex, or freshness of treatment (Table 2).

Comparisons of the captures among treatment pairs reveal that those trap-sites having two lure traps were just as successful as those with one bait and one lure trap ($\chi_1^2 = 0.06$, NS), and trap site success was independent of sex ($\chi_1^2 = 2.7$, NS; Table 3). Overall, trap site success was also independent of season ($\chi_1^2 = 0.64$), but males were caught more often at sites with two lures in the breeding season than expected by chance ($\chi_1^2 = 4.6$, $P < 0.05$; Table 3).

Seven nontarget species were caught (Table 4). The most common was the hedgehog (*Erinaceus europaeus*), which was caught in traps independent of treatment type. Seven weasels were caught, all but one on scent lures, and the two stoats caught were both on scent lures. Five Norway rats (*Rattus norvegicus*) were caught on the artificial lures, and none on the natural product lure (lure D).

Kill-Trapping Experiment. In the Mackenzie Basin study area gin traps treated with artificial scent lure (Lure A) were as successful in trapping ferrets as those baited with meat (Table 5). The catch rate per 100 trap nights on lure was 2.11, compared to 1.79 on bait.

More males than females were caught on lure, due to an overall higher catch of males (41 males to 24 females), but treatment success was independent of sex (Table 5). The number of ferrets caught on lure varied with freshness of treatment, with most ferrets being caught when the lure was fresh, and only five being caught on 3-day-old scent ($P < 0.025$). The catch rate on bait did

TABLE 3. NUMBER OF CAPTURES ON BAIT VS. LURE A AND BAIT VS. LURE D COMBINED (501 TRAP NIGHTS), COMPARED TO THOSE ON ALL THE LURE VS. LURE AND LURE A VS. BLANK PAIRS (878 TRAP NIGHTS)

while none of the 29 harriers (*Circus approximans*) caught were on lure ($P < 0.001$). Hedgehogs were caught equally often on bait and lure (1.27 and 0.87 per 100 trap nights, respectively). Only two other mustelids were caught, both stoats, and both on lure.

DISCUSSION

This study has shown that ferrets find some components of their anal sac odors more attractive than others and that these odorous compounds could be used as scent lures to attract ferrets to traps.

Bioassay Experiments. In all four bioassay experiments it was the combination 2-propylthietane (compound 1) and 2,3-dimethylthietane (compound 2) that was the most attractive, based on time spent investigating the odors. The results of the experiments based on speed of response are not so clear, but in all experiments the odor of 1 + 2 did not elicit a significantly slower response than any of the other odors. Compounds 1 and 2 were the most volatile of the compounds tested and are usually present at high concentrations in female anal sac extracts; compound 1 is also an important component of male odors (Clapperton et al., 1988).

In experiment II, indole (compound 4) proved to be very attractive. Indole is the least volatile of the compounds tested. The combination of 1 + 2 + 4 was not as attractive as either 1 + 2 or 4 alone. Perhaps the fact that 2 is often strong in female odors and 4 is strong in male odors (Clapperton et al., 1988) means that their combination at equal concentrations produced a confusing signal to the subjects. Similarly, combining compounds 5, 6, or 8, all of which are normally minor components of ferret anal sac odors (Crump, 1980a; Clapperton et al., 1988), with 1 + 2 at equal concentrations may not have been an appropriate way of testing these combinations.

Trapping Experiments. Results of both the long-term live-trapping and the intensive kill-trapping experiments demonstrate the viability of scent lures for attracting both male and female ferrets to control devices. Although ferrets preferred to enter bait traps when given a choice, trap sites with lure alone were just as successful as those with bait in both experiments. It could be argued that the lack of differences in trap site success indicates that ferrets would have been caught if no odor was present. However, previous workers have found mustelid traps to be more successful when they contain some odor, either bait or the smell of a previous capture, than when there is no odor present (King, 1973; Lavers, 1973; King and Edgar, 1977). A nonsignificant trend for lower success of clean traps was also seen in the preliminary trial of this study. This would imply that it was the treatments, not some other feature of the traps (e.g., simply their location), that accounted for their success in capturing ferrets. This is also indicated by the significant drop in catch rate on scent lure in the kill-trapping experiment (and a similar trend on bait) as the treatments became stale.

Experimental Design. The difference in results between the no-choice trapping experiments (one trap per site) and choice trapping experiments (two traps per site) has implications for the design of experiments for testing the effects of odors on trappability. If only choice experiments had been used, these may have led to the incorrect conclusion that scent lures would not be as effective as bait in attracting ferrets. Recent investigations on rodents have used choice experiments, with two or three traps with different treatments at each site, to look at the effects of different odors on trappability and, ultimately, their effects on population estimates (Daly et al., 1980; Stoddart, 1980; Wuensch, 1982; Stoddart and Smith, 1984). However, the demonstration of a choice does not imply that, given only one trap to enter, odors will be sufficient to attract or deter animals from entry. Given sufficient replication and an experimental design that does not allow the siting of traps to be a confounding factor, such information is obtainable from no-choice experiments (e.g., Roughton and Bowden, 1979; Gorman, 1984; Van der Berk and Müller-Schwarze, 1984). Choice experiments can, however, give information on the complex social interactions found in communities of small mammals (Stoddart and Smith, 1984). An experimental design that includes analysis of both within- and between-trap-site differences in trap success rate provides more information than either approach on its own (e.g., Stoddart, 1982; this study).

Species Specificity. None of the scent lures were totally species-specific. The capture of the other mustelids on the artificial ferret scent lures is not surprising, considering that one of the components, 2-propylthietane, is an important component of stoat anal sac secretions (Crump, 1980b) and that weasel anal sac secretions contain 2,3-dimethylthietane (Brink et al., 1983). Cats were not attracted by the lures, and harriers were not expected to be caught on the lure as they are visual rather than olfactory hunters (Brown, 1976). Hedgehogs

were caught on all treatments and are thus either indiscriminate about odor or else do not use olfactory cues to determine trap entry. Rodents were not caught on the natural product lure, but did enter traps containing the synthetic lures.

Experimental Limitations. The difficulty of demonstrating significant differences in responses when sample sizes are small is evident in both the laboratory experiments and field trials. This is a common problem in bioassay experiments on mammals (e.g., Müller-Schwarze et al., 1974; Singer et al., 1976; Murphy et al., 1978; McKenna Kruse and Howard, 1983; Crump et al., 1984), and is "inevitable in field experiments with carnivores" (King, 1980).

The repeated use of the same individuals introduces the possibility of the animals habituating to the odor stimuli. Repeated exposure to the odor of 1 + 2 in the bioassay experiments may have led to the ferrets showing relatively high responses to the "novel" odors in the later experiments. This tendency for ferrets to investigate novel stimuli has been demonstrated by Hughes (1964). Even so, 1 + 2 was always as attractive as the other odors tested. In the live-trapping experiments the same individuals were regularly trapped, but the fact that significant differences occurred between captures on some pairs of treatments suggests that ferrets were not becoming "trap-happy," but were making choices based on odor cues.

Future Direction. To be of more use in mustelid control programs or ecological research, improvements to the artificial scent lures should include a determination of the most effective concentration of odor compounds. This would require knowledge of the distance over which ferrets can perceive odors, and their responses to odors of varying concentration. The formulation of a slow-release scent lure should also be investigated. Such a formulation could prove the true advantage of lure over bait by providing a long-lasting attractant that can be used in an extensive trapping program, thereby overcoming the relatively rapid decay in the efficacy of both lure and bait demonstrated in this study. Another future direction of work should be to investigate whether components of ferret anal sac secretions repel other animals, e.g., rodents. The inclusion of such repellent compounds in a lure also containing ferret attractant might maintain the efficacy of a ferret scent lure and at the same time increase its species specificity.

Acknowledgments—The research was supported by a contract from the Chemistry Division, DSIR, and by a grant from the New Zealand Wildlife Service. Martyn Gorman, Phil Moors, and Brian Springett made extensive comments on drafts of the manuscript.

MYRISTICIN, SAFROLE, AND FAGARAMIDE AS PHYTOSYNERGISTS OF XANTHOTOXIN¹

J.J. NEAL²

Department of Entomology
University of Illinois
Urbana, Illinois 61801

(Received August 5, 1987; accepted November 24, 1987)

Abstract—The methylenedioxyphenyl-containing (MDP) inhibitors of mixed-function oxidase detoxification enzymes, myristicin, safrole, fagaramide, and isosafrole, occur with xanthotoxin or other toxic furanocoumarins in plants of the families Umbelliferae and Rutaceae. All four MDP compounds have a synergistic effect on the toxicity of xanthotoxin to *Heliothis zea*. Myristicin also increased the phototoxicity of xanthotoxin in the presence of UV light. The term phytosynergist is used to describe plant compounds that are present at concentrations producing no toxic effect by themselves but have a synergistic effect on cooccurring toxins.

Key Words—Xanthotoxin, *Heliothis zea*, Lepidoptera, Noctuidae, myristicin, fagaramide, safrole, isosafrole, synergism, phytosynergist, phototoxicity.

INTRODUCTION

The occurrence of insecticide synergists in plants has led to speculation that their natural function may be synergism of cooccurring toxins (LaForge and Barthel, 1944; Krieger et al., 1971). This view is supported by experiments in which the insecticide synergist myristicin (Figure 1), at levels present in plants, increased the mortality of first-instar *Heliothis zea* caterpillars fed xanthotoxin (Figure 1), a toxic furanocoumarin occurring with myristicin in many plants of

¹Taken in part from a thesis submitted to the Graduate College of the University of Illinois at Urbana-Champaign in partial fulfillment of the requirements for the degree of Doctor of Philosophy, June 1987.

FIG. 1. Xanthotoxin and plant compounds with a synergistic effect on its toxicity: xanthotoxin (I), fagaramide (II), isosafrole (III), myristicin (IV), and safrole (V).

the family Umbelliferae (Berenbaum and Neal, 1985). In this paper, compounds such as myristicin that are present at concentrations producing little or no toxic effect by themselves but which increase the toxicity of cooccurring toxins will be called phytosynergists.

Myristicin, like many other compounds containing a methylenedioxyphenyl (MDP) substituent, is an inhibitor of mixed-function oxidases (MFOs) (Hodgson and Philpot, 1974). MFOs are detoxification enzymes that metabolize many xenobiotics (Hodgson, 1985) and are primarily responsible for the metabolism of xanthotoxin in at least two species of insects (Bull et al., 1984, 1986). The synergistic effect of myristicin on the toxicity of xanthotoxin to *Heliothis zea* is attributed to its inhibition of xanthotoxin metabolism, which increases the effective xanthotoxin concentration in the insect (Berenbaum and Neal, 1985). Xanthotoxin has two types of toxic action on insects, a "dark" toxicity (toxicity in the absence of UV-A light) and phototoxicity (increased toxicity in the presence of UV-A light) (Berenbaum, 1978), which act through different mechanisms (Murray et al., 1982). Both mechanisms are likely to be important under natural conditions; however, only the synergistic effect of myristicin on the dark toxicity of xanthotoxin has been measured (Berenbaum and Neal, 1985). If myristicin works by inhibiting the detoxification of xanthotoxin, however, its activity should be retained under a variety of environmental conditions and be independent of the mode of action of the toxin. Thus, myristicin should

also be a phytosynergist of xanthotoxin phototoxicity in the presence of UV-A light.

Myristicin is not the only MDP-containing insecticide synergist that occurs with xanthotoxin in plant species. Phytochemical records show that safrole and apiole also occur with xanthotoxin in the Umbelliferae (Ceska et al., 1987; Hodisan et al., 1980; Murray et al., 1982; Hegnauer, 1973; Harborne, 1971), and fagaramide, asarinin, and sesamin occur with xanthotoxin in plants of the family Rutaceae (Thoms, 1911; Thoms and Thümen, 1911; Hegnauer, 1973; Murray et al., 1982). Some rutaceous plants also contain safrole and isosafrole along with other toxic furanocoumarins (Chang, 1976; Hegnauer, 1973; Murray et al., 1982). Thus, myristicin is probably not the only plant compound to function naturally as a phytosynergist of xanthotoxin, and there are many toxins other than xanthotoxin that may occur with phytosynergists.

Three insecticide synergists that are MFO inhibitors, fagaramide, safrole, and isosafrole (Figure 1), were tested as synergists of xanthotoxin toxicity to *Heliothis zea*. In addition, the ability of phytosynergists to maintain activity independent of the mode of action of the toxin was studied by measuring the synergistic effect of myristicin on xanthotoxin in the presence as well as in the absence of UV-A light.

METHODS AND MATERIALS

Chemicals. Myristicin was purchased from Saber Labs (Morton Grove, Illinois); fagaramide, safrole, and isosafrole from Aldrich Chemical Co. (Milwaukee, Wisconsin); and xanthotoxin from Sigma Chemical Co. (St. Louis, Missouri).

Bioassays. Neonates of the corn earworm, *Heliothis zea* (Lepidoptera; Noctuidae), from a culture maintained by Dr. G. Waldbauer at the University of Illinois, were used for testing the oral toxicities of all allelochemicals and combinations of allelochemicals. *H. zea* was chosen for study because it is a generalist feeder, it is susceptible to the toxic effects of xanthotoxin, and because myristicin has a synergistic effect on xanthotoxin toxicity to this insect (Berenbaum and Neal, 1985). Chemicals were administered by incorporation into an artificial diet (Berenbaum and Neal, 1985) in which wheat germ is the only undefined ingredient. In order to ensure uniformity, xanthotoxin (dissolved in acetone) was mixed with the alphacel component of the diet and dried prior to its incorporation into the diet. Myristicin, fagaramide, safrole, and isosafrole were added to hot diet in acetone solution (1% of the total wet weight) prior to gelling.

Neonates (30 per treatment) were placed individually on 200 mg diet in a 1.5-ml polypropylene test tube (Biorad, Richmond, California) and reared in a

25°C incubator under cool, white, fluorescent lights (16 hr light–8 hr dark). When screened by the polypropylene tube, these lights delivered less than 0.2 mW/m² of either UV-A (290–400 nm) or UV-B (200–290 nm) light as measured by a UVX radiometer with UVX 36 and UVX 31 sensors (UVP Inc., San Gabriel, California). Caterpillars were monitored until they died or molted to second instar. Toxicity of the MDP compounds was first measured at 1000 ppm (weight/wet weight diet); concentrations at and above 1000 ppm have been recorded for some of the MDP compounds in plants (Lichtenstein and Casida, 1963; Shulgin, 1966). For compounds toxic at 1000 ppm, lower concentrations were tested until a no-effect level was found. To test for synergism, the toxicity of xanthotoxin alone was compared to its toxicity in the presence of MDP compounds. LC₅₀ values were determined from log dose/probit mortality plots (SAS Institute Inc., 1982). LC₅₀ values were considered significantly different if the 95% confidence intervals did not overlap. Synergistic ratios (SR) were calculated as the LC₅₀ of the toxin divided by the LC₅₀ of the toxin with synergist.

For measuring the effects of myristicin–xanthotoxin combinations on *H. zea* in the presence and absence of UV-A light at simulated natural levels, larvae were reared in 50-mm × 5-mm internal diameter Pyrex test tubes stoppered with a cotton applicator stick. Pyrex transmits solar UV wavelengths (290–400 nm) but eliminates nonsolar UV wavelengths. Natural UV-A light intensities were simulated using two Sylvania BLB bulbs that produced between 1700 and 1950 mW/m² UV-A light and between 0.4 and 0.7 mW/m² UV-B at the surface of the tubes as measured with a UVX radiometer; a 16 hr light–8 hr dark photoperiod was used. For the no-UV-light treatments, filters opaque to wavelengths less than 400 nm were used to exclude UV light. Toxicity was evaluated as described above.

RESULTS

In the absence of xanthotoxin, neither myristicin nor fagaramide showed any toxicity at the highest dose tested. Both safrole and isosafrole were toxic at 1000 ppm, each killing 33% of the first-instar caterpillars. Safrole killed 10% at 700 ppm and was nontoxic at 400 ppm. Isosafrole killed 4% at 400 ppm and was nontoxic at 100 ppm. Therefore, in tests for synergistic effects on xanthotoxin, myristicin and fagaramide were used at 1000 ppm, safrole at 400 ppm, and isosafrole at 100 ppm.

Xanthotoxin has an LC₅₀ of 21,000 ppm (Table 1). The LC₅₀ values for combinations of xanthotoxin with myristicin, fagaramide, safrole, and isosafrole are 3200 ppm, 8300 ppm, 5900 ppm, and 8500 ppm, respectively. These values are all significantly different from the LC₅₀ of unsynergized xanthotoxin. Synergistic ratios are 6.5, 2.5, 3.5, and 2.5 for myristicin, fagaramide, safrole,

and isosafole, respectively (Table 1) but are not directly comparable because of differences in the dosages.

In the presence of UV light, myristicin significantly increases the LC₅₀ of xanthotoxin 3.6-fold (Table 2). UV light also has a significant effect on the toxicity of xanthotoxin-myristicin combinations, increasing the LC₅₀ 2.7-fold (Table 2).

DISCUSSION

Fagaramide, safrole, and myristicin all fit the definition of a phytosynergist; they have a synergistic effect on a cooccurring toxin at levels that are nontoxic. Isosafole, which is also a synergist of xanthotoxin, may be a phytosynergist for other cooccurring toxins. These compounds do not necessarily act exclusively as phytosynergists in all plants that produce them. For example, levels of myristicin in some plant parts (Shulgin, 1966) have an insecticidal effect in some insects (Lichtenstein and Casida, 1963). However, insecticidal concentrations of these compounds are rare in plants compared to sublethal concentrations. The occurrence of these compounds at sublethal concentrations suggests a primary role as a phytosynergist.

Berenbaum and Neal (1985) proposed that myristicin acts as an inhibitor of xanthotoxin detoxification and thereby increases the effective concentration of xanthotoxin in the insect. As predicted, myristicin is a synergist of xanthotoxin in both the presence and absence of near UV light. Phytosynergists may further enhance the effectiveness of phototoxins against nocturnal feeders by extending the length of time a phototoxin remains in an insect. This could prevent elimination of a phototoxin prior to the next photophase.

Little is known about the extent to which phytosynergists occur in the plant kingdom. While MDP compounds are widespread, most have not been tested as inhibitors of MFOs. The ecological advantages to phytosynergists are as yet undefined. Possible benefits include a reduction of the energy expenditure for defense or establishing a more stable defense (Berenbaum and Neal, 1986). Such properties would be desirable in economically important crops where phytosynergists may have practical benefits.

Acknowledgments—Thanks to Dr. May Berenbaum for support, advice, and comments; Drs. David Seigler and Stanley Friedman for advice and comments; Ellen Heining, Keywan Lee, Robert Marquis, James Nitao, Steven Passoa, Sherri Sandburg, and Arthur Zangerl for comments on the text; and Dr. Gilbert Waldbauer, Dr. Randy Cohen, and Nathan Schiff for *Heliothis zea* larvae. (Received August 18, 1987; accepted November 25, 1987)

Abstract—The secretion of the hypertrophied metapleural gland of the ant *Crematogaster deformis* contains a mixture of phenols, consisting mainly of 3-propylphenol, 3-pentylphenol, 3,4-dihydro-8-hydroxy-3-methylisocoumarin (mellein), 5-propylresorcinol, and 5-pentylresorcinol. The secretion is released, as a repellent, when the highly vulnerable petiolar-postpetiolar region of the abdomen is attacked by enemy ants. In addition, small amounts of the secretion are released regularly to serve as an antiseptic, which is considered the original function of the gland. The secretion also has some insecticidal properties.

Key Words—*Crematogaster deformis*, Hymenoptera, Myrmicinae, ant, defensive allomone, repellent, metapleural gland, 3-propylphenol, 3-pentylphenol, 3,4-dihydro-8-hydroxy-3-methylisocoumarin, mellein, 5-propylresorcinol, 5-pentylresorcinol.

¹Presented at the Fourth Annual Meeting of the International Society of Chemical Ecology, July 13–17, 1987, Hull, England.

INTRODUCTION

The exocrine glands of ants are known to produce a remarkable variety of compounds, and extensive investigations have been carried out on their glandular chemistry (Attygalle and Morgan, 1984). However, the metapleural glands located in the thorax, although found in most ants, have received little attention. In the few species that have been studied, only carboxylic acids have been identified. Some of these acids show antibiotic properties (Maschwitz et al., 1970; Schildknecht and Koob, 1970, 1971).

Crematogaster deformis possesses a relatively enlarged metapleural gland, similar to other species of *Crematogaster* belonging to the subgenus *Physocrema*. It had been indicated that the secretions of this gland are used to repel enemies (Maschwitz, 1974). Here, we describe in detail the chemical composition and function of the glandular secretion. For the first time, a unique mixture of phenols, hitherto not described from any arthropod source, has been found.

METHODS AND MATERIALS

Sources of Insect Materials. A large colony of *C. deformis* was dwelling in an inaccessible hole in a tree near the Gombak Valley Field Study Centre of the University of Malaya. A few artificial feeding sites made of honey-water mixtures were provided nearby. Polymorphic workers, which were day-active, were attracted in great numbers within a short time to these sites. The ants were caught, kept in moistened plastic containers, and observed from time to time for 10 days. When the ants were loosely held by the thorax region, with a pair of forceps, they released their metapleural gland secretion. These droplets were withdrawn by glass capillaries (Morgan and Tyler, 1977) and sealed in larger capillaries for later examinations.

A colony of *C. scutellaris* was collected in southern France. Its secretions were isolated and sealed in the same way as described for *C. deformis*.

Gas Chromatography (GC). Gas chromatography was carried out on a Hewlett-Packard 5890 instrument fitted with a 25-m \times 0.22-mm fused-silica capillary column coated with SE-54. The oven was held at 60°C for 2 min and programmed at 6°C/min to 260°C. Further analysis was performed on a United Technologies-Packard 438A instrument equipped with a 25-m \times 0.22-mm fused-silica column coated with SP-2340. The oven was kept at 60°C for 4 min and increased at 4°C/min to 195°C. The samples dissolved in hexane were chromatographed by splitless injection.

Micropreparative gas chromatography was performed on a Hewlett-Packard 5750 instrument fitted with a 2-m \times 4-mm glass column packed with 4%

OV-17 on 80–100 mesh Gas Chrom Q. The effluent was split 99:1 (trap–FID) by an all-glass splitter (Baker et al., 1976). The glandular secretion, dissolved in CS₂, was injected and the effluent volumes corresponding to each major component were trapped in metal U-tubes cooled in Dry Ice. The material trapped was washed directly with CDCl₃ (400 μl) into NMR sample tubes (5 mm) and 400 MHz FT-NMR spectra were measured by a JEOL JNM GX-400 instrument.

Gas Chromatography–Mass Spectrometry (GC-MS). The identification of the major components was achieved by GC-MS. A Finnigan 9502 gas chromatograph, fitted with a Grob-type split-splitless injector, linked to a Finnigan 3200E quadrupole mass spectrometer with a Data System 6000 was used. A fused-silica capillary column (SE-54, 25 m × 0.22 mm) was directly coupled to the mass spectrometer. The carrier gas was helium at 1 ml/min. The oven was held at room temperature for 4 min and programmed at 6°C/min to 260°C.

Acetylation of Extract. The metapleural gland extract in hexane (5 μl) was mixed with an ethereal solution (5 μl) containing 5% acetic anhydride and 5% pyridine. The mixture was left overnight and examined by GC and GC-MS.

Chemicals. 5-Propylresorcinol was kindly provided by Prof. Ayer (University of Alberta). Small samples of mellein were sent by Prof. Mori (University of Tokyo) and Dr. Brophy (University of New South Wales). 5-Pentylresorcinol (olivitol) was purchased from Aldrich Chemicals.

3-Propylphenol (peak 1) was synthesized by a Wittig reaction of ethylenetriphenylphosphorane with 3-methoxybenzaldehyde. The 3-(1-propenyl)-anisole thus obtained [yield 79%, bp 120–130°C/15 torr, kugelrohr (128–129°C/20 torr, Hudson and Robinson, 1941)] was hydrogenated to 3-propylanisole [yield 68%, bp 110–120°C/20 torr, kugelrohr (92°C/11 torr, Parkes, 1948)] using 5% Pd/C as catalyst, and the latter was hydrolyzed with acetic acid–HBr to give 3-propylphenol, peak 1 [yield 15%, bp 80–90°C/20 torr, kugelrohr (100–102°C/6–7 torr, Hartung and Crossley, 1934), mass and [¹H]NMR spectra in Table 1].

3-Pentylphenol (peak 2) was synthesized by a similar procedure, using butylenetriphenylphosphorane for carbonyl olefination. The 3-(1-pentenyl)-anisole formed [yield 84%, bp 73–76°C/0.01 torr (92–99°C/1 torr, Alles et al., 1942)] was hydrogenated to 3-pentylanisole [yield 92%, bp 70–72°C/0.05 torr (97–98°C/3 torr, Alles et al., 1942)] and subsequently hydrolyzed to 3-pentylphenol (peak 2) [yield 82%, bp 69–72°C/0.05 torr (99–100°C/1 torr, Alles et al., 1942), mass and [¹H]NMR spectra in Table 1].

Behavioral Studies. In order to study the attacking behavior of *C. deformis*, a worker of *Oecophylla smaragdina* was placed in an assembly of *C. deformis* at a honey–water feeding site. Similarly, the defence behavior was studied by placing a *C. deformis* ant at an assembly of *O. smaragdina*. The latter species was selected as the test ant species because it occupies the same habitat

^aThe peak numbers refer to Figure 1. All the compounds identified showed identical retention times to those given by authentic samples, on SE-54 and SP-2340 columns.

^b400 MHz FT-NMR spectra were recorded using about 10 to 20-μg samples. Signals not given were masked by impurity peaks.

^cMaterial available was insufficient for a satisfactory NMR spectrum.

and is considered an important competitor of *C. deformis*. The repellent effect of the metapleural gland secretion was studied by offering isolated thoraces of *C. deformis*, or chopped grasshopper parts smeared with one gland-equivalent of the secretion, to an assembly of *O. smaragdina* at a feeding site. The behavior of the ants was observed for 20 min after placing each lure. Similarly, grasshopper parts smeared with 1 μ l of 3-pentylphenol, or honey-water containing 1, 0.1, 0.01, or 0% 3-pentylphenol, were offered to colonies of *O. smaragdina* and *Pheidole* sp. Likewise, 2 gland-equivalents of the secretion were applied to individual mealworm larvae (*Tenebrio molitor*), which were offered to an European pied flycatcher (*Ficedula hypoclea*).

In order to study the toxic effects of the secretion, either 1 gland-equivalent of the metapleural gland secretion or 1 μ l of 3-pentylphenol was applied, by a glass capillary, onto the gaster or head of *O. smaragdina* workers. Thirty ants were subjected to each treatment and observed for 20 hr.

The release of alarm behavior was investigated by presenting crushed body parts, such as a head, excised mandibular glands, thorax, or gaster, on a piece of filter paper, near a feeding site of *C. deformis*. The ants were observed for 1 min after each stimulus was presented. The experiment was repeated six times for each stimulus.

RESULTS

Release of Glandular Secretions. The workers of *C. deformis*, which were kept in closed containers, released small quantities of their metapleural gland secretion even when they were not being disturbed. The secretion is released from the orifices of the reservoirs, which have no closing mechanism. The presence of the secretion could be recognized by its characteristic tarlike smell, when the lid of the container was opened.

When an ant was loosely held, with a pair of forceps, by its antenna, leg, or head, sometimes the release of minute quantities of the metapleural secretion could be observed. However, when the ant was gripped directly by the thorax, or gaster, a large colorless or somewhat violet droplet appeared at the gland orifice. Due to the lipophilic nature of the secretion, it soon spread over the cuticle around the orifice. When the ants were treated more roughly, seized by the head or legs, they released their very sticky brownish-red-colored Dufour gland contents and tried to smear the secretion on the pair of forceps by which they were held.

Chemical Analysis of Secretion. The metapleural gland secretion withdrawn into glass capillaries had a strong phenolic smell. The analysis of the extract by gas chromatography revealed the presence of five major components (Figure 1). The highly polar nature of these components was evident from the

FIG. 1. Volatiles in the metapleural gland secretion of *C. deformis*. Chromatogram obtained on a 25-m \times 0.22-mm fused-silica capillary column coated with SE-54. Oven temperature was held at 60°C for 2 min and programmed at 6°C/min to 260°C. The sample in hexane was introduced by splitless injection. Peak numbers refer to those in Table 1.

large shifts in retention times observed when a chromatogram obtained on a nonpolar column (SE-54) was compared to one on a polar column (SP-2340). All five components showed much longer retention times on the polar column. Complete mass spectra were obtained by GC-MS for all components, and satisfactory NMR spectra were recorded for the three major compounds. The results are summarized in Table 1.

In order to verify the presence of phenols, the mixture was acetylated. Components 1, 2, 4, and 5 underwent complete acetylation, and new peaks corresponding to the products appeared in the chromatogram. The peak 3 was only partially acetylated under the conditions used. The GC-MS analysis of the acetylated mixture showed that components 1, 2, and 3 were monoacetylated, while 4 and 5 were diacetylated. The degree of change in the retention times also indicated this.

The mass spectrum of peak 2 was identical to that known for 3-pentyl-

phenol (Gorfinkel et al., 1969). Both 2- and 4-pentylphenols have the base peak at m/z 107; only the 3-pentylphenol shows the base peak at m/z 108. Although the spectrum of peak 1 was very similar to those from 2-propylphenol and 4-propylphenol (Stenhagen et al., 1974), there were significant differences. For example, the spectrum of peak 1 has a significant peak at m/z 121 (13%) which is absent in those of 2- and 4-propylphenols. Also, the peak at m/z 108 is more prominent in the natural product (50%) than those of 2- and 4-isomers (less than 8%). It appeared that such a prominent even-mass ion at m/z 108 can arise only from a 3-isomer. The pentyl and higher derivatives studied by Gorfinkel et al. (1969) show a similar behavior. In fact, if the alkyl group is pentyl or larger, the m/z 108 peak becomes the base peak. The NMR spectrum (Table 1) could establish that the peak 1 is a *n*-propyl compound and not an isopropyl derivative. 3-Propylphenol was synthesized, and it was chromatographically and spectroscopically identical to the natural product.

Peak 3 could be identified immediately by its mass spectrum, which was congruent with that known for 3,4-dihydro-8-hydroxy-3-methylisocoumarin (mellein) (Brand et al., 1973). The mass and NMR spectra (Table 1) and the retention time of an authentic sample were identical to those from the natural compound.

To be consistent with mass spectroscopic and acetylation results, peak 5 must be a pentylresorcinol. According to the deductions of Occolowitz (1964), only the 1,3,5-isomer of such a compound can yield an even-mass ion at m/z 124. The properties of an authentic sample of 5-pentylresorcinol matched well with those of the natural product. By analogy, peak 4 was suspected to be 5-propylresorcinol, which was later proved correct by comparison with an authentic sample.

The absolute amount of the phenols present per ant varied widely from 2 to 20 μg per sample. Although the relative amounts of compounds also showed a broad variation, the chromatogram shown in Figure 1 can be considered typical.

The mixture of phenols found seems characteristic to the species *C. deformis*. For example, such phenols were not detected in the metapleural glands of *C. scutellaris* or *C. borneensis* (Attygalle, Fiala, and Maschwitz, unpublished observations).

Defensive and Attacking Behavior. The attacking behavior of *C. deformis* could be studied by introducing an alien ant, such as *O. smaragdina* or *Diacamma rugosa*, into a large assembly of *C. deformis* workers at a feeding site. The workers attacked the alien instantly and bit into its body appendages. Spread-eagled by this attack, the alien was unable to move, and in this posture it was dragged along the recruitment trail. The use of metapleural or Dufour gland secretions was not observed during these attacks. On the other hand, when a worker of *C. deformis* was placed in an assembly of *O. smaragdina*, it

too was attacked immediately, either by biting into the body appendages or the body itself. When two or more workers of *O. smaragdina* got hold of the appendages, they pulled and spread-eagled the *C. deformis* worker, immobilizing it in such a way that it was unable to use its defensive glands. Subsequently, it was killed slowly by other ants that reinforced the attack. However, if the attackers initially bit into the head or neck region, *C. deformis* could bend its highly mobile gaster tip forward and smear the attacker with sticky Dufour gland secretion. In 10 of 15 such attacks observed, the contaminated *O. smaragdina* worker stopped the attack and began to clean itself. On the contrary, if the attackers first bit into the posterior thorax, the coxae, the petiolar region, or the proximal gaster region, *C. deformis* released, in defense, its metapleural gland secretions. This immediately stopped the attack. In 18 of 20 cases observed, the contaminated *O. smaragdina* workers immediately started an intensive and prolonged cleaning process. They wiped their heads on the ground and cleaned their mouth-parts with their legs.

The strong repellent effect of the metapleural gland secretion was also evident when we placed isolated thoraces of *C. deformis*, or chopped grasshopper parts, smeared with the secretion, at a feeding site of *O. smaragdina*. While the uncontaminated parts were carried away instantly at the first contact, no objects smelling of the metapleural secretion were taken. Similar results were obtained with grasshopper parts contaminated with 3-pentylphenol. Likewise, honey-water containing 1 or 0.1% 3-pentylphenol was refused by *Pheidole* sp., while untreated solutions were consumed by hundreds of ants. However, a 0.01% solution was also accepted. *O. smaragdina* refused even the uncontaminated solutions. Moreover, the secretion did not manifest any repellent effect when contaminated mealworm larvae were offered to a European pied flycatcher. The bird consumed six mealworms, one after the other, without any hesitation.

Besides the repellent effects, the secretion also shows some toxicity to insects. Table 2 shows the results obtained by treating workers of *O. smaragdina* with the secretion of *C. deformis* or 3-pentylphenol.

Although the metapleural secretion has repellent and some toxic effects towards insects, it has no alarm pheromone properties. Alarm behavior (i.e., fast movements, attraction, opening of the mandibles, and biting behavior) was exclusively released by the mandibular gland secretion (Table 3).

DISCUSSION

The metapleural glands are found in most ants. As far as is known from the few species that have been analyzed, the glandular secretion contains certain carboxylic acids that show antibiotic and antiseptic properties. These acids are supposed to act as topical antiseptics that suppress the growth of fungi and bacteria on the body surface of the adults and brood, and on the nest material (Maschwitz et al., 1970; Maschwitz, 1974; Schildknecht and Koob, 1971; Hölldobler and Engel-Siegel, 1984).

C. deformis regularly releases small amounts of its phenolic metapleural gland secretion to maintain its body and nest hygiene. The bactericidal effect of phenols is well known. The presence of an alkyl chain tends to increase lipid solubility, and from the investigations conducted by Ayer et al. (1983), it is clear that the bactericidal activity increases, up to a certain point, as the length of the side chain increases. Phenols, very similar to those found in the gland are often used in proprietary antiseptics.

The phenolic compounds, except mellein, identified in *C. deformis*, have been reported from biological sources only on rare occasions. 3-Propylphenol is an attractant for tsetse flies and has been isolated in the urine of the host buffalo (Hassanali et al., 1986). It is also found in tobacco smoke (Arrendale, 1984). 3-Propylresorcinol has been found in a lichen (Chamy et al., 1985), and it has been claimed to be present in oakmoss extracts (Gavin and Tabacchi,

1975); however, the published mass spectrum does not correspond to ours obtained from an authentic sample. Long-chain alkyl phenols and resorcinols are characteristic of the oils of Anacardiaceae (Bestmann et al., 1987; Skopp et al., 1987; Oocolowitz, 1964). The only similar compound known from ants is 5-methylresorcinol (orcinol) (Blum et al., 1982a)

Mellein is a fairly ubiquitous compound with antibiotic properties. It was first found as a fungal metabolite (Ayer and Shewchuk, 1986, and references therein), and later its presence was shown in ants (Brand et al., 1973; Brophy et al., 1981; Bellas and Hölldobler, 1985), termites (Blum et al., 1982b), and moths (Baker et al., 1981; Nishida et al., 1982; Kunesch et al., 1987).

Producing an antibiotic secretion may be the sole primary function of the metapleural gland secretion in ants having a "normal-sized" gland; however, at least in those species possessing a hypertrophied (exceptionally enlarged) gland, additional functions can be expected. *C. deformis* has such an enlarged gland, and this hypertrophic development is accompanied by chemical specialization. None of the phenols found in this unique mixture, except mellein, has been previously isolated from any arthropod source. From our observations it is clear that *C. deformis* uses this secretion also as a defensive allomone. In fact, this secondary function is the more important role of the secretion. The strong-smelling secretion has a powerful repellent, and even toxic, effect against enemy ants. The slender petiolar-postpetiolar region of *C. deformis* is highly vulnerable to enemy attacks of biting. The metapleural secretion exclusively provides the chemical defense of this region. The head-neck region, body appendages, and gaster tip of the workers are protected by the defensive secretions from the hypertrophied Dufour gland. This secretion can be applied, at the aforementioned body regions, employing the gaster, which is highly mobile. A highly mobile gaster is a characteristic feature of the genus *Crematogaster*. Thus, *C. deformis* is protected by a two-gland chemical defense system, which has, however, not taken over the alarm function. The alarm pheromone is produced in the mandibular gland. In contrast, in *C. (Physocrema) inflata*, it is produced in the metapleural gland (Maschwitz, 1974). The injecting part of the sting of *C. deformis* is atrophied, similar to those in other species of *Crematogaster*.

It appears that a change has occurred, during phyletic development, from a more primitive system of injecting the hydrophilic venom from the poison gland, to a more advanced defense system using surface-active lipophilic secretions of the Dufour gland. The lipophilic and highly sticky Dufour gland secretion can entangle the enemy. The metapleural secretion is repellent, or sometimes even lethal, to the enemy. Such "new" chemical weapons employing surface-active allomonnes are common in higher Formicidae (Buschinger and Maschwitz, 1986). Although venom gland secretions of ants are often potent toxicants, the injection of the venom into the body of the enemy ant is very

difficult, if not impossible, especially when the opponent is highly mobile, small, or mass-attacking. For fighting against such an enemy, an instantly applicable repellent or a sticky fluid, such as those utilized by *C. deformis*, is much more effective.

Furthermore, the petiolar region of myrmicine and some other ants are usually protected against biting ants by small but sharp epinotal spines. These spines, found in most other *Crematogaster* species, are lacking in *C. deformis* because the petiolar region is well-protected by the metapleural gland secretion. A similar development can be seen in *C. inflata*. It also lacks epinotal spines and produces a sticky glue-like defensive secretion in its enormously enlarged metapleural gland (Maschwitz, 1974).

The genus *Crematogaster* demonstrates an astonishing variety in its defensive chemistry and biology and will be the subject of further investigations.

Acknowledgments—We thank Prof. K. Mori (University of Tokyo), Prof. W.A. Ayer (University of Alberta), and Dr. J.J. Brophy (University of New South Wales) for small samples of chemicals. We also thank Dr. W. Bauer and R. Waibel for their help in obtaining spectra. The financial support of the Deutsche Forschungsgemeinschaft is gratefully acknowledged.

(Received June 30, 1987; accepted December 2, 1987)

Abstract—In order to define the part of olfactory cues in the selective behavior of honeybees, observation on their foraging behavior was carried out on various sunflower genotypes in parallel with chemical analysis of aromatic extracts of the genotypes. Foragers show a preference for the early stages of flowering and, when they are given a choice between couples of parental lines of two commercial hybrids, Marianne and Mirasol, they are randomly distributed on Mirasol parents, but they prefer the female line of Marianne. The comparison of relative proportions of compounds among aromagrams obtained from head space trapping from the two couples of genotypes, reveals (1) a phenological stage effect for 17 compounds among 144 indexed compounds for Marianne lines and for 18 among 136 indexed compounds of Mirasol lines; most of these compounds exhibit higher relative proportions in the early flowering stages, which is related to plant attractiveness towards honeybees; (2) a sex effect for 33 compounds among 144 for Marianne lines and for 14 compounds among 136 for Mirasol lines; further semiquantitative analyses reveal a sex effect for only eight compounds of 134 for Marianne lines and 20 compounds of 250 for Mirasol lines, which represents less than 10% of the indexed compounds. These discriminatory compounds were partly identified by coupled GC-MS. Possible relations between such phenological and genotypical volatile fluctuations and forager attraction are discussed.

Key Words—Sunflower volatiles, genotype effect, phenology effect, honeybee, Hymenoptera, Apidae, foraging behavior, olfactory discrimination, hybrid seed production.

INTRODUCTION

The sunflower crop (*Helianthus annuus* L.) has spread widely in recent years and is now the second largest oilseed crop in the world (Putt, 1978). This increase is linked to improvement in varieties through hybrid production using cytoplasmic sterility (Leclercq, 1969). Hybrid production is then dependent on pollen carriage from male to female lines and the transfer is mainly carried out by insects (Putt, 1940; Free and Simpson, 1964), and more particularly by honeybees (*Apis mellifica* L.) (Radford and Rhodes, 1978; Parker, 1981). However, field observations have shown that low seed yields were linked to a selective foraging behavior of honeybees (Shein *et al.*, 1978; Freund and Furgala, 1982), and it has been established that olfactory parameters are determinant for forager attraction to a food source (Frisch, 1967; Masson, 1983).

Little work dealing with the chemistry of sunflower volatiles has been reported in the literature. Most authors have studied the chemistry of higher molecular weight constituents, such as sesquiterpenic lactones (Iriuchijima *et al.*, 1966; Morimoto, 1966), diterpenic acids (Pyrek, 1970; Stipanovic *et al.*, 1979), fatty alcohols (Gracian and Arevelo, 1980), germacranolides (Ortega *et al.*, 1970; Ohno and Mabry, 1979), sterols (Homberg and Schiller, 1973), and triterpenes (Kasprzyk and Janiszowska, 1971). Gershenzon *et al.* (1981) studied the chemistry of terpenoid constituents of *Helianthus*, and Eckert *et al.* (1973) identified the sesquiterpenic hydrocarbon β -gurjunene and several terpenoids in unrefined sunflower oil.

The first data dealing with more volatile compounds are reported by Popescu (1979, 1982). Popescu *et al.* (1979) identified 19 monoterpenes, and Karawya *et al.* (1980) pointed out five terpenic hydrocarbons and five oxygenated terpenoids; this work was completed by Flath *et al.* (1985), who reported 14 monoterpene hydrocarbons, 25 oxygenated monoterpenes, and several sesquiterpenic hydrocarbons. These authors carried out steam distillation on different parts of cut sunflower heads. Etievant *et al.* (1984) set up direct solvent extraction and head space collection of volatiles from cut heads of various sunflower genotypes. Analysis of extracts by combined gas chromatography and mass spectrometry led to 84 constituents being reported, among which 20 terpenic hydrocarbons, 9 alcohols, 3 phenols, 6 esters, and 19 oxygenated compounds were identified. Moreover this work emphasized qualitative differences in the composition of polar fractions of the genotypes.

In the present work, we have tried to define the part of olfactory cues in selective behavior of the honeybee by the parallel observation of their foraging behavior towards different sunflower genotypes and chemical analysis of aromatic extracts of the corresponding genotypes. In order to carry out the chemical analysis of extracts as close as possible to volatile emissions perceived by insects around the sunflower disk, extracts were obtained after head space trap-

ping of volatiles emitted by living heads. By comparing extracts from different plant genotypes and/or phenological stages, we have tried to point out volatiles likely to be used by honeybees as cues for behavioral discrimination.

METHODS AND MATERIALS

Plant Material. Experiments were carried out during two successive years on flower disks (male and female lines) of two sunflower hybrids (Marianne and Mirasol). These hybrids have highly different seed yields (low yields for Marianne, which is no longer cultivated in France, and high yields for Mirasol, used as the standard for varieties for which selection is in progress).

During the first year, aroma collection and behavioral observations were carried out on the two parental lines and at three phenological stages, I, II, and III, corresponding to 1/3, 2/3, and 3/3, respectively, of disk florets in blossom. During the second year, aroma samples were collected on each genotype at stage II.

Behavioral Observations. Foraging behavior of insects was observed in forced pollination conditions, previously described (Pham-Delegue *et al.*, 1986). A hive containing about 10,000 worker bees gathered around a 1-year-old queen and provided with brood and food combs was placed under a tunnel facing a couple of sunflower parental lines. Forager distribution was recorded on 40 heads per genotype with three observations per day, every other day alternately for each variety throughout the blossom period (six days for Marianne lines and five days for Mirasol lines). The number of foragers per head, as well as the stage of blossom, were taken into account. The frequentation level of a line was estimated by the mean number of foragers per 10 sunflower heads. Attractiveness of parental lines was noted for each couple of lines, by Student's *t* test.

Chemical Analysis. Plant volatile emissions were collected and concentrated using a head space trapping method adapted to sunflower heads.

Purification of Reagents. Solvents were distilled prior to use, and their purity was checked by gas chromatography, as described by Etievant and Bayonove (1983). Porapak-Q (120–150 mesh) was purified for 6 hr using a Soxhlet extractor with nanograde hexane. After solvent evaporation at ambient temperature, further drying was carried out by heating to 110°C for 2 hr. After packing (2.2 g Porapak-Q in 10-cm-long × 1-cm ID glass tubing). Porapak-Q traps were further conditioned at 230°C for 12 hr in a flow of nitrogen (1–2 liters/hr).

Trapping of Volatiles. Volatile compounds emitted by one sunflower head were collected on a conditioned Porapak-Q trap placed between the sampling bag (polyvinyl fluoride film, Tedlar, Dupont de Nemours int., S.A.) and a blade pump (Figure 1). An air intake connected to a coal trap for air purification was

FIG. 1. Scheme of head space trapping of volatiles from living sunflower heads.

set up in the bag. All tubes and connections were made of Teflon. Air flow was adjusted to 150 ml/min by using a Weaton needle valve set between the trap and the pump. Trapping was performed for 24 hr.

Desorption of Volatiles from Traps. Humidity condensed in the traps was first eliminated by a flow of dry nitrogen (150 ml/min for about 1 hr at ambient temperature) applied in the opposite direction to the one chosen for collection of volatiles. Volatiles were then desorbed by percolation of 2 × 25 ml Freon 11. The solution was then concentrated to a volume of about 500 μ l through a Dufton column. Extracts were kept in sealed tubes in a freezer (-25°C) for further analysis.

Separation and Identification of Constituents. Volatile constituents of the aromatic extract were separated according to conditions described by Etievant *et al.* (1984); analyses were carried out with a Girdel 300 gas chromatograph fitted with a split-splitless injector, a flame ionization detector, and a SE-52 glass WCOT capillary column (37 m × 0.4 mm ID; film thickness 0.6 μ m). The gas carrier was helium (17.1 ml/min), temperatures of the injector and detector were, respectively, 230 $^{\circ}\text{C}$ and 220 $^{\circ}\text{C}$, and the temperature of the oven was programmed from 40 to 180 $^{\circ}\text{C}$ at 3 $^{\circ}\text{C}/\text{min}$.

When necessary, identifications were carried out by coupling gas chromatography and mass spectrometry according to conditions previously described by Etievant and Bayonove (1983). Samples were analyzed by both electron impact and chemical ionization using NH_3 as the reagent gas. Acquisition and processing of mass spectra were set by a connected computer (Digital Equipment Corporation PD P8) and identification of compounds was made automatically, referring to a spectra library (National Institutes of Health, Environmental Protection Agency), and checked manually by comparing with published spectra.

Statistical Analysis. The quantitative study of volatile differences according to the genotype (male versus female) and to the flowering stage (Stages I, II, and III) was first carried out on samples collected the first year. Extracts from each stage and each genotype were twice injected in the gas chromatograph, without any internal standard added. The integrated area of each peak was referred to the total area of all indexed peaks of the chromatogram; resulting data obtained from chromatographic profiles of each variety were then submitted to an univariable analysis of variance with two controlled factors (sex, stage), according to a cross-model with interaction. The analysis was carried out with a MINI6 microcomputer (CII) at the INRA of Dijon, using the ANVARM program from the statistical library AMANCE (Bachacou *et al.*, 1981).

The analysis of the stage effect was followed by a multiple comparison of means, using the Scheffe method. Thus the amounts of each constituent that differed significantly according to the stage were classified.

In a second step, analysis was focused on the genotype effect from samples collected at stage II of blossom, with three repetitions for male lines, two repetitions for female lines, and two injections for each sample; 2-hexanone (1 mg), added before concentration of extracts, was used as a standard. The integrated area of each indexed peak was referred to the standard peak area. In order to compare male to female aromagrams, univariable analysis of variance was set up, using the UNFAL program, which calculated for each constituent the mean proportion and the standard deviation as well as the F value of the Fisher test.

RESULTS

The behavioral data are reported in Figure 2, and a foraging preference for the flowering stages I and II appears for all genotypes. Moreover, the foragers exhibit a different foraging behavior among the two couples of genotypes: they are randomly distributed on the parents of the Mirasol hybrid, while they selectively visit the parents of the Marianne hybrid, with a great preference for the female. This emphasizes the honeybees' ability to discriminate between plant genotypes.

During the first step of the physicochemical analysis of lines sex and stage

FIG. 2. Foraging activity of honeybees according to seasonal phenology and to genotypes (stages I-III: 1/3 to all disk florets in blossom).

effects for each couple of plant lines, 144 components were indexed for Marianne parents and 136 components for Mirasol lines. Among these indexed components, 56 of 144 exhibit significant differences with a 0.05 probability level according to sex for Marianne lines (with a higher amount in the female line for 38 components), and 41 components for Mirasol lines (with a higher amount in the female line for 28 components). However, some of those components show a significant sex/stage interaction, which makes interpretation difficult because genotype emissions may fluctuate according to flowering stages. These components showing a sex/stage interaction were rejected, i.e., 23 for Marianne lines and 27 for Mirasol lines. A high proportion of remaining discriminatory components exhibits a higher value for the male line (23 among 33 for Marianne lines, and all 14 for Mirasol lines) (Figure 3).

Concerning the stage effect, it appears that 38 of 144 for Marianne and 54 of 136 for Mirasol present significant differences with a 0.05 probability level. Among these, 17 for Marianne and 18 for Mirasol show a stage effect without any interaction with the sex effect (Figure 4). Most of them exhibit a higher relative proportion at stage I for Marianne lines (9 of 17) and at stage II for Mirasol lines (13 of 18). Such data are related to plant attractiveness towards honeybees, according to flowering stages.

In order to develop the study of possible relationships between honeybee attraction and the relative amounts of volatiles, new experiments were set up; stage III was excluded because of the low number of honeybee visits (see Figure 2). Between the other stages, stage II was preferred to stage I, in order to get a better flowering concordance among male and female lines for simultaneous volatile collection.

Physicochemical analysis was carried out using an internal standard to obtain semiquantitative data, which allow easier interpretation of peak variations. A reference index was reported independent for each variety (134 for Marianne lines and 250 for Mirasol lines were indexed). Statistical analysis was applied to these indexed components, comparing male with female lines. Significant differences appear for eight components of 134 for Marianne lines and for 20 components of 250 for Mirasol lines (Figures 5 and 6), despite some high values of variation coefficients ($> 50\%$ for values obtained for peaks 71 and 105 in the male line of Marianne, and for values obtained for peaks 10, 43, and 179 in the male line and peak 211 in the female line of Mirasol). These variations in the amounts of some components may be related to a low reproducibility of the emission between different flower heads and to a lower precision of the integration of small peaks.

However, it has to be stressed that intergenotype differences are not based on the quantitatively dominant components; qualitative differences (according to detection limits of the GC technique) arise for three components of eight for

FIG. 3. Intergenotype differences in volatiles among Marianne (I) parental lines and Mirasol (II) parental lines. Variables: indexed components with significant differences according to sex, without interaction with stage effect (orthogonal variance analysis with two controlled factors: sex, stage).

$$\log \frac{(a_n \times 10^4)}{A}$$

expresses the ratio of the peak area (a) of a given component (n) to the total area (A) of all the indexed components of the chromatographic profile. *y axis value of the component 13 in Marianne lines is = -3.95.

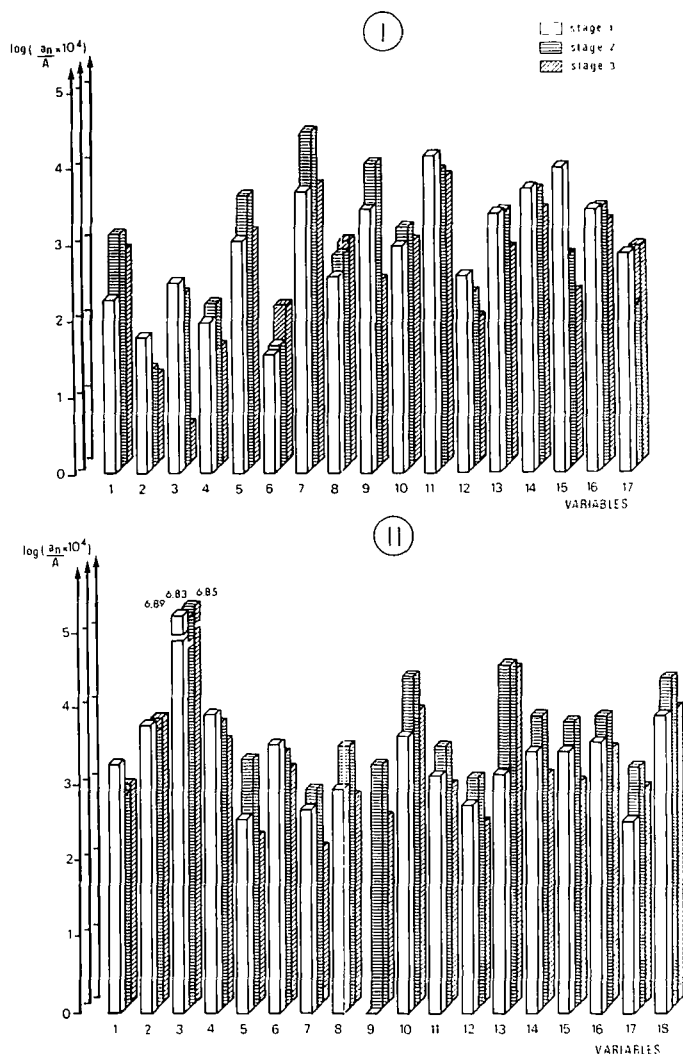

FIG. 4. Phenological differences in volatiles for Marianne lines (I) and Mirasol lines (II).

Marianne and for 12 components of 20 for Mirasol, the volatile component lacking in the female line in most of the cases. Moreover, the amounts of most volatiles are higher in the male line of the Mirasol variety (for 16 components of the discriminatory ones).

As reported in Figures 5 and 6, identification of some of the dis-

FIG. 5. Discriminatory components among male and female parental lines of Marianne from semiquantitative analysis. ♂, ♀, indicate the line where the component has the highest amount. Intergenotype differences are obtained from an univariable analysis of variance with one rank factor (1,5 ddl). * $P < 0.05$; ** $P < 0.01$.

criminatory components was then elucidated by GC-MS coupling; xylene, methyl 3-methyl-2-butenate, limonene, sabinene hydrate, and 2-methyl-6-methylene-1,7-octadien-3-one have been identified among the eight intergenotype discriminatory components of Marianne parents; methylcyclopentane, 2,3,4-trimethylhexane, decahydro-1,6-dimethylnaphthalene,

FIG. 6. Discriminatory components among male and female lines of Mirasol (see legend to Figure 5).

alkylbenzene, triethylbenzene, decahydrotetramethylnaphthalene, decahydro-dimethylethyl-naphthalene, 1-heptenylbenzene, 1,4-dihydro-1-(2H)naphthalenone, and 3(4,8-dimethyl-3,7-nonadienyl)-furan were part of the 20 discriminatory components of Mirasol parental lines.

DISCUSSION

Honeybees are opportunistic foragers whose tendencies for innate responses can be largely obliterated by learning, and mainly by olfactory conditioning. Manning (1957) observed that a change of scent induced a stronger discrimination than a change of flower pattern or shape, and several authors (e.g. Frisch, 1967; Koltermann, 1969) concluded that scent was more important in condi-

tioning honeybees than color, shape, or time of day. Although we are aware that continued foraging by honeybees is dependent on the reward of nectar or pollen, plant selection is based on aroma differences.

The data of honeybee visitation on flowers at different blossom stages indicated a decrease at the later stage (stage III) for all the genotypes considered. These results agree with those of Benedek and Manninger (1972), Delaude *et al.* (1979), and Drane *et al.* (1982), who mentioned a higher attractiveness at the beginning and in the middle of sunflower flowering. It has been shown in the present work that the late flowering stage corresponded to the lowest amounts of stage discriminatory components. Thus a seasonal phenology of volatile chemicals appears in sunflower genotypes, which affects their attractiveness to honeybees. This fact underlines the possible use by honeybees of some volatile components representative of plant flowering. Variations may inform foragers of growth stages and of the corresponding food availability, since visitation by bees is closely linked to the largest caloric reward (Tepedino and Parker, 1982), which decreases throughout the flowering (Simidichev, 1976; Fonta *et al.*, 1985).

Although seasonal variations in the composition of the volatile oil had already been quantified in several plant aromas [e.g., variations in terpenes production of *Tanacetum vulgare* L. volatile oil (Rudloff and Underhill, 1965)], little work had been done to establish relations between volatile fluctuations and insect attraction. Some evidence for such abilities of the honeybee to select plant stage according to volatiles had been pointed out in the soybean (Robacker *et al.*, 1982, 1983), which suggested that some aroma chemicals may communicate flower-readiness information to pollinators.

As for the varietal effect, our data, particularly from semiquantitative analysis, points out differences among coupled genotypes restricted to less than 10% of the chromatographic profiles. This fact emphasizes honeybees' discrimination abilities, since they are able to make long-range selection among genotypes in Marianne lines, using these slight differences. It must also be noted that discriminatory components seem to be chemically different for the two couples considered. Moreover, these differences are not systematically used for selection, since honeybees exhibit preferences only between Marianne parents, which is closely related to differences in glucidic food reward (Fonta *et al.*, 1985). Thus, in a situation of choice, discriminatory components only became significant cues for selective orientation after association with the best reward during the conditioning process.

It had been shown previously that honeybees were able to recognize sunflower aroma from a limited chemical pattern whose active constituents were representative of the whole aroma (Pham-Delegue *et al.*, 1986). Referring to this work, it appears that the chemicals already identified from this active fraction (Etievant *et al.*, 1984; Pham-Delegue *et al.*, 1986) are different from the

discriminatory intergenotype volatiles identified in the present work. Thus, the hypothesis suggested is that foragers may recognize a flower aroma from a limited typical fraction of the blend, while they may use very slight differences, out of this common chemical pattern, to discriminate between genotypes and choose the best food source. Such differences may not be used when the two genotypes are equally supplied, as for Mirasol lines, where both genotypes have equivalent glucidic composition (Fonta *et al.*, 1985). Currently the effort of identification of active compounds is carried out with a synchronous combination of chemical and biological recordings (Thiery *et al.*, in preparation). This method should make it possible to define a few molecular criteria responsible for sunflower attractiveness to honeybees.

Moreover, the genetic basis for such compounds, common to a plant genus or specific to a given genotype has to be checked. Thus, at it has been shown in *Mentha genus* (Hefendehl and Murray, 1976), that the genetic aspect of volatile biosynthesis may be elucidated in order to create the proper combination of genes necessary to accumulate large amounts of single important components. In this research area, Gershenzon *et al.* (1981), reviewing the terpenoid chemistry of sunflowers, have already suggested that some terpenoids, such as sesquiterpenic lactones and diterpenes, are possible sources of resistance to some of the most serious pests.

The present type of research, which needs the cooperation of chemists, physiologists, plant breeders, and geneticists, should lead to the definition of chemicals involved in plant attractiveness to pollinators and likely to be included in plant selection programs for crop improvement through controlled cross-pollination.

Acknowledgments—The authors gratefully acknowledge the technical support of J. Chauffaille for obtaining plant extracts, D. Demaizieres for her valuable assistance in the GC analysis, and E. Boughdad-Leblond for her helpful contribution to data treatment. We also wish to thank Ph. Douault for behavioral observations and the Sunflower Laboratory INRA Clermont-Ferrand for plant material supply.

(Received August 12, 1987; accepted December 2, 1987)

Abstract—Various plants native to arid and semiarid habitats throughout the southwestern United States, Baja California, and northern Mexico were bioassayed for phototoxic natural products. Approximately 115 species representing 57 genera and eight plant families were assayed for phototoxic activity by standard antimicrobial techniques using *Escherichia coli* and *Saccharomyces cerevisiae*. Phototoxic constituents were extracted from numerous members in the Asteraceae (Compositae) and occurred with highest frequency among species of the subtribe Pectidinae (tribe Heliantheae). Extracts of *Pectis*, the largest genus in the Pectidinae, had substantial light-activated biocidal action despite the paucity of acetylenic thiophenes, the phototoxins characteristic of most other genera in the subtribe. Leaf resin from the creosote bush [*Larrea tridentata* (Sesse & Mol. ex DC.) Coville; Zygophyllaceae], a dominant desert shrub, possessed potent antimicrobial activity in the absence of light; however, the toxicity of this extract was slightly enhanced in the presence of UVA irradiation. Phototoxic antimicrobials were not detected in extracts of selected species from the Asclepiadaceae, Chenopodiaceae, Hydrophyllaceae, Lamiaceae, Polygonaceae, or Solanaceae.

Key Words—Photosensitizers, arid/semiarid plants, Asteraceae, Zygophyllaceae, Asclepiadaceae, Chenopodiaceae, Hydrophyllaceae, Lamiaceae, Polygonaceae, Solanaceae.

²Current Address: Department of Biological Sciences, Florida International University, Miami, Florida 33199.

INTRODUCTION

Plant "photosensitizers" or "phototoxins" are chemicals produced by members of at least 30 plant families that adversely affect a wide variety of organisms in the presence of sunlight (Downum, 1986). A partial listing of susceptible organisms includes among others: viruses, phytopathogenic bacteria and fungi, nematodes, and herbivorous insects (see reviews by Towers, 1984, 1986; Downum, 1986; Downum and Rodriguez, 1986; Downum and Nemeč, 1987). In addition to these organisms, Campbell et al., (1982) demonstrated that the growth of various non-phototoxin-containing plants could be inhibited by treatment with photosensitizers common to many species of the Asteraceae (Compositae). Such broad-spectrum biological activity suggests that plant phototoxins may be involved with plant defense against a wide range of potentially deleterious or competing organisms in nature.

Although phototoxic phytochemicals have been isolated from a variety of plants, little is known about their occurrence (or biological activity) in species that evolved under high-light conditions where phototoxic action seemingly would provide a most effective plant defense. The present report is an initial effort to establish the prevalence of photosensitizers in plants that grow in environments exposed to high levels of solar irradiation (i.e., the Chihuahuan, Mojave, and Sonoran deserts of North America). Standard antimicrobial techniques were used for these preliminary survey studies, but the broad-spectrum toxicity associated with many of the previously studied plant phototoxins suggests that they may be responsible for a variety of defensive plant responses, in addition to their *in vitro* antimicrobial effects.

METHODS AND MATERIALS

Plant Material. Bulk collections for extraction and bioassay as well as voucher specimens were collected from various regions of Mexico and the southwestern United States as indicated in Table 1. Plants were air-dried in the field as much as possible and then transported to the laboratory for thorough drying (50°C for five days). Dried, powdered matter (5 g) from each species was extracted with MeOH (50 ml) for 7–10 days at room temperature under darkened conditions. The resulting extracts were filtered and concentrated to approximately 1 ml by rotary evaporation. Concentrated crude extracts were stored at –20°C until they could be bioassayed.

Species of *Pectis* were handled differently to minimize the loss of potential phototoxins, which was reported previously (Downum et al., 1985). These plants were transported from the field on ice and homogenized in MeOH within

^aWhole plant extracts were concentrated and assayed as described (see Methods and Materials). Presence (+) or absence (-) of inhibitory zones surrounding bioassay disks refers to activity following UV-A (3 hr) and dark incubation for 24 hr. Growth inhibition resulting from antibiotic action (not photoinduced) of an extract is denoted anti.

^bAcetylenes reported from genus (Bohlmann et al., 1973).

^cChemistry unknown.

^dThiophenes reported from genus (Bohlmann and Zdero, 1976, 1979; Bohlmann et al., 1973, 1980, 1983; Downum and Towers, 1983; Downum et al., 1985).

^eChromenes reported from genus (Proksch and Rodriguez, 1983).

^fGenus reported to lack polyacetylenes and thiophenes (Bohlmann et al., 1973).

^gSee Downum et al. (1985) for explanation of nomenclatural assignment.

^hGenus reported to lack acetylenic di- and terthiophenes (Downum and Towers, 1983; Downum et al., 1985).

24 hr of collection. Extracts were bioassayed immediately as their phototoxicity quickly disappeared following homogenization.

Voucher specimens of all species were deposited with Herbaria either at California Polytechnic State University, the University of California at Riverside, or the University of Texas at El Paso.

Microorganisms. *Escherichia coli* B, a gram-negative bacterium, and *Saccharomyces cerevisiae*, a yeast, were routinely used to bioassay plant extracts for antibiotic and/or phototoxic plant metabolites. Stock cultures of *E. coli* were obtained from the American Type Culture Collection (ATCC 23226); cultures of *S. cerevisiae* were obtained from the laboratory of Dr. G.H.N. Towers (University of British Columbia). Stationary phase cultures (18 hr) grown aerobically at 30°C (*S. cerevisiae*) or 37°C (*E. coli*) were used for all bioassays. *S. cerevisiae* was grown in Sabouraud dextrose broth (Difco) while *E. coli* was inoculated into nutrient broth (Difco).

Bioassay Techniques. Concentrated plant extracts (20–50 μ l) were applied to replicate sterile cellulose assay disks and then placed onto lawns of *E. coli* and *S. cerevisiae* as described previously (Downum et al., 1983). Duplicate plates were prepared for all assays. One plate was kept in the dark to determine the antibiotic action of an extract, and UV-A activation or enhancement of bio-cidal action was determined on a second plate that was irradiated by four horizontal UV-A lamps (Sylvania F40BLB; 18 W/m²). The level of irradiation used for the bioassays was approximately half that routinely encountered in the desert environment (measured at 365 nm with a Spectroline model DM-365N ultraviolet meter; Spectronics Corp., Westbury, New York).

RESULTS AND DISCUSSION

Extracts of many plants belonging to the sunflower family (Asteraceae) inhibited the growth of *E. coli* and *S. cerevisiae* cultures as did the leaf extract from the creosote bush *Larrea tridentata* (Zygophyllaceae) (Table 1) when exposed to UV-A irradiation. Several of these plant extracts also inhibited the growth of the bioassay organisms without light activation; however, this activity was less pronounced than the phototoxic activity. A limited number of extracts from species representing the Asclepidaceae, Chenopodiaceae, Hydrophyllaceae, Lamiaceae, Polygonaceae, and Solanaceae failed to elicit any kind of biological activity toward *E. coli* or *S. cerevisiae*.

Plants belonging to the Asteraceae were given preference in our survey because they represent a quantitatively important component of most arid and/or semiarid habitats in North America and because UV-mediated antibiotic activity has been associated with many plants from this large family (Camm et al., 1975). Extracts from approximately 35% of the species surveyed elicited

phototoxic responses from the bioassay organisms. Several species also contained effective antimicrobial agents that did not require light activation; these included five species of *Ambrosia*, one species of *Dicoria*, and one species of *Encelia*. The greatest number of phototoxin-containing plants belonged to the tribe Heliantheae [as revised by Robinson (1981)]. Nearly 50% of the plant extracts from members of this tribe tested positive for light-activated toxins. The Pectidinae, a subtribe within the Heliantheae, is of particular note because extracts from all of the plants in this taxonomic grouping were phototoxic toward both *E. coli* and *S. cerevisiae*.

Various polyacetylenic or thiophenic metabolites are most likely responsible for the phototoxicity of extracts from many members of the Asteraceae. Such chemicals are widely distributed in the family (Bohlmann et al., 1973) and many are potent photosensitizers (McLachlan et al., 1984, 1986; Marchant and Cooper, 1987). Thiophenes, which are biosynthetically derived from acetylenic precursors by sulfide addition (Bohlmann et al., 1973), are also powerful phototoxins (Downum et al., 1982, 1983). Although these phototoxic metabolites occur sporadically throughout the Asteraceae (Bohlmann et al., 1973), they are particularly characteristic of genera in the subtribe Pectidinae (Bohlmann et al., 1973; Downum and Towers, 1983; Downum et al., 1985). *Pectis*, the largest genus in this subtribe, is, however, phytochemically distinct from the remainder of the genera in this taxonomic grouping in that thiophenes have yet to be detected in the 20 or so species examined thus far (Downum and Towers, 1983; Downum et al., 1985). The identity of the chemical constituents responsible for the phototoxicity of *Pectis* extracts remains in question.

Leaf extracts from the creosote bush, *Larrea tridentata* (Zygophyllaceae), contained constituents that were effective biocidal agents in the absence of UV-A. The antimicrobial activity of this extract was enhanced slightly on exposure to UV-A. The creosote bush was the only plant outside of the Asteraceae to elicit both dark and UV-A-enhanced biological activity against *E. coli* and *S. cerevisiae*. Several other Zygophyllaceae genera were also bioassayed (e.g., *Guaiaacum*, *Kallistroemia*, and *Viscainoa*), but antimicrobial activity similar to that mediated by *Larrea* extracts was not observed.

Isolation, identification, and bioactivity studies of the toxic chemicals from *Pectis* spp. and *L. tridentata* are currently underway.

This preliminary study suggests that phototoxic phytochemicals are fairly common among taxonomically diverse members of the Asteraceae. Light-enhanced biocidal activity was also associated with extracts of *Larrea tridentata*, a dominant shrub throughout the Chihuahuan, Mojave, and Sonoran deserts. The presence of light-activated antimicrobial agents in plants that typically grow under high levels of solar irradiation suggests that such allelochemicals may mediate important interactions between photosensitizer-containing plants and potentially deleterious organisms in these environments. The prev-

absence of phototoxic phytochemicals in other high-light environments (e.g., tropical and subtropical habitats) is currently being investigated.

Abstract—Insect-resistant and -susceptible geranium plants (*Pelargonium xhortorum*) were chemically and morphologically compared to assess the relative importance of resistance components. Glandular and nonglandular trichome density and quantification of trichome exudate (anacardic acids) from inbred resistant and susceptible lines were determined. Three different extraction procedures were employed to quantify the anacardic acids: (1) capillary solvent extract, (2) leaf wipe, and (3) whole leaf extract. The results support the conclusion that tall glandular trichomes and the exudate they produce are the most important factors in small pest resistance in the geranium. In addition, it was shown that tall glandular trichome densities are less and the ability of the plant to express the anacardic acids as exudate on the trichome head exterior is lacking in the susceptible lines analyzed, even though all lines possessed the capability to synthesize the anacardic acids. A plant line of intermediate resistance character was shown to possess high densities of tall glandular trichomes but resembled susceptible plants in lacking the ability to express the anacardic acids as an exudate in appreciable quantities.

Key Words—Geranium, *Pelargonium xhortorum*, glandular trichomes, anacardic acids, plant defense.

INTRODUCTION

Resistance to mites and insects in the geranium (*Pelargonium xhortorum*) has been shown to be largely chemically based, resulting from a glandular trichome exudate composed of anacardic acids (10'-*o*-pentadecenyl and 12'-*o*-heptadecenyl salicylic acid) (Stark, 1975; Gerhold et al., 1984; Craig et al., 1986).

Structural details of these exudate components have been determined (Gerhold et al., 1984; Walters et al., 1988). Gerhold reported that GC analysis of leaf press collections of mite-susceptible plants did not possess glandular trichome exudate, but his collection technique did not extract material from the leaf tissue, only that found on the trichome surface. Using the leaf disk bioassay described by MacDonald et al. (1971), Winner (1975) developed a resistance index, comprised of mortality and fecundity measurements, to group plants into susceptible and resistant phenotypic classes. Using these techniques, Winner concluded that two dominant complimentary genes were required to produce the resistant phenotype.

Geraniums possess four trichome types, a tall and a short glandular trichome and a tall and short spiny-type trichome, which are easily distinguished under a dissecting microscope (Stark, 1975) (Figure 1). Chang et al. (1972) have previously presented evidence that trichome density might be related to mite resistance in the geranium. However, Chang's study was limited in scope and the researchers failed to separate the tall and short trichomes.

The purpose of the research described here is to further illuminate the important heritable aspects of the resistance mechanism by a comparison of the chemical and morphological characteristics of resistant vs. susceptible plants. Glandular and nonglandular trichome density and chemical quantification of the exudate using three different extraction procedures were performed on inbred lines of resistant and susceptible plants in an attempt to measure the possible importance of these characters in the resistance mechanism.

METHODS AND MATERIALS

Plant Materials. The five lines of geraniums used for this study were propagated as cuttings from greenhouse stock maintained in the Horticulture Department of The Pennsylvania State University. Two of the inbred lines (71-17-7 and 71-17-1) had previously been determined to be mite resistant (Stark, 1975), and two of the lines (71-10-1 and 71-15-4) had been determined to be mite susceptible (Winner, 1975). In addition, a line (71-18-6) classified as resistant by Winner, but which appears to exhibit a degree of susceptibility to mite and aphid attack in the greenhouse, was included. Plants were grown in the greenhouse at approximately 21°C and were watered as conditions dictated. Soluble fertilizer (15-16-17) was applied once a week. All plants were maintained in close proximity and were subjected to similar environmental conditions.

Chemical Analysis. The two major anacardic acids that comprise 98% or more of the trichome exudate were collected using three different techniques in an attempt to determine whether (1) susceptible plants do not synthesize anacardic acids, or (2) susceptible plants synthesize anacardic acids but are unable

FIG. 1. Scanning electron micrographs of trichomes of geranium (*Pelargonium xhortorum*): (A) upper leaf surface, 160 \times ; (B) calyx surface, 50 \times .

to translocate them to the trichome surface from their site of synthesis, thus reducing the efficiency of the system.

The first method of collection was designed to provide an estimate on a per trichome basis of the quantity of anacardic acids present on and in the trichomes of three of the geranium lines. A Pasteur pipet drawn to a fine diameter, just large enough to fit over a glandular trichome, was immersed in CH_2Cl_2 and the tip filled by capillary action. Using a binocular dissecting microscope, the tip containing the CH_2Cl_2 was placed over individual tall glandular trichomes and the solvent was allowed to extract the trichome for 10 sec. After 10 tri-

chomes had been extracted in this manner, the contents were blown into a collection vial. The entire process was repeated 50 times for a total of 500 trichomes extracted. The 500 trichomes extracted came from four leaves from four separate plants for each inbred line. Resistant line 71-17-7, susceptible line 17-10-1, and the line classified by Winner as resistant but of questionable status (71-18-6) were analyzed by this technique. After collection, the extract was evaporated to dryness under N_2 and redissolved in 50 μ l of CH_2Cl_2 containing 50.6 mg/liter octacosane as an internal standard. A 2- μ l aliquot of this final solution was then analyzed by gas chromatography using a 6-ft mixed phase SP2250/SP2401 (1.5%/1.95%) column and N_2 carrier (66.0 ml/min) at 235°C isothermal conditions. Peak areas were determined using a Hewlett Packard 3390-A integrator. A standard curve using known concentrations of anacardic acids was generated to enable approximate concentrations of anacardic acids per trichome to be determined.

The second method of anacardic acid collection is a modification of a technique described by Gerhold et al. (1984), intended to collect only that exudate on the external trichome surface by physical adhesion to the glass slide. Five plants from each of the five lines discussed earlier were included in this technique for a total of 25 plants. Three leaves collected from the third node from the apical shoot meristem were used for each analysis. Two clean glass microscope slides were pressed firmly against the leaf, sandwiching the leaf between them. The exudate was then washed from the slide into a collection vial using three 0.5-ml rinses of CH_2Cl_2 . The entire leaf surface was covered twice using this procedure. The solvent was then evaporated under N_2 , and the extract was redissolved in 200 μ l of CH_2Cl_2 containing the octacosane internal standard (50.6 mg/liter). The extract was analyzed on the gas chromatograph as previously described, immediately after the addition of the solvent. This technique was intended to collect only exudate from the external trichome surface by physical adhesion to the glass slide. This method, although not quantitative, provides a reasonable estimate of the amount of anacardic acid exuded to the trichome surface. The entire analysis was repeated for all 25 plants on two separate dates.

The third method of collection was a whole leaf extraction in which two leaves from each plant were immersed for 20 min in 10 ml of CH_2Cl_2 . The five individually labeled plants of each inbred line were analyzed for a total of 25 plants. The total fresh weight of two healthy leaves from the third node from the apical shoot meristem was determined. Preparatory experiments have shown that approximately 90% of the anacardic acids are removed in this simple immersion technique when compared to a more thorough extraction in which the tissue is homogenized. This recovery was deemed adequate since we were more concerned with relative differences between plant lines than absolute quantification. Following extraction, the solvent was evaporated to dryness

under N_2 and the sample was redissolved in 0.5 ml of CH_2Cl_2 containing octacosane as an internal standard. The sample was then analyzed by gas chromatography as described for the first collection technique.

Correlation analysis between leaf weight (an estimate of leaf "size") vs. total anacardic acid content within lines showed no significant correlation between these parameters so that leaf weight was ignored in comparisons between lines (see Discussion). The use of third-node leaves of similar size should minimize physiological differences based on leaf size or age. The only correction applied to the individually measured peak areas for the two anacardic acids was to divide each area by the area of the internal standard to correct for differences in the extract volume injected. This procedure was performed on all 25 plants in replicate one month apart, to obtain more statistically reliable results and isolate any transient environmental impacts on leaf chemistry.

Data from the second and third extraction procedures were analyzed statistically using a hierarchical design one-way analysis of variance to determine if differences between lines were greater than differences within a line. Different plants within a line was the subordinate factor, and geranium lines was the treatment factor. Means for resistant vs. susceptible, 17-7 vs. 17-1, and 10-1 vs. 15-4 vs. 18-6 were then compared using a priori methods for partitioning of the between group sums of squares (Sokal and Rohlf, 1969).

Morphological Analysis. The same five geranium lines quantitatively analyzed for anacardic acid were also analyzed morphologically for trichome densities. The densities of all four of these trichome types on the leaf surface were determined using scanning electron microscopy. While the short glandular trichomes possess a globular head, there is at present no evidence of a secretory function for this trichome type in geranium. Nevertheless, in this paper we will refer to them as short "glandular" trichomes based solely on appearance. Leaf samples of each inbred line were removed at random from geraniums grown together under uniform greenhouse conditions. Leaves were collected from the second and the fifth nodes, to permit trichome density comparisons between young expanding leaves and older more mature leaves. Square sections (3×3 mm) were removed in equal numbers from the area near the petiole, the middle leaf area, and the area near the leaf edge of each geranium line. A minimum of 10 (usually more) leaf sections from three leaves from three separate plants were observed for each leaf region for both the upper and lower leaf surfaces. This enabled comparisons between upper and lower leaf surfaces to be made and ensured an adequate representation of all areas of the leaf in the analysis.

The leaf sections were fixed in a 1:1:18 (formalin-acetic acid-ethanol) solution and were dehydrated in an ethanol series (from 20% to absolute). The following day the material was critical point dried using a Polaron E 3000 instrument and gold sputtered with a IDI-PS2 sputter coater. Observations were made and photographs taken with a model ISI-60 scanning electron microscope.

The numbers of trichomes of each type occurring on each section were determined and recorded. In all, data were recorded from approximately 900 leaf sections from six inbred lines including the five lines analyzed chemically.

Before statistical analysis, trichome counts were transformed using the square root transformation, $Y^* = \sqrt{0.5 + Y}$, to obtain a more normal distribution (Sokal and Rohlf, 1969). The transformed data were then analyzed using a two-way analysis of variance. Two separate analyses were performed, one in which the factors in the analysis were inbred lines and leaf age (second and fifth nodes) and the other in which the factors were geranium inbred line and leaf surface (upper or lower). In these analyses the data from separate leaf regions were pooled and differences in trichome densities between them were not analyzed statistically. The densities for each trichome type were analyzed individually. Densities of trichomes are reported as retransformed means from the above analysis and therefore exhibit asymmetrical confidence intervals (Sokal and Rohlf, 1969).

For each two-way analysis, the levels of the factor not included in the analysis were analyzed as separate data sets. For instance, in the analysis of variety \times age, two separate analyses were performed, one for the upper leaf surface and one for the lower, to reduce the variability from influences not directly pertinent to the factors of interest.

Since each analysis was performed separately on the four trichome types, a total of 16 sets of two-way analyses were performed. In addition to the above analysis, a stepwise discriminant analysis using the BMDP-7M statistical program package was performed. For this analysis the two resistant lines and the two susceptible lines were used to create the discriminant function between "susceptible" and "resistant" groups. Again these data were grouped using four different combinations of the age factor (second or fifth node) and leaf surface factor (upper or lower) to provide a more homogeneous data set for the analysis. Thus, four analyses of this type were performed. The four variables (trichome densities) were allowed to enter or were removed from the discriminant classification function based upon F statistic values. Variables were entered when $F > 4.0$ and removed if $F < 3.996$. The discriminant functions created by these analyses were then used to classify the 18-6 line which, although classified as resistant by Winner, seemed to resemble the susceptible plants more closely in some respects.

RESULTS AND DISCUSSION

Chemical Quantification. The means and standard errors of the quantification of anacardic acids isolated using the three different extraction techniques are presented in Figure 2.

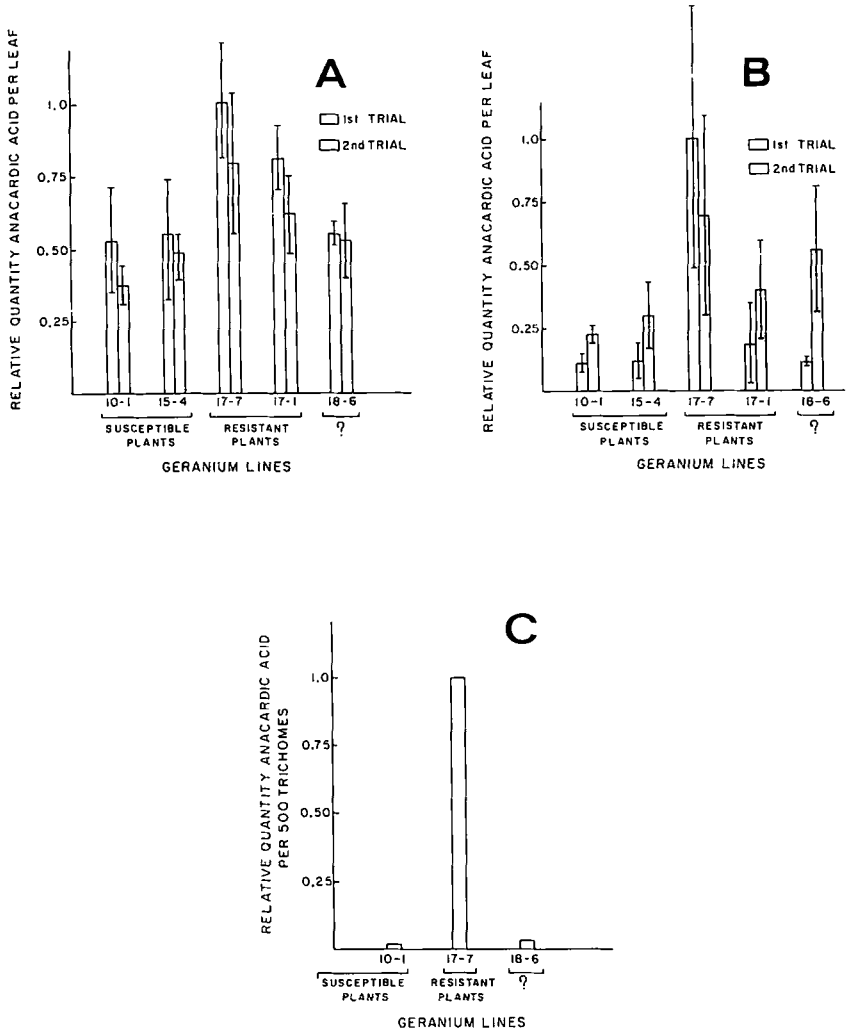

Fig. 2. Graphs of the quantification of anacardic acids from the resistant and susceptible geraniums: (A) whole leaf extract; (B) leaf press method; (C) capillary solvent extraction of individual trichomes.

The first collection technique, that of extracting individual trichomes, showed the most dramatic differences between the susceptible and resistant lines (Figure 2C); the resistant 71-17-7 trichome extract, possessed over 50 times the amount of both anacardic acids found in the susceptible 71-10-1 line extracts.

Using a standard curve based on HPLC purified anacardic acids, resistant line 71-17-7 is estimated to contain 0.11 μg per trichome.

The microscope slide collection technique was employed to estimate the trichome exudate present on the trichome exterior. As shown in Figure 2A and 2B, the differences between geranium lines for anacardic acids collected using this technique were far more dramatic than those shown in whole leaf extracts. The 71-17-7 line exhibited values close to 10 times those seen in the susceptible lines.

From the results of the whole leaf extractions (Figure 2A), it is clear that anacardic acids are present in the susceptible plants, but are less abundant. Analysis of variance of the quantification of anacardic acids showed significant differences between the five inbred lines for whole leaf extractions and microscope slide collection, the resistant plant lines having significantly higher mean concentrations of both compounds (Table 1). A priori decomposition of the between-line sum of squares shows that 44% of the leaf press between group sum of squares and 85% of that for whole leaf extraction are contributed by the resistant vs. susceptible comparison. While the most mite-resistant line (Stark,

1975), 71-17-7, also possesses the highest concentration of anacardic acids from the whole leaf extraction, this concentration is only about double the concentration of anacardic acids in the susceptible plants. This difference may be biologically significant as far as resistance is concerned, but is probably insufficient to explain the extreme differences in susceptibility exhibited by greenhouse populations containing both susceptible and resistant lines.

The results of these experiments suggest that rather than lacking the ability to synthesize the anacardic acids, as suggested by Gerhold et al. (1984), the susceptible plants may lack some essential element for translocating the compounds to the upper parts of the trichome and/or the trichome exterior from some unknown site of synthesis within the leaf or trichome base. Gerhold et al. used a lighter touch to collect the exudate, which might explain why they did not observe the anacardic acids in susceptible plants. The mechanism of transport of the exudate is unknown at this time. The inability to transport the compounds may result in their buildup at the biosynthetic site and feedback inhibition of anacardic acid synthesis or simply a shift in equilibrium between precursors and anacardic acid products. Thus the somewhat reduced levels of anacardic acids determined from the whole leaf extracts of the susceptible plants could be a secondary effect caused by an inefficient or inactive transport mechanism rather than the actual cause of susceptibility.

Line 71-18-6, which had been designated as resistant by Winner (1975), showed levels of anacardic acids as extracted by all three techniques to be more consistent with the levels in the susceptible plants rather than the resistant ones. It is important to note that line 71-18-6 is very closely related to 71-17-1 and 71-17-7 (which are sibs) and that there is no close relationship between 71-18-6 and either of the susceptible lines. When 71-18-6 was compared with the two susceptible lines using a priori decomposition of the sum of squares, no significant differences were observed (Table 1). Day-to-day observations of this plant line in greenhouse cultures have indicated it is of intermediate character concerning pest resistance. The discriminant function based on tall glandular and tall spine trichome density differences between resistant and susceptible lines indicated 71-18-6 to fall in the "resistant" category.

Trichome Density Quantification. Height distributions of the four trichome types are presented in Table 2. These data illustrate the clear separation of both glandular and nonglandular trichomes into discrete long and short size classes with little overlap. In addition to size, the long and short glandular trichomes may be distinguished by observing the epidermal cells adjacent to the trichome base. Long glandular trichomes possess a group of six cells arrayed in a spoke-like pattern about the trichome base, while the short type possess no such associated epidermal cells (Figure 1A). In addition, the brownish yellow exudate present in the long glandular trichomes from resistant plants is completely lacking in all short glandular trichomes.

TABLE 2. GERANIUM LEAF TRICHOME SIZE DISTRIBUTION

Trichome type	Sample size	Mean height (μm)	Standard error (μm)	Height range (μm)
Short glandular	90	46.22	4.87	30-60
Tall glandular	74	206.89	9.06	100-400
Short spines	61	136.88	4.55	60-200
Tall spines	56	328.57	13.74	220-600

Short Glandular Trichomes. A summary of the results of the two-way ANOVAs is presented in Table 3. There is virtually no correlation between mite resistance and the density of short glandular trichomes (Figure 3A). The two-way ANOVA for plant line \times surface showed no significance for plant line when the second-node leaves were compared. The fifth-node leaves did possess significant differences between lines, but there was no apparent association with resistance since the significance resulted from the high density of short glandular trichomes on 71-17-1, with all other lines having lower and similar densities. The two-way analysis for plant line \times leaf age was divided into two data sets, one for the upper leaf surfaces and one for the lower surfaces, as described earlier, to provide for a more homogeneous data set. This is especially important in this analysis since the surface (upper and lower) has a large impact on short glandular trichome density (Figure 3A).

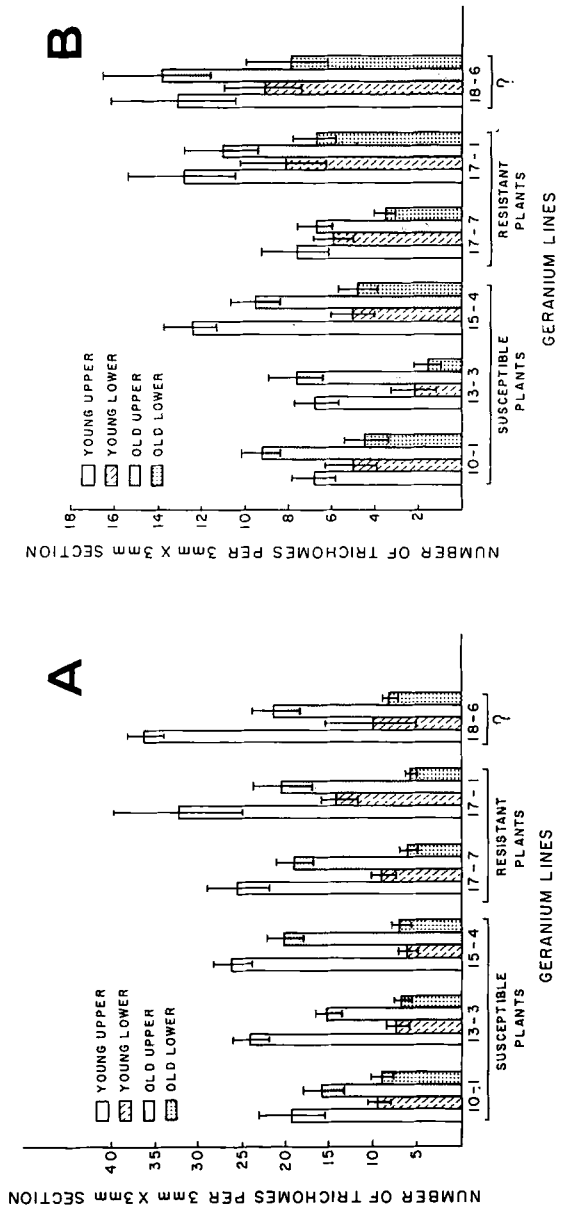

Resistant line 71-17-1 has the greatest density of short glandular trichomes for three of the four leaf surface classes (old upper, old lower, young upper, young lower), but resistant line 71-17-7 has only moderate densities for this trichome type (Figure 3A). Conversely, susceptible line 71-15-4 exhibits high densities of short glandular trichomes on upper leaf surfaces but more moderate densities on the lower surfaces. The fact that upper leaf surfaces possess short glandular trichome densities two to three times that of the lower leaf surfaces and that there is no correlation between degree of resistance and short glandular trichome density indicates these trichomes may not function in the resistance mechanism.

Short Spines. Density data for short spiny trichomes are illustrated in Figure 3B. Again, as with the short glandular trichomes, the ANOVA indicates significant differences in the density of short spiny trichomes among plant lines, but the differences are not related to mite resistance of the plant. As with the short glandular trichomes, resistant line 71-17-1 and susceptible line 71-15-4 exhibit the highest densities, with the other three lines possessing lower, somewhat variable densities. The variety that shows the greatest resistance to mite and aphid attack, 71-17-7, possesses short spiny trichome densities comparable

TABLE 3. SUMMARY OF TWO-WAY FACTORIAL ANOVAS ON TRICHOME DENSITIES^a

Trichome type	Plant line × surface factorial			Plant line × age factorial

FIG. 3. Distribution of geranium trichomes on resistant and susceptible lines: (A) short glandular trichomes; (B) short spine trichomes; (C) tall glandular trichomes; (D) tall spine trichomes.

to those of the susceptible varieties 71-10-1 and 71-13-3. Likewise, in a distribution similar to that of the short glandular trichomes, although to a somewhat lesser extent, the density of the short spiny trichomes is clearly greatest on the upper leaf surface. While of possible importance in pest resistance, this type of trichome appears not to be the character lacking in our mite- and aphid-susceptible plant lines. If such were the case, one might expect 71-15-4 to be more resistant than it is. Figure 3B illustrates the homogeneous distribution of short spine density between plant lines and the lack of association with mite resistance. With some exceptions, the density of short spines decreases in the older more fully expanded leaves parallel to the decrease shown by the short glandular trichomes. It should not be implied here that the short spines are not a factor in pest resistance. Mites and aphids observed on the leaf surface have difficulty in traversing these spines and in finding acceptable feeding locations on the leaf because of them. It can be stated, however, that they alone are unable to provide resistance to the pests thus far assayed (mites, aphids, whiteflies).

Tall Glandular Trichomes. Density data for this portion of the indumentum is presented in Figure 3C. The trichome density differences between lines are highly statistically significant and closely associated with the resistance phenomenon. The most resistant line, 71-17-7, has by far the highest tall glandular trichome densities, followed by its resistant partner, 71-17-1. The density of tall glandular trichomes on 71-17-7 leaves is three or more times that of the susceptible plants in all four leaf regions analyzed. Figure 3C illustrates the extremely large differences between resistant and susceptible plant lines in terms of tall glandular trichome densities. While exhibiting some variability, the density values determined for each of the plant line \times leaf age subclasses are reasonably consistent. It appears that tall glandular trichome density may be a primary factor in determining degree of mite resistance in (*P. xhortorum*). This is in spite of the fact that the short glandular and short spiny trichomes are nearly 10 times as abundant on the geranium leaf surface. In contrast to the previous two trichome types, the tall glandular trichomes do not exhibit a markedly higher density on the upper leaf surface. There is no consistent trend for differences between upper and lower densities; each of the inbred lines exhibits its own trend, and the differences are not pronounced. Differences between young and old leaves are also not as clear in this trichome type as in the others. The two-way ANOVA for plant line \times leaf age, using data for the lower leaf surface, showed the differences to be nonsignificant, while the differences shown among upper leaf surfaces were of borderline significance. This again is probably more a result of the low tall glandular trichome densities and the resulting possibility for somewhat larger error in estimating true densities. This is supported by microscopic observations that young undeveloped tall glandular trichomes are not present on any but the youngest and most undeveloped geranium leaves, and thus they must decrease in density as the leaf expands and ages. It may be noted that although no formal comparisons were made, the tall glandular tri-

chome densities found on the pedicel and sepal surfaces of the inflorescence are clearly several times those found on leaf surfaces in all plant lines examined. Investing much of its defensive energies in protecting structures responsible for continuation of its line might be advantageous for a plant and a further indication of the importance of the tall glandular trichomes in pest resistance.

Tall Spines. The fourth and final trichome type analyzed for density was the tall spines. These data are presented in Figure 3D. Comparison of tall spiny trichome densities between resistant and susceptible plants indicates a fairly close association between high density and resistance (Figure 3D). Both resistant lines possess densities much higher than two of the three susceptible lines; however, 71-15-4 has relatively high densities equal to those of the resistant lines. If, as suggested by the high densities found on the resistant plants, the tall spiny trichomes do play a role in the resistance phenomenon, they clearly are not sufficient in themselves to provide resistance given the high densities found on susceptible 71-15-4. In all cases, save one, comparing the tall spiny trichome density for a specific line and leaf surface shows the younger surface to be more dense than the older one. Inspection of the data shows that tall spiny trichome densities are similar to the tall glandular trichome densities and well below those of the two short trichome types. With two exceptions (young leaves of 71-15-4 and 71-13-3), the upper leaf surface possesses more tall spines than the lower leaf surface following the general trend of both the short spines and the short glandular trichomes.

Analysis of variance of these data generated in this study showed significant differences for most of the interactions and main effects tested for all four trichomes. There is, however, a distinction between statistically significant and biologically meaningful differences as related to their importance in the resistance mechanism. Such differences must be correlated with the expression of resistance in order to suggest a function within the resistance mechanism.

Microscopic observations of many geranium leaf surfaces have shown, without exception, that even extremely young leaves possess a full complement of trichomes which, because of the unexpanded nature of the leaf, are very dense. This may be an economical way for the plant to protect the leaf most when it is young and with a long useful period of productivity ahead of it; it expends less energy and resources on protection of the leaf as it ages and the period of its usefulness to the plant is decreased.

From the results of this study it may be concluded that there are two factors possessed by mite- and insect-resistant lines of geraniums that are lacking in the susceptible varieties used in this study. Resistant lines have higher densities of tall glandular trichomes and are better able to express the anacardic acids as an exudate on the trichome exterior. Furthermore, we have shown that the susceptible lines, while possessing somewhat less anacardic acid per leaf, are nevertheless able to manufacture the compounds in significant quantities. Consequently, one genetic defect in the susceptible plants could be a malfunctioning

component of the translocation system for the defensive compounds. Plant line 71-18-6 is of special interest for future biochemical and genetic work, since it seems to possess a complement of tall glandular trichomes equal to that of the resistant plants but, at the same time, under some conditions, it is deficient in the expression of anacardic acids as exudate on the trichome surface as are the susceptible plants (unpublished data).

Although the tall glandular trichomes are apparently of primary importance in the resistance mechanism, it seems likely that the spiny trichomes are a necessary component as well. The fact that line 71-17-1 is close to 71-17-7 in degree of mite resistance may be due to the high density of short spines 71-17-1 produces, even though it produces less exudate from the tall glandular trichomes. By restricting movement and forcing a mite, aphid, or other small insect to travel between the long spines, the geranium is able to cause increased contact between the pest and the tall glandular trichome exudate. The spines are undoubtedly "cheaper" for the plant to produce and maintain in terms of energy and nutrient resources than an equivalent number of the glandular trichomes. Thus, the plants can increase the effectiveness of a relatively low density of exudate-producing glandular trichomes by producing higher densities of the metabolically less expensive spiny trichomes.

Abstract—The role of intracellular symbionts contributing to their host has been investigated in the planthoppers, *Nilaparvata lugens* Stal and *Laodelphax striatellus* Fallen. We have found that the isolated yeastlike symbionts, identified as a member of the genus *Candida*, from the host's egg produce ergosterol when cultured. A comparative study of sterols in the cultured symbionts, the host insects, aposymbiotic host insects, and dietary plants demonstrated that ergosterol produced in the symbiotes is provided to the host insects and possibly transformed in the host insects into cholesterol via 24-methylenecholesterol. The conversion of injected 24-methylenecholesterol- d_3 into cholesterol has been shown in the brown planthopper (*N. lugens*).

Key Words—Biotransformation, cholesterol, 24-methylenecholesterol, ergosterol, brown planthopper, *Nilaparvata lugens* Stal, smaller brown planthopper, *Laodelphax striatellus* Fallen, Homoptera, Fulgoridae, symbiosis, intracellular symbiont.

INTRODUCTION

Most arthropoda, such as insects and crustaceans, require cholesterol, since they are incapable of steroid synthesis *de novo* (Clayton, 1964) and utilize dietary steroids as the source of membrane constituent as well as the precursor of 20-hydroxyecdysone (Svoboda et al., 1975), the common molting hormone. In contrast with most other insects, plant-sucking homopterans, such as planthoppers, aphids, and leafhoppers, can be reared on a chemically defined artificial

diet free of sterols (Noda and Mittler, 1983), an observation suggesting the nutritional role of symbionts harbored (Nasu, 1965) in these insects. However, this is disputed in a recent study on the aphid *Schizaphis graminum* (Campbell and Nes, 1983). The intracellular symbiotic microorganisms contained within the mycetocytes or fat bodies of aphids, leafhoppers, and rice planthoppers are transmitted into the eggs to the next generation via transovarial infection (Noda and Mittler, 1983). The success in isolating yeastlike symbionts of *L. striatellus* and *N. lugens* and maintaining them in permanent culture (Kusumi et al., 1979, 1980; Nasu et al., 1981) has made it feasible to study the biosynthetic capabilities of these symbionts in the culture medium. Preliminary studies with several symbiotic cultures have demonstrated that symbionts play a dual role (Fredenhagen et al., 1987a), i.e., provision of sterols to the host insect and production of antibiotics for the self-defense of hosts (Fredenhagen et al., 1987a,b).

We describe here qualitative and quantitative analysis of the steroids in the cultured symbionts, the host insects, the aposymbiotic host insects, and the dietary plants. The results indicate that the yeastlike symbionts produce ergosterol and provide it to the host as the possible source of 24-methylenecholesterol and cholesterol. This hypothesis was supported by the transformation (35%) of injected 24-methylenecholesterol- d_3 into cholesterol in the brown planthopper (*N. lugens*).

METHODS AND MATERIALS

Insects and Host Plants. The brown planthopper (rice BPH), *N. lugens*, and the smaller brown planthopper, *L. striatellus*, were obtained from the International Rice Research Institute in the Philippines, while the leersia BPH was collected in Indonesia. The insects were reared in plastic cages with their host plants, *Oriza sativa* L. Koshihikari for rice BPH and *Leersia hexandra* for leersia BPH, the plants being grown in potted soil, 5–10 cm high. The cages containing insects and host plants were kept in a greenhouse at 25–28°C, with a 16-hr light and 8-hr dark photoperiod. For a comparative study, both sexes of third- to fourth-instar nymphs, adults, and aposymbiotic insects were used; the third-instar nymphs and adults were maintained at 35°C for three days and then transferred to room temperature, 25°C, and allowed to feed on rice plant for seven days. These aposymbiotic insects have greatly reduced numbers of symbionts and fail in ecdysis. However, dietary administration of cholesterol rather than sitosterol partly overcomes this problem (Noda and Saito, 1979). The leaves and stems of the dietary plants, Koshihikari, and *L. hexandra* were extracted and analyzed, respectively, as described below.

Symbionts. The morphologically and physiologically different yeastlike symbionts were isolated from the eggs (Kusumi et al., 1979); i.e., Ls-1 and

Ls-2 were from *L. striatellus* and N1-1 and N1-2 were from *N. lugens*. After pasteurization of the surface, the eggs were homogenized in saline and cultured on Grace's agar plate. The symbionts thus isolated were cultured in 1 liter of sterol-free Burkholder medium for four weeks at 30°C. The work-up of the culture broths was as described for the isolation of the sterols from insects (see below). These yeastlike symbionts were identified as a member of the genus *Candida* (Amano, unpublished¹).

Biotransformation. Brown planthoppers *N. lugens*, of third- and fourth-instar nymphs were injected (between the midcoxa and metasternum) with a glass microsyringe with deuterium-labeled 24-methylenecholesterol (see below) emulsified in 20% glycerol and 0.2% Emulgen 913 in water, at a concentration of 2mg/100 μ l (about 0.001 μ l/insect). The injected insects were transferred to cages with rice plants and sacrificed on day 3 or 7 by chilling in a -20°C freezer to see the relative rate of biotransformation.

Isolation of Steroids. Using a Tenbrock grinder 130-200 insects were homogenized in 10 ml chloroform-methanol (2:1) and sonicated for 1 hr. The suspension was centrifuged at 3000 rpm for 5 min, and the organic layer was evaporated to dryness. The residue was then extracted with 40 ml hexane-methanol (1:1) and divided into two fractions. The upper layer, containing free sterols and their esters, was hydrolyzed (90°C, 3 hr) with 0.5 ml 10% methanolic potassium hydroxide in 5 ml water. The lower layer, containing steroidal glycosides, was treated with 5% methanolic hydrogen chloride at 90°C for 3 hr. After work-up of each hydrolysate, the combined free sterol fraction was purified on a silica gel TLC (Kieselgel 60 F254 DC-Fertigplatten Art. 5744 and HPTLC-Fertigplatten Art. 5628, Merck) using ether-hexane (1:1) and the R_f region corresponding to sterols was removed and eluted with chloroform-methanol (2:1). After evaporation of the solvent, the residue was silylated in the usual manner using pyridine, hexamethyldisilazane, and trimethylchlorosilane (2:1:1 v/v). The TMS-derivatized sterols were dissolved in 20 μ l chloroform and 5- μ l aliquots of this solution were analyzed using GC-MS. The TMS-derivatized sterols from the control insects of the same colony reared under identical conditions were used for comparative purposes in the insect biotransformation.

Analysis. Sterols were analyzed with a Hitachi M-80 GC-MS spectrometer equipped with a OV-1 packed column (3 mm \times 1 m). GC conditions were as follows: oven temperature 175-250°C (2°C/min), He gas flow rate 4.7 ml/sec. The Hitachi mass spectrometer was linked to a model M-003 data processing system. The transformation of [23,25-d₃]-24-methylenecholesterol to cholesterol in the insects was measured by intensity enhancement of the M+3 isotope

¹ Referring to Kreger-van Rij (1984), we identified both yeast strains, Ls-1 and NL-2 as a member of the genus *Candida*; Kreger-van Rij, N.J.W. (ed.), 1984. The Yeasts, A Taxonomic Study. XVI + 1082 pp., Elsevier, Amsterdam.

peak due to deuterium incorporation. The dispersion of the M+3 (m/z 461) isotope peak intensity of the standard TMS cholesterol (or recovered TMS cholesterol from insects) at $1 \mu\text{g}/5 \mu\text{l}$ chloroform was maximally 3.5% in 12 repeated runs of 10–20 scans, the m/z 458 M^+ peak being adjusted to 100%.

Chemicals. Sterol standards and reagents were purchased from Nakarai Chemicals, Ltd. and Tokyo Kasei Kogyo Co., Ltd. Emulgen 913 (biological detergent) was a gift from Kao Co., Ltd.

SCHEME 1. Synthetic scheme of 24-methylenecholesterol- d_3 .

Synthesis. The deuterium-labeled [23,25- d_3]-24-methylenecholesterol **1** was synthesized in seven steps from 3 β -hydroxy- Δ^5 -choleonic acid **2** (Scheme 1). The THP-ester **3** (**2** and 3 equiv. of dihydropyran in benzene with pTSA at room temperature under N_2 for 18 hr, 76%) was transformed into the corresponding aldehyde **4**: 3 equiv. of diisobutylaluminum hydride in 1 M hexane solution in toluene at -78°C for 15 min under N_2 (Zakharkin and Khorlina, 1962), quenched with 50% aq. MeOH at -78°C for 30 min and chromatography on alumina, hexane–ether, 85:15, 73%. Grignard coupling of **4** with isopropyl magnesium iodide gave **5** (3 equiv. in diethylether at 25°C for 1 hr followed by usual treatment), which was oxidized to ketosteroid **6** (pyridinium chlorochromate in dichloromethane under N_2 at 25°C for 30 min).

The ketosteroid **6** was transformed into the desired product **1**, overall 80%, by the following sequence: (1) Deuteration of ketosteroid (41.5 mg of **6** in 4 ml methanol- d_4 , 0.5 mg of deuterium oxide and 3 mg of anhydrous sodium carbonate at 70°C for 20 min, evaporated to dryness and the cycle repeated four times; Nolin and Jones, 1952); (2) Wittig coupling to give the 24-methylene steroid **8** (deuterated ketosteroid **7** with 2 equiv. of triphenylmethylphosphorane in ether under N_2 at 25°C for 15 min; Newman, 1960); (3) hydrolysis (1 N HCl in methanol for 1 hr at 25°C , neutralization with sat. aq. sodium bicarbonate, extraction and flash chromatography on Kieselgel 60 Art 9385, hexane–ethyl acetate). The synthetic product **1** was identified by the NMR spectrum recorded on a Nicolet NT-360 spectrometer, $\delta(\text{CDCl}_3)$: 5.35 (1H, m, 6-H), 4.71 and 4.66 (2H, dd, $J = 2, 28$ Hz, 24-H), 3.48–3.58 (1H, m, 3-H); m/z

401, $C_{28}H_{43}D_3O$: (M^+), (26%); $386(M-CH_3)^+$, (39%); $314 (M-C_6H_9D_3)^+$, (100%). The percentages of d_3 (m/z 401), d_2 (m/z 400), and d_1 (m/z 399) of the deuterated 24-methylenecholesterol after subtraction of natural abundance ^{13}C isotope were 54.0, 42.6, and 5.0% respectively.

RESULTS AND DISCUSSION

Sterols from Cultured Intracellular Symbionts. Ergosterol was the only sterol found in the culture broth (1 liter) of Ls-1 and Ls-2. Mixed cultures of Ls-1 and Ls-2 or addition of mevalonic acid (5 mg/l) did not change the products. No sterols could be detected, however, from the cultured medium of symbionts NI-1 and NI-2. Instead, a series of compounds i.e., lanosterol, 24-methylenelanosterol, dihydroergosterol, and ergosterol (major), suggestive of an intracellular biosynthetic buildup of ergosterol from mevalonic acid was detected in the cells of NI-1 and NI-2. The cells of Ls-1 and Ls-2 also contained the same set of compounds, although in much smaller quantities. The above result indicates that ergosterol was found in intact *N. lugens* but only a trace amount in *L. striatellus* (see below). Detection of 24-methylenecholesterol in *L. striatellus* and *N. lugens* may demonstrate differences in the mode in which the symbiont-synthesized sterol was made available to the host, an observation in agreement with the hypothesis that different symbionts fulfill different physiological roles (Griffiths and Beck, 1975; Hinde, 1971).

Sterols in Host Insects. In both rice brown planthopper (BPH) (*N. lugens*) and leersia BPH, the sterols consisted of cholesterol, 24-methylenecholesterol, and ergosterol (Figure 1). It is noted that the relative content of 24-methylenecholesterol is greater in adults than in nymphs. In both adult and nymph of aposymbiotic insects seven days after heat treatment, the amounts of ergosterol and 24-methylenecholesterol relative to cholesterol, as well as the total amount of sterols, were reduced drastically. On the other hand, in the smaller brown planthopper, *L. striatellus*, a small amount of sitosterol was found. This result is in agreement with a previous report (Noda and Saito, 1979). The ratio of nonconverted dietary steroids to insect steroids was rather small. Approximately 4–8 mg of each sterol was detectable in each of the isolated samples from 130 insects by the mass chromatographic GC-MS of the TMS derivatives. The body cholesterol content of the apo-insects was reduced to $\frac{1}{10}$ of that of the control, in agreement with the previous studies (Noda and Saito, 1979).

Sterols in Host Plants vs. Rice BPH and Leersia BPH. Sterols of the rice plant Koshihikari and *L. hexandra* showed that the former contained sitosterol, stigmaterol, campesterol and their respective esters, while the latter contained sitosterol, stigmaterol, campesterol, cholesterol, and their respective esters and

FIG. 1. Sterol constituents in combined sterol fraction from normal and aposymbiotic *N. lugens* (rice BPH and leersia BPH); relative contents of sterols are normalized to cholesterol.

glycosides. The presence of cholesterol in *L. hexandra* may account for the higher ratio of cholesterol in leersia BPH (Figure 1). Thus, the possibility that ergosterol originates from the food chain can be ruled out.

Biotransformation of 24-Methylenecholesterol-d₃ to Cholesterol in BPH.

In vivo conversion was demonstrated upon administration of labeled compound emulsified in glycerin and Emulgen 913® to BPH. The cholesterol-d₃ was found in insects harvested on both days 3 or 7 after injection. On the basis of the injected 24-methylenecholesterol-d₃, 54%, the cholesterol-d₃ recovered from insects was found to be 13 and 19% upon GC-MS (after subtraction of the $\pm 3.5\%$ natural abundance isotope effect, see above), corresponding to conversions of 24 and 35%, respectively. Dealkylation of the 24-methylenecholesterol to cholesterol in BPH was thus proven, the conversion of which was shown previously in *Manduca sexta* (Thompson et al., 1973). The high level of this conversion in the insects demonstrates the utilization of 24-methylenecholesterol as the main source of cholesterol. Although the transformation of ergos-

terol to 24-methylenecholesterol and sitosterol to cholesterol has as yet not been proven quantitatively, comparative study among insects may indicate 24-methylenecholesterol is accumulated after transformation. The conspicuous decrease of 24-methylenecholesterol in the apo-insects may suggest the fast turnover of the ergosterol supplied by the symbionts and not of campesterol from the host plants. Ergosterol is the obligatory nutrient in the ambrosia beetle (*Xyleborus ferrugineus*), which carries endosymbiotic fungi (Rao et al., 1983).

The hypothesis that the sterols are synthesized and supplied, at least partly, by their associated symbionts has been elucidated in the present studies. It has previously been reported that the prokaryotic symbionts in the pea aphids (*Neomyzus circumflexus* and *Acrythosiphon pisum*) synthesize sterols (Ehrhardt, 1968; Houk et al., 1976) in agreement with their possible role as a steroid supplier. However, Campbell et al. (1983) reported that dietary [2-¹⁴C]mevalonic acid was not converted to steroids in the aphid but dietary [4-¹⁴C]sitosterol was converted to cholesterol. Therefore, reinvestigation using isolated symbiont cultures is desirable, because bacteria and mycoplasmal prokaryotes generally lack the ability of steroid synthesis (Nes and Nes, 1980).

Abstract—The responses of individually housed crayfish (*Orconectes virilis*) were recorded during introduction of water from aquaria containing disturbed or undisturbed animals. When female *O. virilis* were disturbed, form II males assumed low-level alert postures significantly more than when those females were undisturbed. Similar results were obtained when the source animals were female *Cambarus diogenes*, a sympatric crayfish. When the newt *Notophthalmus viridescens* was disturbed, the crayfish responses were strong but resembled stress behavior. The responses by crayfish to disturbed vs. undisturbed catfish (*Ictalurus natalis*) were not significantly different.

Key Words—Pheromone, disturbance, crayfish, *Orconectes virilis*, cross-phyletic communication, stress, female crayfish.

INTRODUCTION

The detection of stressed conspecific individuals has been reported in earthworms (Ressler et al., 1968), several types of molluscs (Landauer and Chapnick, 1981; Sleeper et al., 1980), insects (Levinson et al., 1974), and mammals (Valenta and Rigby, 1968). The responses of crayfish to a chemical or chemicals given off by stressed (but not injured) conspecific individuals have been used to demonstrate the existence of disturbance pheromones (Hazlett, 1985a). Observations (Hazlett, 1985b) have indicated that these pheromones are neither specific to a particular form of stress that a crayfish experiences nor are they

species specific. Individuals of *Orconectes virilis* respond to water containing stressed males of *O. virilis*, *O. rusticus*, or *O. propinquus* (Hazlett, 1985b).

Recent work has indicated a number of cases in which chemical communication occurs across phyletic lines. This often is observed in the form of predator detection (Scrimshaw and Kerfoot, 1987; Petranka et al., 1987; Werner, personal communication) and can have both behavioral and morphophysiological consequences for prey animals. The experiments reported herein were designed to look for chemical communication across major phyletic lines as well as to examine the question of release of disturbance pheromones by female crayfish.

METHODS AND MATERIALS

Experiments were conducted at the University of Michigan Biological Station near Pellston, Michigan, during July and August 1986. Methods were identical to those described earlier (Hazlett, 1985a, b). The crayfish tested were all individuals of *Orconectes virilis* collected from either Douglas Lake or the Maple River. Test individuals were housed in individual 10-gallon aquaria that were visually isolated. Each test crayfish was provided with a rock burrow and was tested with just one type of water on any given day. Water was introduced via a peristaltic pump at the rate of 20 ml/min for a test period of 8 min.

The sources of water introduced to the test individuals of *O. virilis* were aquaria that had been filled partially with untreated, well-aerated water from Douglas Lake and in which one or more individuals of the source animals had been living for two to four days. The types of source animals were two species of crayfish and two species of aquatic vertebrates: female crayfish in a different genus (*Cambarus diogenes*), female crayfish of the same species (*O. virilis*), members of a school of young yellow bullhead catfish (*Ictalurus natalis*) that had been collected in Douglas Lake near Sedge Point, and two individuals of the aquatic phase of the red-spotted newt (*Notophthalmus viridescens*) collected in East Point Pond near Douglas Lake. The two latter species were chosen on the bases of being taxonomically unrelated to crayfish, not common predators of adult crayfish, and cooccurring with the test species.

For the tests when the source animals were female *O. virilis*, all of the test crayfish were male *O. virilis*, which were form II, the sexually inactive form of cambarine crayfish (Word and Hobbs, 1958). In the other tests, both form I males and female *O. virilis* were utilized.

For each type of source animal, water was introduced to resting, undisturbed test animals under two conditions: (1) when the source animals appeared quiet and undisturbed and (2) when the source animals were disturbed by a simulated predator (chased by an aquarium net). All statistical tests compared

the responses shown during introduction of water from the disturbed vs. undisturbed condition for a given type of source animal.

The behavior patterns recorded have been described earlier (Hazlett, 1985a, b) and involved three positions (raised, neutral, lowered) of three body parts (chelipeds, cephalothorax, abdomen). Earlier work showed that the primary response by crayfish to disturbance pheromones was assumption of a neutral posture. Therefore the data compared in this study are the number of seconds spent by test crayfish with any body part in the neutral position. Because a number of the comparisons involved data sets with unequal variance, the non-parametric median test was used for statistical comparisons. Not all the test animals were used with both disturbed and undisturbed water, thus paired statistical tests were not used.

RESULTS

The reactions of test crayfish during the introduction of water from different sources are summarized in Table 1. The strongest difference in behavior patterns shown by individuals of *O. virilis* to water from disturbed vs. undisturbed animals was in the case of the salamander *Notophthalmus viridescens*. The crayfish showed no response (remained in the lowered posture typical of resting animals) when water containing undisturbed newts was introduced. When the newts were disturbed, the reactions were quite rapid and unusual. Although the positions assumed by the crayfish were categorized as "neutral," the postures of the chelipeds and walking legs were not the same as those exhibited during introduction of water from other stressed animals (Hazlett, 1985b). The angles between limb segments were unusual and could best be described as contorted. Rather than appearing to be on "low-level alert" (Hazlett, 1985b), the crayfish behaved as if in a distressed state themselves.

TABLE 1. AVERAGE NUMBER OF SECONDS DURING OBSERVATION PERIODS SPENT BY INDIVIDUALS OF *O. virilis* WITH ONE OR MORE PARTS IN NEUTRAL POSITION WHEN WATER FROM VARIOUS SOURCES WAS INTRODUCED^a

Source of water	N	Mean No. seconds		P from median test
		Undisturbed	Disturbed	
<i>Notophthalmus</i>	14	0	196	0.0003
<i>Ictalurus</i>	36	61	116	0.1904
<i>Cambarus</i>	14	41	104	0.0285
<i>O. virilis</i>	23	52	111	0.0291

^aN represents the total number of tests with a particular source.

The responses shown to disturbed and undisturbed bullhead catfish were not significantly different from one another (Table 1). While the crayfish tended to assume neutral postures more frequently when water from disturbed catfish was introduced, the difference was not significant.

In the case of water from disturbed and undisturbed female crayfish of the species *Cambarus diogenes*, the responses shown by individuals of *Orconectes virilis* were significantly different (Table 1). The crayfish assumed the neutral posture much more frequently when water from an aquarium containing disturbed *C. diogenes* was introduced. In a similar fashion, water from female conspecifics elicited different responses on the part of form II male *O. virilis*, depending upon the state of the female crayfish (Table 1). Form II males assumed one of the neutral postures for more of the observation period during the introduction of water from disturbed female conspecific individuals compared to undisturbed individuals.

DISCUSSION

The observation that crayfish of one species (*Orconectes virilis*) react to chemicals from a variety of species of disturbed animals would seem to strengthen the idea (Hazlett, 1985b) that the chemical(s) involved is not very specific. Production of a chemical or class of chemicals that induces low-level alert in totally unrelated individuals points toward the communication resulting from the detection of a chemical that occurs simply from increased activity on the part of another animal. Neither the conditions leading to the increase in activity nor the type of animal involved appear to be critical. While more experiments with crayfish as recipients are needed to test the generality of this suggestion, what may be of more widespread importance is the possibility that whole communities of aquatic animals could cue in on potentially detrimental situations by responding to (the chemical results of) a disturbance to any member of the community.

It was noted earlier (Hazlett, 1985b) that the lack of a clear response by male crayfish to disturbed female crayfish was puzzling and perhaps the result of confounded chemical messages. That is, introduction of water from disturbed female conspecifics could produce stimulation of males with both sex pheromones (Hazlett, 1985a) and disturbance pheromones. Form II male crayfish are said to be sexually inactive, thus they should be less "confused" by reception of any female sex pheromone. The results of this study indicate that when the chemical message channel is simplified (by use of form II males), the production of disturbance pheromones by females is demonstrable. This was also shown by the response differential shown to waters from disturbed and undisturbed females of the genus *Cambarus*. While there appears to be some cross-species detection of sex pheromones within the genus *Orconectes* (Tierney and

Dunham, 1982), the results reported here would indicate little confusion via sex pheromones across genera.

The responses of the crayfish to water from disturbed newts appeared qualitatively different from the responses to other disturbed animals. The newts may have been giving off a toxin (Pough, 1971), rather than a pheromone in the narrow sense. The lack of a clear differential in response to bullhead catfish by crayfish was a bit surprising given the established response by catfish to disturbance (Al-Hassan et al., 1985; Todd et al., 1967). While it is possible that the "undisturbed" catfish in these tests were not really undisturbed, the demonstration of cross-phyta detection of a nontoxic disturbance chemical remains for future work. It is crucial for such tests that laboratory conditions allow maintenance and observation of undisturbed individuals of both the recipient and source species.

DIFFERENTIAL EFFECT OF TOMATINE AND ITS
ALLEVIATION BY CHOLESTEROL ON LARVAL
GROWTH AND EFFICIENCY OF FOOD
UTILIZATION IN *Heliothis zea*
AND *Spodoptera exigua*

(Received August 10, 1987; accepted December 21, 1987)

Abstract—The effect of tomatine on larval growth of *Heliothis zea* and *Spodoptera exigua* was assessed by rearing larvae on diets with different concentrations of the chemical added. When reared from neonates, linear dose-response relationships were obtained for both species, with *S. exigua* being three times more sensitive to tomatine than *H. zea*. Tomatine toxicity was completely alleviated in *H. zea* by the addition of equimolar cholesterol into the diet; however, in *S. exigua* some toxicity was maintained. Larvae of *S. exigua* that were started on control diet were insensitive to tomatine after five days; larvae started on diet with an EC_{50} of tomatine and then switched to control diet after five days failed to recover from toxicosis. Larval growth of *H. zea*, on the other hand, was affected both at the neonate and third-instar stage, but normal growth resumed when the larvae were transferred to control diet. Tomatine had little or no effect on food consumption, assimilation, or dietary utilization of the food by third-instar larvae of *S. exigua*, except at a concentration 10 times the EC_{50} . In contrast, the efficiency of food utilization of *H. zea* larvae decreased with increasing tomatine concentrations. Assimilation of the food tended to increase, although not significantly, as tomatine levels increased. Food consumption of *H. zea* larvae also increased when the tomatine concentration was greater than an EC_{50} . The addition of equimolar cholesterol to diets with an EC_{50} of tomatine restored weight gain and nutritional indices values to control values. These results are related to the utility of using tomatine in host-plant resistance programs.

Key Words—Lepidoptera, Noctuidae, *Heliothis zea*, *Spodoptera exigua*, *Lycopersicon esculentum*, tomato, saponin, glycoalkaloid, tomatine, cholesterol, developmental sensitivity, nutritional indices, allelochemical interactions, host-plant resistance.

INTRODUCTION

Saponins from a variety of plants have been implicated as bases of constitutive resistance to attack by insects. Saponins from alfalfa seed have been shown to inhibit growth of *Tribolium castaneum* (Herbst) larvae (Shany et al., 1970a,b). Growth reduction is mainly due to the aglycone moiety, with the sapogenin medicagenic acid being most toxic. Applebaum et al. (1965, 1969) showed that the developmental incompatibility of the bruchid *Callosobruchus chinensis* L. with soybeans was at least partly due to the presence of soybean saponins. In contrast to *T. castaneum*, toxicity to *C. chinensis* was the result of the larvae being unable to hydrolyze the saponins to their component free sapogenins and sugars, which individually or as a mixture were nontoxic. Triterpene glycosides in organ pipe cactus inhibit the maturation of *Drosophila nigrospiracula* Patterson and Wheeler larvae (Kircher, 1972). Glycoalkaloids from potato affect larval feeding of the Colorado potato beetle *Leptinotarsa decemlineata* (Say) (Sturckow and Low, 1961; Sinden et al., 1980), as well as nymphal survival and duration of settling of the potato leafhopper *Empoasca fabae* (Harris) (Raman et al., 1979). The glycoalkaloid tomatine from tomatoes has been shown to inhibit nymphal growth of the two-striped grasshopper *Melanopus bivittatus* (Say) (Harley and Thorsteinson, 1967) and larval growth of the tomato fruitworm *Heliothis zea* (Boddie) (Isman and Duffey, 1982). Campbell and Duffey (1979) also found that tomatine could reduce pupal eclosion, adult longevity, and cause developmental malformations in the ichneumonid wasp *Hyposoter exiguae* (Viereck) when added to the diet of its host.

In this study, we compare the relative toxicity of tomatine to two herbivorous pests of tomatoes, *H. zea* and *Spodoptera exigua* (Hubner) (Lepidoptera: Noctuidae), and the potential for the alleviation of tomatine toxicity by cholesterol as evidenced before in the wasp *H. exiguae* (Campbell and Duffey, 1981). Tomatine has been implicated as a factor of resistance in the tomato plant to *H. zea* (Juvik and Stevens, 1982). Our study emphasizes that a more effective utilization of plant natural products such as tomatine as a basis of host-plant resistance (HPR) would arise if we better understood some pertinent facts about the toxicity of these chemicals, in terms of (1) the sensitivity of target and nontarget insects to such chemicals, (2) larval feeding patterns, (3) other mediating chemical factors and/or mechanism of action, and (4) the levels of the chemicals within and between plants.

METHODS AND MATERIALS

Eggs of *H. zea* were obtained weekly from Shell Development Company, Modesto, California. Eggs of *S. exigua* were obtained as needed from a laboratory colony. All diets used in this study were based on a semidefined artificial diet (No. 096L4) obtained from Bio-Serv Inc. (Frenchtown, New Jersey). Tomatine and cholesterol were purchased from Sigma Chemical Co. (St. Louis, Missouri).

For dose-response bioassays, tomatine was incorporated into artificial diets at different concentrations by dissolving the compound with the vitamins in the aqueous portion of the diet prior to preparing the complete diet. The concentrations used were 0.0, 0.1, 0.2, 0.3, and 0.4 $\mu\text{mol/g}$ diet wet weight for *S. exigua*, and 0.0, 0.5, 0.75, 1.0, and 1.5 $\mu\text{mol/g}$ for *H. zea*. In the tomato plant *L. esculentum* the average level of tomatine in the foliage is approximately 1.0 $\mu\text{mol/g}$ wet weight, with levels ranging from near 0.0 to >5 $\mu\text{mol/g}$ wet weight. The ability of cholesterol to modify tomatine toxicity was investigated by mixing equimolar ratios of tomatine and cholesterol into the diet based on the EC_{50} 's for tomatine (dietary concentration at which growth is reduced to 50% that of the controls) calculated from the above dose-response curves (EC_{50} 's used were 0.3 and 1.0 μmol tomatine/g diet wet weight for *S. exigua* and *H. zea*, respectively). Cholesterol was added to the dry portion of the diet prior to preparation, owing to its limited solubility in water.

Neonate larvae were sprinkled over 25-well plastic rearing trays (BioServ), with each well containing a small portion of diet. Glass plates were used as covers. Larvae were reared in an environmental chamber at 28°C with a 16:8 hr light-dark photoperiod and were thinned to one per well after three days. When larvae on control diet (2.4% casein) reached an average weight of 200–250 mg (mid-fifth instar; approx. 11 days) for *S. exigua* and 350–400 mg (mid-sixth instar; approx. 11 days) for *H. zea*, the bioassay was stopped and all of the larvae from each treatment were weighed. Throughout the experiments, feces were removed and new diet was added as needed. Each experiment was replicated three to five times ($N = 25/\text{replicate}$).

Diet-shift experiments were performed to determine the relative sensitivity of later-stage larvae of both species (third instar) to toxicosis from tomatine in the diet and to determine if toxicosis could be alleviated by transferring larvae to control diet. Neonate larvae ($N = 100$) were reared for five days on either control diet (C) or diet containing the appropriate EC_{50} of tomatine (T) for each species. After five days, half of each cohort was transferred to control diet and half transferred to tomatine-enriched diet. Larvae were then allowed to continue feeding for an additional four days. Thus, there were 50 larvae for each of four treatments, C/C, C/T, T/T, and T/C. All larvae were weighed daily from the third day on.

To determine the possible effects of tomatine on the efficiency of food utilization by *S. exigua* and *H. zea*, cohorts of larvae were first reared for five days on control diet (to a mean larval weight of approx. 15 mg for *S. exigua* and 20 mg for *H. zea*), then transferred to preweighed portions of diet containing tomatine or tomatine + cholesterol. The dietary concentrations of tomatine tested were 0.0, 0.15, 0.30, 0.60, 1.0, 3.0, and 0.0, 0.5, 1.0, 2.0, 3.0 $\mu\text{mol/g}$ for *S. exigua* and *H. zea*, respectively ($N = 45$ per treatment). A 1:1 tomatine-cholesterol mixture was used based on the EC_{50} for each species. After 36 hr, the larvae, frass, and remaining diet were weighed and nutritional indices (CI, AD, ECI, ECD) calculated as outlined by Waldbauer (1968) and Reese (1979). All calculations were based on wet weights, as the relative humidity in the rearing trays was near 100% and the water content of all test diets was identical.

Data were analyzed using one-way analysis of variance and linear regression with the Statistical Analysis System (SAS). Mean larval weights for different treatments and slopes of the regression lines calculated for the dose-response bioassays were separated using 95% confidence intervals according to Jones (1984). Species comparisons were made by converting larval weights to growth as a percentage of the controls.

RESULTS

Based on dose-response analysis of tomatine toxicity to both species (Figure 1), larvae of *S. exigua* were three times more sensitive to the chemical than were *H. zea* larvae. For *S. exigua* and *H. zea*, respectively, the EC_{50} 's were 0.3 ($y = -423x + 218$) and 1.0 ($y = -174x + 345$) $\mu\text{mol tomatine/g diet wet weight}$ (slopes' significant difference $P < 0.05$).

The effect of tomatine on larval growth was completely alleviated in the fruitworm *H. zea* by the addition of equimolar cholesterol into the diet. However, in *S. exigua* a significant amount of toxicity was maintained (Figure 1). A 1:1 tomatine-cholesterol level in the diet reduced larval weight gain similar to that of a tomatine concentration of 0.1 $\mu\text{mol/g diet alone}$, i.e., about 20% (significant difference from controls $P < 0.05$).

When larvae of *H. zea*, reared from neonate stage for five days on control diet, were transferred to diet with an EC_{50} concentration of tomatine, suppression of growth ensued almost immediately (Figure 2). After nine days, larvae that were continuously reared on control diet significantly outweighed those that had been transferred to diet containing tomatine (247 ± 10 mg vs. 194 ± 12 mg, $P < 0.05$). Larvae, reared for five days on diet containing tomatine, that were then transferred to control diet assumed rapid growth and weighed signif-

icantly more after nine days than larvae that had remained on the tomatine diet (205 ± 9 mg vs. 140 ± 10 mg, $P < 0.05$).

This pattern of growth suppression and recovery did not hold for *S. exigua* (Figure 3). Transferring larvae after five days from control diet to diet with

Error bars = 95% confidence interval about each mean ($N = 75-100$).

FIG. 3. Larval growth curves of *S. exigua* reared on control diet (—●—) or diet with $0.3 \mu\text{mol}$ tomatine/g wet weight ($=\text{EC}_{50}$) (---▲---). Arrow indicates day on which half of the larvae being reared on control diet were transferred to diet with tomatine (○), and half of those on diet with tomatine were transferred to control diet (△). Error bars = 95% confidence interval about each mean ($N = 75-100$).

tomatine, or vice versa, did not alter the larval growth curves. Larvae continued to grow as if the transfer had not occurred, i.e., similar to those reared exclusively on either control or tomatine diet, on whichever the larvae had started.

Results from experiments on efficiency of food utilization supported the results we obtained in the diet-shift experiment (Table 1). Third-instar larvae of *S. exigua* grew as well on diets containing up to two times the EC_{50} of tomatine as they did on control diet. Tomatine also did not affect feeding behavior of later-stage larvae of *S. exigua* (5 days old, third-instar), as evidenced by the fact that there were no significant differences in the consumption indices of larvae that fed on diets of different concentrations of tomatine, except a decrease at $3.0 \mu\text{mol/g}$ diet wet weight or 10 times the EC_{50} . Likewise, tomatine did not reduce approximate digestibility or the dietary utilization of the food for third-instar larvae, again except at the highest dose. Larvae reared on diet with cholesterol added at an equimolar level to tomatine (EC_{50}) also did not differ significantly from controls in weight gain or in any of the nutritional indices measured.

In contrast to *S. exigua*, third-instar larvae of *H. zea* that were shifted from control to tomatine diets showed a significant reduction in larval weight gain (Table 1). In all cases for *H. zea*, as the concentration of tomatine in the diet increased, larval weight gain decreased, going from a weight gain of $>40 \text{ mg}$ with $0 \mu\text{mol}$ of tomatine in the diet to approx. 25 mg at the EC_{50} , and $<18 \text{ mg}$ with $3.0 \mu\text{mol}$ tomatine/g diet. Tomatine also affected the efficiency of dietary utilization of the food. Both the ECI 's and the ECD 's decreased with increasing

tomatine concentrations. Assimilation of the food (AD) tended to increase with increasing amounts of tomatine in the diet. The inhibition of growth was not the result of inhibition of feeding behavior because there were no significant differences in the consumption indices at levels up to the EC₅₀. At two and three times the EC₅₀, the CI actually increased, potentially in compensation for the lowered efficiency of food utilization. The addition of cholesterol into the diet completely alleviated tomatine toxicity. Larvae of *H. zea* reared on control diet or diet with a 1:1 tomatine-cholesterol mixture did not differ significantly in weight gain, CIs, ADs, or ECIs.

DISCUSSION

Glycoalkaloids have been implicated as resistance factors in the solanaceous crops potato and tomato against a variety of insects based on the ability of these chemicals to alter the insects' behavior and/or physiology (Kuhn and Low, 1955; Sturckow and Low, 1961; Dahlman and Hibbs, 1967; Raman et al., 1979; Sinden et al., 1980; Elliger et al., 1981). Tomatine, the major gly-

coalkaloid in tomato plants (Schreiber, 1968), has been discussed as a potential chemical basis of resistance in tomatoes against the Colorado potato beetle *L. decemlineata* (Sinden et al., 1978), the tomato fruitworm *H. zea* (Juvik and Stevens, 1982), and the Mediterranean fruit fly *Ceratitidis capitata* (Wiedemann) (Chan and Tam, 1985).

Our concern has been to assess more thoroughly the potential of tomatine to serve as a basis of resistance against *S. exigua* and *H. zea*, the two primary pests of commercial tomatoes in California (Lange and Bronson, 1981). Juvik et al. (1982) surveyed the genus *Lycopersicon* and found significant genetic variation in foliar tomatine content among 27 accessions tested. Based on these findings, Juvik and Stevens (1982) chose three accessions with different foliar tomatine levels to test the relationship between fruit tomatine content and resistance to larval *H. zea* and *S. exigua*. They found a highly significant, negative correlation between the tomatine content of the fruit and a reduction in larval growth of *H. zea*, but stated that larvae of *S. exigua* were unaffected by the level of tomatine in their diet. These results are inconsistent with our findings that larvae of *S. exigua* were three times more sensitive to dietary tomatine than were larvae of *H. zea* (Figure 1).

Two factors that may explain this apparent discrepancy are (1) the level of phytosterols in tomato foliage and fruit, and (2) larval age and/or prior exposure to tomatine. First, we and other researchers have demonstrated that saponin toxicity can be attenuated or even alleviated by addition of equimolar or supra-molar levels of certain phytosterols to an insect's diet. Therefore, one must examine the composite level of both chemicals before an accurate assessment of toxicity can be given (Shany et al., 1970b; Campbell and Duffey, 1979, 1981; Kelley et al., 1988). Unfortunately, Juvik and Stevens (1982) did not measure the level of sterols in either foliage or fruit. Second, data from our experiments on diet transfers and nutritional indices showed later-stage larvae of *S. exigua* to be insensitive to dietary tomatine (Figure 3; Table 1), whereas larvae of *H. zea* were sensitive at all instars tested (first to third) (Figure 2; Table 1). Thus, by the time larvae initially fed on foliage with a low tomatine content and/or tomatine-to-sterol ratio matured enough to move from feeding on foliage to feeding on fruit (as in the experimental procedure of Juvik and Stevens, 1982), *S. exigua* would no longer be sensitive to tomatine. Hence, one would expect to find only a correlation between fruit tomatine content and reduced larval growth for *H. zea*.

The levels of tomatine (Juvik et al., 1982) and sterols (Campbell and Duffey, 1981) in tomato plants have been shown to vary significantly not only between varieties but between and within plants of a single variety (Duffey and Bloem, 1986; Duffey, unpublished data). Also, larvae of *H. zea* and *S. exigua* are quite mobile and may change their location on a plant to move to new leaves

between successive feeding bouts, to find more favorable microhabitats, and/or to feed on green fruit (tomatoes: Brendler et al., 1985; L.T. Wilson, personal communication; cotton: Baldwin, 1972; Wilson et al., 1980). This suggests that if one is going to inhibit effectively the growth of one or both species throughout larval development, the tomatine/sterol levels in all aerial portions of the plant should be similar (perhaps between an EC_{50} for *H. zea* and *S. exigua*) and/or at least higher in green fruit so that larvae neither develop insensitivity to tomatine nor recover by moving to plant parts containing less tomatine.

The differential sensitivity of herbivorous species to plant natural products must also be considered when assessing the impact of such chemicals on natural enemies (Duffey and Bloem, 1986; Duffey et al., 1986). The ichneumonid wasp *H. exiguae* is a primary biological control agent of both *H. zea* and *S. exigua* larvae in tomatoes in California (Oatman et al., 1983). From the work of Campbell and Duffey (1979, 1981) and additional work by Duffey and Bloem (1986), the sensitivity of the wasp and noctuids to tomatine, in decreasing order, is *S. exigua* > *H. exiguae* > *H. zea*. Thus, the use in planta of an appropriate ratio of tomatine to sterols (e.g., EC_{50} or EC_{75}) directed against *S. exigua* would likely be compatible with biological control efforts utilizing this wasp. However, our dose-response bioassays show that such levels would have little or no effect on *H. zea*. Levels of tomatine effective against *H. zea*, on the other hand, may be incompatible with the use of this wasp (Campbell and Duffey, 1979, 1981; Duffey and Bloem, 1986). Any incompatibility may be compounded if pest populations evolve tolerance to these antibiotics while parasitoid populations remain sensitive (Flanders, 1942; Mueller, 1983; Duffey and Bloem, 1986).

The above considerations underline the need to better understand at a physiological level the effect of plant allelochemicals on an organism(s) before one tries to implicate or utilize specific plant chemicals as bases of defense or resistance. As noted by Birk and Peri (1980), the mode of action of saponins in relation to insect growth and survival is complex and poorly understood. Although several modes of action have been proposed (Shany et al., 1974; Birk and Peri, 1980; Campbell and Duffey, 1981), it is becoming increasingly clear that at least some of their biological activity in certain insects is coupled to their ability to complex with phytosterols, such as cholesterol (Shany et al., 1970b; Campbell and Duffey, 1981; Kelley et al., 1988). In our experiments, the addition of equimolar levels of cholesterol to tomatine-enriched diets completely alleviated (*H. zea*) or significantly reduced (*S. exigua*) tomatine toxicity (Figure 1). The differences observed in our nutrition and feeding studies, coupled with significantly different slopes of the dose-response curves, suggest that it may be simplistic to argue for a single mode of action for tomatine in these species. Additional research is needed, however, to determine whether sterol binding is

directly related to the mode of action of tomatine, or whether binding simply limits the expression of tomatine toxicity.

Resistance of plants to insects is usually thought of as the action of a discrete, definable state or entity of the plant upon a given pest species. We think, as do others (e.g., Price et al., 1980; Futuyama, 1983; Price, 1983; Whitham, 1983; Kogan, 1986), that current theories on plant defensive strategies fail to address adequately the interaction among coingested plant products, the existence of multiple pest species, and the effects of plant defenses as extended through multitrophic systems. The concerns and difficulties we raise for tomatine are not unique. Two phenolics, rutin and chlorogenic acid, have also been proposed as a basis of resistance in tomatoes (Isman and Duffey, 1982). These chemicals are differentially toxic to *H. zea* and *S. exigua*, are modified in toxicity by both polyphenol oxidase activity and dietary protein, and vary significantly in amount within and among plants (Duffey and Bloem, 1986). Likewise, tomato proteinase inhibitors are differentially toxic to *H. zea* and *S. exigua*, and their toxicity depends on the quantity and quality of dietary protein (Broadway and Duffey, 1986a,b, 1988). Clearly, the ability to utilize plant natural products predictively in host-plant resistance programs will require a more profound integration of plant phenology, insect feeding behavior, and the nutritional physiology and toxicology of the chemicals involved.

Acknowledgments—This research has been supported by U.S. Department of Agriculture competitive grants to S.S.D. (82CRC-1-1054 and 84CRC-1-1439) and a National Science Foundation grant to S.S.D. and K.A.B. (DEB-8214555). We thank Dr. R. Karban, G. Felton, C. Ludlum, Dr. G. Kennedy, and J. Barbour for critical reviews of earlier drafts of this paper.

AGGREGATION PHEROMONE COMPONENTS IN
Drosophila mulleri
A Chiral Ester and an Unsaturated Ketone

(Received October 19, 1987; accepted December 21, 1987)

Abstract—Existence of an aggregation pheromone was demonstrated in *Drosophila mulleri*. Mature males produce at least two compounds that are lacking from females and newly emerged males and that attract both males and females in a wind-tunnel bioassay. These compounds are (*S*)-(+)-2-tridecanol acetate and (*Z*)-10-heptadecen-2-one. Both were synthesized, and the flies responded to the synthetic compounds as well as to fly-derived preparations. The flies also responded to racemic 2-tridecanol acetate but not to the pure *R* enantiomer. A more polar, very volatile attractant was also extracted from both sexes of *D. mulleri* but was not identified.

Key Words—*Drosophila mulleri*, Diptera, Drosophilidae, aggregation, pheromone, chirality, enantiomers, ester, ketone, (*S*)-(+)-2-tridecanol acetate, (*Z*)-10-heptadecen-2-one.

INTRODUCTION

Aggregation pheromones have been demonstrated in a number of species of the genus *Drosophila* (Diptera: Drosophilidae) (Moats et al., 1987; Schaner et al., 1987; Bartelt et al., 1986, 1987; and references therein). In these species, sexually mature males possess compounds that attract both males and females in a laboratory wind-tunnel bioassay. These compounds are lacking in females and in newly emerged males. The pheromone components include hydrocarbons,

¹ Present address: USDA-ARS, Northern Regional Research Center, Peoria, Illinois 61604.

esters, and ketones, and mixtures of compounds are often required for optimal responses. Volatiles from fermenting food media usually synergize the pheromones.

Research on pheromones of *Drosophila* species was continued with *D. mulleri* Patterson. A comparison between *D. mulleri* and *D. hydei* (see Moats et al., 1987) was of special interest because both belong to the same (*repleta*) species group. *D. mulleri* was found to possess pheromone components not previously encountered in other *Drosophila*.

METHODS AND MATERIALS

Flies, Extracts, and Bioassays. The *D. mulleri* culture was obtained from the National *Drosophila* Resource Center, in Bowling Green, Ohio (stock number 15081-1371). The flies were reared on Formula 4-24 Instant *Drosophila* Medium (Carolina Biological Supply, Burlington, North Carolina).

The age of maturity of male and female flies was determined as described by Moats et al. (1987), so that appropriate ages for extraction and bioassay could be chosen. We found that males of *D. mulleri* become mature at 5-6 days and females at 2-3 days. In other *Drosophila* species we have studied, pheromone production begins in males as sexual maturity is approached, but flies of any age have usually responded to the pheromones. Thus, to obtain pheromone, flies were not extracted until 6-7 days of age, but 1- to 4-day-old flies were used for most bioassays because the immature males would be less likely to possess pheromones that could compete with bioassay treatments. Flies to be extracted were segregated by sex within one day of emergence and extracted by soaking them overnight in hexane at room temperature.

Bioassays were performed in a wind-tunnel olfactometer essentially as described earlier (Bartelt and Jackson, 1984). About 16 hr before bioassay tests began, ca. 1000 flies were added to the olfactometer. As with the previously studied species, a starvation period was necessary before flies would respond to pheromones. Each bioassay treatment was applied to a filter paper strip lining the lip of a glass vial. A drop of water was added to the bottom of each bioassay vial to arrest responding flies (Bartelt and Jackson, 1984). Two such vials, with treatments to be compared, were placed in the upwind end of the olfactometer. After 3 min the vials were capped, and the captured flies were counted and, in selected experiments, sexed. Tests were performed throughout the day at ca. 10-min intervals. In experiments with more than two treatments, they were tested in all possible pairs (a balanced incomplete block design). Statistical analysis followed the method of Yates (1940) and was done on data transformed as $\log(X + 1)$ to stabilize variance.

Chromatography and Spectra. Crude hexane extracts were chromato-

graphed initially on open columns of silicic acid and eluted with two void volumes of each of the following solvents: hexane; 5%, 10%, and 50% ether in hexane; and 10% methanol in methylene chloride.

All gas chromatography (GC) was conducted on a Varian 3700 using He as the carrier gas. For preparative GC, a 1.3-m \times 4-mm 5% SE-52 column was used, and the effluent was monitored with a thermal conductivity detector. Three columns were utilized for capillary GC: a 30-m \times 0.25-mm DB-1, a 15-m \times 0.32-mm DB-5, and a 30-m \times 0.25-mm DB-225 (J & W Scientific, Rancho Cordova, California). Peaks were monitored with a flame ionization detector. Various temperature programs were used, as described below.

High-performance liquid chromatography (HPLC) was conducted isocratically with a Waters 6000A pump and a Waters 401 differential refractometer. Columns included a 25-cm \times 4.6-mm ID Adsorbosphere silicic acid column (Applied Science, Deerfield, Illinois), eluted with 5% ether in hexane, and a 25-cm \times 4.6-mm ID silicic acid column, coated with AgNO₃ as described by Heath and Sonnet (1980), and eluted with toluene.

Electron impact mass spectra were obtained on a VG-MM16F mass spectrometer. Samples were introduced through a capillary GC column.

Synthetic Esters. (\pm)-2-Tridecanol acetate was prepared by treating dodecanal with methylmagnesium bromide in ether, followed by acetylation of the resulting alcohol with acetic anhydride in pyridine. After chromatography on an open column of silicic acid and preparative GC, the ester was >98% pure by capillary GC. The ester was diluted with hexane to 10 ng/ μ l for bioassays. A portion of the (\pm)-2-tridecanol was set aside for chromatographic studies.

(*S*)-2-Tridecanol was synthesized (Figure 1) from a commercially available, optically active starting material, ethyl (*S*)-lactate (I) (Sigma Chemical Co., St. Louis, Missouri). Synthetic steps were performed as described in the literature for analogous reactions: After conversion to a tetrahydropyranyl (THP) ether (II) (Miyashita et al., 1977), the ester function was reduced with lithium aluminum hydride (Mori, 1976), and the resulting primary alcohol (III) was esterified with *p*-toluenesulfonyl chloride to form the tosylate (IV) (Mori, 1976). Decylmagnesium bromide was linked to this tosylate in the presence of dilithium tetrachlorocuprate to form the THP ether of (*S*)-2-tridecanol (V) (Suguro and Mori, 1979). Finally, the tetrahydropyranyl protecting group was removed (Miyashita et al., 1977). The crude (*S*)-2-tridecanol (VI) crystallized at ca. -10°C from a 20% solution in pentane. By GC, the purity of the recovered product was 88%.

All reactions were monitored by GC and mass spectrometry. All were essentially quantitative except for the alkylation of the tosylate, for which the yield was ca. 50%. Intermediate products were not purified before subsequent reactions, except to dry (Na₂SO₄) and to remove solvents.

FIG. 1. Synthetic scheme for (S)-(+)-2-tridecanol, its acetate, and its (S)-2-(acetyloxy)propanoate. Abbreviations: THP = tetrahydropyranyl group, PPTS = pyridinium *p*-toluenesulfonate, TOS = *p*-toluenesulfonyl group, APC = (S)-2-(acetyloxy)propanoyl chloride.

(*R*)-2-Tridecanol was prepared in an identical manner except that the starting material was methyl (*R*)-lactate (Sigma).

(*S*)-2-Tridecanol was either converted to an acetate for bioassays or was derivatized as described below for GC studies of optical purity and stereochemical configuration. The acetate (Figure 1, VII) was formed by treatment with acetic anhydride in pyridine. After purification by chromatography on silicic acid and preparative GC, the ester's purity was >99%, by capillary GC. Approximately 10 mg of pure ester were prepared. The ester had an identical mass spectrum and GC retention (DB-1, DB-5) as the racemic synthetic (\pm)-2-tridecanol acetate. The specific rotation was determined: $[\alpha]_D^{23} = +4.6^\circ$ ($c = 0.57\%$, hexane) (literature value: $[\alpha]_D^{20} = +4.63^\circ$, absolute configuration not given, Pickard and Kenyon, 1914).

(*R*)-(-)-2-Tridecanol acetate was likewise prepared from the (*R*)-2-tridecanol. The measured purity of the ester was >99% and the optical rotation, $[\alpha]_D^{23} = -4.9^\circ$ ($c = 0.57\%$, hexane). GC retention and mass spectrum were as for the *S* isomer. Both enantiomeric esters were diluted with hexane for bioassays.

Studies of Optical Purity and Absolute Configuration. Diastereomeric esters (Figure 1, VIII) were formed from the synthetic 2-tridecanols so that optical purity could be analyzed on an achiral GC column. The (*S*)-(2-acetyloxy)propanoates (acetyl lactates) were prepared essentially as described by Slessor et al. (1985). The derivatizing reagent was (*S*)-(2-acetyloxy)propanoyl chloride (APC). GC analysis was on the DB-5 capillary column, temperature programmed from 120°C to 150°C at 5°C/min.

To derivatize the 2-tridecanol acetate from *D. mulleri*, the ester was first reduced with LiAlH_4 . To ca. 10 μg of purified *D. mulleri* ester in 20 μl ether was added 15 μl LiAlH_4 reagent (1.0 M in ether). After 10 min at room temperature, the vial was cooled over ice and 2 drops of H_2O were added to decompose excess reagent. The organic layer was transferred to a clean vial and stripped to dryness under N_2 ; then the alcohol was derivatized with APC.

Synthesis of Ketones. (*Z*)-9-Hexadecenoic acid (50 mg, 0.2 mmol, Sigma) in 2 ml dry ether was cooled to 0°C. Methylolithium in ether (0.8 mmol, 0.6 ml) was added in one portion. The mixture was warmed to room temperature, refluxed for 20 min, then cooled to 0°C, after which 1 ml water was added very slowly. The ether layer was washed with dilute HCl, water, and NaHCO_3 solution, then dried over Na_2SO_4 . The resulting (*Z*)-10-heptadecen-2-one was purified on an open column of silicic acid and diluted with hexane for bioassay. The purity was 99+ % by capillary GC. 2-Heptadecanone was similarly prepared in 99+ % purity from palmitic (hexadecanoic) acid.

Preliminary Experiments with Volatile, Polar Attractants. Apparatus was assembled to allow evaporation of a sample (up to 500 μl) under a gentle stream of nitrogen, so that the vapors passed through a $2.5 \times 25\text{-mm}$ column of 20/

35 mesh Tenax porous polymer (Applied Science). Both the fly-derived 10% MeOH-CH₂Cl₂ fraction and a CH₂Cl₂ rinse of rearing medium (inoculated with yeast but without *Drosophila*) were treated in this way. Each sample was reconstituted with an equal volume of fresh solvent immediately as the sample went to dryness, and the Tenax column was eluted with an equivalent volume of pentane. The reconstituted samples and Tenax column rinses were compared to the original samples by bioassay. The Tenax column rinses were examined by GC and mass spectrometry.

RESULTS AND DISCUSSION

Bioassay Characteristics. When the flies were first put into the olfactometer, they formed tight aggregations low on the sides and moved about very little. After starvation for 14–16 hr at a temperature of 24–25°C, these groups dispersed and the flies became more active, usually with ca. 20–30 flies in flight at any given time. Response to an active treatment was usually by an upwind, zigzag, hovering flight, followed by alighting on the vial.

Bioassays of Crude Extracts and Fractions. The crude hexane extract of mature male *D. mulleri* was active in the bioassay (Table 1A), and three fractions derived from this extract were significantly active. Based on standards, the first (eluted with 5% ether-hexane) had the polarity of esters while the second (eluted with 10% ether-hexane) had the polarity of ketones. The last was considerably more polar (eluted with 10% methanol-methylene chloride). Surprisingly, the female-derived extract was also very active (Table 1B), and this activity was located in the most polar fraction. Thus *D. mulleri* was like the previously studied species in that mature males had attractive nonpolar compounds that were lacking in mature females, but *D. mulleri* was unlike the other species in that very active, relatively polar compounds(s) were present in both sexes.

Further purification of the male-derived 5% and 10% ether-hexane fractions was accomplished by preparative GC. The activity from the 5% ether-hexane fraction was retained slightly longer than an alkane of 16 carbons on the nonpolar preparative GC column, and the activity from the 10% ether-hexane fraction was similar in retention to an alkane of 19 carbons. No other GC fractions had significant bioassay activity. Subsequent HPLC on silicic acid produced only one active region from each GC fraction. The activity originally from the 5% ether-hexane silicic acid fraction eluted 5.5–6.5 ml after injection, while that from the 10% ether-hexane fraction eluted at 10–11 ml. Based on standards, these retentions supported that the activity in the former fraction was due to an ester, and the latter, a ketone.

Ester Component. After preparative GC and HPLC, the active ester com-

^aOne fly equivalent per test. Each row is a balanced incomplete block experiment, in which the test treatment, the control, and the male-derived crude extract are tested in pairs, in all possible combinations.

^bIn each row, means followed by *** are significantly different from the control at the 0.001 level (*t* tests). No other differences were significant at even the 0.05 level.

ponent was >98% pure, by capillary GC. Mature males possessed ca. 300 ng of this compound, but it was lacking in females and newly emerged males. In the mass spectrum, no molecular ion was seen, but fragments at m/z 87 (40%) and 182 (15%, M-60) suggested an acetate of the secondary alcohol, 2-tridecanol. The base peak was m/z 43, and peaks also occurred at 198 and 199 (both ca. 1%, M-44 and M-43, respectively). Racemic 2-tridecanol acetate and the *D. mulleri* compound had identical GC retention times (DB-1) and mass spectra. Both reacted with methanolic KOH, resulting in a GC peak with the same retention as authentic 2-tridecanol. Racemic 2-tridecanol acetate was active in the bioassay (Table 2A).

The fly-derived 2-tridecanol acetate, having one asymmetric center, was analyzed for optical purity and absolute configuration (summarized in Figure 2). The two diastereomers derived from racemic 2-tridecanol were easily separated on the DB-5 capillary column. Based on the synthetic standards, the first of these peaks (Kovats index = 1966) corresponded to the *R* configuration, while the peak at KI = 1982 represented the *S* configuration. The derivative

prepared from the *D. mulleri* pheromone had a Kovats index of 1982 and a high degree of optical purity (enantiomeric excess calculated from peak integrations was 98.7%). By comparison to the synthetic standards, the *D. mulleri* pheromone has the *S* configuration. The enantiomeric excess represents a minimum, as the departure from 100% could be due to optical impurity of the derivatizing reagent and/or slight racemization occurring during chemical procedures.

D. mulleri responded in the bioassay only to the enantiomer of 2-tridecanol acetate which they produce (Table 2B). The *S* isomer was clearly active, while the *R* isomer was not. That the *R* isomer was not repellent was consistent with

FIG. 2. GC analysis of optical purity and absolute configuration of the 2-tridecanol acetate produced by *D. mulleri*. Shaded peaks represent (*S*)-2-(acetyloxy)propanoate derivatives of synthetic and fly-derived 2-tridecanol. Kovats indices are indicated at peak apices. The peaks at ca. 4.3 and 5.8 min are *n*-alkanes of 19 and 20 carbons, respectively, conjoined as retention standards. The DB-5 capillary column was 120°C initially and was increased at 5°C/min.

the activity of the racemic synthetic ester. (*S*)-2-Tridecanol acetate adequately accounts for the activity of the male-derived 5% ether-hexane fraction (Table 2C). In this experiment both treatments had equivalent amounts of the ester.

Chiral pheromones have been demonstrated in a number of insect groups. One common pattern is that insects respond only to the optical isomer that they produce but that the other enantiomer is not repellent (Mori, 1985), a pattern which has now been demonstrated in the *Drosophila* also.

Ketone Component. The active "ketone" fraction, after preparative GC

and HPLC on silicic acid, contained two peaks, by capillary GC. Both were small peaks, representing ca. 1 ng/mature male. The latter of the two peaks was identical in GC retention and mass spectrum with 2-heptadecanone [key spectral peaks were at m/z 43 (100%), 58 (80%), and 254 (4%)]. The other peak eluted slightly earlier on the nonpolar DB-1 capillary column, and its mass spectrum indicated a molecular weight of 252 (2%), 2 mass units less than 2-heptadecanone. Fragments still appeared at m/z 43 (100%) and 58 (26%); thus an unsaturated methyl ketone seemed likely. (*Z*)-10-Heptadecen-2-one was synthesized as a standard for comparative purposes. This ketone was accessible in one step from the readily available (*Z*)-9-hexadecenoic (palmitoleic) acid. Fortuitously, this ketone had the same retention on three GC columns as the *D. mulleri* ketone (KI = 1860, 1873, and 2243 on DB-1, DB-5, and DB-225, respectively), and the mass spectra and retentions on the AgNO₃ HPLC column were identical also. Since these chromatographic methods are sensitive to double-bond position and configuration, the data strongly supported (*Z*)-10-heptadecen-2-one as the structure of the unknown compound. Because of the minute amount of ketone in each male, confirmation of double bond location by ozonolysis was not attempted.

(*Z*)-10-Heptadecen-2-one was active in bioassay and accounts fairly well for the activity of the male-derived 10% ether-hexane fraction (Table 2D). 2-Heptadecanone, also found in *D. mulleri* males, was not active in the bioassay by itself, although a mixture of 2-heptadecanone + (*Z*)-10-heptadecen-2-one was somewhat more active than the unsaturated ketone alone (Table 2E).

The extracts were subsequently examined for 2-tridecanone and 2-pentadecanone, pheromone components in the related species, *D. hydei* (Moats et al., 1987). Traces of both ketones were found (2–4 ng/mature male), but the synthetic ketones were not active in the bioassay. None of the ketones were detected in extracts of female flies.

Synergistic Activity of (S)-(+)-2-Tridecanol Acetate and (Z)-10-Heptadecen-2-one. Dose-response data for various mixtures of (*S*)-2-tridecanol acetate and (*Z*)-10-heptadecen-2-one are given in Table 3. The response generally increased with increases in either component, although there was little difference between the 300- and 3000-ng levels of the ester. On a weight-for-weight basis, the ketone was the more active compound. For example, 10 ng of ketone elicited a stronger response than even 3000 ng of ester.

Response by Sex. Both sexes responded readily to all preparations tested. For example, in a paired comparison experiment with the crude hexane extract of mature males (1 equivalent), (*S*)-2-tridecanol acetate (300 ng), (*Z*)-10-heptadecen-2-one (10 ng), and controls, the mean captures (and percent females) for the treatments were 38.7 (45%), 11.8 (47%), 29.5 (45%), and 2.0 (67%), respectively ($N = 6$).

Polar Attractant. Despite concerted efforts, the polar attractant(s) in the

TABLE 3. RELATIVE ACTIVITIES FOR VARIOUS MIXTURES OF (S)-(+)-2-TRIDECANOL ACETATE AND (Z)-10-HEPTADECEN-2-ONE^a

Amount of (Z)-10-heptadecen-2-one (ng)	Amount of (S)-(+)-2-tridecanol acetate (ng)

100	258	364	387	504	555

^aEach test mixture compared to solvent controls and the standard mixture (300 ng (S)-(+)-2-tridecanol acetate plus 1 ng (Z)-10-heptadecen-2-one) in a balanced incomplete block experiment ($N = 8$). Relative activity (RA) based on means from these experiments:

$$RA = 100 \times (\text{test mixture} - \text{control}) / (\text{standard mixture} - \text{control}).$$

^bBy definition, RA for control = 0. Overall, the mean bioassay catch for controls was 4.5 flies per 3-min test.

^cAll samples except this one attracted significantly more flies than the control ($P < 0.01$).

^dBy definition, RA for standard mixture (ca. 1 male equivalent) was 100. Overall, the mean bioassay catch for this standard was 34.8 flies per 3-min test.

10% MeOH-CH₂Cl₂ fraction was (were) not identified. The activity was extremely volatile, compared to the ester and ketone pheromone components. Evaporating the polar fraction carefully to dryness under N₂ and immediately reconstituting the fraction with fresh solvent resulted in the loss of ca. 80% of the bioassay activity (Table 4). When the vapors from the evaporating fraction were directed through a column of Tenax, the activity could be recovered by rinsing the column with pentane. (Evaporation of control solvent through the Tenax trap did not produce a trap rinse that was active in bioassay). Examination of the active trap rinse by GC revealed many minute peaks, but there was little consistency among runs and there was not enough material for definitive mass spectral analysis. It is likely that a mixture of compounds is involved in the response.

The polar attractant was unlike any of the previously studied *Drosophila* pheromone fractions in that those from both sexes were highly active, instead of only those from males. It is possible that this activity is related to the diet medium rather than being pheromonal, since the flies could pick up compounds from their food. A CH₂Cl₂ rinse of diet medium, which was never exposed to *Drosophila*, was similarly attractive in bioassay, and when it was evaporated through Tenax, the rinse from the Tenax column was also active (Table 4). The involvement of the volatile attractants in the ecology of this fly species will require additional research.

TABLE 4. VOLATILE ATTRACTANT IN FLY-DERIVED POLAR FRACTION AND EXTRACT OF REARING MEDIUM

^bResults for fractions from males and females nearly identical; combined data presented.

^cRearing medium inoculated with yeast, but no *Drosophila* present.

^dSamples evaporated gently under stream of N₂; samples reconstituted with fresh solvent immediately after going to dryness.

^eVolatiles from evaporating sample passed through Tenax trap; collection terminated when sample went to dryness. Tenax trap rinsed with pentane.

D. mulleri is like the other, previously studied *Drosophila* species in that attractants exist that are found only in the mature males. *D. mulleri* is similar to *D. hydei* (also of the *repleta* group) in that both species have ester and ketone pheromone components. In *D. hydei*, however, the ester is ethyl tiglate (Moats et al., 1987), while *D. mulleri* uses (*S*)-(+)-2-tridecanol acetate. Indeed, the ester of *D. mulleri* is probably biosynthetically related to the ketone component of *D. hydei*, 2-tridecanone. Yet *D. mulleri* still retains a methyl ketone component, although it is four carbons larger than that from *D. hydei* and is unsaturated.

(Received August 25, 1987; accepted December 22, 1987)

Abstract—Extracts of the intact hairpencil glands and hairs from the hairpencil glands of males of *Heliothis virescens* (F.) were analyzed by capillary gas chromatography (GC) and by GC-mass spectroscopy. These analyses indicated that hexadecanyl acetate (212.4 ng/male), hexadecanol (22.3 ng/male), (*Z*)-11-hexadecenyl acetate (3.5 ng/male), octadecanyl acetate (14.2 ng/male) octadecanol (7.5 ng/male), tetradecanoic acid (2.7 ng/male), hexadecanoic acid (22.3 ng/male), and octadecanoic acid (6.5 ng/male) were present in the extracts. These compounds also were found in volatiles released from the hairpencil glands. In addition, GC analysis using both polar and apolar capillary columns indicated that extracts of the glands and extracts of the hairs from the hairpencil glands contained small amounts of tetradecanyl acetate, (*Z*)-9-tetradecenyl acetate, tetradecanol, (*Z*)-7-hexadecenyl acetate, (*Z*)-9-hexadecenyl acetate, and (*Z*)-11-hexadecanol. No (*Z*)-9-tetradecenal was present. Studies indicated that titers of the compounds increased rapidly during the 36 hr after adult eclosion and then leveled off, being maintained at high levels until released when the glandular hairs were exposed. During exposure of the hair pencils substantial amounts of the compounds were released. In vivo application of 500 ng of suspensions of (*Z*)-11-hexadecenyl acetate, (*E*)-11-hexadecenyl acetate, (*Z*)-11-tetradecenyl acetate, or (*E*)-11-tetradecenyl acetate in dimethyl sulfoxide to the surface of the denuded hairpencil gland showed that biosynthesis proceeds to the alcohol via the acetate.

Key Words—*Heliothis virescens*, Lepidoptera, Noctuidae, hairpencil glands, male-produced compounds, hexadecanyl acetate, hexadecanol, (*Z*)-11-hexadecenyl acetate, octadecanyl acetate, octadecanol, tetradecanoic acid, hexadecanoic acid, octadecanoic acid.

INTRODUCTION

Considerable research has been conducted on pheromone chemistry and on the behavior associated with sex pheromones produced by females of Lepidoptera as well as on the morphology of the glands that produce these compounds (Tamaki, 1986). However, substantially fewer studies have been centered on male-produced pheromones. Studies on the chemistry and both intra- and intersexual behavior associated with pheromones produced by males of Lepidoptera are of importance because such information is critical to the elucidation of the chemical communication systems of these insects (Tumlinson and Teal, 1982).

Epidermal glands that produce and disseminate the pheromones produced by males are of diverse structure and varied anatomical position. This diversity is exemplified among moth species when considering the eversible tubelike cornemata present on the genital segments of male arctiid moths (Nielsen, 1979), the thoracic brush organs of *Phlogophora* species (Birch, 1970), wing glands of tortricid and phycitid moths (Grant, 1978), and hairpencil glands present on the genital segments of numerous noctuid species.

Variability in structure and anatomical position of the pheromone glands of males is paralleled by the types of chemicals released as pheromone components and by the behavioral roles of these compounds in chemical communication (Tamaki, 1986). Chemicals released as pheromone components include such different molecules as benzaldehyde (Clearwater, 1972), methyl-jasmonate (Baker et al., 1981), and (Z,Z,Z)-3,6,9-heneicosatriene (Heath et al., 1987). Functions of pheromones released by males range from the attraction of females (Dahm et al., 1971; Baker et al., 1981), to inducing female quiescence, and inhibition of the approach of other males (Clearwater, 1972; Hirai et al., 1978). Unfortunately, neither the structures nor functions of pheromones released by males of the majority of moth species have been described.

Little work has been conducted on the pheromone produced by the hairpencil gland of males of *Heliothis virescens* (F.), although various functional roles have been ascribed. For example, Hendricks and Shaver (1975) suggested that the pheromone stopped females from calling. Alternatively, laboratory flight tunnel studies of mating behavior caused Teal et al. (1981) to hypothesize that the pheromone caused females to accept courting males. Recently, Jacobson et al. (1984) reported that (Z)-9-tetradecenal (Z9-14:Al) was the pheromone produced by males of *H. virescens*. The production of milligram amounts of this compound was of interest because the corresponding alcohol was not identified. This alcohol is present in extracts of the pheromone gland of females (Teal et al., 1986) and is converted to Z9-14:Al, a critical component of the pheromone blend released by females (Teal and Tumlinson, 1986; Vetter and Baker, 1983). This suggested that males and females of *H. virescens* employ different methods of pheromone biosynthesis.

For the above reasons, we investigated the chemicals produced in the hair-pencil glands of males of *H. virescens*. The following reports the identification of a blend of components from these glands and discusses the results of in vivo studies on biosynthesis of these compounds. We also describe the structure of the hair-pencil gland and discuss the possible mechanism of storage of the compounds identified. A subsequent paper will discuss the behavioral role of the pheromone released from the hair-pencil gland in the reproductive behavior of *H. virescens*.

METHODS AND MATERIALS

General. *Heliothis virescens* used in this study were obtained as pupae from the Bioenvironmental Insect Control Laboratory, USDA, ARS, Stoneville, Mississippi. Pupae were sexed and maintained under a reversed 16:8 light-dark cycle at 25°C and 55% relative humidity. Newly emerged adults were transferred daily to 30 × 30 × 30-cm clear plastic cages and were provided with a 10% sugar solution soaked onto cotton.

Anatomical Studies. The terminal abdominal segments, which include the paired hair-pencil glands, one at the base of each clasper, were everted by applying pressure to the anterior abdominal segments. Glutaraldehyde fixative (2% in phosphate buffer pH 7.2) was then injected into the terminal abdominal segments. After 10 min the hair-pencil glands were removed from the abdomen and placed in a vial that contained fixative plus two drops of Photoflow to reduce surface tension. The vial was placed under vacuum at 4°C for 14 hr. Material was postfixed in 2% OsO₄ in phosphate buffer (4 hr) prior to dehydration in ethanol and propylene oxide. Some tissue was then embedded in Spurr's resin and sectioned at 0.5–1.5 μm using glass knives. Sections were mounted in series on gelatin-coated slides and stained using methylene blue in 2% borax (Teal and Philogène, 1980). The remaining tissue was dried in a desiccator that contained granular SiO₂ prior to mounting on stubs using silver conductive paint. These samples were then sputter coated with gold. Scanning electron microscopy was performed using a Cambridge Stereoscan Mark IIA operated at 10 kV.

Isolation and Identification. In initial studies, rinses of the whole male hair-pencil gland complex, including the elongate glandular hairs and cellular portion, were obtained by removing the abdominal segments of males during the 4th to 6th hr of the dark period of the second complete scotophase after emergence. This was accomplished using forceps by applying pressure to the anterior abdominal segments and dipping the exposed gland into 200 μl of iso-octane (Fisher 99% mole) for ca. 30 sec. Up to 25 rinses were collected in each sample, and the extracts were analyzed without concentrating the iso-octane. Extracts of the elongate hairs associated with the hair-pencil gland were

prepared by cutting the hairs carefully from the surface of the gland, leaving a short portion attached and placing the hairs in a 0.5-ml conical microvial. The hairs were then rinsed with 10 μ l of iso-octane that contained the appropriate internal standards per male equivalent (ME).

Two methods were used to collect the compounds volatilized from the hair-pencil glands. In the first method, individual males were placed in an enlarged holding apparatus similar to that described by Teal et al. (1986). This apparatus was connected to another smaller chamber that contained a rubber septum impregnated with 1 mg of the six-component pheromone blend released by females (Teal et al., 1986). Purified air was passed over the lure and into the chamber holding the males. Volatiles released during hair-pencil displays were collected on charcoal microentrainment filters and were recovered in a small amount of dichloromethane and iso-octane as described elsewhere (Teal et al., 1986). In the second method of volatile collection, the hairpencils were everted using forceps, as described earlier, under a stream of dried N₂ (250 ml/min) and above a conical microvial that contained 250 μ l of iso-octane for 30 sec so that the N₂ would carry volatiles into the solvent. The volatiles from the hair-pencil scales of up to 50 insects were collected in the same sample, and the solvent was never concentrated to less than 25 μ l under the N₂ stream.

Prior to methanolysis, the iso-octane was evaporated completely under N₂ from extracts of the glandular hairs of groups of five males or volatile collections obtained from groups of 10 males. Methyl esters of acids present in the hair-pencil pheromone were formed by acid methanolysis (Bjostad and Roelofs, 1984) and by methanolysis using boron trifluoride in methanol (Morrison and Smith, 1964).

Biosynthesis. Studies on age-related production of the identified compounds were conducted using pharate adults that had been removed from the pupal case manually; adult males sampled after emergence but prior to wing expansion; insects that had just completed expansion of the wings; insects sampled 2, 4, and 6 hr after wing expansion; and adult insects 12, 24, 36, and 48 hr old. Studies on the effect of time of day on pheromone production were conducted using insects sampled during the peak of reproductive activity on the second scotophase after adult emergence and on insects sampled 12 hr later during the next light cycle. Studies on depletion of the compounds from the gland were conducted by flying males in a laboratory wind tunnel. The six-component aldehyde pheromone blend identified as the sex pheromone released by females (Teal et al., 1986) was used as a lure. Males were allowed to land and fully expose their hairpencils during a 5-min test period. Only males that fully exposed the hairpencils and attempted copulation numerous times at the source of the female sex pheromone were sampled. In all of these cases the whole hair-pencil gland complex of individual males was everted, removed, and extracted for 30 sec in 30 μ l of iso-octane containing 10 ng of the appropriate

internal standard immediately after testing in the flight tunnel. The volume of the extract was then reduced to ca. 5 μ l and analyzed.

In vivo studies on biosynthesis of the compounds were conducted using glands that were clamped in a fully exposed position with a smooth jawed alligator clip. The glandular hairs of some preparations then were removed carefully with forceps thus exposing the actual gland. The hairs that had been removed were placed in a conical microvial. Other preparations were left intact. Test alcohols or acetates were then applied, with a 1- μ l syringe at a concentration of 500 ng in 1 μ l of dimethyl sulfoxide (DMSO), to denuded gland surfaces, the removed hairs, or the intact preparations. Treated and DMSO control preparations were then incubated for 1 hr at 25°C prior to extraction as described for the individual glands and gas chromatographic analysis. Experiments were conducted during the reproductive period (ca. 4 hr after dark) and 12 hr later during the light period.

Chemical Analysis. Chromatographic analyses were conducted using Hewlett Packard (Avondale, Pennsylvania) 5792 and 5890 gas chromatographs (GC) equipped with splitless and cool on-column capillary injectors and flame-ionization detectors. The detectors of the 5792 GC were interfaced to a Hewlett Packard 3390 reporting integrator. Data from the 5890 GC were acquired at a rate of 20 points/sec through a Chromadapt interface and Adalab data acquisition system (Interactive Microware, Inc., State College, Pennsylvania) and processed using an Apple IIe computer with Chromatohart software. Fused silica capillary columns used routinely for GC analysis included a 15-m \times 0.25-mm (ID) DB 225 (J & W Scientific, Folsom, California), a 30-m \times 0.25-mm (ID) SPB1 (Supelco), and a 30-m \times 0.25-m (id) Supelcowax 10 (Supelco, Bellefonte, Pennsylvania). Only the DB 225 column was used in conjunction with the cool on-column injector. In this case the initial temperature of 80°C was maintained for 0.5 min and then increased at 15°C/min to a final temperature of 135°C. Conditions of chromatography when using the splitless injectors were as follows: initial temperature, 80°C for 1 min; splitless purge at 0.5 min; temperature increase at 25°C/min to 165°C (Supelcowax 10) or 180°C (SPB1). Hydrogen was used as the carrier gas at a linear flow velocity of 38 cm/sec. The primary saturated acetates of tridecanol and pentadecanol (10 ng each) were used as internal standards for both synthetic and natural product samples and were used to calculate relative retention indices and to quantitate the amounts of compounds present in natural-product samples. Further GC confirmation was obtained by cochromatography of the natural product samples with the individual synthetic compounds on all three columns.

Electron impact (EI) and chemical ionization (CI) mass spectra (MS) were obtained using VG1212F (VG Instruments, Toronto, Ontario) and Nermag R10-10 (Delsi Instruments, Fairfield, New Jersey) instruments interfaced to Hewlett Packard 5792 GCs equipped with cool on-column capillary injectors. Helium

was used as the carrier gas at a linear flow velocity of 18 cm/sec. Both isobutane and methane were used as ionization gases. In addition to positive ion CI-MS we also obtained negative ion (methane) spectra for extracts of the hairpencil scales. Samples were chromatographed on both the SPB1 column used in GC studies and a 50-m \times 0.25-mm (id) DB5 (J & W) column under the following conditions: initial temperature, 80°C; temperature program, 20°C/min after 1 min; final temperature, 225°C. The retention times and fragmentation patterns of both the synthetic compounds and those present in natural products were compared. All synthetic chemicals were obtained from Sigma Chemical Company (St. Louis, Missouri).

RESULTS

Structure of Hairpencil Gland. The modified hairs that make up the cuticular structures of the hairpencil gland are elongate and distinct from the flattened structure of nonspecialized body scales (Figure 1A and B). The glandular hairs have rows of circular pores separated by cuticular ridges extending their length (Figure 1C and D). Pores communicate with a duct in the interior of the structure (Figure 1E and F). The density of the pores diminishes toward the distal tip (Figure 1D).

The cellular units in direct communication with the hairs are trichogen cells having closely associated tormogen and unmodified epidermal cells (Figure 1F and G). Nuclei of the trichogen cells are situated in the basal cell area, are well defined, and of lobulate structure. The central and apical areas of these cells are packed with vacuoles and osmiophilic droplets of similar size and structure to the vacuoles. The vacuoles are assumed to have contained lipid that was extracted during fixation and dehydration because traces of lipid were detected in some vacuoles. The apical cell membrane is involuted, leaving a large space that communicated with the duct of the hair associated with each cell (Figure 1G).

Isolation and Identification. Initial GC analyses obtained on three different capillary columns of one male equivalent (ME) ($N = 25$) of the whole gland extracts indicated the presence of three peaks that were present in a consistent ratio. These peaks had retention indices corresponding to hexadecanol (16:OH), hexadecanyl acetate (16:Ac) and (*Z*)-11-hexadecenyl acetate (Z11-16:Ac). In addition, peaks having retention times corresponding to octadecanol (18:OH) and octadecanyl acetate (18:Ac) were present, but the amounts varied substantially. Three other peaks also were present in chromatograms obtained using the SPB1 column. This column was capable of chromatographing free fatty acids, although peak shape was poor. These peaks had both relative retention indices and peak shapes that suggested that they were tetradecanoic (14:Acid), hexadecanoic (16:Acid), and octadecanoic (18:Acid) acids. Methanolysis of the extracts and subsequent chromatography on the three capillary columns indi-

FIG. 1. Scanning electron micrographs and micrographs of hairpencil glands and scales: (A) unmodified scales of male genitalia adjacent to hairpencil gland (S); (B) elongate hairs of the hairpencil gland modified for dissemination of chemicals; (C) pores (P) and ridges along surface of the hair; (D) tip of the hair showing reduction in pore size and number (P); (E) section through tip of hair showing pores in cuticle (P) and internal ducts (D); (F) section through hairpencil gland complex; H = hair, D = duct of hair, P = pores in scale, SO = socket; (G) section through trichogen gland cell (Tr), N = nucleus, L = lipid droplet, I = infolds in apical cell membrane, To = tormogen cell.

cated that the acid assignments were correct because the methyl esters of the acids were detected at concentrations of 2.7 (± 0.9) ng 14:Acid, 22.2 (± 7.3) ng 16:Acid, and 6.3 (± 1.2) ng 18:Acid.

Gas chromatographic analyses of extracts of the glandular hairs that disseminate the pheromone indicated that all of the above components were present in the same ratio found in whole gland extracts. Extracts of groups of five ME analyzed on all GC columns also contained compounds that had relative retention indices corresponding to tetradecanol (14:OH), tetradecanyl acetate (14:Ac), (Z)-9-tetradecenyl acetate (Z9-14:Ac), (Z)-11-hexadecenol (Z11-16:OH), (Z)-7-hexadecenyl acetate (Z7-16:Ac), and (Z)-9-hexadecenyl acetate (Z9-16:Ac) (Figure 2). The amount of 18:Ac was highly variable, and some extracts did not contain this compound. The ratio and concentrations of these compounds are given in Table 1. Mass spectra (60–400 amu) and relative retention indices of the compounds present in the hair extract of 15–25 ME using both capillary columns coupled with EI, positive ion CI (methane), and CI (isobutane) MS confirmed the presence of 16:OH, Z11-16:Ac, 16:Ac, 18:OH, 18:Ac, 14:Acid, 16:Acid, and 18:Acid. Adequate spectra of the other compounds were not obtained. The use of negative ion CI-MS decreased substantially the amount of each acetate required to obtain spectral data. However, only a single ion, corresponding to M-1, was detected. Alcohols were not detected. When 15 ME of the glandular hair extract was analyzed in this manner, ions representing M-1 ($m/z = 281$) were detected at retention times coin-

FIG. 2. Chromatogram obtained from analysis of five male equivalents of the extracts of glandular hairs using the SPB1 capillary column. 1 = 14:OH, 2 = 14:Acid, 3 = Z9-14:Ac, 4 = 14:Ac, 5 = Z11-16:OH, 6 = 16:OH, 7 = 16:Acid, 8 = Z7-16:Ac, 9 = Z9-16:Ac, 10 = Z11-16:Ac, 11 = 16:Ac, 12 = 18:OH, 13 = 18:Acid, 14 = 18:Ac.

TABLE 1. COMPOUNDS PRESENT IN HAIRPENCIL GLAND EXTRACTS OF MALES OF *Heliothis virescens* BASED ON GAS CHROMATOGRAPHIC ANALYSIS ($N = 20$).

Compound	Mean amount (ng)	SD	Normalized percentage
14:OH	0.35	0.22	0.16
14:Ac	1.2	0.92	0.56
Z9-14:Ac	0.19	0.09	0.09
14:Acid	2.7	2.1	0.13
16:OH	27.3	15.6	12.85
Z11-16:OH	.27	.25	0.13
16:Ac	212.4	78.4	100.00
Z7-16:Ac	0.52	.40	0.29
Z9-16:Ac	0.18	0.15	0.08
Z11-16:Ac	3.5	1.0	1.16
16:Acid	22.2	7.3	10.36
18:OH	2.5	3.6	1.18
18:Ac	14.2	6.2	6.69
18:Acid	6.3	1.15	2.97

cident with synthetic standards of Z7-16:Ac, Z9-16:Ac, and Z11-16:Ac. The ratio of ion intensities for $m/z = 281$ of the peaks corresponding of Z7-16:Ac and Z9-16:Ac was 2.1:1 (mean of three runs), which was similar to the 2.9:1 ratio detected in GC analyses. Although this provides good evidence that Z7-16:Ac and Z9-16:Ac are present, we cannot be certain of their existence without further and more complete spectral data.

Volatiles collected on the charcoal entrainment filter of the pheromone released by males responding to the female sex pheromone contained an 11:1 ratio of 16:Ac to 16:OH. The greatest amount of 16:Ac recovered from a male was 12.2 ng after six hairpencil exposures. Therefore, minor components were not detected due to the small amount of material collected. The 11:1 ratio present in these samples is comparable to the 9:1 ratio found in glandular hair extracts when considering the recovery efficiencies of the acetates and alcohols from the charcoal filter (Tumlinson et al., 1982). In order to obtain greater quantities of the volatile components, we developed the second technique of volatile collection. GC and GC-mass spectral analysis of volatiles collected in this manner confirmed the presence of 16:Ac and 16:OH. GC analyses also indicated the presence of 14:Ac, Z11-16:Ac, and 18:OH. However, background was too high to obtain useful mass spectra of these compounds. GC and GC-mass spectral analyses of the esterified, volatile samples confirmed the presence of 14:Acid, 16:Acid, and 18:Acid. The ratio of all of the components was consistent with that found in extracts.

Biosynthesis. Studies indicated that the glands of pharate adults did not

contain detectable amounts of either 16:Ac or 16:OH. However, detectable amounts of both compounds were present in extracts of the hairpencil glands of males that had just emerged but had not expanded their wings (Figure 3). The amounts of each compound increased rapidly after adult emergence and peaked at the levels found in isolation identification studies within 36 hr after adult emergence. The titer of these compounds remained high at all times of the light or dark period (Figure 3) provided that the male did not evert the hairpencils. Substantial depletion of both 16:OH and 16:Ac occurred when males exposed their hairpencils numerous times in response to the sex pheromone blend produced by females (Figure 4). The greatest reduction, with respect to control males, was 32-fold for 16:Ac and 27-fold for 16:OH for a male that made eight flights from downwind and exposed his hairpencils several times after each landing. The smallest reduction was fivefold for both 16:Ac and 16:OH, and the majority of insects tested maintained titers of these two compounds that were 8- to 12-fold less than in the control insects. Minor components were not detected in any of the extracts obtained from males that had exposed the hairpencils repeatedly, and the amounts of the acids did not appear to be reduced, although esterified samples were not prepared.

FIG. 3. Titers of 16:Ac (○ — ○) and 16:OH (+ ··· +) in extracts of pheromone glands of males sampled at various ages. Values are normalized to the mean amounts of 16:Ac (212.4 ng) and 16:OH (27.3 ng) present in extracts of males 48 hr old ($N = 5$ for each point).

FIG. 4. Comparison of extract obtained from the hairpencil glands of a virgin male *H. virescens* with that obtained from a male that had exposed the hairpencil gland numerous times during four flights from downwind in the flight tunnel. SPB1 column; attenuation = 8× for both chromatograms.

Application of 500 ng of 14:OH or Z11-16:OH to intact hairpencil glands, glands denuded of hairs, and the hairs from denuded glands did not result in changes in the ratios of the corresponding acetates present in extracts. Similarly, other alcohols including (*E*)- and (*Z*)-11-tetradecenol (*E*11-14:OH, Z11-14:OH) or Z9-14:OH were not converted to the corresponding acetates when applied to the gland surface or to either the removed hairs or intact hairs. Scales incubated with 14:Ac, *E*11-14:Ac, or Z9-14:Ac did not convert the acetates to the alcohol analogs. However, substantial amounts of the alcohols were produced when the acetates were applied to the surface of the denuded gland (Figure 5). The conversion showed no specificity for either presence or geometry of double bonds as is indicated by the production of 4.0 (± 1.2) ng more 14:OH

FIG. 5. Comparison of extracts of hairpencil gland (hairs removed) treated with *E11-14:Ac* in DMSO (upper), *E11-14:OH* in DMSO (middle), or untreated (lower) using the SPB1 capillary column.

than was present in glands of untreated preparations ($N = 10$) and $3.7 (\pm 0.7)$ ng ($N = 10$) of $E11-14:Ac$ after a 1-hr incubation. Studies conducted 12 hr after the peak of the reproductive period indicated that the temporal periodicity governing male response to the female pheromone had no effect on the biosynthetic capability of the gland because $3.9 (\pm 0.6)$ ng of $E11-14:OH$ was produced by preparations treated with the corresponding acetate during this period. Similar amounts of $Z9-14:OH$ and $Z11-14:OH$ were produced when glands were treated with the corresponding acetates.

DISCUSSION

Until recently, the components identified as male pheromones, for example, benzaldehyde and 2-phenylethanol (Tamaki, 1986), have had no structural similarity to the components released by females. However, Heath et al. (1988) have documented that males of *Anticarsia gemmatalis* (Hübner) release (*Z,Z,Z*)-3,6,9-heneicosatriene from abdominal scent scales and have shown that this compound is attractive to other males. This compound is one of the pheromone components also produced by females. The identification of the acetates, alcohols, and acids that correspond to the aldehydic components released by *H. virescens* females (Teal et al., 1986) shows a close relationship between pheromone biosynthesis by males and females of this species. This close relationship is also demonstrated by the presence of an acetate esterase that functions to produce alcohol precursors in female glands (Teal and Tumlinson, 1987) as well as in the hairpencil glands where it produces the alcohol components. The function of such esterases is common among females of other moth species, for example *Choristoneura fumiferana* (Clem.) (Morse and Meighen, 1984, 1986), but this is the first report of the function of the esterase in production of pheromone components by males of Lepidoptera.

It is of interest to note that the acetates that correspond to all six of the aldehydes, which comprise the pheromone released by females of *H. virescens*, were found in the hairpencil extracts. However, the ratio of the acetates was very different from that of the aldehydes released by females. For example, the ratio of $16:Ac$ to $Z11-16:Ac$ present in the hairpencil pheromone gland is approximately 68:1, while that of hexadecanal to (*Z*)-11-hexadecenal given off by females is 1:8 (Teal et al., 1986). This indicates that while both sexes possess the enzymes involved in desaturation (see Bjostad and Roelofs, 1983), the enzyme activities are different.

The ratio of the acetates present in greatest amounts to the corresponding alcohols was similar, being about 7:1 for $18:Ac/18:OH$, 8:1 for $16:Ac/16:OH$, 9:1 for $Z11-16:Ac/Z11-16:OH$, and 6:1 for $14:Ac/14:OH$. Therefore, it is probable that the alcohols corresponding to $Z7-16:Ac$, $Z9-16:Ac$,

and Z9-14:Ac are present in the hairpencil gland, but were not identified because of the small amounts present. This hypothesis is supported by our studies on biosynthesis, which have indicated that the acetates are converted to the corresponding alcohols. There also may be a similar correlation between the unsaturated acetates and their corresponding acids, given that the saturated acids that are analogous to 14:Ac, 16:Ac, and 18:Ac were identified. However, this hypothesis cannot be supported at present because, as yet, none of the unsaturated acid analogs have been identified.

The rise in amounts of the alcohol and acetate components present in the hairpencil gland after adult emergence correlates well with reproductive maturity and parallels the increase in production of the sex pheromone produced by females (Shorey et al., 1968). However, while titers of pheromone components drop dramatically after the calling period in the glands of virgin female moths (Pope et al., 1982), the concentration in males remains constant. Therefore, it appears that biosynthesis by males proceeds until a specific titer is reached and then stops with the products being stored, perhaps in the extracellular pocket subtending the hairs. Our data indicate that after depletion of these compounds, during hairpencil exposure, the alcohols and acetates are regenerated at a rate that would ensure that males would have a full titer of these compounds during the next reproductive period. Given that the components released from the hairpencils are important for reproductive success in that they cause females to begin to call and to become receptive to male courtship advances (Teal et al., in preparation), depletion of the compounds during unsuccessful mating attempts would explain why these males are less likely to mate on subsequent attempts during the same reproductive period than are males that have not exposed their hairpencils (Teal et al., 1981).

Abstract—Understory biomass heterogeneity under *Platanus occidentalis* L., *Quercus alba* L., *Celtis occidentalis* Pursh., and *Ulmus americana* L. was studied. Soil pH, Ca, Mg, Mn, Cu, NH₄ nitrogen, total N, and soil moisture were significantly different under all dominant species. The pattern of soil moisture levels under different tree species was not consistent from one sampling period to the next. The aboveground biomass of understory vegetation also varied significantly under different tree species and was not correlated with variation in any of the soil properties. Maximum understory biomass gain (340%) from May to September occurred under oak trees, where soil moisture and most nutrients were the lowest. On the other hand, sycamore and hackberry had continuous release of allelochemicals and the smallest understory biomass gain (103%) during the growing season, even though soil under both species had more moisture and nutrients than the soils under white oak. Eliminating all the factors studied leads to the conclusion that organic substances released in the immediate environment of dominant trees and their litter influenced soils and associated herb growth. In each dominant niche system, understory species may have to develop their own system ("micro-niche") to minimize the stresses of competition and allelochemicals.

Key Words—Allelopathy, biomass, mineral elements, soil moisture, deciduous forest

INTRODUCTION

Vegetation-soil relationships in plant communities are often explained in terms of gradients. Rogers (1983) reported that 10 stands of mesophytic forest sampled were similar with respect to physiography and soil and suggested that many factors (time, weather, floristic composition, frequency, etc.) could be responsible for biomass of understory vegetation. Gauch and Stone (1979) intensively sampled a single 2-ha stand of mixed deciduous forest and found that the main vegetation gradient was due to moisture variability associated with elevation (3 m) differences. However, they also reported that the moisture gradient was accompanied in soil nutrients (pH, N, P, K, Mg, and Mn), texture, and leaf litter. Apparently many soil factors may vary together, forming a complex gradient. McIntosh (1970) stated that in nature, no factor ever varies alone. A "moisture" gradient generally assumes the built-in variation of all available growth-associated factors in a community (Gauch and Stone, 1979).

Parrish and Bazzaz (1976) suggested that species variation in requirements for nutrients can be the cause of niche formation. If different niches are developed by different dominant tree species, then the understory layer under the dominant species would have to develop competitive microniches within the limitation of available resources. Therefore, the biomass of understory species may be influenced under various dominant tree species due to differences in the available resources under them. The niche space cannot be determined by a spectrum of resource types but is due to a spectrum of resource availability (Garbutt and Zangerl, 1983) controlled by the dominant species.

Zinke (1962) studied the patterns of soil properties under single forest trees and found systematic changes in physical and chemical soil properties with varying distances from the tree trunk. Such variation also influenced the ground flora. Similarly, Gersper and Holowaychuck (1971) reported that the soil chemistry pattern under a single forest tree was developed with radial symmetry to the tree. Variations under different species were due to organic litter or to a combination of litter and stem flow (Zinke, 1962; Gersper and Holowaychuck, 1971). Lodhi (1977, 1978b) reported variability in many soil factors under different tree species. Soil pH, Ca, Mg, K, Fe, Zn, Cu, NO_3 , NH_4 , total N, and nitrifying bacteria was found to be different under five different tree species, indicating that tree species exert a strong influence over their own niches.

All these studies reported the variation of factors important for plant growth, but none reported the growth responses of understory vegetation to such factors. Further, there was no indication of the influence of soil moisture on the heterogeneity of nutrient availability and their relation to the understory vegetation under different tree species. Availability of nutrients and their circulation in plants is directly dependent on availability of soil moisture. With these facts in mind, a project was developed to determine the variability of soil moisture

and nutrient conditions in conjunction with understory vegetation growth responses under different tree species in a forest community.

METHODS AND MATERIALS

Location and Description of Study Area. A forest plot was established on the Maryville College campus in St. Louis County, Missouri, ($\approx 39^\circ\text{N}$, 90°W). The vegetation consisted of a mixed bottomland forest in which the important tree species were sycamore (*P. occidentalis*), hackberry (*C. occidentalis*), white oak (*Quercus alba*), red oak (*Q. rubra* L.), and American elm (*U. americana*) with several minor tree species. Important species in the understory were white snakeroot (*Eupatorium rugosum* Houtt.), coralberry (*Symphoricarpos orbiculatus* Moench.), wild rye (*Elymus canadensis* L.), Virginia creeper (*Parthenocissus quinquefolia* (L.) Planch.), and downy brome (*Bromus tectorum* L.), with several minor species.

To describe the quantitative growth of understory vegetation under tree species, 10 randomly located 0.25-m² quadrats were clipped in late May and late September under each of four species: American elm, sycamore, hackberry, and white oak. Sampling in May was to estimate the exploitation of nutrient resources at the start of the growing season. The understory growth estimate in late September was considered to be the biomass accumulation of all species and would reflect the utilization and incorporation of available nutrients and moisture.

Physical and Chemical Analyses of Soil. Soil moisture, pH, and nutrient analyses were made to see if the differences in the growth of understory vegetation under American elm, sycamore, hackberry, and white oak correspond to differences in soil chemical and physical properties.

Soil moisture was determined during the months of April, May, June, and August by taking 10 soil samples at the 0- to 15- and 15- to 30-cm levels under American elm, sycamore, hackberry, and white oak at each sampling time. All samples were weighed, oven-dried for 48 hr at 100°C, and reweighed to determine the amount of water lost.

Soil samples for physical and chemical analyses were collected in early April, before the beginning of the growing season, in order to estimate the maximum nutrient amounts available for plant growth. Ten samples were collected at the 0- to 30-cm level under each of the four tree species. The pH was determined with a glass electrode on a 1:4 suspension of soil in aerated distilled water. Potassium, Ca, Fe, Mg, Zn, Mn, and Cu were determined with an atomic absorption spectrophotometer. Ammonium and nitrate were determined with Orion electrodes. Nine of 10 soil samples were combined into three composite samples and analyzed for total N with a Kjeldahl method. Analyses were done

on air-dry soil, but calculations were on the basis of oven-dry weight. Soil moisture was estimated every four weeks (except in July) starting in April.

Data Analysis. Data were analyzed with procedures given by Sokal and Rohlf (1981). Several data sets were found to be not normally distributed, so nonparametric statistical methods were used. The Kolmogorov-Smirnov test was used to test for differences between different sets of the same variable, and Spearman's rank correlation was used to test for association between variables. The word "significant" used below refers to a probability of 0.05 or lower.

RESULTS

Soil pH, Ca, Mg, Mn, Cu, NH_4 , and total N were significantly different under American elm, sycamore, hackberry, and white oak (Table 1). Except from the 15- to 30-cm May sample, soil moisture at the 0- to 15- and 15- to 30-cm levels was also significantly different between all four tree species (Table 2). The variability of soil moisture between different tree species was not consistent from one sampling period to the next. In seven of eight data sets at two depths, white oak had the lowest amounts of soil moisture, while the highest amounts of soil moisture were found under sycamore and hackberry (three data sets each). American elm and oak were each highest in one data set. Soils were nearly saturated at the May and June sampling periods.

The aboveground biomass of understory vegetation varied under different tree species in both sampling periods (Table 3). The biomass of understory vegetation in May was used as an estimate of utilization of the resources avail-

TABLE 1. SOIL CHEMICAL VARIABLES (MEAN \pm SE)^a

Variable	Hackberry (a)	Sycamore (b)	American elm (c)	White oak (d)
Cu	22.2 \pm 1.6 (d)	18.0 \pm 2.0 (d)	18.4 \pm 2.0 (d)	9.1 \pm 0.6 (a, b, c)

TABLE 3. UNDERSTORY BIOMASS UNDER FOUR DOMINANT TREE SPECIES

Species	Biomass (g/m ²)		Change (%)
	May	September	
American elm	61	110	80
Sycamore	35	71	103
Hackberry	29	88	203
White oak	20	88	340

able in April. September understory biomass was considered to be an estimate of the utilization of resources through the growing season. Field soil moisture and vegetation growth were not correlated in most cases (Tables 2 and 3). The understory vegetation under white oak trees, where soil moisture was lowest in both April and August samples at the 0- to 15- and 15- to 30-cm levels, showed the highest biomass increase (340%) from May to September.

DISCUSSION

Usually vegetation growth responses are reported to vary with certain gradients or factors such as soil moisture (Gauch and Stone, 1979; Pickett and Bazzaz, 1976), light, or nutrients (Parrish and Bazzaz, 1976). However, data collected in this study do not show any association of moisture with understory growth under different tree species. Understory biomass response under white oak trees (with lowest moisture amounts) was greatest, contrary to what was

expected. Some of the soil chemical factors were found to differ significantly under the different tree species (Table 1), but no significant correlations were found between any measured chemical or physical soil variable and herb biomass.

Our data indicate that moisture is not the gradient factor associated with the vegetational responses, even when we consider "moisture" as a complex gradient factor that may act as a passive carrier for available nutrients. In this event, maximum growth should associate with maximum soil moisture. Gauch and Stone (1979) reported that understory and dominant vegetation growth pattern was caused mainly by moisture accompanied by gradients in elevation, soil nutrients, pH, texture, and mineral content of leaf litter. Other reports have indicated that understory growth under trees is greatly influenced by tree leaf litter (Jamison, 1942; Zinke, 1962; Gersper and Holowaychuck, 1971; Lodhi, 1977). It should be mentioned that all these reports also found significant differences between soil nutrients under different tree species. However, the reports did not indicate in what way leaf litter quality may have influenced the understory growth.

The function of leaf litter in patterning of vegetation has not been adequately investigated. Gauch and Stone (1979) reported the role of leaf litter nutrients in patterning of vegetation. It seems quite possible that organic substances released from the litter and stem flow may play a major differential stress role in patterning of understory growth under different tree species (Gersper and Holowaychuck, 1971). Levitt (1972) described stress as a condition imposed upon an organism or a population in response to variations in the levels of environmental factors. Organic substances (allelochemicals) may induce physiological conditions in an organism detrimental to its growth. Lauenroth et al. (1978) define stress as a physiological condition that poses a homeostatic threat to the organism. Allelochemicals released by the litter can differentially interact with the herb layer under different tree species. Vegetation under sycamore, with high soil moisture, showed only 103% understory biomass increase from May to September, as compared to 340% increase under white oak trees associated with soils having the lowest amounts of moisture and the most nutrients. Overall, areas under American elm had the most total understory biomass and the least evidence of allelopathy. All three other species had relatively large amounts of allelochemicals under them, but litter decay was at different rates. White oak had a high overwinter retention of allelochemicals, strongly inhibiting early understory growth, but had a lower rate of litter decomposition during the growing season resulting in reduced inhibition. Understory biomass under white oak had the greatest gain (340%), even with the lowest soil moisture and the most nutrients. This is in agreement with a report by Lodhi (1978a) who found that most allelochemicals in white oak are bonded, which results in a very slow rate of release and the highest accumulation in the soil during the early growing

season. Obviously, this slow release of bonded allelochemicals compounded by a slow litter decay rate was not sufficient to inhibit the understory growth rate at the same intensity as in the initial growing period. On the other hand, sycamore and hackberry had more continuous release of allelochemicals, which kept the understory biomass gain to a minimum (103%) during the growing season, even though soils beneath both species had higher soil moisture and nutrients than the white oak soils.

Allelochemic ecological stress may induce a physiological condition that causes interference in plant-water relationships. Colton and Einhellig (1980) designed elaborate experiments to clearly demonstrate the turgor loss, altered leaf diffusive resistance, and water potential changes in plants growing under such allelochemic ecological stress. Altered leaf diffusive resistance and water potential indicate stomatal closure and a probable reduction in availability of CO₂, thus interfering with the photosynthetic mechanisms (Einhellig et al., 1970; Lodhi and Nickell, 1973). Further, Einhellig and Rasmussen (1979) and Colton and Einhellig (1980) demonstrated that allelochemicals and litter containing allelochemicals can significantly lower the chlorophyll content of plants. Glass (1974a, b) reported that many allelochemicals may interfere with nutrient uptake.

Lodhi (1976, 1978a) reported that sycamore, hackberry, and white oak contained many allelochemicals. Further, the leaf decay rate of hackberry was the highest followed by sycamore and white oak. The white oak stand has the maximum (22% of litter) identifiable as oak litter at the last sampling in August, whereas sycamore and hackberry had only 8 and 0%, respectively, in their stands (Lodhi, 1978a). Sycamore contained many free phenolics, which were released in the associated soils, thus increasing the physiological stress on the understory vegetation. White oak contained one free and several bonded allelochemicals in its associated soil and leaves and influenced the understory growth in May more drastically. Later in the season there was a higher growth rate under white oak (Lodhi, 1976, 1978a). Understory biomass under elm trees was the highest at both sampling times.

If the variability in understory biomass under dominant trees was to be attributed (at least partially) to the allelochemicals released by the intact tree vegetation, then the decaying litter should be able to contribute large amounts of inhibitors to the soil before the next growing season. Furthermore, these inhibitors and those in the litter should allelopathically reduce the growth of understory vegetation. Previous work showed that amounts of all identified inhibitors remained high in soils (Table 4) throughout the year, most importantly in the growing season. The decay rate of the litter is such that it maintained the allelopathic potential even in August and reduced the growth by 24% (Table 4). Therefore, there remains no doubt that allelochemicals are directly released from the litter of dominant trees, thus differentially influencing the growth of the understory vegetation as determined by the dominant trees.

TABLE 4. TOTAL AMOUNTS OF ALLELOCHEMICS IN FOREST SOIL AND DECAYING LITTER AND THEIR TOXICITY^a

Sample	Allelochemics, (kg/ha) ^b	Identifiable litter	
		% of total ^c	Toxicity, % of control ^d
January	5676	80	41
April	4927	40	29
August	1722	13	24

^aSummarized from Lodhi (1978a).

^bMore than 50% inhibition in radicle growth caused by 1097 kg/ha of a single allelochemic.

^cAmounts of combined identifiable litter of allelopathic species as percent of total litter.

^dEffects of decaying leaf litter on radicle growth of brome grass. Peat moss was used as control.

It seems logical that the niche system of each dominant tree species significantly differs from the others. Therefore the understory species would have to respond differently in each niche where "physiological conditions" are different. Furthermore, understory plants would have to compete for available resources under the influence of great variability of allelochemic stress caused by the dominant species. Therefore, in each dominant niche system, understory species would have to develop their own system (microniche) to minimize the stresses of both competition and allelochemics.

It is clear that variability in understory growth under different tree species is not the function of a "moisture" factor/gradient even in its complex sense as discussed by Gauch and Stone (1979) and McIntosh (1970). This leaves the litter type and its organic constituents as an alternate driving force in the variability of the understory biomass. We strongly recommend that physiological stresses should be given serious consideration when vegetation responses are measured at the ecosystem, single stand, and/or at the niche level.

DECREASED SENSITIVITY OF MIXED-FUNCTION OXIDASES FROM *Papilio polyxenes* TO INHIBITORS IN HOST PLANTS

J.J. NEAL¹ and MAY BERENBAUM

Department of Entomology
University of Illinois
Urbana, Illinois 61801

(Received November 5, 1987; accepted December 28, 1987)

Abstract—Caterpillars of *Papilio polyxenes*, the black swallowtail, feed on umbellifers that contain both toxic furanocoumarins and methylenedioxyphenyl compounds such as myristicin and safrole. These phytosynergists enhance the toxicity of furanocoumarins by inhibiting mixed-function oxidases (MFOs), the detoxification enzymes responsible for metabolizing furanocoumarins. In model substrate assays, MFOs from *P. polyxenes* are twice as active as MFOs from *Heliothis zea*, a generalist herbivore not adapted to feeding on either furanocoumarins or furanocoumarin/phytosynergist combinations. *P. polyxenes* MFOs are 10 and 46 times less sensitive to inhibition by myristicin and safrole, respectively, than *H. zea* MFOs and eight times less sensitive to inhibition by safrole than MFOs from *Papilio troilus*, a closely related species that does not encounter furanocoumarin/phytosynergist combinations in its diet. Higher MFO activity and decreased sensitivity to MFO inhibitors are important adaptations that allow black swallowtail caterpillars to feed on many umbelliferous plants.

Key Words—Lepidoptera, *Papilio polyxenes*, *Papilio troilus*, Papilionidae, *Heliothis zea*, noctuidae, myristicin, safrole, xanthotoxin, mixed-function oxidase inhibition, methylenedioxyphenyl.

¹Present address: J.J. Neal, Purdue University, Department of Entomology, Entomology Hall, W. Lafayette, Indiana 47907.

INTRODUCTION

Caterpillars of *Papilio polyxenes* (Lepidoptera: Papilionidae), the black swallowtail, feed on furanocoumarin-containing plants of the families Umbelliferae and Rutaceae (Berenbaum, 1981). While furanocoumarins are toxic and phototoxic to microbes, vertebrates, and many species of insects (Murray et al., 1982), *P. polyxenes* thrives on diets containing linear furanocoumarins such as xanthotoxin (Berenbaum, 1981). The ability of *P. polyxenes* to tolerate xanthotoxin is due to its rapid metabolism and elimination; xanthotoxin is metabolized much faster in *P. polyxenes* than in the fall armyworm, *Spodoptera frugiperda* (Lepidoptera; Noctuidae), an insect not adapted to feeding on furanocoumarins (Ivie et al., 1983; Bull et al., 1984).

Xanthotoxin detoxification in *P. polyxenes* is largely due to mixed-function oxidases (MFOs), detoxification enzymes located in the midgut (Ivie et al., 1983; Bull et al., 1984). One characteristic of these enzymes is their inhibition by methylenedioxyphenyl-containing (MDP) compounds. In many host plants of *P. polyxenes* (Tyler, 1975), furanocoumarins cooccur with MDP compounds such as myristicin and safrole (Berenbaum, 1983; Neal, 1987). Myristicin and safrole inhibit MFOs and are synergists of some synthetic organic insecticides (Hodgson and Philpot, 1974). They are also phytosynergists (plant compounds that have a synergistic effect on cooccurring toxins) of xanthotoxin (Berenbaum and Neal, 1985; Neal, 1987). When incorporated into an artificial diet, both myristicin and safrole increased the toxicity of xanthotoxin to the corn earworm, *Heliothis zea* (Lepidoptera; Noctuidae), a caterpillar not adapted to feeding on furanocoumarin/phytosynergist combinations (Berenbaum and Neal, 1985; Neal, 1987).

In order to metabolize xanthotoxin rapidly, *P. polyxenes* must contend with the inhibitory effects of MDP compounds. Possible adaptations of *P. polyxenes* for feeding on plants containing both toxins and phytosynergists include increased MFO activity or decreased sensitivity of MFOs to inhibition by MDPs. To investigate these possibilities, the inhibition by MDPs and the activity of MFOs from *P. polyxenes* were compared to MFOs from two other species of Lepidoptera, *Heliothis zea* and *Papilio troilus*. *H. zea*, the corn earworm, was chosen because MDPs are known to have a synergistic effect on the toxicity of xanthotoxin to first-instar larvae (Berenbaum and Neal, 1985; Neal, 1987). Thus, MFOs from this species should be strongly inhibited by MDPs. *P. troilus*, the spicebush swallowtail, feeds on leaves of *Sassafras albidum* (Tyler, 1975). While the roots and the bark contain safrole as the primary oil component, safrole is not detectable in the leaves (Kleber, 1899; Gant and Clebsch, 1975). *Sassafras* is not known to contain furanocoumarins (Murray et al., 1982), and *P. troilus* is rarely reported to feed on plants that contain furanocoumarins (Tyler, 1975; Murray et al., 1982). While closely related to *P. polyxenes*, *P.*

troilus is not exposed to furanocoumarins, although it may have some exposure to safrole in its diet. Thus *P. polyxenes* is expected to be adapted to furanocoumarin/phytosynergist combinations while *P. troilus* and *H. zea* are not.

METHODS AND MATERIALS

Chemicals. $MgCl_2$, $NADP^+$, glucose-6-phosphate (G6P), glucose-6-phosphate dehydrogenase type XI (GDH), phenylmethane sulfonyl fluoride (PMSF), sucrose, EDTA, polyvinylpyrrolidone, xanthotoxin, and Tris HCl were purchased from Sigma Chemical Co. (St. Louis, Missouri); safrole and pentamethylbenzene from Aldrich Chemical Company (Milwaukee, Wisconsin); myristicin from Saber Labs (Morton Grove, Illinois); and *p*-nitroanisole (pNA) and *p*-nitrophenol (pNP) from Eastman Kodak (Rochester, New York).

Insect Rearing. *H. zea* larvae from a laboratory culture maintained at the University of Illinois by Dr. G. Waldbauer (Waldbauer et al., 1984) were reared individually to fourth instar on artificial diet (Berenbaum and Neal, 1985). They were then switched to diet containing 0.2% wet weight pentamethylbenzene, a known inducer of *O*-demethylase activity (Brattsten and Wilkinson, 1973) to facilitate measurement of inhibition. *P. polyxenes* and *P. troilus* larvae were reared from eggs collected from females captured in Illinois. *P. polyxenes* were greenhouse-reared on potted wild parsnip (*Pastinaca sativa*) plants grown from seeds collected in Champaign County, Illinois. *P. troilus* were reared in plastic boxes in a growth chamber on leaves of *Sassafras albidum*.

Midgut Microsome Preparations and Activity. All measurements were made on *H. zea* larvae three days after molting to fifth instar and on *P. polyxenes* and *P. troilus* larvae two to four days after molting to fifth instar. Guts were dissected in ice-cold sucrose medium (0.25 M sucrose; 1 mM EDTA; 1% polyvinylpyrrolidone) containing 2 mM PMSF (Crankshaw et al., 1979) and ground with a Ten Broek homogenizer in sucrose medium with 0.5 mM PMSF. The homogenate was centrifuged at 10,000g for 10 min at 4°C; the supernatant was transferred and centrifuged at 100,000 g for 1 hr at 0°C. The resulting supernatant was discarded and the pellet resuspended in 0.4 M Tris buffer (pH 7.4). *H. zea*, *P. troilus*, and *P. polyxenes* produced 0.36, 0.77, and 1.3 mg microsomal protein per larva, respectively.

A model substrate reaction, *O*-demethylation of pNA, was used for studies of inhibitor kinetics. The kinetics of this reaction have been studied in other insects, and no problems with formation of irreversible complexes or end-product inhibition have been encountered (Hansen and Hodgson, 1971). *O*-Demethylation of pNA was measured by the method of Hansen and Hodgson (1971). Approximately 0.8 mg microsomal protein was incubated for 30 min at 31°C in 10-ml Erlenmeyer flasks containing 0.5 mM $NADP^+$, 2.5 mM G6P, 7.5

mM $MgCl_2$, 0.4 units GDH, 50 mM Tris and pNA, and in a final volume of 1.6 ml. The reaction was stopped by adding 0.4 ml 1 N HCl and pNP extracted into 2 ml dichloromethane. After centrifuging to separate the layers, pNP was extracted from a 1.2-ml aliquot of the dichloromethane with 1.2 ml of 0.5 N NaOH and quantified by measuring absorbance at 400 nm in a Perkin-Elmer dual-beam spectrophotometer. To measure inhibition, inhibitors were added to the incubation mixture in 0.02 ml methyl cellulose prior to adding the microsomes to start the reaction. All reactions were run as duplicates and replicated at least once.

I_{50} values (the concentration of inhibitor required to reduce the reaction rate by half) were determined by linear regression of the overall average percent inhibition on the log of the inhibitor concentration. I_{50} values for inhibition of microsomal *O*-demethylation of pNA were determined using 0.5 mM pNA. The Michaelis constant, K_m , for pNA was determined from plots of reciprocal velocity versus reciprocal concentration. The inhibitor constant, K_i , for safrole and myristicin was determined from the overall mean activities by the method of Dixon (1953). Metabolism of xanthotoxin was determined by the method of Nitao (1987). Fifty micrograms xanthotoxin in acetone solution was added to a 10-ml Erlenmeyer flask and the acetone evaporated. Then 1.2 ml of 0.1 M Tris buffer containing the same NADPH-generating system used for *O*-demethylation was added to the flask and the reaction started by addition of a microsomal suspension to produce a final protein concentration of 0.5 mg/ml. The reaction was terminated after 30 min by the addition of 0.4 ml of 0.1 N HCl. Xanthotoxin was extracted in ethyl acetate and quantified by HPLC as described by Nitao (1987). Dye reagent for protein assay and bovine plasma albumin (Bio-Rad Chemical Division, Richmond, California) were used to determine protein content.

RESULTS

The Michaelis constant, K_m , for binding of pNA by microsomes was approximately 0.4 mM for both *H. zea* and *P. polyxenes*; the V_{max} for *P. polyxenes* (3.8 nmol pNA oxidized/min) was almost twice that for *H. zea* (2.1 nmol pNA oxidized/min) at the same protein concentration (0.5 mg/ml) (Figure 1). In other words, the MFOs from both species have similar affinities for the model substrate, but *P. polyxenes* metabolizes the substrate at almost twice the rate as *H. zea*. Too few larvae were available to measure these parameters in *P. troilus*.

Larger differences among species in the inhibition of *O*-demethylase activity by myristicin and safrole were noted. For 50% inhibition of *O*-demethylation (I_{50}), 2 μ M myristicin was required for *H. zea*, and 92 μ M myristicin was

FIG. 1. Double reciprocal plot of *O*-demethylation of *p*-nitroanisole by microsomes from *Heliothis zea* (■) and *Papilio polyxenes* (●). $1/S$ = substrate concentration in $1/\text{mM}$; $1/V$ = velocity in min/nmol . K_m for both *H. zea* and *P. polyxenes* is 0.4 mM . V_{max} is $2.1 \text{ nmol}/\text{min}$ for *H. zea* and $3.8 \text{ nmol}/\text{min}$ for *P. polyxenes*.

required for *P. polyxenes* (Figure 2). The inhibitor constant, K_i , for the dissociation of the enzyme inhibitor complex was $1 \mu\text{M}$ myristicin for *H. zea* and $104 \mu\text{M}$ myristicin for *P. polyxenes*. In *P. polyxenes*, the myristicin concentration required for 50% inhibition of xanthotoxin metabolism ($101 \mu\text{M}$) is similar

FIG. 2. Percent inhibition versus myristicin concentration for *O*-demethylation of *p*-nitroanisole by microsomes from *Heliothis zea* (■) and *Papilio polyxenes* (●) and metabolism of xanthotoxin by microsomes from *P. polyxenes* (○).

FIG. 3. Percent inhibition versus safrole concentration for *O*-demethylation of *p*-nitroanisole by microsomes from *Heliothis zea* (■), *Papilio polyxenes* (●) and *Papilio troilus* (▲).

to that required for *p*NA *O*-demethylation (92 μ M) (Figure 2). K_i was not determined for inhibition of xanthotoxin metabolism by *P. polyxenes*. Metabolism of xanthotoxin by *H. zea* was too slow to detect inhibitory effects in the 30-min assay.

The I_{50} s for inhibition of *p*NA *O*-demethylation by safrole were 6 μ M with *H. zea* MFOs, 8 μ M for *P. troilus* MFOs, and 64 μ M for *P. polyxenes* MFOs (Figure 3). The inhibitor constant, K_i , for the dissociation of the enzyme inhibitor complex was 2 μ M safrole for *H. zea* and 60 μ M safrole for *P. polyxenes*.

DISCUSSION

There are two factors that allow *P. polyxenes* to feed on furanocoumarin/phytosynergist combinations. The first is more rapid metabolism of substrates by *P. polyxenes*. The V_{max} for *O*-demethylation of *p*NA is greater for *P. polyxenes* than for *H. zea*. This difference could be attributable either to a larger amount of *O*-demethylase or to a more active *O*-demethylase in *P. polyxenes* on a per milligram midgut microsomal protein basis. This high activity extends to other substrates as well; in comparison with *Spodoptera frugiperda*, *P. polyxenes* metabolizes xanthotoxin six times faster (Bull et al., 1984).

Among insect species, differences in rates of MFO activity spanning several orders of magnitude have been reported (Krieger et al., 1971; Rose, 1985), and attempts have been made to correlate MFO activity with the degree of host-plant specialization (Krieger et al., 1971) or the presence of certain classes of

allelochemicals such as monoterpenes in the host plants (Rose, 1985). Many host plants of *P. polyxenes* contain monoterpenes, and MFOs may be responsible for their detoxification. However, a causal link between monoterpenes and high constitutive MFO activity has not been established. Another factor necessitating high MFO activity in *P. polyxenes* is the need to metabolize a toxin in the presence of an MFO inhibitor in the diet. The majority of host plants (Berenbaum, 1981) contain furanocoumarins (Murray et al., 1982), and many of these plants contain MFO inhibitors (Berenbaum and Neal, 1985, 1986). Very high MFO activity has also been noted in *Papilio cresphontes* (Neal, 1987), *P. aegaeus*, and *P. anactus* (Rose, 1985), papilionids that also feed on plants containing furanocoumarins and MDP compounds. Thus, rapid substrate metabolism appears to be an adaptation of papilionids that feed on plants containing furanocoumarin/phytosynergist combinations.

The second factor that allows *P. polyxenes* to feed on furanocoumarin/phytosynergist combinations is its decreased sensitivity to inhibition by MDP-containing phytosynergists such as myristicin and safrole. *P. polyxenes* is 46-fold and 10-fold less sensitive than *H. zea* to MFO inhibition by myristicin and safrole, respectively and eight-fold less sensitive to MFO inhibition by safrole than *P. troilus*. This reduced sensitivity applies to other inhibitors as well. Bull et al. (1986) compared aldrin epoxidase activity in *P. polyxenes* and *Spodoptera frugiperda* in the presence of piperonyl butoxide (PB), a synthetic MDP-containing insecticide synergist. From their data can be calculated an I_{50} of 48 μM PB for *P. polyxenes*, a value five times greater than the calculated value of 8.5 μM for *S. frugiperda*.

The exact mechanism for reduced sensitivity in *P. polyxenes* is unknown. MDP compounds such as myristicin are partially competitive inhibitors of MFOs and can form a noncompetitive inhibitor complex with the enzyme (Hodgson and Philpot, 1974). Reduced sensitivity to MDP inhibitors could result from either more rapid metabolism and elimination of the MDP substituent from the enzyme or lower affinity for MDPs.

(Received August 24, 1987; accepted January 4, 1988)

Abstract—*Heliothis armigera* and *Spodoptera littoralis* females produced sex pheromone during their scotophase. Maximum levels of pheromone in *Heliothis armigera* were extracted from 2- to 3-day-old females during their 4.5-hr scotophase. On ligation between the head and the thorax of both species, normal pheromone production was inhibited. Homogenates of brains (consisting of brains, subesophageal ganglia, corpora cardiaca, and corpora allata) from both species induced a normal level of pheromone production by ligated females. Moreover, in *S. littoralis*, female brain hormone induced the production of the two components (*Z*)-9- and (*Z, E*)-9,11-tetradecenyl acetate tested by gas chromatography. Partial separation of brain homogenates, using low pressure C18-silica reversed-phase columns, produced a stable and active hormone source that gave a dose-dependent response. This hormone was found in brain extracts of both male and female *H. armigera* and *S. littoralis* females. In addition, *S. littoralis* induced pheromone production by *H. armigera* ligated females.

Key Words—Hormonal control, sex pheromone, *Heliothis armigera*, *Spodoptera littoralis*, Lepidoptera, Noctuidae.

INTRODUCTION

Most insects are sexually active during specific times of the day, and the production and release of sex pheromone appears to operate on a circadian cycle (Baker and Cardé, 1979; Cardé and Webster, 1981; Raina et al., 1986). The translation of physiological and environmental signals to the production of sex pheromone has been shown to be mediated by the endocrine system in females

of 12 species (Blomquist and Dillwith, 1983). Most of the early studies used behavioral bioassay techniques, and it was not possible to determine whether the synthesis and/or release of sex pheromone components was influenced by hormones. Using a direct chemical determination of pheromone titer, evidence is now accumulating indicating that pheromone production is under hormonal control in *Heliothis zea* (Noctuidae) (Raina and Klun, 1984a, b), in *Chilo suppressalis* (Pyralidae) (Ohguchi et al., 1985), and possibly in *Platynota stultana* (Tortricidae) (Webster and Cardé, 1984). Recently a pheromone biosynthesis activating neuropeptide (PBAN) has been isolated and purified from brain complexes of *Heliothis zea* (Jaffe et al., 1986; Raina et al., 1987). In the present study, we report on further evidence of hormonal control in two other species of Lepidoptera showing that the hormone may be widely distributed in this order.

METHODS AND MATERIALS

Insect Colonies. A colony of *Spodoptera littoralis* was started from several collections of 70–100 insects from the field during their larval feeding stage. Larvae were raised on the following diet: 500 g ground beans, 200 g alfalfa pellets, 75 g bactoagar, 16 g methyl paraben, 16 g ascorbic acid, 16 ml formaldehyde (40%), 5 g sorbic acid, 160 g yeast extract, 3 liters water. Larvae were kept in groups of 5–10 in 100-ml plastic jars (6.5 × 4.0 cm) and maintained in an incubator at 25°C with a 14:10 light–dark cycle. Pupae were removed from the jars and treated in 0.001% formaldehyde solution for 20 min to prevent viral infection. Female and male pupae were separated and placed in 24 × 24 × 13 cm animal cages (Techniplast) adapted by us for insects. Cages containing female pupae (max 60 pupae/cage) were kept in a separate incubator under the above conditions. Similarly a colony of *H. armigera* was started from several field collections of 200 or more insects. Field-collected larvae (from beans, chickpeas, cotton, maize, and tomatoes) were transferred to artificial diet using the above *Spodoptera* diet. Larvae were kept in groups in plastic containers (20 × 20 × 5 cm) during the first stages. Third-instar larvae were transferred, in pairs, to individual jars (50 ml) to prevent cannibalism. Male and female pupae were separated, and cages containing female pupae were kept in a separate incubator under the same conditions.

Calling Behavior. Calling was observed during the scotophase in the presence of a dim red light. Four groups of 10 females each were observed at 10-min intervals, and the number of females with extruded glands were recorded.

Pheromone Extraction and Separation. Pheromone produced by females was extracted by gently squeezing the abdomen and cutting the extruded 8th and 9th abdominal segments. In this way the pheromone gland in the intersegmental membrane between the two segments was removed. Pheromone glands

were subsequently extracted for 10 min in 100 μ l hexane containing 37.77 ng tridecanyl acetate (Sigma) as the internal standard. A Tracor gas chromatograph with FID and an LDC integrator was used to separate standards and extracts using the following conditions: The initial temperature of 70°C was held for 2 min then increased to 185°C at 10°C/min. The detector temperature was held at 230°C; column inlet temperature was at 225°C. Helium was used as the carrier gas at flow pressure of 22 psi. Separations were performed with a splitless injector on a Carbowax 20 M (Supelco) or a DB 225 (J&W) fused tube glass capillary column.

Preparation of Brain Extracts. Brains (comprising brains, subesophageal ganglia, corpora cardiaca, and corpora allata, and henceforth referred to as brains) were dissected under ice into saline containing: 9.82 g/liter NaCl, 0.48 g/liter KCl, 0.73 g/liter $MgCl_2 \cdot 6H_2O$, 0.84 g/liter NaH_2PO_4 , 0.18 g/liter $NaHCO_3$, and 0.001 g/liter phenol red, at pH 7. Subsequently the tissues were homogenized using 1-ml glass homogenizers. Processing of saline brain homogenates was performed on a low-pressure C18-silica cartridge (Sep-pak, Waters Assoc.), a solvent exchange step in which large proteins and salts are removed from the active sample, rendering a stable extract. All extracts were eluted using 80% methanol after loading, as reported previously (Rafaeli et al., 1985). The methanol was evaporated using a Speedvac concentrator (Savant) and reconstituted in saline before injecting into ligated female abdomens.

In Vivo Bioassay for Hormone Response. The ligation method (Raina and Klun, 1984a) was used to examine the role of brain extracts on pheromone production of both species of Lepidoptera in this study. At the beginning of photophase, 1- to 2-day-old females were ligated between the head and thorax. During the following scotophase 3 hr before maximum pheromone production, the ligated females received an injection of brain homogenate or extract in saline prepared from brains of conspecific males or females. Saline and muscle extract injections were tested as controls. Twenty microliters of the test solution was injected into each female through the intersegmental membrane of the abdomen using a Hamilton syringe.

Statistical Analyses. Statistical analyses were performed on a Vax computer housed at the Agricultural Faculty in Rehovot utilizing SAS statistical software, release 82.2 (SAS, 1982). Treatment means were compared by Student's *t* test to determine significant differences when compared to the controls.

RESULTS AND DISCUSSION

The diel rhythm of pheromone production by *H. armigera* was tested by extracting glands from 2- to 3-day-old females at various time intervals during scotophase. Three-day-old *H. armigera* females produced detectable amounts of Z11-16:Ald, and although a high variability of pheromone concentrations

was observed, maximum levels occurred at 4.5 hr scotophase (Figure 1). The diel rhythm was also evident when calling behavior was observed in 2- to 3-day-old females, and peak activity occurred at 7-8 hr into scotophase (Figure 1), 2-3 hr after maximal levels of pheromone production. A similar phenomenon was observed in the yellow peach moth (Konno, 1986).

Ligation stopped the production of pheromone by females of both *S. litoralis* and *H. armigera* (Tables 1 and 2). In addition, on injecting the abdomens of such ligated females with brain homogenates from males (Table 1) and

FIG. 1. Pheromone production and calling behavior by 2- to 3-day-old *Heliothis armigera* females at various times during their scotophase (6.30-16.30 hr). Data on calling behavior are presented as means \pm SEM of four replicate experiments.

Treatment	Z11-16: Ald concentration (ng/gland \pm SEM) ^a	
	2-day-old ♀	3-day-old ♀
Control ligated females	0.00 \pm 0.000b (6)	4.22 \pm 2.027d (5)
Unligated females	9.48 \pm 2.579a (9)	not tested
Ligated females + male brain	8.80 \pm 1.919a (7)	34.67 \pm 12.200c (7)
Ligated females \pm female brain	not tested	60.36 \pm 23.966c (7)

^aNumber of replicates indicated parentheses. Values with different letters are significantly different ($P < 0.001$, 2-day-old $P < 0.01$, 3-day-old, Student's t test).

females (Tables 1 and 2) pheromone production was restored to a level not significantly different from normal female pheromone production, and no significant difference was found between male and female homogenates as was found in *H. zea* (Raina et al., 1984a). Both species responded in the same manner. Clearly, a brain factor is responsible for the control of pheromone production in *H. armigera* and *S. littoralis* females after their ability to do so was inhibited by ligation. This finding supports the existence of a brain hormone that induces pheromone production. Our preliminary results indicate that the hormonal concentration in brains is high at 2 hr into scotophase (11.33 ± 3.67 ng/gland; $N = 9$) and subsequently declines (5.21 ± 4.12 ng/gland; $N = 7$) at 7 hr of scotophase.

Presumably, ligation prevented the timely release of the stimulating hor-

TABLE 2. INFLUENCE OF BRAIN HOMOGENATES ON PRODUCTION OF Z9-14: Ac AND Z,E9,11-14: Ac BY 2-DAY-OLD *Spodoptera littoralis* FEMALES AT HOUR 4 OF SCOTOPHASE

Treatment	Amount (ng/gland \pm SEM) ^a	
	Z9-14: Ac	Z, E9,11-14: Ac
Ligated female control	0.99 \pm 0.990b	0.95 \pm 0.953b (6)
Unligated females	12.31 \pm 2.211a	4.30 \pm 3.543b (7)
Ligated females + male brain (1 brain equiv)	12.80 \pm 4.107a	5.31 \pm 2.380b (6)

mone from reaching the target tissue. In *H. zea* (Raina and Klun, 1984a, b) and *C. suppressalis* (Ohguchi et al., 1985) ligation or decapitation at later time intervals before peak pheromone production showed a smaller inhibition of pheromone production due to this timely release of the hormone into the blood. It can be seen that *S. littoralis* female production of both pheromone components (*Z*)-9- and (*Z, E*)-9,11-tetradecenyl acetate were stimulated by brain hormone (Table 2). A similar phenomenon was observed in *C. suppressalis*, where levels of (*Z*)-11-hexadecenal and hexadecenal were stimulated by injections of brain extracts (Ohguchi et al., 1985). Thus, where tested, the brain extracts stimulated the production of more than the main pheromone component and, most likely, it can be speculated that the correct pheromone blend is produced.

Fresh saline homogenates were unstable, unless used fresh under ice, and we thus tested the effect of processed brain homogenates. Male and female processed brain homogenates showed an increase in pheromone production in ligated *H. armigera* females that was not significantly different from normal unligated females (Table 3). This increase in pheromone production is similar to that found with fresh brain homogenates (Table 1). A control extract of thoracic muscle was tested and showed no increase in pheromone production.

The response to these brain extracts increases with increasing incubation time after injection (Figure 2) and is dose-dependent (Figure 3), revealing a typical hormonal dose-response relationship.

Purified *S. littoralis* brain extracts were tested on the response of ligated *H. armigera* females. The results showed that *H. armigera* ligated females were stimulated to produce Z11-16:Ald by *S. littoralis* brain hormone to the same extent as stimulation by brain hormone from *H. armigera*. The fact that *S. littoralis* brain hormone was capable of inducing pheromone production by *H. armigera* females, in which the pheromone components differ widely from those

TABLE 3. EFFECT OF *Spodoptera littoralis* FEMALE AND *Heliothis armigera* FEMALE AND MALE PARTIALLY PURIFIED BRAIN HORMONE ON PRODUCTION OF Z11-16:Ald BY 2 TO 3-DAY-OLD *Heliothis armigera* LIGATED FEMALES

of *S. littoralis*, supports a possible universal role of a brain hormone in this order, as was suggested by Raina and Klun (1984a, b). This may indicate that hormonal stimulation is effective at least before the desaturation of the pheromone precursor, if we presume a saturated fatty acid as precursor (Bjostad and Roelofs, 1983; Arai et al., 1984; Dunkelblum et al., 1985). It can thus be speculated that the brain hormone induces some general and early step in the biosynthetic pathway involved in pheromone production; however, this awaits further investigation into the biosynthetic pathway of lepidopteran pheromones.

Acknowledgments—This work was supported by BARD grant US 784-84. We would like to thank Dr. J. A. Klun (USDA, Beltsville, Maryland) and Prof. I. Harpaz (Department of Entomology, Faculty of Agriculture) for helpful advice and R. Ben-Zaken for technical assistance.

INTRASPECIFIC VARIATION OF TWO COMPONENTS IN SEX PHEROMONE GLAND OF *Planotortrix* *excessana*¹ SIBLING SPECIES

S.P. FOSTER, J.R. CLEARWATER, and S.J. MUGGLESTON

Entomology Division, DSIR, Mt. Albert Research Centre
Private Bag, Auckland, New Zealand

(Received July 6, 1987; accepted January 5, 1988)

Abstract—Two components, (Z)-5- and (Z)-7-tetradecenyl acetates, in the sex pheromone gland of a *Planotortrix excessana* sibling species, were found to vary continuously from a ratio of 3:97 to 71:29 in individual female moths reared from wild larvae collected around New Zealand. Two laboratory colonies were established from populations representing extremes of these ratios. Although both the ratios and the total quantities of the components in individual female moths from both colonies were significantly different from each other, there was a small number of females that overlapped in both ratio and quantity. The variation was confirmed as intraspecific in a field cage experiment with male moths from both populations mating with tethered female moths from both populations.

Key Words—Sex pheromones, *Planotortrix excessana*, Lepidoptera, Tortricidae, leafroller, intraspecific variation, (Z)-5-tetradecenyl acetate, (Z)-7-tetradecenyl acetate.

INTRODUCTION

Female-produced sex pheromones of the Lepidoptera are generally multicomponent blends of chemicals derived from mono- or polyunsaturated long-chain fatty acids (Tamaki, 1985). Common to many species are precisely regulated mixtures of opposite *E* and *Z* geometric isomers that are critical for the specificity of the chemical communication system (Roelofs and Cardé, 1974).

In a study on the redbanded leafroller, *Argyrotaenia velutinana*, Miller and

¹Lepidoptera: Tortricidae: Tortricinae.

Roelofs (1980) found that the ratio of (*E*)- and (*Z*)-11-tetradecenyl acetates (*E*- and *Z*11-14:OAc) in individual female pheromone glands was precisely regulated at 9.1 ± 1.8 (% *E*11-14:OAc \pm SD) and 7.0 ± 1.4 in field-collected and laboratory colony populations respectively. Significant variation from a precisely regulated ratio as above has been used as a way of differentiating closely related, morphologically similar sibling species (Roelofs and Comeau, 1969). In this case, male responses to synthetic lures paralleled the differences in female production.

Although ratios of *E* and *Z* geometric isomers appear to be tightly controlled, significant variation has been noted in the ratios of monounsaturated acetates that are not geometric isomers; these include the summerfruit tortrix moth, *Adoxophyes orana* (Guerin et al., 1986); the turnip moth, *Agrotis segetum* (Löfstedt et al., 1985, 1986); and the larch budmoth, *Zeiraphera diniana* (Guerin et al., 1984). In a recent report, Du et al. (1987) showed that the amount of (*E*)-11-tetradecenyl acetate to its geometric isomer, (*Z*)-11-tetradecenyl acetate, was less variable than the relative amounts of other components in *Yponomeuta padellus*. In species where pheromone component ratios are not precisely regulated, it is important to determine the amount of intraspecific variation within female production and the parallel conspecific male responses, in order to separate this from possible interspecific differences.

Galbreath et al. (1985) reported pheromone differences in the endemic New Zealand leafroller moth pest *Planotortrix excessana* (Walker). Populations collected from Auckland (northern North Island) and Christchurch (mid-coastal South Island) were found to use a mixture of (*Z*)-8-tetradecenyl acetate and tetradecyl acetate. A population from Tokoroa (mid-North Island), however, used two completely different monounsaturated acetates, (*Z*)-5- and (*Z*)-7-tetradecenyl acetates (*Z*5-14:OAc and *Z*7-14:OAc). In a field cage experiment, males of the two populations (Christchurch and Tokoroa) were attracted only to pheromone extracts from females of their own population, leading Galbreath et al. (1985) to suggest that these two populations are sibling species.

This work was extended (Foster et al., 1986) by sampling individual females from a greater number of geographical areas. Within the *Z*5-14:OAc/*Z*7-14:OAc sibling species reported by Galbreath et al. (1985), two distinct groupings of females were observed. One produced ratios of the two components (*Z*5-14:OAc-*Z*7-14:OAc) from 46:54 (not 54:46 as misprinted in Foster et al., 1986) to 70:30, with an average quantity of the two components of 3.5 ng per female, and the other produced ratios from 12:88 to 33:67, with an average quantity of 22 ng per female.

In order to ascertain whether these differences are real, we analyzed a much greater number of female moths collected from various locations, including a number from laboratory colonies, to determine the variation within single populations. Further, to test the biological significance of this variation of female

production for male moths, we developed a rigorous field cage technique in which tethered virgin females from different populations are tested with males of one of the populations to determine whether mating occurs.

METHODS AND MATERIALS

Insects. Insects were collected as larvae from the North, South and Stewart Islands and reared to adult on a synthetic diet (Singh, 1974). Pupae were sexed, and male and female pupae kept separate.

Laboratory colonies of the two populations studied in detail (Waikato, North Island; and Dunedin, South Island), were established by mating groups of three to five males and females each in capped 100-mm-diameter \times 60-mm-high plastic containers. A thin layer of vermiculite was placed on the bottom of the container. Honey solution in a dental wick was available for the moths to feed on. Females oviposited on scored plastic removable liners located inside the containers. Neonate larvae were harvested and reared to adulthood as described in Singh (1974).

The insects were generally maintained at 18°C, but the temperature was changed to 10°C at times throughout the development of the larvae and pupae, to ensure synchronization of the two colonies. For the work reported here, the colonies originating from Waikato and Dunedin were in their fifth and second laboratory generations, respectively.

Females for capillary gas-liquid chromatographic (GLC) analysis were maintained on a reverse light-dark cycle (16 hr light-8 hr dark).

For field cage experiments (see below), pupae were conditioned outside for at least a week prior to emergence, before use.

GLC Analysis. The pheromone glands of individual female moths between 3 and 5 days old were excised 1-2 hr into the scotophase period using fine forceps under a binocular microscope and extracted by allowing to stand in ca. 10 μ l of distilled pentane for approximately 24 hr at ambient temperature.

The gland extracts of individual female moths were analyzed on Pye Unicam 4500 and Varian 3500 gas chromatographs. Both machines were equipped with splitless injection and flame ionization detection. Three fused silica capillary columns were used: a 50-m \times 0.32-mm ID, S.G.E. Corp. (Ringwood, Australia) BP20 (stabilized Carbowax 20 M); a 50-m \times 0.25-mm ID, Quadrex Corp. (New Haven, Connecticut) CPS-1 (bonded SP2340); and a 50-m \times 0.25-mm ID, Silar 10C (Quadrex Corp.). These columns were temperature programmed after a delay of 1 min at the initial temperature as follows: 100-200°C at 4°C/min (BP20 column), 100-180°C at 3°C/min (CPS-1 column), and 60-140°C at 8°C/min then to 180°C at 2°C/min (Silar 10C). Nitrogen was the carrier gas at linear flow rates of 25 cm/sec (BP20 and CPS-1 columns) and 8

cm/sec (Silar 10C). Quantities of chemicals were calculated relative to added tridecanyl acetate internal standard.

Statistical comparisons of pheromone production by individuals of populations were carried out using the Wilcoxon rank-sum test. All differences are reported to $P < 0.05$.

Field Cage Trial. The trial was conducted in two 10-m \times 10-m \times 2.4-m-high field cages, covered with 20 \times 30 mesh fiberglass cloth (Sarlon Reid, Auckland, New Zealand). The two cages were situated approximately 50 m apart and sited at Mt. Albert Research Centre, Auckland.

Twenty-five, 75-cm-long bamboo poles were suspended from the roof of each field cage in a symmetrical 5 \times 5 grid. The base of each pole was located approximately 1 m from the floor of the field cage and just above the plant growth inside the field cage, which consisted of *Griselinia littoralis* (Raoul) (a native host plant of *P. excessana*) and various unidentified weeds.

Three-day-old virgin female moths were tethered by a piece of fine cotton (80 grade), approximately 40 cm long, formed into a noose and placed and tightened around the base of the forewing and hindwing on one side of the moth. The other end of the cotton was wedged into a slit on the bamboo pole. This left the moth free to move around the pole and as free as possible to call and mate. Females were replaced every one or two days. After females had been replaced, their genitalia were dissected under a binocular microscope and the presence or absence of a male spermatophore in the female bursa copulatrix was recorded.

Male moths 2–3 days old were released daily into the field cages, commencing one day prior to the start of the experiment. Male moths inside the cages were left to accumulate during the course of the experiment (10 days).

Tethered females from two populations (Waikato and Dunedin) were placed inside both field cages. Waikato males were released into one cage and Dunedin males into the other cage. In the cage containing Waikato males, a total of 61 Dunedin females and 87 Waikato females were used. In the cage containing the Dunedin males, a total of 38 Dunedin females and 51 Waikato females were used. Totals of 233 Waikato males and 65 Dunedin males were released into the cages.

Analysis of this experiment was conducted using least significant difference tests with percentages transformed to their arcsine value.

RESULTS

The results of analyses of 145 individual females of the Z5-14:OAc/Z7-14:OAc sibling species of *P. excessana* (Galbreath et al., 1985) collected as larvae are summarized in Figure 1. These data show a wide range both of ratios

FIG. 1. Plot of total quantity of (Z)-5- and (Z)-7-tetradecenyl acetates (Z5- and Z7-14:OAc) and percentage of Z5-14:OAc in individual feral-collected female *Planotorix excessana*.

of Z5-14:OAc-Z7-14:OAc from 3:97 to 71:29 and quantities of these two chemicals per female from 0.4 ng to 71.5 ng. Quantities of these chemicals greater than 15 ng occurred only with the relatively tight ratios between 14:86 and 45:55, while insects with less than 5 ng had ratios covering the entire range. The mean ratio and quantity were $31:69 \pm 14$ and 10.9 ± 12.1 ng respectively. If the data from wild-collected individuals from the Waikato region (mid-North Island) are ignored (see below), then there are no significant differences in ratio or quantity between North Island and South Island individuals.

Two populations representing the greatest differences, one from Waikato and the other from Dunedin (southern South Island), were selected for further analysis. The wild-collected individuals from these populations show significant differences (Figure 2) in both ratio and quantity. Colonies of these two populations were established, and larger numbers of individual female moths from both populations were analyzed by GLC.

These analyses confirmed the differences between the populations in both ratio and quantity. The Dunedin colony females had a relatively tight range of ratios (Z5-14:OAc-Z7-14:OAc) from 11:89 to 42:58 with a mean of $24:76 \pm 7.7$. The quantity was more variable, ranging from 2.4 ng to a maximum of 59.3 ng with a mean of 13.2 ± 11.2 ng. The Waikato colony females, on the other hand, showed a much wider range of ratios from 23:77 to 81:19, mean $46:54 \pm 17$, but the quantity was less variable, ranging from 0.4 ng to 7.2 ng, mean 2.4 ± 1.6 ng.

It is important to note that, while the two colonies are significantly different

FIG. 2. Plot of total quantity of (Z)-5- and (Z)-7-tetradecenyl acetates (Z5- and Z7-14:OAc) and percentage of Z5-14:OAc in individual female *Planotortrix excessana* from laboratory colonies originally collected from Dunedin and Waikato. Feral-collected individuals from these regions are included for comparison.

in both ratio and quantity of these two components, there is some overlap of these two characters between the two colonies (Figure 2).

In the field cage containing Waikato males, a greater percentage of Dunedin females were mated than the Waikato females (18.0% to 6.9%), although this was not significant ($P > 0.05$). The cage containing Dunedin males gave significantly ($P < 0.05$) greater mating of Dunedin females than Waikato females (28.9% to 9.8%). Although not significant ($P > 0.05$), both mating percentages in the cage containing Dunedin males were higher than in the cage containing Waikato males, despite a much lower density of Dunedin males. Total numbers of mated females of both colonies were almost the same in both cages.

DISCUSSION

Analysis of the sex pheromone produced by female moths of the Z5-14:OAc/Z7-14:OAc *P. excessana* sibling species (Galbreath et al., 1985) shows that the ratio and quantity of two components are highly variable in both wild-collected and laboratory colony individuals.

Our initial observation (Foster et al., 1986) that two discrete groups of ratios and quantities existed, i.e., type B, ratio 46:54 to 70:30, mean quantity 3.5 ng; and type C, ratio 12:88 to 33:67, mean quantity 22 ng, is shown to

be untrue. Sampling of more individuals shows a near continuous range of ratios from 3:97 to 71:29 and a near continuous range of quantities up to 36 ng/female. A few female moths with quantities greater than this were observed, up to 71.5 ng.

However, within these wide ranges there are significant differences between populations. All the wild-collected and colony individuals analyzed from the Waikato population showed a very low quantity of the two components (mean quantity = 2.4 ng, maximum found in an individual = 7.2 ng). Additionally, a very wide range of ratios of the two components were found in these individuals (23:77 to 81:19). The distributions of quantities and ratios in both wild and colony individuals from the Waikato population were significantly different (Figure 2) from those from the Dunedin population that contained on average a much greater quantity of the two components and lower Z5-14:Ac-Z7-14:Ac ratios. However, a number of individuals (both wild-collected and colony-reared) from the two populations, coincided in both quantity and ratio (Figure 2).

The significance of this variation was tested in the field cage experiment. This showed clearly that males of both populations mated with females of both populations under simulated field conditions. Moths of both populations likely completed the whole gamut of male and female behavioral responses through to the transfer of a male spermatophore to the female's bursa copulatrix.

The differences between populations in female production of the two components, Z5-14:OAc and Z7-14:OAc, are therefore probably examples of intraspecific variation and not an interspecific difference, i.e., characters not capable by themselves of conferring reproductive specificity or characters paralleling other significant differences ensuring reproductive specificity of the populations. The two populations used in this study are, however, geographically isolated, and the prospect for direct gene flow between them is extremely unlikely. The wide range of ratios observed in other feral populations throughout New Zealand (Figure 1) is consistent with the above interpretation.

The differences between the populations are nevertheless interesting, particularly as they appear to be heritable and, in the case of the Waikato population at least, have survived through five generations of a laboratory-reared colony. Whether these differences are polymorphic expressions of a gene or gene complex or are environmentally induced polyphenisms (Shapiro, 1976) is unknown and will be the subject of further study.

Previous studies noting intraspecific variation in female pheromone production have not tested the behavioral responses of male moths to females from the different populations. In the case of the turnip moth, the differences noted between populations in female production have been paralleled by differences in attraction of male moths to synthetic blends approximating the observed female pheromone differences (Arn et al., 1983) and in male antennal receptor

frequencies (Löfstedt et al., 1986). In order to differentiate interspecific differences from intraspecific variation in morphologically similar populations, it is important that the behavioral responses of males from different populations to the female moths from the same and different populations are tested. This is particularly necessary where the difference is more difficult to resolve, i.e., between ratios of common components.

The lack of such a behavioral comparison between the different pheromone "dialects" reported by Löfstedt et al., (1986) leaves the true biological significance of this variation unanswered, i.e., whether the differences observed in the French population are representative of intraspecific variation or of interspecific differences from the Swedish, Hungarian, and English populations.

In our field cage experiment, there was a greater bias in mating by males from both populations with the Dunedin females. This may indicate that females of the Dunedin population are more attractive (possibly due to quantity or ratio of chemicals) to males than the Waikato females. This was paralleled by the lower percentages of mating of both Waikato and Dunedin females by the Waikato males, despite a much higher density of males in this cage compared to the cage with Dunedin males. In the absence of further evidence, we are cautious about attaching too much significance to this result, particularly as the overall mating was low. We suggest that the bias may be an artifact of laboratory rearing. At the time of the experiment, the Waikato colony had been in culture for five generations, and the Dunedin colony for only two generations. This or the temperature manipulation used to synchronize the colonies may have resulted in poorer sexual fitness of the Waikato colony.

The technique of using tethered females as a measure of cross-mating offers several advantages over the usual, but less rigorous, method of using virgin females as baits in sticky traps (Sanders et al., 1977). First, all necessary behaviors leading up to copulation must be effectively carried out, including long-range pheromone-mediated flight and any necessary specific male behavioral or chemical responses. Second, the presence of a male spermatophore in the female bursa copulatrix indicates genitalic compatibility, and third, males are not constantly being removed from the environment and therefore fewer are required for the experiment.

The major disadvantage of this method compared to the method using caged female moths in sticky traps is that the responses of two or more different "types" of male moths cannot be compared competitively in the same cage. Additionally, greater numbers of female moths are required for this method.

The variation in pheromone production reported here and in the limited examples noted for other species that do not use mixes of opposite geometric isomers, is substantially greater than the variation reported for species using mixtures of geometric isomers. Until we understand better the mechanisms involved in pheromone production and perception, and how precise ratios and

variable ratios are regulated and perceived in species, the biological importance of pheromone component variation will remain speculative.

Acknowledgments—We wish to thank our many colleagues from around New Zealand for collections of insects.

EFFECTS OF PHENOLIC ACIDS ON GERMINATION AND EARLY GROWTH OF HERBACEOUS WOODLAND PLANTS

A.T. KUITERS

*Department of Ecology and Ecotoxicology, Biologisch Laboratorium
Vrije Universiteit, Postbus 7161, 1007 MC Amsterdam, The Netherlands*

(Received December 17, 1986; accepted January 5, 1988)

Abstract—Four herbaceous plant species from woodland (clearings), *Deschampsia flexuosa*, *Scrophularia nodosa*, *Senecio sylvaticus*, and *Chamaenerion angustifolium*, were tested for their sensitivity to phenolic acids. Seven commonly occurring phenolic compounds were used in a germination experiment in concentrations ranging from 0.01 to 10 mM, i.e., salicylic, *p*-hydroxybenzoic, syringic, caffeic, vanillic, *p*-coumaric, and ferulic acids. Germination was delayed rather than inhibited. Radicle elongation was strongly affected; at lower concentrations stimulatory effects were observed, whereas at high concentrations radicle elongation was severely reduced. Salicylic acid was the most effective phenolic compound, whereas caffeic acid caused no effects. Early growth was studied in more detail in a second experiment with *Deschampsia flexuosa* and *Senecio sylvaticus* and the phenolic acids, ferulic and *p*-coumaric acid. Primary root length, number and length of secondary roots, and dry weight were stimulated at 0.01 mM but were inhibited at 10 mM of both compounds. The results are discussed in view of the allelopathic relations between trees and herbaceous understory vegetation.

Key Words—Phenolic acids, allelopathy, woodland plants, germination, early growth, *Deschampsia flexuosa*, *Scrophularia nodosa*, *Senecio sylvaticus*, *Chamaenerion angustifolium*.

INTRODUCTION

In forestry, litter is recognized as a potential selective agent for germination and growth of tree seedlings (Leibundgut, 1976; Rice, 1984; Becker and Drapier, 1984) and for herbaceous woodland plants (Lohdi, 1975; Ahlgren and

Ahlgren, 1981; Lohdi and Killingbeck, 1982). The toxic effects are often ascribed to phenolic substances (Flaig, 1973; Rice, 1984) released in high amounts from decomposing litter (Anderson, 1973; Blaschke, 1979; Kuiters and Sarink, 1986). Although polymerization to more complex humus compounds such as humic and fulvic acids occurs (Flaig, 1973), phenolic acids are permanently present in the soil solution with some seasonal fluctuation (Lohdi, 1975; Kuiters and Denneman, 1987). Due to their water solubility and their relatively simple molecular structure, they are easily taken up by plants (Flaig, 1973).

Many investigations have revealed that phenolics can seriously interfere with metabolic processes during germination, seedling, and later growth stages. Most of these studies have been carried out with crop or weed species (Demos et al., 1975; Rasmussen and Einhellig, 1977; Einhellig and Rasmussen, 1978; Lynch, 1980; Williams and Hoagland, 1982; Blum et al., 1984; Nandakumar and Rangaswamy, 1985), and little information is available about the sensitivity of woodland plants for phenolic substances. In this study we investigated the effects of commonly occurring phenolic acids on the germination of several woodland (-clearing) species and studied their effects on early seedling growth in more detail.

METHODS AND MATERIALS

Germination and Radicle Elongation

Four plant species, i.e., *Scrophularia nodosa* L., *Deschampsia flexuosa* (L.) Trin., *Senecio sylvaticus* L., and *Chamaenerion angustifolium* (L.) Scop., were tested in separate experiments for their sensitivity to phenolic acids. Seeds were collected at several woodland clearings in The Netherlands during the summer of 1984. Fifty seeds were placed on Whatman No. 1 paper on a plastic floater drifting on 50 ml test solution in small plastic containers (8 × 8 × 10 cm). The test solution consisted of phenolic acids commonly occurring in litter and soil of woodlands (Rice, 1984; Whitehead et al., 1982; Kuiters and Sarink, 1986; Kuiters and Denneman, 1987). The acids *p*-hydroxybenzoic, vanillic, caffeic, salicylic, syringic, *p*-coumaric, and ferulic were each tested in concentrations of 0, 0.01, 0.5, and 10 mM. In addition, an equimolar mixture of the seven phenolic acids, where the total phenolic acid concentration was either 0, 0.01, 0.5, or 10 mM, was tested. Each treatment was replicated five times. The plastic containers were placed at random in a climate room with a light-dark regime of 16:8 hr, light intensity of 50 W/m², temperature 21°C ± 3, and a relative humidity of 70%. The number of germinated seeds was recorded each day for 35 days, although germination was completed after 28 days. A seed was considered germinated if the radicle protruded from the seed coat by at

least 1 mm. Three variables were measured: total seed germination, 50% germination day, and radicle length of the 15 first germinated seedlings after 30 days. The 50% germination day (the day on which 50% of the total germinated seeds had germinated) was used as variable measuring the germination rate. All variables were calculated as percentage of the control (distilled water). For *Scrophularia* no radicle elongation was measured. Data were tested for homogeneity with Bartlett's test and, if necessary, were log-transformed. The statistical model was a two-way analysis of variance (Sokal and Rohlf, 1981). Although no statistical comparisons could be made between plant species, as they were tested in distinct experiments, some general observations could be made.

Early Seedling Growth

In an additional experiment, early seedling growth was studied in more detail. Plastic pots were filled with plastic beads and 300 ml test solution. Two phenolic acids, ferulic and *p*-coumaric, were used in concentrations of 0, 0.01, 0.5, and 1 mM. The phenolic acids were added to a 0.1 strength Hoagland solution (Hoagland and Arnon, 1950). A combined treatment (total concentration: 1 mM) was also used to determine if interference between both compounds occurs. Seven-day-old seedlings of either *Deschampsia* or *Senecio* were placed in the plastic pots. Each treatment was replicated three times, with eight seedlings per pot. After 21 days, plants were harvested and five variables were measured: dry weight, primary root length, number and length of secondary roots, and shoot length. Data were analyzed per plant species using Bartlett's test for homogeneity. If necessary data were log-transformed before a two-way ANOVA model was used (Sokal and Rohlf, 1981).

RESULTS

Germination Experiment

Total Seed Germination. The phenolic acids only slightly reduced total seed germination (Figure 1), although from Table 1 it can be concluded that for all species except *Scrophularia*, the effects were significant ($P < 0.001$). Moreover, the effects were dependent on the phenolic compound ($P < 0.001$). At concentrations of 0.01 and 0.5 mM neither of the phenolic acids influenced total seed germination. Only at the highest concentration (10 mM) was germination inhibited by some of the compounds. Salicylic acid and caffeic acid had the largest and smallest effect on total seed germination, respectively. The complete inhibition of germination of *Chamaenerion* seeds on 10 mM vanillic acid is striking. The other species were less severely inhibited by this compound. In

general, *Chamaenerion* and *Deschampsia* were most inhibited, whereas *Scrophularia* and *Senecio* were hardly affected by the phenolic acids.

50% Germination Day. The 50% germination day was used as a measure for the germination rate. This variable was slightly more affected by the phenolic compounds than total seed germination (Figure 2). Phenolic acids had a significant effect on the 50% germination day of all plant species ($P < 0.001$), and the effects were dependent on the type of phenolic compound (Table 1). At 0.01 and 0.5 mM, no distinct effects occurred, but at 10 mM the effects were considerable. At a concentration of 10 mM salicylic acid, the germination rate of seeds of *Chamaenerion* and *Deschampsia* was delayed by 260% and 150%, respectively. Germination rate of seeds of *Scrophularia* and *Senecio* was much less influenced.

Radicle Elongation. Radicle elongation was much more affected than germination (Figure 3). Phenolic acids had a significant effect on the radicle-length of the seedlings of each plant species ($P < 0.001$), and these effects were dependent on the phenolic compound (Table 1). At the lower concentrations (0.01 and 0.5 mM) some stimulatory effects occurred, especially by *Senecio*, but most of these roots were threadlike with very few hair roots. Radicle elongation of *Senecio* and *Chamaenerion* was severely inhibited by all phenolic acids at 10 mM. The radicle elongation of seedlings of *Deschampsia* was relatively unaffected by the phenolic compounds.

Order of Effectiveness of Phenolic Compounds. A comparison of the effectiveness of the phenolic acids (averaged over all tested plant species) revealed the following order from high to low:

Total seed germination: salicylic > ferulic > vanillic > syringic = *p*-coumaric > *p*-hydroxybenzoic = caffeic acid.

50% germination: salicylic > vanillic > ferulic = *p*-coumaric > *p*-hydroxybenzoic > syringic > caffeic acid.

Radicle elongation: *p*-coumaric > ferulic > salicylic > *p*-hydroxybenzoic > vanillic = syringic = caffeic acid.

The order differed slightly between the tested parameters. A comparison of the effects of the combination of compounds with each of the phenolic acids indicates that the effectiveness of each compound hardly changed when applied in combination with the others.

Seedling Experiment

Ferulic and *p*-coumaric acid affected seedling development of both *Deschampsia* and *Senecio* (Table 2). The phenolic acids had a significant effect on primary root length ($P < 0.001$), on number ($P < 0.01$) and length of secondary roots ($P < 0.01$), but not on shoot length (Table 3). With increasing phe-

nolic acid concentration, the dry weight of the seedlings decreased, although this effect was not significant. Effects were strongly dependent on the plant species ($P < 0.001$). No significant differences could be established between these phenolic compounds. The effects were most pronounced for *Deschampsia*, in which primary root length and secondary root development was largely stimulated at 0.01 mM *p*-coumaric acid. At the intermediate concentration of 0.5 mM of both compounds, no distinct effects were observed. At the highest concentration of both compounds (1 mM) the number of secondary roots was reduced, whereas the other parameters were hardly influenced. Comparing the effects of the combined treatment (0.5 mM of each compound) with those of

the treatments where the phenolic acids were added singly in concentrations of 0.5 or 1 mM, reveals that the effects were related to the total concentration rather than to an additional or synergistic effect of each individual compound.

DISCUSSION

Both experiments clearly indicate that phenolic compounds occurring in organic-rich soils can influence germination and seedling development of herbaceous plant species. The observed effects are highly dependent on the phenolic acid concentrations. Low concentrations of 0.01 mM often have a stimulatory effect, whereas concentrations of 1 mM and higher have an inhibitory effect. This was also observed by Scheffer and Ulrich (1960) and Flaig (1973). Germination was delayed rather than inhibited, conforming to the results of Williams and Hoagland (1982). Under field conditions, where competitive interference between herbs occurs, delay of seed germination may be as important as the inhibition of germination (Van Baalen et al., 1984). Root development was severely affected by phenolic compounds, as also found in other investigations (Hennequin and Juste, 1967; Rasmussen and Einhellig, 1977; Williams and Hoagland, 1982). Besides primary root elongation, the development and growth of secondary roots was severely affected. Low concentrations of *p*-coumaric and ferulic acid stimulated the development of secondary roots. Large differences in effectiveness were observed between the tested phenolic

acids. Salicylic, *p*-coumaric, and ferulic acids were most effective, while the effects of syringic and caffeic acids were relatively small. The order of activity we found more or less resembled that of Reynolds (1978), who used lettuce as test species. Apparently, the effectiveness of phenolic acids is determined to a large extent by chemical structure, but the sensitivity of the tested plant species clearly varied. No evidence was found in these experiments showing that the effects of phenolic acids on germination or radicle development are different when the compounds are applied in combination.

Several mechanisms for the effect of phenolic acids on germination and development of plants have been suggested. Phenolic acids may interfere with IAA (indole-acetic acid) metabolism, mitochondrial metabolism and respiration, photosynthesis, synthesis of proteins, and ion uptake and transport (Rice, 1984; Einhellig, 1986).

Among the tested species, *Deschampsia flexuosa* was the least and *Chamaenerion angustifolium* the most affected species. Compared to crop or weed species, the four species we tested were less sensitive to phenolic acids. Growth inhibition occurred beyond 1 mM, whereas crop species are often inhibited above a threshold value of 0.25 mM (Williams and Hoagland, 1982; Rasmussen and Einhellig, 1977; Einhellig and Rasmussen, 1978). The large amounts of phenolics present in forest leaf litter may have resulted in a selection so that woodland herbs are better adapted to these organic compounds than crop species.

Nevertheless, even this resistance may not be sufficient, as demonstrated by the inhibition of seedling development by high concentrations of phenolic acids. The high concentrations of phenolic substances in autumn during and after the leaf fall period (Kuiters and Sarink, 1986) may act as such a severe selecting agent (combined with mechanical stress) that germination in spring is favored. Indeed, most woodland herbs are spring germinators (Grime et al., 1981). The selection of a winter annual type of *Senecio sylvaticus* in Dutch coastal forests, however, may indicate that the factors determining germination time may be more complex (Ernst, 1985). The seedling stage seems to be a sensitive phase in the life cycle of plants with respect to phenolic compounds in the humus layers. The success of establishment of emerging seedlings is, besides other factors, presumably largely influenced by the chemical impacts of litter. The species composition of the herb layer in forests may be partly dependent on the litter type and not just on the preference of species for certain abiotic conditions, like shade, water, or nutrient conditions. Further knowledge of the effects of forest litter on germination and subsequent growth of seedlings, especially in relation to other soil factors (Ernst and Nelissen, 1979), is essential for a better understanding of species distribution and succession phenomena in forests.

CHARACTERIZATION AND PARTIAL PURIFICATION OF ATTRACTANTS FOR NEMATODE *Orrina phyllobia* FROM FOLIAGE OF *Solanum elaeagnifolium*

A.F. ROBINSON AND G. SALDANA

Agricultural Research Service, USDA
Subtropical Agricultural Research Laboratory
Weslaco, Texas 78596

(Received November 9, 1987; accepted January 8, 1988)

Abstract—An unknown attractant for the nematode *Orrina phyllobia* was extracted with water from foliage of *Solanum elaeagnifolium*. Stability, solubility, ionic character, and chromatographic purification were investigated using a bioassay based on nematode aggregation in agar. Activity was non-volatile, dialyzable, heat stable below 60°C, and partially lost within 30 min at 100°C. Activity was unchanged from pH 5 to 12, but was entirely lost at pH 2. Loss of activity at low pH did not appear to result from direct effects of pH on nematode behavior and was partially recovered by readjustment to pH 7. The attractive factor was most soluble in water and appeared to be cationically but not anionically exchangeable. Activity appeared to chromatograph as several compounds by high-performance liquid chromatography employing reverse phase C₁₈ and amine-bonded columns. Various known compounds that are common to *Solanum* spp. or that attract other nematodes were unattractive. Extraction of *S. elaeagnifolium* foliage specifically for solanaceous glycoalkaloids using methods developed for *S. tuberosum* did not yield an attractive product.

Key Words—*Orrina phyllobia*, *Solanum elaeagnifolium*, foliar nematode, host finding, nematode chemotaxis, silverleaf nightshade.

INTRODUCTION

More than 4000 nematode species parasitize plants and considerable research has been done toward learning how soil-borne infective stages find roots and stems (reviewed by Steiner, 1925; Croll, 1970; Green, 1971; Prot, 1980; Zuckerman and Jansson, 1984). Nematode orientation to temperature and soil mois-

ture gradients may assist host finding, but most evidence indicates chemotaxis is primarily responsible. Very little is known concerning specifically phytogetic attractants. Many nematodes are attracted to root leachates; in at least two cases, root leachate attractiveness was removed with activated charcoal, suggesting an organic nature (Miller and McIntyre, 1976; Peacock, 1961). Various common biogenic chemicals, largely amino acids, attract or repel some bacteriophagous, phytoparasitic, and zooparasitic nematodes on agar or agarose gels (Dusenbery, 1983; Pye and Burman, 1981; J.B. Ward et al., 1984; S. Ward, 1973). These include L-tryptophan, glutamic acid, aspartic acid, cysteine, L-tyrosine and other amines, cAMP, cGMP, gibberellic acid, glutathione, ascorbic acid, and pyridine. These responses were discovered by screening hundreds of known compounds and none has been established to mediate orientation within soil (Dusenbery, 1983). Failure to identify plant-specific attractants has encouraged the view (Klingler, 1965; Prot, 1980; Wallace, 1973) that phytoparasitic nematodes in soil may rely primarily on nonspecific chemical stimuli, such as CO₂ and inorganic ions for orientation. Several species orient on gradients of CO₂, Na⁺, Cl⁻, or OH⁻.

Progress toward understanding nematode chemotaxis as it relates to specific plant hosts has been made with the pine-wood nematode, *Bursaphelenchus xylophilus* (Futai, 1980). Various terpenes and other compounds common to the coniferous plants are attractive or repellant in vitro (Tominaga et al., 1983, 1984). The life cycle of this nematode differs from most phytoparasitic species in that it is normally transmitted to the trunk and branches of the host tree by a pine sawyer beetle (*Monochamus alternatus*), rather than by moving through soil. Thereafter, nematodes move and feed within resin canals where behavioral responses to terpenes may play an important role. Chemotactic preferences for tree saps appear related to host suitability among tree genera but not among pine species (Futai, 1980).

A second nematode whose behavior appears attuned to specific plants is *Orrina phyllobia*. It is known to parasitize only foliar parts of certain plants within the genus *Solanum* and is specifically attracted to leachates from stems of four *Solanum* spp. These are *S. tuberosum* (potato), *S. melongena* (eggplant), *S. carolinense* (Carolina horse nettle), and *S. elaeagnifolium* (silverleaf nightshade). Leachates from rhizomes of *Solanum* spp. and from stems of 30 plant species in other genera spanning 12 plant families were not attractive (Robinson et al., 1979). Attraction to stems is ecologically valuable to *O. phyllobia* because its life cycle entails aggregation of infective juveniles, which are about 700 μm long, within soil around stem bases and emerging shoot tips. When stem surfaces are moist, the juveniles ascend as far as 50 cm and invade foliar meristems to initiate new infections (Robinson et al., 1978). We have begun to characterize and chromatographically purify attractant from foliage of the common host,

S. elaeagnifolium, with a view toward understanding this rather host-specific behavior by a phytoparasitic nematode.

METHODS AND MATERIALS

Bioassay Procedure. Stems and leaves of *S. elaeagnifolium* were collected from field-grown plants, freeze dried intact, and ground with a Wiley mill. The powder obtained was stored in a desiccator over anhydrous CaSO_4 and used as a standard source of attractant. Preparations from plants collected on other occasions were similarly attractive. The assay we adopted was a modification of methods described by Balan et al. (1976) and Tominaga et al. (1983) for studying chemotaxis in other nematodes. Infective juveniles of *O. phyllobia* were removed daily from dried leaf galls of *S. elaeagnifolium* as previously described (Robinson et al., 1979) and suspended in a continuously aerated dilute salt solution (4.5 mM NaCl, 0.4 mM KCl, 0.05 mM CaCl_2 , 0.05 mM MgCl_2) to reduce ion regulation stress. Bacto-Agar (1.5%, Difco) was dissolved in water (w/w) supplemented with dilute salts equivalent to those in the nematode suspension. Equal parts of nematode suspension (22°C) and agar (42°C) were then mixed and poured into a 35-mm-diameter Petri dish to obtain a 2-mm-deep film of 0.75% agar containing about 3000 juveniles. The mixing procedure induced a brief reduction in motility from which nematodes completely recovered within several minutes. A 3-mm-diameter disk of filter paper (Whatman No. 1) saturated with the test solution and air-dried was placed halfway between the center and the edge of the dish. Trials with aqueous solutions of the biological stain safranin-O indicated that the pattern of diffusion of material from the dried disk was hemispherical downward. Two untreated disks were then placed equidistant from the center, 1 cm from each side of the treated disk. After 90 min, a 5-mm cork borer and small spatula were used to transfer agar cylinders containing the disks to counting dishes where the nematodes within each cylinder were dispersed into water and microscopically counted.

The response index (*RI*) was defined as $RI = T/(T + U)$ where *T* = nematodes under the treated disk and *U* = average number of nematodes under untreated disks in the same dish. *RI* > 50% indicated aggregation and *RI* < 50%, repulsion. *RI* values were binomially distributed and examined statistically after arcsine transformation. In each experiment except where noted, five dilutions spanning two orders of magnitude were prepared for bioassay from filtered aqueous extract of the dry plant powder (6% w/w). The 6% concentration will be referred to as standard foliar extract (SFE).

Nematode chemotaxis experiments are frequently conducted without light to mimic soil conditions. In preliminary experiments, we found that bioassay

results obtained under laboratory light were identical to results obtained in the dark. Small temperature gradients (ca. $0.1^{\circ}\text{C}/\text{cm}$) that resulted from differential evaporation of water within dishes strongly influenced nematode distributions. However, dishes were covered and oriented identically to minimize the effect. We recognized that test solutions might generate behaviorally important extremes of pH, ionic strength, and osmotic potential. To evaluate their contributions, we bioassayed aqueous solutions of acetic acid, HCl, and NaOH at 0.01, 0.1, 1, 10, and 100 mM. We also bioassayed solutions with osmotic pressures from 100 to 500 mM by supplementing water and foliar extract with sucrose or inorganic ions in ratios described. Standard foliar extract had 100–120 mM osmotic pressure by freezing point depression and pH 6.3–6.5. Bioassays were performed in five replicates. Experiments were repeated at least once. Reproducibility was sometimes confirmed by assigning numerical ratings to aggregations instead of counting nematodes.

Preliminary Characterization of Attractants. Standard foliar extract was bioassayed after each of the following procedures: dialysis against distilled water across 3500 MWCO dialysis tubing; filtration through activated charcoal; heating to 50, 60, 70, 90, and 100°C for various intervals up to 75 min; pH adjustment with HCl/NaOH; and readjustment to pH 7. Extract had appreciable buffering capacity near pH 6.5, and neutralization beyond 3 pH units required excessive dilution of extract or increases in Na^{+} and Cl^{-} concentrations >200 mM. These are physiologically significant levels; therefore, control solutions were prepared with similar osmotic pressures by adding NaCl to extract without pH adjustment. To examine attractant solubility, foliar powder was extracted (2% w/w) with solvent mixtures in a polarity series including water, methanol, 95% ethanol, 1-propanol, 1-butanol, diethyl ether, and hexane. Each extract was then filtered, evaporated to dryness, and reextracted with water at original volume. Residue obtained from the first filtration was separately reextracted with water and all solutions assayed. Ionic character was examined with pre-filled Poly-Prep columns (Bio-Rad) containing 2 ml of AG 50W-X8 and AG 1-X8 ion exchange resins in the H^{+} and Cl^{-} forms. Aqueous extract was prepared at 67% the concentration of SFE. After washing with distilled water, resin was drained under vacuum, and 3 ml of extract was passed through each column. Columns were then washed with 9 ml distilled water and eluted with 4 ml 100 mM KNO_3 , followed by another 4 ml 1 M KNO_3 . Eluates and washes were bioassayed before and after adjustment to pH 7 with NaOH.

Toward HPLC Purification. Preliminary separations were made with a Waters HPLC system equipped with a reverse phase C_{18} Semi-Prep column (7.8 mm \times 30 cm) (Waters) and a variable wavelength detector set at 254 nm. Solvent flow was 1.5 ml/min as follows: 15 min isocratic water, 10 min linear gradient to 100% methanol, 10 min hold, 20 min linear gradient to 100% water. Eleven 5-min fractions were collected separately from three 50- μl injections of

67% SFE, composited, evaporated to dryness (60°C), redissolved with 2 ml water, then reevaporated to dryness in small dishes under vacuum (50°C), and finally redissolved in 150 μ l water for bioassay. Solvent controls were also tested. A cleanup procedure using disposable C₁₈ preparatory columns (Sep Pak, Waters) was then developed based on the column volume equivalents of eluants needed for a stepwise approximation to the HPLC solvent gradient. Active fractions were prepared in quantity with the cleanup procedure. Further separations were done with an analytical C₁₈ Radial Pak cartridge (8 mm \times 10 cm) or an amine-bonded column (3.9 mm \times 30 cm) (Waters). Mobile phase for the C₁₈ cartridge was a 25-min water-methanol linear gradient (1.0 ml/min) from 20% to 80% methanol. Mobile phase for the amine-bonded column was a 20-min CH₃CN-water linear gradient (2.0 ml/min) from 90% to 65% CH₃CN, a 5-min hold, and a linear gradient back to initial conditions. Thirty-five 1-min fractions were collected separately from two injections, composited, evaporated, reextracted with 25 μ l water, and bioassayed.

Examination of Known Substances for Activity. Commercial preparations (Sigma) of various compounds were bioassayed because they are associated with *Solanum* spp. or because they have chemotactic activity to other nematodes. These included the common solanaceous glycoalkaloids α -chaconine and α -solanine at pH 7.5. With the view that attractants might occur among other *Solanum*-specific glycoalkaloids, the procedures described by Allen and Kuc (1968), by Bushway et al. (1985), and by Carman et al. (1986) for extracting glycoalkaloids from potato were applied to the *S. elaeagnifolium* foliar powder and confirmed by HPLC of product against commercial preparations of α -chaconine and α -solanine.

RESULTS AND DISCUSSION

Bioassay Procedure. The *RI* reached equilibrium after ca. 60 min (Figure 1A). The *RI* always approximated a log decay function of concentration that asymptotically approached 85–95%. The least-squares line relating *RI* and log₁₀ concentration was employed to express bioassay results in terms of the apparent concentration of attractant as well as in *RI* units (Figure 1B). Results of one experiment (Figure 3 below) are presented in both ways to convey the exponential relationship between attractant concentration and statistical uncertainty. Independent effects of pH on the bioassay were not detected with acetic acid and HCl solutions of pH > 2. NaOH > 10 mM caused weak aggregation and at pH 12 was equivalent to the effect of 3% SFE. Adding sucrose or mixed salts to water and foliar extract to generate osmotic pressures as high as 500 mM did not change bioassay results. Osmotic pressures of test solutions in subsequent experiments were <300 mM. Some species of nematodes respond

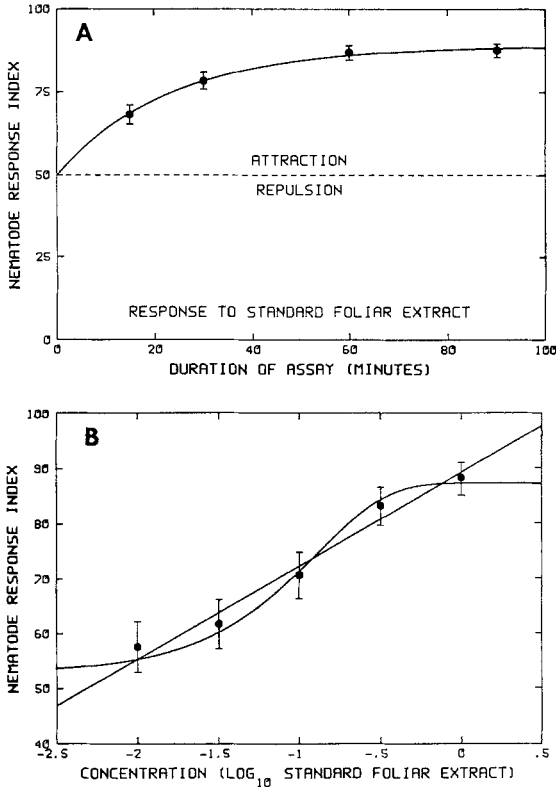

FIG. 1. Effects of bioassay duration and foliar attractant concentration on the nematode response index. (A) Increase in nematode response during 90-min exposure to aqueous extract of *Solanum elaeagnifolium* foliage. (B) Representative concentration-response curve for aqueous foliar extract. Concentrations are expressed as percentage of a standard concentration of dry foliage in water (6% w/w). Brackets indicate confidence intervals for five replicates obtained after arcsine transformation. The straight line and the sigmoid log decay function [$dy/dx = (Y - y)K$, where y = response index, x = concentration, Y = the maximum value of y , and K = a constant] were fitted by least squares.

behaviorally to pH, ion, and osmotic pressure gradients much smaller than we imposed (Dusenbery, 1983; Prot, 1980). If *O. phyllobia* also responds to them, their effects are very small under our assay conditions compared with the effects of attractant within *S. elaeagnifolium* foliage.

Preliminary Characterization of Attractants. Attractant from *S. elaeagnifolium* was essentially nonvolatile, freely dialyzable, and heat stable for 90 min under the conditions we used for evaporating test solutions ($< 60^{\circ}\text{C}$). How-

ever, some activity was lost within 30 min at 100°C (Figure 2A). Further losses were not detected up to 90 min, suggesting that heating generated a repulsive product or that two or more attractants were present and differed in temperature sensitivity. Activity was highly polar or ionic in character, not removed with activated charcoal, and most soluble in water (Figure 3). The attractiveness of standard foliar extract was completely lost by adjusting pH to 2 with HCl but was partially recovered after readjustment to 7 (Figure 2B). Addition of NaCl to standard foliar extract at concentrations equal to those generated by pH adjustment did not reduce activity, suggesting that direct effects of Na^+ and Cl^- on nematode behavior were not important factors. Disks with SFE at low pH frequently induced nematodes to aggregate in a halolike ring surrounding the disk 2–4 mm from its edge. When a second disk, which had been saturated with 0.1 N NaOH and dried, was placed on top of the first disk, the nematodes

Note the exponential effect of attractant concentration on statistical uncertainty.

comprising the ring accumulated underneath the disks within 15 min. Measurements of agar pH various distances from the disk with a 2-mm micro-pH electrode indicated that pH elevation to about 4 was required for aggregation. This effect may result from repellents or attractants that are pH reversible in activity.

Passage of 67% SFE through anion (Cl^-) and cation (H^+) exchange columns lowered pH to ca. 2 and removed activity. Upon readjustment to pH 7, extract from the anion exchange column was strongly attractive and extract from the cation exchange column was unattractive (Table 1). Elution with 100 mM

KNO₃ followed by adjustment to pH 7 yielded weak activity from the cation but not from the anion exchange resin. Therefore, attractant appeared completely unretained by anion exchange. Failure to recover full activity in the 100 mM KNO₃ cation exchange eluate may have resulted from incomplete elution, acid hydrolysis of attractants, or assay interference from NO₃⁻. Both 1 M KNO₃ eluates were repellent.

Toward HPLC Purification. High levels of activity were detected in the 6- to 10- (I) and 31- to 35- (II) min fractions obtained with the C₁₈ Semi-Prep column. Similar activity occurred in the corresponding fractions of the Sep-Pak cleanup (Figure 4). Bioassay results for subfractions of II from the analytical C₁₈ cartridge showed activity in a baseline separated peak eluting at 9.0 min. Fraction I was evaporated to dryness and reextracted with original volumes of CH₃CN-water mixtures. These were bioassayed, and the solubility of activity (Figure 5) was used to calculate appropriate concentrations of subfractions obtained for bioassay from the amine-bonded column. Most activity occurred in three distinct fractions (Figure 6), two of which contained consistently identifiable absorbance peaks at 230 and 254 nm. Absorbance maxima of active fractions occurred at 203 nm, where solvent interference prevented HPLC detection. The first strongly active fraction to elute induced a mean nematode response equivalent to 34% SFE. The material injected was 100 μl of I in 90:10 CH₃CN in water with an activity concentration equivalent to ca. 12% SFE (Figure 5), and fractions were assayed at a final volume of 25 μl. Therefore, the first active fraction to elute accounted for most of the activity injected.

Known Compounds. Several compounds were weakly attractive, but even the strongest response, to α-chaconine, was weaker than to 5% SFE. Pyridine was strongly repellent (Table 2). Pyridine attracts the bacteriophagous nematode *Caenorhabditis elegans* (Dusenbery, 1976). Extraction of the foliar powder specifically for solanaceous glycoalkaloids, using methods established for potato, yielded products that were neither attractive nor repellent at neutral pH.

Our results indicate that several substances within *S. elaeagnifolium* foliar extract attract infective juveniles of *O. phyllobia* in vitro. They appear to be similarly nonvolatile, dialyzable, polar, ionizable, water soluble, sensitive to very low pH, and stable at biological temperatures. We do not know if common functional groups are involved. Small, stable, water-soluble compounds from foliage would seem ideal for attracting nematodes within soil to plant stem bases. Nematodes, in general, move in water films, and optimum physical conditions for locomotion in soil occur at high water contents, near the inflection point of the soil moisture release curve (Wallace, 1968). We cannot be certain that our attractive HPLC fractions contain compounds that naturally occur in behaviorally active concentrations near living plants; we know nothing concerning their anatomical compartmentalization and occurrence in natural foliar leachates. Our approach has been to develop chromatographic methods for

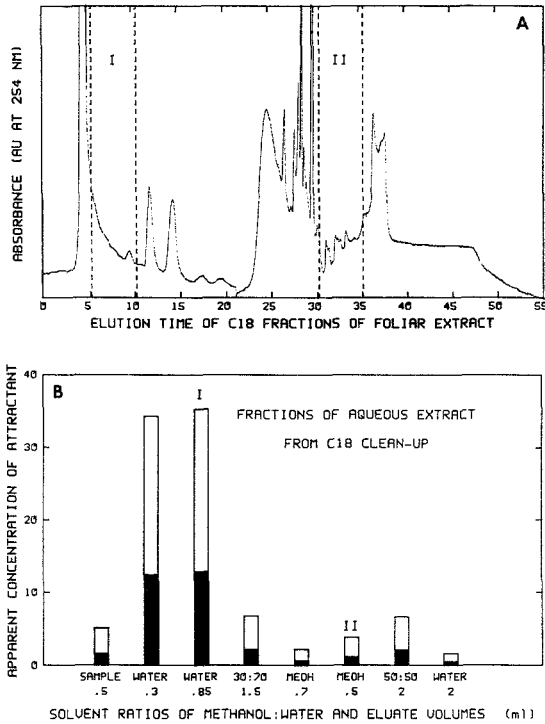

FIG. 4. Preliminary HPLC separation of strong (I) and weak (II) sources of activity in aqueous extract of *Solanum elaeagnifolium* foliage using a water-to-methanol gradient on C₁₈ Semi-Prep column, and assay results for eluates obtained through a C₁₈ Sep Pak cleanup procedure using solvent volumes that approximated the HPLC gradients. detecting attractive substances before trying to find them in soil. Further research toward that goal is underway.

The potato cyst nematode, *Globodera rostochiensis*, is a serious agronomic pest in potato production. It is ecologically similar to *O. phyllobia* as a nematode closely associated with *Solanum* spp. hosts. Since 1922, considerable effort has been put toward isolation and identification of a factor in root leachates from *Solanum* spp. that stimulates *G. rostochiensis* egg hatching. The active factor, which is still unidentified, chromatographs as several compounds that

FIG. 5. The apparent concentration of attractant, relative to standard aqueous extract of dry *Solanum elaeagnifolium* foliage (6% w/w), in CH₃CN–water extracts of dry fraction I. Fraction I was obtained by a C₁₈ Sep Pak cleanup procedure, then evaporated to dryness and reextracted with an original volume of the solvent mixture indicated. Note that the concentration of attractant in 90% CH₃CN is only 30% of the concentration in water. Brackets indicate confidence intervals as in Figure 3B.

FIG. 6. Nematode attractant activity in 35 1-min HPLC subfractions of fraction I obtained with amine-bonded column and a CH₃CN–water mobile-phase gradient. Solvent concentrations described in text. Bars indicate confidence intervals as in Figure 4B. The strongly attractive fraction eluting at 7–8 min accounted for 75% of the total activity in the injected material.

are highly polar and water soluble in character (Atkinson et al., 1987). Before initiating characterization of the *O. phyllobia* attractants, we speculated that they might be solanaceous glycoalkaloids or might be related to the potato cyst nematode hatching factor. Our observations support neither prediction. Saturated solutions of the common *Solanum* glycoalkaloids α -chaconine and α -solanine did not attract *O. phyllobia* appreciably; extraction specifically for glycoalkaloids did not yield attractive products; and attraction to SFE occurred at alkaline pHs (>10), at which many *Solanum* glycoalkaloids precipitate from

water. Recent work on potato cyst nematode hatching factor has shown it to be anionically but not cationically exchangeable (Atkinson et al., 1987); the converse was observed for *O. phyllobia* attractant.

Acknowledgments—We thank Dr. Roger Albach (Agricultural Research Service, USDA) for valuable discussion and advice during the course of this study.

(Received October 6, 1987; accepted January 13, 1988)

Abstract—The female sex pheromone of the Asian corn borer, *Ostrinia furnacalis*, widespread in Taiwan, was confirmed as (*Z*)-12-tetradecenyl acetate and its geometric isomer (*E*)-12-tetradecenyl acetate in a ratio of ca. 3:1 by gas chromatography and gas chromatography-mass spectrometry in selected ion monitoring mode. Males were attracted by the mixture of these two synthetic components in the field, but the attractiveness was less than by virgin females. The presence of minor components in the sex pheromone was therefore suggested.

Key Words—Lepidoptera, Pyralidae, *Ostrinia furnacalis*, sex pheromone, Asian corn borer, (*E*)- and (*Z*)-12-tetradecenyl acetate.

INTRODUCTION

The corn borer is an important pest of corn, peanut, and sorghum fields in Taiwan. From the external morphology, the Asian corn borer, *Ostrinia furnacalis*, is almost indistinguishable from the European corn borer, *Ostrinia nubilalis*. However, Mutuura and Munroe identified the species *Ostrinia furnacalis* as the Asian corn borer (Mutuura and Munroe, 1970; Cardé et al., 1978). The sex pheromone components from the Asian corn borer, *O. furnacalis* have been identified as (*E*)- and (*Z*)-12-tetradecenyl acetate. The ratio of these geometric

isomers *E* to *Z* was 53:47 (Cheng et al., 1981; Jiang and Klun, 1981) or 2:3 (Ando et al., 1980) in China and Japan, respectively. Those ratios are different from those of the sex pheromone components of the European corn borer, *O. nubilalis*, which is distributed widely in Europe and the United States (Kennedy and Anderson, 1980; Klun and Junk, 1977; Klun, 1975; Kochansky et al., 1975) and which has the same pheromone components.

Therefore, we attempted to determine the species and sex pheromone components of corn borer in Taiwan. We are specially interested in monitoring the population and/or development of mass trapping systems for this pest in the field. Female sex pheromones of nocturnal moths have been proved mostly to be unsaturated, straight-chain aliphatic acetates, alcohols, or the corresponding aldehydes. A classical approach to identify the insect sex pheromone involves the isolation of each component in pure form, and oxidative cleavage at the unsaturated center with ozone, followed by identification of the fragments by mass spectrometry. Those methods are tedious and difficult when the amount of material available is very small. Here we show that the corn borer in Taiwan is the Asian corn borer of which the pheromone is (*Z*)- and (*E*)-12-tetradecenyl acetate at a ratio of ca. 3:1 by gas chromatography and gas chromatography-mass spectrometry in the selected ion monitoring mode.

METHODS AND MATERIALS

Insect Materials. Larvae of the corn borer were reared successively on corn artificial diet at 25°C and relative humidity 70% under a 12-hr photoperiod. Female and male pupae were separated, and adult female moths were used for extraction of pheromone. For isolation of the pheromone, abdominal tips of 2-day-old virgin females were extracted with *n*-hexane. The crude preparations were stored at 0°C in a refrigerator until use.

Laboratory Bioassay for Monitoring Active Fractions. Male moths were kept under the same conditions as above until use. Two days after emergence, 10 males were placed in a 300 ml Erlenmeyer flask, and their behavior toward a piece of filter paper loaded with a sample was observed. The bioassay was carried out 9 hr after the light was turned off. When an active sample was introduced, the male moths showed hairpencil extension or wing vibration and quick flying followed by resting quietly at the filter paper.

Chemicals. The synthetic pheromones and standards were obtained from Dr. Tay-Yuan Chau, Department of Chemistry, National Chung-Hsing University, Tai Chung, Taiwan; and Shin-Etsu Chemical Co., Tokyo, Japan. All other chemicals were obtained from E. Merck Darmstadt, F.R. Germany.

Column Chromatography. Column chromatography with Florisil (60–100 mesh) was carried out according to a class-separating method for lipids (Carroll,

1961). Hexane, 5, 15, 25, and 50% ether in hexane, 2% methanol in ether, and 4% acetic acid in ether were successively used as eluting solvents.

High-Performance Liquid Chromatography. High-performance liquid chromatography was performed with a ERC-8710 high-pressure pump equipped with a Rheodyne model 7125 injector and ERC-8710 variable wavelength UV detector. The separation was carried out on a 30 cm \times 3.9 mm μ Porasil column eluted with 1% EtOAc in *n*-hexane at 0.8 ml/min flow rate and monitored at 235 nm.

Gas Chromatography. Gas chromatography was performed with a Hewlett-Packard model 5840A gas chromatograph equipped with a flame ionization detector, on-line to a Hewlett-Packard 5840 GC terminal. The packed column separation was carried out on a 3.05-m \times 2-mm ID, 3% OV-17 column (80°C for 2 min, then 10°C/min to 180°C then 5°C/min to 240°C, injection temperature = 200°C and detector temperature = 250°C). The separation was also carried out on a 50-m \times 0.32-mm fused silica capillary Carbowax 20 M column (60°C for 6 min then 15°C/min to 180°C then 4°C/min to 250°C, injection temperature 265°C and detector temperature 250°C); 55-m \times 0.32-mm fused silica capillary SP-2340 column (60°C for 6 min, 12°C/min to 180°C then 4°C/min to 240°C, injection temperature 245°C and detector temperature 250°C); 50-m \times 0.22-mm fused silica capillary CP Wax51 column (60°C for 6 min, 15°C/min to 180°C then 4°C/min to 240°C, injection temperature 265°C and detector temperature 250°C); and 25-m \times 0.32-mm fused silica capillary OV-1 column (60°C for 3 min, 10°C/min to 140°C then 4°C/min to 220°C, injection temperature 180°C and detector temperature 250°C).

Gas Chromatography-Mass Spectrometry. A Hewlett-Packard model 5985 mass spectrometer coupled with a gas chromatograph (model 5840A) and a mass data system (7900A) was used. The same GC capillary columns as listed under gas chromatography were used for separation. An electron impact ion source was used and the energy was set at 70 eV with the emission current at 300 μ A. The temperatures of column, injector, and detector were the same as under gas chromatography. The carrier gas was adjusted to a column head pressure of 10 psi.

Field Trapping. Field trapping of *O. furnacalis* by using synthetic materials was conducted in the field of Taiwan Agricultural Chemicals and Toxic Substances Research Institute (TACTRI), Taichung, and Tainan District Agricultural Improvement Station (TDAIS), Tainan, during the flight season. A wing trap was used for this purpose. Synthetic materials were dissolved in *n*-hexane and loaded on an Aldrich rubber septum as bait. Two-day-old virgin females and unbaited traps were also used as references. The height of the trap above the ground usually was about 0.7–1 m. The lures in the traps were changed in a different direction every night over the experimental period; the recording was done every three or six nights.

RESULTS AND DISCUSSION

Florisil column chromatography of the crude extract from 2000 virgin females revealed that the active substances were eluted from the column by 5% ether in *n*-hexane (Table 1). The active substances were chromatographed on high-performance liquid chromatography, then fractionated by gas chromatography.

The sex pheromone of the corn borer was suggested to be either (*Z*)- and (*E*)-11-tetradecenyl acetate or (*Z*)- and (*E*)-12-tetradecenyl acetate for the European corn borer and the Asian corn borer, respectively (Cheng et al., 1981; Jiang and Klun, 1981; Kennedy and Anderson, 1980; Klun et al., 1980; Klun and Brindley, 1970; Nagai et al., 1977; Ren et al., 1983; Webster and Cardé, 1984). Separation of (*Z*)-7-, (*Z*)-9-, (*E*)-11-, (*Z*)-11-, (*E*)-12-, and (*Z*)-12-tetradecenyl acetate was successful on Carbowax 20 M, SP-2340, and CP Wax51 (Table 2).

Comparison of the chromatographic retention times of authentic tetradecenyl acetates on different capillary columns with the natural pheromone (Table 2) suggests that the corn borer in Taiwan is the Asian corn borer, *Ostrinia furnacalis*, where the sex pheromone is a mixture of (*E*)- and (*Z*)-12-tetradecenyl acetate.

For confirmation, analyses of the pheromone extract by gas chromatography-mass spectrometry (GC-MS) selected ion monitoring (SIM) were conducted with the fused silica CP Wax51 capillary column. The four fragment ions at $m/e = 254$ (M^+), 194 ($M^+ - \text{HOAc}$), 96, and 82 were selected for the

examination of the monoenyl acetates (Figure 1a). The ratio of *Z* and *E* isomers of the pheromone of our corn borer is about 3 by comparison with the area of each chromatograph of *Z* to *E* at each mass fragment of Δ -12-tetradecenyl acetate (i.e., 3370/1105, 2762/830, and 469/149 in Figure 1b). In Figure 1b, the

FIG. 1. Gas chromatogram (CP Wax 51 column) monitored by *m/e* = 254, 194, 96, 82, of (a) authentic (*E*)- and (*Z*)-12-tetradecenyl acetate and (b) extract from corn borer *O. furnacalis*.

GC-MS profile at 19–20 min showed some impurities, probably fatty acids. In search of lepidopteran sex pheromones, it has been shown that most pheromones identified from female moths are unsaturated straight-chain alcohols and/or their derivatives. By using a series of synthetic compounds, we may use the crude extract from the insect directly for GC-MS/SIM to identify the sex pheromone.

For further confirmation of the sex pheromone of *O. furnacalis*, field trials were carried out. The amount used for male attractiveness was in the 50- to 500- μ g range (Table 3). Four different compositions were tested, and results are summarized in Table 4. The best ratio of (Z)- to (E)-12-tetradecenyl acetate was 3 : 1, no male moths were caught with the combination of (Z)- and (E)-11-tetradecenyl acetate (unpublished result). These results coincide with the data obtained from GC-MS. The different ratios of (E)- and (Z)-12-tetradecenyl acetate of the sex pheromone of *O. furnacalis* at China, Japan, and Taiwan may be due to population differences. The numbers of males caught by the synthetic pheromone trap are far fewer than those caught by using two virgin females as

a pheromone source. This fact clearly indicates that both (Z)- and (E)-12-tetradecenyl acetate are the major components of the pheromone, and the possibility of some minor components in the sex pheromone is also suggested. Research to identify the minor components and the broad-range ratios of (Z)- and (E)-12-tetradecenyl acetate in the field test is underway.

OVIPOSITION STIMULANTS FOR THE BEETLE, *Monochamus alternatus* HOPE, IN INNER BARK OF PINE

T. YAMASAKI, M. SAKAI, and S. MIYAWAKI

*Department of Bioresource Science, Faculty of Agriculture
Kagawa University, Miki-Tyo, Kagawa-Ken 761-07, Japan*

(Received October 8, 1987; accepted January 14, 1988)

Abstract—Field and laboratory ovipositional responses of *Monochamus alternatus* Hope, respectively, to methanol and water extracts from pine inner bark were examined in comparison with those to pine inner bark, especially using a laboratory-built apparatus for the latter bioassay. Irrespective of the existence of volatiles from paraquat-induced lightwood, pine inner bark and its methanol and water extracts stimulated ovipositional response only in the presence of free moisture.

Key Words—*Monochamus alternatus* Hope, Coleoptera, Cerambycidae, pine inner bark, methanol extracts, water extracts, oviposition stimulants, lightwood.

INTRODUCTION

It has been well known that the cerambycid beetle, *Monochamus alternatus* Hope, is a vector of the pine wood nematode, *Bursaphelenchus xylophilus* Steiner et Buhrer, which causes severe mortality of pines (Morimoto and Iwasaki, 1972; Mamiya and Enda, 1972).

Recently, attractiveness of pines, treated with the herbicide paraquat, to *M. alternatus* has been confirmed (Yamasaki et al., 1980a). Paraquat induces an extensive area of oleoresin-soaked lightwood in the xylem of the pines (Roberts et al., 1973; Conley et al., 1977; Yamasaki et al., 1980b; Yamasaki and Sogo, 1982). The attraction of both sexes of *M. alternatus* arises from volatiles involved in the paraquat-induced lightwood (Yamasaki and Suzuki, 1982).

After landing on a dying (Katagiri et al., 1964) or paraquat-treated pine (Yamasaki and Sunago, 1983), a *M. alternatus* female moves to a site favorable

for oviposition, cuts a characteristic pit in the outer bark, inserts her ovipositor into the inner bark through the pit, and deposits eggs. In the case of the paraquat-treated tree, the site of oviposition is restricted within the area over the lightwood (Yamasaki et al., 1980a).

The role of chemical stimulants in the oviposition of *M. alternatus* is not known. This paper presents evidence that nonvolatile oviposition stimulants for *M. alternatus* occur in the pine inner bark.

METHODS AND MATERIALS

Field Test Materials. For lightwood, 17-year-old *Pinus densiflora* Sieb. et Zucc. trees were frill-treated with paraquat (1,1'-dimethyl-4,4'-dipyridinium dichloride) early in May 1986 (Yamasaki and Sogo, 1982). The paraquat-induced lightwood was harvested in mid-July 1986. Five lightwood samples (7 × 35 × 2.5 cm) were immediately used in the field, and the remainder was used for collection of volatiles.

For methanol extract, air-dried inner bark (0.9 kg) of *P. densiflora* trees of the same age, harvested late in April 1986, was milled and extracted with boiling methanol (2.8 liters) for 3 hr. Filtrate was concentrated under reduced pressure.

For impregnating filter paper, a sheet (21 × 35 cm) of 0.2-mm-thick filter paper (dry weight 6.459 g) was impregnated with 10 ml of the concentrate (19.38 w/v%) using a pipet, dried in air, in vacuo at 80°C for 12 hr in the presence of desiccating agents, and weighed. After standing in air for two days, the sheet containing 30% methanol extract was weighed again.

Field Bioassay. The bioassay was conducted from 8:00 PM on July 15 to 8:00 AM on July 16, 1986, in a stand where severe mortality of pines was caused by nematodes.

Four of the fresh lightwood samples were wrapped with a sheet of the test filter paper with or without methanol extract or a sheet (21 × 35 cm) of freshly harvested inner bark of *P. densiflora*. A tinfoil sheet (40 × 40 cm) to hold eggs was nailed to one of the two cross sections of the remaining lightwood sample without wrapper. After moistening the sheets of the test filter paper with a calculated volume of water, the baits with and without wrapper were hung on a wire 2 m above the ground at 5-m intervals along a ridge. The total number of *M. alternatus* attracted to each bait was counted at 8:30, 9:30, and 10:30 PM. The assayed wrappers were torn into pieces about 1 mm wide, and the number of eggs laid by *M. alternatus* was counted. To prevent hatching, eggs laid in parts awaiting examination were kept at 5°C.

Laboratory Test Materials. Lightwood volatiles (LW volatile) were collected by letting air from a cylinder pass through particles of the fresh lightwood and leading the gas into cooled traps (Yamasaki and Suzuki, 1982).

For test substrates, after being cut into 4×5 cm pieces in order to remove volatiles, bark, inner bark, and about 6-mm-thick outer bark of 17-year-old *P. densiflora* trees, harvested late in April 1986, were first dried in air for two months, then in an air-circulating oven at 80°C for seven days, in vacuo at 80°C for seven days, and weighed. Pieces of 4×5 -cm \times 1.5-mm-thick veneer made of commercial lumber of *P. densiflora* also were dried and weighed. In addition to these substrates, 4×5 -cm pieces of 1-mm-thick stainless steel were prepared.

For moistening these substrates, except the stainless steel, prior to laboratory bioassay, moisture content was achieved variously: (1) One series of 12 pieces was stood on an electronic balance, until the content reached 1.3%. (2) Another series to 5–6% by exposure to a cloud of steam. (3) A third to 18–56% by spraying with water, and, after 85–97% of a calculated water volume was adsorbed, the remainder was added using a syringe.

For fractions of water extract, the remainder (2 kg) of the fresh inner bark was reduced to particles and extracted with 3.9 liters of boiling water for 1.5 hr. The extract was fractionated as shown in Figure 1. Pieces of filter paper, 4×5 cm \times 0.7 mm thick, containing the 30% fraction I were prepared in the same way. Pieces of laminated filter paper, 4×5 cm and 1.1 to 1.3 mm thick, containing 30% fractions II, III, IV, or V were prepared as shown in Figure 2.

FIG. 1. Fractionation of water extract from fresh inner bark of *P. densiflora*.

FIG. 2. Makeup of laminated filter paper containing powdery fraction II, III, IV, or V. Two 8.3×5 -cm pieces (dry weight 0.708 g for two) of 0.2-mm-thick filter paper were moistened with water (0.9 ml), and dusted with the sample (0.212 g). One piece was folded in two, and placed on the other. The other was folded back. This laminated filter paper with the sample was pressed under a pressure of 50 kg/cm^2 for 1 min.

The pieces were dried in vacuo at 80°C for 12 hr, weighed, and moistened with a calculated volume of water immediately before the laboratory bioassay.

The Insect. *P. densiflora* trees surviving where many other trees were dying were frill-treated with paraquat early in July 1986. About 200 *M. alternatus* females attracted to these trees were caught in mid-July and held in individual glass bottles (Yamasaki and Suzuki, 1982).

Laboratory Bioassay. The apparatus consisted of a hardware cloth chamber ($60 \times 7 \times 15$ cm) without one side (60×7 cm), a tin-plated chamber ($60 \times 7 \times 5$ cm) without one side (60×7 cm), and a hardware cloth screen (63×10 cm), as shown in Figure 3. The hardware cloth chamber was partitioned into eight compartments using tinplate sheets wrapped with hardware cloth.

A series of eight test pieces moistened with a calculated volume of water as described above was fastened on the hardware cloth screen with hairpins (Figure 3). LW volatile (0.5 ml) was placed into each of three Petri dishes (2.5

FIG. 3. Bioassay apparatus for *M. alternatus*: (a) compartment for each insect; (b) chamber in which LW volatile was placed; (c) hardware cloth screen; (d) insect entry hole (5×9 cm) with cover; (e) ovipositional substrates fastened on bed sheet (vener or stainless steel) with hairpins or wiring.

cm ID \times 1.8 cm) inside the tinplate chamber. The apparatus was assembled with wire. Individual *M. alternatus* females were placed into each of the eight compartments. The bioassay was conducted from 8:00 PM to 8:00 AM. As a control, bioassay in the absence of LW volatile was conducted in another room (about 100 m away). The surface of the assayed materials was observed, and the number of eggs laid was counted. The percentage of ovipositional response was calculated as follows: Ovipositional response (%) = $100 \times \text{No. which responded} / 8 \text{ individuals}$.

RESULTS

Field Attraction and Oviposition of M. alternatus. Both sexes of *M. alternatus* were attracted to every bait in the field (Table 1). This table shows that at least one or two females were attracted to each of the baits (e.g., two females to the bait without wrapper). Four and 25 eggs laid by *M. alternatus* were present in or under the moistened filter paper with methanol extract and the fresh inner bark, respectively. It is impossible to compare the numbers of eggs (4 vs. 25) because the real number of the females attracted to each of the baits is not shown in this table. No eggs, however, were observed at the other baits; with that the two former observations are comparable.

Oviposition of M. alternatus in Laboratory Affected by Free Moisture. Figure 4 shows the effect of moisture content of pine inner bark at the onset of

^aMoisture content: a, 20-35%; b, 50%; c, 9%; d, 67%.

FIG. 4. Effect of moisture content of inner bark of *P. densiflora* on oviposition by *M. alternatus*. The laboratory test was conducted July 18–19, 1986, using LW volatile. Veneer with moisture content almost equivalent to that of the corresponding inner bark was used as a bed sheet. When fresh inner bark with 64% moisture was assayed, veneer with 56% moisture was used. Moisture contents of eight series of another four pieces which were placed outside their respective apparatus for 12 hr were substituted for those of inner bark after bioassay.

bioassay on oviposition by *M. alternatus*. Moisture contents of 1.3 and 5.0% at the onset increased to a level of 13.6–14.6% overnight. The contents of 18.0 and 21.0% decreased to levels of 16.4–17.0% and of 16.9–19.1%, respectively. The contents of 26.0% and more also decreased to a level of 21.7–26.4%. When inner bark with 18.0% or less moisture at the onset was assayed, neither egg laying nor the slight scoring of the inner bark prior to ovipositor insertion was observed, although a few scars produced by gnawing or feeding beetles were observed. Under inner bark with 21.0% moisture, three eggs were laid by one of eight beetles. Thirty-four eggs were laid in or under inner bark with 26.0% moisture by six of eight beetles, and in or under inner bark with 41.0% or more moisture 35–40 eggs were laid by seven of eight beetles. Besides the scars, openings resulting from ovipositor insertion, like pinholes of less than 1 mm ID in the respective scores also were observed in the assayed inner bark with 21.0% and more moisture.

Oviposition of M. alternatus in Various Substrates. Materials tested in the laboratory are shown in Table 2. Bed sheet alone and filter paper with or without the bed sheet did not induce oviposition by *M. alternatus*. Scars different from those on inner bark were left on the filter paper, but were not observed on the bed sheet alone. Outer bark containing 5–6% moisture elicited no oviposition.

TABLE 2. LABORATORY OVIPOSITION OF *M. alternatus* IN VARIOUS SUBSTRATES WITH AND WITHOUT VOLATILES (JULY 22-25, 1986)

Bark + stainless steel			75	42

^aVolatiles extracted from paraquat-induced lightwood.

^bMoisture content at the onset was 5-6%; all others were 49-56%, except stainless steel.

On the other hand, when outer bark with 49-56% moisture was assayed, one of eight beetles laid two eggs; otherwise, no eggs were observed. Pits, slots, or galleries of various sizes in every series of the outer bark were 9-13 in number. In contrast to these results, even in the absence of LW volatile, 42, 39, and 40 eggs were laid in or under moistened inner bark by six, seven, and seven of eight beetles, respectively. In or under moistened bark 53, 38, and 42 eggs were laid by seven, eight, and six of eight beetles, respectively. On average, 21 pits were left on a series of eight bark pieces.

Oviposition of M. alternatus in Laboratory Affected by Fractions of Water Extract. Five fractions of water extract were assayed (Table 3). Beside scars, small openings were observed in every series, except dried filter paper containing fraction IV, which elicited no oviposition. One of eight beetles laid two or three eggs under moistened filter paper with fraction I. One beetle laid four eggs under moistened filter paper with fraction III in the presence of LW volatile. On the other hand, moistened filter paper with fractions II, IV (Figure 5), and V elicited ovipositional responses of 75% of the 17 or 20 eggs laid, 87.5% of 21 or 18; 87.5% of 20; and 75% of 24, respectively.

TABLE 3. EFFECT OF FRACTIONS OF WATER EXTRACT ON OVIPOSITIONAL RESPONSE OF *M. alternatus* (JULY 26-28, 1986)

Material with veneer ^a	LW volatile present		LW volatile absent	
	Ovipositional response (%)	Eggs laid	Ovipositional response (%)	Eggs laid
Filter paper containing 30% fraction I	12.5	3	12.5	2
Laminated filter paper containing 30% fraction II	75	17	75	20
Laminated filter paper containing 30% fraction III	12.5	4	0	0
Laminated filter paper (a) containing 30% fraction IV	0	0	0	0
Laminated filter paper containing 30% fraction IV	87.5	21	87.5	18
Laminated filter paper containing 30% fraction V	87.5	20	75	24
Inner bark	87.5	42	87.5	38

^aMoisture contents of materials and veneer at the onset, respectively, were 55 and 50-56%, except the case of (a); in this case filter paper material and veneer, respectively, containing 6% and 5% moisture were used.

FIG. 5. Six eggs laid under moistened filter paper with fraction IV by a *M. alternatus* female. The assayed substrate is turned inside out and placed on veneer. This beetle laid two other eggs in the substrate. Openings resulting from ovipositor insertion also are shown.

DISCUSSION

It is evident from Tables 1–3 that oviposition of *M. alternatus* is not evoked by volatiles, but by nonvolatiles occurring in the inner bark of *P. densiflora*. The oviposition stimulants are extractable in methanol, dimethyl formamide, or water, but are insoluble in ethyl ether. The ovipositional response elicited by fraction II, IV, or V was equivalent to 86–100% of that elicited by inner bark as a control, whereas the number of eggs laid was only 40–60% of that laid in the inner bark (Table 3).

The bed sheet was found to be unnecessary for oviposition (Table 2), but it is convenient to prevent the loss of eggs laid. Oviposition of *M. alternatus* appears to be independent of cambium or xylem of host pine.

It has been known that in the sphingid *Manduca sexta* L. (Sparks, 1973) and noctuid *Anadevidia peponis* F. (Ichinose and Sasaki, 1975) moisture itself evokes oviposition. In *M. alternatus*, however, free moisture must be present in order for the chemical stimulants from inner bark to elicit oviposition (Figure 4, Tables 1 and 3). Critical moisture content necessary for oviposition appears to be between 18% and 21% under these experimental conditions. Contact chemoreception through intervention of free moisture has been confirmed in some butterflies such as *Byasa alcinous* K., *Leudhorfia japonica* L., *Papilio xuthus* L., *P. machaon hippocrates* C. et F., *P. macilentus* J. (Nishida, 1977), *P. protenor demetrius* C. (Ichinose and Honda, 1978), and *P. bianor dehaanii* C. et F. (Abe et al., 1981). In *M. alternatus*, however, chemoreceptors have not been identified.

The behavior of cutting a pit in the outer bark prior to ovipositor insertion was independent of moisture content. Moisture content of the outer bark of a living pine varies with atmospheric conditions, unlike that of inner bark. It was alluded that volatiles from bark of dying pines evoke this behavior (Yamane et al., 1975). In this study, however, the behavior of cutting a pit in outer bark was observed even in the absence of LW volatile. On inner bark with free moisture, the behavior of slightly scoring it prior to ovipositor insertion was observed. On filter paper with fractions I to V of water extract, no pit-making behavior was observed. Nonvolatiles in outer bark may induce this behavior. In the absence of LW volatile, fraction III elicited no oviposition (Table 3), but 10 openings were produced by four of eight beetles. Ovipositor insertion appears to be induced by a wide variety of factors, in addition to oviposition stimulants, involved in pine inner bark.

The present results suggest the feasibility of controlling *M. alternatus* by using oviposition stimulants in combination with attractants produced by paraquat-induced lightwood without insecticide application.

Acknowledgments—Thanks are due to Mr. T. Oka for his assistance in the field bioassay. Part of this study was supported by a Grant-in-Aid for Scientific Research from the Japanese Ministry of Education.

RECEPTOR CHIRALITY AND BEHAVIORAL
SPECIFICITY OF THE BOLL WEEVIL, *Anthonomus
grandis* Boh. (COLEOPTERA: CURCULIONIDAE),
FOR ITS PHEROMONE, (+)-GRANDISOL

Abstract—Electrophysiological recordings from antennal olfactory receptors and field behavioral experiments showed both male and female boll weevils, *Anthonomus grandis* Boh. (Coleoptera: Curculionidae), to respond specifically to (+)-grandisol, an enantiomer of compound I of the boll weevil aggregation pheromone. Single-cell recordings revealed antennal olfactory neurons in both male and female weevils keyed to (+)-grandisol. Electroantennograms in response to serial dilutions of the grandisol enantiomers showed a threshold 100 to 1000 times lower for (+)-grandisol relative to its antipode. In field behavioral experiments, both sexes were significantly more attracted to (+)-grandisol in combination with the three other pheromone components than the combination with (–)-grandisol. When (–)-grandisol was placed with the (+)-enantiomer at equal dosages, a slight although statistically insignificant inhibition occurred. Subsequent field tests showed that the low level of attraction exhibited by (–)-grandisol in combination with the other three pheromone components could be attributed to the other three components alone. These results are in contrast with an earlier study, which found (–)-grandisol to be as attractive as the (+)-enantiomer.

Key Words—Boll weevil, olfaction, receptor cell, *Anthonomus grandis*, Coleoptera, Curculionidae, enantiomer, grandisol, chirality, electroantennogram, aggregation pheromone, neurobiology, structure-activity.

INTRODUCTION

The importance of chirality in insect chemical communication is well known (Silverstein, 1979; Mori, 1984). Sensitivity and specificity in the detection and translation of pheromonal messengers by insects are especially crucial since chiral chemical cues may be important in their orientation to conspecifics for aggregation and/or mating. In general, insects that produce a chiral pheromone detect and respond behaviorally to the predominant enantiomer or blend of enantiomers released (Iwaki et al., 1974; Borden et al. 1976, 1980; Hedden et al., 1976; Klimetzek et al., 1976; Vité et al., 1976a,b; Wood et al., 1976; Yamada et al., 1976; Birch et al., 1977, 1980; Harring and Mori, 1977; Kra-wielitzki et al., 1977; Miller et al., 1977; Lanier et al., 1980; Levinson and Mori, 1980; Mustaparta et al., 1980; Payne et al., 1982; Dickens et al., 1985; Kodama et al., 1987). However, the antipode of the insect's pheromone may be released by a sympatric species or a different population of the same species and may inhibit response to the pheromone (Vité et al., 1976b; Light and Birch, 1979).

Male boll weevils, *Anthonomus grandis* Boh. (Coleoptera: Curculionidae), release in their frass an aggregation pheromone that consists of four components: I, (+)-*cis*-2-isopropenyl-1-methylcyclobutane ethanol; II, *cis*-3,3-dimethyl- $\Delta^{1,\beta}$ -cyclohexane ethanol; III, *cis*-3,3-dimethyl- $\Delta^{1,\alpha}$ -cyclohexane acetaldehyde; and IV, *trans*-3,3-dimethyl- $\Delta^{1,\alpha}$ -cyclohexane acetaldehyde (Tumlinson et al., 1969). Although one of these pheromone components, I (grandisol), is produced as the (+)-enantiomer by the insect, its antipode, (-)-grandisol, was shown to have biological activity equal to the isolated pheromone component (Mori et al., 1978).

The biological activity of (-)-grandisol (Mori et al., 1978) has been an anomaly in insect pheromone biology. This remains as one of only two reports in which an insect produced one enantiomer of a compound as its pheromone, and its antipode, once synthesized, had equal biological activity (Mori et al., 1978, 1981). Although Silverstein (1979) reported that no instances had been documented in which an insect produced only a single enantiomer and could not distinguish between it and its antipode, he did cite earlier work in which humans were sometimes unable to distinguish between enantiomers (Lensky and Blum, 1974).

The purpose of the experiments reported here was to investigate detection of the enantiomers of grandisol by the boll weevil through electrophysiological recordings from the antennal receptors. In addition, due to results of the electrophysiological experiments, which indicated a lack of detection of (-)-grandisol, quantitative behavioral experiments were done in the field to reinvestigate previously reported biological activity of the antipode of the pheromone component (Mori et al., 1978).

METHODS AND MATERIALS

Insects. Adult *A. grandis* used in these experiments were obtained from a small laboratory colony annually infused with feral insects maintained at the USDA-ARS Boll Weevil Research Unit. Upon emergence, insects were sexed and fed cotton squares. For electrophysiological studies, groups of five insects of the same sex were maintained on moist filter paper in Petri dishes until use following receptor maturation at four days postemergence (Dickens and Moorman, 1987). Insects used in these studies were 4–7 days of age. For field experiments, groups of 50 insects of the same sex were held in paper cartons (ca. 0.5 liter) with screen tops. Insects used in the field releases were 6–13 days postemergence. All insects were held in incubators at 26°C under a photoregime of 16 hr of light (ca. 700 lux) and 8 hr of darkness.

Chemicals. Optical isomers of grandisol were 100% optically and chemically pure as prepared by Mori and Miyake (1987). Racemic grandisol, II, and III + IV (a 50:50 mixture), each >95% chemical purity, were obtained from Albany International, Controlled Release Division, Buckeye, Arizona. All compounds were prepared as 10 $\mu\text{g}/\mu\text{l}$ dilutions in hexane. Serial dilutions of (+)- and (-)-grandisol were prepared in hexane from 0.01 to 10 $\mu\text{g}/\mu\text{l}$ for electrophysiological studies. From these dilutions, a 50:50 mixture of the enantiomers was also prepared. 1-Hexanol, used as a standard in electroantennogram (EAG) experiments, was 98% chemically pure as obtained from Aldrich Chemical Co., Milwaukee, Wisconsin.

Electrophysiology. Single-cell recording techniques are described in detail elsewhere (Dickens, 1979; Dickens et al., 1984) and were essentially a modification of an earlier technique (Boeckh, 1962). In brief, microelectrodes used for recordings were constructed from 50.8- μm -diameter tungsten wire electrolytically sharpened to a tip of 1–2 μm . The recording electrode was positioned under optical control (150–200 \times) with a Leitz high-power micromanipulator near either the base of one of the three sensory bands encircling the club or the base of an individual sensillum just distal to each sensory band region. The ground electrode was inserted in either the rostrum or distal end of the pedicel. Action potentials were amplified and conditioned by a Grass P-15 AC preamplifier and Tektronix 5A22N amplifier prior to visualization on a Tektronix 5223 digitizing oscilloscope. The signal then passed through a Teac R51-D data recorder for recording on cassette tapes prior to visualization on a Tektronix 5111 analog storage oscilloscope. Data were photographed from the analog oscilloscope with a Tektronix C-5C oscilloscope camera and Polaroid film. Trains of action potentials were counted either visually or by a Frederick Haer slope height window discriminator and timed counter. Single-cell responses were recorded from 12 males and 7 females. One or two spike heights were observed for each preparation.

EAGs were recorded as previously described (Dickens, 1984). Ag-AgCl capillary electrodes filled with physiological saline (Oakley and Schafer, 1978) were used. Following prepuncture with a sharpened tungsten needle, the recording electrode was inserted in the distal end of the club; the ground electrode was inserted into the distal end of the pedicel. The signal was then amplified by a Grass P-16 DC preamplifier prior to visualization on a Tektronix 5111 analog oscilloscope and recording for storage with a strip-chart recorder.

Serial dilutions of grandisol were delivered as 1- μ l aliquots placed on filter paper (8 \times 18 mm) inserted into glass cartridges (80 mm \times 5 mm ID) oriented toward the preparation from a distance of 1 cm. Molecules evaporating from the filter paper were carried over the preparation by hydrocarbon-free air, which had been filtered and dried. Serial dilutions were delivered from the lowest to the highest concentration. Stimulus duration was 0.5 sec and 1 sec for single-cell and EAG preparations, respectively. Air flow was 1 liter/min. More than 3 min were allowed between EAG stimulations, while 2-3 min elapsed between presentations of stimuli to single cell preparations. These time intervals were adequate for recovery of both EAG and single cell activity.

In EAG studies, three replicates were recorded for serial dilutions of each grandisol enantiomer and mixture of enantiomers for both male and female *A. grandis*. 1-Hexanol at the 100- μ g dosage was used: (1) to normalize all responses; (2) to ensure viability and constancy of the preparation; and (3) to allow for relative comparisons with previously recorded species (Dickens, 1984; Dickens and Boldt, 1985; Dickens et al., 1986; Glancey and Dickens, 1988; Light et al., 1988). Stimulation with the standard both preceded and followed each serial dilution level. Responses to the enantiomers at a given dosage were expressed as a percent of the mean of the two nearest responses to the standard (Dickens, 1981, 1984). The threshold of response in the EAG studies was considered to be the dosage at which the standard error of the mean of the response was not equal to or less than zero (Dickens, 1984).

Field Experiments. Compounds were placed in 0.5-dram screw-cap vials as 10- μ l aliquots of 10 μ g/ μ l dilutions of the pheromone components using glass capillaries. These vials were then sealed with Teflon-lined screw caps and placed in a cooler until use in the field. Grandisol was always kept in a separate vial. Upon reaching the field, screw caps were removed from the vials and both caps and vials were placed in the top of an aluminum film container (3 cm diam. \times 4.3 cm height) that had five holes (0.23 cm diam.) drilled near its outer edge. The bottom of the can was then screwed onto the top, and the inverted container was then placed in the trap beneath the screen funnel.

The experimental design consisted of placing four traps (Mitchell et al., 1976), one at each corner of a 20-m square, in an open, isolated area. The two treatments being tested were placed alternately and thus were located adjacent each other at the corners of the square. One hundred insects (50 males and 50

females) were then released 20 m from each side of the square at ca. 1400 hr (400 insects total for each replicate of each experiment). Traps were then immediately baited. Each trap was checked and the weevils removed on the day of release at 1500 hr, 1600 hr, and 1800 hr, and the following day at 1500 hr and 1600 hr prior to removal of the baits at 0830 hr the next day.

Three replicates of each of the following three treatment combinations were tested: (1) (+)-grandisol (400 μg), II (300 μg), III + IV (100 μg) vs (-)-grandisol (400 μg), II (300 μg), III + IV (100 μg); (2) (+)-grandisol (400 μg), II (300 μg), III + IV (100 μg) vs (+)-grandisol (400 μg), and (-)-grandisol (400 μg), II (300 μg), III + IV (100 μg); and (3) (\pm)-grandisol (400 μg), II (300 μg), III + IV (100 μg) vs II (300 μg), III + IV (100 μg).

Statistical Analyses. Trap catches for simultaneous paired treatments in the field experiments were compared using a paired *t* test (Ostle, 1963).

RESULTS

Electrophysiology. Of 43 neurons recorded from male and female *A. grandis*, three were reliably activated by racemic grandisol. Optical isomers of grandisol were available for stimulation of two of these neurons (one male and one female), which were both activated by (+)-grandisol (Figure 1). Responses increased with increasing dosages (Figure 2). While an intermediate response was given to the mixture of enantiomers, significant responses were elicited by (-)-grandisol only at very high dosages.

Results from the EAG studies were similar to those obtained in the single-cell recordings. Both male and female weevils had a threshold between 0.1 and

FIG. 1. Activity of a single cell in the medial sensory band of an *A. grandis* female. Spontaneous activity (a). Response to volatiles emanating from: (b) 1 μg of (+)-grandisol; (c) 1 μg of (-)-grandisol; (d) 1 μg of a 50:50 mixture of (+)- and (-)-grandisol. Horizontal line represents duration of stimulus (500 msec). Vertical bar is 2 mV.

FIG. 2. Dosage-response data obtained from a cell in the medial sensory band of an *A. grandis* male in response to the enantiomers of grandisol. Broken horizontal line represents spontaneous activity level.

1.0 μg on filter paper for (+)-grandisol (Figure 3a and b). An intermediate response was elicited by the mixture of enantiomers, while significant EAGs were elicited by the (-)-enantiomer only at 100 μg .

Field Experiments. Competitive field experiments in which the grandisol enantiomers were each paired with the three other pheromone components clearly demonstrated the combination with the (+)-enantiomer to be the most attractive ($P < 0.01$) (Table 1).

To further demonstrate the inactivity of the (-)-enantiomer, it was paired with the (+)-enantiomer and placed in competition with the (+)-enantiomer alone, each treatment in combination with the other three pheromone components. This experiment showed no significant difference between the combination of enantiomers and the (+)-enantiomer alone. If the (-)-enantiomer were active, one might expect a greater response to the combination of enantiomers since a larger quantity was released. This was not the case. Indeed, a smaller,

FIG. 3. Dosage-response curves constructed from EAGs of male (a) and female (b) *A. grandis* to serial dilutions of (+)-grandisol, (-)-grandisol, and a 50:50 mixture of (+)- and (-)-grandisol. Each point represents a mean from three replicates. Vertical bars represent standard errors.

Table 1. Mean (\pm SE; $N = 3$) Response of *Anthonomus grandis* in Competitive Field Tests with Enantiomers of Grandisol

Treatment pair	\bar{X}^a (\pm SE) capture/replicate	Sex ratio M:F
(+)-I, II, III + IV	35** (\pm 8.02)	0.85:1
vs.		
(-)-I, II, III + IV	2.67 (\pm 2.67)	1.25:1
(+)-I, II, III + IV	27 (\pm 7.00)	1.16:1
vs.		
(+)-I, (-)-I, II, III + IV	21.67 (\pm 4.33)	1.60:1
(\pm)I, II, III + IV	22.67* (\pm 6.96)	1.38:1
vs.		
II, III + IV	2 (\pm 1.15)	5.00:1

^a * $P < 0.05$; paired t test; ** $P < 0.01$; paired t test.

although not significantly smaller, number of weevils were captured by the combination of enantiomers.

A third field experiment was done to determine if the few weevils captured by the combination of (-)-grandisol and II, III + IV in the first experiment might be attributable to the attractiveness of II and III + IV alone. In this experiment, the number of weevils captured by II and III + IV alone was significantly less than the combination with racemic grandisol and was nearly identical to the number captured by II and III + IV with (-)-grandisol in the first experiment.

DISCUSSION

The greater activity of (+)-grandisol relative to its antipode is clearly demonstrated by our results. In fact, competitive field experiments involving (+)-grandisol vs (-)-grandisol or (+)- and (-)-grandisol in combination with the other three pheromone components indicate very little attraction by (-)-grandisol and slight, although insignificant, inhibition when placed in combination with the (+)-enantiomer (Table 1). Results of a third field experiment indicated that the attractiveness of (-)-grandisol, II, and III + IV could be attributable to II and III + IV alone. These results are in contrast with results obtained in an earlier study, which indicated (-)-grandisol to be as attractive as the naturally occurring pheromone component, (+)-grandisol (Mori et al., 1978). Results of this earlier study might be explained by the fact that: (1) the enan-

tiomers used were not 100% optically pure, and (2) conclusions concerning the activity of the enantiomers were based only on a few "no choice" laboratory behavioral bioassays. Mori et al. (1978) mention that the enantiomers were not 100% optically pure, and results of the current field tests and earlier laboratory bioassays (Tumlinson et al., 1969) indicate the combination of II, III, and IV to be somewhat attractive alone.

Our electrophysiological data correlate well with the field behavioral data. Both male and female *A. grandis* had a 100- to 1000-fold lower threshold for (+)-grandisol relative to its antipode (Figure 3). EAGs elicited by the mixture of enantiomers were intermediate to the two individual enantiomers at each dosage. Dosage-response curves for each enantiomer and the mixture of enantiomers were parallel. These results indicate that (-)-grandisol at a very high dosage might stimulate either receptors for the (+)-enantiomer or other less specific receptors. Our current single-cell data support the former notion that (-)-grandisol at a very high dosage can stimulate cells primarily driven by the (+)-enantiomer (Figure 2).

Although our data support the conclusion that (-)-grandisol is inactive for the population of boll weevils occurring in our region, variation in both the production of and response to enantiomers of aggregation pheromone components occurs in different populations of other Coleoptera, e.g., *Ips pini* (Birch et al., 1980; Lanier et al., 1980). Eastern *I. pini* produce and respond to a 65:35 blend of (+)- and (-)-ipsdienol, while the western population produces and responds to only (-)-ipsdienol and is interrupted by the (+)-enantiomer. Receptor cells keyed to each enantiomer occurred in individuals from each population, although they occurred in different proportions (Mustaparta et al., 1980). Since only three grandisol cells have been recorded to date, and the enantiomers of grandisol were available for stimulation of only two of them, our results are too preliminary to conclude the nonexistence of (-)-grandisol cells. Furthermore, we have not yet investigated other populations of boll weevils. However, additional electrophysiological and behavioral studies are already in progress on boll weevil populations in Arizona, Mexico, and South Carolina, and investigations are planned on the receptor system of another curculinoid genus, *Pissodes*, which also uses grandisol as an aggregation pheromone component (Booth et al., 1983). Also, in light of the current study, the other reported example, in which the antipode of the German cockroach pheromone was as active as the naturally occurring compound (Mori et al., 1981), deserves reinvestigation. Synthetic attempts to prepare 100% optically pure German cockroach pheromone will commence immediately.

Abstract—For two decades, the aggregation pheromone of the boll weevil, *Anthonomus grandis* Boh. (Coleoptera: Curculionidae), was thought to consist of four compounds: I [(+)-(Z)-2-isopropenyl-1-methylcyclobutane ethanol]; II [(Z)-3,3-dimethyl- $\Delta^{1,\beta}$ -cyclohexane ethanol]; III [(Z)-3,3-dimethyl- $\Delta^{1,\alpha}$ -cyclohexane acetaldehyde]; and IV [(E)-3,3-dimethyl- $\Delta^{1,\alpha}$ -cyclohexane acetaldehyde]. Evidence is presented from behavioral and electrophysiological studies to show that only three of these components, I, II, and IV, are essential for attraction. Competitive field tests, in which each possible three-component blend was tested against the four-component mixture, demonstrated that omission of I, II, or IV resulted in decreased trap captures ($P < 0.01$). Trap captures by these blends lacking I, II, or IV resembled those by the hexane solvent alone in a similar experiment. However, omission of III did not significantly alter field attractiveness of the blend. Dosage-response curves constructed from electroantennogram responses of both males and females to serial dilutions of III, IV, and a 50:50 mixture of the geometric isomers III and IV showed both sexes to be 10- to 100-fold more sensitive to IV than III. Data from the electrophysiological studies were consistent with a single acceptor type for the (E)-cyclohexylidene aldehyde, IV, for males, and possibly one or two acceptor types for III and IV for females. Possible roles for the (Z)-cyclohexylidene aldehyde, III, and implications for the pheromonal attractant currently used in boll weevil eradication/suppression programs are discussed.

Key Words—Boll weevil, *Anthonomus grandis*, aggregation pheromone, multicomponent, behavior, electroantennogram, neurobiology, structure-activity, geometric isomers, cotton, Coleoptera, Curculionidae.

INTRODUCTION

The boll weevil, *Anthonomus grandis* Boh. (Coleoptera: Curculionidae), is a pest of cotton, *Gossypium hirsutum* L. in the United States and Central and South America (Cross, 1983). It is narrowly oligophagous, feeding primarily only on cotton and its close relatives in the family Malvaceae (Cross et al., 1975). Once male boll weevils locate their host plant, feeding ensues, and they release in their frass an attractant pheromone (Cross and Mitchell, 1966; Keller et al., 1964). This pheromone aggregates both sexes at various times of year (Hardee et al., 1969, 1972) and consists of four components: I [(+)-(Z)-2-isopropenyl-1-methylcyclobutane ethanol]; II [(Z)-3,3-dimethyl- $\Delta^{1,\beta}$ -cyclohexaneethanol]; III [(Z)-3,3-dimethyl- $\Delta^{1,\alpha}$ -cyclohexane acetaldehyde]; and IV [(E)-3,3-dimethyl- $\Delta^{1,\alpha}$ -cyclohexane acetaldehyde) (Tumlinson et al., 1969) (Figure 1). The identification of this multicomponent pheromone was based on laboratory behavioral bioassays (Tumlinson et al., 1969) with its activity in nature verified by subsequent field experiments (Hardee et al., 1972).

Since the identification of the boll weevil aggregation pheromone nearly two decades ago (Tumlinson et al., 1969), and the subsequent report of lack of chiral specificity for I (grandisol) (Mori et al., 1978), research on the pheromone has focused on the determination of attractive ratios of its four components (Hardee et al., 1974), and the development of formulations for use in the field (McKibben et al., 1971, 1980). In contrast to earlier work (Mori et al., 1978), we recently showed that boll weevils respond behaviorally only to (+)-grandisol and possess olfactory cells specific for this enantiomer, while (-)-grandisol is inactive or slightly inhibitory (Dickens and Mori, 1989). This discovery prompted us to reinvestigate the activity of each of the boll weevil pheromone components (Tumlinson et al., 1969). We report here the results of our electrophysiological and behavioral experiments.

METHODS AND MATERIALS

Insects. Adult *A. grandis* used in these experiments were obtained from a small laboratory colony annually infused with feral insects maintained at the USDA-ARS Boll Weevil Research Unit. Upon emergence, insects were sexed and fed cotton squares. For field experiments, groups of 50 insects of the same sex were held in paper cartons (ca. 0.5 liter) with screen tops. Insects used in the field releases were 5–14 days postemergence. For electrophysiological stud-

FIG. 1. Compounds composing the boll weevil aggregation pheromone (Tumlinson et al., 1969). Although (-)-I was not originally identified as a pheromone component, it is included since it was previously considered active (Mori et al., 1978) and occurs in current pheromone formulations as a result of racemic synthesis of I.

ies, groups of five insects of the same sex were maintained on moist filter paper in Petri dishes until use following receptor maturation at four days postemergence (Dickens and Moorman, 1987). Insects used in these studies were 4–7 days of age. All insects were held in incubators at 26°C under a photoregimen of 16 hr of light (ca. 700 lux) and 8 hr of darkness.

Chemicals. Racemic grandisol [= (±)-I], II, and III + IV (a 50:50 mixture as derived from a nonstereoselective synthesis), each >95% chemical purity, were obtained from Albany International, Controlled Release Division, Buckeye, Arizona. Compound III was 100% pure as prepared by the Mr. W.-C. Sun, State University of New York at Stony Brook (Prestwich et al., 1987)

by extensive recycle MPLC chromatography. Compound IV, used in electrophysiological studies, was >99% pure, while that used in the field studies had 96% geometrical purity. A 50:50 mixture of III (100% pure) and IV (>99% pure) was prepared for electrophysiological studies. Serial dilutions (0.0001–10 $\mu\text{g}/\mu\text{l}$) of all compounds were made in nanograde hexane. 1-Hexanol, used as a standard in electroantennogram (EAG) experiments, was 98% chemically pure as obtained from Aldrich Chemical Co., Milwaukee, Wisconsin.

Field Experiments. Compounds (\pm)-I, II, and the synthetic mixture of III + IV were apportioned as 10- μl aliquots of 10 $\mu\text{g}/\mu\text{l}$ dilutions. Compound III was apportioned as a 5- μl aliquot of a 10- $\mu\text{g}/\mu\text{l}$ dilution. Compound IV was apportioned as a 10- μl aliquot of a 5- $\mu\text{g}/\mu\text{l}$ dilution. (\pm)-I, and II, III, and IV were placed in separate 0.5-dram screw-cap vials using measured glass capillaries which remained in the vials. These vials were then sealed with Teflon-lined screw caps and placed in a cooler until use in the field. In the field, screw caps were removed from the vials, and both caps and vials were placed in the top of an aluminum film container (3 cm diam. \times 4.3 cm height) that had five holes (0.23 cm diam.) drilled near its outer edge. The bottom of the can was screwed onto the top, and the inverted container was then placed in the trap (modified after Mitchell et al., 1976; and in current use in the Boll Weevil Eradication Program) beneath the screen funnel.

The experimental design consisted of placing four traps in a square 20 m apart in an open, isolated area. The two treatments being tested were alternated among the traps. One hundred insects (50 males and 50 females) were released 20 m from each side of the square at ca. 1400 hr (400 insects total for each replicate of each experiment). Traps were then immediately baited. Each trap was checked, and the weevils removed on the day of release at 1500 hr, 1600 hr, and 1800 hr, and the following day at 1500 hr and 1600 hr, prior to the final trap check and removal of the baits at 0830 hr the next day.

In order to test the importance of each pheromone component, all possible three-component blends were each tested in competition with the four-component blend [(\pm)-I 50% (400 μg), II 37.5% (300 μg), and III 6.3% (ca. 50 μg) + IV 6.3% (ca. 50 μg) (100 μg)]. This blend of the four components was chosen since it approximated the natural mixture obtained from boll weevil frass: I, 52.3%; II, 39.4%; III, 4.1%; IV, 4.1% (Tumlinson et al., 1969), and relatively similar blends were significantly more attractive compared to other dissimilar blends (Hardee et al., 1974). The three-component blends tested in competition with the four-component blend were: (1) II (300 μg), III + IV (100 μg); (2) (\pm)-I (400 μg), III + IV (100 μg); (3) (\pm)-I (400 μg), II (300 μg), IV (50 μg); and (4) (\pm)-I (400 μg), II (300 μg), III (50 μg). The four-component blend was also tested against: (\pm)-I (400 μg), II (300 μg); and (\pm)-I (400 μg), II (300 μg), IV (100 μg). A competitive experiment tested the following three-component blends against each other: (\pm)-I (400 μg), II (300 μg), and III (50 μg) vs. (\pm)-I (400 μg), II (300 μg), and IV (50 μg). A control consisting of

(\pm)-I (400 μg), II (300 μg), and III + IV (100 μg) vs. hexane (80 μl) determined the attractiveness of the colored trap and solvent alone. Three replicates were run for each competitive treatment and the control.

Electrophysiology. EAGs were recorded as previously described (Dickens, 1984). Ag-AgCl capillary electrodes filled with physiological saline (Oakley and Schafer, 1978) were used. Following prepuncture with a sharpened tungsten needle, the recording electrode was inserted in the distal end of the club; the ground electrode was inserted into the distal end of the scape. The signal was amplified by a Grass P-16 DC preamplifier prior to visualization on a Tektronix 5111 analog oscilloscope and recording for storage with a strip-chart recorder.

Serial dilutions of III, IV, and a 50:50 mixture prepared from III and IV were delivered as 1- μl aliquots placed on filter paper (8 \times 18 mm) inserted into glass cartridges (80 mm \times 5 mm ID) oriented toward the preparation from a distance of 1 cm. Molecules evaporating from the filter paper were carried over the preparation by hydrocarbon-free air, which had been filtered and dried. Serial dilutions were delivered from the lowest to the highest concentration. Stimulus duration was ca. 1 sec with air flow of 1 liter/min. More than 3 min were allowed between presentations of olfactory stimuli, which was adequate for recovery of EAG activity.

Three replicates were recorded for serial dilutions of both III and IV, and a 50:50 mixture of III and IV for both male and female *A. grandis*. 1-Hexanol at the 100- μg dosage was used: (1) to normalize all responses; (2) to ensure viability and constancy of the preparation; and (3) to allow for relative comparisons with previously recorded species (Dickens, 1984; Dickens and Bolt, 1985; Dickens et al., 1986; Glancey and Dickens, 1988; Light et al., 1988). Stimulation with the standard both preceded and followed each serial dilution level. Responses to odorous stimuli at a given dosage were expressed as a percent of the mean of the two nearest responses to the standard (Dickens, 1981, 1984).

Statistical Analyses. Percent trap catches for simultaneous paired treatments in the field experiments were compared using a paired *t* test (Ostle, 1963). Results from tests not run simultaneously were compared by a *t* test for two means. Dosage-response curves resulting from the electrophysiological studies were compared by analysis of variance and Duncan's new multiple-range test (Duncan, 1955).

RESULTS

Three-Component Blends vs. Four-Component Blend. Competitive field experiments, in which each of the possible three-component blends were tested against the four-component mixture demonstrated the necessity of I, II, and IV

(Table 1). The removal of any one of these odorants led to a significant decrease in trap capture relative to the four-component blend ($P < 0.01$) with the attractancy of the resultant three-component mixtures not significantly different from the hexane solvent alone vs. the four-component blend. However, removal of III from the four-component mixture resulted in a three-component blend that did not differ significantly in trap capture from the four-component blend in competitive experiments.

Electrophysiological and Behavioral Experiments with III and IV. Since the (*Z*)-cyclohexylidene aldehyde, III, was not an essential component for capture of male and female boll weevils in traps in the field, we investigated further its detection and possible behavioral role in boll weevil aggregation. Dose-response curves constructed from EAGs recorded from male and female boll weevils to serial dilutions of III and IV showed both sexes to be 10–100 times more sensitive to IV (Figure 2). Antennal receptors of male boll weevils were significantly more responsive to IV than III ($P < 0.05$) at all concentrations after reaching threshold (ca. 0.1 μg) with an intermediate response to the mixture of geometric isomers (Figure 2a).

TABLE 1. MEAN PERCENT (\pm SD; $N = 3$) RESPONSE OF *Anthonomus grandis* IN COMPETITIVE FIELD TESTS WITH THREE-COMPONENT BLENDS VS. FOUR-COMPONENT BLEND, AND HEXANE SOLVENT VS. FOUR-COMPONENT BLEND^a

Treatment pair	$\bar{X}\%$ (\pm SD) capture/replicate	Sex ratio M:F
(\pm)-I, II, III + IV vs. II, III + IV	93.37** (\pm 7.21) 6.63 (\pm 7.21)	1.38:1 5.00:1
(\pm)-I, II, III + IV vs. (\pm)-I, III + IV	92.82** (\pm 5.09) 7.18 (\pm 5.09)	1.38:1 1.43:1
(\pm)-I, II, III + IV vs. (\pm)-I, II, IV	55.17 (\pm 6.21) 44.83 (\pm 6.21)	0.88:1 0.74:1
(\pm)-I, II, III + IV vs. (\pm)-I, II, III	86.93** (\pm 2.50) 13.07 (\pm 2.50)	0.94:1 1.00:1
(\pm)-I, II, III + IV vs. Hexane solvent	93.89** (\pm 4.44) 6.11 (\pm 4.44)	0.98:1 0.88:1

^a Dosages in each test were: (\pm)-I (400 μg), II (300 μg), III + IV (100 μg), III (50 μg), IV (50 μg), hexane solvent (80 μl).

** $P < 0.01$; paired *t* test.

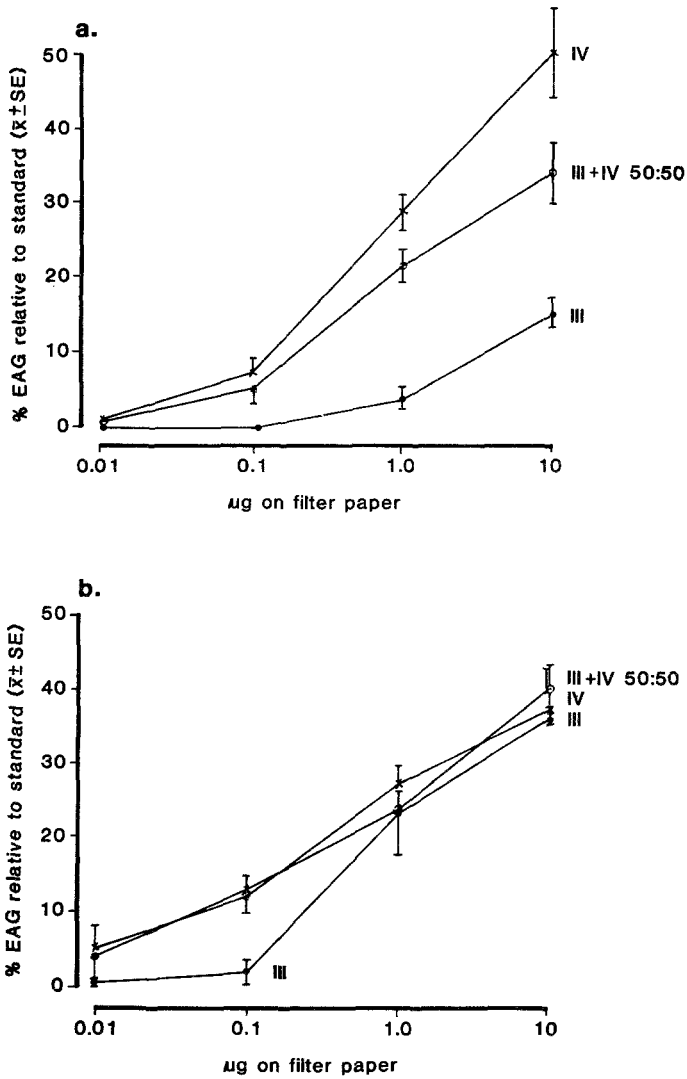

FIG. 2. Dosage-response curves constructed from EAGs of male (a) and female (b) *A. grandis* to serial dilutions of III, IV, and a 50:50 mixture of III and IV. Each point represents a mean of three replicates. Vertical bars represent standard errors.

Dosage-response curves for females to III, IV, and the mixture of III and IV differed from those obtained for males (Figure 2b). Responses of antennal receptors of females to serial dilutions of IV, and the III and IV mixture did not differ. Furthermore, after reaching threshold at 1 µg, responses to III did not differ from either IV alone or the mixture of III and IV.

Additional field experiments were conducted to determine: (1) whether IV was essential in the three-component blend of I, II, and IV when compared to the four-component blend; (2) whether increasing the dosage of IV affected trap capture by the three-component blend of I, II, and IV relative to the four-component blend; and (3) how the attractiveness of the three-component blend of I, II, and IV compared with the blend of I, II, and III (Table 2). The removal of IV decreased trap capture by the three-component blend of I, II, and IV when compared to the four-component blend (Table 2) to a level not significantly different from the other three-component blends or hexane control vs. the four-component blend (Table 1). Although doubling the amount of IV (100 μg) (Table 2) released with I and II in the three-component blend relative to our initial experiment (50 μg) (Table 1) against the four-component blend resulted in a higher percentage of weevils captured, this difference was not significant. In our final competitive field experiment, the blend of I, II, and IV captured significantly more weevils than I, II, and III ($P < 0.01$) (Table 2).

DISCUSSION

The essentiality of I, II, and IV for boll weevil aggregation is clearly demonstrated by our current competitive field tests with the three-component blends vs. the four-component blend. Previous knowledge of the activity of individual pheromone components and certain blends was based largely on results of lab-

oratory bioassays done at the time of the initial identification of the pheromone (Tumlinson et al., 1969) and subsequent field tests (Hardee et al., 1974). While the laboratory bioassays showed various levels of activity for individual components and two-component blends, activity was substantially increased with the three-component blends of I, II, and IV, and especially I, II, and III, which was as attractive as live male boll weevils. The attractiveness of the four-component mixture exceeded both the live male boll weevils and each of the three-component blends (Tumlinson et al., 1969). However, the laboratory bioassay device used in these studies was an olfactometer in which the insects were offered a "choice" between various odorants and a blank or solvent control. These ambulatory responses of females to the various compounds and blends were then compared to female responses to live boll weevils in separate tests. Results from such an olfactometer can be misleading, since attraction may be related to the context in which an odorant or odorous blend is detected. Thus an odorant may elicit an attractive response when presented alone, but might be unattractive when presented in competition with another odorant, as previously shown for the boll weevil (Dickens, 1986). While previous field tests showed individual components to be unattractive, two- and three-component blends were not tested (Hardee et al., 1974). We point out that IV used in our current study was 96% chemically pure with 4% of its geometric isomer III. Thus we cannot yet rule out the possibility that III might be active as a minor or trace component of the attractant pheromone. This will await future experiments as additional quantities of III, and IV of greater purity become available. However, we can say that III (100% purity) alone is ineffective in enhancing trap capture in combination with I and II at the biologically meaningful dosages tested relative to the combination of IV with these odorants.

Both the low olfactory threshold for IV, and the significantly lower EAGs elicited by III relative to IV for male boll weevils (Figure 2) correlate well with the role of IV as a pheromone component. The dosage-response curve for III was parallel to that of IV, only shifted closer to the abscissa. A dosage-response curve intermediate and parallel to the other two was obtained for the mixture of III and IV. Similar results were obtained for the enantiomers of grandisol (I) in the boll weevil (Dickens and Mori, 1989) and are consistent with a single acceptor type for IV (Kaissling, 1971). However, while antennal olfactory receptors of females were more sensitive to IV than III, EAGs elicited at higher dosages by III, IV, and a mixture of III and IV were not significantly different (Figure 2). Furthermore, shapes of dosage-response curves for III and IV for females were different. Dosage-response curves of different shapes, and responses to the III and IV mixture which were similar to III and IV alone at higher dosages, may be indicative of separate populations of acceptors for III and IV in females. Detection of III by female boll weevils plays no apparent role in their orientation to pheromone traps in the current study, since sex ratios

seemed to vary among tests rather than individual treatments within a test (Tables 1 and 2). It might be speculated that III may function in close range orientation of females to pheromone-producing males and/or in the assessment of oviposition sites by providing a cue to avoid squares already damaged by male feeding.

If III is not essential in the boll weevil attractant response, then what is its function? As mentioned before, III might play a role in short-range orientation and/or other behaviors of females. Compound III might also be involved in the biosynthesis of II through a stereoselective aldehyde reductase or some other biosynthetic mechanism. It is also possible that the (*Z*)-cyclohexylidene aldehyde, III, arises by nonbiological oxidation of the (*Z*)-cyclohexylidene allylic alcohol II or that III is intermediate in the degradation of the alcohol II to an inactive carboxylic acid (Sun and Prestwich, unpublished). In this regard, both the biosynthesis of lepidopterous pheromones (Morse and Meighen, 1986) and the conversion by microsymbionts of certain host monoterpenes to bark beetle pheromones (Brand et al., 1975; Brand, 1976; Leufven et al., 1986) involve alcohol precursors that are oxidized to aldehydes or ketones. The possible role of III in pheromone biosynthesis or degradation (Prestwich, 1987) and in boll weevil behavior will be investigated further.

Our discovery of the relative inactivity of III in boll weevil trap capture, and our recent elucidation of the lack of detection and behavioral response of boll weevils to (-)-I (Dickens and Mori, 1989) could be of importance in current boll weevil eradication/suppression programs (Ridgway and Lloyd, 1983). These programs depend heavily on traps baited with (\pm)-I, II, III, and IV for detection of boll weevils for both survey and evaluation of various control measures. When one considers the inactivity of (-)-I and III, then inactive compounds make up 40% of the current bait. Furthermore, increased ratios of III + IV relative to I and II decrease the attractiveness of the four-component mixture (Hardee et al., 1974; Huddleston et al., 1977), and (-)-I might be slightly inhibitory (Dickens and Mori, 1989). In light of our current knowledge, the effects of increasing III + IV on trap capture may be due to III alone, since increasing IV in our experiments only led to increased trap captures (Tables 1 and 2). We are currently investigating the possibility of obtaining I composed primarily of the (+)-enantiomer and IV separated from III for more efficient use of the pheromone in field programs.

Acknowledgments—The authors are grateful for critical reviews of the manuscript provided by: Dr. Armand Whitehead, Department of Zoology, Brigham Young University; Dr. W.L. McGovern, USDA-ARS, Boll Weevil Research Unit; and Dr. D.E. Rowe, USDA-ARS, Crop Science Research Laboratory. J.C.D. thanks Mr. William Harris and Mrs. Essie Mattix for assistance with the field tests. G.D.P. thanks the National Science Foundation and the Herman Frasch Foundation for financial support, and Mr. W.-C. Sun for providing purified III and IV for this study.

(Received August 3, 1987; accepted January 19, 1988)

Abstract—The enantiomeric composition of α -pinene in individual Norway spruce trees [*Picea abies* (L.) Karst.] was determined on a chiral GC column after stereoselective hydroboration–oxidation followed by a reaction with isopropyl isocyanate to form the carbamate derivative. The enantiomeric composition varied considerably between trees of different genetic origin. There was a strong correlation between the chirality of α -pinene in host spruce trees and the *cis/trans* ratio of verbenols found in the hindguts of the bark beetle *Ips typographus* (L.) infesting the trees.

Key Words—Enantiomeric composition, chiral separation, GC, pheromone, plant–insect relations, Norway spruce, *Picea abies*, α -pinene enantiomers, *cis*-verbenol, *trans*-verbenol, *Ips. typographus*, Coleoptera, Scolytidae.

INTRODUCTION

Many bark beetles in the genus *Ips* are known to produce *cis*- and *trans*-verbenol when they are exposed to the vapors of α -pinene or oleoresins from their

¹Coleoptera; Scolytidae.

²Parts of this work have been presented at the 14th International Symposium on the Chemistry of Natural Products in Poznan, Poland, July 9–14, 1984.

host trees (Renwick et al., 1976; Byers, 1981). This production, which is a stereospecific allylic hydroxylation, gives (1*S*, 4*S*, 5*S*)-*cis*-verbenol from (–)-1*S*, 5*S*)- α -pinene, whereas (1*R*, 4*S*, 5*S*)-*trans*-verbenol is produced from the (+)-(1*R*, 5*R*)-enantiomer of α -pinene. Moreover, males of *I. typographus* produce *cis*- and *trans*-verbenol in ratios that were found to reflect the enantiomeric composition of the α -pinene, to which they were exposed in a laboratory experiment (Klimetzek and Francke, 1980). (*S*)-*cis*-Verbenol is also identified as a component of the aggregation pheromones of both *I. paraconfusus* (Silverstein et al., 1966) and *I. typographus* (Krawielitzki et al., 1977), while the attraction to *trans*-verbenol is small or uncertain (Dickens, 1981; Schlyter et al., 1987).

It is well known that there are genetic and seasonal variations of the monoterpene compositions of conifers (Juvonen, 1966; Rudloff, 1967). However, very little is known about the enantiomeric compositions due to the lack of convenient analytical methods.

α -Pinene is produced in different enantiomeric compositions by various conifer species (Klimetzek and Francke, 1980). Even within the same genus, i.e., *Pinus*, different species are known to vary from almost pure (+)- to almost pure (–)-enantiomer; α -pinene from *P. halipensis* exhibits $[\alpha]_D = +48.30^\circ$, whereas that of *P. pinaster* (French turpentine) has $[\alpha]_D = -43.4^\circ$ (Mirov, 1961). Pure (+)- α -pinene has been reported to have $[\alpha]_D = +52.4^\circ$ (Comyns and Lucas, 1957). The intraspecific variation in the enantiomeric composition of monoterpene hydrocarbons, such as α -pinene, has to our knowledge not been investigated.

The methods available for the determination of the enantiomeric compositions of hydrocarbons are limited. The classical polarimetric method and NMR techniques require comparatively large amounts of pure samples and are not suitable for complex mixtures, whereas chromatographic techniques require relatively small sample amounts, and crude samples of complex mixtures can be analyzed.

Several chiral GC phases are known, and it is also possible to separate enantiomers as diastereomers on ordinary GC phases, but none of these techniques is general or works well for the resolution of monoterpene hydrocarbon enantiomers. The aim of the present investigation was to develop a sensitive chromatographic method for the determination of the enantiomeric composition of α -pinene in biological samples. Recently, methods for gas-chromatographic determinations of the enantiomeric compositions of secondary alcohols have been reported. The optical purity can be determined either via separation of diastereomeric derivatives [N-TFA-(L)-alanine esters] (Kruse et al., 1979) or by separation of isopropyl carbamates on a chiral GC phase, Chirasil-Val (König et al., 1982). There are also some reports on direct separation of alcohol enantiomers using chiral metal complexes as GC phase (Schurig et al., 1985).

It is possible to convert olefinic hydrocarbons regio- and stereoselectively

into secondary alcohols via a hydroboration–oxidation reaction (Zweifel and Brown, 1964). We have applied this reaction to convert α -pinene into isopinocampheol. For this purpose we have used the two-phase technique of Brändström et al. (1972). The isopinocampheol was separated as its isopropyl carbamate according to the method of König et al. (1982) (Scheme 1).

SCHEME 1.

We have used this method to study the enantiomeric composition of α -pinene in individual spruce trees, *Picea abies*, and compared it to the *cis/trans*-isomer ratio of verbenol found in the hindguts of male bark beetles, *Ips typographus*, attacking some of these trees.

METHODS AND MATERIALS

Biological Material. Phloem samples were taken from 29 different individual spruce trees [*Picea abies* (L) Karst.] at three different localities. The first was a forest plantation close to Uppsala, 70 km north of Stockholm. Samples were taken from 21 different 10-year-old cloned trees originating from Finland (SF) and West Germany (BRD). These samples were taken in February 1983 and stored as logs for six to eight months in individual polyethene bags at -18°C . Two spruce trees close to the laboratory in Stockholm made up a second group. The third source of phloem samples were six trees infested by spruce

bark beetles, *Ips typographus*, sampled close to Torsby, province of Värmland, western Sweden, during the main swarming period in early June 1982 (cf. Birgersson et al., 1988). These phloem samples were removed with a knife and stored in liquid nitrogen until extraction and analysis.

From each spruce tree in the third group, male bark beetles were also collected and analyzed for their hindgut volatiles as described in detail by Birgersson et al. (1984).

Sample Preparation. The outer cork bark was removed with a knife, and the phloem sample was removed from the log with a rasp. On the infested trees the stored phloem sample was chopped with a knife. The phloem sample (1 g) was extracted with pentane (Merck p.a.) for 15 min in an ultrasonic bath. The pentane extract was washed with saturated sodium bicarbonate and passed through a short alumina column (2 g Merck, Aktiv 60, base treated) to remove chlorophyll and polar compounds. Most of the pentane was evaporated and dry dichloromethane (1 ml) was added. The solution was transferred to a 3-ml reaction vial equipped with a PTFE-coated septum. Tetrabutylammonium boronate (Brändström et al., 1972) (50 mg) was added. The vial was flushed with argon. Ethyl bromide (50 μ l) was added with a syringe, and the reaction mixture was kept at 60°C for 30 min. A few drops of water were added to destroy the excess of hydride. Aqueous sodium hydroxide (2 N, 100 μ l) was added, followed by a slow addition of hydrogen peroxide (35%, 70 μ l). The vial was left at room temperature for 1 hr. Most of the dichloromethane was evaporated, and water and pentane were added. The pentane phase was separated and concentrated.

The concentrated pentane extract was dissolved in dichloromethane (200 μ l), and isopropyl isocyanate (100 μ l) was added. The mixture was heated to 100°C for 20 min. Dichloromethane and the excess of isopropyl isocyanate were evaporated and the residue dissolved in pentane and analyzed on GC.

The gas chromatographic analyses were performed on a PYE 204 GC and on a Hewlett-Packard 5830 GC both equipped with fused silica columns coated with XE-60-(S)-valine-(S)- α -phenylethylamide (Chrompac 50 m, ID 0.23, $df = 0.14$ mm, HETP = 0.21 mm). The oven was kept at 165°C isothermal, and injector and detector temperatures were 250°C. Helium was used as carrier gas (16–22 cm/sec). The α -factor for the two enantiomers was 1.0178.

Preparation of Test Mixtures and Isopinocampheol References. A test sample containing 60.0% of (–)- α -pinene was prepared by mixing (+)- and (–)- α -pinene isolated earlier at the Department of Organic Chemistry, Royal Institute of Technology (0.045 g of $[\alpha]_D = 19.6^\circ$ and 0.053 g of $[\alpha]_D = -36^\circ$) and used to check the steric course of the hydroboration step. Small samples (25, 50, 100, and 150 μ g) were taken from the test mixture and hydroborated as described for the pentane extracts of spruce trees.

Isopinocampheol. Ethyl bromide (3.27 g) was slowly added to a solution of tetrabutylammonium boronate (2.57 g) and α -pinene (2.72 g) of high optical

purity (Fluka) in dry dichloromethane (10 ml) under an atmosphere of argon. The mixture was refluxed for 30 min. The excess of hydride was destroyed with water. Aqueous sodium hydroxide (2 N, 5 ml) was added, followed by dropwise addition of hydrogen peroxide (35%, 3 ml). The mixture was stirred at room temperature for 1 hr. The dichloromethane phase was separated and dried, and the solvent was slowly evaporated to yield crude isopinocampheol, which was used as reference compound for the GC analysis.

RESULTS AND DISCUSSION

The α -pinene samples from the test mixture were analyzed and found to contain $60.9 \pm 0.7\%$ (min 59.9%, max 61.4%, $N = 6$) of the (-)-enantiomer, close to the expected 60.0%. The experiment shows that the hydroboration is stereoselective and that both accuracy and precision of this method for detecting the enantiomeric composition of α -pinene are good.

The enantiomeric composition of α -pinene in the phloem of Norway spruce trees was found to vary between 32 and 98% of the (-)-enantiomer (corresponding to 38% ee of (+)- α -pinene and 96% ee of (-)- α -pinene) (Table 1).

Males of the spruce bark beetle (*Ips typographus*) were collected from six infested Norway spruce trees and the hindguts were extracted and analyzed for the total amount of *cis*-verbenol (Birgersson et al., 1988) and the ratio of *cis*- to *trans*-verbenol. The relative amounts of verbenol isomers correlated strongly ($r = 0.91$, $P < 2\%$) to the relative amounts of (-)- and (+)- α -pinene in the phloem (Figure 1). This result is in accordance with the laboratory experiments performed by Klimetzek and Francke (1980).

FIG. 1. Percentage *cis* isomer of verbenol from *Ips typographus* male hindguts versus percentage (-)-enantiomer of α -pinene found in *Picea abies* phloem extracts from infested trees (I–VI). \square = attack phase 3, $\bar{X} \pm \text{SD}$; \circ = attack phase 6, $\bar{X} \pm \text{SD}$, attack phases according to Birgersson et al. (1984). ($N = 10$; $k = 0.91$; $m = 9.23$ ($y = kx + m$); $r = 0.91$; $r^2 = 0.82$.) In tree III, no beetles in attack phase 6 were found, and in tree VI no beetles in attack phase 3 were found.

The intraspecific variation in the enantiomeric composition of α -pinene in spruce was probably the reason for the findings by Birgersson et al. (1984) that batch samples of *I. typographus* males attacking different spruce trees varied in their ratios of *cis*- and *trans*-verbenols.

Since *cis*-verbenol is an essential component of the aggregation pheromone of *Ips typographus* and as there is a direct relation between the *cis* ratio of verbenols found in the hindguts of the bark beetle and the enantiomeric composition of α -pinene in the phloem of the host tree, we assume that there also exists a relationship between the enantiomeric composition in the Norway spruce and its resistance to attacks of *Ips typographus*. Trees with a very low content of (-)- α -pinene may thus be resistant to bark beetle attacks. Further studies to test this hypothesis are in progress.

There is also a strong indication that the enantiomeric composition within a clone is constant. However, the amount of material investigated is too small

to settle this point. Work is in progress to study the inheritance of the enantiomeric composition of α -pinene.

During the course of this investigation, a new method using α -cyclodextrin and formamide as the stationary phase in gas chromatography for the separation of α -pinene has been published (Koscielski et al., 1983). This method has been shown to be very useful for the enantiomeric separation of several of the common monoterpene hydrocarbons (Lindström et al., 1987). However, further development is needed before this method can be applied to complex mixtures.

Acknowledgments—We thank Åke Lindelöw, The Swedish University of Agricultural Sciences, Uppsala, for supplying us with cloned trees. Ann-Britt Wassgren is gratefully acknowledged for information regarding chiral GC columns. This study was made within the Swedish project "Odour Signals for Control of Pest Insects," funded by the Swedish Research Councils (NFR, FRN, SJFR and STU), Nils and Dorothy Troedssons Forskningsfond, and Swedish forest industries.

Abstract—The defense secretions of five species of Malaysian *Nasutitermes*, *N. longinasus*, *N. matangensis*, *N. havilandi*, *N. johoricus*, and *Nasutitermes species 01*, are compared. *N. longinasus* and *N. species 01* provide triterpene alcohols, *N. havilandi* mainly tricyclic trinervitene and tetracyclic kempene alcohols and acetates, whereas *N. matangensis* furnish acetyl/propionyl derivatives of trinervita-11(12),15(17)-dien-3 α ,9 β ,13 α -triol (XXI and XXII). A new diterpene, assigned as trinervita-11(12),15(17)-dien-3 α ,13 α -diol-3,13-*O*-diacetate (XVII), is isolated from *N. havilandi*. The mono- and diterpenoid compositions, being species-specific, are useful for chemotaxonomic and phylogenetic studies.

Key Words—Isoptera, Termitidae, defense secretions, interspecific variations, *Nasutitermes*, diterpenes.

INTRODUCTION

The genus *Nasutitermes* belongs to the subfamily Nasutitermitinae in which the soldiers are characterized by conical, nozzle-shaped projections from which they eject defensive secretions produced by the enlarged frontal glands located within the head capsules. Behaviorally, most *Nasutitermes* species forage under covered trails. The covered trails may run extensively on the jungle floor and up along tree trunks, with most species feeding on dead plant material. The soldiers protect their foraging trails by positioning themselves along the fringes once

the trail is disturbed or exposed. Defense is effected by ejecting gluey secretions at their enemies. Although Malaysian *Nasutitermes* are very widespread, they are less studied than the free-ranging genera such as *Laccositermes*, *Hospitalitermes*, and *Longipeditermes* (Goh et al., 1984). The biology of Malaysian *Nasutitermes* is still relatively unknown. This paper presents the compositional and structural variations of the defense secretions of the soldier termites of *N. longinasus*, *N. matangensis*, *N. havilandi*, *N. johoricus*, and an unidentified species which will be referred to as *N. species 01*.

METHODS AND MATERIALS

Termite Material. Soldier termites used for the present studies were all collected from within closed canopy dipterocarp forests from the following localities of Peninsular Malaysia (Figure 1): (1) Gunong Jerai forest reserve [5°40'N, 100°15'E; 1200 m above sea level (ASL)]—an upper hill dipterocarp forest in the state Kedah; (2) Sungei Lallang forest reserve (5°30'N, 100°20'E; 50 m ASL)—a logging forest in the state of Kedah; (3) Muka Head Field Station (5°20'N, 100°8'E; 200 m ASL)—a coastal hill dipterocarp forest reserve in Penang; (4) Taman Negara (4°20'N, 102°25'E; 1,000 m ASL)—the national park of Peninsular Malaysia in the state of Pahang; (5) Jerantut forest reserve (3°50'N, 102°20'E; 50 m ASL)—a forest reserve area in the states of Pahang, Trengganu and Kelantan; (6) Cameron Highlands (4°30'N, 101°25'E; 1500 m ASL)—a highland resort in the state of Pahang; (7A) Gombak forest reserve (3°20'N, 101°46'E; 300 m ASL); (7B) Genting Sempah forest reserve (3°14'N, 101°46'E; 500 m ASL); (7C) Templer Park (3°22'N, 101°40'E; 200 m ASL); (7D) Gunong Sempit forest reserve (3°20'N, 100°49'E; 500 m ASL); (7E) Puchong forest reserve (3°10'N, 100°40'E; 50 m ASL)—7A–7E are hill dipterocarp forests in the state of Selangor; (8) University of Malaya Campus (3°10'N, 100°40'E; 50 m ASL)—a hill forest reserve at university campus in Wilayah Persekutuan; and (9) Pasoh forest reserve (2°58'N, 101°55'E; 100 m ASL)—a lowland dipterocarp forest in the state of Negeri Sembilan which has been the site for intensive ecological studies under the auspices of the International Biological Programme.

Analytical Methods. Gas chromatography (GC) was performed on a HP 5790a instrument fitted with a flame ionization detector. Two glass columns (1.6 m × 3 mm 3% OV-17 and 1.6 m × 3 mm 3% OV-101 on 100–120 Gas Chrom Q) were used for the diterpenoids and a 3-m × 5-mm stainless-steel column packed with 10% Carbowax 20 M on 120–140 Gas Chromsorb Q was used for the monoterpenes. Gas chromatography–mass spectrometry (GC-MS) was performed on a Pye 104 gas chromatograph interfaced to a double-beam Kratos MS30 mass spectrometer by a membrane separator. Mass spectra were

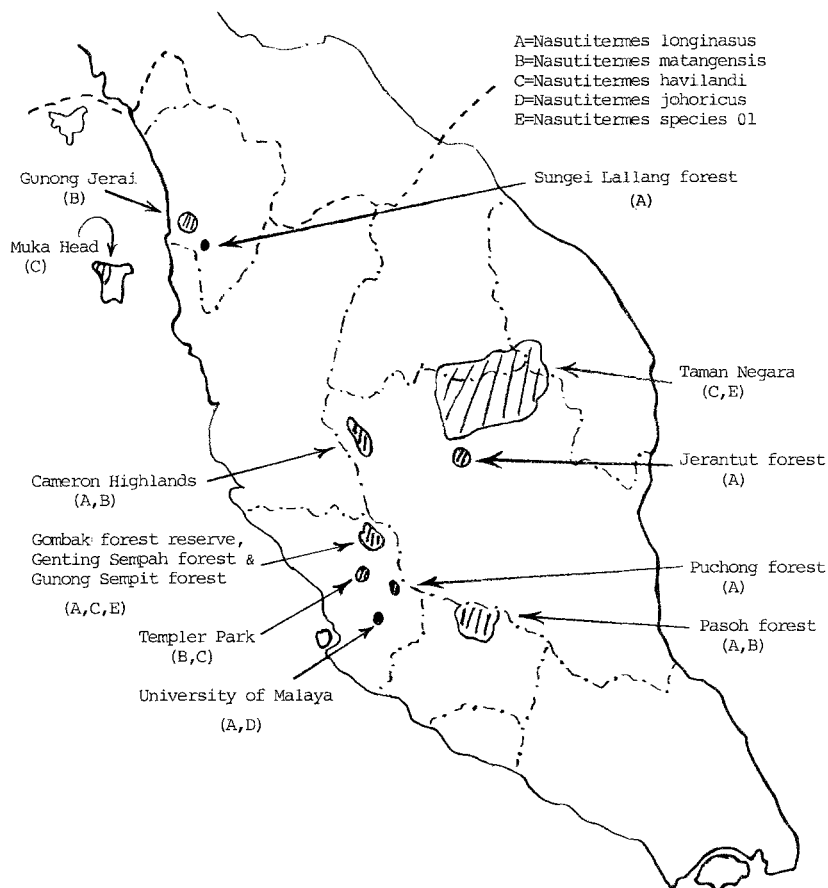

FIG. 1. Distribution of *Nasutitermes* in peninsular Malaysia.

obtained at 70 eV with the MS source at 100°C and membrane interface temperature at 230°C. Mass spectral data were accumulated by a Kratos DS55 data system. The data on the monoterpenes, characterized by GC, GC-MS and coinjection with standards, are summarized in Table 1. The diterpenes (VI-XXII) were characterized by the NMR and MS spectral comparison to reported data (Vrkoc et al., 1978a,b; Prestwich, 1979a,b; Dupont et al., 1981) and by coinjection with compounds previously identified (Chuah et al., 1983, 1986; Goh et al., 1982, 1984). The results are summarized in Table 2. The entire gas chromatographic profile of each defense secretion was typically obtained by on-column injection at 90°C and then programmed at 8°C/min to 300°C on 1.6 m × 3-mm 3% OV-101 and 1.6-m × 3-mm 3%-OV-17 glass

FIG. 2. Diterpenes from the defense secretions of Malaysian *Nasutitermes*.

columns. Retention indices of all diterpenes were made relative to n-alkane standards, and R_f values on silica gel TLC plates are summarized in Table 3 below.

Small-scale preparative separations were by HPLC on a Waters 440 instrument fitted with a 25-cm \times 1/4-in Ultrasphere silica gel column. Elution of the diterpenoids was by a gradient of 5–20% ethyl acetate in hexane. All isolated diterpenes were checked by GC and TLC on 5 \times 10-cm 0.25-mm silica gel 60

plates. The isolated known diterpenes were identified by their [¹H]NMR and mass spectral data and by comparison of their *R_f* and retention times with those previously identified (Chuah et al., 1983, 1986; Vrkoc et al., 1978a,b; Prestwich, 1979a,b; Dupont et al., 1981). In *N. havilandi*, a new diterpene (XVII) was obtained and, based on NMR, IR and MS data, its structure was assigned as trinervita-11(12),15(17)-dien-3 α ,13 α -diol-3,13-*O*-diacetate (XVII). The mass spectrum of this diterpene, XVII, showed peaks at *m/z* 388 (M^+ , 1, $C_{24}H_{36}O_4^+$), 328 (5, $M^+ - AcOH$), 286 (4, $M^+ - AcOH - CH_2CO$), 268 (100%, $M^+ - 2AcOH$), 253 (26, $M^+ - 2AcOH - CH_3$), 135 (27, $C_{10}H_{15}^+$), 60 (30, $AcOH^+$), 43 (72, CH_3CO^+), 41 (15, $C_3H_5^+$). Calculated exact mass for $C_{24}H_{36}O_4$, 388.2613; found, 388.2508. [¹H]NMR [100 MHz] and [¹³C]NMR [25 MHz] spectra are given below in Tables 5 and 6, respectively.

RESULTS AND DISCUSSION

The evolution and development of the frontal gland in the subfamily Nasutitermitinae, of which over 500 species have been reported (Tho, 1982), must be closely paralleled by the development of chemicals for the defense of the termite colony against predators. The biosynthesis of such chemicals in the cephalic gland has provided the termites with a vast array of defense chemicals against attacks by hostile organisms with whom they have to share their environment.

The results from the present study of the defense secretions of five *Nasutitermes* species show that there are marked differences in the distribution of monoterpenes (Table 1) and diterpenes (Table 2). Interspecifically, these species can be differentiated by such variations, including the presence or absence of certain diterpenes, which generally have complicated structures or display complex compositional patterns. Intraspecifically, there are only small but detectable quantitative variations in monoterpene and diterpene composition. The monoterpene components in the defense secretions of *N. longinasus* and *N. havilandi* comprise α -pinene, β -pinene and limonene, whereas in *N. matangensis* the monoterpenes are predominantly myrcene and limonene. The monoterpene contents in *N. johoricus* comprise α - and β -pinenes, whereas in *N. species 01* predominant amounts of limonene and terpinolene are shown. The diterpenes of these five species also show marked interspecific variations. In this respect, *N. longinasus* produces mainly the common diterpene mono-alcohols VI, VII, and VIII; diols XI and XII; diol monoacetate X; and triol monoacetate XIII; whereas the *N. havilandi* soldier secretes a mixture of ketokempene monoacetate XIV, tricyclic diterpene diacetate XVII, and kempene diacetates XV and XVI. In *N. matangensis*, the soldier secretes the dipropionate monoacetate XXI and the tripropionate XXII, whereas *N. johoricus* secretes two unknown diterpenes U1 and U2, which are different from those given above as indicated by GC and TLC data (Table 3). The occurrence of the above propionate esters (XXI and XXII) reported earlier (Prestwich et al., 1981c) and now confirmed as secreted from the species *N. matangensis*, provides clues to the biogenetic pathway of the various diterpene structures. In this respect, the presence of the 11(12)-olefinic bonds in the tricyclic skeleton (e.g., XXI and XXII) allows for the biosynthetic ring closure to tetracyclic kempene (XV) and rippertane (VI) as well as spirotetracyclic longipane structures (Goh et al., 1984).

The chemistry of the secretion of *N. species 01* is quite similar to that of *N. longinasus* but can be differentiated on the basis of monoterpene distributions (Table 1). In the former species, the soldiers are monomorphic, while those of *N. longinasus* are dimorphic. Heads of the major soldiers of *N. longinasus* are relatively bigger than the heads of *N. havilandi*, *N. johoricus*, and *N. matangensis*; thus the amount of its defense secretion is relatively higher (Table 4). As with many other genera, the size of the soldier head gives an indication of the storage capacity of the defense secretion.

Four major compounds were isolated from extracts of *N. havilandi*. Three compounds, viz., kempa-6,8-dien-3 β ,14 α -diol-3,14-*O*-diacetate (XV), kempa-6,8-dien-3 α ,14 α -diol-3,14-*O*-diacetate (XVI), and 3-oxokempa-6,8-dien-14 α -ol-14-*O*-monoacetate (XIV), are similar to those reported for another Malaysian termite *Bulbitermes singaporensis* (Prestwich et al., 1981b). The mass spectrum of the new diterpene diacetate XVII with M^+ at 388, compatible with

^aPercent based on body weight of termite soldier.

molecular formula $\text{C}_{24}\text{H}_{36}\text{O}_4$, shows characteristic fragment ions corresponding to the elimination of one and two molecules of acetic acid. The IR spectrum shows a strong band at 1732 cm^{-1} (ester $\text{C} = \text{O}$). The ^1H NMR (Table 5) exhibited three methyl, two acetate methyl, and three olefinic proton signals. The ^{13}C NMR spectra (Table 6) show two acetyl groups, a quaternary, seven methine, six methylene, and four olefinic carbons. Some characteristic carbon absorptions of the diterpene XVII at $\delta 38.31(\text{C}1)$, $33.81(\text{C}2)$, $80.14(\text{C}3)$, $48.61(\text{C}4)$, $36.27(\text{C}5)$, $30.23(\text{C}6)$, $36.80(\text{C}7)$, $129.69(\text{C}11)$, $131.56(\text{C}12)$, $73.47(\text{C}13)$, $37.44(\text{C}14)$, $148.41(\text{C}15)$, $60.02(\text{C}16)$, $112.49(\text{C}17)$, and $19.83(\text{C}18)$ match quite closely with $38.43(\text{C}1)$, $35.52(\text{C}2)$, $79.44(\text{C}3)$, $48.14(\text{C}4)$, $36.15(\text{C}5)$, $30.01(\text{C}6)$, $36.79(\text{C}7)$, $123.84(\text{C}11)$, $135.89(\text{C}12)$, $73.24(\text{C}13)$, $37.44(\text{C}14)$, $146.89(\text{C}15)$, $59.43(\text{C}16)$, $112.9(\text{C}17)$, and $19.71(\text{C}18)$, respectively, of the known tripropionate XXII from *N. matangensis*. The ^1H NMR data show characteristic exocyclic $\text{C}(17)\text{H}_2$ absorptions and the 16-H doublet, but the 11-olefinic proton appears as a broad flat-top peak (half-width ca. 18 Hz) which could accommodate a doublet-doublet of ca. 6-10 Hz. The broadening of 11-H, not present in compounds XXI and XXII, may be due to the lack of an acetate/propionate group at the C-9 position, allowing for a limited rotation of the C(8)-C(12) bridge in the vicinity of the exocyclic olefin bond. Two protons with α -acetoxy groups have comparable chemical shifts and coupling constants as those of previously described compounds XXI

1983, 1984; Dupont et al., 1981; Baker and Walmsley, 1982; Gush et al., 1985; Valterova et al., 1986) have documented that considerable interspecific variation occurs in the monoterpene and diterpene distribution for 15 *Nasutitermes* species from various parts of the world. This documentation and discriminator studies have shown the possible use of such distribution as chemotaxonomic characters (Prestwich, 1983) in establishing the interrelationships within this genus. In this respect, it is noteworthy that the current studies (Table 7) of the chemical defense secretions of *Nasutitermes* as reported here

will eventually contribute towards the better understanding of the taxonomic position of the genus in relation to the other genera in the subfamily Nasutitermitinae. The generic separation of the species within the subfamily, based mainly on morphological characteristics of the soldiers, is still far from being satisfactory. For example, the basis for generic distinction between *Bulbitermes* and *Nasutitermes* is based largely on the constricted head capsule in *Bulbitermes* soldiers. As demonstrated in this study, the major chemical components of the defense secretion of *Nasutitermes havilandi* come close to that of *Bulbitermes singaporensis* (Prestwich et al., 1981b). On the other hand, *Nasutitermes matangensis* would appear to be distinct from these two species. A comparison of the chemistry of the different species of these genera may in many ways provide further insight into the phylogenetic relations of such species and genera.

(Received November 10, 1987; accepted January 28, 1988)

Abstract—In reclamation fields of salt-affected wasteland, five plant communities colonized the undisturbed land, represented by *Cynodon dactylon*, *Desmostachya bipinnata*, *Prosopis juliflora*, *Sporobolus arabicus*, and *Suaeda fruticosa*. Kallar grass (*Leptochloa fusca*), a highly salt tolerant plant when cultivated, shared dominance with *Cynodon*, *Desmostachya*, and *Sporobolus* in 15-month-old fields, whereas *Polypogon* was the only dominant species in 30-month-old kallar grass fields. Through successional stages, soil pH, salinity, sodicity, and Na, K, Ca + Mg significantly decreased due to leaching. Electrical conductivity successively changed from 13.0 to 3.0 to 1.0, while soil total nitrogen, NH₄ nitrogen, NO₃ nitrogen and available P significantly increased. In high-density kallar grass fields, six weed species appeared only in well-defined patches and radially eliminated or reduced kallar grass growth. Many soil factors, such as pH, EC, NH₄ nitrogen, NO₃ nitrogen and available P analyzed in patch vegetation soils, were mostly either comparable or significantly better than those of surrounding kallar grass fields. On the other hand, aqueous extracts of all six invading species and kallar grass significantly reduced kallar grass seed germination to varying degrees. Further, decaying leaf powder of allelopathically suspected species significantly reduced kallar grass biomass, which varied from species to species and in most cases corresponded with field data of kallar grass in patch vegetation. It should be strongly pointed out that allelopathic behavior discussed in patch

⁴Permanent address: Department of Biology, Forest Park College, St. Louis, Missouri 63110.

dynamics was in areas where soil saline-sodic conditions had improved greatly (e.g., EC = from 13.0 to only 1.0) due to kallar grass plantation. Further, *Suaeda* appeared to be a poor competitor when soil conditions improved for other species as well, and it could not capitalize on its evolutionary strategic trait of performing well in saline-sodic conditions. To our knowledge, this is the first report indicating that allelopathy may be a factor in determining growth and distribution of plants in saline or sodic soils.

Key Words—Revegetation, reclamation, salinity, succession, kallar grass, *Leptochloa fusca*, nutrients, allelopathy.

INTRODUCTION

Due to agricultural practices, salinity is a rapidly growing global problem, predominantly where agriculture has been prominent for centuries. It is paradoxical that the irrigation canal system in Pakistan has resulted in salinization and/or water-logging of irrigated soils, which now exist as wastelands. Reclamation of such wasteland is essential; one effective way is by selecting and growing salt-tolerant plant species (Chaudri et al., 1964; Kleinkopf et al., 1975; Sandhu and Malik, 1978; Wallace et al., 1982; Naqvi, 1983).

Salt-affected soils are by no means devoid of vegetation. An ecological understanding of such vegetation may provide some useful information regarding the nature and intensity of salinization (Bodhla et al., 1981; Rutter and Sheikh, 1962). Subsequently, new species of economic importance may be introduced. Sandhu and Malik (1975) successfully introduced kallar grass [*Leptochloa fusca* (L.) Kunth.] in these wastelands for increased plant establishment and biomass production. Kallar grass is highly tolerant of salt (Sandhu et al., 1981) and sodicity (Aslam et al., 1979).

Even though the cultivation of kallar grass has clearly improved soil conditions (Malik, 1978), there were no systematic studies found in the literature describing the vegetation and soil properties of the saline lands and successive changes after kallar grass planting. With this in mind, a project was designed to document: (1) vegetation and soil composition of undisturbed areas, (2) successive changes after planting kallar grass and its own productivity, (3) invasion of kallar grass fields by various species, (4) patch dynamics of invading species, and (5) their allelochemic dominance in kallar grass fields. Nomenclature follows Stewart (1972), unless otherwise noted.

METHODS AND MATERIALS

Survey of Vegetation. The studies were carried out at the Biosaline Research Station (BSRS) of the Nuclear Institute for Agriculture and Biology, Faisalabad. BSRS is located near the village of Dera Chahl situated on Bedian Road, 30 km

from Lahore. The study site had not been cultivated for at least 40 years and remained free of human activities, chiefly due to the salinity. There may have been minor grazing by small wild animals. Therefore, this site will be referred as the undisturbed wasteland. For vegetational analysis, study plots were roughly delimited at five different sites within undisturbed wasteland by their dominant species without reference to the subordinate species. Four line transects, each 20 m long, were placed at random at each site and cover of species along each transect was recorded. Each community was named after the species most representative of the cover. For distribution of weed species in kallar grass fields, a quadrat method was used. Twenty quadrats (1-m² size) were randomly placed in fields where kallar grass had been grown for 15 or 30 months. Percent frequency (F) and density (D) (number of plants per quadrat) of weed species were recorded. Importance values (IV) were calculated as $IV = (F + D)/2$.

During our sampling of kallar grass fields, it was surprisingly obvious that the invading weeds nearly always appeared in well-defined dense patches surrounded by kallar grass. To describe this observation quantitatively, five patches of each of such weeds were located and quantified by a line transect method to indicate their range of invasion in kallar grass fields. Cover of weed species and kallar grass was recorded.

To determine kallar grass biomass, four 0.25-m² quadrats were randomly located in 15- and 30-month-old fields of kallar grass, and shoot biomass was harvested and dried to constant weight.

Soil Analysis. Four soil samples were collected from each site at the 0- to 15-cm level for physical and chemical analysis of the soil. Soil texture was determined by the hydrometer method (Bouyoucos, 1962) and water holding capacity by the Keen-Reckzowski box method (Piper, 1942). Soil pH was determined by a glass electrode pH meter, electrical conductivity (EC) by the Solu bridge conductivity meter, Na and K by flame photometry, and Ca + Mg by titration with ethylene diamine tetraacetate (EDTA). CO₃ and HCO₃ were determined by titration with H₂SO₄, and Cl by titration with AgNO₃ (USDA, 1954). Soil samples were extracted with 2 N KCl and analyzed for NH₄ and NO₃ by steam distillation with Devarda's alloy and MgO (Bremner and Keeney, 1965), and total nitrogen was determined following Bremner (1965). Available phosphorus was determined by the Olsen method (Watanabe and Olsen, 1965), and total phosphorus was determined after digestion with perchloric acid (Ogner et al., 1984).

Allelopathy Studies: Effects of Invading Species on Kallar Grass Seed Germination. To determine the effects of six major species invading kallar grass fields, aqueous extracts of each species and kallar grass were prepared and tested against kallar grass seed germination. Plant material was immersed in hot water (approx. 45°C) for 5 min to stop microbial activity before preparing the bioassay extracts. A 10% aqueous extract of each species was prepared by soaking the shoot material in water for 30 min at 25°C, and diluting to 2.5 and 5.0 (w/

v) percent solutions for experimentation. Final pH of all dilutions was adjusted to 6.0. Fifty kallar grass seeds were planted on filter paper in a Petri plate in triplicate and watered with various concentrations of extracts of all invading species. Seeds were allowed to germinate in the dark at a constant temperature of 25°C. Controls were treated in the same manner, except Petri plates were watered with distilled water. Germination was terminated after six days and recorded as percent germination.

Effects of Decaying Leaves of Invading Species on Kallar Grass Growth. Air-dried shoot material of each of six invading species and kallar grass was mixed in soil at a rate of 2 g/100 g soil and placed in 10-cm-diameter plastic pots. Shoot material was allowed to decay for two weeks and planted with four stubbles of kallar grass in each of four pots for each species. Seedlings were allowed to grow for four weeks, harvested, oven dried, and biomass recorded.

RESULTS

Vegetation. Five plant communities dominated by *Desmostachya bipinnata*, *Sporobolus arabicus*, *Suaeda fruticosa*, *Cynodon dactylon*, and *Prosopis juliflora* were recognized in the non-kallar grass fields in this study (Table 1). Apart from the dominant species, one or more of these five species were found

TABLE 1. MEAN PERCENTAGE COVER OF PLANT SPECIES IN DIFFERENT COMMUNITY TYPES

Species	Community type				
	<i>Desmostachya bipinnata</i>	<i>Sporobolus arabicus</i>	<i>Suaeda fruticosa</i>	<i>Prosopis juliflora</i>	<i>Cynodon dactylon</i>
<i>Desmostachya bipinnata</i>	62.04	1.25		1.55	
<i>Sporobolus arabicus</i>	8.54	37.58	10.16	2.66	10.50
<i>Suaeda fruticosa</i>	1.96	6.24	33.74	2.33	10.75
<i>Prosopis juliflora</i>			7.87	61.11	1.00
<i>Cynodon dactylon</i>	0.16	0.67	10.01	19.55	47.05
<i>Kochia indica</i>		1.66	1.50		2.00
<i>Acacia modesta</i>	0.50	1.21	0.50		
<i>Chenopodium album</i>		0.25			
<i>Polypogon monspeliensis</i>		0.16	0.12		
<i>Cyperus rotundus</i>			0.62		0.25
<i>Spergula rubra</i>			0.12		2.37

to be codominant. Kallar grass-introduced fields were invaded by weeds over a 30-month period (Table 2). *C. dactylon*, *D. bipinnata*, *S. arabicus*, and *S. fruticosa* were prominent weeds in 15-month-old kallar grass fields, while *Polypogon monspeliensis* was the principal invader followed by *C. dactylon*, *Kochia indica*, *Cnicus arvensis*, *Cyperus rotundus*, *Scirpus martius*, *Rumex dentatus* and *Spergula rubra* in 30-month-old fields (Table 2).

Six major weeds invaded established kallar grass fields in well-defined patches. Kallar grass growth was very poor and stunted when growing in association with the invading weeds. However, its vigor improved gradually away from the patch boundaries. Kallar grass biomass in 30-month-old fields was significantly lower than in 15-month-old fields (Table 3).

Soils. The soils in undisturbed sites were generally saline-sodic, and the degree of salinization varied for different plant communities (Figure 1, Table 4). The soils under *Suaeda* were highly saline and sodic, whereas those under *Desmostachya* and *Sporobolus* were moderately saline and highly sodic. *Cynodon* dominated slightly saline and moderately sodic soil, and *Prosopis* nonsaline but moderately sodic soils. The soils associated with *Cynodon* were relatively fine textured and had a higher water-holding capacity compared with soils dom-

inated by the rest of the species. All soils were alkaline. The predominant anions were CO₃ and HCO₃ (Table 4).

Through successional stages, soil conditions improved remarkably from natural to 15-month- and 30-month-old kallar grass fields. Importantly, soil pH, salinity sodicity, Na, K, and Ca + Mg, significantly decreased, whereas soil total nitrogen, NH₄-N, NO₃-N, and available phosphorus significantly increased in 15-month- and 30-month-old kallar grass fields (Table 3). Electrical conductivity significantly correlated with pH, Na, K and available P, but not with Ca + Mg, NO₃-N, NH₄-N, total N, and total P ($r = 0.91, 0.97, 0.80, 0.71, 0.57, 0.32, -0.51, -0.66, -0.33$, respectively). Consequently, all factors correlated with EC also improved as EC decreased from 13.0 to 2.9 to 1.1 in three respective chronological periods (Table 3).

The soil conditions in patch vegetation associated with kallar grass fields did not show any definite trends to explain reduced kallar grass growth. Soils associated with *Desmostachya*, *Kochia*, and *Sporobolus* were moderately saline and highly sodic, and soils under *Polypogon* and *Suaeda* were nonsaline and nonsodic. *Cynodon* soils were nonsaline and moderately sodic. Soil pH values in all patches were comparable to surrounding kallar grass fields with some significant variations (Table 5). pH values in *Suaeda* and *Polypogon* and EC

values in *Cynodon* and *Polypogon* were significantly lower than in kallar grass fields (Table 5). Electrical conductivity in *Suaeda* patch soils was not significantly different when compared with kallar grass soils. Available phosphorus and available nitrogen ($NH_4 + NO_3$) were always higher in patch soils than in kallar grass soils. Of the two available nitrogen sources measured, NO_3-N was always significantly higher in patch soils, whereas NH_4-N was lower in two

Allelopathy Studies. Aqueous extracts of five of the six invading species and kallar grass were significantly inhibitory to kallar grass seed germination, at least at one test concentration (Figure 2). *Cynodon* extracts were an exception, where kallar grass seed germination was not significantly different from control. Kallar grass seed germination was affected significantly in varying degrees depending on the species, extract concentrations, species \times concentration, and overall factors (Figure 2).

Decaying material from shoots of all six invading species, kallar grass, and farm manure significantly reduced shoot dry weight of kallar grass (Table 7). Maximum growth inhibition of kallar grass was caused by *Suaeda*, followed by kallar grass, *Desmostachya*, *Cynodon*, *Sporobolus*, *Kochia*, *Polypogon*, and farm manure (Table 7). Degree of inhibition of kallar grass varied significantly between allelopathically invading species and, in most cases, corresponded with the field data of kallar grass cover in patch vegetation (Tables 6 and 7).

FIG. 2. The effects of aqueous extracts of different species on kallar grass seed germination. ANOVA, $P \leq 0.05$ or better; species LSD = 13.8; concentration LSD = 5.25; species \times concentration LSD = 19.63; overall LSD = 13.88. ^aMeans followed by the same letter are not significantly different, Duncan's multiple-range test. $P \leq 0.05$.

DISCUSSION

Vegetation of an area is governed by a complex of environmental factors, both physical and biological. In a particular area, climate controls the general distribution of vegetation, whereas microenvironmental conditions determine if a species can survive. Soil plays an important role in this regard as it affects plant growth and distribution.

Cynodon dactylon, *Desmostachya bipinnata*, *Prosopis juliflora*, *Sporobolus arabicus*, and *Suaeda fruticosa* were dominant in the five community types recognized in undisturbed areas (Table 1). *Cynodon* had appreciably high cover in slightly saline and moderately sodic soils (Figure 1, Table 4). The species may extend into high salinity areas, although with smaller cover values (Rutter and Sheikh, 1962; Sheikh and Irshad, 1980). Although slight salinity on the surface does not appear to harm *Cynodon*, salinity in the root zone disturbs its nutritive functions, causing a reduction in yield (Malik et al., 1984).

The soils under *Prosopis* were nonsaline and moderately sodic (Figure 1, Table 4). Other *Prosopis* species are reported to dominate salt- and sodium-free soils (Kayani and Sheikh, 1981). The lower salinity and sodicity may be due to enhanced leaching of salts in the *Prosopis* covered area as the sodium adsorption ratio was significantly lower at the center of tree canopies than in soil between trees (Virginia and Jarrell, 1983). *Desmostachya* was restricted to moderately saline but highly sodic soils and had a high cover value (Figure 1, Table 4). The species is known to occur on soils with a range of salinities from 2.7 to 27.0 mS/cm (Rutter and Sheikh, 1962). *Desmostachya* is an arid zone species, normally occupying nonsaline soils, but it also manages to tolerate or

avoid salinity. The species has a wide ecological amplitude and cannot be depended upon as an indicator of specific soil conditions (Malik et al., 1984).

Sporobolus arabicus was a common species throughout the study area (Table 1). The soils of the *Sporobolus* community were moderately saline and highly sodic (Figure 1, Table 4). The species is reported to occupy a wide range of soils with reference to salinity and sodicity (Rutter and Sheikh, 1962; Sheikh and Mahmood, 1986). Occasionally, *Sporobolus* may grow where salinity exceeds 35 mS/cm, although with smaller cover values than those it attains at low salinity (Rutter and Sheikh, 1962; Malik et al., 1984). Saline and nonsodic soil conditions seem more hospitable for *Sporobolus* (Sheikh and Mahmood, 1986).

Suaeda has been reported to be dominant on very highly saline (45–80 mS/cm) and sodic soils (Rutter and Sheikh, 1962, Malik et al., 1984). The species constitutes the main natural vegetation on saline-sodic sand dunes and is also present on soils free from salinity and sodicity (Din and Farooq, 1975). The species was also found at low salinity, although with smaller cover values than those it attained at high salinity, suggesting that *Suaeda* is a poor competitor when soil conditions were improved for other species (Figure 1, Table 4). Sheikh and Mahmood (1986) reported that soil under *Suaeda* was marginally saline because of leaching of salts to a lower depth in the soil profile. Additionally, low soil surface salinity may be due to the fact that a dense stand of *S. fruticosa* can accumulate approximately 2.5 tons/hectare of NaCl annually (Chaudhri et al., 1964). Clearly, salinity does seem to play a major role in distribution of plant species in the area and correlates with several soil factors (Table 4).

In general, the undisturbed soils were saline, sodic, and alkaline (Table 4). A direct relationship between pH and sodicity of soil has been suggested (Fireman and Wadleigh, 1951; Rutter and Sheikh, 1962). The presence of high concentrations of CO_3 and HCO_3 seem responsible for high alkalinity. If soils are affected by sodium and potassium salts capable of alkaline hydrolysis, e.g., NaHCO_3 and Na_2CO_3 , sodicity and alkalinity will occur together (Szabolcs, 1979).

Soil pH, salinity, and sodicity appreciably decreased, while total nitrogen, $\text{NH}_4\text{-N}$, $\text{NO}_3\text{-N}$, and available phosphorus increased in 15- and 30-month-old kallar grass fields (Table 3). Such nutritional changes through succession have been reported in natural communities (Rice et al., 1960) and in surface coal mining areas (Lodhi, 1979), allowing nonannual species to invade and revegetate these areas. Similarly, kallar grass fields were successively invaded by plant species not recorded in undisturbed fields, in addition to the species found in undisturbed areas (Table 2). Chaudhri (1952) reported that the vegetation of the fields under reclamation was a mixture of exotic species and natural flora, the latter being replaced by the former depending on the degree of reclamation.

The species invading kallar grass fields clearly appeared in dominant

patches and radially eliminated or reduced kallar grass cover in all patches, with lowest cover in the *Cynodon* patch followed by *Suaeda*, *Desmostachya*, *Kochia*, *Sporobolus*, and *Polypogon* patches (Table 6). On the other hand, soils associated with various vegetational patches did not show any definite trend with nutritional status. In *Cynodon* and *Polypogon* patches, where kallar grass cover was the lowest and the highest respectively, the associated soil pH and EC were significantly lower than the surrounding kallar grass fields (Table 5). However, EC and pH in *Desmostachya*, *Sporobolus*, and *Kochia* patches were significantly higher than in kallar grass fields. Further, salinity–sodicity factors were not unsuitable for kallar grass growth because the species is highly tolerant to salinity (Sandhu et al., 1981) and sodicity (Aslam et al., 1979). Additionally, available P, $\text{NH}_4\text{-N}$, and $\text{NO}_3\text{-N}$ amounts were always significantly higher in all patches as compared to kallar grass field soils, with the exception of $\text{NH}_4\text{-N}$ in *Sporobolus* and *Polypogon* patches which were significantly lower (Table 5). Thus, the elimination of kallar grass from the weed patches cannot be attributed to the soil factors analyzed, while it failed to persist in patch-associated species (Table 5, 6).

Plant interactions are known to play an important role in distribution and coexistence of species in both natural and agroecosystems. Competition for necessary growth factors (allelopathy) and addition of toxic substances to the environment (allelopathy) can play a major role in plant growth (Szczepanski, 1977; Rice, 1984). Our preliminary data indicated, based on soil analyses, that competition may not be the leading cause of kallar grass elimination from patch vegetation. On the other hand, aqueous extracts and decaying leaf material of all six invading species and kallar grass significantly reduced kallar grass seed germination (Figure 2) and shoot growth (Table 7). The allelopathic influence on kallar grass varied from species to species and in most cases clearly corresponded with field data (Table 6, 7). It should be strongly pointed out that allelopathic behavior discussed in patch dynamics was in areas where soil saline–sodic conditions had improved greatly (review Table 3, and correlations discussed in results) due to kallar grass cultivation. Further, *Suaeda* appeared to be a poor competitor (Table 2) when soil conditions improved for other species as well, and it could not capitalize on its evolutionary strategy of performing well in high saline–sodic conditions. Therefore, growth inhibition in kallar grass caused by *Suaeda* was due to allelopathy, perhaps somewhat accentuated by ions in its shoot tissue. Our ongoing research indicates that relatively ion-free *Suaeda* extract retained its allelochemic influence. In general, species competing for a limited growth factor can allelopathically influence the growth of other species to minimize competition (Tremmel and Peterson, 1983; Rice, 1984). Such interactions can only accentuate the invasion by incoming species. Detailed investigations are in progress to ascertain the relative importance of patch dynamics relating to kallar grass susceptibility to competition and allelopathy.

Acknowledgments—This research was initiated while M.A.K.L. was a visiting scientist with the Nuclear Institute for Agriculture and Biology, sponsored by UNDP. The secretarial assistance of Frances O'Brien and Cassandra Hamilton is humbly appreciated.

(Received December 7, 1987; accepted February 1, 1988)

Abstract—The sex pheromone of *Cydia toreuta* (Grote), the eastern pine seedworm, was investigated using electroantennogram (EAG) measurements, gas chromatography (combined GC-FID-EAD) measurements, and field tests. (*E,Z*)-8,10-dodecadienyl acetate (*E,Z*8,10-12:Ac) and (*E,E*)-8,10-dodecadienyl acetate (*E,E*8,10-12:Ac) produced both the highest EAG and EAD responses. Only a single antennal stimulatory peak was observed when female abdominal tip extracts were analyzed by GC-FID-EAD, which corresponded exactly with that of authentic *E,Z*8,10-12:Ac. Field tests confirmed *E,Z*8,10-12:Ac as the major pheromone component. The *E,Z* isomer by itself caught equivalent numbers of male moths as did caged females. The addition of the *E,E* isomer to the *E,Z* form increased trap catch, although not significantly ($P = 0.05$). The addition of (*Z,Z*)-8,10-dodecadienyl acetate to the *E,Z* isomer significantly ($P = 0.05$) reduced trap catch, while the addition of (*Z,E*)-8,10-dodecadienyl acetate to the *E,Z* form also decreased trap catch, but not significantly ($P = 0.05$).

Key Words—Sex pheromone, *Cydia toreuta*, Lepidoptera, Tortricidae, Olethreutinae, (*E,Z*)-8,10-dodecadienyl acetate.

INTRODUCTION

The eastern pine seedworm, *Cydia* (= *Laspeyresia*) *toreuta* (Grote) feeds on the seeds of several North American conifers including jack pine, *Pinus banksiana* Lamb.; loblolly pine, *P. taeda* L.; lodgepole pine *P. contorta* Dougl.; red pine, *P. resinosa* Ait.; shortleaf pine, *P. echinata* Mill.; and Virginia pine, *P. virginiana* Mill. (Hedlin et al., 1981). Usually, one to three larvae inhabit a cone, but there may be 12 or more in cones of some host trees (Lyons, 1957). Each larva generally consumes 4–15 seeds (Ciesla and Bell, 1966; Mattson, 1978). Last-instar larvae overwinter within the cone axis, with pupation taking place the following spring. Male emergence slightly precedes that of the females, and emergence is normally completed within a two-week period during May and/or June. Little is known about adult behavior.

All identified sex attractants in the Tortricidae have been mono- or diunsaturated straight-chain alcohols, acetates, or aldehydes. A review of identified sex attractants revealed that, with few exceptions, the subfamily Olethreutinae responds to compounds with a 12-carbon chain length (Roelofs and Brown, 1982). Furthermore, all species investigated within the genus *Cydia* are attracted to compounds within the 12-carbon chain series (Roelofs et al., 1971; Dix et al., 1984; Greenway, 1984; Chisholm et al., 1985; Sartwell et al., 1985; Stevens et al., 1985). Chisholm et al. (1985) conducted a field screening test in a forested area northeast of Saskatoon, Canada, in which all four geometrical isomers of 7,9- and 8,10-dodecadienes with acetate, alcohol, and aldehyde functional groups were utilized. *C. toreuta* males were caught in sticky traps baited with (*E,Z*)-8,10-dodecadienyl acetate (*E,Z*8,10-12:Ac). Using those results as a starting point, this paper further investigates the sex pheromone of *C. toreuta* using a solvent extract of the pheromone glands of virgin female moths, electroantennogram (EAG) investigations with synthetic 10-, 12-, and 14-carbon compounds, and field tests with possible attractants.

METHODS AND MATERIALS

Insects and Pheromone Collection. *C. toreuta* adults were obtained from field-collected mature red pine cones that contained diapausing last-instar larvae. Cones were collected during January and February 1987 and were maintained under a 16:8 light-dark photoperiod at 24°C. Emergence began ca. 25 days after exposure to laboratory conditions. Pheromone was collected from 1- to 3-day-old virgin females 1–2 hr after the beginning of scotophase. The ovipositor was forcibly everted and, along with the terminal three abdominal segments, excised and extracted with dichloromethane for 30 min. Extracts from

28 females were collected ca. one week before use, divided into two equal portions and each was reduced under a stream of N_2 to $<2 \mu\text{l}$. Further, two groups of 10 females each were excised the same day that they were to be used for gas chromatographic analysis and the extracts likewise reduced under a N_2 stream.

Analyses. A gas chromatograph (GC) (Hewlett Packard 5710) equipped with both a flame ionization detector (FID) and an electroantennogram detector (EAD) (combined GC-FID-EAD) (Arn et al., 1975) was used to detect pheromone components eluting from the column and analyzing synthetic standards. The effluent split between detectors was ca. 70:30, favoring the FID. The GC was equipped with a DB-5 column (bonded methyl 5% phenyl silicone 30 m \times 0.32 mm), and injected samples were ramped from 40 to 90°C in 30 sec, and then programmed from 90 to 230°C at 2°C/min. Helium carrier gas linear velocity was 22.9 cm/sec. (at 150°C).

Electroantennogram (EAG) and Synthetic Chemicals. Syntheses and chromatographic purification of chemicals used for the EAG studies and the field trials were carried out in the laboratory (Plant Biotechnology Institute, Saskatoon, Canada) as previously described (Chisholm et al., 1985). All had a purity of 97–99+%. Isomers (*E,E*; *E,Z*; *Z,E*; *Z,Z*-8,10-dodecadienyl acetates) that had high EAG activity were further assayed for purity using the GC-FID-EAD. This was done by GC analysis of 5 ng of each isomer. Pure compounds were recognized by a single appropriate FID peak and a corresponding single EAD peak, or no EAD peak for compounds that were not stimulatory.

The antennal response of *C. toreuta* to synthetic chemical standards was measured by EAG as previously described (Chisholm et al., 1975). Synthetic standards of 12-carbon monounsaturated and all isomeric 8,10-diunsaturated acetates, alcohols, and aldehydes were tested at least three times and 10- and 14-carbon monounsaturated acetate compounds twice. Values for air blanks applied to antennae were subtracted from values for test standards. All standards were tested using 1 μg applied to filter paper disks.

A dose-response was run on antennae using *E,Z*8,10-12:Ac. Dosages ranged from 1×10^{-6} to 10 μg applied to filter paper disks.

Field Studies. Pherocon 1C traps were used for field trapping and contained rubber septa (A.H. Thomas No. 8753-D22) that had been impregnated with synthetic chemical lures. Two drops of a 10% solution of the antioxidant 2,6-di-*tert*-butyl-4-methylphenol (BHT) in acetone were added to each septum. In addition, one treatment consisted of two virgin females placed in separate cages attached to the inside roof of a trap. Females were replaced daily with freshly emerged individuals. Previous field trapping with caged females indicated that maximum calling occurred within 24 hr after emergence. Tests were conducted in the field from May 5 to May 30, 1987, during the flight period of *C. toreuta*.

Traps were placed in a 17-year-old red pine stand near the city of New Richmond, St. Croix County, Wisconsin. Trees were ca. 6 m in height. Traps were hung at a height of 3–4 m on the end of an exposed branch at the edge of the crown. Individual traps were placed ca. 20 m apart. Field experiments were set out in a randomized complete-block design, with three blocks, each block separated by ca. 100 m. Moth captures were recorded daily and trap bottoms were replaced as required. Traps within blocks were rerandomized every second day. Catch/trap treatment data were transformed ($\sqrt{x + 1}$), analyzed by an analysis of variance (ANOVA), and significantly different means were separated by Duncan's (1955) multiple-range test ($P = 0.05$).

RESULTS

EAG Profile. The greatest antennal responses to monounsaturated 10-, 12-, and 14-carbon acetates were elicited by *E*10–12:Ac (3.35 ± 0.6 mV above background, $N = 6$), *Z*10–12:Ac (2.8 ± 0.6 mV, $N = 7$), and *E*8–10:Ac (2.4 ± 0.4 mV, $N = 2$). Other relatively high responses were elicited by *E*8–12:Ac (1.75 ± 0.3 mV, $N = 10$), *E*9–12:Ac (1.7 ± 0.4 mV, $N = 4$), *Z*8–12:Ac (1.6 ± 0.2 mV, $N = 9$), and *Z*9–12:Ac (1.6 ± 0.5 mV, $N = 4$). All other monounsaturated compounds, including the 12-carbon alcohols and aldehydes, gave lesser (< 1.0 mV) responses.

The greatest overall antennal responses for this study were elicited by the 8,10 diunsaturated 12-carbon acetates, namely, *E,Z*8,10–12:Ac (7.6 ± 0.5 mV above background, $N = 15$), *E,E*8,10–12:Ac (7.55 ± 0.8 mV, $N = 8$), *Z,E*8,10–12:Ac (4.9 ± 0.7 mV, $N = 5$) and *Z,Z*8,10–12:Ac (4.6 ± 0.9 mV, $N = 5$). Other strong responses were recorded for *E,Z*8,10–12:Ald (3.2 ± 0.3 mV, $N = 5$) and *E,E*8,10–12:Ald (2.3 ± 0.3 mV, $N = 5$). All other diunsaturated compounds gave lesser (< 2.0 mV) responses.

Antennal recovery times were not measured precisely; however, it was clearly noticeable that recovery time of an antenna following exposure to *E,Z*8,10–12:Ac was much greater than for any other tested compound.

The response of male antennae to varying concentrations of the *E,Z* isomer was investigated using the EAG (Figure 1). At dosages as low as 1×10^{-4} μ g antennal responses were > 1 mV.

GC-FID-EAD. Injection of a mixture of synthetic 8,10–12:Ac isomers, 5 ng each, resulted in strong antennal stimulation in response to both the *E,E* and *E,Z* isomers and a lesser response to the *Z,E* isomer (Figure 2). There was no discernible EAD response elicited by the *Z,Z* isomer. When the four isomers were injected individually (Figure 3), each gave a single FID peak, indicating high isomeric purity of the synthetic material. However, single EAD responses

FIG. 1. Mean mV responses from EAG recordings of *C. toreyuta* male antenna to *E,Z,8,10-12:Ac* dosages ranging from 1×10^{-6} to $10 \mu\text{g}$. Error bars indicate standard error.

were observed that corresponded with the injected parent compound only for the *E,Z* and *E,E* isomers. When the *Z,E* isomer was injected, EAD responses corresponding to both the *Z,E* and *E,Z* forms were observed. In the case of the *Z,Z* isomer, no EAD response was elicited that corresponded with the parent compound; rather, a response corresponding with the retention time of the *E,Z* isomer was observed.

Only a single pheromone component was detected when female abdominal tip extracts were analyzed by GC-FID-EAD (Figure 2). In each of four analyses, a single antennal stimulatory peak was observed that had a retention time that corresponded exactly with that of authentic *E,Z,8,10-12:Ac*. No other EAD peaks were consistently present in the analyses.

Field Tests. Table 1 shows the 1987 field tests of traps baited with 8,10-12-carbon acetates. Significant differences between means were indicated when ANOVA was applied to transformed data ($MSE = 12.9$, $F = 20.1$, 11 *df* for treatment and 22 *df* for error, $P < 0.001$). The highest catches per trap were recorded for the mixture of *E,Z,8,10-12:Ac* ($200 \mu\text{g}$) + *E,E,8,10-12:Ac* ($20 \mu\text{g}$) with a mean of 613.0 moths/trap. However, there were no statistical differences in mean catch per trap between that lure composition and the *E,Z,8,10-12:Ac* ($200 \mu\text{g}$) + *E,Z,8,10-12:Ac* ($2 \mu\text{g}$), *E,E,8,10-12:Ac* ($200 \mu\text{g}$), *E,Z,8,10-12:Ac* ($50 \mu\text{g}$), and/or caged females. The *E,E,8,10-12:Ac*, *Z,E,8,10-12:Ac*, and the *Z,Z,8,10-12:Ac* isomers alone did not catch moths in a quantity greater than the blank traps. The *Z,Z* isomer combined with the *E,Z* isomer significantly ($P = 0.05$) reduced trap catch when compared to *E,Z*

FIG. 2. Paired GC-FID-EAD chromatograms recorded from male *C. toreuta* antenna subjected to (top) a standard isomer mixture of *Z,E*-, *E,E*-, *E,Z*-, and *Z,Z*-dodecadienyl acetates, 5 ng of each; (bottom) a female abdominal tip extract (14 FE). Cross-hatched peaks are internal standards decyl alcohol and tetradecyl acetate, respectively. Conditions: DB-5 column 30 m \times 0.32 mm, programmed from 90 to 230°C/min, splitter ratio was 70:30 favoring FID.

+ *E,E* isomer combinations as well as to the *E,Z* form alone. The addition of *Z,E* isomer to the *E,Z* isomer significantly ($P = 0.05$) reduced trap catch when compared to *E,Z* + *E,E* mixtures, but not compared to the *E,Z* form alone.

DISCUSSION

Based on the EAG study both *E,E*8,10-12:Ac and *E,Z*8,10-12:Ac appeared to be good candidates for major sex pheromone components. Both compounds elicited strong EAG responses of about equal value, although the *E,Z* isomer

FIG. 3. FID and EAD responses to synthetic 8,10-dodecadienyl acetates, 5 ng of each. (a) Flame ionization detector (FID) responses to mixed isomers; order of elution is *Z,E*; *E,E*; *E,Z*; and *Z,Z*. (b) FID and electroantennogram (EAD) responses to individual injections of (1) *Z,E*; (2) *E,E*; (3) *E,Z*; and (4) *Z,Z* isomers. A trace impurity of the *E,Z* isomer in both the *Z,E* (1) and the *Z,Z* (4) compounds was detected by the EAD response. Except for the *Z,Z* isomer (4), each compound elicited an EAD response. Conditions: DB-5 column 30 m × 0.32 mm, programmed from 90 to 230°C at 4°C/min, splitter ratio was 70:30 favoring FID.

EAG response trace exhibited a much slower return to baseline. In many lepidopterous species the EAG produced by the attractant has a much slower recovery time than the other test chemicals; however, in other studies inhibitors have been characterized by a much slower return to baseline (Roelofs and Comeau, 1971).

The purity of the geometrical isomers of 8,10-12:Ac was investigated with the GC-FID-EAD after all gave strong EAG responses of >4.5 mV. This was done because conjugated dienes are not stable and are known to isomerize (Shani and Klug, 1980; Ideses et al., 1982; Chisholm et al., 1985). For the *Z,E* isomer, two EAD peaks were detected. One peak corresponded to the *Z,E* isomer FID peak, while the other eluted at the proper time for the *E,Z* isomer,

^a Means within a column followed by the same letter are not significantly different ($P = 0.05$).

thus indicating that a small contamination of the *E,Z* form was present although it was too small for the FID to detect. For the *Z,Z* isomer only a single EAD peak was detected; however, that peak corresponded to the *E,Z* isomer elution time. Again, the contamination was too small for the FID to detect. In the case of the *Z,Z* isomer the presence of a small quantity of the *E,Z* form may have influenced the EAG results by increasing the mV response noted for the *Z,Z* isomer, especially since the *Z,Z* isomer itself did not appear to elicit an EAD response. However, a strong response from the *E,Z* isomer contaminant on the EAD may have influenced the antennal response to the *Z,Z* isomer, which eluted 0.10 min after the *E,Z* isomer. In addition, *E,Z* isomer contamination within the *Z,E* isomer may have increased the EAG response obtained for the *Z,E* form. The dose-response curve indicated that *E,Z* dosages as low as 1×10^{-4} μg could elicit EAG responses > 1 mV. Both the *E,E* and *E,Z* isomers appeared to be highly pure. However, since the *Z,Z* isomer did not elicit an EAD peak, its presence within the *E,E* or *E,Z* material could not be precluded.

Further, EAD analysis of female extracts indicated that the *E,Z* isomer is a pheromone component within the female abdominal tip. However, the amount of *E,Z* in 14 female equivalents was undetectable on the FID. Although the male responds strongly to *E,E*, this compound was not detected in the female abdominal tip.

Field tests confirmed *E,Z*,10-12: Ac as the major component of the sex pheromone of *C. toreuta*. The *E,Z* isomer by itself caught statistically equiva-

lent numbers of moths as female baited traps. The *E,E* isomer, which by itself is unattractive, may act as a synergist, since addition of *E,E* to *E,Z* increased trap catch, although not significantly. The *Z,E* and *Z,Z* isomers, when combined with the *E,Z* form, both caused reduced trap catch and therefore appear inhibitory. Roelofs and Comeau (1971) speculated that inhibitors would be compounds similar to the attractant, which both the *Z,E* and *Z,Z* isomers are.

The evidence presented strongly implicates *E,Z*,8,10-12:Ac as the major component of the sex pheromone of *C. toreuta*. *E,Z*,8,10-12:Ac by itself or in combination with small quantities of *E,E*,8,10-12:Ac provides a pheromone bait that is as attractive as virgin females and can be used for field sampling. Further investigation is needed to correlate economic insect damage/infestation with adult male captures using synthetic pheromone baited traps.

(Received August 26, 1987; accepted February 3, 1988)

Abstract—The allelopathic effects of *Prosopis juliflora* were studied both in the laboratory and in nature and compared with that of *Prosopis cineraria* to understand the chemical nature of allelochemicals. Both species occupy the same habitats but *P. cineraria* does not appear to have any toxic effect on other plants under its canopy. *P. juliflora* is highly allelopathic and does not allow the growth of any other species. Leaf extracts and leaf leachates of *P. juliflora* were inhibitory. Decaying leaves were also inhibitory at early stages of decomposition. Live roots were not found to be inhibitory in cogermination and interplanting of seeds. Chemical investigation of the extracts showed the allelopathic compounds to be phenolic in nature in both the species. Slow decomposition and heavy accumulation of leaf litter below *P. juliflora* may possibly result in accumulation of toxic substances in soil layers, inhibiting growth of other species.

Key Words—Allelopathy, *Prosopis juliflora*, *Prosopis cineraria*, *Cassia occidentalis*, radish.

INTRODUCTION

Prosopis juliflora Swartz and *Prosopis cineraria* (Linn.) Druce are two common trees of arid and semiarid zones in India. *P. cineraria* is a native slow-growing tree and is beneficial for the growth and development of other species. *P. juliflora*, on the other hand, is an exotic species and grows luxuriantly on sandy soils and is being introduced on a large scale in arid zones because of its

faster growth and soil-binding capacity. It has been realized for some time that *P. juliflora* does not allow the establishment of ground vegetation (Lahiri and Gaur, 1969; Sankhla et al., 1965). Earlier studies on *P. juliflora* suggest that the leaves and the soil below this tree contain inhibitory chemical substances (U. Goel, and G.S. Nathawat, unpublished observations). Allelopathic patterning is clearly visible in the area with heavy accumulation of leaf litter in the case of *P. juliflora*, but *P. cineraria*, despite heavy litter fall, supports much ground vegetation. In earlier studies on the comparative nature of the two species, *P. cineraria* was not found to be allelopathic in laboratory bioassays. In view of this, a comparative study of *P. juliflora* and *P. cineraria* was undertaken to understand the allelopathic effects of the former and to characterize the active principles.

METHODS AND MATERIALS

Species Selection. Field observations revealed that the understory vegetation in the study area is mainly dominated by *Brachiaria ramosa*, *Dactyloctenium indicum*, *Crotolaria medicagena*, *Corchorum tridens*, *Indigofera linnaei*, and *Cassia occidentalis*. The growth of the herbaceous species was observed to be better under *P. cineraria* than under *P. juliflora*. Saxena (1978) recorded the above-ground biomass to be 234.8 g/m² below *P. cineraria*, and bare areas were observed under *P. juliflora*.

Effect of Pericarp, Bark, and Leaves. To determine the most toxic part of *P. juliflora* and *P. cineraria*, pericarp, bark, and leaves were collected from trees in the field and aqueous extracts of 1% and 10% concentrations were obtained by soaking the pericarp, bark, and leaves in hot distilled water for 1 hr, which was considered to be sufficient for extraction. The extracts were suction-filtered through Whatman No. 1 filter paper. Control was maintained by using distilled water.

Twenty-five seeds of radish were planted for germination on moistened filter papers in Petri dishes. The treatments were replicated five times. Germination in this experiment and all subsequent experiments was recorded daily, and radicle and plumule lengths were measured after 10 days. Seedlings were dried for 24 hr at 80°C.

Effect of Field Soil. To determine the stability of toxic compounds in the soil, soil was sampled to a depth of only 10 cm below the canopy of the tree, as most biological activity is encountered close to the surface. The soil was air dried and sieved. Five and ten grams of soil collected from under each tree species was used to make a thin layer under moistened filter papers. Twenty-five seeds of radish and *Indigofera linnaei* were planted for germination in each of the Petri dishes (replicated five times).

Effect of Decomposition of Litter. Field study indicated that *Prosopis* species add 10 g dried leaves per kilogram of 0–10 cm soil in the study area. To test the toxicity of decomposing litter, 15 g of leaf litter was mixed in 2 kg of loam soil and allowed to decay for 8, 4, 2, and 0 weeks prior to the sowing of seeds. Twenty-five seeds of *Cassia occidentalis* were planted in five pots per treatment containing the soil–leaf mixture and watered with tap water when necessary. Seed germination was determined after two weeks and then all pots were thinned to three seedlings per pot. Seedlings were harvested after 16 weeks, and oven dried shoot and root weight was recorded. After the harvest, the soil was tested for residual toxicity by germinating twenty-five seeds of radish on moistened filter papers which were placed on 10 g of soil–litter mixture.

Effect of Age. Fresh leaves of *P. juliflora* and *P. cineraria* from 1-, 6-, and 12-month-old trees were collected from potted plants and 1 g leaf material of each type were spread under the filter paper in Petri dishes. Twenty-five seeds of *C. occidentalis* were planted for germination. Five replicates were maintained for each treatment.

Cogermination of Seeds. To determine the allelopathic effect of roots, 10 seeds of *P. juliflora* were cogerminated with 10 seeds each of *C. occidentalis* and radish. For controls, 20 seeds of each species were germinated.

Growth of C. occidentalis and P. juliflora in Pure and Mixed Stands. To test the toxicity of exudates of live roots, two plants of each species of *P. juliflora* and *C. occidentalis* were planted in pure and mixed cultures in plastic pots of 2-kg capacity containing loam soil. After two months, the plants were harvested, and oven dried weights of roots and shoots were determined.

Extraction and Fractionation of Prosopis Species. One kilogram of air-dried, powdered plant material was extracted in ethyl alcohol for 36 hr. The plant residue was removed by filtering the extract. Alcohol was evaporated and the residue was dissolved in ethyl acetate. The soluble portion was fractionated into acidic, nonacidic, and alkaline fractions by washing it repeatedly with saturated sodium bicarbonate and sodium hydroxide solutions. The bicarbonate soluble portion was acidified to pH 2 with dilute HCl and extracted with ethyl acetate. Similarly, the sodium hydroxide-soluble portion was neutralized with dilute HCl and then extracted with ethyl acetate. All three fractions, bicarbonate, phenolic, and neutral, were washed thoroughly with water and concentrated on a water bath and stored for studying the biological activity. The neutral portion was further fractionated with column chromatography using various solvents as given in Table 8 below. All fractions were concentrated and examined for their biological activity.

Biological Activity. The biological activity of various fractions was determined by dissolving 1 drop of each fraction in 2 ml of water. These solutions were added to Petri dishes containing 25 seeds of radish on filter paper. The germination was recorded according to the procedure described previously.

Aqueous Extract after Extraction with Ethanol. After extracting 10 g of the dried leaf material with ethanol, the residue was filtered, dried, and reextracted with water. The filtrate obtained was made up to 100 ml using distilled water.

The data was statistically analysed using Student's *t* test.

RESULTS

Aqueous Extracts. Seed germination and radicle and plumule growth of radish were significantly inhibited by leaf extracts and 10% concentration of the pericarp and bark extract of *P. juliflora*. In *P. cineraria*, leaf extract and 10% pericarp extract was found to be toxic (Table 1).

The soil was not inhibitory to germination and early seedling growth of the test species (Table 2).

Litter Decomposition. The litter of *P. juliflora* in early stages of decomposition inhibited germination of *Cassia occidentalis* seeds, whereas the 8-week-old decaying litter did not inhibit growth or germination. The dry weight yields of test species were significantly higher in all cases except when the litter was not allowed to decay previously.

The litter of *P. cineraria* did not affect seed germination at any stage, and also the dry weights were higher in all cases as compared to the control (Table 3).

The soil litter mixture did not retain any toxins at the time of harvest (Table 4).

Age Effect and Leaf Decaying. The inhibitory effect of *P. juliflora* during leaf decay was observed on percentage germination followed by its effect on radicle and plumule growth. This effect was not related to age of *P. juliflora*.

In *P. cineraria* inhibition of decaying leaves was not observed; the age of the plants had no effect on germination of the test species (Table 5).

TABLE 3. SEED GERMINATION AND DRY WEIGHT YIELD PER POT OF *C. occidentalis* AS AFFECTED BY DECOMPOSING LITTER OF *P. juliflora* AND *P. cineraria*^a

^a Average of 50 seedlings. Mean values not significantly different from control.

Cogermination and Interplantation. Cogermination of seeds of *P. juliflora* and *C. occidentalis* and radish seeds in Petri dishes did not show any adverse effects of *P. juliflora* on test species. Interplanting *P. juliflora* with *C. occidentalis* in pots gave no indication of the inhibitory nature of the former (Tables 6 and 7).

Fractionation of Ethanolic Extracts of Prosopis Species and Biological Activity. Of all the elutions isolated from the neutral fraction by polar and non-polar solvents, the methanol fraction and phenolics in *P. juliflora* were inhibitory to seed germination and radicle and plumule growth of the test species. Acids were not inhibitory. In *P. cineraria* under laboratory conditions, phenolics, methanol fraction, and acids reduced early seedling growth but the extent of inhibition was less as compared to *P. juliflora* (Table 8).

Water Extract after Ethanolic Extraction. The water fraction derived after

extraction of plant material of both the species with ethyl alcohol was most effective in retarding the radicle and plumule growth of the seeds kept for germination (Table 9).

DISCUSSION

It has been hypothesized that leaf litter and canopy leachates greatly influence soil properties like fertility and underground cover (Zinke, 1962; Aggarwal et al., 1976). Chou and Yang (1982) reported that the regulation of understory species in stands of *Phyllostachys edulis* and *Leucaena leucocephala* (Chou and Kuo, 1986) was primarily due to the allelopathic effect of leaf litter. Similarly, in the present studies, leaves seem to influence the understory growth. Leaf extracts in *P. juliflora* were more toxic as compared to *P. cineraria*. In an earlier investigation (U. Goel and G.S. Nathawat, unpublished observations), litter was shown to be highly toxic to seed germination and seedling growth of the test species.

Leaf extracts of *P. cineraria* were significantly toxic in laboratory bioassays. Phenolics, phenolic acids, and the methanolic fraction of the neutral portion were also inhibitory, but the phytotoxins never accumulate to toxic levels in soil. According to Stowe (1979), the experimental conditions of bioassays never adequately simulate natural conditions. Jameson (1970) noted that although phytotoxic effects of *Juniperus osteosperma* leaves could be demonstrated in the laboratory, many associated species were relatively unaffected in the field.

Litter decomposition studies of *P. juliflora* clearly reveal that the inhibitors released to the soil environment are degraded within two months, subsequently leaving no traces of toxicity. In nature, however, litter build-up is a continuous process, and some of it is always in a stage of early decomposition, which is

inhibitory to germination of other species. The litter of *P. cineraria* was non-toxic for germination and seedling growth during decomposition.

Age of the plant is considered to be an important factor as it has been shown that the quantity of inhibitors varies at different ages of *Celosia argentea* (Pandya, 1977), but in *P. juliflora* age of the plant did not alter the inhibitory activity.

Soil texture also plays an important role in allelopathy. In an earlier experiment (U. Goel and G.S. Nathawat, unpublished observations), sandy soil below *P. juliflora* was found to be toxic, and the seedlings of *Indigofera linnaei* had died after two to three days, whereas in the present experiment, the clay soil below the tree was nontoxic to any of the test species. Probably, the retention of moisture in clay tends to have a diluting effect, whereas the sand tends to be dry. The other explanation could be that there is better growth of microorganisms in clay, which may decompose the allelochemicals much faster than in sandy soils. Patrick (1971) also observed greater inhibition of corn height and weight in sandy and light textured soils. Rice (1979) mentioned that phytotoxins can be effective in fine-textured soils also, where they are apparently absorbed and accumulate to toxic proportions.

Oksana et al. (1986) reported water-soluble allelochemicals in *Sorghum bicolor* when cogerminating with the test seeds in Petri dishes and interplanted in pots. No such inhibitory effects were observed in *P. juliflora*, indicating that the live roots were not involved in the production of allelochemicals. The observation that toxicity is evident even after extraction with ethanol, as also shown for many tropical grasses (Chou, 1977), suggests that perhaps more than one toxin is involved in allelopathy.

The studies clearly reveal that phenolic acids and the methanolic fraction of the neutral portion (which may also contain phenolic acids) in combination with nonpolar compounds present in the hexane and benzene fraction may be responsible for inhibiting the germination of seeds and early seedling growth as observed by other workers (Alsaadawi and Rice, 1982; Lodhi, 1978, 1979). It is quite likely that phenolic acids affect higher plant growth through their influence upon soil microorganisms in addition to direct effects on the plants (Rice, 1964). The enhanced allelochemic activity in *P. juliflora* may be ascribed to the combination of major and minor phenolic acids and nonpolar organic compounds that act in synergism with each other. According to Goer and Barney (1968), litter decomposes more rapidly below *P. cineraria* because of better growth of microorganisms. Slow decomposition and heavier accumulation of litter in *P. juliflora* may result in accumulation of toxic substances in soil layers, thus inhibiting growth of other species.

(Received October 19, 1987; accepted February 4, 1988)

Abstract—The biological activity of analogs of the pheromone components of the European corn borer, *Ostrinia nubilalis*, (*Z*)- and (*E*)-11-tetradecen-1-ol acetate, in which modifications were made in the terminal alkyl portion were studied in the three pheromonal types of the insect. European corn borer males respond to pheromonal stimuli at three levels of behavioral activity, i.e., short-range sexual stimulation, activation in the flight tunnel, and response in the field. Structural requirements for elicitation of response at these levels were found to be increasingly restrictive, respectively. Flight-tunnel activity was induced only by compounds that had a total chain length of 13 or 14 carbons and in which branching at carbon 13 was limited to one methyl group or a cyclopropyl group. Three new analogs were active in the flight tunnel, viz., (*E*)- and (*Z*)-13-methyl-11-tetradecen-1-ol acetate and (*Z*)-12-cyclopropyl-11-dodecen-1-ol acetate. The cyclopropyl analog was the most active analog against the *ZZ* type of the European corn borer. The *E* isomer, however, was pheromonally inactive in the *EE* type and was shown to be a pheromone antagonist. This dissimilarity is most likely due to differences in structure of the receptors in the European corn borer strains. Analogs that were biologically active against the European corn borer were tested against the redbanded leafroller, *Argyrotaenia velutinana*, which also uses (*Z*)- and (*E*)-11-tetradecen-1-ol acetate as part of its pheromone. Results showed that the redbanded leafroller pheromone acceptor system is different from that of the European corn borer; marginal behavioral response was elicited by only one of the new analogs. Thus, although both species use 11-tetradecen-1-ol acetate isomers as their pheromone, the mechanisms by which they are perceived are different.

INTRODUCTION

During the past two decades, tremendous strides have been made in the elucidation of the chemistry of insect sex pheromones (Inscoc, 1982; Arn et al., 1986). To make use of this newly gained knowledge in efficient ways there is a need to gain insight into the mechanisms involved in pheromone perception. We conducted this study to provide clues to the spatial and/or functional group requirements for biological activity and to develop a description of pheromone acceptor sites.

The male European corn borer (ECB), *Ostrinia nubilalis*, chemoreceptor system offers an excellent opportunity for such a study. Its female sex pheromone is a simple mixture consisting of the geometrical isomers of 11-tetradecen-1-ol acetate. Furthermore, the ECB has three pheromonal types that use different proportions of the isomers (Klun and Maini, 1979). Also, other moths, such as the redbanded leafroller (RBLR), *Argyrotaenia velutinana*, employ the same compounds as part of their sex pheromone (Bjostad et al., 1985). Thus, the opportunity exists for both intra- and interspecific comparative studies of structure-activity relationships. The compounds involved in this study are shown in Figure 1.

Early on, it was discovered that for the ECB and the RBLR mixtures of (*Z*)- and (*E*)-11-tridecen-1-ol acetate (**3** and **4**) could mimic the pheromone (**1** and **2**) (Klun and Robinson, 1972; Cardé and Roelofs, 1977). Similarly, **3** elicited male response in two tortricid species, *Adoxophyes orana* and *Clepsis spectrana*, which use (*Z*)-11-tetradecen-1-ol acetate as a component of their pheromone (Voerman et al., 1975). Chapman et al. (1978a,b) synthesized the racemate and the optically pure enantiomers of 9-(2-cyclopenten-1-yl)-nonan-1-ol acetate (**5**), a cyclic analog of **1**, and tested male sex stimulation activity of the compounds in the ECB and RLBR. They found that the receptor for (*Z*)-11-tetradecen-1-ol acetate was chiral in the two species but that the manner in which the last four carbon atoms in the pheromone coil within the receptor differs. Bestmann et al. (1980) studied the electroantennogram (EAG) activity of chiral 13-ethyl analogs of (*Z*)-11-tetradecen-1-ol acetate, viz., [*R*-(*Z*)]- and [*S*-(*Z*)]-13-methyl-11-pentadecen-1-ol acetate, the racemate (**6**), and Chapman's cyclopentenyl compounds in the two species of insects. They found that the receptors distinguished between the enantiomers and that the magnitude of EAG activity for the open-chain analogs was greater than that of the cyclopen-

tenyl analogs. This difference in activity was ascribed to the greater flexibility of the open-chain compounds and to the better opportunity of the acceptor to adapt to the less rigid compound. Because the cyclopentenyl compounds had previously proven to be active in the sex stimulation bioassay, we felt it would be interesting to determine whether the open-chain analogs had greater behavioral activity than the cyclopentenyl analogs. We report the results of these tests and the discovery of new behaviorally active analogs, in which structural modifications were made at the 13 carbon. The bioassay tests were carried out with the three ECB types at three behavioral assay levels, i.e., a short-range sex stimulation assay, upwind response in a flight tunnel, and field trapping. The biological activity of the new analogs was also evaluated against the RBLR.

METHODS AND MATERIALS

Insects. ECB males used in the laboratory bioassays were from colonies that were homozygous for *ZZ* or *EE* female sex pheromone production genes or hybrids obtained by crossing the *ZZ* and *EE* genotypes. The homozygous colonies had been selected from progeny lines of females that were collected in the vicinity of Beltsville, Maryland (Klun and Huettel, 1988). The *ZZ* colony utilized 97:3 (*Z:E*)-11-tetradecen-1-ol acetate as its pheromone, *EE* used 3:97 (*Z:E*), and the *ZE* hybrid used 35:65 (*Z:E*) as its pheromone. Correspondingly, the geometrical proportions of pheromonal analogs tested against males from the respective colonies were always similar to the proportions produced by sibling females. RBLR males were from a colony that was established in our laboratory from eggs supplied to us by W.L. Roelofs, Geneva, New York. All insects were reared on an artificial diet described by Reed et al. (1972). Inasmuch as the ECB and the RBLR are, respectively, nocturnal and crepuscular with regards to their mating activities, the colonies were maintained in environmental chambers under a reversed photoperiod (80% relative humidity; 16 hr light–8 hr dark, 26°C–20°C). This arrangement allowed us to conduct the insect bioassays during normal working hours of the day.

Flight-Tunnel Bioassays. The flight tunnel used in all bioassays was the same as described by Raina et al. (1986). Conditions in the tunnel were: 18–20°C, 40–65% relative humidity, 2.5 lux (red light), and a wind speed (laminar flow) of 50 cm/sec. Most test compounds were applied to a 0.5 × 4-cm filter paper strip in nanogram amounts in 3–5 μ l of heptane, and the strip was positioned on a clip that was suspended on a vertical wire 16 cm from the tunnel floor and 20 cm from the upwind screen-covered end of the tunnel. Males were positioned in a release tube that was 300 cm downwind of the stimulus. When the lid of the release tube was removed, the stimulus plume passed directly through the tube. In one experiment, ECB males were preexposed to phero-

monal analogs and subsequently exposed to a mixture of pheromone and the analog. The preexposure was accomplished by placing a male in the release tube, screened on its upwind end, into the air stream containing the analog evaporated from a paper strip on the clip. The male was preexposed to the analog for 3 min, and then a paper strip treated with pheromone plus analog was positioned on the clip, the screen covering the release tube was removed, and responses to the mixture were observed. In some cases, tests were conducted using rubber septa that were treated with microgram amounts of compound and attached to the clip at the upwind end of the tunnel. Adult males, 2–3 days old, were used in the bioassays after they had been held in the flight tunnel room for ca. 30 min at 2.5 lux and 20°C. Males were tested individually against a treatment and then discarded. Tests with the ECB were conducted during hours 5–6 of scotophase and tests with the RBLR were conducted 1 hr before scotophase or during the first hour of scotophase. In RBLR assays, *E* and *Z* analogs were substituted for the 11-tetradecen-1-ol acetates in the RBLR pheromone mixture identified by Bjostad et al. (1985). All assays were conducted using a randomized complete-block design with replication over time. Each male tested was allowed 3 min to respond after the lid of the release tube was removed. The percentage of males that took flight, oriented upwind in the stimulus plume, and traversed the length of the tunnel in the plume to within 2 cm of the stimulus or landed on it provided a measure of the relative biological potency of each treatment. Treatments referred to as pheromone or natural pheromone throughout this paper are those mixtures of synthetic compounds that are considered to comprise a species' female sex pheromone in nature. The percentage response variables were transformed to arcsin and analyzed by the analysis of variance. Significance was tested by the *F* test, and the means that were significantly different ($\alpha < 0.05$) were separated using the least-significant-difference procedure.

Male Sex Stimulation Assays. Some pheromone analogs did not elicit upwind responses from males in the flight tunnel. The relative biological potency of these compounds was evaluated using a sex stimulation assay. In this assay, a set of five 2- to 3-day-old males in a 6 × 8-cm cylindrical screen cage were positioned in a 50 cm/sec airflow at 19–20°C that was vented outdoors. The set of males was then exposed to 100 ng compound on a 0.5 × 4-cm filter paper that was gently waved 5–6 cm upwind of all males in the cage for 1 min. The number of males that responded to the treatment in the 1-min exposure period with wing fanning, extension of genitalia, and copulatory strikes were recorded for each treatment. A set of five males was exposed to one treatment and discarded. Assays were conducted using a randomized complete-block design with replication over time. The response data were subjected to analysis of variance. Significance was tested using the *F* test, and the significantly different ($\alpha < 0.05$) means were separated using the least-significant-difference procedure.

Field-Trapping Tests. ECB trapping experiments were conducted in the field using a modified *Heliothis* Scentry trap (Scentry, Chandler, Arizona 85224) that has been described (Webster et al., 1986; Klun and Huettel, 1988). In the first test, 10 of the cone-shaped traps were positioned ca. 1 m from the ground and 50 m apart at the perimeter of a cornfield in the vicinity of Beltsville, Maryland. Traps were each randomly baited with a rubber septum that had been treated with 100 μg of compound in 10 μl of heptane. Each compound in the test had previously been demonstrated to cause upwind flight responses in the flight tunnel. The septum was positioned at the center of the circular opening at the bottom of the trap attached to a paper clip and a string that was strung across its diameter. Freshly treated septa were placed in the traps every third night of the test, and male captures were recorded daily over 12 consecutive days.

The second field-trap test involved five treatments that were positioned in the traps using a randomized complete-block design with three replicates. The test was conducted over four consecutive nights and was designed to determine if the addition of a proportionately small amount of the natural pheromone component, (*E*)-11-tetradecen-1-ol acetate (**2**), added to analog **9** would enhance male captures over responses to **9** alone. The test was also designed to determine comparative effectiveness of the geometric mixture with that of a 97:3 (*Z*:*E*) mixture of 11-tetradecen-1-ol acetates. Determination of the rate of evaporation of analog **9** from rubber septa showed (Heath et al., 1986) that it was 0.4 times as volatile as 11-tetradecen-1-ol acetates; therefore, the analog was applied to the septa at a load 2.5 times greater than that of the (*Z*)-11-tetradecen-1-ol acetate.

Chemicals. Compounds **1–4** were commercial products and were purified by preparative high-performance liquid chromatography (HPLC) on two 25-cm \times 10-mm (ID) stainless-steel tubes packed with 10 μm silica impregnated with 20% AgNO_3 using toluene as eluant. Racemic **5** and its enantiomers were supplied by O. Chapman; racemic **6** and its enantiomers were supplied by H.J. Bestmann and O. Vostrowsky. The synthesis of compounds **7**, **8**, **11**, and **12** has been described (Schwarz et al., 1986). Compounds **9** and **10** were prepared as mixtures via the Wittig reaction of (cyclopropylmethylidene)triphenylphosphorane and 11-acetoxyundecanal and were purified by preparative HPLC. Similarly, compounds **13** and **14** were prepared as mixtures from (cyclobutylmethylidene)triphenylphosphorane and 11-acetoxyundecanal, and purified by AgNO_3 HPLC. All new compounds had IR, NMR, and mass spectra fully consistent with the proposed structures.

Minimum Energy Calculations. Minimum energy calculations were performed for the *E* and *Z* isomers of 3-hexene, 2-methyl-3-hexene, 2,2-dimethyl-3-hexene, and 1-cyclopropyl-2-pentene. These compounds represented those parts of the molecule that were altered. The acetate-bearing moiety of the molecules remained constant for all analogs, and was not expected to affect the

total conformation of each molecule differently. Default values for bond angles and bond distances were taken from Streitwieser and Heathcock (1976). The computer program used was the January 1986 version of the CHEMX program written by Chemical Designs Limited, Inc. Energy minimization operations were run for a minimum of 100 cycles in 15-cycle intervals until the change in energy for each compound was less than 0.9 kcal/mol for two consecutive 15-cycle runs.

RESULTS

Response of ZZ-Type Male ECB to Its Female Sex Pheromone and Selected Analogs in Flight-Tunnel and Sex-Stimulation Assays. Results (Table 1) of the sex-stimulation assay of the enantiomers and racemates of **5** and **6** revealed that (\pm)-**5** and (-)-(S)-**5** were twice as active as (\pm)-**6** and (-)-(R)-**6**. Bestmann et al. (1980) have measured the relative EAG activities of these compounds and observed that in their assay (-)-(R)-**6** was 33 times as active as (-)-(S)-**5**. Racemic **5** and **6** and their enantiomers were 0.2–0.4 times as active as the natural pheromone blend. Mixtures of **3** and **4** (50:50 and 97:3), the closely related analog **7**, and a mixture of **7** and **8** (97:3) were ca. 0.7 times as active as the pheromone. In the flight tunnel, no upwind flight response was elicited by **5** or **6**, but the other analogs were active.

Response of Three Male ECB Pheromonal Types to 11-Tetradecen-1-ol Acetates and Its Analogs in Flight Tunnel. When ZZ ECB males were exposed to treatments with their natural pheromonal blend of **1** and **2** (97:3) and the pure Z isomers of **3**, **7**, **9**, and **11**, the upwind flight responses to compounds **3**, **7**, **9** were 59%, 56%, and 53%, respectively, while response to compound **11** was only 5% (Table 2). When EE ECB males were exposed to their natural pheromone blend of **1** and **2** (3:97) and the pure E isomers **8**, **4**, **12**, and **10**, the upwind flight responses to **8**, **4**, **12**, and **9** was 56%, 31%, 12%, and 2%, respectively. When ZE males were exposed to compound **9**, the (Z)-cyclopropyl analog, or to a mixture of **9** and **2**, they showed nearly the same response to the analogs as to the natural hybrid pheromone. The same response was also observed when the ZE males were exposed to compound **1** alone or to a blend of (E)-cyclopropyl compound **10** and **1**. Compound **10** by itself had very low activity, while compound **2** by itself was completely inactive. Similarly, compound **7** alone or in combination with compound **8** in a 40:60 ratio showed activity that was equal to that of the natural hybrid isomer ratio, while the activity of **8** by itself was much lower.

Comparison of Responses of EE-Type Males to Mixtures of 11-Tetradecen-1-ol Acetates and Analogs With and Without Preexposure to Same Analogs in Flight Tunnel. Exposure (Table 3) of EE males to a mixture of the natural pheromones (3:97, Z:E) and **10** resulted in a significant reduction in upwind

flight response relative to the pheromone alone. When ECB moths in a cage were preexposed to analog **10** alone for 3 min and then exposed to the mixture, a similar reduction in upwind flight response was observed. Exposure of *EE* males to a mixture of the natural pheromone (3:97, *Z:E*) and **12** resulted in no reduction of upwind flight response, nor was any reduction in upwind flight response observed when the moths were preexposed to analog **12** and then exposed to the mixture.

Response of ZZ and EE Males to 11-Tetradecen-1-ol Acetate Isomers. Results (Table 4) of exposing *ZZ* males to pure (*Z*)-11-tetradecen-1-ol-acetate (**1**) or the 97:3 natural pheromone blend of **1** or **2** at different doses showed

Field Capture of ECB Males in Traps Baited with Synthetic Sex Pheromone and with Pheromonal Analogs. Among the analogs tested (Table 5), only the (*Z*)-cyclopropyl analog (**9**), showed a modicum of activity. The effectiveness of **9** was not enhanced by the addition of 3% of the *E* compound **10**. However, the effectiveness of **9** was enhanced by the addition of **2** (Table 6). This series of trials also confirmed the very low order of activity of pure **1** under field conditions.

Response of RBLR Male Moths to Pheromonal Analogs in Flight Tunnel.

When compounds **7** and **8** were substituted for a 100:9 mixture of **1** and **2** in the natural pheromone, only a weak upwind flight response was elicited, and when **9** and **10** were substituted for **1** and **2**, no response was observed (Table 7). Substitution of **1** and **2** with **3** and **4** in the natural pheromone or a mixture of **3** and **4** alone evoked high upwind flight activity.

DISCUSSION

At the outset of this investigation we were intrigued by the report (Bestmann et al., 1980) that (*R*)-**6** was 33 times more EAG active than (*S*)-**5**, which was reported by Chapman et al. (1978a,b) to be their most active analog in an ECB sex-stimulation bioassay. We anticipated that the former compound might

also be proportionately more active than the latter in the whole organism behavioral bioassay. The results of the flight-tunnel and sex-stimulation assays (Table 1), when compared with the EAG data presented by Bestmann et al. (1980), show that even though the relative EAG activities within each set of compounds were consistent with the results observed in the male sex stimulation assay, the relative biological activity of the compounds in the sex stimulation assay was completely different: (*S*)-**5** was twice as active as (*R*)-**6**. It is evident in this case that EAG is not necessarily a reliable predictor of the behavior inducing potency of a compound.

Data in Table 1 also show that although the Chapman and Bestmann compounds evoked sex stimulation responses, they were not adequate to cause upwind flight in the tunnel. Only the first five treatments in Table 1 induced ECB males to fly to the source and, of these, only blends of **3** and **4** quantitatively mimicked the natural pheromone. Furthermore, from previous work (Klun and Robinson 1972), 11-dodecen-1-ol acetate is known to be completely inactive. It is apparent from the results that for an analog to evoke an upwind flight response, it must have a flexible structure of either 13 or 14 carbons in length. It should be noted that **7** falls within that criterion and was active in the flight tunnel while **5** and **6** were not. Flight-tunnel test results with the three types of ECB males (Table 2) showed that cyclopropyl analog **9**, which may be formally considered a 14-carbon analog, possessed considerable activity in the flight tunnel, while the (*E*)- and (*Z*)-cyclobutyl analogs **13** and **14**, which may be considered 15-carbon analogs, were completely inactive in all assays. In contrast, (*E*)- and (*Z*)-*tert*-butyl analogs **11** and **12**, which are of 14-carbon chain length, showed only marginal activity. Thus, results show that biological activity is not only dependent upon a 13- or 14-carbon chain length, but is also impacted by the bulk at carbon 13 and/or the absence of a proton at that position.

These general structural requirements held true in our flight-tunnel tests against *ZZ* type males. However, the results of tests with analog **10** against *EE* males were unexpected. The activity of all *E* analogs against *EE* males paralleled the activity of the *Z* analogs against the *ZZ* males with the exception of **10**; it was biologically inactive against the *EE* males. Similarly, **10** was inactive against the *ZE* males while **9** was active. To account for the surprising lack of biological activity of **10** against *ZE* and *EE* males, we considered the possibility that (*E*)-cyclopropyl analog **10** might assume a minimum energy conformation that was very different from the conformations assumed by the other active *E* compounds, and that the active *Z* compounds, including the (*Z*)-cyclopropyl analog **9**, might assume similar minimum energy conformations. Calculations showed that this was the case; however, the energy required for **10** to assume a conformation resembling the minimum energy conformation of the active *E* compounds was only ca. 1 kcal/mol higher than its intrinsic minimum energy

conformation. This energy difference was too small to prevent (*E*)-cyclopropyl analog molecules from assuming a conformation that resembles the active *E* compounds.

The inactivity of **10** most likely is related to intrinsic differences of the *E* and *Z* receptors and to the fact that **9** and **10** interact differently with these receptors. Normal binding is thought to involve a three-pronged interaction of the pheromone molecule with the acceptor by hydrogen bonding and/or electrostatic interaction to the functional group, electrostatic interaction with the double bond, and much weaker dispersion forces responsible for binding to the terminal alkyl group (Liljefors et al., 1985). Dispersion forces are considered to be very weak, and they fall off rapidly with the distance between interacting centers. Thus, as Liljefors et al. (1985) have pointed out, a close fit between the terminal alkyl group and receptor site is extremely important to make it possible for this interaction to take place. We speculate that the cyclopropyl group of analog **10**, as a consequence of its electron-donating properties, may bind to an electrophilic site of the *E* receptor. This electrophilic site may not be present in the *Z* receptor. The forces that bind **10** to the (*E*)-11-tetradecen-1-ol acetate receptor site probably involve electrostatic interactions also at the cyclopropyl moiety, and these forces may be stronger than those that bind the other biologically active compounds at their terminus. However, because binding takes place in a manner that is inappropriate for transmission of a pheromonal signal, no behavioral activity is observed.

To test the hypothesis that **2** and **10** interact with the same receptor, a competition experiment consisting of three treatments was carried out (Table 3). In one treatment males were exposed to pheromone alone, and in another males were exposed to a mixture of pheromone and **10**. In a third treatment males were preexposed to **10** and then exposed to the mixture. The purpose of the preexposure was to cause sensory adaptation to **10**. If the binding site for **10** were different from the pheromone receptor site, one would expect the response of males subsequently exposed to pheromone containing **10** to be the same as the response elicited by pheromone alone; males would perceive and respond to the mixture as if only pheromone was present. Results showed that response to the mixture, with or without preexposure to **10**, was significantly reduced relative to the response to pheromone alone. Therefore, by inference, **10** and **2** must interact with the same receptor.

In a corollary experiment, the behavioral effects of a mixture of the natural pheromone and (*E*)-*tert*-butyl analog **12**, with and without preexposure to **12**, was compared with the activity of the natural pheromone alone. Results (Table 3) showed that **12** did not interfere with perception of **2**. Thus, although **10** and **12** each fail to induce a male behavioral response, the physical basis for the inactivity of each is different. The biological inactivity of **10** is related to an inappropriate interaction with the receptor. On the other hand, the inactivity of

12 is the consequence of the steric bulk of the *tert*-butyl group, which prevents it from interacting with the pheromone receptor.

An additional factor involved in the dissimilar biological activities of **9** and **10** may also be associated with differences in structure between the *E* and *Z* receptors in the pheromonal types. Flight-tunnel results of tests with *ZE* type males (Table 2) showed not only that **10** was inactive, but that **2**, which constitutes the major component of the natural hybrid pheromone, also proved inactive when tested by itself, while **1**, when tested alone, was active. Nevertheless, **2** was active when tested singly in the flight tunnel against the *EE* type males (Table 4).

Because the pheromones of all three ECB types are known to be mixtures of **1** and **2**, it was of interest to learn what effect substitution of one of the components of the natural pheromones by an analog of identical geometrical configuration would have on male responses in the flight tunnel. Preliminary to these assays, we tested the biological activities of pure **1** and the natural 97:3 blend of **1** and **2** in the *ZZ* type, and pure **2** and the natural 3:97 blend of **1** and **2** in the *EE* type. As shown in Table 4, under our flight-tunnel conditions, both types of males were unable to differentiate among these treatments. Therefore, undertaking of these substitution experiments was obviated. It should be noted, however, that under field conditions there is no doubt that geometrically pure **1** exhibited only negligible activity and that a blend of 97:3 of **1** and **2** is substantially more effective in trapping male ECB (Table 6).

The most conclusive test for biological activity of a sex pheromone analog is a field test, because biological screening at this level most effectively shows how closely the analog mimics the natural product on all behavioral levels. For practical purposes all analogs, except for marginal activity of analogs **9** and **10**, were inactive in field trapping tests (Table 5). The activity shown for the 3:97 mixture of **9** and **10** may be attributed to the presence of **9**, and the relatively large number of ECB captured by this treatment would be due to the preponderance of *ZZ*-type ECB in the Beltsville, Maryland, area (Klun and Huettel, 1988). A second field trial (Table 6) conducted with analog **9** showed that in their natural habitat, the insects discriminate between probes. Thus, a mixture of **9** and **2** in the appropriate ratio to mimic the natural pheromone blend, captured 3.5 times as many insects as **9** did by itself.

Another objective of our study was to examine interspecific relationships of pheromone perception. The RBLR uses as its pheromone a mixture of seven acetates, of which **1** and **2** are the major components (Bjostad et al., 1985). It had been shown previously (Chapman et al., 1978a,b) that in sex stimulation bioassays, (*R*)-**5**, (*S*)-**5**, and racemic **5** elicited strong male responses from RBLR. Sex stimulation responses were also observed when RBLR males were exposed to **7** and **8**. However, no sex stimulation behavior was observed when RBLR males were exposed to **9** and **10**. In flight-tunnel bioassays (Table 7) of

mixtures of **7** and **8**, only ca. 7% of RBLR males responded by flying to the source, and no response in the flight tunnel was observed to mixtures of **9** and **10**. When these treatments were administered simultaneously with the natural pheromone, they neither enhanced nor inhibited the effect of the latter. These results suggest that the RBLR and the ECB have pheromone receptor systems of different structures, a fact that was already indicated by Chapman et al. (1978a,b).

In summary, we have shown that the ECB pheromone receptor system imposes severe structural limitations on candidate mediators of sexual signals. Among the analogs discussed, where only changes in the terminal alkyl group were made, chain length and bulk are closely circumscribed. The ECB males display a hierarchy of sexual responses, and the effects of modification of pheromone structure can be monitored at the various behavioral levels by the use of sex-stimulation bioassays, flight-tunnel assays, or field trials. Each of these tests imposes progressively higher strictures on the permissible modification of chemical structure. The dissimilarity of impact of the (*Z*)- and (*E*)-cyclopropyl analogs, **9** and **10**, on the chemoreception systems of the *EE* and *ZZ* types of the ECB may be a consequence of differences in structures of the pheromone receptor site in European corn borer pheromonal types. Finally, we have shown that even though the ECB and RBLR use the same pheromonal compounds, the nature of the acceptor systems for (*E*)- and (*Z*)-11-tetradecen-1-ol acetate are different.

Acknowledgments—We wish to thank O.L. Chapman, H.J. Bestmann, and O. Vostrowsky for gifts of chemicals. We are indebted to R.R. Heath for the determination of the rates of evaporation of some of the analogs.

PHYTOTOXICITY OF WATER-SOLUBLE SUBSTANCES FROM ALFALFA AND BARLEY SOIL EXTRACTS ON FOUR CROP SPECIES¹

J.J. READ² and E.H. JENSEN

(Received November 13, 1987; accepted February 10, 1988)

Abstract—Problems associated with continuously planting alfalfa (*Medicago sativa* L.) or seeding to thicken depleted alfalfa stands may be due to autotoxicity, an intraspecific form of allelopathy. A bioassay approach was utilized to characterize the specificity and chemical nature of phytotoxins in extracts of alfalfa soils as compared to fallow soil or soil where a cereal was the previous crop. In germination chamber experiments, water-soluble substances present in methanol extracts of soil cropped to alfalfa or barley (*Hordeum vulgare* L.) decreased seedling root length of alfalfa L-720, winter wheat (*Triticum aestivum* L. Nugaines) and radish (*Raphanus sativa* L. Crimson Giant). Five days after germination, seedling dry weights of alfalfa and radish in alfalfa soil extracts were lower compared to wheat or red clover (*Trifolium pratense* L. Kenland). Growth of red clover was not significantly reduced by soil extracts from cropped soil. Extracts of crop residue screened from soil cropped to alfalfa or barley significantly reduced seedling root length; extracts of alfalfa residue caused a greater inhibition of seedling dry weight than extracts of barley residue. A phytotoxic, unidentified substance present in extracts of crop residue screened from alfalfa soil, which inhibited seedling root length of alfalfa, was isolated by thin-layer chromatography (TLC). Residues from a soil cropped continuously to alfalfa for 10 years had the greatest phytotoxic activity.

Key Words—Allelopathy, autotoxicity, *Medicago sativa* L., germination, seedling establishment, alfalfa, crop residues, phenolic acids.

INTRODUCTION

Many crop and weed plants contain phytotoxic substances which, when released into the environment, can cause reduced plant growth (Rice, 1984). Patrick (1971) found the majority of phytotoxic material present under field conditions is confined to the loci of decomposing residue rather than the surrounding soil. Guenzi and McCalla (1966) reported ferulic and *p*-coumaric acids were among the inhibitors present in the mature crop residues of corn (*Zea mays* L.), wheat, sorghum (*Sorghum bicolor* L., Moench.), and oat (*Avena sativa* L.) and in the soil (0–7.5 cm depth) under stubble-mulched plots (Guenzi and McCalla, 1966). Guenzi et al. (1964) found alfalfa phytotoxicity interacted with growth stage but not with cultivars, and water extracts of immature alfalfa forage had the greatest phytotoxic effects on corn seedlings in laboratory studies.

A water-soluble phytotoxin derived from alfalfa residues has been implicated in the problems associated with poor stand establishment on soils continuously cropped to alfalfa, giving rise to the term "alfalfa-autotoxicity" (McElgunn and Heinrichs, 1970; Miller, 1983). Webster et al. (1967) observed a larger yield increase from sterilized soil and soil fumigation by Vapam (sodium *N*-methyl dithiocarbamate) application than fertilization of two "alfalfa-toxic soils." They concluded improved growth by sterilization indicates the alfalfa autotoxin is of biological origin. Jensen (1984) reported alfalfa seedlings were smaller when grown in alfalfa soil compared to fallow soil, even though both soils were steam sterilized. Ground foliage or roots of alfalfa added to both soils significantly inhibited alfalfa seedling size and the number of plants established. Similarly, Ells and McSay (1984) reported that adding alfalfa foliage to soil inhibits germination of cucumber (*Cucumis sativus* L.).

Research in Illinois suggests alfalfa is difficult to establish, and yields are reduced when alfalfa is planted continuously (Klein and Miller, 1980). Kehr et al. (1983) reported average yields over a three-year period were 34% higher on land not previously cropped to alfalfa compared to land reseeded to alfalfa. They concluded autotoxicity was involved in lower yields of continuous alfalfa if moisture and pathogen conditions are included. Miller (1983) reported a significantly lower seedling population and second-year dry matter yield with a continuous cropping of alfalfa even though P and K deficiencies were corrected and seeds were treated with Captan (*N*-trichloromethyl thiotetrahydro-phthalimide) to protect seedlings against fungal attack.

Tesar (1984) at Michigan obtained successful stands of alfalfa following alfalfa when seeding in spring or summer after at least two weeks following spraying an old stand with glyphosate. However, he prefers spring seeding on a prepared seed-bed after fall plowing of alfalfa. Improper management does not appear to be responsible for difficulties in reestablishment in many instances.

Red clover and alsike clover (*Trifolium hybridum* L.) are not affected by the unknown phytotoxin (Webster et al., 1967; Jensen, 1984).

The objectives of this research were to determine: (1) the ecological source of the phytotoxic material from soil or plant residues, (2) the degree of auto-toxicity in soils where alfalfa had been grown for various periods of time, and (3) the chemical nature of the phytotoxins.

METHODS AND MATERIALS

Sampling. Approximately 75 liters of soil were collected by soil auger (0–15 cm depth) from each of five fields in the fall of 1984 subsequent to the last harvest date at each location. The soils collected were from a one-year alfalfa stand, an eight-year alfalfa stand, a 10-year alfalfa stand, a spring barley stand recently turned under, and from ground fallowed for four years, hereinafter referred to as 1-MESA, 8-MESA, 10-MESA, 1-HOVU, and fallow soil, respectively.

Subsamples of each soil (15 liters) were separated into three fractions: (1) soil as taken from site, hereinafter referred to as whole soil, (2) soil screened to pass a 1.2-mm sieve, and (3) plant residues from screened soil, i.e., plant residues not passing a 1.2-mm sieve. The fallow soil treatment consisted of unscreened whole soil. Residue samples were characterized as having 0.3- to 3.0-cm-long pieces of stem and root; adhering soil particles were not removed. Soil and residue samples were stored at -10°C .

Extraction. Extracts were prepared prior to each trial. Following the method of Guenzi and McCalla (1966), the amount of soil used is expressed on an oven-dry basis, but extractions were made at approximately the same moisture content as existed at the time of sampling. A 250-g sample of oven-dry soil (whole or screened) was extracted with anhydrous methanol (1:1, w/v). Barley or alfalfa residues (16.6 g fresh weight) were mixed in a blender with 250 ml anhydrous methanol. Soil and residue samples were extracted separately for 2 hr on a reciprocating shaker and left to stand for 12 hr. Extracts were filtered through Whatman No. 4 filter paper, reduced to dryness in a rotary flask evaporator at 40°C , and the dried residue resuspended in 50 ml autoclaved water. Extracts were stored at 4°C overnight in sterile tubes.

Bioassays of Soil and Residue Extracts. Sterile Petri dishes ($9 \times 9 \times 1$ cm) were fitted with blotter paper moistened with 2 ml autoclaved, distilled water. Fifty surface-sterilized seeds of alfalfa or red clover and 25 seeds of wheat or radish were established in these dishes. Extracts (5 ml) of soil or crop residue were delivered aseptically, with an additional 5 ml added after 24 hr. The germination chamber for the germination and seedling development tests

was held at 20°C with relative humidity near saturation. Electrical conductivity (EC) and pH were determined on the portion of extract (10 ml) not used for a bioassay in each trial.

Each Petri dish, with a ruler alongside as a reference scale, was photographed 48 hr after planting. Fifteen seedlings in the photograph were measured to the nearest 0.5 mm. Dishes were returned to the germinator for an additional three days. Seedlings received 12 hr of fluorescent light (17.5 W/m²) 108 hr after planting. Five days after initiating the trial, seedlings were counted and dried at 60°C for 48 hr and average dry weight per seedling determined (AOSA, 1983).

Statistical design was a split-split plot with soils as main plots, soil or crop residue extracts as subplots, and species as sub-subplots. Seedling root lengths and average seedling dry weights of the four bioassay species were determined in four replications. Data, expressed as a percent of the fallow soil extract, were subjected to analysis of variance (SAS, 1984), and treatment means were compared by Duncan's new multiple-range test at the 5% level of significance (Steele and Torrie, 1980).

Chromatographic Biosassay. An aliquot (7 ml), obtained from a pooled sample (about 30 ml) of whole soil or crop residue extracts, was reduced to dryness in a rotary flask evaporator at 40°C. The dried residue was resuspended in 2 ml anhydrous methanol. Spotting of TLC plates (0.25 mm thick, Silicagel G, F254 nm) was done using 40 µl of barley or alfalfa residue extracts (1.16 g residue/ml) and 40 µl of whole soil extracts (17.5 g soil/ml). Since most phytotoxic substances were thought to be phenolic in nature, 20 µl of each of 10 phenolic compounds (1 mg/ml methanol) were developed simultaneously. Compounds separated by one-dimensional TLC in a solvent system of *n*-butanol-acetic acid-water (4:1:5, v/v) were observed by fluorescence quenching (254 nm).

Based on the methods of Liebl and Worksham (1983), 200 µl of an extract were spotted in each of six lanes on 2.0-mm-thick TLC plates. Six identical spots of an isolated compound observed under UV light were scraped from a TLC plate, eluted with 10 ml acetone, and filtered through Whatman No. 42 filter paper. Acetone was evaporated under N₂ and the extract resuspended in 10 ml autoclaved, distilled water. Forty surface-sterilized seeds of alfalfa were soaked in an extract solution for 4 hr at room temperature. Ten seeds were removed from a flask and transferred to a sterile Petri dish (9 × 9 × 1 cm) fitted with germination paper which then received 1/4 of the remaining volume of bioassay solution remaining after 4 hr of imbibition. The radicle lengths of 10 alfalfa seedlings were measured in four replications after incubation for 72 hr. Statistical design was a two-way factorial arrangement with *R_f* values as treatment levels in bioassays of residue extracts from the four cropped soils.

Data were subjected to analysis of variance and means separated by the least significant difference (LSD) test at the 5% level of significance (Steele and Torrie, 1980).

RESULTS

Germination of alfalfa, red clover, radish, or wheat was not significantly inhibited by the various soil extracts. In terms of seedling root length and dry weight, individual species responded differently to extracts from soils with different cropping histories (Tables 1 and 3). Root length of wheat was inhibited significantly more than the other species by 10-MESA soil extracts, and root length of red clover was inhibited the least (Table 1). The extracts from 8-MESA and 10-MESA soils were most inhibitory to wheat. Root lengths of alfalfa were reduced more than those of red clover, but responded similarly to extracts of soils with different cropping histories. Extracts of 1-HOVU significantly inhibited root length of radish more than extracts from soils cropped to alfalfa (Table 1).

Extracts from screened soil increased root length of all species compared to extracts from fallow soil except for wheat (Table 2). Alfalfa and wheat root lengths were inhibited the most by residue extracts, while radish was inhibited to a lesser degree. Roots of alfalfa were significantly longer when grown in extracts from screened soil than either whole soil or residue extracts. This indicates the toxic properties of soil to seedling root growth of alfalfa is related to the residue fraction of the soil. Red clover root lengths were not significantly different when grown in extracts from the three soil treatments. This agrees with

TABLE 1. PERCENT CHANGE IN SEEDLING ROOT LENGTH OF FOUR SPECIES GROWN IN EXTRACTS OF FOUR SOILS WITH DIFFERENT CROPPING HISTORIES COMPARED TO GROWTH IN EXTRACTS FROM FALLOW SOIL

Species	Root length (% change)			
	1-MESA	8-MESA	10-MESA	1-HOVU
Red clover	+0.86d ^a	-1.25d	+1.38d	-1.88cd
Alfalfa	-3.55cd	-6.58bcd	-10.10bcd	-14.78bc
Wheat	-8.13bcd	-19.72b	-36.68a	-6.02bcd

our field observations (Jensen, 1984). The interaction of soils \times soil treatment \times species was not significant at the 5% level of probability.

Seedling dry weights of alfalfa and radish were reduced significantly more by 1-MESA or 8-MESA soil extracts than were red clover or wheat (Table 3). Seedling dry weight of wheat was reduced when grown in extracts from 8-MESA and 10-MESA soils compared to extracts from an unscreened fallow soil. Alfalfa seedling weights were reduced most when grown in alfalfa soil extracts and least when grown in extracts from a 1-HOVU soil. Dry weights of radish seedlings were affected in a similar manner as alfalfa when grown in extracts from soil with different cropping histories.

Average dry weights of seedlings grown in extracts from soil residue were significantly reduced more than those grown in extracts from whole or screened

TABLE 3. PERCENT CHANGE IN SEEDLING DRY WEIGHT OF FOUR SPECIES GROWN IN AQUEOUS EXTRACTS OF FOUR SOILS WITH DIFFERENT CROPPING HISTORIES COMPARED TO GROWTH IN EXTRACTS FROM FALLOW SOIL

Species	Dry Weight (% change)			
	1-MESA	8-MESA	10-MESA	1-HOVU
Red clover	-0.62cd*	+2.06d	-2.54bcd	-2.47bcd
Alfalfa	-10.30ab	-11.75a	-8.82bc	-5.51bcd
Wheat	+7.31d	-1.35cd	-10.57ab	+1.74d
Radish	-11.35ab	-13.45a	-10.58ab	-5.34bcd

^a Any means followed by the same letter are not significantly different at the 5% level of probability using Duncan's new multiple-range test.

soil (Table 4). Seedling weight reductions were intermediate in the seedlings grown in extracts from screened soil and least when grown in extracts from whole soil. The interaction of soil treatment \times species was not significant and neither was the interaction of soils \times soil treatment \times species.

The results of these trials suggest seedling vigor of alfalfa was inhibited by extracts of 1-, 8-, and 10-MESA over the five-day period (Tables 2 and 3). In addition, the seedling root length and dry weight of radish were inhibited to the same extent as alfalfa. Thus, seedling vigor of radish may be useful as an indicator for bioassays involving phytotoxins extracted from alfalfa residues.

Extracts of residue screened from the barley, 10-, 1-, and 8-year alfalfa soils, and fallow soil had pH values of 5.0, 4.6, 5.5, 6.1, and 6.8, respectively. The presence of dissolved salts did not interact with reduced seedling vigor. Inhibitory extracts had EC values less than fallow soil, which had an average EC of 3.48 dS/m.

Water-soluble substances in extracts of crop residues concentrated at $R_f = 0.78$ significantly inhibited alfalfa root length when compared to substances at $R_f = 0.87$. These substances present in 10- or 1-MESA residue significantly inhibited root length of alfalfa seedlings (Table 5). The substances with an $R_f = 0.78$ in 10-MESA residue caused an irreversible inhibition of germination. When these alfalfa seeds were washed with autoclaved water and placed back in the germinator, they did not germinate. A relatively high germination in solutions of 1-MESA residue ($R_f = 0.78$) was not accompanied by good seedling growth. Toxic substances caused symptoms other than inhibition of root growth. These were a swelling of root tips, curling of the root axis, discoloration, and lack of root hairs.

TABLE 4. PERCENT CHANGE IN DRY WEIGHT OF FOUR SPECIES GROWN IN EXTRACTS OF WHOLE SOIL, SCREENED SOIL, AND SOIL RESIDUE COMPARED TO GROWTH IN EXTRACTS FROM FALLOW SOIL

Species	Dry weight (% change)

TABLE 5. R_f VALUES AND ROOT LENGTH OF ALFALFA SEEDLINGS IN SUBSTANCES ISOLATED BY TLC FROM CROP RESIDUES^a

Origin of residue extracts	Root length (mm)	
	$R_f = 0.78$	$R_f = 0.87$
1-HOVU	10.3	11.0
1-MESA	7.7	11.5
8-MESA	13.9	11.1
10-MESA	1.0	10.7
Distilled water	14.3	14.3

^aLSD (0.05) = 1.5; CV = 10%.

A possible explanation for growth inhibition is the presence of phenolic substances, since the inhibitory band developed with an R_f similar to *p*-coumaric acid ($R_f = 0.74$) and *trans*-cinnamic acid ($R_f = 0.75$) and similarly quenched fluorescence of the silica gel phosphor. The fluorescence emission of the inhibitory region and ferulic acid ($R_f = 0.67$) were similar, but differing mobilities indicate toxicity from ferulic acid is unlikely.

Further examination of this inhibitory band ($R_f = 0.78$) from 1-, 8-, and 10-MESA and 1-HOVU crop residues was performed by elution with acetone and concentration to 1 ml. Methylation of the eluted band followed by gas chromatographic analysis did not reveal significant amounts of either cinnamic or *p*-coumaric acid. Methylation of the crude methanol extract of 10-MESA residue followed by gas chromatographic analysis similarly did not reveal any high concentration of compounds that could be responsible for the observed phytotoxicity. Although concentrations of about 10^{-4} M were detected with these methods, some phenolic acids, in particular some of the monomeric phenolic acids, are toxic to plants and to certain microorganisms at concentrations greater than about 10^{-5} M to 10^{-4} M in solution (Whitehead et al., 1982).

DISCUSSION

In dealing with production of phytotoxins in soil, methods for detection should reflect the ecological condition of the soil as encountered by the plant. In this study, the residue extracts represented 6.67% (1:15 w/w) of the soil mass on a fresh weight basis. Patrick (1971) found the severity of injury to seedling roots was related to the amount of plant residue in the immediate vicinity of the root. He reported toxic substances were only extracted from clumps of residue in which the percentage of soil did not exceed 80% on a fresh weight

basis. Under field conditions, phytotoxins were most abundant in the early stages of decomposition of plant residues during periods of water saturation (Patrick, 1971).

Results from this bioassay suggest inhibition of alfalfa seedling establishment on soils continuously cropped to alfalfa is due to phytotoxins derived mainly from residues of alfalfa incorporated into the soil. Adsorbed substances on the soil colloids apparently have a minor contribution to the phytotoxicity in the soil. Extracts of crop residues caused a greater inhibition of seedling development than either whole or screened soils and were found to be low in pH and dissolved salts. Although residues from soil from old alfalfa stands were more inhibitory to seedling dry weight than residues from a soil cropped to alfalfa for one year, we suggest a management practice that allows regrowth of alfalfa shoots, regardless of the age of the stand, prior to plowing under would possibly introduce a large supply of phytotoxic material. This study supports evidence that red clover growth is stimulated and alfalfa growth is depressed on soils previously cropped to alfalfa (Jensen, 1984).

When extracts of alfalfa residue were examined by a fluorescence technique on developed TLC plates, the greatest inhibition to alfalfa root length was located in the region with $R_f = 0.78$. The greatest inhibition of alfalfa root length was observed in this region isolated from alfalfa residue screened from soils cropped to alfalfa for 10 years. Phytotoxic compounds, suspected to be phenolic in nature, could not be identified by gas chromatography of the crude alfalfa residue extract or the eluted band.

CONCLUSIONS

Our results do not indicate a specificity of response of alfalfa to phytotoxins extracted from alfalfa residues. However, we found that the phytotoxicity reportedly occurring from the decomposition of alfalfa residues in soil (McElgunn and Heinrichs, 1970; Jensen, 1984) is due to water-soluble substances. Bioassays utilizing TLC demonstrated decomposing alfalfa residues release phytotoxins that are not retained by soil colloids and that a high degree of autotoxicity is associated with residues collected from a soil cropped to alfalfa for 10 years.

Abstract—The resident skin surface microflora of 12 male and three female *Saguinus fuscicollis* was studied. The suprapubic–circumgenital gland surface and the perirectal area were most heavily colonized (10^6 – 10^8 colony forming units/cm²), but high numbers of organisms were also present on the abdomen, the sternal gland surface, and palms and plantar surfaces. Bacteria were also recovered from hair clippings as well as from shaven skin surface, although at much lower densities (10^2 – 10^4 colony forming units/cm²). Coagulase negative staphylococci, gram-negative bacteria, *Streptococcus* species and coryneform bacteria were most dominant. *Staphylococcus aureus* and species of *Bacillus* were also present. Fungi, yeast, and dermatophytes were infrequently recovered or completely absent. The microbial flora of these tamarins appears to be closely associated with the secretions of the circumgenital scent gland and would therefore be ideally situated to participate in the generation or modification of chemical signals.

Key Words—Saddle-back tamarin, *Saguinus fuscicollis*, primates, Callitrichidae, surface microflora, chemical communication.

INTRODUCTION

Chemical communication, probably the oldest mode of communication among organisms, fulfills important behavioral and physiological functions (Vandenbergh, 1983). The possible role of microorganisms in the production of chemical signals has received increasing attention (Albone, 1984). Both aerobic and anaerobic microflora have been implicated in the production or modification of chemical signals. Gosden and Ware (1976) demonstrated that the aerobic bacterial flora of the anal sac of the red fox was composed of a wide range of organisms, including *Streptococcus* spp., *Proteus* spp., coliform bacteria, *Staphylococcus* spp., *Pseudomonas* spp., *Neisseria* spp. and *Bacillus* spp. The microflora of the inguinal pouches of the wild rabbit, *Oryctolagus cuniculus* is dominated by *Staphylococcus aureus* and the yeast *Candida kruzei*. Other isolates include *Bacillus subtilis*, *Escherichia coli*, and *Streptococcus faecalis* (Merritt et al., 1982). Albone et al. (1974) have compared the chemistry and the microbiology of the anal sac secretion of the red fox (*Vulpes vulpes*) with the anal sac secretion of the lion (*Panthera leo*) and demonstrated gross similarities in volatile and microbiological composition. Ware and Gosden (1980) have demonstrated that a variety of anaerobes, including species of *Bacteroides*, *Clostridium*, *Fusobacterium*, *Eubacterium*, *Peptostreptococcus*, and *Bifidobacterium* can also be isolated from the anal sac of the red fox.

Scent glands and scent-marking behavior are well developed in several groups of primates, among them the South American callitrichid monkeys (Epple et al., 1986). The saddle-back tamarin, *Saguinus fuscicollis*, a member of the family Callitrichidae, possesses an apocrine scent gland on the midchest, above the sternum, and a large, almost hairless pad of holocrine and apocrine glands in the circumgenital-suprapubic area (Perkins, 1966; Zeller et al., 1988). Males and females frequently scent mark with the suprapubic-circumgenital gland, depositing glandular secretions, urine, and possibly genital discharge (Epple et al., 1986). Behavioral studies have shown that scent marks communicate a variety of information relating to species, subspecies, gender, individual, endocrine condition, and social status (Epple et al., 1986).

It is conceivable that bacteria present on the glandular surface of the saddle-back tamarin are involved in the production or modification of the volatile constituents of the scent marks. The present study represents a first step in elucidation of this possibility: the characterization of the microbial flora.

METHODS AND MATERIALS

The first phase of this study involved three female and three male tamarins (group 1). The animals were sedated with 0.2 ml ketamine hydrochloride, 100 mg/ml (Bristol Laboratories, Bristol-Meyers, Syracuse, New York) and sam-

pled for the presence of aerobic and anaerobic microflora. Gloves were worn when handling and sampling the animals. Samples were taken from the suprapubic gland surface (scent pad), the sternal gland surface, the perirectal area, palm and planar surface, back (unshaven), and abdomen (unshaven).

Cyclical changes in the skin gland secretions may occur in females, which may in turn have an effect on the bacterial population. Therefore in the second phase of the study an additional nine males only (group 2) were studied in the following year for the presence of bacteria on the scent pad, the sternal gland, and the perirectal region. Samples from the back were also obtained from three of these animals after the hair had been cut from an area of 3 cm². The hairs were also collected for microbiological examination.

For sampling of the skin surface, a sterile cotton-tipped swab was moistened with 2 ml of sterile 0.1% Tween 80 and was rotated five times in a clockwise direction and then five times counterclockwise on an area of approximately 3 cm². The swab was returned to the culture tube, and the procedure was repeated four times. For the isolation of anaerobic bacteria, the swabs were placed into 2 ml, sterile, prereduced thioglycollate broth (BBL, Becton Dickinson, Cockeysville, Maryland) with 0.1% Tween 80. The hair clippings were placed directly into the 2 ml of sampling fluid.

In the laboratory, 10-fold dilutions of the samples were made in 0.05% Tween 80 or thioglycollate broth and appropriate dilutions were drop-plated onto the following media: (1) Trypticase soy agar with 5% sheep blood and 0.5% yeast extract—general nutrient medium for aerobes and anaerobes; (2) blood agar with 0.5% Tween 80—general nutrient medium; (3) MacConkey agar—selective isolation of Gram-negative rods; (4) phenylethylalcohol agar with 5% sheep blood—selective isolation of Gram-positive organisms; (5) manitol salt agar—selective isolation of *Staphylococcus aureus*; (6) Mycosel agar—selective isolation of dermatophytes; (7) Sabouraud dextrose agar with 0.05% chloramphenicol— isolation of fungi; (8) Schaedler agar with 0.1% Tween 80 and standard salt solution—anaerobic medium; and (9) Rogosa SL agar—selective isolation of lactobacilli. All media were from BBL. Aerobic plates were incubated at 35°C for three days, and then at room temperature for another four days. Anaerobic plates were incubated for seven days at 35°C in anaerobic jars in an anaerobic atmosphere enriched with CO₂ (BBL GasPak, Anaerobic Systems). All media for isolation of anaerobes were prereduced prior to inoculation by incubation in an anaerobic atmosphere at 4°C.

Organisms were identified according to colony morphology, Gram stain reaction, and biochemical tests, which were performed on washed 3-day-old bacteria inoculated as 25 μl of a turbid suspension of 0.15 M NaCl according to standard identification procedures (Paik, 1980). Tests for nitrate reduction and hydrolysis of indole and urea were performed in Stuart's medium. Catalase production was tested by the slide method, on bacteria grown on Trypticase soy agar with 0.5% yeast extract. All other tests were performed using the API

identification system: API 20E enteric system, API Staph indent, and API 20S *Streptococcus* system (Analytab Products, Plainview, New York). Non-spore-forming, catalase-positive, aerobic, Gram-positive rods were identified as coryneform bacteria. Yeast were identified to the genus level, and fungi were identified on the basis of macromorphology.

Three 4-mm punch biopsies were taken from the suprapubic gland of one male *S. fuscicollis* that had been sacrificed. Thin sections were processed and examined for the presence of bacteria using scanning electron microscopy according to Lehmann et al. (1983).

RESULTS

High numbers of bacteria were present on all body sites of male and female saddle-back tamarins (Table 1). The composition and the density of the flora of the three males (group 1) that were sampled for comparison with the three females in the first phase of the study were similar to the second group of nine males (group 2) sampled at a later date (Tables 2 and 3).

The flora was dominated by aerobic and facultatively anaerobic bacteria; anaerobic isolation did not yield any strict anaerobes. Electron microscopy of thin sections of the suprapubic gland of the sacrificed animal showed the presence of large multiacinar sebaceous glands devoid of any bacteria in the glands or at the opening of the glandular ducts.

Coagulase-negative staphylococci, Gram-negative bacteria, *Streptococcus* species, and coryneform bacteria were the predominant organisms in both males and females (Tables 2 and 3). *S. aureus* was present in lower numbers, and

yeast, fungi, and anaerobic spore formers were occasionally recovered. No dermatophytes were present. The overall composition of the flora of males and females was very similar. Seven species of coagulase-negative staphylococci were tentatively identified: *S. haemolyticus* (with an overall prevalence of 72%), *S. epidermidis* (61%), *S. simulans* (56%), *S. warnerii* (37%), *S. saprophyticus* (26%), *S. sciuri* (2%), and *S. intermedius* (2%). Of the Gram-negative bacteria, *Pseudomonas fluorescens* was most frequently isolated at a 96% prevalence, followed by *Escherichia coli* (72%), *Proteus mirabilis* (35%), *Acinetobacter calcoaceticus* (33%), and *Serratia rubidea* (7%). Two streptococcal species were isolated: *S. faecium* and *S. faecalis* with a prevalence of 93% and 89%, respectively. Coryneform bacteria were also commonly isolated (63%). Members of the genus *Bacillus* (27%) represented the aerobic spore formers, but these were not identified to the species level. Similarly, species of the yeast *Candida* were recovered at a 13% isolation frequency. The fungi were identified as members of the genus *Penicillium* and were present in three of the 75 samples.

The most prevalent organisms on the surface of the shaven skin and on the hair clippings were the coagulase-negative staphylococci, Gram-negative bacteria, and the streptococci (Table 3). The densities of these organisms on the skin and the hair were also very similar, but the streptococci were recovered in highest densities from hair clippings.

DISCUSSION

The resident microflora of the saddle-back tamarin is dominated by coagulase-negative staphylococci, Gram-negative bacteria, streptococci, and coryneform bacteria. It is possible that this flora is, at least in part, of fecal origin (Lewis et al., 1987). The isolation rates of *S. aureus* and *Bacillus* species were more variable. This suggests that these organisms are part of a transient flora and may be transferred from the personnel caring for the tamarins or from the surrounding environment. The fungi also appear to be part of environmental contamination. The humid and warm environments of the scent pad, perirectal area, and the abdomen stimulate high bacterial proliferation. Thus, the bacteria are ideally situated for interacting with secretions of the suprapubic-circumgenital gland. The examination of the samples taken from shaven skin and hair clippings showed that the numbers of bacteria were higher on the hair. In contrast, Leyden et al. (1981) have demonstrated that in the human axilla, insignificant numbers of bacteria are present on the hairs and that these are translocated from the abundant resident population on the skin. Since hairs are a poor substrate for growth of bacteria, it is likely that in the tamarins the majority of organisms on sites other than the glandular areas, abdomen, and

perirectal area are translocated by contact with other members of the group and with the environment, rather than originating from the surface of the skin.

Yarger et al. (1977) and Belcher et al. (1986) have documented the presence of butyrate esters (C_{16} – C_{24}) and squalene in scent marks of *Saguinus fuscicollis*. More recently, the presence of some short-chain fatty acids, steroid hormone metabolites, and proteins has been established (Belcher et al., unpublished results). Albone et al. (1974) have attributed the presence of various short-chain fatty acids in anal sac secretions to microbial action on carbohydrates and proteins. Short-chain fatty acids, although present, are not among the major volatile components of *S. fuscicollis* scent marks. However, bacteria that reside on human skin (Kearney et al., 1984) actively hydrolyze triglycerides to free fatty acids, which fall in the molecular weight range of those acids that are detected in the scent marks from *S. fuscicollis*. Bacterial cell wall fatty acids typically include these chain lengths (Goodfellow and Minnikin, 1985), hence, it is possible that bacterial debris contributes to the composition of the scent marks. Bacteria are also capable of degrading cholesterol, and it has been suggested that bacteria also esterify cholesterol into cholesteryl esters (Turtiff, 1948; Puhvel, 1975). Nixon et al. (1984) have reported that bacteria that colonize the human axilla are capable of metabolizing testosterone with the subsequent production of 17β -hydroxy- 5α -androstan-3-one and 17β -hydroxy- 5β -androstan-3-one, and according to Labows et al. (1982), several authors have demonstrated that the androgen steroids account for some of the odors of the human axilla. It is possible that bacteria similarly metabolize androgens in the deposited scent marks of the marmoset.

Tamarins in this study lived in social groups and were not separated from one another prior to the study. Translocation of the bacterial flora by contact probably occurs also in nature and thus is part of the behavior of these primates. Albone and Perry (1975) have emphasized the importance of translocation of the microbial flora within the population, and speculated that a group of animals living together would be expected to share a common microflora that characterizes the group. If the microorganisms are responsible for the production of specific volatiles, these may serve as important signals that are characteristic to the group and the microflora that it shares.

The bacterial flora of the saddle-back tamarins includes several species that have also been isolated from other mammals, such as the red fox (Albone et al., 1974; Gosden and Ware, 1976) and the rabbit (Merritt et al., 1982), in which chemical communication is important. Streptococci, namely *Strep. faecium* and *Strep. faecalis*; staphylococci, *S. aureus* and the coagulase-negative staphylococci, Gram-negative bacteria; *E. coli*; and *Proteus mirabilis* have all been reported to be associated with the glandular regions responsible for the generation of the signals. Previous authors have not attempted to speciate the coagulase-negative staphylococci that have been isolated. We found, using the

API identification system, that the organisms could be tentatively assigned to the following seven species: *S. haemolyticus*, *S. epidermidis*, *S. simulans*, *S. warnerii*, *S. saprophyticus*, *S. sciuri*, and *S. intermedius*. Although speciation of these organisms is tentative at this point, it should be pointed out that Brun et al. (1978) have reported excellent correlation between the identification method of Kloos and Schleifer (1975) and the API system.

Several authors have reported that anaerobes form a resident bacterial flora found in sacs, pouches, and invaginations of many other species that are known to depend on chemical communication (Albone, 1984; Svendsen and Jollick, 1978; Ware and Gosden, 1980). The present study indicates that the saddle-back tamarin is heavily colonized by aerobic and facultatively anaerobic bacteria. However, the suprapubic scent gland consists of a pad of glandular skin in which pouches and invaginations are not present (Epple et al., 1986). The gland surface is constantly exposed to air. It thus would be highly unlikely that strict anaerobes, such as *Bacteroides* spp. or *Fusobacterium* spp. (Ware and Gosden, 1980; Merritt et al., 1982) found in other species, would be present on *Saguinus fuscicollis*. Electron microscopy of thin sections from the scent pad confirmed that no organisms were present in the glands or glandular ducts, where an anaerobic environment might prevail. To confirm these observations, further work will be conducted involving sampling the tamarins in an anaerobic environment, as described by Ware and Gosden (1980). This will be the subject of a future communication.

In summary the skin surface microflora of *Saguinus fuscicollis* is composed of aerobic and facultatively anaerobic bacteria. High numbers of coagulase-negative staphylococci, Gram-negative bacteria, streptococci and coryneform bacteria are consistently recovered. The suprapubic scent gland and the perirectal area are most heavily colonized; thus the bacteria are ideally situated to participate in the generation or modification of chemical signals. In vitro studies on the production of volatiles by bacteria in the presence of scent-gland secretions are currently being pursued.

Acknowledgments—This study was supported by National Institutes of Health research grant 5R01 NS21790 and a grant from the Simon Greenberg Foundation, Philadelphia, Pennsylvania. We are grateful to Dr. R.M. Lavker and Mr. Kenneth J. McGinley of the Department of Dermatology, University of Pennsylvania School of Medicine, for assistance in electron microscopic studies and in the identification of bacteria.

AGE-SPECIFIC TITER AND ANTENNAL PERCEPTION
OF ACETIC ACID, A COMPONENT OF MALE
Pseudaletia unipuncta (HAW.)¹
HAIRPENCIL SECRETION

(Received September 8, 1987; accepted February 10, 1988)

Abstract—Hairpencil secretion of *Pseudaletia unipuncta* (Haw.) contains acetic acid as well as previously identified benzaldehyde and benzyl alcohol. Age-specific titers of acetic acid were significantly greater than those of benzaldehyde and, at 25°C, accumulation of both compounds in the hairpencils peaked on the second day after emergence. Excised antennae of males and females perceived both compounds. Antennal response to acetic acid did not vary significantly with age or sex, but male response to benzaldehyde was significantly greater than female response at all ages tested. Antennal response of both males and females to benzaldehyde tended to be greater on the fourth and eighth days after emergence than on the second.

Key Words—*Pseudaletia unipuncta*, Lepidoptera, Noctuidae, hairpencils, male pheromone, acetic acid, benzaldehyde, benzyl alcohol, antennal response.

INTRODUCTION

Studies of pheromone composition and perception in Lepidoptera usually focus on female pheromones which, due to their role as male attractants, have considerable potential in pest management programs. Male pheromones, on the other hand, have little evident applicability and have therefore received less

¹Lepidoptera: Noctuidae.

attention. The deployment and function of male pheromones varies among species, although most are released just prior to copulation and promote successful courtship (Fitzpatrick and McNeil, 1988).

Pseudaletia unipuncta male pheromone is released from abdominal hair-pencils as the male attempts genital contact with the female (Fitzpatrick and McNeil, 1988). The pheromone facilitates copulation (Farine, 1982), apparently by inhibiting female rejection behavior (Fitzpatrick and McNeil, 1988). It has also been suggested that *P. unipuncta* male pheromone inhibits conspecific males from approaching and attempting to copulate with calling females (Hirai et al., 1978). However, results of more recent work fail to support this hypothesis (Fitzpatrick et al., 1988).

It has been known for some time that *P. unipuncta* male pheromone contains benzaldehyde and benzyl alcohol (Grant et al., 1972) and that antennae of both sexes respond to these compounds (Grant et al., 1972; Seabrook et al., 1979). Benzaldehyde was believed to be the only active pheromone component; it is enzymatically derived from benzyl alcohol during the two days following emergence (Clearwater, 1975; Hirai, 1980) and is thereafter reported to be the major component of hairpencil secretion (Grant et al., 1972; Hirai, 1980; Fitzpatrick et al., 1985). However, Grant et al. (1972) reported a third, unidentified compound that was resolvable only on a polar column and had a retention time less than that of benzaldehyde.

During routine analyses of *P. unipuncta* male pheromone, we also noticed an additional peak, which proved to be acetic acid, the major component of male scent. Here we report its titer as a function of male age and its perception by antennae of both sexes.

METHODS AND MATERIALS

Insects. *P. unipuncta* males came from a laboratory population established from mated females collected at Normandin, Québec, Canada. Larvae were individually reared on a pinto bean diet (modified from Shorey and Hale, 1965), sexed after pupation, and the sexes maintained in separate incubators thereafter. Adults were kept individually in 16-dram clear plastic vials where they had continual access to 8% sucrose. All stages were maintained at $25 \pm 1^\circ\text{C}$, $65 \pm 5\%$ relative humidity, under a 16:8 light-dark photoperiod.

Identification of Acetic Acid. Four-day-old males were inactivated by chilling at -10°C for 15 min, a procedure that does not affect hairpencil content (Fitzpatrick et al., 1985). Hairpencils were quickly removed with fine forceps and placed in chilled Teflon-capped 1-dram amber vials containing methylene chloride (two hairpencils per male per vial). All hairpencil excision took place

during the last hour of scotophase, which corresponds to the end of the period of sexual activity at this temperature and photoperiod.

Identification of acetic acid was carried out by capillary gas-liquid chromatography (GLC) and verified by gas chromatography-mass spectroscopy (GC-MS). GLC analyses were conducted on a Hewlett Packard 5890 GLC fitted with flame ionization detectors and coupled to a Hewlett Packard 3392A integrator. The acetic acid peak, which first became apparent during low-temperature runs on a nonpolar methyl silicone column, was best resolved on a polar DX-4 column (0.25 mm \times 15 m) using hydrogen as the carrier gas. Injections to the DX-4 were made in split mode, and temperature was increased from 60°C to 125°C at 40°C/min after an initial hold of 1 min. GC-MS verification was conducted on a Kratos MS-80 using nonpolar DB-1 and polar DX-3 columns, with helium as the carrier gas. Mass spectra of insect-derived compounds were compared to those of standards, and the identity of acetic acid confirmed.

GLC Quantification of Acetic Acid as a Function of Male Age. Hairpencils of newly emerged (day 0) and 1-, 2-, 4-, 6-, 8-, and 10-day-old males were excised and placed in solvent-containing vials as described above. A known quantity of the internal standard, naphthalene, was added to each vial, and the vials stored at -10°C for up to nine days before analysis. Acetic acid was quantified by comparing electronically integrated acetic acid peak areas with those of naphthalene. Two injections from each sample were analyzed, and results averaged to yield amounts of acetic acid per male. Benzaldehyde titers were analyzed in the same manner.

Electroantennograms. EAGs were recorded on an apparatus similar to that described by Nagai et al. (1977). Odor stimuli were delivered from glass cartridges (5 mm \times 5 cm) in 2-sec puffs along the longitudinal axis of the antennae. Just prior to use, cartridges were loaded with 10 μ l of the test dilution and rolled, to ensure even distribution of compounds, until all liquid had evaporated. Each cartridge was used only once.

Excised antennae from 2-, 4- and 8-day-old males and females were tested for their response to each compound during the last 3 hr of scotophase. By testing individuals of these ages, we were able to monitor antennal perception from the onset of sexual activity to mid-life, since male response to female pheromone (Turgeon et al., 1983), male reproductive activity (Fitzpatrick and McNeil, 1989) and female calling behavior (Turgeon and McNeil, 1982) do not begin before the second day after emergence at 25°C. Acetic acid, dissolved in methylene chloride, was applied to cartridges at a concentration of 2.5×10^2 μ g/10 μ l. Preliminary tests showed that antennal responses of both sexes to concentrations less than this did not differ from responses to control cartridges loaded with methylene chloride and that 5×10^2 μ g/10 μ l exceeded saturation. Benzaldehyde, 96% pure by GLC, was applied to cartridges at a

concentration of 10^2 $\mu\text{g}/10$ μl of methylene chloride. This did not exceed saturation, but was as concentrated as possible because, at higher concentrations, benzoic acid accumulated in cartridges and antennal response of both sexes decreased. Each antenna was subjected to three consecutive stimuli: (1) airflow from an empty cartridge (to ensure that the response of mechanoreceptors stimulated by the airflow could be recorded); (2) methylene chloride control, and (3) acetic acid or benzaldehyde dilution. There was a 3-min recovery period between stimuli. The EAG response was calculated as the response to acetic acid or benzaldehyde minus the response to methylene chloride.

RESULTS

Analysis of hairpencil content as a function of male age showed that acetic acid titer tracked that of benzaldehyde, rising to a peak two days after emergence, decreasing from day 4 to day 6, then subsequently increasing (Figure 1). Acetic acid titer was significantly higher than benzaldehyde titer at all ages (two-way ANOVA; $F = 27.38$, $P < 0.001$, $df = 1, 128$). This difference may even be underestimated, as subsequent work has shown that, although neither benzaldehyde or benzyl alcohol evaporate during storage at -10°C , some acetic acid may be lost. Benzyl alcohol, the precursor of benzaldehyde, peaked on day 1 and was not detectable after day 6 (Figure 1).

Electroantennogram recordings indicated that both male and female antennae respond to acetic acid (Figure 2A). Female response decreased gradually

FIG. 1. Titers of acetic acid (—●—), benzaldehyde (---●---), and benzyl alcohol (—○—) in diet-fed, virgin *P. unipuncta* males. The number of males analyzed per age is given on the upper graph.

FIG. 2. EAG responses of excised male (—●—) and female (---●---) *P. unipuncta* antennae to source concentrations of (A) $2.5 \times 10^2 \mu\text{g}$ of acetic acid and (B) $10^2 \mu\text{g}$ of benzaldehyde dissolved in $10 \mu\text{l}$ of methylene chloride. Six individuals were tested per age, sex, and compound.

with age, although the decline was not significant (ANOVA; $F = 0.67$, $P = 0.53$, $df = 2, 15$), while male response remained relatively constant (ANOVA; $F = 0.07$, $P = 0.93$, $df = 2, 16$). There were no differences between male and female EAG responses (two-way ANOVA; $F = 0.14$, $P = 0.71$, $df = 1, 31$). Antennae of both sexes also responded to benzaldehyde (Figure 2B), as reported by Grant et al. (1972) and Seabrook et al. (1979). Both male and female responses were greater on days 4 and 8 than on day 2, although these increases were not significant for either sex (ANOVA; males: $F = 2.12$, $P = 0.16$, $df = 2, 17$; females: $F = 1.02$, $P = 0.38$, $df = 2, 17$). However, male responses

to benzaldehyde were significantly higher than female responses (two-way ANOVA; $F = 5.04$, $P = 0.03$, $df = 1, 30$).

Waveforms to both compounds approximated normal EAGs (Boeckh et al., 1965): rapid depolarization followed by slower repolarization (recovery phase). Responses to acetic acid were sometimes characterized by a period of hyperpolarization after repolarization.

DISCUSSION

Acetic acid has not been reported in the male scent of any other lepidopterans, although similar low-molecular-weight carboxylic acids have been identified in scent brushes of several noctuids and one geometrid (Aplin and Birch, 1970). *Leucania impura* (Hueb.), *L. conigera* (Schiff.), and *L. pallens* (L.), all in the Hadeninae, the same subfamily as *P. unipuncta*, produce isobutyric acid. In these three species, benzaldehyde is the major scent brush component and isobutyric acid makes up 20% of the secretion (Aplin and Birch, 1970).

In *P. unipuncta* males, acetic acid predominates, both in terms of mass (Figure 1) and of number of molecules. Given that the molecular weight of acetic acid is 60 and that of benzaldehyde 106, each microgram of acetic acid contains 1.77 times as many molecules as each microgram of benzaldehyde. Thus on day 4, when scent brushes contain on average 80 μg of acetic acid and 47 μg of benzaldehyde, the molecular ratio is approximately 3 : 1. When scent is released just before a male's first copulation, the molecular ratio of the released compounds is lower but still favors acetic acid. On average, 6 μg of acetic acid and 8 μg of benzaldehyde are given off (Fitzpatrick and McNeil, 1988) i.e., 1.34 molecules of acetic acid per molecule of benzaldehyde.

The temporal pattern of acetic acid accumulation during the two days after emergence follows that of benzaldehyde (Figure 1). During this period, benzaldehyde is being enzymatically converted from benzyl alcohol (Clearwater, 1975; Hirai, 1980; Miller et al., unpublished results), which is in turn a degradation product of a glycoside precursor (Clearwater, 1975) emptied onto the hairpencils from the Stobbe glands at emergence (Birch, 1970; Clearwater, 1975; Miller et al., unpublished results). Storing benzaldehyde as a glycoside circumvents its toxic effects on cell metabolism (Clearwater, 1975). It is therefore probable that acetic acid is also stored as a nontoxic precursor until enzymatic conversion. Research on this possibility is presently underway.

Antennae of both males and females perceive acetic acid. EAG responses do not vary significantly with age or sex, although the response of female antennae tends to decline slightly with age. Benzaldehyde is also perceived by antennae of both sexes, and our data show that male response to benzaldehyde is significantly greater than the response of females, contrary to the results of

Grant et al. (1972), but in agreement with those of Seabrook et al. (1979). Given that the EAG is thought to be the summed potential of activated receptor cells of the antenna (Boeckh, 1969), our results suggest that male antennae possess more acceptor sites or receptor cells for benzaldehyde than do female antennae. Seabrook et al. (1979) also reported that peak sensitivity to benzaldehyde occurs at a much younger age in males than in females (day 3 vs. day 8–9).

Both benzaldehyde and acetic acid are structurally similar to compounds that may serve as feeding stimuli. Many noctuids are attracted to exudates of tree wounds (R. Webster, personal communication), which may contain phenols (Kevan et al., 1983) and, depending on the type of bacterial fermentation present (Lehninger, 1975), low-molecular-weight carboxylic acids. *P. unipuncta* is one of a number of noctuids attracted to phenylacetaldehyde, a phenolic very similar to benzaldehyde, given off by the bladder flower (Cantelo and Jacobson, 1979). There is as yet no general agreement on the type(s) of receptor cells used to perceive male pheromone components (e.g., Birch, 1971; Grant, 1971; Priesner, 1979; Seabrook et al., 1979). However, if male scent must be distinguished from closely related food odors, the responsiveness of the receptor cells involved may vary as a function of factors such as the physiological state (e.g., Davis, 1986) and sex of the perceiver, as well as time of day and relative proportions of the two compounds. This possibility awaits further electrophysiological and behavioral studies.

Acknowledgments—We thank I. Weatherston for help with the chromatography, M. Benn for GC-MS identification of acetic acid, and J. Lavoie-Dornik for use of, and assistance with, the electroantennogram apparatus. Thanks also to L. Marshall and J. Richardson for comments on earlier versions of the manuscript. This study was supported by an NSERC postgraduate scholarship to S.F. and by NSERC and FCAR grants to J.N.M.

URINARY VOLATILE PROFILES OF PINE VOLE, *Microtus pinetorum*, AND THEIR ENDOCRINE DEPENDENCY

MEGAN L. BOYER, BOZENA JEMIOLO, FRANCA ANDREOLINI,
DONALD WIESLER, and MILOS NOVOTNY

(Received September 18, 1987; accepted February 10, 1988)

Abstract—The volatile compounds identified by combined gas chromatography-mass spectrometry in *Microtus pinetorum* urine include alcohols, aldehydes, hydrocarbons, ketones, nitriles, and pyrazines. Several lactone derivatives were found to be characteristic urinary substances of this species. Ovariectomy depressed concentrations of only five out of a great number of profile constituents. Elevating estrogen levels (by exposing females to male-soiled bedding or treating them with estradiol) tends to depress the urinary concentration of a number of selected volatiles. Estrogen implantation provoked a periodic increase in the level of three compounds (nonanal, benzaldehyde, and an unidentified substance). The volatile profile of castrate male urine was similar to that of intact male urine. Female urine contained γ -octanoic lactone and two pyrazine derivatives in higher concentrations and *p*-methyl-propenylbenzene in a lower concentration, when compared to male urine. No qualitative differences between the urinary profiles of males and females were observed.

Key Words—Pine voles, *Microtus pinetorum*, capillary gas chromatography, urinary chemosignals.

INTRODUCTION

It is becoming increasingly clear that both small and large molecules can act as mammalian pheromones. Some attempts to isolate the active fraction of urine and to structurally characterize these chemosignals have been successful in murines, with a particular focus on the house mouse, *Mus musculus*. The male's

ability to hasten the onset of puberty in female mice is mediated by a high-molecular-weight, nonvolatile urinary fraction (Vandenbergh et al., 1975, 1976). The male-produced chemosignals involved in the estrous synchronization effect appear to be volatile (Jemiolo et al., 1986). The female mouse urinary cue that inhibits puberty onset in other females (Drickamer, 1982a,b, 1983) is a mixture of urinary volatile compounds (Novotny et al., 1986).

Similar to spontaneously ovulating murines, the inductively ovulating microtines are also sensitive to reproductive activation by urinary chemosignals from conspecifics. Actual contact of a juvenile and an adult female vole with a strange mature male or his urine provides a particularly potent stimulus for her reproductive development (Clarke and Clulow, 1973; Richmond and Stehn, 1976; Carter et al., 1980; Baddaloo and Clulow, 1981; Milligan, 1982; Jemiolo, 1987). Suppression of puberty in voles can occur in animals reared in mixed-sex or same-sex groups (Batzli et al., 1977; Getz et al., 1983).

While it has also been demonstrated that urinary volatile constituents are involved in the control of reproductive activities of female mice, no similar chemical studies have been performed on microtines. The present study has been undertaken to investigate the urinary profiles of volatile substances excreted by female and male pine voles, *M. pinetorum*, and their dependence on the endocrinological status of the investigated animals. Selected volatiles were measured quantitatively by established chromatographic methods and identifications were made through mass spectrometry followed by verification through chromatographic retention of authentic compounds.

METHODS AND MATERIALS

Animals. All pine voles, *Microtus pinetorum*, used in this study were from a laboratory-bred colony. The voles were housed individually in plastic cages (30 × 15 × 13 cm) under conditions of controlled temperature (21°C) and light (0600–2000 hr). They were fed Purina Rat Chow and Wayne Guinea Pig Diet ad libitum, supplemented daily by a slice of apple and carrot. Water was constantly available. Bedding was changed weekly.

The animals under investigation were a gift from Dr. John Vandenbergh of North Carolina State University, Raleigh, North Carolina.

Sample Collection. Urine samples used for the chemical analysis were obtained by placing voles into drip-metabolism cages. Each collection period, lasting 6 hr, was begun at the same time of the day, i.e., from 0900 to 1500 hr. Urine from each metabolism cage drained into a collection vessel, which was maintained on Dry Ice to ensure immediate freezing of the sample. Samples were stored at –20°C until analysis. All urine samples were collected between the months of May and September.

Sample Analysis. Urinary volatiles were concentrated onto a porous polymer, Tenax GC (Applied Science Laboratories, State College, Pennsylvania) using the headspace technique developed by Novotny et al. (1974). Purified helium gas at a flow rate of 100 ml/min sparged the volatiles from 1.0-ml urine samples for 1 hr. The headspace sampling was performed at room temperature. Volatiles were absorbed onto a precolumn packed with 4 mg of Tenax GC. Following sampling, volatiles were desorbed into the heated injection port (240°C) of a gas chromatograph (Series 1400, Varian Instruments, Walnut Creek, California) equipped with a flame ionization detector, and retrapped into a liquid-nitrogen-cooled section of a glass capillary column (60 m × 0.25 mm, ID), which had been statically coated with UCON-50-HB-2000 (Supelco, Inc., Bellefonte, Pennsylvania). Column temperature was programmed from 30°C to 160°C at a rate of 2°C/min. Relative quantitative comparisons of peak areas were made with a Perkin-Elmer Sigma 10 Gas Chromatography Data Station (Perkin-Elmer, Norwalk, Connecticut).

Volatile constituents were identified through capillary GC-MS (Hewlett-Packard 5981 dodecapole mass spectrometer), using electron impact ionization at 70 eV. In addition, the components were verified through retention-time measurements of authentic compounds.

Study 1: Volatile Profiles of Female Pine Vole Urine. All *M. pinetorum* females were between 90 and 120 days of age and were virgin at the beginning of the study. Urine was collected from four groups of animals: (1) unexposed females ($N = 7$), which were kept alone in their home cage for at least four weeks before urine collection; (2) exposed females ($N = 7$), which were placed for 24 hr in a cage previously used by unfamiliar, mature males for at least one week; (3) ovariectomized females ($N = 4$) that were gonadectomized under methoxyflurane anesthesia four weeks before urine collection; and (4) ovariectomized and estradiol-treated females; ovariectomy was performed four weeks before the estradiol capsule was implanted. A capsule containing 17 β -estradiol (Sigma Chemical Company, St. Louis, Missouri), was 5.0 mm long and prepared from Silastic Medical Grade Tubing (Dow Corning Corp., Midland, Michigan). The ends of the capsule were sealed with Silastic Medical Adhesive (Silicone Type A, Dow Corning) so as to leave a compartment 2–3 mm in length. This technique permits delivery of relatively precise and small quantities of hormone over a long period of time (Henderson et al., 1977; Moore, 1981). A capsule was implanted subdermally into the back of the neck of each female ($N = 6$). Urine collection was made at 48, 72, 96, 120, 144, and 312 hr after implantation. Urine collected from intact and ovariectomized females was used to establish a baseline. The collection from intact and ovariectomized females is represented at 01 and 02 hr after implantation.

Study 2: Volatile Profiles of Male Pine Vole Urine. All *M. pinetorum* males, sexually inexperienced at the beginning of this study, were 90–120 days of age.

Urine was collected from two groups of males: (1) intact ($N = 7$) and (2) castrated ($N = 5$), all housed separately. Males were castrated at least four weeks prior to the first urine collection.

Statistical Analysis. Statistical comparisons of the levels of excreted volatiles were made using t test and one-way analysis of variance (ANOVA). The number of samples run for the first three groups of females was 7, 7, and 4, respectively (1 ml of urine from each female). For the estrogen-treated females, a single run for a different time was evaluated (1 ml of urine was collected from six females for each period of time after implantation). The number of samples run for male urine was 7 for the intact and 5 for the castrated animals.

RESULTS

The capillary gas chromatograms shown in Figure 1 are representative of pine vole urinary volatile profiles obtained from (A) unexposed females, (B) females exposed to male-soiled bedding, and (C) intact males. Twenty-three volatile compounds were positively identified by combined capillary gas chromatography-mass spectrometry and retention measurements of authentic compounds (Table 1). Identified substances include pyrazines, aldehydes, nitriles, ketones, hydrocarbons, and alcohols.

Through careful visual inspection of the profiles and statistical comparison of integrated peak areas of the urinary volatiles obtained from six experimental groups of animals, we established that 13 constituents (including two unidentified substances) showed obvious variations in their chromatographic peak areas (Table 1). The remaining substances listed in this table demonstrated relatively constant concentration in the urine samples of all investigated animals.

Study 1: Volatile Profiles of Female Pine Vole Urine. A quantitative comparison of urinary profiles from unexposed and exposed females revealed that exposure depresses the level of certain volatile compounds (Figure 2). Pyrazines (peaks 3 and 6) were absent in the urine of exposed females. A significant ($P < 0.01$) decrease in concentration was observed with phenylacetonitrile (peak 16) and three ketones (peaks 14, 15, and 19). Statistical analysis revealed that only two compounds, nonanal (peak 8) and an unidentified substance (peak 22), significantly ($P < 0.01$) increased their concentration after exposure (Figure 2).

Figure 3 (A-F) displays plots for concentrations of selected compounds at various times after estrogen implantation. The selected compounds were those that exhibited fluctuation in concentration compared to the control values obtained from intact females (01 h after implantation). Ovariectomy (02 h after implantation) significantly ($P < 0.01$) depressed the concentration of some urinary volatiles when compared to intact values. These compounds were pyrazines (peaks 3 and 6), phenylacetone (peak 14), γ -octanoic lactone (peak 17),

22	unidentified	+
23	<i>p</i> -ethylphenol	
24	γ -decanoic lactone	
25	δ -decanoic lactone	

and an unidentified compound (peak 22). Only peak 13 (unidentified) increased ($P < 0.01$) in concentration after removal of the ovary.

Urine from estrogen-treated females collected at 48–72 hr after implantation contained compounds such as ketones (peaks 14, 15, and 19; Figure 3A, B), pyrazines (peaks 3 and 6; Figure 3C), and nitriles (peaks 12 and 16; Figure 3D) in considerably lower concentration than did intact and ovariectomized animals. Urinary profiles of the females implanted with estrogen for 48–72 hr tended to mimic the profile of exposed animals. At 144 hr postimplantation, all these compounds returned toward the control, intact values (Figure 3A–D). Only the γ -octanoic lactone (peak 17) exhibited quick return to the intact level within 48 hr after estrogen implantation. This lactone exhibited the greatest fluctuation in concentration throughout the estrogen test period. As seen in Fig-

FIG. 2. Urinary constituents exhibiting significant changes in the peak areas (\pm SEM) between unexposed and exposed female pine voles. Letter a indicates 0.01 level of significance over unmarked bars.

ure 3E, aldehyde concentrations were changed during estrogen implantation. Nonanal and benzaldehyde (peaks 8 and 9) displayed two separate periods of increase after estrogen implantation, the first at 48 hr for both compounds and the second at 96 hr for benzaldehyde and at 120 hr for nonanal. In the 312-hr postimplantation period, concentrations of these aldehydes were found near the control levels of intact animals. Nonanal also displayed elevated concentration after exposure to male-soiled bedding (Figure 2).

Two unidentified compounds (peaks 13 and 22) displayed different behavior after estrogen treatment when compared to identified compounds (Figure 3F). Peak 13 decreased dramatically within 48 hr after estrogen implantation and was not present in the urine for the next five collection periods. This compound appeared again at a low level at 312 hr after implantation. The level of compound 22 rose gradually from 48 hr to 72 hr after treatment, and decreased to zero level at 120 hr. The presence of this compound was detected again at 312 hr after estrogen implantation, but still at a lower level than for the controls.

Study 2: Volatile Profiles of Male Pine Vole Urine. The profile of castrate male urine was very similar to that of intact male urine. Quantitative comparisons showed that only the phenylacetone level (peak 14) was significantly higher

FIG. 3. Relative effect of estrogen treatment on urinary volatiles in adult pine vole females. The control conditions: intact and ovariectomized values are represented at 01 h and 02 h after implantation. The peak area (arbitrary units) of selected compounds at various times after estrogen implantation are presented in the following groups: A, ketones; B, lactone and ketone; C, pyrazines; D, nitriles; E, aldehydes; and F, unidentified. The arrows indicate the time of capsule implantation. The asterisks indicate a significant ($P < 0.01$) difference between peak areas (\pm SEM) of intact and ovariectomized females.

in intact male urine than in castrate urine (1.4 ± 0.3 vs. 0.5 ± 0.1 arbitrary units; $P < 0.05$).

A quantitative comparison of the urinary volatiles of intact males and intact females showed four compounds at significantly ($P < 0.05$) different levels (Figure 4). Peaks 3, 6, and 17 (2,5-dimethylpyrazine, 2,3,5-trimethylpyrazine, and γ -octanoic lactone) were significantly higher in female urinary samples as compared to the male samples. Only one compound, *p*-methylpropenylbenzene (peak 10), was significantly higher in the male urine in comparison to the female urine. No compounds typical to either the female or male were observed.

FIG. 4. Sex-dependent changes in peak areas (\pm SEM) of urinary volatiles from pine vole, *Microtus pinetorum*. Lettered bars (a) indicate significant changes ($P < 0.05$) over unmarked bars.

DISCUSSION

A typical gas-chromatographic profile of pine vole urine contains relatively few volatile constituents (around 30) as compared with the volatile-rich house mouse urine (well over 100 constituents; Schwende et al., 1986).

Many of the compounds present in pine vole urine have also been recognized as mouse urinary volatiles (Schwende et al., 1986; Andreolini et al., 1987; Jemiolo et al., 1987). Benzaldehyde, *p*-cresol, phenol, phenylacetone, and 6-methyl-5-hepten-2-one are common to both vole and house mouse urine. However, some urinary constituents appear to be typical to the vole. These compounds are γ -octanoic lactone, γ -nonanoic lactone, γ -decanoic lactone, and δ -decanoic lactone.

In female pine voles, 10 identified volatiles demonstrated significant changes in concentration after hormonal manipulation. Ovariectomy depresses the concentration of pyrazines, phenylacetone and γ -octanoic lactone when compared to the levels recorded for intact animals. Twenty-four-hour exposure to male-soiled bedding or 48- to 96-hr estrogen treatment of mature female pine voles also tended to depress the concentration of selected compounds in great proportion when compared to intact animals. Both male-soiled bedding and estrogen implantation provoke an increase in concentration of only two compounds: nonanal (peak 8) and an unidentified substance (peak 22). The similarities in appearance of volatile profiles from exposed females to these from estrogen-treated animals can be attributed to the elevated estrogen levels in exposed females triggered by male chemosignals. It has been shown that chemical cues from male urine may trigger the hormonal system, leading to secretion of estrogen and reproductive activation in immature and adult virgin female voles (Carter et al., 1980; Baddaloo and Clulow, 1981; Petersen, 1986).

Urine from female voles (Getz et al., 1983; Frankiewicz and Marchlewska-Koj, 1985), similar to that from the house mouse (Drickamer, 1977), features a chemical signal that suppresses reproductive maturation in other females. We have previously established that 2,5-dimethylpyrazine present in the urine of grouped female mice delays puberty in female conspecifics (Novotny et al., 1986). Results of the present study reveal that urine of *Microtus pine-torum* also contains two pyrazine derivatives: 2,5-dimethylpyrazine and 2,3,5-trimethylpyrazine. Ovariectomy significantly depressed concentration of both compounds. Exposure and estrogen implantation abolished their presence in the urine. In mice, ovariectomy does not change the puberty-delaying biological activity of urine. Urine from ovariectomized animals is equally as effective in delaying puberty as intact urine (Drickamer et al., 1978). In contrast to *Mus musculus*, pine voles are induced ovulators (Schadler and Butterstein, 1979). The reproductive system of female voles remains in a quiescent state in the absence of stimulation from males. Induced ovulation arises as a direct result

of the acute initiation of a surge of LH secretion by external (sexual) stimuli. An LH surge initiated by endogenous mechanisms involving endocrine feedback is typical for spontaneous ovulators such as the house mouse. The different hormonal environment of female pine voles can thus have a different influence on the levels of metabolites excreted in the urine as compared to the house mouse.

Castration of males in both *Mus musculus* (Bruce, 1965), and *M. ochrogaster* (Carter et al., 1980) reduces the stimulatory potency of their urinary chemosignals. In the present study, however, only one urinary volatile exhibited significant quantitative differences after castration. This compound, phenylacetone, has also been observed in the urine of several other mammals (Schwende et al., 1986; Raymer et al., 1986). The lack of differences between intact and castrate urinary volatiles may indicate that chemosignals of male pine voles are either not dependent upon testosterone levels or that they are nonvolatile substances and, therefore, not observed in the volatile profile. Lepri and Vandenberg (1986) reported that intact and castrate urine were equally effective in eliciting female reproductive activation.

There are no qualitative differences between urinary profiles of male and female pine voles. It is, however, worthwhile to note that female urine contains three volatiles in higher concentration than male urine: γ -octanoic lactone (ovariectomy decreased its level) and two pyrazines (structurally similar to the puberty delay factor in female mouse urine). Male vole urine contained only one compound (*p*-methylpropenylbenzene) that was present in higher concentration when compared with female urine. Its concentration, however, was not changed after castration.

This paper describes, for the first time, a chemical analysis of urinary volatiles in pine voles. Several lactone derivatives were found as the typical constituents of this species. In contrast to the previous investigation of the house mouse by this laboratory, no drastic quantitative differences were found due to a variety of endocrinological manipulations, although statistically significant excretion changes were noticed. Future inquiries into the role of chemicals in the reproduction of the pine vole may need to concentrate on the nonvolatile urinary fraction.

ECOLOGICAL ASPECTS OF CACTUS TRITERPENE GLYCOSIDES I. THEIR EFFECT ON FITNESS COMPONENTS OF *Drosophila mojavensis*

JAMES C. FOGLEMAN and LYDIA ARMSTRONG

Department of Biological Sciences
University of Denver
Denver, Colorado 80208

(Received October 20, 1987; accepted February 16, 1988)

Abstract—The effects of pentacyclic triterpene glycosides extracted from agria and organ pipe cacti on three fitness parameters of the cactophilic fruit fly, *Drosophila mojavensis* were tested. Triterpene glycosides from organ pipe increased development time and reduced larval viability while those from agria produced smaller adults (reduced fecundity). In addition, the microbial communities in the organ pipe saponin media were less dense than those in the media to which agria saponins had been added. The role of cactus triterpene glycosides in the ecology of this *Drosophila* species is discussed.

Key Words—*Drosophila*, Diptera, Drosophilidae, triterpene glycosides, cactus, fitness components, host-plant relationships.

INTRODUCTION

One of the most interesting classes of natural organic compounds is the triterpenoidal saponins (triterpene glycosides). These compounds have comparatively large molecular weights and high polarity, are structurally diverse, and are widely distributed among members of the plant kingdom. The interest in these compounds stems from the incredible variety of biological activities that they reportedly exhibit. In addition to the characteristic foaming when aqueous solutions are shaken, saponins are hemolytic and have been used as herbal drugs with expectorant, antitussive, tonic, and diuretic activities. Certain purified saponins have been demonstrated to be antiinflammatory, work on the central

nervous system, prevent stress ulcers, have antifatigue activity, be antibacterial and antifungal agents, stimulate lipid metabolism, promote nucleic acid and protein synthesis, have antitumor or anticancer effects, and kill fish and some insects (Natori et al., 1981; Chauhan and Srivastava, 1978; Chandel and Rastogi, 1980). Many of the biological effects of the famous Oriental herb drug, ginseng root, are attributed to the saponins that are present in this plant (Chandel and Rastogi, 1980). The biological activity is not necessarily the sole property of the sapogenin (aglycone) portion of these molecules since recent studies of saponins isolated from Oriental drugs have discovered that saponins consisting of the same sapogenin, but with different sugar sequences, have different biological activities (Natori et al., 1981).

Investigations into the triterpenes of columnar cacti began in the 1950s with the work of Carl Djerassi and his colleagues. They reported the presence of glycosides of oleanolic acid and thurberogenin in organ pipe cactus (Djerassi et al., 1953; Marx et al., 1967) and glycosides of gummosogenin, machaeric acid, and machaerinic acid in agria cactus (Djerassi et al., 1954, Djerassi and Lippman, 1955). In the 1970s, William Heed and Henry Kircher joined in the study of cactus saponins, prompted by their suspicion that these compounds played a role in *Drosophila* ecology. Organ pipe cactus (*Stenocereus thurberi*) and a related species, agria cactus (*S. gummosus*), are endemic to the Sonoran Desert of North America, and necrotic stems of both cacti are used as feeding and breeding substrates of the cactophilic fruit fly, *Drosophila mojavensis* (Heed, 1978). Kircher (1977, 1980) identified a third pentacyclic triterpene, queretaroic acid, in the glycoside fraction of organ pipe. He also reported that the concentration of triterpene glycosides in organ pipe stems decreases from the surface to the inner part of the plant and that glucose and rhamnose are two of the constituent sugars. It was suggested that the concentration gradient of triterpene glycosides may reflect their role as a protective agent against herbivores and/or for osmotic protection against freezing.

Subsequent studies (reported in Kircher, 1982) of the saponins of agria and organ pipe have demonstrated their relatively high concentration and contributed some structural information. On a dry weight basis, the tissue averages of saponins for organ pipe and agria are 28% and 36%, respectively. Each of the triterpenes in organ pipe is attached to a tetrasaccharide consisting of two glucose and two rhamnose residues. The structural relationships among agria triterpene glycosides is not as well understood. A preliminary study involving the hydrolysis of agria triterpene glycosides resulted in an approximate 2:1 ratio of glucose to rhamnose and a 4:1 ratio of sugars to aglycones.

Information on the role of triterpene glycosides in *Drosophila* ecology has been rather fragmentary. The fact that *D. nigrospiracula*, another cactophilic fly, does not typically use agria and organ pipe rots has been known since the

early 1970s (Fellows and Heed, 1972). One of the major chemical differences between these cacti and the typical host plants for *D. nigrospiracula* (saguaro, *Carnegiea gigantea*; and cardon, *Pachycereus pringlei*) is the presence of triterpene glycosides. For this reason, agria and organ pipe saponins were thought to be involved in determining host plant utilization patterns by the desert-adapted flies. Kircher (1977) first reported that the addition of organ pipe triterpene glycosides to the medium inhibited the development of *D. nigrospiracula* larvae. Subsequent studies, using first-instar larvae rather than adults as the starting material, failed to substantiate the previous study and, instead, pointed to several other compounds as being the primary determinants in excluding *D. nigrospiracula* from agria and organ pipe necroses (Fogleman et al., 1986). However, a statistically significant reduction in the larval viability of *D. mojavensis* in the presence of organ pipe triterpene glycosides was demonstrated.

Several other ecological aspects of agria and organ pipe cacti and their resident drosophilids are noteworthy. First, the geographic distributions of these two species of cacti are different. Organ pipe occurs on both the Baja peninsula and on the mainland (Sonora, Mexico), while agria is essentially limited to the peninsula (Heed, 1978). The populations of *D. mojavensis* in the two regions are genetically differentiated and partially reproductively isolated (Heed, 1978; Zouros and d'Entremont, 1980). *Drosophila mojavensis* on the peninsula primarily use agria rots as substrates even though organ pipe cacti are present, and, finally, the thorax lengths of wild-caught *D. mojavensis* females from agria in Baja are smaller than those from organ pipe on the mainland (0.8–0.9 mm vs. approx. 1.0 mm, respectively; Mangan, 1982). Thorax length in flies is a fitness parameter that is positively correlated to fecundity (Mangan, 1978) and migratory ability (Roff, 1977).

In an extensive set of experiments, Etges and Heed (1987) investigated the variation in three fitness components, egg-to-adult viability, development time, and adult thorax size, between Baja and mainland populations of *D. mojavensis* as adaptive responses to the host plant shift from agria to organ pipe. They found that organ pipe rots were qualitatively poorer substrates than agria rots for both populations, especially at higher larval densities. Using organ pipe as a substrate caused longer egg-to-adult development times, lower viabilities, and smaller thorax sizes than agria. But since whole tissue was used, these experiments do not specifically address the question of which chemical constituents of the cacti are responsible for the observed variation in fitness components. The experiments reported herein were designed to test the effect of agria and organ pipe saponins on fitness parameters in *D. mojavensis* in order to clarify their role in producing differences in these fitness components. This information should contribute to our understanding of the adaptation of *D. mojavensis* to agria and organ pipe as it relates to host plant utilization.

METHODS and MATERIALS

Triterpene Glycoside Extraction. Organ pipe and agria triterpene glycosides were extracted from fresh tissue as follows: cactus tissue (without the skin and the woody core) was homogenized in a blender with an equal volume of methanol. The homogenate was filtered through a Buchner funnel, and the residue was exhaustively extracted with 2:1 chloroform-methanol solvent in a continuous Soxhlet extractor. The original methanol and the chloroform-methanol filtrates were combined, evaporated to dryness, and distributed between water and ether in a large separatory funnel. The aqueous phase was removed and extracted with *n*-butanol. Purified triterpene glycosides were obtained by concentration of the butanol via a rotary evaporator followed by drying in a 50°C oven. Several kilograms of tissue from each cactus species were used in order to insure that a sufficient amount of triterpene glycosides was obtained. Purity of the glycosides was checked by thin-layer chromatography.

Test Media. Media for testing the effect of triterpene glycosides on larval viability, developmental rate, and thorax length were prepared by adding the glycosides to homogenized saguaro tissue that had been previously rotted. Saguaro was used as the basic substrate because its secondary chemistry does not include triterpene glycosides or any other compounds at concentrations that would affect the larval viability of *D. mojavensis* (Kircher, 1982). In addition, the use of saguaro provides a substrate that is much closer to natural agria and organ pipe rots with respect to substrate consistency and microorganismic growth characteristics than artificial media. The test substrate was prepared by homogenizing 2 k of fresh saguaro tissue and inoculating it with tissue and rot liquid from an established rot. After 10 days of incubation, the saguaro rot was divided into five batches of 300 g each and triterpene glycosides (TTGs) were added as follows: no TTGs (control), 13.5 g of agria TTGs, 18.0 g of agria TTGs, 13.5 g of organ pipe TTGs and 18.0 g of organ pipe TTGs. The quantities, 13.5 and 18.0 g, represent 30% and 40% dry weight, respectively, which are close to the published concentrations of 28% dry weight in organ pipe and 36% in agria (Kircher, 1982). In all cases, the resulting mixture was blended to ensure homogeneity and distributed into 12 Petri plates (25 g of homogenate per plate). Each plate was then inoculated with 1 ml of a suspension of six species of cactophilic yeasts commonly isolated from natural rots of both agria and organ pipe. The suspension was made by harvesting 48-hr cultures of each species. These yeasts were originally obtained from Dr. Tom Starmer (Syracuse University) and had been kept in lab culture for several years. The yeast species (with Syracuse University identification numbers) were *Pichia cactophila* (78-32), *P. mexicana* (79-289.2), *P. amethionina* var. *amethionina* (81-265.1), *Candida sonorensis* (80-334.4), *C. ingens* (81-208.3), and *Cryptococcus cereanus* (80-322.6). All

plates were incubated for three days in order to allow the yeasts to reach a reasonable density.

Drosophila mojavensis Larvae. A multifemale strain of *D. mojavensis* was established from approximately 50 males and females collected from natural agria rots at Punta Onah, Sonora, Mexico, in December 1985. Agria and organ pipe cacti are sympatric in this area. The strain had been maintained in the laboratory on Carolina instant *Drosophila* food (Formula 4-24) for six months. First-instar larvae were obtained by allowing adults to oviposit on water-agar Petri plates which contained a 2.5 cm patch of paste made from bakers' yeast and water. The paste stimulates oviposition. Adults were transferred to new plates on a daily basis, and eggs were given 24 hr to hatch. First-instar larvae were, therefore, 24 hr old or less. A small probe was used to transfer the larvae from the oviposition plates onto a 2.5 cm square of paper towel in the center of each plate of test medium. Two different larval densities, 50 larvae per plate and 400 larvae per plate, were used. These densities were chosen so that comparisons could be made with previous experiments (Etges and Heed, 1987). Six replicates of each test medium were produced. A replicate series, then, consisted of 10 Petri plates: 50 larvae-no TTGs, 50 larvae-30% agria TTGs, 50 larvae-30% organ pipe TTGs, 50 larvae-40% agria TTGs, 50 larvae-40% organ pipe TTGs, 400 larvae-no TTGs, 400 larvae-30% agria TTGs, 400 larvae-30% organ pipe TTGs, 400 larvae-40% agria TTGs, and 400 larvae-40% organ pipe TTGs. Each replicate series was set up using larvae from the same collection batch. All experiments were performed at ambient temperature and humidity. These conditions varied slightly during the experiments, but all plates were exposed to the same environmental conditions.

Microbial Density Determinations. Replicate series numbers 3, 4, and 5 were sampled one week after the introduction of larvae. A small amount (0.1 g) of the medium from each plate was taken and examined to ensure that no larvae were inadvertently included. These samples were serially diluted, and aliquots of the dilutions tubes were plated on both acidified yeast extract-malt extract agar (AYMA) and nutrient agar (NA) containing antifungal chemicals. AYMA is a general yeast medium that supports the growth of all cactophilic yeasts. It was acidified to pH 3.8 with 1 N H_3PO_4 in order to inhibit the growth of bacteria. Nutrient agar is a general growth medium for bacteria. Cycloheximide (100 $\mu\text{g}/\text{ml}$) and amphotericin B (10 $\mu\text{g}/\text{ml}$) were added to the NA to inhibit the growth of yeasts. The number of colonies that appeared on each plate was recorded and used to calculate the colony forming units (CFUs) per gram of test substrate.

Data Collection and Analysis. The number of adults that eclosed from each plate was recorded daily until eclosion ceased. The total for each plate divided by the number of larvae that were introduced (multiplied by 100) represents the

percent viability (larva to adult). Mean developmental rate was calculated as the average of the frequency distribution relating the number of flies that eclosed (Y axis) to the number of days after the start of the experiment (X axis). Thorax length was measured on a random sample of five males and five females eclosing during the first three days of the eclosion period for each plate. Data were analyzed using two-way analysis of variance tests (Sokal and Rohlf, 1981).

RESULTS AND DISCUSSION

The means and standard deviations of the fitness parameters that were measured are presented in Table 1, and the statistical analyses of these data are given in Table 2. In general, the results of the two-way analyses of variance were the same for all of the fitness parameters: high significance ($P < 0.01$) with respect to treatments (triterpene glycoside type and concentration) and larval density and no significant interaction. Each fitness parameter will now be discussed in turn.

Estimates of larval viability of *D. mojavensis* under various conditions have appeared in several recent reports (Fogleman, 1984; Fogleman et al., 1986; Etges and Heed, 1987). Different substrates (agria, organ pipe, and saguaro) and different larval densities are known to influence this parameter. The control data for larval viability in saguaro homogenate given in Table 1 are comparable to the average viabilities of cactophilic *Drosophila* species in their typical cactus substrate, which was reported as about 75% (Fogleman, 1984). From the statistical analysis, substrate treatment and larval density were about equal in significance. At a larval density of 50 per replicate, the two concentrations of organ pipe triterpene glycosides resulted in the lowest average percent viabilities. At the higher larval density of 400 per replicate, 40% organ pipe saponins again produced the lowest viability. Thus, the glycosides of organ pipe appear to be more effective than those of agria. In all cases, the addition of triterpene glycosides to the medium resulted in lower viability, and the greater the concentration, the lower the parameter value.

All other parameters being equal, development time is negatively correlated with fitness in *Drosophila* (Lewontin, 1965). The statistical analysis of the larva-to-adult development rate shows that, although both treatment and larval density are significant sources of variation in this parameter, larval density produces the major effect ($F = 4.297$, $P < 0.01$ vs. $F = 182.550$, $P \ll 0.001$ for treatments and larval density, respectively). The pattern of the effects produced by the various triterpene glycosides and larval densities is, however, identical to that for larval viability. That is, at 50 larvae per replicate, the two concentrations of organ pipe saponins resulted in the longest development times and, therefore, the lowest fitness. At 400 larvae per replicate, the longest devel-

opment times were measured in the two 40% concentration treatments regardless of the source of saponins, but the addition of organ pipe triterpene glycosides at 40% dry weight resulted in the longest development time. With one exception (30% organ pipe TTGs), addition of triterpene glycosides increased the larva-to-adult development time and lowered fitness.

One of the goals of these experiments was to clarify the role of cactus triterpene glycosides in producing the observed differences in thorax sizes of *D. mojavensis* using agria on the Baja Peninsula and those using organ pipe on the mainland. Analysis of treatment effects on thorax lengths (Table 1) were performed keeping sexes separate since female *Drosophila* are typically larger than males. The data clearly demonstrate that, while larval exposure to organ pipe triterpene glycosides results in flies with thorax sizes similar to those from control substrates, agria triterpene glycosides make flies noticeably smaller. Since the 30% organ pipe and 40% agria TTG treatments are closest to the average tissue values for these cacti (Kircher, 1982), mean thorax sizes from these treatments were statistically compared to means from the controls using the Student-Newman-Keuls (SNK) procedure (Sokal and Rohlf, 1981). The results are given below (underlining connects treatments whose means are not significantly different at the 0.05 level):

Females, 50 larvae/replicate: Agria < Organ pipe Control

Females, 400 larvae/replicate: Agria < Organ pipe Control

Males, 50 larvae/replicate: Agria Organ pipe Control

Males, 400 larvae/replicate: Agria Organ pipe Control

The reduction in thorax length by agria triterpene glycosides was more significant in females than in males, but, in all of the above cases, the agria saponins produced significantly smaller flies as compared to controls. The females that eclosed from the agria treatments were also significantly smaller than the females from the organ pipe treatments.

Measuring the thorax size of the flies that were first to emerge might be misleading if thorax size changes as a function of development time. In order to check on this phenomenon, thorax measurements were taken on a smaller sample of flies that emerged approximately one week after the initial group. Although the differences in thorax lengths of flies emerging from the organ pipe TTG medium as compared to the agria TTG medium were reduced in this sample, the overall conclusions regarding the effect of triterpene glycosides on thorax sizes remained unchanged.

The statistical analyses of thorax sizes (Table 2) exhibit the same patterns as the previous analyses in that larval density is the major source of variation.

^aThe effects of triterpene glycosides (TTGs) from *agria* and organ pipe cactus (treatment) on larva-to-adult viability, development time, female thorax length, male thorax length, and bacterial growth at two different larval densities are indicated. Data on bacterial growth were log₁₀-transformed prior to analysis.

However, with respect to thorax size, it is the *agria* saponins, rather than those of organ pipe, that reduce fitness.

Etges and Heed (1987) concluded that organ pipe is a nutritionally poorer substrate than *agria* and suggested that this may be partly due to differences in the density of the microbial communities residing in rots of the two cactus species. Microbes are known to be essential components of the ecology of *D. mojavensis* since sterilized organ pipe tissue does not support the development of axenic larvae (Starmer, 1982). *Drosophila mojavensis* larvae (from sterilized eggs) are also not viable on fresh *agria* tissue (Etges and Heed, 1987). Determinations of yeast community density (cells per gram) from naturally occurring

agria and organ pipe rots show a large amount of variation between samples even within a species (Fogleman and Starmer, 1985). The largest yeast densities, however, have been measured in agria.

The results of the experiment on the effect of triterpene glycosides from agria and organ pipe on the growth of yeasts and bacteria are given in Table 3. The data on yeast density were not statistically analyzed as before due to the large number of samples in which the density was below the limits of detection. The detection limit was 1000 cells/g of tissue (a \log_{10} of 3.000) due to the dilution series that was employed. The dilutions that were plated were chosen primarily because previous experience suggested that the densities would be considerably higher than the detection limit, and, therefore, the lower dilutions were not plated. In general, yeast growth in the control substrate and in the substrates with organ pipe triterpene glycosides was minimal. Addition of agria saponins promoted the growth of the yeast community. Previous experiments

^aThe figures presented represent the logarithm of the colony forming units (CFUs) per gram of necrotic tissue. Counts were taken seven days after the introduction of larvae.

have demonstrated that some cactophilic yeasts can use cactus triterpene glycosides as a carbon source (Williams, 1985) while others (not included in this study) are definitely inhibited by the presence of cactus triterpene glycosides (Starmer et al., 1980; Phaff et al., 1985). The most likely explanation for the low cell density of yeasts in the control substrate is the absence of triterpene glycosides and the relatively low concentration of other usable carbohydrates (Kircher and Al-Azawi, 1985). Differences in the response to the saponins of the two cactus species may be related to the differences in their chemical structures, particularly with respect to the carbohydrate moieties. The fact that yeast density was significantly greater in the 30% agria TTG treatment than in the 40% agria TTG treatment ($F = 13.876$; $df = 1,8$; $P < 0.01$) demonstrates the complexity of the interaction between cactus saponins and yeasts. Further experimentation is necessary to fully elucidate these relationships.

Table 3 also contains the results of the determinations of bacterial densities in the experimental media. The statistical analysis of these data appears in Table 2. When all of the data are analyzed together, the treatment effect (TTGs) was the only significant source of variation in the data, and the bacterial communities in media containing organ pipe saponins were noticeably less dense. When the data from the organ pipe treatments are analyzed by themselves, however, larval density is also shown to significantly reduce the bacterial concentration ($F = 8.140$; $df = 1,8$; $P < 0.01$). The overall conclusion from this portion of the experiments is that triterpene glycosides do influence microbial communities in that both yeasts and bacteria are reduced in density when exposed to organ pipe saponins as compared to those of agria. Since these microbes are nutritional components for *Drosophila*, organ pipe cactus may be a nutritionally poorer substrate due to the triterpene glycosides.

With respect to viability and development time, our results agree very well with those of Etges and Heed (1987). As previously mentioned, they found that organ pipe tissue caused lower viabilities and longer development times than agria tissue for both mainland (Arizona) and Baja populations of *D. mojavensis*, especially at higher larval densities. Our data, however, strongly conflict with theirs on the subject of thorax sizes. They reported that, regardless of the larval density (e.g., 50, 100, 200, and 400 eggs/25 g cactus) and the population (mainland or Baja), thorax sizes of both males and females were smaller on organ pipe tissue than on agria. The results reported herein indicate that their observations on thorax sizes are not due to the cactus saponins since the saponins, by themselves, produce the opposite effect. A similar set of experiments using other chemical constituents of these cactus species would be useful in substantiating their data and implicating the chemical components (if any) that are responsible. Organ pipe lipids have been shown to significantly reduce the thorax size of *D. mojavensis* (Starmer, 1982), but, unfortunately, no comparable study using agria lipids has been done. Several chemical constituents of

the organ pipe lipid fraction (e.g., fatty acids and sterol diols) have been shown to have biological activity on fitness components of cactophilic *Drosophila* (Fogleman et al., 1986; Fogleman and Kircher, 1986), although they have not been individually tested for their effect on thorax size. Finally, it is possible that different geographic strains of *D. mojavensis* may vary in their response to cactus saponins. This idea, however, is not supported by the work of Etges and Heed (1987), since the two strains that they used (Arizona and the Baja Peninsula) were qualitatively identical with respect to their fitness response patterns.

In addition to their effect on fitness components, cactus triterpene glycosides have been implicated as playing a major role in host-plant selection by *D. mojavensis*. In general, *D. mojavensis* prefers agria over organ pipe in areas where the two cacti are sympatric (Fellows and Heed, 1972). Laboratory experiments have shown that this behavioral preference is determined by the pattern of volatile alcohols, esters, and fatty acids that are produced during microbial decay (Downing, 1985; Fogleman and Heed, 1989). The volatile pattern in naturally occurring necroses of agria and organ pipe are significantly different (Fogleman and Heed, 1989), and, since triterpene glycosides represent the major source of fermentable carbohydrates, they appear to be the chemical basis of host-plant selection, at least for *D. mojavensis*.

In summary, our results demonstrate that the saponins from agria and organ pipe cacti do affect the three fitness parameters that were measured for *D. mojavensis*. Triterpene glycosides from organ pipe increased development time and reduced larval viability while TTGs from agria produced smaller adults (reduced fecundity). In addition, the microbial communities in the organ pipe media were less dense than those in the agria media. It is difficult to state which effect(s) may be the most important to the flies with respect to inclusive fitness, but, if one views the behavioral preference for agria as a result of natural selection to maximize fitness, then necrotic organ pipe tissue is the poorer substrate. The triterpene glycosides appear to be involved in the ecology of this *Drosophila* species from the standpoints of both host-plant utilization and host-plant selection.

Acknowledgments—The authors would like to thank Joan Foster, Mike Frank, and Drs. Jesus Abril, Tom Starmer, and Bill Etges for critically reviewing an earlier version of this paper. This research was supported by NIH grant GM34820 to J.C.F.

Aplysia SEA HARE ASSIMILATION OF SECONDARY
METABOLITES FROM BROWN SEAWEED,
Styopodium zonale

WILLIAM H. GERWICK and GEORGE WHATLEY

College of Pharmacy
Oregon State University
Corvallis, Oregon 97331

(Received November 16, 1987; accepted February 11, 1988)

Abstract—Juvenile *Aplysia dactylomela* were found feeding in abundance on the tropical brown alga *Styopodium zonale*, a seaweed previously shown to contain numerous unique terpene-quinone natural products. Lipid extracts of these herbivorous mollusks were shown by TLC and HPLC-NMR analyses to contain appreciable quantities of two *S. zonale* metabolites as well as one new but closely related compound. Spectroscopic analyses of the new compound in concert with functional group modifications identified this new compound as 3-keto epitaondiol. A careful analysis of the seaweed extract failed to locate this ketone, and thus, it most likely represents an *Aplysia*-biotransformed compound. This is the first clear reported observation of metabolite transfer between an alga of the phylum Phaeophyta and a sea hare.

Key Words—Sea hare, *Aplysia dactylomela*, *Styopodium zonale*, mollusk, brown seaweed, Phaeophyta, diterpene-quinone, metabolite transfer, biotransformation, 3-ketoepitaondiol.

INTRODUCTION

There are numerous examples of the isolation of terpenoid compounds from sea hares of the genus *Aplysia*, which probably originate from their algal diet (Faulkner, 1984). Most of these examples are for the assimilation of red (Rhodophyta) algal secondary metabolites (Erickson, 1983). By contrast, there are relatively few metabolites reported from sea hares that have as an ultimate biogenetic origin a brown (Phaeophyta) (Amico et al., 1980; Gonzalez et al., 1983; Ireland et al., 1976; Midland et al., 1983; Sun and Fenical, 1979), green (Chlorophyta), or blue green algae (Cyanobacteria) (Rose et al., 1978). There are

only three circumstantial cases (isolation of structurally related metabolites from the two sources) in which it has been hypothesized that a sea hare assimilates the secondary metabolites of a brown alga. Specifically, related bicyclic diterpenes were isolated from the sea hares *Dolabella californica* (Ireland et al., 1976) and *Aplysia dactylomela* (Gonzalez et al., 1983) and from the brown algae *Dictyota dichotoma* (Amico et al., 1980) and *Glossophora galapagensis* (Sun and Fenical, 1979). Further, lactone-containing diterpenes related to acetoxycrenulide were isolated from both the sea hare *Aplysia vaccaria* and the brown alga *Dictyota crenulata* (Midland et al., 1983).

Thus, it was of interest to us to observe, in the context of a survey of the biomedicinal potential of Puerto Rican seaweeds (Ballantine et al., 1987), numerous juvenile *Aplysia dactylomela* feeding upon the tropical brown alga *Styopodium zonale*, a well-recognized source of several unique terpenoid secondary metabolites (Gerwick et al., 1979; Gerwick and Fenical, 1981). We were particularly curious to examine these herbivorous mollusks for the presence of any *S. zonale* natural products or related biotransformation products. The seaweed substances had been previously shown to be strongly toxic to predaceous tropical reef fish, and hence, of potential importance to the adaptive strategy of these plants (Gerwick and Fenical, 1981). By extension, it is possible that the assimilation of these brown algal metabolites by sea hares could be of importance to their survival in predator rich environments.

A combination of thin-layer chromatography (TLC), high-performance liquid chromatography (HPLC), and nuclear magnetic resonance (NMR) spectroscopy were employed in the analysis of the lipid extract obtained from these mollusks and conclusively showed that several of the seaweed metabolites were present in appreciable quantities in the sea hares. Furthermore, a new, although closely related, compound was isolated from the sea hares and its structure determined by classic spectrochemical methods. Based on the structural similarities of this new compound to others reported from the seaweed, and found in the sea hares, this new compound most likely represents a biotransformation product. A careful examination of the seaweed blades upon which the *Aplysia* were found feeding failed to find detectable quantities of the new metabolite. It would appear that these sea hares are capable of assimilating the secondary metabolite chemistry from a wide variety of diets, including *S. zonale*, and furthermore that the secondary metabolites of a wide variety of algae can function in the sea hares' chemical defense strategy.

METHODS AND MATERIALS

General. Ultraviolet spectra were recorded on an Aminco DW-2a UV-Vis spectrophotometer and infrared spectra on a Perkin Elmer 727 spectrophotometer. Nuclear magnetic resonance (NMR) spectra were recorded on Varian

EM 360, FT-80A and Bruker AM 400 spectrometers, and all shifts are reported relative to an internal TMS standard. Low-resolution mass spectra (LRMS) were obtained on a Varian MAT CH7 spectrometer, while high-resolution mass spectra (HRMS) were obtained on a Kratos MS 50TC. High-performance liquid chromatography (HPLC) was done using a Waters M-6000 pump, U6K injector, and R401 differential refractometer, while thin-layer chromatograms (TLC) were made using Merck aluminum-backed TLC sheets (silica gel 60 F₂₅₄). All solvents were distilled prior to use.

Collection and Extraction. A total of 133 individuals of juvenile (average fresh weight per animal = 130 mg, approximately 1 cm long) *Aplysia dactylomela* were collected from the surfaces of *Styopodium zonale* found growing in abundance in 2- to 6-m water depth at Vega Baja on the North Coast of Puerto Rico in June and July 1984. These were preserved in MeOH and subsequently repetitively extracted with chloroform and methanol (2:1). The chloroform-soluble material (956 mg) was analyzed by thin-layer chromatography and then preparatively fractionated employing vacuum chromatography over silica gel (Kieselgel). A steep gradient of isoctane-ethyl acetate-methanol was used to rapidly fractionate this extract into 13 fractions. Recombination of fractions 4-6 (eluting with 30-50% ethyl acetate in isoctane) gave 78.9 mg from which approximately 10 mg of (+)-epitaondiol (**2**) (identified from its high-field NMR spectrum and showing $[\alpha]_D = +31^\circ$; lit = $+43^\circ$) and 30 mg of the new compound (**3**) were isolated using HPLC (3.9 mm \times 50 cm μ -Porasil, 15% EtOAc-isoctane) (Scheme 1). *S. zonale* collected at the same time as the *Aplysia* collection was similarly stored in MeOH, extracted with CHCl₃-MeOH (2:1), and repetitively fractionated over silica gel in the vacuum mode to yield concentrated fractions of materials of the same polarity characteristics as the new compound.

3-Ketoepitaondiol (3). Pure **3** showed the following: IR (CHCl₃) 3380, 2950, 1700, 1605, 1480, 1380, 1145, 1130, 990, 860 cm⁻¹; LRMS (*m/z*, 70 eV) obs. M+ 410 (100), 382 (5), 273 (38), 217 (5), 215 (5), 205 (6), 203 (6), 189 (13), 175 (36), 161 (11), 137 (55), 121 (23), 107 (17), 95 (18), 81 (19), 58 (25), 55 (30); HRMS obs. M+ 410.2844 (C₂₇H₃₈O₃, 2.3 mamu dev., 1.5%); [¹H] NMR (400 MHz, CDCl₃) δ 6.45 (1H, d, *J* = 2.9 Hz), 6.39 (1H, d, *J* = 2.9 Hz), 4.31 (1H, bs), 2.72 (2H, m), 2.53 (2H, m), 2.31 (1H, ddd, *J* = 15.5, 12.2, 2.5 Hz), 2.09 (3H, s), 1.92 (2H, s), 1.74 (1H, dd, *J* = 13.4, 5.0 Hz), 1.28 (3H, s), 1.20 (3H, s), 1.09 (3H, s), 1.04 (3H, s), 0.81 (3H, s).

Acetate 4. The acetate was formed by stirring 10.1 mg of a crude fraction containing **3** in 1 ml pyridine and 1 ml acetic anhydride for 26.5 hr. The reaction was worked up by simple in vacuo removal of solvents to yield a mixture of related products. These were easily separated over HPLC (μ -Porasil, 3.9 mm \times 50 cm, 15% ETOAc in isoctane) to yield approximately 6 mg of **4**, which showed the following: $[\alpha]_D = +68.1^\circ$ (CHCl₃, *c* = 0.34); [¹H]NMR (400 MHz, CDCl₃) δ 6.64 (1H, bs) 6.62 (1H, bs), 2.75 (1H, dd, *J* = 13, 16 Hz),

are very limited; and (3) the assimilation and biotransformation of brown algal secondary metabolites by *Aplysia* is not well recognized. Hence, we made a substantial collection of these *S. zonale* grazing sea hares and have analyzed the crude lipid extract for the algal metabolites and related biotransformation products.

The alcohol-preserved specimens of *A. dactylomela* were extracted by normal methodology to yield a relatively rich organic extract, characteristic of the *Aplysia* sea hares (Faulkner, 1984). Comparison of this lipid extract with that obtained from the *S. zonale* plants upon which the sea hares were feeding showed that the distinctive red orthoquinone stypoldione (**1**), the major secondary metabolite in *S. zonale*, was clearly present in these animals (co-TLC with authentic material, approx. 5% of crude extract). Furthermore, by TLC analysis, several related compounds of a less polar nature were present in substantial quantities as well. Characterization of these, however, required vacuum liquid chromatography (Coll and Bowden, 1986) and HPLC separation followed by high-field NMR description.

Fractions eluting from a vacuum silica gel column with 30–50% ethyl acetate in isooctane were enriched in compounds which, on TLC, showed UV and acid-char characteristics similar to other known *S. zonale* secondary metabolites. These were combined and rechromatographed using normal-phase HPLC to give first the known compound (+)-epitaondiol (**2**) followed by a new compound (**3**), the spectroscopic structure elucidation of which is described below.

The new *Aplysia* natural product gave a small parent ion in the high-resolution mass spectrum, affording a molecular formula of $C_{27}H_{38}O_3$, a similar molecular formula to that of epitaondiol but containing an additional degree of unsaturation. The high-field [1H]NMR spectrum of **4** contained bands highly indicative of the diterpene-quinone structure type commonly observed in *Styopodium*. Specifically, two meta-coupled aromatic protons at δ 6.45 and 6.39 shifted to δ 6.64 and 6.62 in the monoacetate derivative (**4**). A broadened aromatic methyl group at δ 2.09 and a singlet methyl group at δ 1.28 in **3** provided further evidence for a chromane ring system as found in epitaondiol (**2**). A very favorable comparison between the chemical shifts and coupling constants for the coupling between H-2 β and H-1 α and H-1 β , the magnitudes of which are diagnostic for the stereochemistry of the protons at C-1 and C-2, showed the new compound to be stereochemically related to epitaondiol at C-2. Four additional methyl groups at chemical shifts similar to those found for epitaondiol were also in the high field [1H]NMR spectrum of **4**, suggesting a tricyclic skeleton as found in most of the other *Styopodium* metabolites. This was confirmed by high-field [^{13}C]NMR work, including a 1H - ^{13}C heteronuclear correlated NMR experiment, and provided a favorable comparison with epitaondiol [^{13}C]NMR shifts.

The major difference between the new metabolite (**3**) and other previously

described *Styopodium* compounds, such as epitaondiol (**2**), was the lack in the new compound of the C-14—CH(OH)— proton. Instead, the third oxygen in **3** was present as a ketone at C-14 as indicated by a 1700 cm^{-1} ketone stretch in the IR and a δ 219.9 carbonyl carbon in the ^{13}C NMR spectrum, thus accounting for the additional degree of unsaturation. The downfield chemical shift of this carbonyl is consistent with adjacent gem dimethyl groups, thereby further supporting the C-14 placement of this ketone functional group. Lack of sufficient sample precluded establishment of the absolute stereochemical relationship of 14-ketoepitaondiol (**3**) to naturally occurring (+)-epitaondiol (**2**). Most likely, however, this represents *S. zonale*-derived (+)-epitaondiol, which the sea hares have assimilated and selectively oxidized at the C-14 position.

Acknowledgments—We are grateful to Ms. Belinda Alvarado and Mr. Pablo Guevara for their help in collection and extraction of these marine organisms, and Mr. Chuck Cuttress for identifying our collections of juvenile *Aplysia dactylomela*. We appreciate the assistance of Mr. Rodger Kohner in obtaining high-field NMR data on the Department of Chemistry's Bruker AM 400 spectrometer, purchased in part through grants from the National Science Foundation (CHE-821690) and from the M.J. Murdock Charitable Trust. We further appreciate the help of Mr. Don Griffin and Brian Arbogast for help in obtaining high-resolution MS on a Kratos MS 50 TC spectrometer located at the College of Agricultural Chemistry, Oregon State University, and purchased with grants from the National Institutes of Health Division of Resources (DRR IS10RR01409). This work was supported by the Oregon Sea Grant Program (R/PD-51).

Abstract—Syntheses of all four stereoisomers (2*S*,5*S*; 2*S*,5*R*; 2*R*,5*R*; and 2*R*,5*S*) of chalcogran, a major component of the aggregation pheromone of *Pityogenes chalcographus*, and of all four isomers (2*Z*,4*Z*; 2*Z*,4*E*; 2*E*,4*E*; and 2*E*,4*Z*) of methyl 2,4-decadienoate (MD), the second major pheromone component, are briefly described. Attraction responses of walking beetles of both sexes were tested to mixtures of the synergistic pheromone components or analogs. These bioassays showed that the *E,Z* isomer of MD is the most active when tested with chalcogran. When tested with (*E,Z*)-MD, (2*S*,5*R*)-chalcogran was the most active stereoisomer, while 2*R*,5*R* and 2*R*,5*S* isomers had intermediate activities, and the 2*S*,5*S* isomer was inactive. There was no evidence that the relatively less active stereoisomers of chalcogran inhibited or promoted attraction to (2*S*,5*R*)-chalcogran with (*E,Z*)-MD. Male beetles only produce the active *E,Z* isomer of MD (inactive alone) and their hindguts contain the most active (2*S*,5*R*)- and least active (2*S*,5*S*)-chalcogran. A mixture of all MD isomers with racemic chalcogran was not significantly different in attractivity compared to (*E,Z*)-MD with racemic chalcogran, indicating no synergistic or inhibitory effects of the inactive isomers of MD.

Key Words—Synergism, aggregation pheromone, *Pityogenes chalcographus*, Coleoptera, Scolytidae, chalcogran, methyl (2*E*,4*Z*)-2,4-decadienoate, enantiomers, isomers, stereoisomers, synthesis, bioassay, structure-activity.

INTRODUCTION

The six-spined spruce bark beetle, *Pityogenes chalcographus* (in Germany called *Kupferstecher*), is a serious pest in Europe of Norway spruce [*Picea abies* (L.) Karst.], especially the younger trees. Both sexes of these tiny beetles (2 mm long) aggregate on host trees in response to a pheromone (Vité, 1965). Francke et al. (1977) isolated from males a unique spiroketal, chalcogran, which when released in the forest at 15 mg/hr attracted conspecifics. They isolated chalcogran by treating 100,000 beetles of both sexes with a juvenile hormone analog to induce synthesis of chalcogran in males. They then used a differential diagnosis method (Vité and Renwick 1970) to compare the sexes for volatile chemical differences, which revealed *E* and *Z* isomers of chalcogran and 1-hexanol as being unique to the male. However, when 1-hexanol was added to synthetic racemic chalcogran (46% *E*:54% *Z*, Koppenhoefer et al., 1980), there was no apparent increase in attraction (Francke et al., 1977). Furthermore, due to the rather large amounts of chalcogran required to elicit attraction in the field (15 mg/hr), Francke et al. (1977) suggested that (1) "a second component may be necessary for maximum response" or (2) "it is also possible that the enantiomeric composition of the isomers is critical for maximum beetle response." Using gas chromatography (GC) on a chiral liquid phase, Koppenhoefer et al. (1980) were able to separate synthetic chalcogran containing all four stereoisomers into the individual components (two diastomeric pairs of enantiomers). Using the same technique, Schurig and Weber (1984) found that an extract of male beetles consists of a mixture of only two of the stereoisomers, namely the diastereomers 2*S*,5*R* 1 and 2*S*,5*S* 1 (Figure 1). However, the attraction activities of these, and the "unnatural" stereoisomers, have not been determined for male and female beetles.

Byers et al. (1988, 1989) further investigated the attractive pheromone system of *P. chalcographus* by undertaking an isolation of semiochemicals using chemical fractionation and behavioral bioassays. However, they used a new procedure, "subtractive combination" of gas chromatographic (GC) fractions and bioassay, which usually requires far fewer behavioral tests than the previously used and similar "additive combination" method (Silverstein et al., 1966, 1967, 1968; Pearce et al., 1975). Chalcogran and a "second" pheromone component were revealed by the new methods and found to be produced and released only when males feed on host-tree tissue. However, it was necessary to further isolate the second pheromone component from a complex mixture of insect and host volatiles by using two-dimensional GC (Deans, 1981) and bioassay (Byers et al., 1989). Methyl (2*E*,4*Z*)-2,4-decadienoate (*E*,*Z*-MD) was then isolated

FIG. 1. Diastereomers and enantiomers of chalcogran. The two natural enantiomers found in male *Pityogenes chalcographus* are to the right of the mirror plane, with the behaviorally active one in the lower right.

and identified by GC-MS and found to be strongly synergistic with chalcogran (Byers et al., 1988, 1989). The males produce only the (*E,Z*)-MD isomer, but there are three other possible isomers that might have weaker or stronger synergistic effects on the attraction response when tested with chalcogran.

Here we briefly describe the syntheses of all four stereoisomers of chalcogran as well as the four isomers of methyl 2,4-decadienoate (MD) and their use in bioassay. The objectives were to determine which of the isomers/enantiomers of the pheromone components are bioactive by comparing (1) the attraction activities of each of the chalcogran stereoisomers when combined with the beetle-produced (*E,Z*)-MD and (2) the attraction activities of each of the MD isomers when combined with racemic chalcogran. We also wanted to determine if the mixture of chalcogran plus the four MD isomers has inhibitory or synergistic effects on attraction when compared to chalcogran plus the (*E,Z*)-MD isomer.

METHODS AND MATERIALS

Synthesis of Chalcogran Stereoisomers. Mixtures of the *E* and *Z* diastereomers of chalcogran were obtained enantiomerically pure using the synthetic pathway shown in Figure 2 (Högberg et al., 1987). The required γ -caprolactone enantiomers **2** (Figure 2) were conveniently obtained via resolution by chiral-

FIG. 2. Schematic pathway for synthesis of the chalcogran stereoisomers.

phase chromatography on microcrystalline triacetylated cellulose using the chromatographic system described by Isaksson and Roschester (1985). This gave (*R*)-(+)- and (*S*)-(–)- γ -caprolactone in 90% and 97% enantiomeric excess, respectively. These were subsequently reacted separately at -80°C with the alkyllithium obtained from the bromide **3** (Figure 2), each yielding a mixture of two diastereomers (*2R,5R/S*)-**1** and (*2S,5S/R*)-**1**, respectively. The diastereomers were separated by repeated silica gel chromatography using a gradient elution technique. All four isomers were obtained (Figure 1) in relatively high purity (Table 1) as shown by capillary GC on a chiral stationary phase (Schurig and Weber, 1984; Koppenhoefer et al., 1980).

Synthesis of Geometric Isomers of Methyl 2,4-Decadienoate. For details

regarding the syntheses, see Baeckström et al. (1988). The *E,E* isomer was prepared (Figure 3) starting from methyl crotonate in a way similar to previously described procedures (Barneji and Pal, 1983; Crombie and Denman, 1984; Roush, 1980; Garigipati and Weinreb, 1983). NBS-bromination gave the product **4**, and an Arbuzov reaction with triethylphosphite yielded the phosphonate **5**. An Emmons-Horner-Wadsworth reaction with LDA and hexanal then gave (*E,E*)-MD. The isomeric purity was 93% and was improved to >99% using urea inclusion complexes (Leadbetter and Plimmer, 1979; Fieser, 1964). Since ethyl (*2E,4Z*)-2,4-decadienoate (**6**) is commercially available (Oril products Chimiques, Neuilly, France), the *E,Z* isomer was prepared simply by reesterification with sodium methoxide in methanol (Figure 3). The isomeric purity was increased from 85% to >99% with the urea inclusion procedure above. (*Z,E*)-MD was prepared from propiolic acid (Figure 3). HBr addition to the triple bond in the presence of cuprous bromide and subsequent esterification of the acid with sulfuric acid in methanol gave methyl (*Z*)-3-bromopropenoate (**7**) (Weir et al., 1980). This compound was coupled with (*E*)-1-heptenyl-1,3,2-benzodioxaborole (**8**) in the presence of Pd(PPh₃)₄ and sodium methoxide (Björkling et al., 1987). The cross-coupling reaction gave the *Z,E* isomer with 92% purity. Contaminating (*E,E*)-MD was removed by the use of urea inclusion

FIG. 3. Schematic pathway for synthesis of the geometrical isomers of methyl 2,4-decadienoate.

complexes. (*Z,Z*)-MD was prepared from **7** in two steps (Figure 3). A palladium-catalyzed cross-coupling with 1-heptyne according to Weir et al. (1980) yielded the enyne ester **9**. Reduction with hydrogen and Lindlar's catalyst (Rickards and Weiler, 1978) provided (*Z,Z*)-MD in 99% purity after preparative GC. The four MD isomers were analyzed and identified with GC-MS and [¹H]- and [¹³C]NMR, and the spectroscopic data were in agreement with those earlier reported (Stille and Groh, 1987).

Bioassay of Attraction Response of Pityogenes chalcographus to Chalcogran Stereoisomers and Methyl 2,4-Decadienoate Isomers. The open arena olfactometer for walking beetles was used for all bioassays (Browne et al, 1974; Byers and Wood, 1981; Byers et al., 1985). *P. chalcographus* (originally from Lardal, Norway) were obtained from a laboratory culture maintained on their natural host logs (28 × 10 cm diam.), Norway spruce, from Lund, Sweden. Beetles were separated according to sex and tested in groups of 10 in the olfactometer. They were released about 20 cm "downwind" from the odor source. Charcoal-filtered air was passed through a manifold to produce a laminar air flow across the arena of about 0.6 m/sec. Semiochemical mixtures were released in diethyl-ether solvent from a 5- μ l capillary (Drummond). Beetles that approached the odor source closer than 1 cm within the time of semiochemical release (about 2 min) were recorded as responding. Unresponsive beetles were tested a second time after refilling the capillary.

Purities of the chalcogran stereoisomers and MD isomers are shown in Table 1. Mixtures of each of the four chalcogran stereoisomers with the beetle-produced isomer of MD (Byers et al., 1988, 1989) were tested (Table 2) to see which stereoisomer was most active. Mixtures of racemic chalcogran (92.5% Shell Agrar, Table 1) with each of the four possible MD-isomers (Table 2) were also tested to determine their individual synergistic activities. Finally, tests were done to determine if the combination of all four MD-isomers were more active (synergism) or less active (inhibition) than the *E,Z* isomer when assayed with racemic chalcogran (Table 3).

RESULTS

The purities of the stereoisomers of chalcogran (Table 1) were sufficiently high to show differences in attraction activity (Table 2). In conjunction with (*E,Z*)-MD, (*2S,5S*)-chalcogran was the least active while the (*2S,5R*)-chalcogran was the most active for both sexes (Table 2). Again, in conjunction with (*E,Z*)-MD, racemic chalcogran [containing about 23% (*2S,5R*)-] was not significantly different from (*2S,5R*)-chalcogran in attraction activity, which indicates that the other stereoisomers of chalcogran are neither inhibitory nor synergistic (Table 2). The MD isomers were also of sufficiently high purity

TABLE 2. RESPONSES OF MALE AND FEMALE *Pityogenes chalcographus* IN LABORATORY BIOASSAY TO STEREOISOMERS OF CHALCOGRAN PRESENTED WITH (*E,Z*)-MD OR TO ISOMERS OF MD PRESENTED WITH RACEMIC CHALCOGRAN (JULY 27-28, 1986)^a

^aRacemic chalcogran (*R*) and each stereoisomer was released at 2.2×10^{-9} g/min and the MD isomers at 2.2×10^{-10} g/min. Parentheses enclose 95% binomial confidence limits for proportions (95% BCL) and 60 beetles of each sex were tested for each chemical blend. Percent responding followed by different letters were significantly different at $P < 0.01$, using a chi-square test.

TABLE 3. BIOASSAY FOR INHIBITORY OR SYNERGISTIC EFFECTS OF *E,E*, *Z,Z*, and *Z,E* ISOMERS OF METHYL DECADIENOATE (MD) ON RESPONSES OF MALE AND FEMALE *Pityogenes chalcographus* TO RACEMIC CHALCOGRAN PLUS (*E,Z*)-MD (OCTOBER 8, 1986)^a

	Percent responding (95% BCL)	
	Females	Males
Racemic chalcogran + (<i>E,Z</i>)-, (<i>E,E</i>)-, (<i>Z,E</i>)-, and (<i>Z,Z</i>)-MD	41.7 (30.1-54.3)	41.7 (30.1-54.3)
Racemic chalcogran + (<i>E,Z</i>)-MD	55.0 (42.5-66.9)	41.7 (30.1-54.3)

^aRacemic chalcogran was released at 2.2×10^{-9} g/min and each MD isomer at 2.2×10^{-10} g/min. Brackets enclose 95% binomial confidence limits for proportions (95% BCL) and 60 beetles of each sex were tested for each chemical blend. No significant differences were observed with a chi-square test, $P > 0.05$.

(>99%, Table 1) to yield differences in attraction activity (tested in combination with racemic chalcogran), with (*E,Z*)-MD being significantly more active than any other isomer or racemic chalcogran alone (Table 2). While (*Z,Z*)-, (*Z,E*)-, and (*E,E*)-MD tested with chalcogran were each somewhat more attractive than chalcogran alone, none of these combinations were statistically significantly different from chalcogran alone ($P > 0.05$, Table 2). The synergistically active (*E,Z*)-MD is not attractive when released alone (Table 2). When the mixture of all four isomers of MD plus chalcogran were compared to (*E,Z*)-MD plus chalcogran, there was no significant difference in attraction of either sex (Table 3), which indicates that the "inactive" MD isomers are neither synergistic nor inhibitory when combined with (*E,Z*)-MD.

DISCUSSION

Our bioassay tests revealed that the beetle-produced (*E,Z*)-MD was the only isomer of MD with significant synergistic activity with chalcogran. Apparently the configuration of both double bonds is important for the activity of the compound. The small activities of each of the other three MD isomers could be due to real effects or to the minute impurities of (*E,Z*)-MD. The expected release rates of any (*E,Z*)-MD impurity would have been on the order of 10^{-12} g/min or less, but this rate has produced a similar increase in response which is nearly or is statistically significant compared to response to chalcogran alone (Byers et al., 1989).

P. chalcographus males produce two of four possible stereoisomers of chalcogran (Shurig and Weber, 1984): (*2S,5R*)-1 and (*2S,5S*)-1, which we found were the most active and inactive, respectively, in our bioassay tests. There is some question as to the biosynthetic production of chalcogran because of rapid epimerization at carbon 5 to give a mixture of approximately 46% (*2S,5R*)-1 and 54% (*2S,5S*)-1 in solvents like benzene, ether, and chloroform (Smith et al., 1978; Francke et al., 1980). However, we found that our purified samples of chalcogran enantiomers were stable in hexane or pentane for over one year at -20°C by storage in alkaline-washed bottles. Thus, it is possible that the male beetle produces only one enantiomer that epimerizes in some part of the acidic gut to produce the 46:54 ratio as observed earlier (Francke et al., 1977; Shurig and Weber, 1984; Byers et al., 1989). Byers et al. (1989) found chalcogran predominantly in the abdomen (and more precisely in the hindgut; Birgersson and Byers unpublished) at 10.4 ± 2.4 ng (\pm SD) compared to only 2.6 ± 1.5 ng in the head/thorax. In contrast, (*E,Z*)-MD was found predominantly in the head/thorax of the male (11.2 ± 4.6 ng) compared to 2.3 ± 0.9 ng in the abdomen. This indicates different biosynthetic sites for the two pheromone components.

The structure-activities of the four chalcogran stereoisomers indicate that the configurations of all three major structural parts are important. Exchanging the ethyl and hydrogen groups at carbon 2 on the active (2*S*,5*R*)-chalcogran decreases response to an intermediate level for the (2*R*,5*R*)-**1** (Table 2). A 180° rotation of the center tetrahydrofuran ring on the active (2*S*,5*R*)-chalcogran also decreases response to an intermediate level for the (2*R*,5*S*)-**1**. Finally, 180° rotation of the end tetrahydrofuran ring at carbon 5 has the most severe effect, abolishing activity by forming (2*S*,5*S*)-chalcogran (Table 2).

Double-bond isomers of fatty acids of 12-, 14-, and 16-carbon chains are well known to have different behavioral effects or activities (Cardé and Baker, 1984). However, our report is the first case where such positional effects on long acetogenic carbon chains are important to bark beetles. It is well known that bark beetles use specific enantiomeric pheromone components (Wood et al., 1976; Borden et al., 1976; Wood, 1982), and *P. chalcographus* is yet another example. The *E* (2*S*,5*R*) and *Z* (2*S*,5*S*) chalcogran of *P. chalcographus* is analogous to *cis*- and *trans*-verbenol biosynthesis from α -pinene in *I. paracconfusus*, in which only one enantiomer of one compound is active, (–)-(*S*)-*cis*-verbenol (Silverstein et al., 1967; Renwick et al., 1976).

Our characterization of the synergistically bioactive stereoisomers of chalcogran (2*S*,5*R*)-**1**, and methyl 2,4-decadienoate, (*E*,*Z*)-MD, may be useful in control programs that use grids of pheromone-baited traps to catch the most vigorous (flying and responding) adults. This could reduce population levels below the tree-killing threshold so that tree resistance mechanisms can kill or repel the remaining potential colonizers. Pheromone trap-out may be a significant type of mortality which does not compete directly with other mortality factors such as adverse weather or desiccation/exhaustion of adults during the dispersal and host-seeking flight. The (*E*,*Z*)-MD and chalcogran components have recently been marketed under the name Chalcoprax, as a trap lure for *P. chalcographus* in Europe and northern Asia (Shell Agrar GmbH & Co. KG, D-6507 Ingelheim am Rhein).

Acknowledgments—We thank E. Jirle and E. Annerfeldt for maintaining the laboratory *P. chalcographus* culture and J. Jönsson for maintenance of the rearing chamber. We also thank International Flavors and Fragrances, Stockholm, for providing us with ethyl (2*E*,4*Z*)-decadienoate.

SENSITIVITY OF *Beauveria bassiana* TO SOLANINE AND
TOMATINE:
Plant Defensive Chemicals Inhibit an
Insect Pathogen

SCOTT D. COSTA and RANDY R. GAUGLER

(Received December 23, 1987; accepted February 16, 1988)

Abstract—The alkaloids solanine and tomatine and the polyene antibiotic nystatin were tested *in vitro* against the entomopathogenic fungus *Beauveria bassiana*. Nystatin was the most inhibitory compound tested, reducing colony formation, growth, and development of conidiophores to a greater degree and at lower concentrations than the alkaloids. Tomatine inhibited colony formation and growth more than solanine, which had relatively little effect on the fungus. The toxicity of tomatine suggests that germination of conidia and subsequent hyphal growth would be inhibited when an insect consumes conidia along with foliage containing 0.100 mg/g (fresh weight) of this compound. The sensitivity of *B. bassiana* to alkaloids appears to be in the middle of the range found with other fungi.

Key Words—Entomopathogen, fungus, *Beauveria bassiana*, inhibition, plant defenses, alkaloids, solanine, tomatine, nystatin.

INTRODUCTION

Insect susceptibility to entomopathogens is influenced by the insect's host plant, yet the factors involved are poorly understood (Hare and Andreadis, 1983; Ramoska and Todd, 1985). Hare and Andreadis (1983) found that a host plant can indirectly influence the success of fungal infection with *Beauveria bassiana* through changes in insect fitness; less fit insects are more susceptible to infec-

tion. However, an anomaly in their results and the findings of Ramoska and Todd (1985) suggest that antifungal compounds in plants can have a direct, negative effect on *B. bassiana* and thereby retard infection of an insect. The glycoalkaloid tomatine was implicated in the reduced susceptibility to *B. bassiana* infection of the Colorado potato beetle, *Leptinotarsa decemlineata*, when fed tomato, *Lycopersicon esculentum* (Hare and Andreadis, 1983). The toxic and inhibitory effects of steroidal glycoalkaloids to fungal pathogens of plants has been reported often (Sinden et al., 1973; Arneson, 1967; Arneson and Durbin, 1967, 1968a,b; Allen, 1965; Wolters, 1964; McKee, 1959; Irving et al., 1946), but it is unknown whether glycoalkaloids are sufficiently toxic to *B. bassiana* to impede infection of an insect.

The toxicity of tomatine to fungi apparently results from the compound complexing with sterols in cell membranes and subsequently increasing membrane permeability (Arneson and Durbin, 1968a). Arneson and Durbin (1968a) mentioned that some fungi less sensitive to tomatine (Arneson, 1967) are also tolerant of nystatin, a polyene antibiotic with a similar mode of action (Fowlks et al., 1967; Kinsky, 1961). Tolerance in fungi can result from a lack of sterols in cell membranes for the alkaloids to bind to (Fowlks et al., 1967) or an ability to metabolize the compounds to a less toxic form (McKee, 1959; Arneson and Durbin, 1967). Determining the response of *B. bassiana* to nystatin helps to clarify its degree of tolerance to alkaloids in relation to other fungi and the general nature of the tolerance if found.

The undissociated bases of tomatine and the structurally similar alkaloids solanine and chaconine (Allen and Kuc, 1968) are probably the toxic form (Sinden et al., 1973; Arneson and Durbin, 1968a). While these alkaloids are all toxic and/or inhibitory to certain fungi, it can take approximately two and five times more solanine, depending on pH, than chaconine and tomatine, respectively, to have the same effect (Sinden et al., 1973; McKee, 1959). Because only unprotonated alkaloids complex with sterols, the inhibitory activity of tomatine is 300 times greater at pH 8.0 than at pH 3.0 (Arneson and Durbin, 1968a). Sodium and potassium also increase the toxicity of alkaloids to fungi (McKee, 1959), and when potassium is replaced by sodium in the buffer, the activity of nystatin is enhanced (Kinsky, 1961).

This investigation was undertaken to determine if alkaloids could suppress *Beauveria bassiana* as Hare and Andreadis (1983) suggested. Hare and Andreadis inoculated Colorado potato beetle larvae per os using a leaf disk, which put the *B. bassiana* and plant alkaloids in contact with each other inside the insect's gut. The gut pH of this insect is slightly acidic (Grayson, 1958), so a similar pH was used in our trials to allow for the effect of pH on alkaloid toxicity (McKee, 1959). Additionally, the response of *Beauveria* to alkaloids was evaluated in relation to that published for other fungi.

METHODS AND MATERIALS

The two glycoalkaloid treatments, solanine and tomatine, and the fungal antibiotic nystatin were incorporated into buffered and unbuffered oatmeal dodine agar (ODA) (Chase et al., 1986). The ODA consisted of either 1 liter deionized or 1 liter buffered water, and 20 g oatmeal, 20 g agar, 0.5 g dodine (65% AI), 0.01 g crystal violet, and 1 ml each of penicillin G and streptomycin sulfate stock solutions. The stock solutions contained either 0.7 g penicillin G or 1 g streptomycin sulfate in 10 ml sterile deionized water. The oatmeal was boiled for 20 min, vacuum filtered through cheese cloth, and the volume brought to 1 liter. The agar, dodine, and crystal violet were added before sterilization. The penicillin and streptomycin were added after cooling the media to 45°C.

Five concentrations (100, 40, 14, 5, and 1 mg/liter medium) of each alkaloid and nystatin (Sigma Chemical Co.) were tested. Stock solutions of the alkaloids were made by diluting each compound (4.3 mg/ml) with 10 mM HCl. An appropriate amount of the stock solution to give the desired concentration of the test compound, along with enough 10 mM HCl to make the volume 6 ml, was added to 250 ml of ODA before plating; controls received only the 10 mM HCl. The pH in the buffered ODA was set at 6.35 with a buffer (500 ml of 0.1 M KH_2PO_4 + 126 ml of 0.1 M NaOH brought to 1 liter with distilled water), whereas the pH in unbuffered ODA was adjusted to 6.35 with 0.1 M NaOH after addition of the treatment chemicals. A set of 12 plates for each treatment concentration and 36 plates for controls were made from randomly selected batches of ODA.

Beauveria bassiana conidia (technical powder; Abbott Labs, ABG-6178 lot No. 76015BR) were diluted serially with deionized water containing 0.05% Tween-80 (pH 6.35). Each plate was inoculated by spreading 0.5 ml of the conidia preparation on the agar with a bent glass rod. Inoculated plates were wrapped in plastic to conserve moisture and incubated in the dark at 25°C. The number of colonies present was recorded four days after plating, and colony diameter was measured five and seven days after plating. Measurements of the two colonies first appearing in the microscopic field that were not crowded by other colonies were taken from each plate. The magnification used was varied with colony size. Colonies were examined for the presence of conidiophores on day 7.

An analysis of variance was used to determine the effects of media, treatment compound, and concentration on number of colonies, and their diameter during the first and second measurement. The colony counts were transformed before analysis by taking the base 10 log of each count. Tukey's multiple-range test was used to determine significant differences among treatments and dosages. A probability level of 0.05 was used in all statistical analyses.

RESULTS

Nystatin restricted colony formation to a greater extent and at lower concentrations than either alkaloid treatment (Figure 1a and b). The fungal response to alkaloids varied and was influenced by buffering agents. Both alkaloids inhibited colony formation on unbuffered media except for solanine at 1 and 40 mg/liter (Figure 1b). However, when the media were buffered, the alkaloids stimulated colony formation at lower concentrations, and in greater amounts had no significant effect (Figure 1a).

The measurements of colony diameter five days after plating revealed that both alkaloids had reduced colony size compared to the control, with tomatine having the greatest effect (Figure 2a and b). The response to solanine was most apparent at 5 mg/liter, the next-to-lowest concentration tested. This concentra-

tion of tomatine inhibited growth more than the next higher concentration tested (14 mg/liter) and in unbuffered media 1 mg/liter also had a negative effect. However, alkaloids incorporated into buffered media were generally more inhibitory to fungal growth than when the medium was not buffered. The complete inhibition of colony formation by the highest dose of tomatine in unbuffered medium was the exception. Little or no growth was observed on plates containing nystatin in all but the lowest concentration tested.

Colonies on plates containing nystatin had increased in diameter by the seventh day after plating, but remained significantly smaller than those on most alkaloid treatments (Figures 3a and b). Several concentrations of tomatine continued to inhibit colony growth in both media, whereas solanine's influence was most apparent when the media were buffered. The initial retardation of growth

caused by 5 mg/liter of the alkaloids (Figures 2a and b) had diminished by this time, but in unbuffered medium, 1 mg/liter of tomatine was still inhibitory, while the two successively higher concentrations were not.

The presence of conidiophores in a particular treatment was an all-or-nothing response, either all colonies observed had them or none did. Conidiophores formed at all the concentrations of solanine tested and all but the highest concentration of tomatine in unbuffered medium (Table 1). Only the lowest concentration of nystatin permitted production of conidiophores in either medium. This datum was not treated statistically because of the absolute nature of the response.

The presence or absence of buffer in the media had a significant influence on colony size; this is evident when the controls from both media are compared (Figures 2 and 3). The type of medium also interacted significantly with treat-

ment compound and concentration for all the parameters measured, except conidiaphore production, which was not analyzed statistically.

DISCUSSION

The negative response of *B. bassiana* to tomatine was greater than with solanine, but was it enough to substantiate the suggestion of Hare and Andreadis (1983) that tomatine might inhibit infection of an insect? Although the tomatine content of the tomato variety Rutgers that Hare and Andreadis (1983) used is not available to us, Campbell and Duffey (1981) presented data for five other varieties. The unweighted mean from their results for all the varieties was 0.163 mg/g (fresh weight) or an equivalent of 163 mg/liter in agar medium. Colony formation and growth of *B. bassiana* were severely inhibited by 100 mg/liter of tomatine in unbuffered media, implying that higher concentrations would also be inhibitory. Therefore, the tomatine presumably present in the Rutgers variety could have had a toxic effect on the fungus and retarded insect infection.

Tomatine's greater ability to inhibit *B. bassiana*, compared to that of solanine, parallels the findings of McKee (1959) with nonentomopathogenic fungi. Solanine's limited ability to retard fungal growth tends to support Hare and Andreadis's (1983) conclusion that the decreased susceptibility of insects fed *S. tuberosum* was a result of their greater fitness. Although the solanine and chaconine content previously reported for the variety they used was not tested in this trial (Gregory et al., 1981; Raman et al., 1979), given the trends observed, an influence far less than that caused by tomatine would be expected.

The smaller colonies and slower growth in the unbuffered control indicate

poor nutrition of the fungus; this may, in turn, have contributed to tomatine's greater toxicity at its highest concentration in this medium. Sodium could have been a limiting nutrient. No more than 0.2 mM Na was added when initially adjusting the pH, whereas 12 mM was incorporated into the buffered media—concentrations above 86 mM do not increase the growth response of *B. bassiana* (Samsinakova, 1966). The greater toxicity might also have resulted from a rise in medium pH, which occurs with *B. bassiana* growth (Samsinakova, 1966). McKee (1959) reported that the growth of *Fusarium caeruleum* increased media pH and resulted in eventual toxicity of solanine. However, the pH increase was larger than what Samsinakova (1966) reported for *B. bassiana*.

The greater toxicity of tomatine at its highest concentration in unbuffered media does not coincide with the tendency toward an increased alkaloid toxicity in buffered media. The additional sodium and potassium in the media could have increased the influence of the compounds as they did with solanine's toxicity to *F. caeruleum* (McKee, 1959). However, this effect did not extend to the initial colony formation after plating. Lower concentrations of the alkaloids stimulated the formation of colonies in buffered media.

The sensitivity of *B. bassiana* to alkaloids appears to be in the middle of the range reported for other fungi. The corn pathogen *Drechslera* (= *Helminthosporium*) *carbonum* is more sensitive than *B. bassiana*, having a 50% reduction in growth caused by 61 mg/liter of solanine at a lower pH (Allen and Kuc, 1968), which would have made the alkaloid less toxic. The potato pathogen *Alternaria solani* is similar in sensitivity, having only an 8% reduction in growth by 100 mg/liter (Sinden et al., 1973); *B. bassiana* growth was reduced 23% by the same amount at a comparable pH. The conidia of *B. bassiana* are similar in their sensitivity to tomatine to those of *F. caeruleum*, a potato pathogen that can hydrolyze solanine (McKee, 1959).

The negative response of *B. bassiana* to nystatin, although greater than with alkaloids, also indicated a tolerance relative to other fungi. Colonies developed, albeit poorly, with concentrations of nystatin up to 40 mg/liter and produced conidiophores with 1 mg/liter present, whereas *Colletotrichum lagenarium* and *Neurospora crassa* are completely inhibited by 0.6 and 2 mg/liter (Fowlks et al., 1967; Kinsky, 1961). The tolerant fungus *Pythium aphanidermatum*, which apparently has no sterols in its cell membrane for binding nystatin, was not inhibited by 100 mg/liter of the antibiotic (Fowlks et al., 1967). The response of *B. bassiana* to nystatin and its concurrent sensitivity to alkaloids suggest that *Beauveria*'s cell membranes possess sterols.

The relative tolerance of *B. bassiana* to alkaloids and nystatin implies that some mechanism may have evolved to deal with these compounds. The ability of certain fungi to hydrolyze alkaloids to less toxic forms has been demonstrated in plant pathogens (Arneson and Durbin, 1967; McKee, 1959). In our trial, colony size was initially smaller in the 5-mg/liter alkaloid treatments than in

the next higher concentration, and subsequently the effect diminished. This suggests that the tolerance was due to a detoxification system that is activated only when sufficiently challenged, rather than to a lack of sterols for binding the compounds. The tolerance of fungi specializing on alkaloid-containing plants is understandable given the degree of selective pressure they encounter. Less clear is how this pressure could be strong enough on an entomopathogenic fungus.

Further research is required to fully explain the response of *B. bassiana* to alkaloids. The relative tolerance of *B. bassiana* to alkaloids compared to other fungi needs to be confirmed with assays that test sensitivities of several fungi concurrently. A potential complication is that local populations of the fungus may vary in alkaloid tolerance as they do in their tolerance of pesticides (Anderson and Roberts, 1983; Olmert and Kenneth, 1974). Finally, consideration of *Beauveria's* response to alkaloids and other phytochemicals (Ramoska and Todd, 1985) should be incorporated into the development of strategies seeking to use this pathogen for the control of insect pests.

(Received September 9, 1987; accepted February 19, 1988)

Abstract—The emission of five pheromone components by individual *Cacoecimorpha pronubana* females was measured during 15-min sampling intervals. Pheromone was only released during female calling. Blend ratios emitted by individual females were constant over three calling periods, despite variations in release rates. Release ratios of the $\Delta 11$ -components Z11-14:Ac, E11-14:Ac, and Z11-14:OH were similar for all females tested, but release ratios of Z9-14:Ac to the $\Delta 11$ -components showed significant interindividual variation.

Key Words—*Cacoecimorpha pronubana* Hbn., Lepidoptera, Tortricidae, sex pheromone emission, release rates, blend ratios, calling behavior, airborne collection.

INTRODUCTION

Airborne pheromones emitted by individual calling female moths have been trapped on substrates like Porapak Q and Tenax, on glass-wool or active carbon (Golub and Weatherston, 1984). Such adsorbants possess large surfaces with respect to the quantity of emitted pheromone. The subsequent elution of adsorbed compounds from these materials may result in contamination and loss of pheromone. Analysis of pheromone emission has thus often been confined to the measurement of only the main component during sampling intervals of 30 min and more.

Baker et al. (1980) demonstrated the use of glass surfaces for the efficient

¹ Present address: Swiss Federal Research Station, CH-8820 Wädenswil, Switzerland.

adsorption of pheromone without introducing impurities from the adsorbant. Trapping pheromones in glass capillary tubes allows desorption with minimal quantities of solvent for direct sample analysis (Shani and Lacey, 1984). In collection systems designed by Sower et al. (1971) and Baker et al. (1981), pheromone was collected from forcibly extruded female glands. This technique has been adapted by several authors to isolate minor pheromone components (Pope et al., 1982, Haynes et al., 1984, Du et al., 1987). Other methods have been developed where females were allowed to assume the natural calling position during collection (Bjostad et al., 1980, Charlton and Cardé, 1982, Shani and Lacey, 1984, Schal and Cardé, 1985).

The carnation tortrix, *Cacoecimorpha pronubana* is an important, multi-voltine pest of various flower, vegetable, and fruit cultures (Bovey, 1972). The sex gland secretion of *C. pronubana* contains approximately 80% (*Z*)-11-tetradecenyl acetate (*Z*11-14:Ac), together with a number of related alcohols and acetates, including (*E*)-11-tetradecenyl acetate (*E*11-14:Ac), (*Z*)-9-tetradecenyl acetate (*Z*9-14:Ac), tetradecyl acetate (14:Ac), and (*Z*)-11-tetradecen-1-ol (*Z*11-14:OH) (Descoins et al., 1984, Frérot et al., 1989). A detailed study of the release rate of pheromone by individual females was undertaken as a prerequisite to the analysis of male pheromonal behavior.

METHODS AND MATERIALS

Insects. Insects were obtained from a continuous culture maintained in the laboratory (for approx. 30 generations) on a semiartificial diet. The laboratory strain originating from Antibes (southern France) in 1983 was regularly interbred with wild insects collected at the same site. Sexed pupae were kept under a 14:10 light-dark photoperiod at 80% relative humidity. After adult emergence females were kept individually in 200-ml plastic jars and fed with a 2% sucrose solution when not being tested.

Collection Apparatus. Pheromone collection was performed with an apparatus (Witzgall, 1987) integrating important features of the collection systems described by Shani and Lacey (1984) and Charlton and Cardé (1982). A glass bulb divided in two, fitted with a ground glass joint, contained the insect. The calling female rested freely on a metal support held by a wire fixed to the upper half of the bulb. A capillary tube (1 mm ID, 15 cm long) was connected to the outlet of the bulb. The extruded gland was next to the orifice (Figure 1C). A constant flow (40 cm³/min) of purified air (activated carbon) passed over the female into the capillary tube. The lower part of the glass cage could be rapidly exchanged without disturbing the female.

Preliminary Measurements with Synthetic Pheromone and Calling Females. To evaluate the efficiency of pheromone collection in this apparatus,

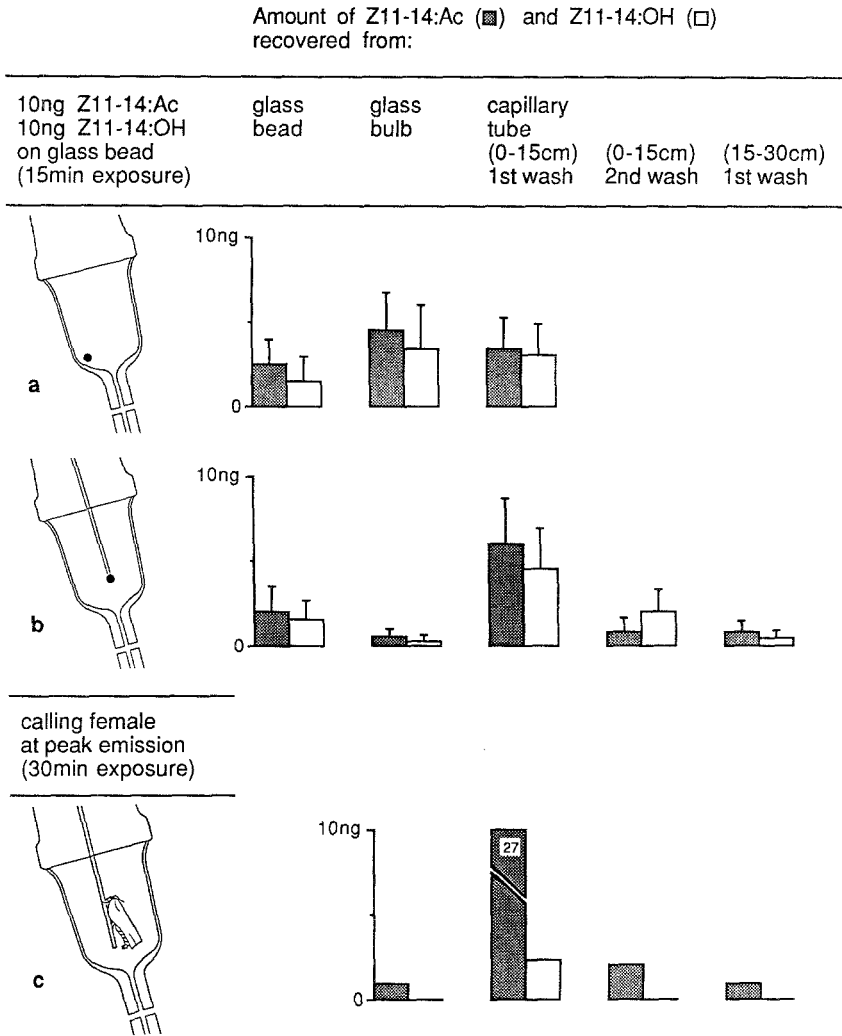

FIG. 1. Amount of the pheromone components Z11-14:Ac and Z11-14:OH recovered by elution with hexane from different parts of collection device. a, b: synthetic pheromone applied to a glass bead; $N = 10$. c: calling *C. pronubana* female.

we first undertook measurements with synthetic pheromone components. A 5- μ l hexane solution containing 10 ng of Z11-14:Ac and 10 ng of Z11-14:OH was applied to the round tip of a glass rod. After solvent evaporation, the dispenser was either fixed to the metal support or placed on the surface of the glass bulb with the tip 1 cm from the outlet (Figure 1A and B). One to two minutes

elapsed between application of the pheromone solution and the onset of the air flow. The glass dispenser was washed with 30 μ l hexane (Merck, for residue analysis) 2 min after solvent application and after a 15-min exposure in the collection apparatus. The lower part of the holding chamber was washed with 20 μ l hexane before and after application of the synthetic source. The first half, near the source (0–15 cm) of a capillary tube (30 cm long; broken in two), was rinsed with 5 μ l of hexane twice and the second half (15–30 cm) once. Amounts of Z11–14:Ac and Z11–14:OH recovered were quantified by GC analysis.

The recovery of 10 ng synthetic Z11–14:Ac and Z11–14:OH emanating from the artificial dispenser in different parts of the collection system after a 15 min exposure is shown in Figure 1A and B. The adsorption of synthetic pheromone in the lower part of the bulb was 4.7 ± 2.2 ng Z11–14:Ac ($N = 10$), when the artificial dispenser was in contact with the glass cage. With the dispenser fixed to a metal support in the center of the glass bulb, the total amount of pheromone detected in the bulb never exceeded 1 ng (10%) and the amount recovered from the capillary tube increased accordingly. This result and the observation that calling female moths usually remain in the same position led to the design of our glass-collection system shown in Figure 1C.

Recovery efficiency of the first wash of the capillary tube was generally lower for Z11–14:OH than for the corresponding acetate, although more Z11–14:OH was detected by the second wash. After direct injection of 10 ng Z11–14:Ac and 10 ng Z11–14:OH (5 μ l hexane solution) into the tube, followed by elution of the capillary after solvent evaporation, we recovered both compounds in an 85:74 ratio (8.5 ± 0.7 ng, 7.4 ± 0.6 ng, $N = 10$). Extraction of the dispenser 2 and 15 min after solvent application revealed similar recovery rates. This suggests a stronger adsorption of Z11–14:OH to the glass surface. Cooling of the tubes did not increase recovery rates of either compound. Silanization of the capillaries slightly increased the amount of Z11–14:OH recovered but was not applied routinely.

When females were placed directly in the glass bulb, the amount of Z11–14:Ac (the main pheromone component) measured in the capillary never exceeded 3 ng for 15-min intervals. Even 1 hr after the calling female was removed from the bulb, pheromone could still be detected in the capillary. This was probably due to secondary desorption of pheromone from the glass surface of the bulb. The minor components Z9–14:Ac, E11–14:Ac, 14:Ac and Z11–14:OH were only to be detected during peak emission. Up to 24.5 ng of Z11–14:Ac was detected for 15-min intervals in the capillary, when the female was placed on the metal support. The amount of pheromone eluted from the bulb was then always less than 5% of the amount detected in the capillary (Figure 1C).

Measurement of Female Pheromone Emission. *C. pronubana* is day-active. Insects emerge during the dark period and start calling during the following

light period. Ten females were tested individually zero, two, and four days after emergence during the entire calling period. Females were allowed to climb the support (Figure 1C) 1 to 2 hours after onset of the light period. They started calling 30–60 min later and rested on the platform during calling and when capillary tubes and the lower part of the holding chamber were exchanged. Calling behavior was observed at 15-min intervals. Pheromone was collected twice an hour during 15-min periods (0–15 and 30–45 min) into a capillary tube 15 cm long. Tube eluates were immediately submitted to GC analysis. The first rinse of the capillaries with 5 μ l hexane containing 5 ng of each 12:OH and Z9, E12–14:Ac as internal standards was used to quantify pheromone emission according to peak areas. A single factor analysis of variance showed that the amounts of 12:OH and Z9, E12–14:Ac did not differ among measurements with different females. All data represent actual values and were not adjusted. Tubes were used only once. The lower part of the glass cage was exchanged once an hour.

For statistical analysis of release ratios, we calculated the integrals of the emission rate of each compound for each calling period, since the consecutive measurements during 15-min intervals could not be treated as independent variables. To test for differences in the release ratios of any two compounds between females, we performed a Kruskal-Wallis test with tied ranks (Weber, 1980) on the integrals of the release rates.

GC Analysis. Hexane rinses were injected without further treatment on a Girdel 300 with Ross injector and FID detector (250°C) equipped with a fused silica column (WCot, CPWax 57 CB, 25 m, 0.22 mm ID). Helium was used as carrier gas, column temperature was held at 150°C.

RESULTS

Release Rates and Release Patterns. The 10 females tested on the first, third, and fifth days released an average of 0.45 ± 0.11 ng Z11–14:Ac/min/calling period, as measured in a 15-cm capillary tube. A similar pattern of release was observed for all five chemical components: Release rates were highest after the onset of calling, when the female lifted the abdomen from the platform and extruded the gland. Generally, release rates declined towards the end of the calling period and ceased when females stopped calling. No pheromone was detected before and after the calling period.

A typical diel pattern of pheromone release by an individual female is shown in Figure 2. It is important to note that pheromone release was correlated with the extrusion of the gland. Continuous observation of the calling behavior showed that after peak emission, females sometimes slightly retracted the gland for periods of 30 to 60 min and lowered the abdomen. Such partial retraction

of the gland generally resulted in important decreases of pheromone emission (Figure 2). However, emission never ceased entirely between the onset and the end of the calling period.

Release Ratios. The average composition of the bouquet Z11-14:Ac, E11-14:Ac, Z9-14:Ac, 14:Ac, Z11-14:OH released by the 10 females was 82:5:1:5:7. Despite the temporal variations in overall release rates, release ratios between the components detected were surprisingly constant for individual females. A given female emitted, for instance, Z11-14:Ac/Z11-14:OH, or Z9/E11-14:Ac at almost the same ratio during the entire calling period on the three days tested (Figure 3A and B).

FIG. 2. Pheromone release by an individual *C. pronubana* female at two 15-min sampling intervals per hour, over an entire calling period. Circles at bottom denote calling behavior at the beginning of each sampling interval. Solid circle: fully extruded pheromone gland, abdomen lifted high from platform. Half circle: gland less extruded, lowered abdomen. Open circle: gland not visible, abdomen on platform. The female was placed on the support 1.5 hr after onset of the light period.

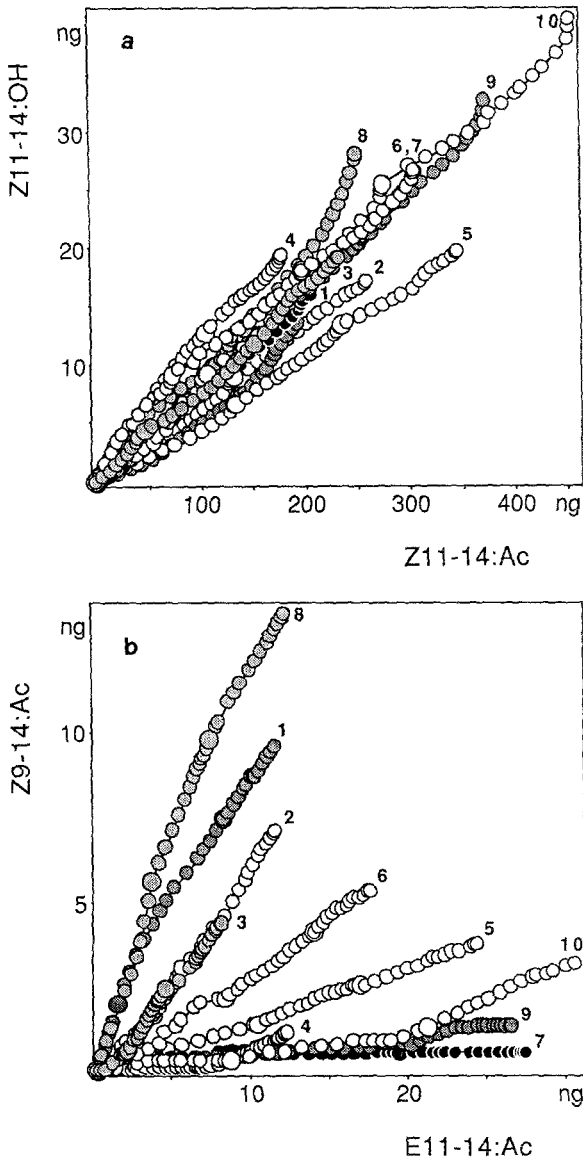

FIG. 3. Cumulative amounts of Z11-14:Ac/Z11-14:OH (a) and E11-14:Ac/Z9-14:Ac (b) released by 10 individual *C. pronubana* females over three calling periods 0, 2, and 4 days after emergence. Larger circles denote the first measurement of each calling period.

This individual constancy of release ratios is contrasted by the strong inter-individual variation of release ratios between Z9-14:Ac and the Δ 11-components. For example, the Z9-14:Ac/E11-14:Ac release ratio (Figure 3B), ranged from 0.04 to 1.17. A nonparametric analysis of variance (Kruskal-Wallis test; $P = 0.05$) showed that not only the Z9/E11 ratio, but also Z9/Z11-14:Ac and Z9-14:Ac/Z11-14:OH ratios were significantly different between females.

On the other hand, no significant interindividual variation could be detected for the release ratios between the Δ 11-compounds Z11-14:Ac, E11-14:Ac, Z11-14:OH. For example, the Z11-14:Ac/Z11-14:OH ratio measured was almost the same for all 10 females and ranged from 0.06 to 0.11 (Figure 3A). In this case, the actual emission ratio should be slightly higher, as less alcohol was eluted from the glass surface by comparison with the corresponding acetate (Figure 1A and B). Similarly, the 14:Ac/Z9-14:Ac ratio did not vary significantly between females.

DISCUSSION

The glass-adsorption collection device described in this study proved efficient for short-term measurement of five components of the sex gland secretion emitted by individual *Cacoecimorpha pronubana* females. A blend of four of these compounds (Z11-14:Ac, E11-14:Ac, Z9-14:Ac, and Z11-14:OH) has been shown to elicit male pheromonal behavior in the wind tunnel and in the field as observed with calling female moths (Witzgall, 1989).

A quantitative assessment of the minor pheromone components during 15-min intervals even outside peak emission periods was possible only after a modification of the collection system described by Shani and Lacey (1984). When the female was placed on a support within a glass bulb (as in Bjostad et al., 1980) the amount of pheromone trapped in the glass capillary tube increased appreciably. Pheromone is otherwise adsorbed within the glass bulb (Figure 1A and B), or probably on the body of the female (Baker et al., 1980; Ramaswamy and Cardé, 1984). In addition, secondary desorption of pheromone from the bulb modifies subsequent measurements.

In our system, pheromone could only be detected when females assumed the typical calling position (Figure 1C). A similar correlation between female calling and pheromone release has been established in *Trichoplusia ni* (Bjostad et al., 1980), *Choristoneura fumiferana* (Ramaswamy and Cardé, 1984), *Ephestia cautella* (Barrer et al., 1987), and *Holomelina lamae* (Schal et al., 1987). Interestingly, pheromone emission from forcibly extruded glands of *Heliothis virescens* (Pope et al., 1982) or *Platyptilia carduidactyla* (Haynes et

al., 1983) showed a diel periodicity similar to the calling cycle of undisturbed females. It therefore appears that gland extrusion merely coincides with the availability of pheromone for release. Gland extracts of individual *C. pronubana* females contained up to 100 ng Z11-14:Ac at the onset, but only a few nanograms at the end of the calling period (Frérot and Witzgall, 1989).

Blend proportions were remarkably constant for each individual female during three calling periods (Figure 3). This is consistent with results on *Ephesia cautella* (Barrer et al., 1987) and *Yponomeuta padellus* females (Du et al., 1987). In addition to this notable individual constancy of blend composition, we found no significant interindividual variation for the release ratios between the $\Delta 11$ -components [E11/Z11-14:Ac, Z11-14:Ac/OH (Figure 3A), E11-14:Ac/Z11-14:OH]. Rigid control of the E/Z11-14:Ac blend ratio in *Argyrotaenia velutinana* (Miller and Roelofs, 1980) has been shown to be the result of a common biosynthetic pathway of these two compounds (Bjostad and Roelofs, 1981). As functional groups of pheromone components can be readily interconverted in the insect (Morse and Meighen, 1986; Teal and Tumlinson, 1986, 1987; Wolf and Roelofs, 1987), we suspect that biosynthesis of $\Delta 11$ -14 alcohols and acetates follows the same pathway.

Most conspicuous, however, was the broad interindividual variation of the Z9/ $\Delta 11$ ratios (for example Z9/E11-14:Ac, Figure 3B). This considerable range in release ratios corresponds well with the results of our wind tunnel studies, where attraction of *C. pronubana* male moths occurred with a wide range of Z9/ $\Delta 11$ ratios (Witzgall, 1989). Likewise, Z9/Z11-14:Ac ratios varied widely in *Adoxophyes orana* females (Guerin et al., 1986). This suggests that production of Z9-14:Ac is controlled independently from the $\Delta 11$ -14-components. In *Trichopusia ni* production of Z9-14:Ac and Z11-14:Ac differs in at least terminal steps (Bjostad et al., 1984).

The importance of specific E11/Z11 ratios for the reproductive isolation of tortricid species is now well established. The "list of sex pheromones of Lepidoptera and related attractants" (Arn et al., 1986) cites 52 chemically identified tortricid sex pheromones containing Z11-14:Ac, 37 of which contain, in addition, E11-14:Ac. So far, there are only five tortricid species sharing all three $\Delta 11$ -components (E11/Z11-14:Ac and Z11-14:OH) with *C. pronubana*. Emission of these compounds in constant proportions should ensure reproductive isolation of the day-active carnation tortrix; interindividual variation of $\Delta 11$ -14:Ac/Z9-14:Ac ratios accounts for a diversity of the chemical signal that might play a role in intraspecific communication.

Acknowledgments—We are grateful to Dr. C. Descoins who proposed the subject and accepted P.W. in his laboratory. We thank Dr. H. Arn, Wädenswil for valuable discussion and for the use of Arancha's visionary computer. Drs. P. Guerin, Neuchatel; E. Priesner, Seewiesen; and E. She-

pard, Wädenswil, critically reviewed the manuscript. The assistance of C. Malosse, Brouessy, in GC analysis was essential. We are obliged to Dr. H.-R. Roth, ETH Zürich, for his advice on statistical analysis.

This work has been supported by the Max-Planck-Gesellschaft and the CNRS.

(Received December 15, 1987; accepted February 19, 1988)

Abstract—In laboratory choice experiments, the spices dill, paprika, black pepper, chili powder, ginger, and red pepper deterred *Delia antiqua* oviposition by 88–100%. Dose–response choice tests demonstrated that 1 mg of ground cayenne pepper (GCP) placed within 1 cm of artificial onion foliage reduced oviposition by 78%. A synthetic analog of capsaicin, the principal flavor ingredient of red peppers, deterred oviposition by 95% when present at 320 ppm in the top centimeter of sand (the ovipositional substrate). However, in no-choice conditions 10 mg GCP was not an effective deterrent. Sevana Bird Repellent and Agrigard Insect Repellent both use red pepper as a principal ingredient; at recommended field rates, neither of these materials was an effective ovipositional deterrent either in laboratory or field. Capsaicin-based materials do not appear to be candidates for onion maggot control via behavioral modification.

Key Words—Onion fly, *Delia antiqua*, Diptera, Anthomyiidae, oviposition, deterrent, capsaicin.

INTRODUCTION

In accepting hosts, insects integrate, via multiple sensory modalities, a diversity of external excitatory and inhibitory inputs with internal excitatory and inhibitory inputs, that establish internal “physiological status” (Dethier, 1982; Miller and Strickler, 1984). As for many insect herbivores, external excitatory inputs affecting onion fly oviposition have been investigated much more extensively

¹Paper No. 12514 of the Michigan Agricultural Experiment Station.

(Harris et al., 1987; Harris and Miller, 1982, 1983, 1984), than external inhibitory inputs.

We investigated pungent spices as ovipositional deterrents of *D. antiqua*. After ascertaining that various spices deter *D. antiqua* oviposition in choice tests, ground cayenne pepper was chosen for detailed study involving both choice and no-choice conditions because: (1) a synthetic analog of the principal flavor ingredient was readily available, (2) commercial products, including an insect repellent mixture available for field use, contain capsicum oleoresin as a principal ingredient, and (3) at least in vertebrates, capsaicinoids cause stimulation of chemoreceptors and heat and pain receptors (Virus and Gebhart, 1979), making animal behavioral responses likely.

METHODS AND MATERIALS

D. antiqua *Culture*. A laboratory culture was started from pupae collected from onion culls left in harvested fields in Grant, Michigan, in September 1986. Adults were housed in 80 × 65 × 60-cm screened cages provisioned with water, food (Ticheler, 1971), and ovipositional resources and were held at 16:8 light-dark photoperiod, 21 ± 1°C, and 70 ± 5% relative humidity. Larvae were reared on bisected onions. Flies used in all experiments were three to five generations removed from the field.

Laboratory Ovipositional Bioassays. Ovipositional assays were conducted in a second walk-in environmental growth chamber having conditions identical to the rearing chamber except this room was free of onion volatiles. All choice experiments were conducted in 57-cm-diam. × 57-cm-tall cylindrical cages stocked with ca. 50 male and 50 female flies provisioned with diet (Ticheler, 1971) and water. These cages rotated once every 13 min, thus experimental error was minimized by distributing environmental gradients evenly over all treatments (Weston and Miller, 1985).

Ovipositional dishes consisted of 50 g white silica sand (Unimin Granusil, Grade 40, Oregon, Illinois) moistened with 3 ml distilled water, tamped into a 4-cm-diam. × 4-cm-tall plastic cups. Standing upright in the center of each dish was one of the Harris et al. (1987; Harris and Miller, 1982, 1983, 1984) surrogate onions consisting of an onion-green 4-mm-diam. × 12-cm-long glass tube coated with paraffin wax containing 0.05% *n*-dipropyl disulfide. The surrogate onion was swiveled in the sand to provide a 1-mm space for ovipositor probing. This surrogate onion foliage has been shown to be competitive with similarly sized onion foliage (Harris et al., 1987), and offers a highly controlled ovipositional resource for testing putative deterrents. Since critical host examining behaviors and oviposition mostly occur within 1 cm of the juncture of

foliage and soil (Harris et al., 1987), deterrents should be assayed most effectively by placing them in this region.

With the exception of the no-choice experiment, all tests were randomized complete-block designs, with treatments placed 5 cm from the perimeter of the cage in randomized order and blocked over time intervals, usually by day. Replicates with combined treatment counts of less than 50 eggs were pooled to minimize sampling error. Egg counts were not distributed normally; however, log-transformed $[\ln(x + 1)]$ counts fulfilled assumptions for analysis of variance. A two-way analysis of variance general linear models procedure (SAS Institute, Cary, North Carolina) was used, and means were separated with the Student-Newman-Keuls' test for multiple comparisons.

Botanicals. Pungent spices were presented as choices in one cage, along with a foliar surrogate control. Treatments consisted of 5–7 mg of each of the following spices scattered within 1.5 cm of the surrogate onion foliage: crushed red pepper, consisting of 3×5 -mm flakes with seeds; chili powder, containing chili pepper, onion, cumin, garlic, oregano, cayenne pepper, black pepper, caraway and silicon dioxide; dill weed, flakes 1 cm \times 1 mm; ground ginger; and coarsely ground black pepper (R. T. French Co., Rochester, New York 14692). This experiment was replicated three times, and flies were allowed to oviposit 5, 6, and 48 hrs., respectively, for each replicate.

Dose-Response Series. Dose-response choice tests were conducted simultaneously in three cages, each cage with various concentrations of one test material. Ground cayenne pepper (GCP) (McCormick & Co., Baltimore, Maryland) or Sevana Bird Repellent (SBR) powder (Sevana Co., Fresno, California) were applied in quantities of 0 (control), 1, 2, 5, 10, 22, and 46 mg, placed within 1 cm of the surrogate onion. Agrigard Insect Repellent (AGR) (Sevana Co., Fresno, California) diluted to 1, 3.2, 10, 32, 100, and 320 ppt in deionized distilled water was sprayed (ca. 0.175 ml) on the sand surface with a TLC atomizer.

Ovipositional deterrence of synthetic capsaicin was assayed in a dose-response choice test with 50 males and 50 females per cage. Synthetic capsaicin (97% *n*-vanillyl-*n*-nonamide, Pfaltz & Bauer, Waterbury, Connecticut) was dissolved in 95% ethanol and diluted to 6.32, 20.0, 63.2, 200, 632, 2000, and 6320 ppm. Twenty milliliters of each solution was added to 200 g white silica sand, mixed thoroughly, and allowed to air dry. Final concentrations were 0.316, 1.00, 3.16, 10.0, 31.6, 100, and 316 $\mu\text{g/g}$ sand. Each sand treatment was moistened with 10 ml deionized distilled water and added in a 1-cm layer on top of clean sand in oviposition cups.

No-Choice Test. GCP was assayed in a no-choice context that employed a 2×2 factorial, completely randomized design that quantified effects of exposures during both prereproductive and reproductive periods. Prereproductive

exposure was effected by placing 120 flies (not sexed, less than 24 hr posteclosion) for five days in a cage with food, water, and a foliar surrogate treated with 10 mg GCP. A second group received similar treatment but no GCP. Females from these two groups were transferred individually to 9-cm-diam. screen-sided cages and provided with two males, food, water, and an ovipositional dish. Half the females experiencing GCP prereproductively were provided standard foliar surrogate; half were provided foliar surrogate plus 10 mg GCP. Similar reproductive exposure treatments were provided to females that had not experienced GCP.

Egg counts were taken daily from day 6 to day 15 posteclosion to measure days until first oviposition as well as daily oviposition. Onion flies in this experiment tended to lay most eggs on alternating days, which hindered data analysis because of zero counts. This problem was eliminated by pooling counts every two days. Egg counts for flies that died during the experiment (18% of total flies) were not used in the analysis; however, their ovipositional record was included when comparing days until first oviposition. Days to first oviposition data could not be analyzed by parametric methods due to nonhomogeneity of variance. These data were therefore analyzed with the Kruskal-Wallis test (Steel and Torrie, 1980); treatment comparisons were then conducted with the Wilcoxon-Mann-Whitney test (Steel and Torrie, 1980).

We hypothesized that if habituation or adaptation to GCP had occurred in the no-choice experiment, then flies with the greatest exposure would show diminished GCP deterrence in a follow-up choice test, e.g., when compared to flies not exposed or exposed only prereproductively. Therefore, groups of three females were pooled from each treatment and placed in 9-cm-diam. screen cages with food, water, and two oviposition cups, one with 10 mg GCP, one without. The percent ovipositional deterrence was then compared for the four treatment groups.

Field Trials with Capsaicin-Based Products. Field trials of AGR and SBR ovipositional deterrence to *D. antiqua* were carried out in 1986 in a commercial onion field (Eaton Rapids, Michigan) with historically moderate onion fly population pressure. Plots consisted of 3 m of treated row, separated by 3 m of buffer row, in a linearly arranged randomized complete-block design replicated six times. Blocks were separated by ca. 35 m. SBR treatments were 0.05, 0.5, or 5 g/plot, applied to the soil at the base of onion plants with salt shakers. AGR treatments were 1.5 mg, 15 mg, 150 mg, 1.5 g or 15 g plus 15 mg Vaporguard (Miller Chemical Co., Hanover, Pennsylvania), in 70 ml distilled water per plot, using Chapin compressed air sprayers (Model 110, R.E. Chapin Manufacturing Works, Inc., Batavia, New York 14020), with Teejet 730077 fan nozzle at 20 psi (Spray Systems Co., North Ave, Wheaton, Illinois 60188). Negative controls for these treatments were 70 ml water and 15 mg Vaporguard in 70 ml water applied in 3-m plots in each block. There were nine applications

made of SBR and AGR, on a 7- to 10-day schedule starting May 27. Damage estimates in conventionally pesticide-treated rows (liquid chlorpyrifos, ca. 1.1 kg AI/hectare) were made in 3 m of row 1 m laterally from untreated plots. Stand counts were made May 27 and at two-week intervals. Analyses were conducted on percent damage [(100 × stand count on August 6)/stand count May 27]; these data did not require transformation.

RESULTS AND DISCUSSION

Botanicals. In choice experiments, pungent spices all significantly deterred onion fly oviposition (Figure 1). Mean percent ovipositional deterrence of these commercial spices was: paprika (88.6%), red pepper (95.9%), ginger (99.0%), dill (99.3%), chili powder (99.8%), and black pepper (100%).

Black pepper, red pepper, and ginger were pungent spices that showed great promise in choice tests. Unfortunately, the pungent flavor components of black pepper, predominantly piperine, are suspected carcinogens (Buchanan, 1978), while gingerol, the pungent principle ingredient of ginger (Wildholz, 1976), is relatively expensive. Red pepper was chosen for further studies based on its relatively well-known physiological effects on taste perception in mam-

FIG. 1. Number of eggs laid with 5–7 mg of the following spices placed within 1.5 cm of surrogate onion in choice tests: CON, control; GIN, ginger; DIL, dill; PPK, paprika; RPP, red pepper; CHL, chili powder; BPP, black pepper. Means followed by the same letter are not significantly different (SNK test, 2 *df*).

mals and the availability of synthetic capsaicin. Capsaicinoids, the pungent principal flavor ingredients in red pepper, cause bursts of activity from contacted chemoreceptors and nociceptors (Virus and Gebhart, 1979). Capsaicinoids have some similarities to warburganal, a potent *Spodoptera exempta* antifeedant from the bark of an African tree (Nakanishi, 1980). Both capsaicin and warburganal have a pungent flavor and are used as spices (Todd et al., 1977; Nakanishi, 1980); in both cases these chemicals cause rapid firing from chemoreceptors that then become unresponsive to stimulation (Virus and Gebhart, 1979; Ma, 1977). It may be that such nonspecific activity at the level of gustatory chemoreceptors enables these spicy substances to interfere with normal host acceptance behavior.

Dose-Response Series. In dose-response choice tests, oviposition of onion flies was reduced 78-99% by the presence of 1-46 mg GCP (Figure 2) ($F = 26.1$; $df = 6, 24$; $P < 0.001$). Increasing quantities of GCP clearly caused greater reductions in the number of eggs laid next to treated surrogate foliage. Agrigard deterred oviposition ($F = 10.0$; $df = 6, 36$; $P < 0.001$) at the highest rates tested, with 98% deterrence at 100 ppt and 100% deterrence at 320 ppt (Figure 3); recommended field rates correspond approximately to 32 ppt, which was not significantly different from the control. Sevana Bird Repellent showed no deterrence, even at the highest rate tested ($F = 0.58$; $df = 6, 36$). Synthetic

FIG. 3. Dose-response curve for oviposition when substrate was sprayed in choice tests with 0.175 ml of Agrigard Insect Repellent solutions. Standard error based on 6 *df*.

capsaicin incorporated into the top 1 cm of ovipositional substrate significantly deterred oviposition when present at concentrations greater than 600 ppm ($F = 35.4$; $df = 7, 77$) (Figure 4).

As summarized by Dethier et al. (1952), many chemicals are deterrent or repellent at high concentrations, including host-plant chemicals, which at lower concentrations are involved with host acceptance. These dose-response choice tests were conducted to be certain that low rates of a promising material did not stimulate oviposition. Any material showing stimulatory activity at low concentrations would cause logistical problems when applied in the field, because chemical decomposition would eventually decrease the concentration to levels that could stimulate insect damage. Dose-response experiments with capsaicin-based products elicited no increased oviposition through the range of rates tested, unlike dipropylsulfide, which shows deterrent activity at high concentrations (Matsumoto and Thorsteinson, 1968) and stimulatory activity with an optimum concentration in surface wax of about 0.05% (Harris et al., 1987). Direct visual observations of fly behavior suggested that, even at the highest rates tested, onion flies did not orient away from GCP; so, the end result appears to be mediated by deterrence upon contact rather than repellency.

No-Choice Test. In the no-choice experiment, there was no evidence that GCP deterred oviposition (Figure 5). Prereproductive exposure showed no significant effect on two-day egg counts ($F = 0.19$; $df = 1, 39$); exposure during

FIG. 4. Dose-response relationship for oviposition with synthetic capsaicin placed within the top centimeter of sand.

peak reproductive activity also was not significant ($F = 0.39$; $df = 1, 39$) (Figure 5). There were significant differences between treatments in days to first oviposition (Kruskal-Wallis test, $H/D = 11.25$, $P < 0.025$) (Steel and Torrie, 1980). Multiple comparison of treatments showed only one significant difference, flies not exposed to GCP laid eggs sooner (mean of 6.9 days) than flies of the reproductive-exposure-only treatment (mean of 7.8 days) (Wilcoxon-Mann-Whitney test, $T' = 89.5$, $n_1 = 10$, $n_2 = 14$, $P < 0.05$) (Steel and Torrie, 1980).

No-choice tests of deterrents are a rigorous test of deterrence, because insects under these conditions face increasing internal excitatory inputs that can override the presence of external inhibitory inputs. No-choice situations may simulate some field situations (where alternative acceptable ovipositional substrates may not be available), and also assist in determining whether choice test deterrence is caused predominantly by sensory vs. sublethal physiological effects (Landis and Gould, 1989). Our no-choice tests effectively ruled out the possibility that effects of GCP seen in choice tests were caused by sublethal toxicity, since all no-choice groups laid similar numbers of eggs. This is in contrast to preliminary screening with pyrethroids, in which "deterrent" concentrations were accompanied by convulsions or tremors in onion flies (unpublished data).

In the choice test bioassay of flies previously used in the no-choice experiment, all groups laid similar percentages of eggs on the control ($84 \pm 2.7\%$,

FIG. 5. Cumulative oviposition for 2×2 factorial experiment investigating prereproductive and reproductive exposure to GCP. ---◇---, no exposure; ---□---, exposure only prereproductively; ---△---, exposure only reproductively; —○—, continual exposure.

mean \pm SE) ($F = 0.49$, $df = 3, 6$), implying that these groups retained the same ability to sense and respond to the presence of GCP. Whether habituation or adaptation were responsible for the lack of differences in the no-choice experiment is still unclear; either dishabituation occurred rapidly or another mechanism was responsible for acceptance of GCP-treated ovipositional substrates. Perhaps flies simply tolerated deterrent because they were becoming deprived.

Field Trials. Field tests of AGR and SBR in 1986 for the most part agreed well with laboratory studies; however, the trends in field data were not statistically significant. There was a trend toward higher mean damage for all three rates of SBR in the field than in the control plots (Figure 6). These field results suggested that SBR may have stimulated oviposition, in contrast to the lack of response (stimulatory or deterrent) to SBR in the laboratory. Under the wet field conditions experienced in 1986, there exists the possibility that SBR, which consists of 10% ground red peppers and 4% ground garlic, could have decomposed to form microbial products stimulatory to onion fly oviposition (Coley-Smith and King, 1969; Dindonis and Miller, 1980).

The most highly concentrated sprays of AGR suppressed damage to a level intermediate to the untreated controls and the conventionally pesticide-treated areas. These sprays were irritating to those applying them, and at elevated rates

FIG. 6. Percent damage to seedling onions by onion fly. Means followed by the same letter are not statistically different (SNK test, 5 *df*).

caused onions to have stunted, yellow foliage. These field results with AGR agree with the laboratory studies that indicated that ovipositional deterrence only occurred at concentrations exceeding the field recommended rates.

General Discussion. Ovipositional and feeding deterrents should be tested with hosts or host models that accurately reflect normal sensory input (Städler, 1983). Using natural stimuli allows normal sequences of behaviors to proceed. Allowing the full repertoire of behaviors involved with host acceptance to be expressed implies that each behavior has an opportunity to be influenced by the presence of deterrents. When using highly artificial substrates, internal excitatory inputs may override inputs associated with normally nonstimulatory substrates to provide abnormal behavioral responses. An example demonstrating how ovipositional substrates can influence results while studying ovipositional deterrents is the recent work of Tingle and Mitchell (1986). Their data show that in choice tests, elderberry extracts were more deterrent to *Heliothis virescens* when applied to tobacco (a preferred host) compared to a standard paper towel substrate.

External excitatory inputs for the onion fly, *Delia antiqua* (Meigen), involve synergism between visual and chemical stimuli (Harris and Miller, 1982). Yellow or green vertical cylinders ca. 4 mm diam. that emit *n*-dipropyl disulfide from surface waxes elicit preovipositional behaviors, including foliar

runs, ovipositor examining of foliage and soil, and ovipositor probing (Harris et al., 1987). These surrogate onions provided a highly standardized ovipositional resource that accurately simulated host stimuli. We suggest they are highly suitable and convenient for studying ovipositional deterrence.

Ovipositional deterrents have not previously been tested for the onion fly with host models. Wiens et al. (1978) were able to reduce oviposition by ca. 78% over controls in choice tests using hydrated bean (*Phaseolus vulgaris*) extracts. Alfaro et al. (1981), using cedar (*Thuja plicata*) leaf oil, found an 84% ovipositional deterrence. Both of these experiments used inverted beaker ovipositional bioassays (Vernon et al., 1977). Deterrence assays with pine oil (Javer et al., 1987) similarly used halved onion bulbs rather than onion foliage or foliar models. Irrespective of bioassay method, results to date suggest that a wide variety of compound classes can appreciably deter onion fly egg laying, and some, such as pine oil at dosages of 5 mg/onion, deter appreciably in the no-choice situation.

While pungent spices appear to be highly deterrent materials for onion fly oviposition in laboratory choice tests and could perhaps be of some use in the small home garden, we do not feel that they hold much promise for commercial field use. The poor results in 1986 field tests may have been due partially to extremely wet weather or to the lack of a highly acceptable alternative ovipositional resource (trap crop). A follow-up test in 1987 (unpublished data) suggested that poor deterrent activity probably was not due to the lack of availability of suitable ovipositional resources. Materials that are both less costly and show greater activity in both choice and no-choice tests are currently being investigated.

Abstract—Four sesquiterpenoids (**2**, **4**, **7**, and **9**) have been isolated and characterized from the termiticidal fraction of *Dipterocarpus kerrii* resin. The major constituent of this resin is α -gurjunene (**1**).

Key Words—Resins, *Dipterocarpus kerrii*, termite, sesquiterpenes, α -gurjunene, epicyclocolorenone, fungicidal, termiticidal, bioassay.

INTRODUCTION

Trees of the plant family Dipterocarpaceae dominate many lowland primary forests of Southeast Asia. Often attaining a height of 70 m or more, these hardwoods can comprise 80% of the emergent vegetation in some areas (Ashton, 1982). With species richness at a maximum on the Indonesian island Kalimantan, Dipterocarpaceae range from Africa to Papua New Guinea. Because of their abundance and durability, these timbers have become important economic commodities.

Southeast Asian dipterocarps produce copious amounts of resins (Ashton, 1982; Torquebiau, 1984). Exuded from natural or artificially induced trunk wounds, these viscous and sticky resins have long been items of commerce

¹Presented at the Third Annual Meeting of the International Society of Chemical Ecology, June 21–24, 1986, University of California, Berkeley.

⁴Present address: Department of Chemistry, Williams College, Williamstown, Massachusetts 01267.

(Marsden, 1783). Dipterocarp resins contain a large and complex array of chemical constituents (Hegnauer, 1966; Bisset et al., 1971; Ashton, 1982), many of which are terpenes. The diversity of terpene and other fractions indicates that dipterocarps dedicate a large number of biosynthetic pathways to the production of resin chemicals. These biosynthetic pathways must be metabolically costly, but in the absence of data on biological roles of dipterocarp resins, the adaptive benefits (if any) of maintaining these pathways remain obscure.

Several lines of evidence suggested that dipterocarp resins might contain biologically active molecules. Considering evidence scattered throughout the literature of Asian forestry, we postulated that some of the chemicals made by dipterocarps might play a defensive role. Dipterocarp timbers are well known to resist biological attack from many sources. *Shorea robusta* was shown highly resistant to the termites *Microcerotermes beelsoni* and *Heterotermes indicola* (Sen-Sarma, 1963; Sen-Sarma and Chatterjee, 1968). Particle boards constructed from *Shorea* species are also protected against *Cryptotermes cynocephalus* (Moi, 1980). Fresh resins of *Anisoptera thurifera* appear to protect bee nests from termites (Messer, 1984).

Dipterocarp woods cause substantial mortality to insects feeding on them. Over a three-month test period, termites feeding on *Shorea* species suffered 99% and 86% mortality, while termites feeding on the nondipterocarp *Dyera costulata* showed only a 13% death rate (Moi, 1980). Tested as a possible substrate for insect culture, dipterocarp sawdust killed stable fly larvae in the first instar, while other woods did not (Sutherland, 1978).

Chemical factors in resins may also protect dipterocarps from microbial attack. Untreated dipterocarp timbers are reported to be highly resistant to fungal invasion (Bakshi et al., 1967), and volatile components of *Hopea papuana* were shown to inhibit fungal growth (Messer, 1985). Bacterial growth inhibitors of dipterocarp origin include essential oils of *Vateria indica* (Bhargava and Chauhan, 1968) and stemnopolol and alpha-copalliferol from Sri Lankan dipterocarps (Sootheeswaran et al., 1983).

The research described here tested the hypothesis that dipterocarp resins contain biologically active components that protect the trees against insects and fungi. Antifungal and termiticidal properties of whole resins and resin fractions were evaluated, and novel compounds possibly mediating the observed biocidal properties were isolated and characterized.

METHODS AND MATERIALS

Tree Resins

Fresh resins of *Dipterocarpus kerrii* King were collected by tapping trees cultivated at the Forest Research Institute, Kepong, Malaysia. Resins were stored in sealed glass ampoules for transport to the United States.

Termite Bioassays

Zootermopsis angusticollis (Hagen) termites were taken from a permanent laboratory culture. Termites selected for bioassay experiments were undifferentiated larvae ("workers") beyond the third instar, and weighed 10–15 mg. Ten termites were placed in a 5-cm plastic Petri dish containing a 4.5-cm-diameter filter paper treated with compounds of interest. Treatment of filter papers involved uniform application of a methylene chloride solution of the chromatographic fractions of interest, followed by evaporation of the solvent. Three to four duplicate dishes were used for each condition. Mortality was checked at 24-hr intervals, and dead termites were removed.

Pilot experiments established that termite mortality was dose dependent. All filter papers were thus treated with the amount of a compound normally found in 10 mg of crude *D. kerrii* resin.

Fungal Bioassays

Ten milligrams of crude *D. kerrii* resin dissolved in methylene chloride was applied to a 10 × 20-cm polyester TLC plate and eluted with 50% ether-hexane. After the solvents had evaporated, the plate was sprayed with a suspension of *Cladosporium cucumerinum* spores. The suspension was prepared by scraping spores from three confluent plates into ≈ 5 ml of sterile water, mixing this solution with 50 ml of 0.35% green bean juice agar at 37°C, and sonicating the solution for 3 min prior to spraying the TLC plates. Plates were examined for regions of antifungal activity after incubating for 48 hr at room temperature in TLC tanks lined with moist paper towels. Zones of fungal inhibition were apparent as white bands against the background of grey-green fungal growth.

Isolation

Crude *D. kerrii* resin was dissolved in methylene chloride and applied to 1000 μm preparative TLC plates (silica gel GF, Analtech, Inc., Newark, Delaware), which were eluted with 100% pentane or 50% ether-hexane. Component bands were visualized by means of a UV light and/or anisaldehyde spray reagent (90% of a 5% solution of anisaldehyde in 95% ethanol–5% acetic acid–5% conc. H₂SO₄). Bands of interest were removed from the plates, and the silica gel was repeatedly washed with methylene chloride, which was removed by evaporation in vacuo.

Further purification was effected by high-performance liquid chromatography (HPLC) using a Waters Associates M6000A solvent delivery system and a preparative scale column (20 mm ID × 250 mm) packed with 5-μm silica. The HPLC column was eluted with 5% ether-hexane at a flow rate of 1.5 ml/min. Ultraviolet detection was performed at 254 nm with a Perkin-Elmer model

LC-65T variable wavelength UV detector. Eluent from HPLC peaks of interest was collected and concentrated at ambient pressure using Kaderna-Danish (Ace Glass, Inc.) microscale concentrators.

Final purification of resin components was effected by semipreparative gas-liquid chromatography (GLC) with a Varian model 2100 gas chromatograph equipped with a flame ionization detector and a glass column (3 mm \times 1 m) packed with 3% OV-1 on 100/120 Supelcoport (Supelco, Inc.). Nitrogen was used as the carrier gas at a flow rate of 30 ml/min, and the column temperature was held at 150°C for 6.5 min, and then programmed to 200°C at 20°/min. The effluent from the column was split in a 1:9 ratio between the detector and 25-cm glass capillary collection tubes (Brownlee and Silverstein, 1968) that were cooled in a Dry Ice-acetone bath. Analytical GLC was performed with the aforementioned Varian system or a Shimadzu Mini-2 equipped with a fused silica capillary column (007-methylsilicone, 0.25 mm \times 15 m, Quadrex Corp., oven temperature 200°C isothermal, helium as carrier gas at a linear flow of 2 kg/cm), a capillary split injection system with a 100:1 split, and a flame ionization detector.

Identification

The components of interest were identified using a combination of gas chromatography-mass spectrometry [GC-MS, using both electron impact (EI) and chemical ionization (CI)], gas chromatography-Fourier transform infrared spectroscopy (GC-FTIR), ultraviolet (UV) spectroscopy, and Fourier transform-nuclear magnetic resonance (FT-NMR) spectroscopy. Both proton [^1H]- and carbon [^{13}C]FT-NMR were utilized.

Mass spectra were obtained on a Finnigan model 3300 mass spectrometer equipped with a Systems Industries model 150 data reduction system, or a Finnigan model 4500 GCMS system. EI mass spectra were obtained at 70 eV; CI mass spectra utilized methane as the reagent gas. High-resolution mass spectra (HRMS) were measured on an Associated Electronics Industries MS-902 spectrometer interfaced to a VG Micromass 2040 data reduction system.

Microscale trimethylsilylation of purified resin components was performed in methylene chloride solution with excess Sylon-BTZ (Supelco, Inc.) at room temperature (10 min). Portions of these solutions were analyzed by GC-MS (EI).

Infrared spectra were obtained in CHCl_3 solution using a Perkin-Elmer model 299B infrared spectrophotometer; GC-FTIR spectra were obtained on an IBM model 98 GC-FTIR system coupled to a Hewlett-Packard model 5790A capillary gas chromatograph (007-methylsilicone column, 0.25 mm \times 25 m, Quadrex Corp.).

[^1H]NMR spectra were obtained using either a Bruker model WM-300

(300 MHz) or a Varian model XL 400 (400 MHz) NMR spectrometer. [^{13}C]FT-NMR spectra were obtained using either the aforementioned Varian system (at 100 MHz), or a Jeol model FX-90Q (at 22.5 MHz) NMR spectrometer. NMR spectra were measured in CDCl_3 or deuteriobenzene, which were stored over anhydrous K_2CO_3 and passed over a column of neutral alumina immediately prior to use.

Ultraviolet spectra were measured in cyclohexane or 95% ethanol using a Hewlett-Packard model 8450A UV-visible spectrophotometer. Optical rotations were measured on a Perkin-Elmer model 141 polarimeter.

RESULTS AND DISCUSSION

Fungal Bioassays

Several components of *D. kerrii* resin inhibited fungal growth, as shown in Figure 1. Strong inhibition was shown by compounds with $R_f = 0.04$ and $R_f = 0.11$, as well as by a broad band at $R_f = 0.45$. Compounds with $R_f = 0.22$ and $R_f = 0.35$ produced less intense fungal growth inhibition.

Termite Bioassays

Guided by the termite bioassay, initial fractionation of crude resin was performed by TLC on 1000 μm preparative plates which were eluted with 50% ether-hexane. Resolved components were bioassayed at levels that mimicked a 10-mg dose of crude resin. After three sequential fractionations, termiticidal activity was found in a single TLC band that was UV active and that stained intensely with anisaldehyde. This TLC band, comprising ca. 12% of the crude resin, had the same R_f (0.45) as that which displayed strongest inhibition in the fungal bioassays. Toxicity results are shown in Figure 2A.

Further fractionation of the TLC active zone using preparative HPLC yielded one minor peak (1) and two major peaks (2 and 3, Figure 3). The major peaks were isolated and each was found to represent $\approx 4\%$ of the crude resin. As shown in Figure 2B, peaks 2 and 3 displayed essentially equivalent toxicity when bioassayed at levels corresponding to the 10-mg crude resin dose level.

Final fractionation of HPLC peaks 2 and 3 was accomplished using semi-preparative GLC. HPLC peak 2 was found to contain two major components (A and B), as was HPLC peak 3 (C and D, see Figure 4). The major GLC peaks were isolated in the following quantities: A: 2 mg; B: 0.2 mg; C: 2 mg; D: 0.8 mg. All isolated GLC peaks were found to be $\geq 95\%$ pure upon reinjection by analytical GLC. These materials were extremely labile and exhibited significant decomposition, even when stored at -10°C . Decomposition was

FIG. 1. Fungicidal bioautograph of crude *Dipterocarpus kerrii* resin against *Cladosporium cucumerinum*. Details in text.

exceptionally rapid in NMR solvents containing traces of acid (e.g., CDCl_3). As a result, these solvents were carefully pretreated with neutral alumina immediately prior to use. Due to these stability restrictions, and the quantities of materials needed for structure elucidation, bioassays of the individual components A, B, C, and D have not yet been completed.

Isolation of Major Resin Component

In the preliminary stages of this study, examination of crude *D. kerrii* resin by GLC had shown the presence of a single major volatile component. Fractionation of resin by preparative TLC showed that the major volatile component corresponded to the most mobile TLC band, which was UV active and which

FIG. 3. High-performance liquid chromatogram of preparative TLC band ($R_f = 0.45$).

FIG. 4. Capillary GLC analysis of HPLC peaks 2 and 3.

stained intensely with anisaldehyde. Isolation of this component was accomplished by preparative TLC ($R_f = 0.95$, 1000 μm silica plate) using 100% pentane as eluent. This component, a colorless oil, comprised $\approx 24\%$ of the crude resin and was shown to be $\geq 95\%$ pure by analytical GLC ($R_t = 3.6$ min, 3% OV-1, 150°C). This material exhibited the same degree of lability as did the individual components A–D. Naturally, since this component did not elute with the TLC active zone, it did not display any toxicity in the bioassay.

Structural Analysis

Major Volatile Component. Analysis of the major volatile component by CI-MS established that the molecular weight of this material was 204. From HRMS analysis of the ion at $m/z = 204$, its molecular formula was found to be $\text{C}_{15}\text{H}_{24}$, indicating that this component was a sesquiterpene with four sites of unsaturation. The ^{13}C NMR spectrum of this material displayed a single pair of olefinic carbons (δ 137.26, 136.04) implying the presence of one double bond and three rings. Further, the ^1H NMR of this material exhibited three prominent methyl group signals [δ 0.84 (s), 0.91 (d), 1.66 (br.d)], and no olefin proton signals. Comparison of these data with information recorded in compilations of sesquiterpene data (Devon and Scott, 1972; Ourisson, 1966) allowed

the major volatile component to be identified as α -gurjunene, **1** (Figure 5). This compound, a member of the aromadendrane family of sesquiterpenes, was originally isolated from *Dipterocarpus dyeri* (Palmade et al., 1963) and has since also been found in resin from *Shorea flava* (Bisset et al., 1971). Our measured values for other physical properties of **1** (IR, UV, $[\alpha]_D$) were also in good agreement with the literature values (Palmade et al., 1963).

Peak A. Low-resolution EI-MS analysis of component A, a colorless oil, showed a very weak peak at $m/z = 220$ with diagnostic peaks at $m/z = 205$ [M-15 (CH₃)] and $m/z = 202$ [M-18(H₂O)], suggesting that A was a labile alcohol. The CI-MS spectrum of A also displayed a weak molecular ion signal at $m/z = 220$. HRMS analysis of this ion suggested the molecular formula of C₁₅H₂₄O. Finally, treatment of A with Sylon-BTZ followed by low-resolution GC-MS (EI) analysis showed quantitative conversion to a more volatile product with a molecular ion at $m/z = 292$. A gain of 72 mass units implied that A had been trimethylsilylated and strengthened the conclusion that A was an alcohol. This conclusion was also supported by observation of a weak OH band at 3637 cm⁻¹ in the GC-FTIR. The [¹³C]NMR spectrum of this material showed a single pair of olefinic carbons (δ 153.46, 106.25). Taken together with the HRMS data, this suggested that A was a tricyclic sesquiterpene alcohol with one double bond.

Comparison of this information, and extensive [¹H]NMR data, with liter-

FIG. 5. Structures of previously identified sesquiterpenes isolated from *D. kerrii* resin, with the exception of cyclocolorenone, **3**, which has been isolated from *P. colorata*. Details in text.

ature data allowed identification of A as spathulenol, **2** (Figure 5). Like α -gurjunene, this material is an aromadendranoid sesquiterpene and was first isolated from *Eucalyptus spathulata* (Bowyer and Jefferies, 1963). In subsequent studies, spathulenol has been isolated from several other plant sources (cf. cotton plant, Elzen et al., 1984; *Citrus junos*, Shinoda et al., 1970). An especially extensive NMR/structural study of **2** was recently published (Inagaki and Abe, 1985). Our measured NMR data (conventional [^1H]- and [^{13}C]NMR spectra as well as two-dimensional [^1H]- and [^{13}C]NMR spectra) completely match these data.

Peak D. Analysis of D, also a colorless oil, by low-resolution CI-MS showed a molecular ion at $m/z = 218$. HRMS analysis of the $m/z = 218$ ion gave a molecular formula of $\text{C}_{15}\text{H}_{22}\text{O}$, implying that D was a sesquiterpene with five sites of unsaturation. GC-FTIR analysis showed an intense band at 1690 cm^{-1} and a moderately intense band at 1627 cm^{-1} , suggesting the presence of a conjugated enone; no OH band was observed. This was supported by the [^{13}C]NMR spectrum, which showed distinctive carbon signals at δ 200.96 (carbonyl), 141.60, and 99.47 (double bond).

Comparison of this information with tabulated sesquiterpene data (Devon and Scott, 1972; Ourisson, 1966) suggested that D was the known enone **3**, cyclocolorenone (Figure 5), first isolated from *Pseudowintera colorata* (Corbett and Speden, 1958). However, the UV data ($\lambda_{\text{max}} = 264\text{ nm}$; $e = 13,000$; EtOH) and optical rotation ($[\alpha]_{\text{D}} = -400^\circ$) reported for cyclocolorenone did not match our measured values: UV: $\lambda_{\text{max}} = 252\text{ nm}$ ($e = 4400$, EtOH); $[\alpha]_{\text{D}} = -200^\circ$ ($c \approx 0.8\text{ mg}$ in 5.0 ml , EtOH). These results lead us to conclude that D was actually **4** (Figure 5), the known C-1 epimer of cyclocolorenone. This compound, referred as epicyclocolorenone, has been obtained from **3** upon treatment with KOH (Corbett and Young, 1963) or upon chromatography on basic alumina (Büchi and Lowenthal, 1962). To the best of our knowledge, it would appear that our isolation of epicyclocolorenone from *D. kerrii* represents the first report of this material as a naturally occurring substance.

Our data for D correlated well with data reported for **4** (Büchi and Lowenthal, 1962; Corbett and Young, 1963; Büchi et al., 1966); UV: $\lambda_{\text{max}} = 253$ ($e = 9300$, EtOH); $[\alpha]_{\text{D}} = -167^\circ$ (EtOH). Especially diagnostic was the signal for the C-10 methyl group [δ 0.99 (d)] in the [^1H]NMR spectrum of D. As originally discussed by Büchi in his synthesis of epicyclocolorenone (Büchi and Lowenthal, 1962; Büchi et al., 1966), the C-10 methyl doublet in **4** is observed at δ 1.02, while in naturally derived cyclocolorenone this signal appears at δ 0.78. These chemical shift differences can be accounted for by consideration of the most stable conformations of cyclocolorenone and epicyclocolorenone (Büchi and Lowenthal, 1962; Büchi et al., 1966), as depicted in structures **3a** and **4a**, respectively (Figure 5). In **3a**, the seven-membered ring is in a pseudoboat form and the C-10 methyl group is in the shielding region of the extended

chromophore. In **4a**, however, the more stable conformer is the pseudochair form, which disrupts conjugation of the cyclopropyl group with the enone and places the C-10 methyl group in a pseudoaxial position. This accounts for the both the higher field position of the C-10 methyl in **4a** and for the large differences in the UV spectra of **3a** and **4a**.

Peak B. Low-resolution MS analysis of B, an extremely labile colorless oil, showed a very weak signal at $m/z = 220$ (both EI and CI), as well as moderately intense peaks at $m/z = 205$ [M-15(CH₃)] and 202 [M-18(H₂O)]. These data, like those for A, suggested that B contained a labile alcohol group. Also in common with A, GC-MS analysis of B after treatment with Sylon-BTZ showed quantitative transformation to a more volatile product with highest molecular weight ion at $m/z = 277$ [M(292)-15(CH₃)]. As before, this result suggested that B was an alcohol that had been trimethylsilylated. GC-FTIR analysis showed the presence of a very weak OH band at 3637 cm^{-1} and a moderately intense band at 1635 cm^{-1} (double bond). In analogy with data for A, the 3637 cm^{-1} IR signal implied that B was a tertiary alcohol. HRMS analysis of the B molecular ion gave a molecular formula of C₁₅H₂₄O. Taken together, these data suggested that B was a sesquiterpene alcohol with four sites of unsaturation.

The nature and number of the multiple bonds in B were deduced using several lines of information. First, because so little of B was isolated (0.2 mg), only a very poor [¹³C]NMR spectrum of this material could be obtained (20,000 transients). However, this spectrum showed four olefinic carbon signals: δ 149.1, 140.95, 131.32, 116.53 (d₆-benzene), implying the presence of two double bonds. Secondly, the [¹H]NMR spectrum (Figure 6) of B displayed two, one-proton olefin signals (δ 5.67, 5.40), which were not coupled, implying that both double bonds were trisubstituted. Finally, the UV spectrum of B showed $\lambda_{\text{max}} = 243\text{ nm}$ ($\epsilon \approx 2400$; cyclohexane), implying the presence of a conjugated diene. Hence, it was concluded that B was a bicyclic sesquiterpene alcohol containing a conjugated diene chromophore.

Compound B displayed four methyl group signals in its [¹H]NMR spectrum characterized as follows: δ 1.71 (m, olefinic methyl group); 1.225, 1.220 [singlets, implying two nearly equivalent methyl groups α to the tertiary alcohol moiety: C(CH₃)₂OH]; 0.70 (d, implying a CHCH₃ group). Accounting for the five carbons in these groups left 10 carbons to be distributed in the bicyclic system. Of the various possibilities, similarities between the [¹H]NMR spectra of B and compound **4** led us to begin with partial structure **5** (Figure 7). Thus, in compound **4**, the protons at position 2 appeared as a geminally coupled set with relatively low field positions [δ 2.58 (dd, $J = 6.4, 16.8\text{ Hz}$); 2.08 (br. d, $J = 16.8\text{ Hz}$)] due to the presence of an sp² center (carbonyl) at C-3. In B, a similar pair of signals was observed [δ 2.45, H_d (dd, $J = 7.8, 18\text{ Hz}$); 2.12, H_f (br. d, $J = 18\text{ Hz}$)] implying a similar arrangement of groups, in this case

FIG. 6. 300-MHz PMR spectrum of compound B, identified as 7 (Figure 7).

with an olefinic carbon providing the sp^2 center at position 3. Very weak spin-spin coupling was observed between H_d and the olefin proton at δ 5.65 (H_a) and between H_a and the olefinic methyl group, indicating the double bond substitution pattern shown in 5. In addition, H_d was coupled ($J = 7.8$ Hz) to a methine signal at δ 3.34 (m, H_c) implying that the C-2 methylene was flanked by a bridgehead proton, as shown in 5.

Placing the remaining groups on the now required seven-membered ring in 5 was straightforward. Thus, methine proton H_c was coupled to a one-proton

FIG. 7. Partial structures (5 and 6) and final structure for compound B, identified as 7.

signal at δ 1.93 (H_g) which was, in turn, coupled to the methyl doublet at δ 0.70. This implied that H_c was flanked by the $CHCH_3$ group. Finally, the unassigned $C(CH_3)_2OH$ group was placed in the remaining allylic position (C-7) giving structure **6** (Figure 7). This connection was consistent for several reasons: (1) it allowed assignment of H_e (δ 2.28, e.g., allylic and α to OH); (2) it corresponded to a conventional substitution pattern for a sesquiterpene; and (3) it correlated well with the observed lability of B (e.g., acid-catalyzed dehydration would produce a highly conjugated product). Hence, we assign structure **6** to B.

A computer search of the Chemical Abstracts On-Line data base for structure **6** produced a single entry, which has the stereochemistry shown in formula **7**. Ourisson reported the synthesis of **7** in the course of determining the structure of α -gurjunene, **1** (Streith and Ourisson, 1963). Oxidation of **1** with SeO_2 /acetic anhydride, followed by $LiAlH_4$ reduction, produced an "extremely labile compound," which was assigned structure **7**. Our measured values for B matched Ourisson's physical data for **7** well: UV: $\lambda_{max} = 243$ nm (cyclohexane); IR: 1630 cm^{-1} ($CHCl_3$); $[^1H]NMR$: δ 0.70 (d, 3H), 1.15 (s, 6H), 1.7 (m, 3H), 5.38 (1H), 5.6 (1H) ($CDCl_3$, 60 MHz). Our observation of **7** in *D. kerrii* resin represents the first isolation of this sesquiterpene from nature.

Peak C. Much of the chemical behavior of C in the early stages of analysis matched that of A and B. Thus, this material, also a colorless oil, displayed a very weak molecular ion at $m/z = 220$ and moderately intense peaks at $m/z = 205$ [M-15(CH_3)] and 202 [M-18(H_2O)]. GC-FTIR analysis showed a very weak OH band at 3741 cm^{-1} and a moderately intense band at 1643 cm^{-1} , implying the presence of a tertiary alcohol group and C-C double bonds, respectively. Low-resolution GC-MS analysis, after treatment with Sylon-BTZ, showed quantitative transformation to a more volatile product with a molecular ion at $m/z = 292$. Finally, HRMS analysis of the molecular ion for C once more indicated a molecular formula of $C_{15}H_{24}O$. In addition, C exhibited four olefinic carbon resonances in its $[^{13}C]NMR$ spectrum (δ 152.09, 145.83, 123.86, 110.96), and showed UV absorption ($\lambda_{max} = 219$ nm, $e = 1400$), implying the presence of a conjugated diene. Altogether, this information indicated that C was a bicyclic sesquiterpene containing a tertiary hydroxyl group and two conjugated double bonds.

Although rather complex, the $[^1H]NMR$ spectrum of C (Figure 8) displayed the following salient features: (1) three one-proton olefin signals [δ 5.71, H_a , dd ($J = 3.85, 6.7$ Hz, no coupling with other olefin signals); 4.77, H_b , br. s; and 4.68, H_c , br; coupling between H_b and H_c ($J \approx 2$ Hz), as well as the chemical shift and general appearance of these signals, implied that they represented a terminal methylene group]; (2) two downfield methine signals (δ 3.03, H_d , m; 2.85, H_e , m); and (3) three methyl group signals [δ 1.70, br. s (implying an olefinic CH_3 group); 1.27, s (implying a CH_3 α to the tertiary

FIG. 8. 400-MHz PMR spectrum of compound C, identified as **9** (Figure 9).

hydroxyl group, as in **A**); 0.81, d (implying a CHCH_3 group)]. The remaining proton absorbances were located in two broad, complicated bands centered roughly at δ 1.75 ($\approx 5\text{H}$) and 1.4 ($\approx 4\text{H}$). Finally, by $[^{13}\text{C}]\text{NMR}$ analysis using an INEPT pulse sequence (Morris and Freeman, 1979; Doddrell and Pegg, 1980), **C** was found to contain three methyl (δ 27.27, 21.51, 14.76), five methylene (δ 110.96, 41.33, 32.86, 26.87, 25.33), four methine (δ 123.86, 46.65, 45.43, 32.86), and three quaternary (δ 152.09, 145.83, 80.74) carbon atoms.

Partial structure **8** (Figure 9) can be proposed for **C** on the basis of exhaustive decoupling studies (one- and two-dimensional), which yielded the following spin-spin coupling relationships. First, weak coupling between the olefin methyl group and the terminal methylene protons (H_b/H_c), together with a lack of coupling between H_a and H_b/H_c and the olefin methyl, suggested that the diene was composed of an isopropylidene group conjugated with a trisubstituted, endocyclic double bond. Secondly, **C** contained three nonolefinic methine carbons. One of these had to be present in the $-\text{CHCH}_3$ group. Indeed, irradiation at δ 1.89 (H_f , on the shoulder of the complicated band centered at δ

1.75) collapsed the methyl doublet at δ 0.70, establishing the chemical shift of this methine proton. Since C had been shown to be bicyclic, and since all of the quaternary carbon atoms had already been accounted for (olefins and tertiary alcohol), it was deduced that the remaining methines had to occupy bridgehead positions. The one-proton multiplets were obvious candidates for these methines. Thirdly, olefin proton H_a coupled to both of these methine signals (H_d , δ 3.03, $J = 3.8$ Hz; H_e , δ 2.85, $J = 6.7$), which were, in turn, coupled to each other. This implied that H_a , H_d , and H_e were on contiguous centers; the relative magnitudes of the H_a/H_d and H_a/H_e coupling constants indicated that H_e was the nearer to H_a . Finally, H_f coupled to H_d but not to H_e , while H_d was coupled to signals in the δ 1.85 region but not so for H_e . This implied that H_e was bordered by the remaining quaternary center, the tertiary alcohol, and that H_d was bordered by one of the unassigned methylene groups.

At this stage, only placement of the remaining four methylene groups was needed to complete a structure assignment for C. Of the various possibilities, a symmetrical distribution of the methylenes in the two rings of the bicyclic system was judged to best fit the $[^1H]NMR$, producing structure **9** (Figure 9). The nonsymmetrical distributions were ruled out as each would have produced highly distinctive features in the $[^1H]NMR$ that were not observed. In structure **9**, extensive coupling interaction between the methylene groups in the two sets would be expected to produce complex and broad $[^1H]NMR$ absorptions, just as is observed for C. To the best of our knowledge, this is the first report of structure **9** in the literature, constituting a new addition to the guiane family of sesquiterpenes. Studies to establish the stereochemical configuration of **9** are in progress.

What we can conclude from these studies is that the resin of *Dipterocarpus kerrii* contains small quantities of four labile sesquiterpenoids, closely related to α -gurjunene, which are responsible for the resin's termiticidal and antifungal activity. We hope to prepare each of these components in quantities sufficiently large to permit more detailed evaluation of their biological properties.

EFFECTIVE ATTRACTION RADIUS: A Method for Comparing Species Attractants and Determining Densities of Flying Insects

JOHN A. BYERS, OLLE ANDERBRANT, and JAN LÖFQVIST

Department of Ecology, University of Lund
S-223 62 Lund, Sweden

(Received October 15, 1987; accepted February 23, 1988)

Abstract—The catches of bark beetles (Coleoptera: Scolytidae) were compared between attractive traps releasing semiochemicals and passive traps (cylindrical sticky screens hung, at 10 heights of 0.7–11.5 m, on poles). A central attractive-trap pole was surrounded by three passive-trap poles spaced 50 or 100 m away at the apices of an equilateral triangle. The catches of *Tomicus piniperda* and other scolytid species on the attractive-trap pole baited with host monoterpenes, or the catches of *Ips typographus* attracted to synthetic pheromone, were compared to passive trap catches in a Scots pine forest or in a Norway spruce clear-cut, respectively. Information about flight height distributions of the above scolytid species, and *Hylurgops palliatus*, *Cryphalus abietis*, *Pityogenes chalcographus*, *P. quadridens*, *P. bidentatus*, and *Trypodendron domesticum* were obtained on the passive and attractive trap poles. A new method is presented for determining the densities of flying insects based on the passive trap's dimensions and catch, duration of test, and speed of insect. Also, a novel concept, the effective attraction radius (EAR), is presented for comparing attractants of species, which is independent of insect density, locality, or duration of test. The EAR is obtained by the ratio of attractive and passive trap catches and the dimensions of the passive trap, and thus should correlate positively with the strength of the attractant and the distance of attraction. EARs are determined from catch data of *T. piniperda* and *I. typographus* as well as from the data of previous investigations on the same or other bark beetles.

Key Words—Bark beetle, *Ips typographus*, *Tomicus piniperda*, Coleoptera, Scolytidae, pheromone, host attractants, dispersal, flight, *Pityogenes*, *Hylurgops*, *Cryphalus*, *Trypodendron*

INTRODUCTION

It is of ecological interest to determine the relative abundance of flying insects at various heights above ground. Also, such knowledge should be considered when using pheromone traps at certain heights for monitoring the abundance of a pest species. Information concerning the density of flying insects (per volume air or per area over land) is often required to build models of host and/or mate location, dispersal, and disease vector relationships. It is also of interest in chemical ecology to be able to compare the attractivities of various attractants of different strengths or blends within a species as well as between species at different times or under different environmental conditions. For instance, one question might be whether host attractants are relatively as attractive to one species, which does not employ long-range pheromones [*Tomicus piniperda* (L.); Byers et al., 1985], as are pheromone components to another species [*Ips typographus* (L.); Schylter et al., 1987].

We present a method that provides information helpful for a better understanding of the above three topics: flight height, flight density, and comparison of attractant strengths both within and between species. The method involves comparing the catches of flying insects, exemplified by bark beetles, that are passively intercepted by cylindrical sticky screens suspended at various heights above ground on 12-m poles to the catches of these insects attracted to attractants released from sticky-screen traps on a similar pole in the same area.

METHODS AND MATERIALS

It is obvious that passive insect traps placed at various heights above ground will catch the proportion of insects flying at each of the respective heights. However, we believe such an arrangement of traps can also be used to determine with reasonable success the average densities of insects flying in the vicinity of the traps. Cylindrical sticky screens in the forest can be considered as "filtering" or intercepting bark beetles that fly or are carried through the area during their dispersal and host- and mate-seeking flight. If one had a cylindrical trap as long as a standing tree, or at least sample traps at many heights encompassing most of the levels of flight activity, then one can consider this system in a two-dimensional sense. The trap then can be visualized as a circle on a plane surface. The trap (or circle) then will catch an average number that is dependent on the trap's diameter ($2 \times$ radius), time length of trapping, average speed of flying beetles, and the density of flying beetles (number per area) as shown in equation 1:

$$\text{Catch} = 2 \times \text{radius} \times \text{time} \times \text{speed} \times \text{density} \quad (1)$$

However, if the passive sticky traps with a certain radius are placed in the forest for a specific time and catch, and we assume an average flight speed (either from observations of flying beetles or assuming a flight speed equal to the wind speed), then the density can be determined:

$$\text{Density} = \text{catch}/(2 \times \text{radius} \times \text{time} \times \text{speed}) \quad (2)$$

Passive and attractive (attractant releasing) traps can also be used in a new concept and method, the effective attraction radius (EAR), for comparing semi-quantitatively the attraction distances of attractants both within and between species of insects. A maximum possible distance of attraction can be imagined with the earlier concept of the active space, in which a time-averaged volume (plume) containing above-behavioral-threshold semiochemical concentrations elicits attraction responses when entered by the insect (Bossert and Wilson, 1963; Nakamura and Kawasaki, 1977; Baker and Roelofs, 1981; Elkinton and Cardé, 1984). This concept can be modified to an attraction space to find distances from the source within which, for example, 50% of the entering insects are successful in finding the source. The average distance of attraction is another measurement which may be of interest. We now introduce a new concept, the EAR, which is equivalent to the distance from an attractive source within which all insects are assumed to be attracted. The EAR is the radius of a circular plane oriented perpendicular to the incoming insects and thus can be regarded as the radius of a spherical volume that surrounds the attractive source:

$$\text{EAR} = (\text{ATC} \times \text{LCSAPT} \times \text{PTC}^{-1} \times \pi^{-1})^{1/2} \quad (3)$$

where ATC is the attractive trap catch, PTC is the passive trap catch, and LCSAPT is the longitudinal cross-sectional area of the passive trap.

It is probable that "all" insects are never attracted to semiochemicals if within a specific distance of the source, and thus the EAR is not a "real" biological distance. However, the EAR does have positive relationships to the "real" maximum, 50% responding, and average distances of attraction as mentioned in the concepts above. While the active space model, the attraction space model, or the average attraction distance cannot be investigated easily with trap catches (Elkinton and Cardé, 1984), the EAR can be found in a straightforward manner by simple comparison of two trap catches. For example, if a passive trap area in longitudinal cross section, A , containing no attractants, intercepts X number of beetles per time unit, and if, in the same vicinity, a similar trap containing attractant catches $20X$ beetles per time unit, then the effective area (longitudinal cross section) of the attractive trap is 20 times larger than the passive trap, and the $\text{EAR} = (20A/\pi)^{1/2}$. This ratio of catch between the passive and attractive traps should remain similar regardless of the density of flying beetles, so consistent measurements of the EAR can be obtained on different

dates or in different areas. The type and strength of attractant should be the most important factor in affecting the ratio.

To demonstrate our ideas concerning measurement of flight density and EAR, we placed metal poles holding cylindrical sticky screens at 10 levels (from 0.7 to 11.5 m) in or near the forest. Three poles with passive traps were positioned at the apices of an equilateral triangle while a fourth pole with attractive traps (host attractants or pheromone) was placed in the center of the triangle. Each pole was 12 m high and constructed of four 28-mm diameter steel tubes (3 m long) interconnected and held upright by two sets of four guy wires attached at 6- and 12-m heights. At the top of each pole was a 30-cm arm with pulley which suspended a string of 10 cylindrical sticky screens so that they could be drawn up or down the pole between test periods. Each sticky screen was 30 cm tall by 15 cm radius (LCSAPT of 0.09 m²) of 6.5-mm square mesh coated with Stikem Special (Seabright Enterprises, Emeryville, California).

The attraction of *Tomicus piniperda* (L.), the European pine shoot beetle, and associated bark beetles to host monoterpenes (Byers et al., 1985) was investigated using the poles inside a Scots pine (*Pinus sylvestris* L.) forest, 60 years old, near Ångelholm, Sweden (April–May 1984). The passive poles were 50 m from the central attractive pole, forming a triangle of 87 m on a side. Each tubular trap had two open polyethylene vials (No. 730 Kartell, Italy), 30 mm × 6-mm ID, for each of the host monoterpenes, (+)- α -pinene (99% pure by GLC; $[\alpha]_{546}^{20} = +57.4^\circ$), (-)- α -pinene (>99.5% GLC; $[\alpha]_{546}^{20} = -50 \pm 1^\circ$), (+)-3-carene (>99% GLC; $[\alpha]_{\text{D}}^{20} = 17 \pm 0.5^\circ$), and terpinolene (>97.3% GLC). Chemicals were from Fluka AG, West Germany, and Carl Roth, Sweden. Each trap released about 10–20 mg/day of each of the monoterpenes except for about 3–5 mg/day of terpinolene (these rates are equivalent to that released from a freshly cut Scots pine log, 28 cm × 15 cm diam.; Byers et al., 1985).

Flight characteristics of *Ips typographus* (L.), the European spruce bark beetle, were similarly studied within a year-old clear-cut area adjacent to Norway spruce [*Picea abies* (L.) Karst.] forest in Esrum forest district, near Hillerød, Denmark (May 1984). The passive poles were positioned 100 m from the central attractive pole in the corners of a triangle 173 m on a side. These distances between passive and attractive trapping poles were chosen because trap and semiochemical interactions are minimal (Schlyter et al., 1987; Byers, 1987) while population levels of flying beetles are still expected to be rather uniform within this area. Each cylindrical trap on the attractive pole had two pheromone dispensers, which released 5 mg/day of 2-methyl-3-buten-2-ol and 0.1 mg/day of (4*S*)-*cis*-verbenol (Schlyter et al., 1987). Trapping in both areas was done in the afternoon for the time periods and dates as shown in Table 1. Wind speeds were taken with a fan anemometer. Bark beetles of all species caught on the sticky traps during each period were removed at the end of the test time, cleaned in petroleum ether, and sex determined for *T. piniperda* and *I. typographus*.

Since it is possible that too small an active trap would catch a dispropor-

^fBeetle density actually measured at center location, while pheromone bait was at position B.

tionately small number attracted to the source and thus adversely affect measurement of the EAR, we tested four trap sizes each with the same pheromone bait as above on *I. typographus*. Cylindrical sticky screens were similar to those above and of the same length (30 cm) but varied in radius, at 3.75, 7.5, 15, and 30 cm. These traps were each held at 1.5 m height by wires from a 22-mm-diam. steel tube driven into the ground. Two sets of each of the four sizes were tested in May and June of 1984 and 1985 for a total of 21 replicates with rotation among positions. Linear and logarithmic regressions of the total catches and of the proportions among trap sizes at each trap radius were compared.

RESULTS

Height above Ground of Flying Bark Beetles. Catches of bark beetles by the passive sticky screens indicate that most species fly above 0.7 m (the lowest trap level), are most abundant at 1.9–5.5 m, and gradually fly less frequently at still higher levels (Figures 1 and 2). This pattern is shown best by *Hylurgops palliatus* Gyll., *Pityogenes bidentatus* Hbst., *P. quadridens* Hart., *Trypoden-*

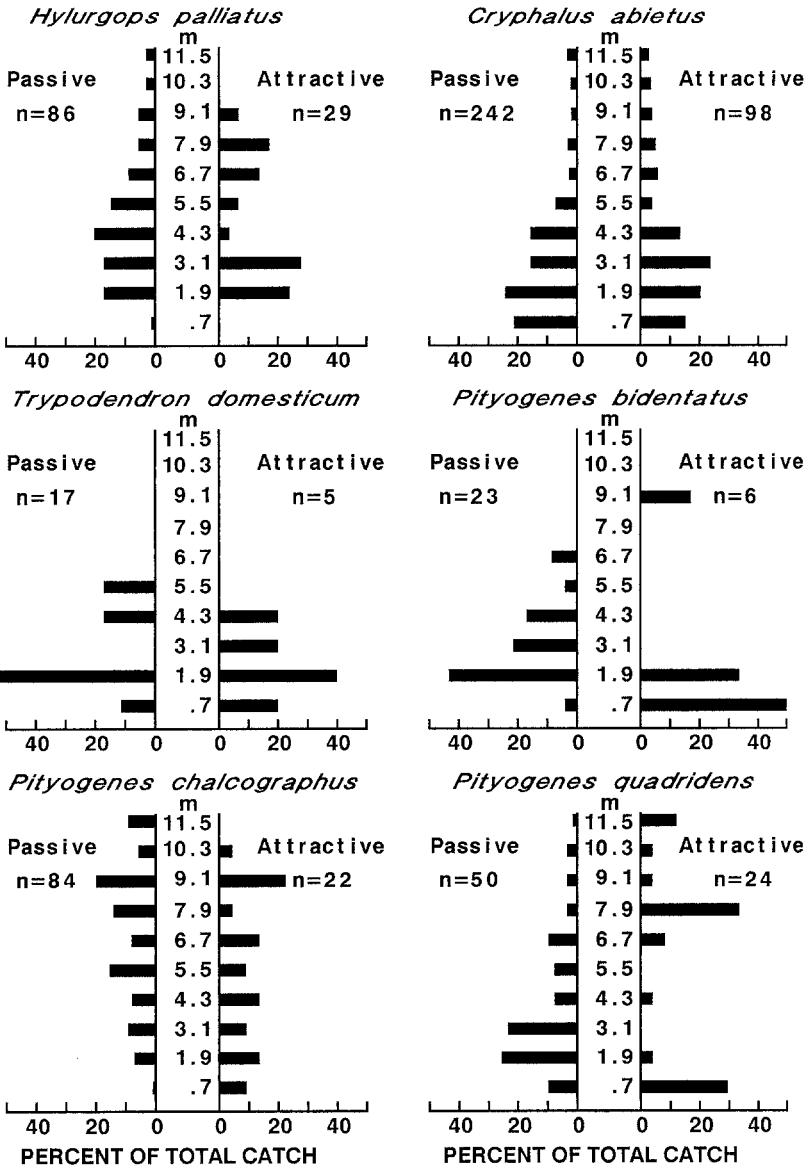

FIG. 1. Height of flying bark beetles as percent of total catch on passive sticky-screen traps or "attractive" sticky-screen traps releasing host monoterpenes at each level [(+)- α -pinene, (-)- α -pinene, (+)-3-carene each at 10-20 mg/day and 3-5 mg/day of terpinolene]. Passive traps at each height on three 12-m poles were spaced 50 m away from a central active trap pole in Scots pine forest (May 1, 1984).

FIG. 2. Height of flying bark beetles as percent of total catch on passive sticky-screen traps or attractive sticky-screen traps releasing host monoterpene attractants (*T. piniperda*) or pheromone components (*I. typographus*). Placement of trap poles was as in Figure 1 for *T. piniperda* (April 15 and 21, 1984). For *I. typographus* the passive poles were spaced 100 m away from the attractive pole in a clear-cut of Norway spruce forest (May 17, 19, 20–22, 1984). Monoterpene attractant release as in Figure 1, while the pheromone components, 2-methyl-3-butene-2-ol and *cis*-verbenol, were released at 5 and 0.1 mg/day, respectively, at each trap level.

dron domesticum L. (although catch was low), and *I. typographus*. *P. chalcographus* L. and *T. piniperda* also did not fly near the ground but they seemed to exhibit a more uniform distribution of flight heights (Figures 1 and 2), although the numbers for *T. piniperda* are too low for reliable estimates.

Most of the distributions of beetles at the heights seemed unaffected by semiochemicals since chi-square comparisons of the passive and attractive distributions yielded no significant differences for each species ($P > 0.1$) except for *P. quadridens* ($P < 0.05$), *T. piniperda* ($P < 0.05$), and *I. typographus* ($P < 0.001$). However, the distributions of *P. quadridens* on the attractive traps is based on a low number, and it is difficult to explain the pattern. The pattern of *T. piniperda* is also based on low numbers, but it is consistent with the pattern for *I. typographus* in which attractive pheromone traps catch proportionately more beetles on the lowest traps (Figure 2).

Density of Flying Bark Beetles. The number of bark beetles caught on passive and attractive sticky-screen traps, trapping periods, and speeds of beetles (either observed or assumed to be equal to the measured wind speed) were used to calculate the densities of flying beetles per hectare in the level from 0 to 12 m using equation 2 and multiplying by 4 to account for the gaps between traps (Table 1). The densities of flying beetles (per hectare) were estimated for each trap pole on each day for *T. piniperda* and *I. typographus* (Table 1) and for six other species of bark beetle (Table 2) to indicate the variation in density with respect to time, area of forest, and species.

TABLE 2. DENSITIES OF FLYING BARK BEETLES IN SCOTS PINE FOREST NEAR ÄNGELHOLM, SWEDEN, DURING AFTERNOONS (1330–1730 Hr) OF SPRING DAYS AS ESTIMATED FROM PASSIVE STICKY SCREENS ON 12-M POLES^a

^aDensities were calculated from equation 2, where trapping was for 4 hr; all species were assumed to fly at 1.6 m/sec as observed for *T. piniperda*; and catch = actual catch \times 4 to correct for incomplete trapping surfaces.

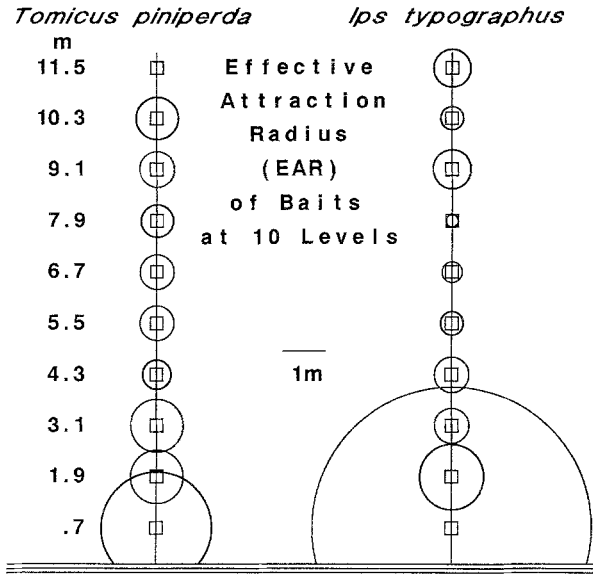

FIG. 3. Comparisons of the effective attraction radii (EAR) of attractive, monoterpene-releasing, sticky-screen traps (*T. piniperda*) or of pheromone-releasing, sticky-screen traps (*I. typographus*). Release of semiochemicals as in Figures 1 and 2.

Effective Attraction Radius for Comparing Attractants of Insects. The average of EARs for the traps on the entire trap pole in both *T. piniperda* and *I. typographus* were similar as were the EAR estimates for each day (Table 1). The lowest EARs for *I. typographus* were correlated with the highest wind speeds (Table 1). The EAR was largest at the bottom trap level for both species, and it was larger for the pheromone compared to host monoterpenes at the dosages used (Figure 3). At other levels, the EARs were similar within a species as well as between the two species. The sticky-screen traps of increasing radius (3.75–30 cm) caught increasing numbers of beetles in a logarithmic relationship (Figure 4). This curve may be expected if beetles have increasing difficulty finding a point source of pheromone (i.e., must turn more rapidly than possible near the source). The coefficient of determination ($r^2 = 0.90$) was larger than that for a linear relationship ($r^2 = 0.90$).

DISCUSSION

Height above Ground of Flying Bark Beetles. Several studies have investigated the height at which a particular species of bark beetle flies. However, most of these studies have used only: (1) traps with pheromone, (2) traps at just

FIG. 4. Logarithmic relationship between number of *I. typographus* caught on pheromone baits and increasing radius of the sticky-screen trap at 1.5-m height. Traps released 5 mg/day of 2-methyl-3-butene-2-ol and 0.1 mg/day of *cis*-verbenol. The encircled point shows the size of trap used in the attractive and passive pole experiments.

a few levels, (3) traps at widely spaced levels (up to 150 m height), or (4) traps that collected beetles for several months. Our 10 passive traps from 0.7 to 11.5 m high appeared sufficient to determine with some precision the distribution of flight heights over the normal flight range for *H. palliatus*, *Cryphalus abietis* Ratz., *T. domesticum*, *P. bidentatus*, *P. quadridens*, and *I. typographus* but not, apparently, for *P. chalcographus* and *T. piniperda* (Figures 1 and 2). The catch for *T. piniperda* was too low to reliably estimate the distribution. On the other hand, *P. chalcographus* exhibited a uniform distribution, except at the bottom level, which probably indicates they were flying also at higher levels than the range of traps, as if they were dispersing through the pine forest (a nonhost tree).

In one of the first studies of flight-height distribution in bark beetles, Gara and Vité (1962) used rotary net traps to suggest that no differences in flight activity of *Dendroctonus brevicomis* LeConte and other bark beetles occurred from ground level to lower crown regions, but "in the upper crown and above forest stands, bark beetles seemed to fly less frequently." Shore and McLean (1984) found *Trypodendron lineatum* Ol. responded over 76 days to lineatin-baited traps at 0-, 1-, 2-, 3-, and 4-m heights with most (31.6%) caught on the 1-m trap at the level just above the underbrush (effectively the lowest trap). The

highest catch on the "lowest" trap of a column of traps releasing semiochemicals is the same result we found for *T. piniperda* and *I. typographus* (Figure 2). It is possible that these high catches on the lowest trap were due either (1) to beetles flying lower in order to avoid flying against higher wind speeds, (2) to increasing inability to orient to the source at higher levels due to relatively stronger, more turbulent wind or a decrease in the optomotor response further from the ground, or (3) to the absence of a visual silhouette (tree) in conjunction with odor stimuli, and thus they were trying to land on a fallen tree.

Schmitz (1980) intercepted *I. pini* Say as they flew to a source of naturally produced pheromone (0- to 2-m height) by four columns, one in each cardinal direction, of 11 flat sticky traps from 2 to 17 m high about 45 m from the source. He found most beetles flew below 10 m as they approached the source. However, these results cannot be compared either to our passive trap catches or to our column of semiochemical release.

Cuthbert and Peacock (1975) placed flat sticky traps baited either with multilure or not at about 3.5-, 7-, and 12-m heights in healthy or diseased elm trees. They found that *Scolytus multistriatus* Marsh. was caught predominantly at the 3.5-m height in baited or unbaited traps, a result similar to our studies. Forsse and Solbreck (1985) placed suction traps at 2, 9, 43, and 93 m on a TV tower and caught *I. typographus* only at 2 and 9 m. They report that the density-height profile of all bark beetle species caught (Solbreck, 1985) indicates that less than 14% of any species flies above 20 m. Using a similar regression technique (exponential without 0.7-m height for all $r^2 > 0.78$), we predict that 87% of *I. typographus* fly between 1 and 11.5 m high of all those flying up to 100 m high. Similarly, 84% of *H. palliatus*, 89% of *C. abietis*, and 89% of *P. quadridens* fly below 11.5-m height.

Duelli et al. (1986) placed pheromone traps near passive traps at nine heights from 1.7 to 150 m on a weather tower and found that less than 5% of *I. typographus* fly above 10 m. In contrast, *P. chalcographus* had a more gradual decrease in proportion, flying at higher levels (14% flew higher than 10 m), which is similar to our results for this species (Figure 1). However, their results on the passive catches are uncertain because complete or partial pheromone blends were placed at the same heights on the tower as were the passive traps.

Density of Flying Bark Beetles. The density of flying insects can be determined either by active methods, whereby suction fans or rotary nets capture insects, or by passive methods such as our sticky traps. Our investigation is the first to use such passive methods to determine densities of flying beetles, but the results of previous studies can be reanalyzed according to equation 2 for comparison. However, studies that report catches of bark beetles in barrier traps are less accurate for this purpose because beetles may avoid them due to air turbulences or may recover their balance after striking the barrier (Chapman

and Kinghorn, 1958). Also, a conversion from the width of flat traps to a diameter ($2 \times$ radius) for tubular traps must be done according to the average trap interception area:

$$2 \times \text{radius} = 2 \times \text{width} * \pi^{-1} \int \cos A = 0.637 \times \text{width}$$

Thus, assuming a 5-hr flight for each day of a 37-day test and 2 m/sec speed of beetle or wind, then Cuthbert and Peacock (1975) had a density of flying *S. multistriatus* in the healthy elms (0–12 m height) of 1/hectare and in the diseased elms of 2069/hectare. The results of Schmitz (1980) for *I. pini* can be similarly adjusted to yield an average density of 43/hectare (0- to 17-m height) at 45 m away from a source of pheromone. Byers et al. (1985) report a catch of 52 *T. piniperda* on two blank sticky traps (25 cm diam.) for 15 hr (time unpublished) during the maximum swarming, which yields about 401 flying beetles per hectare (0–10 m), clearly a higher population level than that in Table 1.

Our method of flight density estimation assumes that beetles do not avoid, or are attracted to, the passive traps and thus cause us to under- or overestimate the population level. Nijholt (1983) questioned whether sticky-screen traps appear transparent to bark beetles because he found a nonrandom distribution of catch on a 60×80 -cm-wide screen held 60 cm above ground. The average catch of the peripheral areas of the trap was less than the center. However, it is possible that through the beetles' movements to free themselves from the stickem, they gradually slid down the sticky screens so that the top periphery of the trap was depleted of beetles over time, thus accounting for the difference. Furthermore, the bottom area may have caught less beetles simply because fewer beetles fly near the ground.

Bark beetles are known to respond to visual silhouettes of the size of a tree trunk often in combination with attractive semiochemicals (Tilden et al., 1983; Borden et al., 1986; Payne, 1986). The resolving power of insect eyes depends on the number of facets and the ommatidial angle. Insects with higher visual acuities have higher numbers of ommatidia; the eye of the lamellicorn beetle *Polyphylla fullo* has 12,150 facets, the housefly about 4000, and dragonflies about 10,000–28,000 (Wigglesworth, 1972). Bark beetles are known to have rather low acuity, which is explained by the low number of ommatidia. Using scanning electron micrographs of several genera of Scolytidae, we found that the eyes of all species have similar low numbers of ommatidia. For example, *I. typographus* has 215 facets per eye, *T. piniperda* also has 215, *Scolytus laevis* Chap. has 235, and *P. chalcogaphus* only 110. In comparison, the bark beetle predator, *Thanasimus formicarius* (L.) (Cleridae), has 610 facets per eye, and the cerambycid, *Acanthocinus aedilis* (L.), has about 650.

Our sticky-screen traps were at least 75% transparent while Stikem Special

is translucent, thus, the traps are similar to spider webs, which are effective in catching insects with moderate to poor visual acuity. Therefore, it is probable that the bark beetle species collected neither were attracted to nor avoided the visual outlines of the sticky traps.

As mentioned above, capture methods have usually been used to estimate flight densities. Chapman and Kinghorn (1958) used 6 m/sec rotary nets 2 m above log piles during spring swarming of *T. lineatum* to find maximum densities of 1.521/m³. This value can be converted to densities for a 0- to 12-m layer (182,520/hectare) or for a 0- to 3-m layer (45,630/hectare). Forse and Solbreck (1985) used suction traps that generated an airflow of 1.67 m³/sec to capture bark beetles at four heights. However, estimation of densities from this method is doubtful as insects are only captured when very near the suction inlet. This distance of capture is hard to estimate because it is different for every insect, depending on their size and speed (Leos-Martinez et al., 1986).

The results of our passive sticky-screen catches indicate that at the densities we measured, few trees in the forest would escape being closely passed by or landed upon by the common bark beetle species. This is in accordance with findings for *D. ponderosae* Hopkins (Burnell, 1977; Raffa and Berryman, 1980; Hynum and Berryman, 1980), showing that beetles land on most trees in the forest and that this pattern can result from randomly flying beetles. Primary attraction indicating more susceptible hosts to *T. piniperda* (Byers et al., 1985) would thus not need to reach very far (on the order of our EARs) to attract the pioneer beetles. If the host conditions were suitable, these pioneers could generate aggregation pheromone (although this does not appear to be the case for *T. piniperda*) or increase the release of the primary attractants through boring activities (secondary attraction).

Effective Attraction Radius for Comparing Attractants of Insects. Vité and Gara (1962) hypothesized that the number of bark beetle attacks in a source of attractant influenced the distance over which beetles were drawn, but few experiments have tested this or determined the distance-concentration relationship. Using rotary-net traps at the pheromone source and at 15 and 30 m away, Vité and Gara (1962) showed that *I. paraconfusus* Lanier were attracted from at least 15 m away to the infested logs. Possibly even at 30 m there was an increased capture rate, but control data were not presented to establish a difference. Byers (1983) used a grid of passive sticky traps in three rows distant from a pheromone source of *I. paraconfusus* to show that "wild" beetles of both sexes were attracted from at least as far away as 18 m. While an average or a maximum attraction distance must exist for each specific attractant/species combination, they are difficult to determine, as noted above. On the other hand, the EAR is easy to establish and yields an index of the attraction distance so that comparisons can be made between different times, areas, semiochemical releases, and insect species.

EARs were calculated at 10 heights for *T. piniperda* attraction to monoterpenes released equivalent to a "small log" (28 cm × 13 cm diam.; Byers et al., 1985) and for *I. typographus* attraction to "medium" levels (Schlyter et al., 1987) of pheromone (Figure 3). However, these estimates at different heights may have been greatly influenced by semiochemical interactions between traps. It would be interesting to test only one pair of traps alone at each of the levels to see how this affects the EARs. The EAR estimates for *T. piniperda* appear similar to those that can be obtained from the data of Byers et al. (1985) for a small log (EAR = 0.59 m) or a 30 male + 30 female infested log (EAR = 0.65 m) or small log-equivalent in monoterpene release (EAR = 0.91 m) and check log (EAR = 1.02 m) at 1.5 m height.

Our EAR estimates for *I. typographus* were probably affected by the higher than usual wind speeds in the clear-cut (Figure 3, Table 1). Schlyter et al. (1987) compared a "high" dose (10 × "medium") of *I. typographus* pheromone to a blank, 12 m away at 1.5-m height, and so we can calculate an EAR of 1.90 m, and for their "medium" dose an EAR of 0.57 m. If the blank had been placed further away, so as not to intercept any pheromone-responding beetles, then the EAR estimate would have been higher and more appropriate. Thus, as expected, higher release rates of pheromone have higher EARs. Similar procedures can be used to calculate EARs on previous work that used sticky traps. For example, Byrne et al. (1974) used sticky traps to catch 6724 *Gnathotrichus sulcatus* on two sulcatol-baited traps (each releasing 48–240 µg/day) versus 51 on two control traps (0.0954 m² interception area), which yields an EAR of 2.00 m.

An EAR can be calculated for any semiochemical and responding insect species if the passive trap effectively "filters" the flying population according to the trap's size (sticky traps). However, the attractive trap, while not needing to be of the same type or dimension as the passive trap, does need to (1) effectively catch a significant proportion of the insects responding and (2) be similar or smaller in size than the passive trap in order to obtain consistent EARs for a particular chemical–insect combination. The trapping efficiencies (percentage of beetles contacting the trap that are caught) of the passive and attractive traps within a test pair would not affect the EAR, as long as the efficiencies were similar. The efficiencies could even be different on different occasions and not change the EAR unless the efficiencies change disproportionately between the passive and attractive traps.

Trap size does effect trapping efficiency since Tilden et al. (1979) showed that many more *D. brevicornis* were attracted to the vicinity of a pheromone source and small surrounding trap than were caught on this trap. EAR estimates obtained by increasing the passive and attractive trap radius would tend to increase as a function of the trapping efficiency (size) of the attractive trap

(Figure 4). Thus, the question arises: how does one determine the optimal size of attractive trap to obtain consistent and maximum EAR estimates?

Ideally, one should compare several attractive traps of increasing radii to determine the function of trapping efficiency with trap size and the effect on the EAR. In this way, the appropriate trap size can be determined that yields a consistent and nearly maximum EAR, with a minimum of trap size for practical reasons. In *I. typographus* (Figure 4), we found that little further benefit in maximizing the EAR estimate is gained with increasingly larger attractive traps beyond 15- to 30-cm radius (we used the 15-cm radius on the poles), while there are increasing costs of further enlargements of trap radius. It can also be seen in Figure 4 that *I. typographus* seem to find it increasingly more difficult to locate pheromone sources that are much smaller than the diameter of a tree. We predict that such curves for moth species will be shifted to the left on the x axis, indicative of the smaller target of a female moth.

Several environmental factors will influence the active space (Elkinton and Cardé, 1984), as well as the EAR, such as temperature, wind speed, and their variation over time. However, these parameters are rather consistent when bark beetles are responding to semiochemicals. For valid EAR measurements, the height of the passive and attractive traps should be the same but the level is, in theory, not too important as different heights would appear as tests at different densities of flying beetles, which has little effect on the EAR. However, our measured EARs at different heights indicate that height may be important either due to windy conditions, response variation with height, or trap interactions.

Thus, it appears that EAR estimates for a particular species should be qualified by specifying the height of the attractive and passive traps, the release rate of the semiochemical, and the sizes of the traps. Since most pheromone catches of scolytids have been done at the 1.5-m height, and we obtained the largest EAR at about this level, we think this level is appropriate for interspecific comparisons.

Acknowledgments—This work was supported in part by grants from Sweden, STU (84-3937) and others, NFR, FRN, and SJFR; and from the USA, NSF (INT-8503520). We are grateful to E. Jirle, J. Jönsson, E. Marling, and B. Hansson for help in setting up the poles in the field. E. Jirle and J. Börnfors provided assistance in the sex and species determination of the bark beetles collected. F. Schlyter provided appropriate baits for *I. typographus*. J. Jönsson gave helpful assistance in the construction of the 12-m poles. We thank foresters in Esrum forest district for their cooperation and appreciate the use of Strødam Biological Station in Denmark. We thank F. Schlyter and T.C. Baker for review of the manuscript.

(Received April 27, 1987; accepted February 25, 1988)

Abstract—An effluvial method was developed to collect the pheromone, glandure from actively calling male boll weevils, *Anthonomus grandis* Boheman. The adsorbant, Porapak Q (ethylvinylbenzene–divinylbenzene), was utilized to trap and concentrate the pheromone. Captured pheromone was desorbed from columns packed with Porapak Q by elution with *n*-pentane and quantified by capillary column gas–liquid chromatography. In recovery studies with known amounts of synthetic glandure, we found that the amount of each pheromone component collected was a function of collection duration, elution volume, and initial concentration. This effluvial method was capable of recovering as much as 94.9% of a known quantity (80 µg) of glandure. The chromatograms were free of extraneous peaks. In studies of insect-produced pheromone, the effluvial method was used to collect pheromone from the air space surrounding male boll weevils as they fed on flower buds from CAMD-E cotton. The quantity and quality of boll-weevil-produced pheromone was determined for days 6, 8, 10, 11, 12, 13, and 14 of boll weevil adulthood. The maximum quantity of natural pheromone was produced on day 13 (4.2 µg/weevil) with a pheromone component ratio of 2.41:2.29:0.95:1 for components I, II, III, and IV, respectively. The effluvial method described in this report is an efficient method to collect and quantify boll weevil pheromone from the atmosphere surrounding actively calling insects. Other applications of this method are suggested.

INTRODUCTION

The ability of boll weevils, *Anthonomus grandis* Boheman, to locate the host plant, *Gossypium hirsutum* L., is thought to be mediated, at least in part, by the insect's olfactory response to host-plant volatiles and the multicomponent pheromone, grandlure. The pheromone is produced by males as they feed on pollen in flower buds. Boll weevil pheromone composition has been determined from the frass by means of steam distillation (Tumlinson et al. 1969). The pheromone consisted of four terpenoid components, two alcohols [I, (+)-*cis*-2-isopropenyl-1-methylcyclobutane ethanol; and II, *cis*-3,3-dimethyl- $\Delta^{1-\beta}$ -cyclohexane ethanol] and two aldehydes [III, *cis*-3,3-dimethyl- $\Delta^{1-\alpha}$ -cyclohexane acetaldehyde; and IV, *trans*-3,3-dimethyl- $\Delta^{1-\alpha}$ -cyclohexane acetaldehyde], in the ratio 12:9:1:1, respectively. For the pheromone to stimulate an attractive response in boll weevils, both alcohol components and at least one of the aldehydes must be present (Tumlinson et al., 1969). The pheromone acts as an aggregant by itself (Lopez et al., 1978) and becomes a sex attractant in the presence of cotton-plant volatiles (Dickerson et al., 1981; Hardee et al., 1969). However, the actual composition of pheromone in the atmosphere surrounding actively calling males has not been determined. Collection of boll weevil pheromone from the atmosphere surrounding actively calling boll weevils would provide accurate quantification of the naturally released pheromone components and their ratios.

Porapak Q has been used to trap and concentrate bark beetle host volatiles (Pearce et al., 1975) and a blend of bark beetle pheromones from actively calling insects (Peacock et al., 1975). However, the effectiveness of Porapak Q as a trapping agent was reported to be limited by its low thermal stability and the production of artifacts in chromatograms from pheromone analysis (Golub and Weatherston, 1984; Zlatkis et al., 1973). In previous studies we have found that Porapak Q was an effective effluvial collection agent for airborne monoterpene volatiles, such as α -pinene, β -pinene, β -myrcene, *d*-limonene, and β -ocimene (Chang et al., 1986). Under our experimental conditions, no artifacts due to Porapak Q breakdown were encountered, suggesting that Porapak Q may be suitable for boll weevil pheromone collection.

In the present study we report on: (1) the efficiency of Porapak Q to trap and concentrate known quantities of the synthetic boll weevil pheromone, grandlure; (2) a method to collect natural pheromone from the atmosphere surrounding male boll weevils, as they actively feed and release pheromone; and

(3) the quantities and ratios of each pheromone component produced by boll weevils on days 6–14 of adulthood.

METHODS AND MATERIALS

Conditioning Porapak Q. Before Porapak Q (ethylvinylbenzene–divinylbenzene) was used for collection of pheromone, it had to be conditioned by heating at 180°C for 24 hr with a nitrogen flow of 30 ml/min, as described by Zlatkis et al. (1973). After conditioning, the Porapak Q was washed three times, 30 min each time, with dichloromethane (CH_2Cl_2) using a power stirrer to remove the residual monomers. Following the last wash, the dichloromethane slurry was poured into a 20 × 300-mm glass column with a medium fritted glass filter. Nitrogen was forced through the column at the rate of 1.8 liters of air per minute (LPM) for 1.5 hr to dry the polymer. The solvent effluent from the column was drawn into a vacuum trap using a Chapman-type filter pump. The Porapak Q was then utilized in the assembly of air-cleaning columns (to clean the air entering into the effluvial system) and pheromone collection columns.

Preparation and Activation of Air-Cleaning and Collection Columns. Columns were made of Pyrex glass tubing, 210 mm × 8 mm outer diameter (OD). Each air-cleaning and collection column was packed with ca. 1.0 and 0.6 g of Porapak Q, respectively. The Porapak Q was secured within the glass tubing between two acetone-rinsed glass wool plugs.

Prior to pheromone collection, the columns were cleaned and activated. To accomplish this, columns were heated and maintained at 120°C, while 8 cc of glass-distilled acetone were forced through each column, in 2 cc volumes, with a metal-tipped glass syringe (a 40 mm length of 8-mm-ID Teflon tubing was slipped onto the metal tip of the syringe and connected to the columns). This treatment removed water and water-soluble contaminants. The remaining acetone was removed by flushing with 1.8 LPM of nitrogen for 2 min. Each column was then reactivated by pushing 8 cc of CH_2Cl_2 , in 2 cc volumes through the column, then flushing and drying with 2.7 LPM of nitrogen for 4 min, and sealing with glass caps until utilized to capture pheromone.

Effluvial Method for Collection of Airborne Pheromone. The volatile pheromone collection apparatus consisted of 10 trapping units operated simultaneously by means of a manifold which was connected to a Gast rotatory vacuum pump (AS55NXGTE-4145). A single volatile collection unit consisted of a 473-ml boll weevil glass holding jar (Mason-type jar), with an inlet for the air-cleaning column and an outlet for the collection column. The columns were fit with two lengths of 8-mm-ID Teflon tubing inserted through the metal lid of the jar. A short length of tubing (30 mm) joined each air-cleaning column to

the jar. The outer end of the second piece of tubing (300 mm) was connected to a pheromone collecting column while the inner end extended to the bottom of the jar and was plugged with acetone-rinsed glass wool to keep the boll weevils from escaping. The jar lids were sealed with Teflon tape before the retaining ring was placed in position. Each collection unit was connected by Tygon tubing to a flowmeter (Matheson 7262). The air-flow rate through the system was maintained at 0.225 LAPM with the flowmeter. The air-flow path was from the atmosphere through the air-cleaning column, boll-weevil-holding jar, collection column, flowmeter, manifold, and vacuum pump (operated at 635 mm Hg).

Recovery of Grandlure with Effluvial Method. The capacity of Porapak Q to trap and concentrate grandlure was tested using two concentrations of grandlure, 10 and 100 $\mu\text{g}/\text{ml}$ per component. The grandlure concentrations were prepared from 99% pure grandlure components (Albany International, New York). Aliquots (2 ml) of each concentration (20 and 200 $\mu\text{g}/\text{component}/\text{aliquot}$) were pipetted separately into jars of the effluvial collection system, and each treatment was replicated eight times. Then the grandlure was trapped in the collection columns for 4 hr. The trapped grandlure from the collection column was eluted with 3 ml of HPLC grade *n*-pentane, and the volume of the eluate brought back to the initial 2 ml amount with *n*-pentane. α -Terpineol was used as the internal standard for capillary column gas-liquid chromatography (GLC) to adjust volume and retention time of pheromone components. Also the 20 μg of each grandlure component was also recovered at two different time intervals (4 or 8 hr), two different volumes of elution (2 or 3 ml), and quantified without α -terpineol. The recovery efficiency for this study was determined directly from the analysis of trapped grandlure from the standard concentrations.

Collection of Boll Weevil Pheromone with Effluvial Method. Boll weevils used in these studies were cultured by the USDA, ARS, Boll Weevil Research Facility, Starkville, Mississippi. They were reared to adulthood on artificial diet. Three cohorts of 200 newly emerged male boll weevils were kept in clear plastic containers (90 \times 170 \times 300 mm) with an organdy-covered opening 40 \times 120 mm at each end. The plastic containers were held in Percival environmental chambers at ca. 30°C and 16:8 hr photophase-scotophase. Initially a layer of debracted flower buds was placed in half of the container, which was positioned toward the light source (20 W cool white GE fluorescent lamp) of the incubator. The next day, a layer of fresh flower buds was placed in the empty second half of the container and turned towards the light source. After 48 hr, the old flower buds were removed and fresh ones added, placing the newly changed side toward the light source. This reduced the handling of the boll weevils during flower bud changes. After five days of feeding on the flower buds, a cohort of 100 individuals was drawn at random from each of the three

plastic containers and enclosed separately with 50 debracted flower buds in three glass jars of the effluvial collection system. The flower buds were freshly collected from CAMD-E cotton, cultivated at College Station, Texas, under normal agronomic practices. Each glass jar with 50 debracted flower buds and 100 male boll weevils was considered a replicate. Three replications were conducted for each collection day. Boll weevil pheromone was collected from 0800 to 1600 hr (CST) on days 6, 8, 10, 11, 12, 13, and 14 of adulthood.

Quantification of Natural and Synthetic Pheromone. The captured synthetic or natural pheromone was eluted from the collection columns with HPLC grade *n*-pentane into 1-dram vials by solvent gravity flow. The vials were sealed with Teflon-lined screw caps and stored at -45°C . When elution was completed, the remaining solvent was forced from the column with nitrogen.

Eluted pheromone samples were analyzed by GLC. Quantification of the pheromone was determined by injection $1\ \mu\text{l}$ of the eluate, with an on-column SGE syringe, into a temperature-programmed Tracor model 565 gas chromatograph equipped with an Alltech RSL-150 (30 mm \times 0.25 mm bonded FSOT) capillary column, SGE OC-3 on column injector, and flame ionization detector. The column was preheated at 60°C for 4 min and programmed to increase at a rate of $10^{\circ}/\text{min}$, until it reached 180°C , then maintained at this maximum temperature for 7 min. Throughout the analytical determinations the following conditions were maintained: injector temperature, ambient; detector temperature, 220°C ; hydrogen flow rate per minute (FRPM), 40 ml; air FRPM, 400 ml; nitrogen as carrier gas FRPM, 2.2 ml; and nitrogen as make-up gas FRPM, 21.4 ml.

The recovery studies were conducted using synthetic pheromone. Quantification of synthetic pheromone was determined by response factors from $1\text{-}\mu\text{l}$ injections of a standard containing $10\ \mu\text{g}/\text{ml}$ of each grandlure component and $10\ \mu\text{g}/\text{ml}$ of α -terpineol, the internal standard. The analog signals from the electrometer (detector) were processed by a Hewlett-Packard 3392A integrator for visual display of chromatographic peaks, retention times, peak areas, and calculation of the concentration of each grandlure component and α -terpineol. The internal standard reference was turned off at the integrator level when analyzing samples without α -terpineol. Recovery results for samples with and without α -terpineol served to compare the accuracy and repeatability of the recovered grandlure aliquots injected into the GLC for analysis. During pheromone collection, when no internal standard was used, three initial and one final injections were conducted daily with a standard containing $10\ \mu\text{g}/\text{g}$ grandlure component, to monitor the condition of the capillary column, based on retention time and shifts in calibration parameters.

All pentane eluates from the synthetic pheromone recovery studies were brought back to the initial 2-ml volume. The $200\ \mu\text{g}/\text{component}$ eluates were further diluted to 1:10. The individual grandlure components in the pentane

eluates from the collection columns were identified by comparing their retention times against the retention time of the 10- μg grandlure standard. To clearly identify the natural pheromone components in the samples collected from the air space surrounding actively calling boll weevils, a known dilution of the standard containing 1 μg /grandlure component was used to spike the pheromone samples collected from boll weevils.

RESULTS AND DISCUSSION

Recovery of Synthetic Pheromone with Effluvial Method. The effluvial method efficiently captured and concentrated synthetic grandlure, allowing a maximum recovery of 94.9% of a known amount (Table 1). The capacity of Porapak Q to capture known quantities of grandlure was mainly affected by the initial concentration, collection time, and volume of eluting solvent. A significantly higher percentage of grandlure was recovered from the treatment with 20 μg /component than the treatment with 200 μg /component, 93.7 and 85.2%, respectively (with an internal standard, a 4-hr collection period, and 3 ml of eluting solvent). A significantly higher percentage of grandlure was recovered using 3 ml of *n*-pentane than 2 ml, 93 and 86.9%, respectively (using an 8-hr collection period, 20 μg /component, and without an internal standard). The lower percent recovery with 200 μg suggests that some grandlure may have been lost because it passed completely through the collection column (hereafter called breakthrough). Breakthrough at 200 μg could be the result of the sudden release of a large volume of volatile material in the collection jar. Additionally breakthrough of grandlure may be due to the presence of the hexane solvent used to dilute the grandlure components, which was not present in the studies with natural pheromone. Breakthrough was not a concern with our studies of naturally released pheromone since the release of pheromone into the collection jar was gradual over an 8-hr period. Furthermore, two collection columns were placed in series in the same vacuum line during the collection of natural pheromone. We did not find pheromone breakthrough; all pheromone was captured in the first collection column.

Extraneous peaks on chromatograms have been reported in the literature by other researchers when Porapak Q was used (Byrne et al., 1975; Golub and Weatherston, 1984; Krumperman, 1972). They suggested that the extraneous peaks were breakdown products from the Porapak Q and/or breakdown products from the trapped compounds. We did not find extraneous peaks in the chromatograms, thus indicating that Porapak Q was not breaking down, and furthermore, it may have prevented degradation of the trapped grandlure components. This could be due in part to our experimental conditions and procedures for conditioning and activating of Porapak Q. We used solvents as

^bThe grandlure components are: I = (+)-*cis*-2-isopropenyl-1-methylcyclobutane ethanol; II = *cis*-3,3-dimethyl- $\Delta^{1,\beta}$ -cyclohexane ethanol; III = *cis*-3,3-dimethyl- $\Delta^{1,\alpha}$ -cyclohexane acetaldehyde; IV = *trans*-3,3-dimethyl- $\Delta^{1,\alpha}$ -cyclohexane acetaldehyde. Means within columns followed by different letters are significantly different ($P < 0.05$, Duncan's multiple-range test).

cleaning and activating agents of Porapak Q at 120°C in a procedure requiring approximately 20 min. This procedure reduced the 24-hr heating periods, the concomitant nitrogen flushing, the special equipment, and the disassembly of the collection columns required by other researchers' procedures (Golub and Weatherston, 1984). The effluvial method described here is a practical and efficient method to capture and quantify grandlure in the atmosphere.

Collection of Natural Boll Weevil Pheromone with Effluvial Method. The mean total quantity of pheromone produced by the laboratory strain of boll weevils was dependent upon the age of the insect (Table 2). The largest amounts of pheromone released during the first two weeks of adulthood occurred from days 11 to 14, with a peak on day 13 (4.2 $\mu\text{g}/\text{insect}$).

The mean amount of each pheromone component is dynamic in that it changed with boll weevil age (Table 2). Using the concentration of component IV as the unit reference value, the ratios of the other three pheromone components were calculated for days 6, 8, 10, 11, 12, 13, and 14 of adulthood (Table 3). The ratios were found to fluctuate with the age of the insect. The alcohol components, I and II, were found in greater concentrations than the aldehyde components, III and IV. The ratio for component I was always greater than component II. On day 13, the largest drop occurred in the ratio for the alcohol components, while the concentrations of both aldehydes were equivalent. The pheromone ratio on that day was 2.41:2.29:0.95:1 for components I-IV, respectively. Hardee et al. (1974) found the most attractive ratio as 2.37:1.74:1.0:1.0 for components I-IV, respectively. They also established that the ratio of the components in the pheromone was more important for attracting boll weevils than the dose. Their most attractive ratio was very similar to the ratio we found on day 13. Tumlinson et al. (1969) determined that the boll weevil pheromone ratio was 12.6:9.5:1:1 by steam distillation of the frass. Their results, when compared to ours, suggest they sustained a loss in the aldehyde components during the prepurification stage with the steam distillation method. The pheromone ratios determined in our studies with the effluvial method are believed to be the true atmospheric ratios of the pheromone components produced by actively calling cultured boll weevils.

CONCLUSION

The effluvial method described in this report was found to be an efficient technique to capture boll weevil pheromone for quantification with capillary column gas chromatography. The two major advantages to the method are: (1) pheromone and other comingling odors are captured during active insect production and at biologically active concentrations, and (2) these potentially biologically active odors (pheromone and plant volatiles) are captured free of

nonvolatile contaminants and thus are relatively pure and easily quantified. Furthermore, the effluvial method may be of value to entomological science for other reasons (Baker and Longhurst, 1981): (1) it provides a means to easily determine the ratios of pheromone components as they are found in the air surrounding actively calling insects; (2) it may be useful in the identification of geographic races of an insect pest; (3) in insect-pest-control programs utilizing sterile releases, pheromone production could be monitored with the method to evaluate the pheromone competitiveness between laboratory-reared insects and the natural field populations; (4) in studies of host-plant resistance, the effects of variety on pheromone production could be determined; (5) varieties might be developed that suppress pheromone production, thus being less attractive to insect pests; and (6) since plant volatiles from secondary metabolism are also involved in insect selection and colonization of host plants, the effluvial method of collection may be utilized by breeders in selection plants that have a less attractive aroma to insect pests.

INSECT SEX PHEROMONES

Effect of Temperature on Evaporation Rates of Acetates from Rubber Septa¹

(Received January 5, 1988; accepted March 4, 1988)

Abstract—The half-lives ($t_{1/2}$) for evaporative loss of *n*-alkyl and *n*-alkenyl acetates from rubber septa were determined at temperatures varying from 15 to 35°C. The changes in $t_{1/2}$ with temperature gave high correlations with the equation, $\ln t_{1/2} = \Delta H/RT + y_0$ where ΔH is the heat of vaporization, R is the gas constant, T is the absolute temperature, and y_0 is a constant. Half-lives changed dramatically with temperature and the degree of change with temperature increased with increasing molecular weight. For mixtures, component ratios changed with temperature, but the degree was modest. At 20°C there was a 7.5-fold ratio of $t_{1/2}$ between members of the homologous *n*-alkyl or *n*-alkenyl acetates differing by two carbon atoms. The large change in $t_{1/2}$ with temperature and with number of carbon atoms is a consequence of the thermodynamic relationships and the temperature range of pheromone usage. Therefore, a similar degree of change in $t_{1/2}$ with temperature and number of carbon atoms will apply to other formulations of the same type (those in which the rate of evaporation is first order). The values of $t_{1/2}$ at 20°C mainly agreed very well with those reported previously at room temperature. However, our previously reported values for pentadecyl and hexadecyl acetate were revised. Half-lives were shown to depend on the vapor pressure of a compound in the formulation substrate, but not on the vapor pressure of the pure compound.

Key Words—Insect sex pheromones, controlled release, formulations, formulation substrates, acetates, *n*-alkyl acetates, *n*-alkenyl acetates, heat of vaporization, enthalpy of vaporization.

INTRODUCTION

The natural rubber septum (Roelofs et al., 1972) is the most commonly used controlled release substrate for insect sex pheromones in monitoring traps. In previous work from this laboratory, it was established that pheromones evaporate from rubber septa by a first-order process (Maitlen et al., 1976). Also, correlations of chemical structure of pheromones and analogs with half-lives from rubber septa were established, making possible calculations of evaporation rates of single compounds and vapor component ratios for mixtures containing acetates and/or alcohols (Butler and McDonough, 1979, 1981; McDonough and Butler, 1983). Olsson et al. (1983) reported a correlation of half-lives from rubber septa with vapor pressures as determined by a novel gas chromatographic method. Subsequently, Heath and Tumlinson (1986) and Heath et al. (1986) showed that half-lives from rubber septa correlate with vapor pressures and with gas chromatographic retention times from a liquid crystal liquid phase and that vapor component ratios from rubber septa of mixtures containing aldehydes, acetates, and alcohols could be predicted from their correlation. In other studies, evaporation rates or loss rates of sex pheromones from rubber septa of the pink bollworm (Flint et al., 1978), oriental fruit moth (Baker et al., 1980), the pea moth (Greenway et al., 1981), the red scale (Leonhardt and Moreno, 1982), and the olive fly (Jones et al., 1983) have been reported.

An important aspect not previously addressed is the influence of temperature on evaporation rates and on component ratios from rubber septa. Limited studies of the effect of temperature on evaporation rates for other controlled-release substrates have been reported. Bierl et al. (1976) reported the effect of temperature on the evaporation rates of disparlure from plastic laminate dispensers. Sower and Daterman (1977) studied the effect of temperature on the release rate of (*Z*)-6-heneicosen-11-one from plastic films, and Rothshild (1979) compared the release rates of (*Z*)-8-dodecen-1-ol acetate from several dispensers at three temperatures. More recently Leonhardt et al. (1988) reported the effect of temperature on the release rate of grandlure from different formulation substrates.

Our purpose was to develop a systematic study of the effect of temperature on evaporation rates and component ratios of homologous series of unsaturated and saturated acetates from red, natural rubber septa. Here we report our study showing that evaporation rates change dramatically with temperature while the change in component ratios with temperature is moderate.

METHODS AND MATERIALS

Method for Determining Half-Life. A pheromone or other test compound, impregnated in a rubber septum, was allowed to evaporate in a stream of nitro-

gen, and the evaporated pheromone was collected on an adsorbent (McDonough and Butler, 1983). The septum and adsorbent were individually extracted, and the amount of pheromone from each was determined. The half-life, $t_{1/2}$, was calculated from the equation:

$$t_{1/2} = \frac{P \ln 2}{R} \quad (1)$$

where R is the rate of evaporation (i.e., the amount of pheromone collected per unit of time on the adsorbent) and P is the amount of pheromone remaining in the septum.

Apparatus. A schematic drawing of the apparatus is shown in Figure 1. Nitrogen, purified by passing through a column of reverse phase (octadecyl-silica gel), passed through a flowmeter (Gilmont Instruments/Van Rogers & Waters, Seattle, Washington) and into the apparatus consisting of two 10-ml syringes sealed at the large ends with a rubber gasket and held together by a clamp (not shown). A Sep Pak liquid chromatographic cartridge (Waters Associates, Milford, Maine) containing RP-18 (Cat. No. 5190) was connected to the small end of the second syringe for collection of evaporated pheromone.

Procedure for Determining Half-Life. A red, natural rubber septum (West Co., Phoenixville, Pennsylvania) impregnated with the test compound (10–15 mg) was allowed to age for three or more days to allow any possible surface-deposited material to evaporate, and then placed in the syringe closest to the Sep Pak in the described apparatus (Figure 1). The nitrogen flow rate over the septum was 20 cm/sec, and the collection period was 1–12 hr, depending on the volatility of the test compound. After a run, the septum was removed and extracted for 4 hr with 50 ml dichloromethane, reextracted overnight with 50 ml more of dichloromethane, and the solutions were combined. Then 30 ml of heptane was added and the solution was concentrated to about 25 ml by rotary evaporation and made up to the desired volume with heptane. The compound in the Sep Pak was eluted by adding 20 ml of dichloromethane–methanol (9:1) in portions to the syringe to which the Sep Pak was attached and forcing the solvent through with the syringe piston. To the dichloromethane–methanol solution, 6 ml of heptane was added, and the resulting solution was concentrated to 5 ml with a rotary evaporator.

The solutions were analyzed by gas chromatography. The value of each determination of the half-life was the average of two values, one made on non-polar (methyl silicone, DB-1) and the other on polar (polyethylene glycol, DB-

FIG. 1. Apparatus for determination of half-life by collection of emitted vapor.

Wax) 15 m, megabore columns (J & W Scientific, Inc., Rancho Cordova, California).

The values of the half-lives of each compound were determined three times at each of three temperatures. For the 10- to 14-carbon acetates, the temperatures were 15, 22.5, and 35°C. For the 15- and 16-carbon acetates, the temperatures were 20, 27.5, and 35°C. The temperature was controlled by placing the entire apparatus in an insect environmental control chamber (model M-31, Environmental Growth Chambers, Chagrin Falls, Ohio), which controlled the temperature within $\pm 0.2^\circ\text{C}$. Temperature was monitored with a thermometer meeting National Bureau of Standards specifications (accuracy = $\pm 0.3^\circ\text{C}$).

Recovery Experiments. The ability of the Sep Pak cartridge to adsorb and retain pheromone vapors was determined by adding 20 or 50 μl of a dichloromethane solution of 1 $\mu\text{g}/\mu\text{l}$ of a test compound to the Sep Pak cartridge, rinsing it into the cartridge with another 50 μl dichloromethane, connecting the cartridge to the apparatus in the temperature control chamber, and passing nitrogen through it at the usual flow rate for various periods of time. The test compounds, the conditions, and the percent recoveries are summarized in Table 1.

Statistical Calculations. For the modified Clausius-Clapeyron equation,

$$\ln t_{1/2} = \frac{\Delta H}{RT} + y_0 \quad (2)$$

ΔH is the heat of vaporization (calories/mole), R is the gas constant (1.98 calories/degree), T is the absolute temperature ($^\circ\text{K}$), and y_0 is a constant. The ΔH values and 95% confidence limit of ΔH were calculated from the regression analysis of $\ln t_{1/2}$ versus $1/T$ from the expression:

$$\frac{\Delta H}{R} \pm \frac{t(n-2, 1-\frac{1}{2}\alpha)s}{[\sum(X_i - \bar{X})^2]^{1/2}}$$

where $t(n-2, 1-\frac{1}{2}\alpha)$ is the $(1-\frac{1}{2}\alpha)$ percentage point of a t distribution with $(n-2)$ degrees of freedom (the number of degrees of freedom on which the

estimate s^2 is based); $\Delta H/R$ is the slope; α is 0.05; and s is the residual variation (Draper and Smith, 1966).

RESULTS

Because of differing volatilities, the half-lives of the n -alkyl acetates were not all determined at the same temperatures. In order to compare half-lives of the series at the same temperatures, the nine $t_{1/2}$ values for each compound were subjected to regression analysis according to the modified Clausius-Clapeyron equation (equation 2). The parameters ΔH (in kilocalories/mole), y_0 , their 95% confidence limits, and the correlation coefficients (r^2), are summarized in Table 2 (unbracketed values). These parameters were then used in equation 2 to determine $t_{1/2}$ values for each compound at temperatures of 15, 20, 25, 30, and 35°C. Values of $t_{1/2}$ at each of the chosen temperatures were then analyzed according to the equation:

$$\ln t_{1/2} = aN + b \quad (3)$$

where N is the number of carbon atoms in the alkyl group of the homologous series of the n -alkyl acetates. The correlation coefficients (r^2) for these analyses were >0.99 .

Equations 2 and 3 represent two different relationships for defining $t_{1/2}$ values. If one assumes the validity of these equations and that deviations from them are a result of experimental error, then it is possible to improve the $t_{1/2}$ values by reiteratively calculating them from the regression lines of equation 2, equation 3, equation 2, . . . , etc., until a set of values is arrived at that fall exactly on the regression lines for both equations (for these new parameters of equation 2 see the bracketed values in Table 2). The values of the equation 3 parameters are given in Table 3. Therefore, the bracketed parameters of Table 2 and the values of Table 3 define $t_{1/2}$ values that correlate perfectly with both equations 2 and 3. The bracketed parameters of Table 2 are within the 95% confidence limits of the values calculated directly from the original experimental data in every case except for 10:Ac where the values are still quite close.

The compounds Z7-12:Ac and Z9-14:Ac also constitute a homologous series. When the ratios of $t_{1/2}$ for these compounds (relative to the adjusted $t_{1/2}$ values of the saturated acetates, Table 2) were calculated at 15, 25, and 35°C, no discernible trend in ratios was evident. These ratios were averaged (0.709 ± 0.026). This average ratio was then used to calculate half-lives at 20°C from the values of the saturated analogs for the compounds Z7-12:Ac, Z9-14:Ac, and Z11-16:Ac. The half-lives so obtained were substituted into equation 3 using the parameters a and b of the saturated analog, and the N values at 20°C were calculated. The N values are the equivalent chain length

Z13-16:Ac	ND [23.08]	ND [-32.2352]	ND [1.0000]

^aUnbracketed values of the saturated acetates were calculated directly from the experimental data. Bracketed values were derived to be consistent with the regression lines for the equation $\ln t_{1/2} = aN + b$ and the Clausius-Clapeyron equation (see text). ND signifies not determined experimentally. Parameters for unsaturated acetates were calculated differently (see text). For Z7-10:Ac, Z11-16:Ac, and Z13-16:Ac, ΔH and y_0 were calculated from parameters for the other members of their homologous series (see text).

values relative to the saturated acetates, and were assumed to be constants over the temperature range under consideration (15-35°C). The N values were: Z7-12:Ac, 11.66; Z9-14:Ac, 13.66; and Z11-16:Ac, 15.66. The same procedure was used for the homologous series Z9-12:Ac and Z11-14:Ac and the relative retention ratio averaged 0.901 ± 0.097 and gave N values of: Z7-10:Ac, 9.90; Z9-12:Ac, 11.90; Z11-14:Ac, 13.90; Z13-16:Ac, 15.90. The

TABLE 3. PARAMETERS FOR $\ln t_{1/2} = aN + b$ AT GIVEN TEMPERATURES FOR *n*-ALKYL ACETATES^a

Temperature (°C)	<i>a</i>	<i>b</i>
15	1.04216	-8.34697
20	1.00721	-8.48142
25	0.973428	-8.61135
30	0.940763	-8.73700
35	0.909158	-8.85857

^a(*N* = number of carbon atoms in alkyl group). For *n*-alkenyl acetates the same parameters apply but *N* values are decreased relative to the saturated analogs. Thus, for Z7-12:Ac, Z9-14:Ac, Z11-16:Ac, *N* = 11.66, 13.66, 15.66, respectively. For Z7-10:Ac, Z9-12:Ac, Z11-14:Ac, Z13-16:Ac, *N* = 9.90, 11.90, 13.90, 15.90, respectively.

$t_{1/2}$ values for the unsaturated acetates from equation 3 at different temperatures were then used to obtain equation 2 parameters shown in Table 2. In every case, these parameters (bracketed values, Table 2) are within the 95% confidence limits of the values calculated directly from the original experimental data.

The bracketed parameters of Table 2 were used to calculate $t_{1/2}$ values of saturated and unsaturated acetates from 15 to 35°C at 5° intervals. These values are given in Table 4.

DISCUSSION

Effect of Temperature on $t_{1/2}$ Values. The effect of temperature on $t_{1/2}$ is striking (Table 4). When the temperature is changed from 30 to 20°C, $t_{1/2}$ changes from 1.96 to 4.91 days (a factor of 2.5) for 10:Ac and from 553 to 2.07×10^3 days (a factor of 3.7) for 16:Ac. Therefore, if the temperature range in which a male insect responds to the pheromone is 10°C, then evaporation rates will vary in the range of these factors.

The rate of change of $t_{1/2}$ with temperature for a given compound is determined by its ΔH value. ΔH values for pheromones in a natural rubber matrix have not been reported previously, but ΔH values for some pheromones in the pure state have been reported (Hirooka and Suwanai, 1978; Olsson et al., 1983). For compounds in common with ours, the values of Olsson et al. and ours (in kcal/mol) are, respectively: 10:Ac, 17.27 and 16.19; Z7-12:Ac, 18.27 and 18.13; Z9-14:Ac, 21.37 and 20.47. For compounds in common with ours, the values of Hirooka and Suwanai and ours are: 12:Ac, 14.35 and 18.53; 14:Ac, 15.87 and 20.87; Z9-14:Ac, 17.23 and 20.47. Our values are from 0.14 to 1.08 kcal/mol smaller than those of Olsson et al. and from 3.24 to 5.00 kcal/mol larger than those of Hirooka and Suwanai. The difference in values of Olsson et al. and ours can reasonably be attributed to the difference in the condensed state in the two experiments (i.e., the pure liquid pheromone versus a solution of the pheromone in rubber). We cannot account for the large difference between our values and those of Hirooka and Suwanai. Olsson et al. have previously noted the large difference between their value and that of Hirooka and Suwanai for Z9-14:Ac (the only compound in common in their two studies) and suggested that the value of Hirooka and Suwanai was too small compared to other literature values for similar compounds.

Effect of Temperature on Component Ratios. Because ΔH determines the rate of change of $t_{1/2}$ with temperature for a given compound and ΔH increases with chain length (Table 2), the ratio in the vapor of components of different chain lengths will change as temperature changes. However, the effect of temperature on component ratio is fairly modest. To take an extreme example, if a septum contained 553 μg of 16:Ac and 1.96 μg of 10:Ac, at 30°C the ratio in the vapor of these components would be 50:50 and at 20°C the ratio would be 60:40 in favor of 10:Ac. In a less extreme and more likely situation, a septum containing 61.2 μg of Z9-14:Ac and 402 μg Z11-16:Ac would produce a ratio in the vapor of 50:50 at 30°C and 54:46 in favor of Z9-14:Ac at 20°C.

Criteria for Homologous Series that Obey Thermodynamic Relationships. A homologous series of compounds is one in which adjacent members differ only by a methylene group. For such a series, thermodynamic properties (such as ΔH) should differ between adjacent members by a constant amount determined by the methylene group, providing no additional intramolecular effects occur. For a short-chain alkyl series such as methyl, ethyl, and *n*-propyl, one

would expect additional intramolecular effects to occur because in each case there will be shielding of the acetate group by the methylene groups and methyl group (with a corresponding decrease in its effective polarity) for each member of the series (Kovats, 1965; McReynolds, 1966). As chain length increases, the shielding of the functional group will become constant and not increase as N increases. For n -alkyl acetates this occurs when $N > 3$ (McReynolds, 1966). For n -alkenyl acetates, the position of the double bond will affect half-life or gas chromatographic retention time. Its position relative to both the polar and nonpolar end of the molecule is significant. It is not known how close the double bond can be to the acetate without mutual influence occurring, but because of carbon bond angles, influence is negligible for double bonds $> \Delta 6$. For the series Z7-12:Ac, Z9-14:Ac, Z11-16:Ac, the double bond is sufficiently removed from the polar end of the molecule and is at a constant position relative to the nonpolar end of the molecule. Therefore, this homologous series should show a constant incremental thermodynamic change between adjacent members. This was the basis for calculating the parameters for Z11-16:Ac from data for Z7-12:Ac and Z9-14:Ac. These equivalent chain lengths are in reasonable agreement with those estimated by Heath and Tumlinson (1986) and by Heath et al. (1986) for Z7-12:Ac, Z9-14:Ac, and Z11-16:Ac from their correlation with GC data (11.81, 13.66, and 15.62, respectively, versus our values of 11.66, 13.66, and 15.66). Z5-10:Ac was not included in this series. Both Z7-10:Ac and Z13-16:Ac were included in the series with Z9-12:Ac and Z11-14:Ac. Heath and Tumlinson (1986) reported the equivalent chain length by their GC method for just one compound of this series, Z9-12:Ac. Their value of 11.98 was similar to our determination of 11.90.

Comparison of $t_{1/2}$ Values with Earlier Values by Residue Method. In earlier work from this laboratory (Butler and McDonough, 1979) the $t_{1/2}$ values of the n -alkyl acetates and some unsaturated analogs were reported at room temperature. The values had been determined by the residue method and room temperature had been estimated at 22-23°C. For the majority of the compounds, the values corresponding to our present study at 20°C (Table 4) agree well with those earlier values. Considering the large effect of temperature on $t_{1/2}$ and that in the previous work temperature was not controlled, it is not surprising that the earlier values agree best with our present values at a slightly different temperature. However, there was a significant difference between the earlier values of the 15- and 16-carbon acetates and our present ones. Previously 16:Ac was reported to behave anomalously and to have a shorter $t_{1/2}$ than 15:Ac (earlier values at room temperature and present values at 20°C: 15:Ac, 1353 and 755; 16:Ac, 481 and 2.07×10^3). In our present study 16:Ac did not behave anomalously and agreed with the equation 3 relationship. The earlier reported anomaly may have occurred because of the difficulty in determining the small changes in residue level for compounds with long half-lives, and because of the lack of temperature control. However, there may be other factors

involved since Heath et al. (1986) also reported similar anomalous behavior for 16:Ac. They suggested that since 16:Ac is a solid at room temperature, a solid-liquid phase equilibrium could be established and would lead to lower estimated $t_{1/2}$ values.

Importance of Rubber Septa Data for Other Formulation Substrates. For the homologous series of saturated acetates at 20°C, one observes a 7.5-fold ratio in $t_{1/2}$ for members of the series differing by two carbon atoms, whereas in gas chromatography, typically one finds about a twofold ratio in retention time for members of the series differing by two carbon atoms. This difference is a result of the nature of the Clausius-Clapeyron equation (equation 2) and the difference in the temperature ranges at which gas chromatography is conducted and pheromones are used. Thus, if one uses the bracketed parameters of Table 2 to calculate the half-lives of 12:Ac and 14:Ac at 170°C, then the $t_{1/2}$ of 14:Ac is 2.0 times that of 12:Ac. This principle is further reflected by the changes in slopes for the equation $\ln t_{1/2} = aN + b$ at different temperatures as shown in Table 3 for the homologous series. As the temperatures increase, the slopes decrease.

A similar effect of change of magnitude of $t_{1/2}$ change with temperature occurs when comparing the change in $t_{1/2}$ at different temperature levels. For 16:Ac a 10° change in temperature from 170 to 160°C will increase $t_{1/2}$ by 1.8-fold whereas a 10° change from 30 to 20°C will increase $t_{1/2}$ by 3.7-fold.

Because the magnitudes of the variation of $t_{1/2}$ with temperature are a function of the laws of thermodynamics and the temperature range over which pheromones are used, similar magnitudes of the variation of $t_{1/2}$ with temperature and chemical structure will apply to other formulations using other formulation substrates of the same type. Formulation substrates of the same type are those that release pheromone by a first-order evaporation, such as PVC pellets (Daterman, 1974) or plastic film laminates (Leonhardt and Moreno, 1982). Open-ended microcapillaries release pheromone at a rate proportional to the square root of the vapor pressure (Brooks, 1980) and therefore are not of the same type. In this case the variation in evaporation rate with temperature will be determined by $\Delta H/2$.

Relationship of $t_{1/2}$ Values to Vapor Pressures. Vapor pressures of pure compounds have occasionally been used to account for evaporation rates from formulation substrates or GC elution rates. Although this may be a good approximation in a given circumstance, as a general principle it does not hold. The vapor pressure of a component in a formulation substrate or GC liquid phase determines the half-life or retention time, but it is not necessarily related to the vapor pressure of the pure compound.

In an ideal mixture, the vapor pressure of a component is directly proportional to the mole fraction of that component and the proportionality constant is the vapor pressure of that component in the pure form (Raoult's law). How-

ever, in the situations of concern here, the solute (pheromone component) is dissolved in a nonvolatile solvent (gas chromatographic liquid phase or formulation substrate such as a rubber septum) and an ideal mixture is not attained. Instead Henry's law would be expected to apply: the vapor pressure of a solute is proportional to its concentration, but the proportionality constant is empirically determined and is not the vapor pressure of the pure component.

Since in septa the rate of evaporation of a pheromone component is directly proportional to its concentration (first-order evaporation) and the evaporation rate is directly proportional to the vapor pressure, then vapor pressure is directly proportional to concentration. Therefore, a first-order evaporation from a nonideal mixture implies that Henry's law applies.

For Henry's law to apply, the solute molecules must be completely surrounded by solvent molecules (concentration less than about 10%). Then, as concentration changes, the molar free energy (ΔG) of the binding forces between the solvent molecules and the solute molecules does not change. The reason retention time or half-life may give approximate correlations with vapor pressure of pure compounds is that the free energy of the solute-solvent binding forces may be similar in the septum or GC liquid phase to the free energy of the molecule-molecule binding forces in the pure compound. Most pheromone components are of low polarity (long hydrocarbon chain terminated by one polar group) and therefore are somewhat comparable to rubber or nonpolar GC liquid phases. Polar GC liquid phases and polar formulation substrates are not expected to give even an approximate correlation with the vapor pressures of the pure compounds. For example, in a nonpolar GC liquid phase such as methyl silicone, alkenyl acetates elute before their saturated analogs (the alkenes have higher vapor pressures than the saturated analogs, the same order as observed for the pure compounds), while in a polar GC liquid phase such as polyethylene glycol, alkenyl acetates elute after their saturated analogs (alkenes have lower vapor pressure than their saturated analog, the opposite of the order observed for the pure compounds).

Abstract—The assembly behavior of the tick *Argas persicus* Oken in response to guanine has been found to be humidity dependent. Nymphal and adult male *A. persicus* assemble on guanine-treated paper disks only at low relative humidities ($25 \pm 5\%$). Exposure of the ticks to high relative humidities ($85 \pm 5\%$) results in a gradual induction of a negative response to the pheromone.

Key Words—Tick, Argasidae, Ixodidae, *Argas persicus*, assembly pheromone, guanine.

INTRODUCTION

Three different categories of pheromones are involved in the chemical communication system of ticks: assembly pheromones, sex pheromones, and aggregation-attachment pheromones (Sonenshine et al., 1982; Sonenshine, 1985). Of these, assembly pheromones are the most widely distributed, being associated with both argasid and ixodid ticks (Leahy et al., 1973, 1975a,b; Leahy, 1979; Graf, 1975; Treverrow et al., 1977; Uspensky and Emel'Yonova, 1980; Petney and Bull, 1981). They are deposited on the tick's natural substratum off the host where, on contact, they arrest the ambulatory activity of wandering ticks, contributing to the formation of tight clusters of akinetic ticks. This behavior is believed to protect the species during stressful conditions of the

nonparasitic phases of its existence and to improve its chances of finding its host when these return to their previous habitats under favorable conditions (Leahy, 1979).

It has long been recognized that tick assembly pheromones are nonvolatile, insoluble in less polar solvents, and relatively stable in the environment (Leahy, 1975a). A prominent feature is their relative lack of specificity, eliciting responses from different life stages of the same species as well as those of other species (Leahy et al., 1975b; George, 1981; Petney and Bull, 1981). It has been suggested that this phenomenon implies the operation of a common ancestral pheromone system retained by stabilizing selection for a behavior that has continued to play an important role in ensuring the survival of the species (Petney and Bull, 1981). The recent identification in our laboratory of guanine as the common assembly pheromone of both argasid and ixodid species supports this view (Otieno et al., 1985).

The present work is based on a fortuitous observation of erratic responses of *Argas persicus* nymphs to guanine during a rainy period in Nairobi, Kenya. Earlier, Hefnawy (unpublished, cited in Sonenshine et al., 1982) working with the ixodid *Rhipicephalus appendiculatus*, had observed that the assembly responses of the adults of this tick to filter papers treated with water extracts of nymphal and adult excreta were confined to periods of dry weather. Unfortunately, details of this work were not published. The possible ecological implications of these observations prompted us to examine the effects of extremes of humidity on the responses of *A. persicus* to the assembly pheromone under controlled conditions, and herein we describe the results obtained.

METHODS AND MATERIALS

Nymphal (mixed stage) and adult male *Argas persicus* were obtained from a colony at the Hebrew University in Jerusalem, Israel. As in our previous study (Otieno et al., 1985), this species was used because its assembly response in bioassays is higher than those of other species (Leahy et al., 1975b; Leahy, 1979). Guanine used for the experiments was obtained from Sigma Chemical Company (Sigma white crystals grade).

Guanine solutions were prepared weekly by stirring 10-mg samples in 10 ml of double-distilled water for 16 hr at 22°C. The sample was centrifuged at the same temperature and the supernatant containing 0.7 mg guanine/100 ml (Otieno et al., 1985) was retained for bioassays.

A two-choice bioassay system was used to monitor the assembly responses of *A. persicus*. It comprised four 1.7-cm-diameter filter paper (Whatman No. 3) disks, two tests and two controls, arranged in diagonal pairs in a glass Petri dish (6 cm). These were placed on slide warmers (Fisher), incubated at 28°C,

and kept in the dark at $25 \pm 5\%$ or $80 \pm 5\%$ relative humidity. Humidities were controlled by ZnCl_2 and water, respectively, placed in a series of smaller dishes. Fifty microliters of guanine solution was applied using a syringe to each of the test disks, which were then allowed to dry in a stream of warm air before being placed in the Petri dish. The control disks were treated with double-distilled water only. Twelve *A. persicus* nymphs or adult males were placed in the center of the dish, and the assay system was left for 20–22 hr before counts of ticks assembled on treated and untreated disks were made. Each bioassay set comprised four replicates at the lower humidity and four at the higher humidity. At the end of each run, the ticks were returned to their storage containers, the Petri dishes thoroughly cleaned, and freshly treated paper disks were used for the next set of replicates. Assembly responses of ticks at the following physiological states were tested: (1) nymphal and adult male *A. persicus* from batches kept under ambient conditions for two to three weeks after moulting; (2) nymphal and adult male *A. persicus* from batches kept continuously either at $25 \pm 5\%$ or $80 \pm 5\%$ relative humidity at 28°C ; (3) nymphs from a freshly moulted batch assayed daily at the two humidities from the first day for 30 days.

RESULTS

Table 1 gives the data (pooled from 18 replicates) representing the assembly responses of nymphs and male adults, three weeks after moults, to a choice of guanine-treated and control paper disks. Significant differences in assembly

preference between treated and untreated disks are observed at the lower humidity for both stages of the ticks. At the higher relative humidity, the differences in assembly responses were not significant, although data from successive batches of 3- to 4-week-old ticks consistently suggested a possible avoidance reaction to guanine-treated disks. A second set of assays was carried out using a batch of ticks that had been kept at the higher humidity for a longer period (six weeks) to see if the guanine avoidance response could be accentuated. Table 2, comprising assay data pooled from 22 replicates, summarizes the results obtained. Preferences for the untreated disks were significantly higher than for guanine-treated disks, clearly showing the development of a negative response to the pheromone.

During the course of the present study, preliminary observations with several batches of freshly moulted *A. persicus* nymphs or adults suggested a different pattern of response at this physiological stage of the tick. Accordingly, the responses of several batches of nymphs were monitored daily from the first day after the moult to see if a consistent set of behavior is demonstrated at the two humidity levels. Table 3 illustrates the pattern of results obtained. Recently moulted nymphs were indifferent to choices of guanine-treated and untreated paper disks at lower relative humidities. At the higher relative humidity, the ticks showed a brief positive response to guanine, followed by a period of indifference before the induction of a negative response. Observation of a batch of nymphs for eight weeks showed that no further change in behavior takes place after the development of a positive response to guanine at the lower humidity and a negative response at higher humidity level.

DISCUSSION

Several adaptive roles ascribed to the tick assembly pheromone have been the subject of debate in the literature (Leahy, 1979; George, 1981; Petney and Bull, 1981; Sonenshine, 1985; Otieno et al., 1985). A consensus view is that the pheromone exerts a significant influence in arresting activity during times when the weather conditions outside the resting sites are unfavorable (low humidity, high temperature) and host animals are unlikely to be available, and this contributes to the formation of tight clusters to minimize water losses. In addition, it has been suggested that the pheromone functions to hold the ticks within the habitats to which the host animals return periodically, thus increasing the chances of encounter with their hosts (Leahy, 1979). These views are consistent with the finding that a sustained positive response to guanine is associated with continued exposure of the ticks to low relative humidities. Moreover, the selection of a semiochemical that is nonvolatile, present in relatively large amounts, and environmentally persistent is most appropriate for long-term performance needed for such purposes. However, a chemical with such characteristics would also create a major problem: how to release the tick from its positive influence when the weather conditions improve. Our findings show clearly the

development in *A. persicus* of a negative response to the semiochemical at the higher relative humidity. A similar trend was apparently observed by Hefnawy (unpublished, cited in Sonenshine et al., 1982) with *R. appendiculatus*, and it may turn out to be a general behavioral phenomenon among both the argasids and the ixodids, although the level of humidity at which the reversal in response takes place may vary from one species to another.

Recently moulted *Argus persicus* nymphs are largely indifferent to guanine (Table 3), apart from a brief positive response at the high relative humidity. Thus, sensitivity of the tick to the purine appears to be influenced by the availability of metabolic water, which is likely to be relatively high in recently moulted ticks, and is consistent with the pheromone's role as an assembly stimulus when conservation of water becomes an important factor. The brief positive response to guanine at the high humidity (Table 3, data for days 1-3) has been demonstrated by three different batches of recently moulted nymphs, but its significance, if any, is unclear.

To our knowledge, guanine represents the first example of a pheromone system that can play two opposite roles depending upon the environmental condition. The way this occurs is a matter of speculation. We suggest three alternative mechanisms: (1) at high humidity the pheromone may undergo a reversible change to a molecular species that elicits an avoidance response; (2) the information from the pheromone receptor, apparently present on the palpal tarsi (Leahy et al., 1975a), is interpreted against a background of messages from humidity receptors (Sonenshine, 1963) and the final response of the organism depends upon a summation of the two; (3) the pheromone receptor protein is moisture sensitive and readily hydrates at elevated humidities to give a conformation that interacts in a different mode with guanine, resulting in different information to the central nervous system. The first alternative appears to be least likely. Water extracts of guanine-treated filter disks left within the bioassay system at low and high humidities gave identical UV spectra and high-pressure liquid chromatograms. Moreover, solid-phase (KBr) IR spectra of samples of powdered guanine kept at low and high humidities were essentially identical, indicating that no significant shift in the equilibrium between N(7)H and N(9)H tautomers had occurred in the solid phase. In any case, the small free energy difference (~ 1 kcal/mol) between these tautomers (Pullman and Pullman, 1971) means that there would be a facile drift of the equilibrium position to the one most favored at the receptor site, irrespective of the initial position. In our view, one or the other of the remaining alternatives might be the mechanism by which guanine plays a dual semiochemical role. Carefully designed behavioral studies in conjunction with sensory physiological work would help shed some light on the question.

FOLLOWING OF CONSPECIFIC AND AVOIDANCE OF
PREDATOR CHEMICAL CUES BY PINE SNAKES
(*Pituophis melanoleucus*)

JOANNA BURGER

*Department of Biological Sciences
Nelson Biological Laboratory
Piscataway, New Jersey 08855-1059*

(Received December 14, 1987; accepted March 7, 1988)

Abstract—The ability of hatchling pine snakes (*Pituophis melanoleucus*) to follow or avoid the chemical trails of conspecifics and a king snake (*Lampropeltis getulus*) on paper substrates was investigated in Y-maze experiments. Hatchlings entered the arm with the adult conspecific trail and avoided the arm containing the king snake trail at a frequency much greater than that due to chance. The data support the hypotheses that pine snakes follow the chemical trails of adult conspecifics and avoid the chemical trails of a predator.

Key Words—Chemical cues, predator avoidance, pine snake, *Pituophis melanoleucus*, odor trails.

INTRODUCTION

Trailing of conspecifics or prey by chemical means has been demonstrated in controlled laboratory experiments for snakes (Brown and Maclean, 1983; Chiszar et al., 1986; Ford, 1982; Ford and O'Bleness, 1986; Ford and Schofield, 1984; Gehlbach et al., 1971; Heller and Halpern, 1981) and for lizards (Cooper and Vitt, 1986a). Further, reptiles often respond to odors or those on applicators by increased tongue flicks (Cooper and Vitt, 1984, 1986b; Cooper et al., 1986). In some cases pheromonal communication is suspected because adult male skinks follow the trails of adult conspecific females, but not those of other males (e.g., *Eumeces laticeps*; Cooper and Vitt, 1986c). For reviews of the role of chemoreception in reptiles, see Burghardt (1980), Simon (1983), and Von Achen and Rakestraw (1984).

Earlier studies have shown the use of chemical abilities in several important contexts, including recognition of prey (Burghardt, 1973; Chiszar et al., 1986), detection of conspecifics (Cooper and Vitt, 1984), discrimination of male from female conspecifics (Cooper and Vitt, 1984), discrimination of conspecific and closely related syntopic congeners (Cooper and Vitt, 1986c), trailing conspecifics to find hibernacula (Brown and Maclean, 1983) or mates (Ford and O'Bleness, 1986), and differentiation of ophiophagous from nonophiophagous snakes (Weldon and Burghardt, 1979; Weldon, 1982). However, Weldon's (1982) studies dealt with changes in tongue-flick frequency. There has been no clear demonstration in snakes of discrimination of ophiophagous from nonophiophagous snakes. Snakes can distinguish conspecific from heterospecific odor trails (Ford and O'Bleness, 1986). Because some snakes are predators on other snakes, it would be advantageous for prey species to be able to detect the chemical trails of potential predators and avoid them. This would be particularly true for hatchlings that are more vulnerable to predators because of their small size. In this article I report experiments designed to examine choice discrimination by hatchling pine snakes (*Pituophis m. melanoleucus*) of the odor trail of conspecifics and of a heterospecific predator of pine snakes, the king snake (*Lampropeltis getulus*).

METHODS AND MATERIALS

Under appropriate state permits, pine snake eggs were collected from the Pine Barrens of southern New Jersey (Ocean, Cumberland, and Monmouth counties), and 200 hatchlings were hatched and maintained in the laboratory in 1986. Date of hatching was noted, so the exact age of each snake at testing was known. Snakes were maintained individually in plastic (30 × 15 × 9 cm) cages containing paper for shelter. Snakes were given the opportunity to drink water daily and to eat young laboratory mice once a week. Not all snakes had eaten, but there were no significant differences in behavior as a function of this variable. Snakes were sexed by hemipenis eversion, a reliable rapid procedure for young snakes (Schaefer, 1934; Fitch, 1960; Gregory, 1983; Gutzke et al., 1985).

To determine whether pine snakes could make directional responses to chemical trails, Y-maze experiments were conducted. The base arm of the Y maze was 1 m long and 15 cm wide, with 15-cm-high wooden sides. At the end of the base arm, two side arms (experimental arms, 45° angle from the base arm) were the same dimensions as the base arm. The floor of the maze was covered with paper that was changed after each trial. Plexiglas was placed over the maze to prevent the snakes from escaping from the center, choice point of

the maze. All ends of the maze were open during testing, allowing the snake to leave the apparatus at the end of the trial.

There were four experiments: (1) control ($N = 30$, no chemical trail on either side), (2) hatchling conspecific versus no trail ($N = 74$, trail on one side), (3) adult conspecific (snout-vent length = 120 cm) versus no trail ($N = 44$, trail on one side), (4) adult king snake (snout-vent length = 86 cm) versus no trail ($N = 117$, trail on one side). Trials were conducted from September 25 to October 15 on hatchlings that were 25–35 days old. Each snake was tested once in either the control or predator experiment and once in either the hatchling or adult conspecific experiment. The order of the experiments was selected randomly each day. Snakes were assigned randomly to each experiment. Sample size varied because snakes were used only in one type of conspecific test. I was primarily interested in their responses to hatchlings (that they would encounter in nature) and the predator; thus I used more snakes in these two tests. On some trials a snake would not enter the test (they had recently eaten or were otherwise overactive), accounting for further unequal sample sizes. The temperature was maintained at 27°C during all experiments, which were conducted from 1100 to 1400 hr.

The base arm contained no chemical trail, and there was no odor trail in one of the experimental arms. A chemical trail in the other experimental arm was produced by letting the stimulus (hatchlings, adult pine snake, or king snake) move freely over the paper and shavings for 10 min while both ends of the experimental arm were closed. The hatchling trail was established by allowing three hatchlings from a brood not otherwise included in the sample to move freely over the experimental arm. Only one king and three pine snake adults were used for the odor trail because that is all that were available. I do not believe that these adults possessed an idiosyncratic odor different from other conspecifics. The chemical trail extended the full length of the experimental arm: the trail-providing snakes were seen to move the entire length of the arm. When handling snakes, paper, or shavings, the experimenters wore disposable surgical gloves to avoid imparting human or snake odors. Following each trial, the paper and shavings were changed, and the location of the experimental arm was changed. Whenever a snake contacted the sides of the maze, all walls were subsequently washed with soap and water. After every 10 trials the entire apparatus and floor were also cleaned with soap and water.

Each snake was placed by hand into the base arm facing the opening with its head at the entrance and allowed to move freely up the arm to the intersection, where it usually moved into one of the experimental arms. The trial ended when the snake left the *Y* maze, usually through the experimental arms, although some went back out the base arm after arriving at the *Y* junction. The time each snake was in the base and experimental arm, time at the *Y* junction, and the

number of tongue flicks when the snake was in each location were recorded. An assistant released the snake into the maze. The behavior of hatchlings in conspecific tests did not differ as a function of their choice; however, behavior did vary in the predator test, and these data are presented. Chi square tests were used to determine the significance of the responses frequency in the four experiments, and Kruskal-Wallis chi square tests were used to determine differences in central tendencies of time and tongue flicks under several conditions. Data are presented as means \pm 1 SD in the text.

RESULTS

Most snakes moved rapidly to the Y junction, remained motionless for a few seconds ($\bar{X} = 18.4 \pm 6$ sec), explored the Y junction for 5–35 sec ($\bar{X} = 19.9 \pm 11.2$ sec), and moved rapidly down one of the arms.

When there was no chemical trail (control experiment), there was no significant difference in their choice (Table 1). Pine snake hatchlings did not follow the chemical trails of other conspecific hatchlings, but they did follow the trails of adult pine snakes (Table 1). In these conspecific trials, only one snake turned around and went back out the base arm, and none tried to go over the top of the maze.

Hatchling pine snakes avoided the king snake chemical trail and chose the arm with no chemical trail (Table 1). In this experiment 100 of the snakes selected an arm, and 17 either turned around and went out the base arm ($N = 8$), tried to climb over the top displacing the Plexiglas ($N = 4$), or moved back

^b

and forth between the two experimental arms ($N = 5$). It appeared that some hatchlings were responding to airborne odors by their obviously increased activity and attempts to get out of the *Y* maze.

As might be expected, there were no differences in the time each snake was in the base arm as a function of its final choice (Table 2). However, snakes emitted significantly more tongue flicks when exploring at the *Y* junction and when they went down the king snake chemical trail compared to the arm with no chemical trail. Similarly, they explored longer when they selected the king snake arm and moved significantly more slowly down the king snake arm compared to the blank (Table 2).

There were no significant differences as a function of age (15–25 days old) or sex of the hatchling, time of day, or location of the experimental arm ($P < 05$).

DISCUSSION

Hatchling pine snakes detect and follow the chemical trails of adult conspecifics and avoid the chemical trails of adult king snakes. In nature, pine snake hatchlings emerge from their underground nests in September and find

hibernacula in the next few weeks (Burger and Gochfeld, 1985; Burger et al., 1988). New Jersey Pine snakes hibernate in underground burrows that they dig themselves (Burger et al., 1988), although elsewhere gopher snakes (*Pituophis melanoleucus deserticola*) hibernate in mammal burrows with other species of snakes (Parker and Brown, 1973). It would be adaptive for pine snake hatchlings to locate and follow the trails of adult pine snakes to such sites. In the field I have observed hatchling pine snakes shift direction and follow the trail left by a released adult pine snake. Recognition of a conspecific chemical odor is particularly adaptive in New Jersey where pine snakes hibernate in small groups of up to 14 individuals (Burger et al., 1988), in contrast to some other species of snakes which hibernate in coiled groups of several to hundreds (Brown et al., 1974; Aleksuik, 1976). Thus, a keen ability to recognize the chemical trail of one or two adults would be useful in quickly finding a hibernaculum. In the New Jersey Pine Barrens, adult pine snakes move back toward hibernacula in September, before some hatchlings have emerged (Burger and Zappalorti, unpublished data).

Failing to find an adult chemical trail, it might be adaptive for a hatchling to follow the trail of another hatchling, although hatchlings did not significantly select the hatchling trails over no trails. It may be that the trail left by only three hatchlings is insufficient to distinguish and choose, or that the trail of hatchlings is disadvantageous to follow because it represents the wanderings of another "naive" hatchling that has yet to reach a hibernaculum. This issue cannot be decided on the basis of present results (Burghardt, 1983).

In these experiments, pine snakes avoided the king snake chemical trail. King snakes prey on other species of snakes (Fitch, 1963; Ditmars, 1935), including pine snakes in the New Jersey Pine Barrens (R.T. Zappalorti, personal communication). Thus, pine snakes were avoiding a potential predator by avoiding the arm with the king snake trail.

Snake species respond defensively to ophiophagous snakes by body bridging (Weldon and Burghardt, 1979), biting (Klauber, 1972), head hiding in coils (Carpenter and Gillingham, 1973), freezing, and rapid escaping behavior (Weldon, 1982; Marchisin, 1980). Carpenter and Gillingham (1975) reported that the colubrid snakes they tested were unresponsive to king snakes during staged encounters, but they used only body bridging as an indication of response. More recently, Weldon (1982) showed that naive garter snakes (*Thamnophis elegans*) emitted significantly more tongue flicks to swabs rubbed against the skin of king snakes than to those from generally nonophiophagous snakes or blank swabs. Similarly, *T. sirtalis* emitted more tongue flicks to swabs rubbed against black racers (*Coluber constrictor*), another ophiophagous species, than to that of nonophiophagous snakes (Weldon, 1982). These studies clearly demonstrate a differential chemical response. Alternatively, one might suggest that such studies demonstrate recognition of familiar compared to unfamiliar scents (Chiszar et al., 1978).

In these experiments, hatchling pine snakes required longer to explore in the choice situation when they traversed the king snake odor trail. More of their responses were ambivalent in the king snake test compared to the other experiments. Furthermore, pine snakes gave significantly more tongue flicks to the king snake arm while exploring the choices, corroborating the findings of Weldon (1982) for other species. However, since only a subset of snakes selected the king snake arm, their behavior may be aberrant. Similar increases in tongue flicks emitted to ophiophagous snakes have been reported in lizards (*Lacerta vivipara*; Thoen et al., 1986). In total, these findings suggest that some snakes and other squamates can distinguish the chemical deposits of ophiophagous and nonophiophagous snakes and follow the trail of conspecifics.

Acknowledgments—I thank R.T. Zappalorti for providing the pine snake eggs, R. Fengya for providing the king snake, and J. Sollazzo, M. Mikovsky, B. Lauro, and W. Boarman for help with the preliminary experiments.

ATTRACTION OF SCOLYTIDS AND ASSOCIATED BEETLES BY DIFFERENT ABSOLUTE AMOUNTS AND PROPORTIONS OF α -PINENE AND ETHANOL

L.M. SCHROEDER and Å. LINDELÖW

Swedish University of Agricultural Sciences
Division of Forest Entomology
P.O. Box 7044, S-750 07 Uppsala, Sweden

(Received December 22, 1987; accepted March 7, 1988)

Abstract—The attraction of bark and ambrosia beetles as well as associated beetles to α -pinene and ethanol was studied in field experiments with flight barrier traps. α -Pinene and ethanol were released individually and as combinations in approximately 1:1 or 1:10 ratios and at four different release rates. Ethanol attracted *Tomicus piniperda* (L.), *Hylurgops palliatus* (Gyll.), *Trypodendron lineatum* (Oliv.), *Hylastes cunicularius* Er., *H. brunneus* Er., *H. opacus* Er., and *Anisandrus dispar* (F.) (Scolytidae); *Glischrochilus quadripunctatus* (L.) and *Epuraea* spp. (Nitidulidae); *Thanasimus formicarius* (L.) (Cleridae); and *Rhizophagus depressus* (F.) (Rhizophagidae). α -Pinene attracted all these species with the exception of *T. lineatum*, *H. cunicularius*, and *A. dispar*. Combinations of α -pinene and ethanol resulted in synergistically increased attraction of all species with the exception of *H. opacus* and *A. dispar*. *A. dispar*, the only hardwood-associated species in the study, was repelled by α -pinene. Both the release rates and the ratio at which the two substances were released influenced the response of the beetles. The differences in response between the beetle species seem to reflect dissimilarities in the release of the two substances among the various types of breeding material to which the species are adapted.

Key Words—Coleoptera, Scolytidae, *Tomicus piniperda*, *Trypodendron lineatum*, *Hylurgops palliatus*, *Thanasimus formicarius*, host attraction, host volatiles, ethanol, α -pinene, synergism.

INTRODUCTION

Several scolytid species are known to utilize host volatiles such as monoterpenes and the degradation product ethanol when searching for suitable host

substrate. The release rates of terpenes and ethanol and the proportions in which they are released can be expected to vary greatly among various types of breeding substrate. Hence, the response of various scolytids to combinations of terpenes and ethanol can be expected to differ depending on their breeding substrate preferences. Earlier studies have demonstrated the effects of increasing the release rate of ethanol in combination with a fixed release rate of host terpenes on the attraction of scolytids and associated beetles (Klimetzek et al., 1986; Schroeder, 1988). However, no studies have been reported on the response of scolytids to combinations of terpenes and ethanol in which the release rates of the host terpenes are varied. α -Pinene was chosen to represent the terpenes in the present study since it is one of the major monoterpenes in both Scots pine, *Pinus sylvestris* L., and Norway spruce, *Picea abies* (L.) Karst, the two dominant conifers in Scandinavia.

The aim of this study was to compare the attraction of various scolytid species and associated beetles to combinations of α -pinene and ethanol in proportions of approximately 1:1 and 1:10 when released at four different rates. We were especially interested in establishing whether synergistic attraction occurs for any of the tested release rate combinations.

METHODS AND MATERIALS

All experiments were conducted in a 40-year-old Scots pine stand in the province of Uppland in central Sweden in 1987. The attraction of beetles to the different compounds or combinations of compounds was estimated using baited flight barrier traps (Schroeder, 1988; type b) modified from the type described by Chapman and Kinghorn (1955). Under the barrier (a 40 × 40-cm transparent plastic sheet) a funnel ending into a water-filled jar was hung. The chemicals used were (–)- α -pinene (Fluka 97%, $[\alpha]_D^{20} -42 \pm 3^\circ$) and 95% ethanol (5% water). The supply of α -pinene in the laboratory was stored at +4°C. Chemical analyses of samples of this supply before and after the experimental period revealed no detectable amounts of oxidation products. The analysis was performed on a Finnigan 4021 GC-MS instrument. The α -pinene contained 91% (–)- α -pinene (82% ee), and this analysis was performed on a α -cyclodextrin GC column.

The substances were released at different rates from polyethylene vials with different-sized openings. When combinations of α -pinene and ethanol were tested, the two substances were released from separate vials. When exposed to air, α -pinene autoxidizes to a variety of compounds (Borden et al., 1986). To minimize the release of these oxidized substances during the field experiments, new vials supplied with fresh compounds were applied (between 10 AM and noon) on each day of the experiment.

Experiment 1. The experimental design consisted of 10 blocks (replicates)

with 14 treatments (traps) in each block. An overview of the experiment and the release rates is given in Table 1. The traps in each block were placed 10 m apart in a circle. Within each block (circle) all traps were oriented in the same compass direction. The minimum distance between blocks was 15 m. The treatments were randomly assigned to the trap positions within each block. Baits were placed out on each of five days between April 23 and July 22. The positions of the treatments in the circle of traps were not changed during the experiment. The captured beetles were collected after each day and pooled for each trap in the analysis.

Experiment 2. In this experiment a particularly low release rate of α -pinene was tested (Table 1). The treatments were (1) unbaited control, (2) α -pinene, (3) ethanol, and (4) α -pinene plus ethanol. The experimental design was similar to that in experiment 1, but each block only consisted of four traps (treatments), and there were 14 blocks. This experiment was baited only on April 23.

^aThe release rates of α -pinene and ethanol were estimated in the laboratory by measuring the weight loss of the vials over 6 hr when placed in a wind tunnel at 0.5 m/sec and 15°C. Three replicates in each sample.

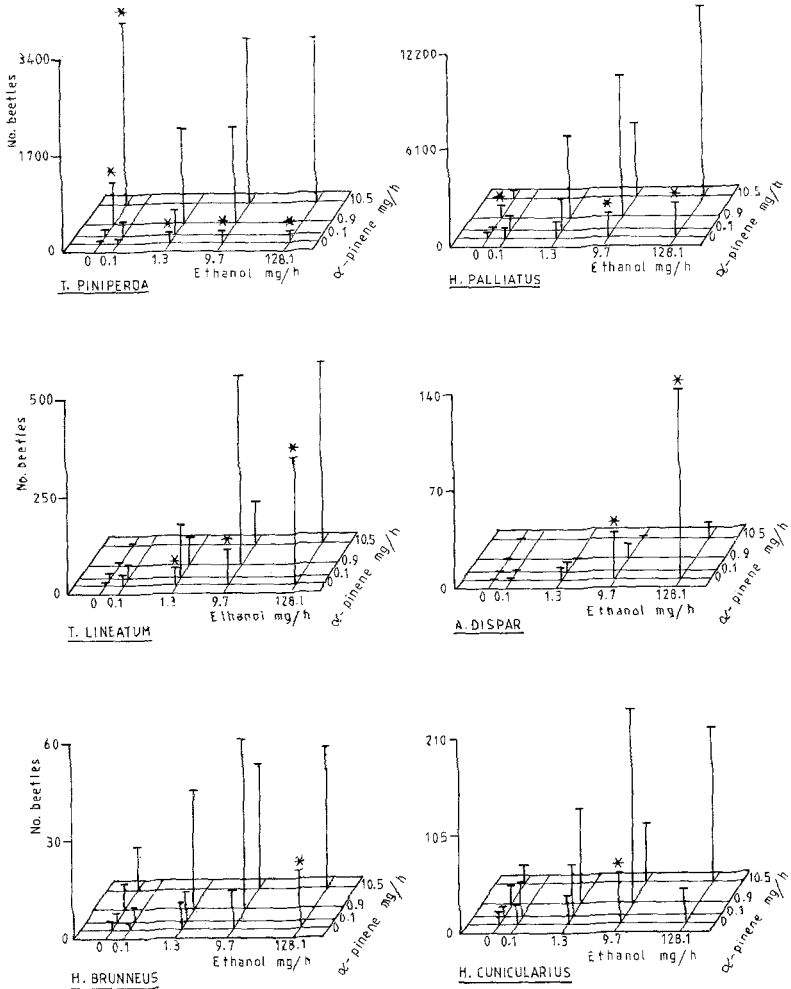

FIG. 1. Total number of beetles caught in flight barrier traps baited with α -pinene, ethanol, or both. Ten replicates of each treatment. Note the different scales of the catches and that the release rates have been transformed to $\log(x + 0.1)$ when arranged on the axes. An asterisk indicates a significant difference between the catch of treatment and that of the unbaited control at $P = 0.05$ level. Only those treatments in which α -pinene or ethanol were presented alone were tested for significant differences against the unbaited control.

When comparing the number of beetles caught in traps baited with α -pinene or ethanol at different release rates with the number caught in unbaited traps (Figure 1), data were analyzed with Friedman's test followed by a nonparametric test of Dunnett's type (Zar, 1984). Wilcoxon's signed rank test was used

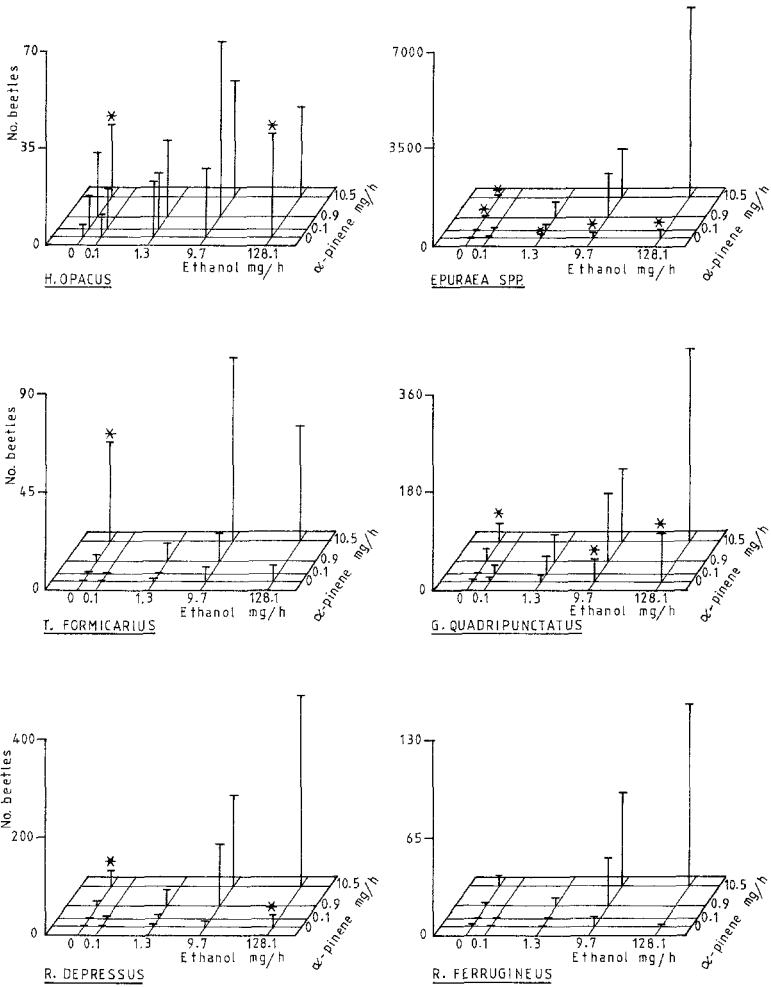

FIG. 1. Continued.

to test for synergism between ethanol and α -pinene (i.e., whether the combined treatment caught significantly more beetles than the sum of the two separate treatments).

RESULTS

The data from experiment 1 are presented in Figure 1, which gives an overview of the trap catches of the various species with regard to α -pinene, ethanol, and combinations of the two substances. Traps baited with α -pinene

alone caught significantly higher numbers than unbaited traps of the scolytids *Tomicus piniperda* (L.), *Hylurgops palliatus* (Gyll.), and *Hylastes opacus* Er.; the nitidulids *Epuraea* spp. and *Glischrochilus quadripunctatus* (L.); the clerid *Thanasimus formicarius* (L.); and the rhizophagid *Rhizophagus depressus* (F.). Catches of *Hylastes brunneus* Er. and *Hylastes cunicularius* Er. were also greater at α -pinene baits than in blank traps, but the differences were not significant. In contrast, the scolytids *Trypodendron lineatum* (Oliv.) and *Anisandrus dispar* (F.) were not caught in higher numbers in α -pinene-baited traps than in unbaited traps.

Traps baited with ethanol alone caught significantly higher numbers of all species than unbaited traps with the exception of *Rhizophagus ferrugineus* (Payk.) and *T. formicarius*. The catch of *T. formicarius* was higher at ethanol baits than in blank traps, but the difference was not significant.

Also in experiment 2, significantly more *T. piniperda* were caught in ethanol-baited traps ($\bar{X} = 7.8$) than in unbaited traps ($\bar{X} = 2.0$) (Wilcoxon signed rank test, $P < 0.05$). At the very low rate of α -pinene release used in this experiment, there was no significant difference in the catch of *T. piniperda* between α -pinene-baited traps ($\bar{X} = 3.3$) and control traps ($\bar{X} = 2.0$) and of *H. palliatus* between ethanol- ($\bar{X} = 2.2$) or α -pinene-baited traps ($\bar{X} = 0.4$) and control traps ($\bar{X} = 1.2$).

With the exception of *A. dispar* and *H. opacus*, the catches to the combinations of α -pinene and ethanol tested in experiment 1 were significantly higher for all species than the corresponding sums of the separate treatments, at one or more levels of release (Table 2). *A. dispar* was caught in the highest numbers in traps baited with ethanol alone, while traps baited with α -pinene alone caught no individuals. At the two higher α -pinene release rates, significantly fewer *A. dispar* were caught in the combined treatments than in the corresponding treatments baited with ethanol only (Wilcoxon signed rank test, $P < 0.01$).

α -Pinene and ethanol interacted synergistically in attracting *T. piniperda* at the two lower release rates of α -pinene. At the highest release rate of α -pinene, the combinations caught lower numbers (not significant) of *T. piniperda* than did α -pinene alone.

For *H. palliatus*, *T. lineatum*, *R. depressus*, *R. ferrugineus*, *Epuraea* spp., *H. cunicularius*, and *G. quadripunctatus*, synergism was strongest when the ethanol was released along with α -pinene at a rate approximately 10 times that of the latter. For *T. piniperda* and *H. brunneus*, the extent of synergism did not differ between combinations with an approximate 1:1 or 1:10 ratio between the release rates of α -pinene and ethanol.

In experiment 2 the catch at the combination of α -pinene and ethanol was significantly higher for *H. palliatus* ($\bar{X} = 4.4$), but not for *T. piniperda* ($\bar{X} = 14.7$), than the corresponding sum of the separate treatments (*H. palliatus*, $\bar{X} = 2.6$; *T. piniperda*, $\bar{X} = 11.1$) ($P < 0.05$, Wilcoxon signed rank test).

TALBE 2. SUMS OF BEETLES CAUGHT IN WINDOW TRAPS BAITED WITH α -PINENE ALONE, ETHANOL ALONE, AND NUMBER CAUGHT IN TRAPS BAITED WITH BOTH SUBSTANCES AT CORRESPONDING RELEASE RATES.

^aA: release rates of α -pinene and ethanol are of the same magnitude; B: ethanol released at a rate approximately 10 times higher than that of α -pinene.

^bNumber of beetles caught by the combined treatment is significantly different from the sum of beetles caught by the separate treatments ($p < 0.05$; Wilcoxon signed rank test).

DISCUSSION

All scolytid species in the present study, with the exception of *A. dispar*, breed in conifers (Lekander et al., 1977) while the beetle species of other families occur together with various conifer scolytids (Nuorteva, 1956; Mills, 1983). *A. dispar*, which breeds in dead or dying trees of several hardwood species, was the only species in our study that was strongly repelled by the conifer monoterpene α -pinene. Similar results were earlier obtained for the scolytid

Trypodendron domesticum (L.), which also breeds in hardwood species (Nijholt and Schönherr, 1976). The strong attraction of *A. dispar* to ethanol alone has earlier been demonstrated by Magera et al. (1982) and Klimetzek et al. (1986). Moeck (1971) observed a strong attraction of *Anisandrus pyri* Peck. to ethanol alone.

In contrast to the other scolytids in this study, *T. piniperda* generally breeds in relatively fresh material, e.g., newly windbroken or windthrown trees and winter- or spring-cut logs (Trägårdh, 1921; Annila, 1975; Långström, 1984). Since such material has only just begun to deteriorate, the release of ethanol should be rather low, while high amounts of terpenes may be released from resin exuding from damaged parts. Accordingly, *T. piniperda* was the species most strongly attracted by α -pinene alone (see also Byers et al., 1985; Schroeder, 1988). Ethanol also attracted this species, but to a much lesser degree than α -pinene. Magera et al. (1982) caught higher numbers of *T. piniperda* in traps baited with ethanol (no release rates given) than in control traps, but the difference was not statistically significant. In a previous study (Schroeder, 1988), ethanol-baited traps did not catch higher numbers of *T. piniperda* than unbaited traps in two different experiments. But the number of *T. piniperda* caught in one of these experiments was low.

Vité et al. (1986) reported that up to 14 times more *T. piniperda* were caught in traps baited with a combination of racemic α -pinene plus terpinolene (1:1) and ethanol than in traps baited with the terpene mixture alone (no release rates given). The stronger synergistic effect in their study compared with the present one might be a result of differences between the ratios at which the host terpenes and ethanol were released in the two experiments and/or a result of differences between the monoterpenes baits used in the studies. However, there is no evidence in the literature suggesting that the differences in monoterpene baits between the present and the cited study should have influenced the results. In the study of Vité et al. (1986) a mixture of ethanol, racemic α -pinene, and terpinolene caught about the same number of *T. piniperda* as did a mixture containing the first two mentioned substances only (the terpenes were not tested alone in that experiment). Byers et al. (1985) caught about the same number of *T. piniperda* with (+)- α -pinene as they caught with (-)- α -pinene, and the combination of enantiomers did not have any synergistic effect on the attraction.

Although not significant, the decrease in attraction of *T. piniperda* that occurred when ethanol was added to the highest release rate of α -pinene in the present study is in agreement with the result of a similar experiment in a previous study (Schroeder, 1988). In that study the same α -pinene release rate (10 mg/hr) was combined with several ethanol release rates ranging from 7 times lower to 21 times higher than the release rate of the α -pinene. Each one of these combinations attracted fewer *T. piniperda* than did the α -pinene alone, and the difference was significant at the two highest ethanol release rates. Evidently,

maximal attraction of *T. piniperda* is attained by the α -pinene alone at this high release rate: attraction cannot be increased further by adding ethanol. Instead, high release rates of ethanol may decrease the attraction of *T. piniperda*, although the ratios between the substances are approximately the same as those that result in synergistic attraction at lower release rates.

Klimetzek et al. (1986) noted a fivefold decrease in catch of *T. piniperda* when increasing release rates of ethanol from 1 to 5 mg/hr (estimated in laboratory) in combination with a fixed release rate (not given) of the terpene mixture used by Vité et al. (1986).

H. palliatus, *T. lineatum*, *H. cunicularius*, *H. brunneus*, and *H. opacus* generally reproduce in dead or dying trees. The first three species prefer logs cut during the autumn of the previous year over newly cut logs (Trägårdh, 1921; Annila, 1975; Pulliainen, 1983). This type of older breeding material may release relatively high amounts of ethanol produced in deteriorating tree tissue (cf. Cade et al., 1970; Moeck, 1970), while monoterpenes are probably released in lower amounts compared with the amounts released from newly felled or broken trees (cf. Ikeda et al., 1980). None of the five scolytid species was attracted as strongly to α -pinene alone as was *T. piniperda*. The ambrosia beetle *T. lineatum* was not attracted at all by α -pinene and, for *H. cunicularius*, the difference in catch between α -pinene-baited traps and unbaited traps was too small to be interpreted as evidence of attraction to α -pinene. Ethanol strongly attracted *T. lineatum*, while attracting more weakly *H. palliatus* and the three *Hylastes* species. Ethanol alone has earlier been demonstrated to attract *H. palliatus* and *T. lineatum* (Moeck, 1970, 1971; Nijholt and Schönherr, 1976; Magema et al., 1982; Kohnle, 1985; Klimetzek et al., 1986; Schroeder, 1988).

Combinations of α -pinene and ethanol resulted in synergistic attraction in *H. palliatus*, *T. lineatum*, *H. cunicularius*, and *H. brunneus*. The lack of synergism in *H. opacus* is difficult to explain since this species inhabits a similar type of breeding material as the other two *Hylastes* species. Combinations with an approximate 1:10 ratio between the release rates of α -pinene and ethanol resulted in a stronger synergism than the corresponding 1:1 combination for *H. palliatus*, *T. lineatum*, and *H. cunicularius*. This illustrates that for these species the ratio at which the substances are released affects the beetle response.

Earlier studies with *T. lineatum* have demonstrated synergism in attraction between α -pinene and ethanol (Bauer and Vité, 1975; Nijholt and Schönherr, 1976), and data presented by Kohnle (1985) for *H. palliatus* suggest synergism between ethanol and spruce resin.

T. formicarius, *G. quadripunctatus*, *R. depressus*, *R. ferrugineus*, and *Epuraea* spp. are all species associated with bark- and wood-living beetles. With the exception of *T. formicarius*, adults of these species inhabit scolytid galleries. In this kind of substrate, deterioration processes should result in a gradual increase in the production of ethanol, released together with host ter-

penes. This could explain the strong synergistic effect of combinations of α -pinene and ethanol on attraction in these species. In contrast to the other species, *T. formicarius* adults prey on adults of several species of bark beetles, and among these is *T. piniperda* (Gauss, 1954; Nuorteva, 1956). The wide range of prey species, which in their turn are attracted to different kinds of breeding material, may explain the strong attraction of *T. formicarius* to α -pinene alone as well as to combinations of α -pinene and ethanol (see also Schroeder, 1988).

The present study demonstrates great differences between beetle species in their response to α -pinene, ethanol, and to combinations of the two. These differences probably reflect dissimilarities in the release of these volatiles among the various types of breeding material to which the species are adapted. Both the absolute release rates and the ratio at which the two substances were released influenced the response of the beetles to the combinations.

CARDENOLIDE FINGERPRINT OF MONARCH
BUTTERFLIES REARED ON COMMON MILKWEED,
Asclepias syriaca L.

STEPHEN B. MALCOLM, BARBARA J. COCKRELL, and
LINCOLN P. BROWER

*Department of Zoology
University of Florida
Gainesville, Florida, 32611*

(Received December 14, 1987; accepted March 7, 1988)

Abstract—Monarch butterfly, *Danaus plexippus* (L.), larvae were collected during August 1983 from the common milkweed, *Asclepias syriaca* L., across its extensive North American range from North Dakota, east to Vermont, and south to Virginia. This confirms that the late summer distribution of breeding monarchs in eastern North America coincides with the range of this extremely abundant milkweed resource. Plant cardenolide concentrations, assayed by spectrophotometry in 158 samples from 27 collection sites, were biased towards plants with low cardenolide, and ranged from 4 to 229 $\mu\text{g}/0.1$ g dry weight, with a mean of 50 $\mu\text{g}/0.1$ g. Monarch larvae reared on these plants stored cardenolides logarithmically, and produced 158 adults with a normally distributed concentration range from 0 to 792 $\mu\text{g}/0.1$ g dry butterfly, with a mean of 234 $\mu\text{g}/0.1$ g. Thus butterflies increased the mean plant cardenolide concentration by 4.7. The eastern plants and their resultant butterflies had higher cardenolide concentrations than those from the west, and in some areas monarchs sequestered more cardenolide from equivalent plants. Plants growing in small patches had higher cardenolide concentrations than those in larger patches, but this did not influence butterfly concentration. However, younger plants and those at habitat edges had higher cardenolide concentrations than either older, shaded, or open habitat plants, and this did influence butterfly storage. There were no apparent topographical differences reflected in the cardenolides of plants and butterflies. Twenty-eight cardenolides were recognized by thin-layer chromatography, with 27 in plants and 21 in butterflies. Butterflies stored cardenolides within the more polar 46% of the plant R_f range, these being sequestered in higher relative concentrations than they occurred in the plants. By comparison with published TLC

cardenolide mobilities, spots 3, 4, 9, 16, 24 or 25, 26, and 27, may be the cardenolides syriocide, uzarin, syriobioside, syriogenin, uzarigenin, labri-formidin, and labriformin, respectively. Cochromatography with cardenolide standards indicated that desglucosyriocide did not occur in the plants but did occur in 70% of the butterflies, and aspecioside was in 99% of the plants and 100% of the butterflies. The polar aspecioside was the single most concentrated and diagnostic cardenolide in both plants and butterflies. Butterfly R_f values were dependent on those of the plant, and both showed remarkable uniformity over the range of areas sampled. Thus contrary to previous reports, *A. syriaca* has a biogeographically consistent cardenolide fingerprint pattern. The ecological implications of this for understanding the monarch's annual migration cycle are significant.

Key Words—*Asclepias syriaca*, biogeography, cardenolide fingerprint, chemical defense, *Danaus plexippus*, Lepidoptera, Danaidae, emetic potency, migration, milkweed, monarch butterfly, plant-herbivore interaction, predation, sequestration.

INTRODUCTION

The "common milkweed," *Asclepias syriaca* L., is the most abundant and widespread milkweed in northeastern North America and occurs in a wide diversity of open habitats (Woodson, 1954). Because the distribution of summer breeding monarch butterflies appears coincident with the geographical distribution of *A. syriaca*, this milkweed has been assumed to be the principal larval host plant of the monarch's eastern population (Urquhart, 1960, 1976; Urquhart and Urquhart, 1979). Furthermore, *A. syriaca* remains available as a food plant into the late summer when the last one or two generations of monarchs that migrate south are produced (Borkin, 1982; Malcolm et al., 1987). Consequently it is speculated that *A. syriaca* is the principal food plant of the autumn migrant monarchs that overwinter in Mexico (Fink and Brower, 1981; Brower et al., 1984a; Brower, 1985; Seiber et al., 1986).

Such speculation remains unsubstantiated, as the monarch's late summer breeding range has not been investigated but has been tautologically assumed to coincide with the distribution of *A. syriaca*. In this paper we present evidence that late summer breeding monarchs do in fact use this milkweed as a larval food resource across their range. We then describe the cardenolide storage patterns found in monarchs that have fed upon *A. syriaca* throughout this range.

Monarch butterflies store milkweed-derived cardenolides in ways that are characteristic of their larval host-plant species, making it possible to identify which plant species a wild, adult monarch had fed on as a larva (Roeske et al., 1976; Brower et al., 1982, 1984a,b; Cohen, 1985; Lynch and Martin, 1987;

Martin and Lynch, 1988; L.P. Brower, J.N. Seiber, C.J. Nelson, and S.P. Lynch, in preparation). Of the 108 North American species of milkweed in the genus *Asclepias* (Woodson, 1954), at least 28 are larval food plants of the monarch (Malcolm and Brower, 1986). Plant-butterfly cardenolide storage patterns, or "cardenolide fingerprints," for monarchs reared on eight of these milkweed species have been described, including six from California and two from Texas and Louisiana.

Since many of the North American *Asclepias* species have distinct geographical and temporal distributions, the fingerprinting technique allows a large-scale biogeographical analysis of the monarch's annual North American migration and breeding pattern through time and space. Fingerprinting wild-captured butterflies throughout their annual cycle can also be used to determine how monarchs exploit the various species of their milkweed hosts.

Recently, Seiber et al. (1986) found that the cardenolide aspecioside was present in 85% of overwintering monarchs in Mexico. Since this cardenolide has only been isolated from the two common northern milkweeds, *A. syriaca* and *A. speciosa* Torr., Seiber and his colleagues suggest that all overwintering monarchs with this cardenolide had fed as larvae on either or both of these milkweeds.

Although the presence of a single unique cardenolide is good evidence for what they termed, "the cardenolide connection" between northern, summer breeding monarchs and later, overwintering monarchs, knowledge of the cardenolide fingerprint and range of cardenolide concentrations across the breeding range of the butterfly is needed to provide a more reliable label of larval host plant origin.

No quantitative, detailed study of the cardenolide characteristics and fingerprint of *A. syriaca*-reared monarchs has previously been published. This is an obvious omission given the wide geographical range of this milkweed, the highly varied environments in which it occurs, and claims that it may have several races (Brower et al., 1982) and varying numbers of cardenolides (Roeske et al., 1976).

The purposes of the present study were to determine: (1) whether late summer breeding monarchs do use *A. syriaca* as a larval food resource across their range from North Dakota east to New England and south to Virginia (Figure 1); (2) the quantitative pattern of cardenolide sequestration and the cardenolide fingerprint of monarchs collected as larvae from *A. syriaca* across most of its range; (3) the influence of geographical area, topography, and habitat on cardenolide storage patterns; and (4) the reliability of the *A. syriaca* cardenolide fingerprint as a tool for biogeographical analyses of the monarch's annual migration cycle.

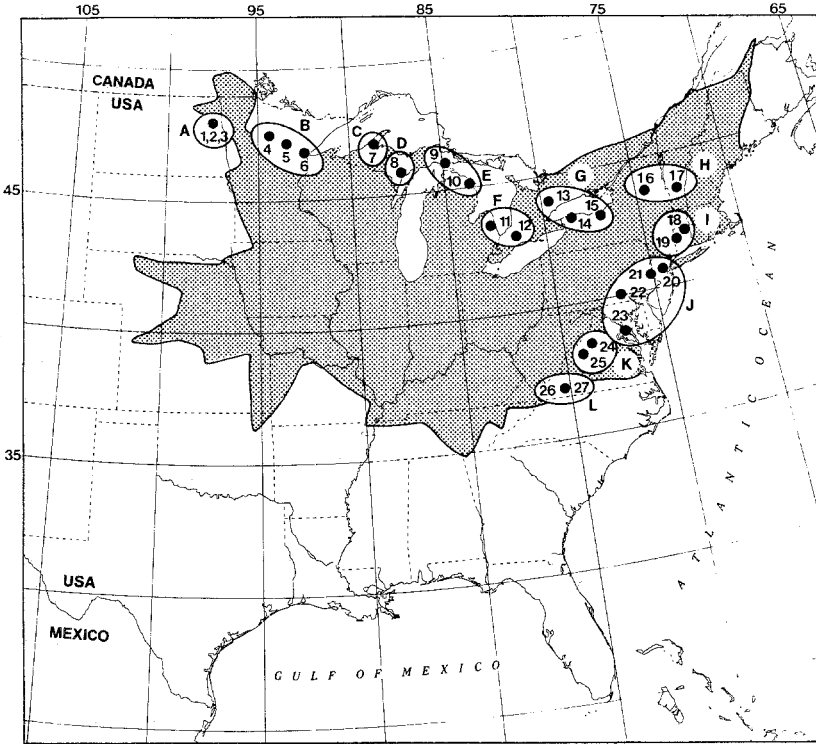

FIG. 1. Location of the 27 collection sites, during August–September 1983, grouped into the 12 areas, A–L, listed in Table 1, in relation to the distribution of *A. syriaca* (after Woodson, 1954).

METHODS AND MATERIALS

Distribution of Asclepias syriaca

We followed Woodson's (1954) distribution of *A. syriaca* to organize our collection of samples spanning the plant's range from its western limit in eastern North Dakota, east to New England and then south to the Appalachian Mountains in Virginia. Our 1983 field sampling showed that the distribution of *A. syriaca* agreed with that given by Woodson (Figure 1). Our subsequent field work in 1986 showed the presence of *A. syriaca* from southwest Missouri and east Kansas north through Nebraska and Iowa to Minnesota, thus confirming the western limits of Woodson's *A. syriaca* distribution. There is, however, no doubt that the species is considerably more common than Woodson indicated, since it occurs abundantly through Wisconsin and Michigan—areas that are largely devoid of location records on his map.

Location, Dates, and Methods of Sample Collections

Immature monarchs and leaf samples were collected from *A. syriaca* during the four-week period from August 7 to September 2, 1983, at the 27 sites in Table 1 and Figure 1, from North Dakota east to Vermont and south to Virginia. During sampling, we drove east and south with time so that the site numbers also indicate the order of collection. Sites consisting of *A. syriaca* patches were discovered en route, at approximately 150-km intervals, where we

^aMilkweed patch sizes increase from 1 = <500 stems, to 2 = 500-1000, and 3 = >1000 stems per patch searched. Topographical proximity to one of the Great Lakes is indicated by "Lake."

counted stem numbers per patch and searched intensively for larvae to estimate larval density per stem. The pairwise collection procedure established in Brower et al. (1982) was followed, with part of the plant material on which a larva was feeding stored on Dry Ice for subsequent analysis and the remainder kept refrigerated for rearing the larva to maturity. No pupae were found. Of the 158 individuals analyzed, 92 (58%) were collected as fifth instars, plus 15 (9%) fourth instars, 16 (10%) third instars, 23 (15%) second instars, 10 (6%) first instars, and 2 (1%) eggs. Early developmental stages were collected since bagging of plants (Brower et al., 1982) was not feasible. Larvae were reared on their respective leaves in 10-cm-diameter plastic containers at ambient temperature. After a monarch pupated on the lid, a screen cylinder was inserted in the container to allow space for the emergent adult to expand its wings. Approximately 24 hr after emergence, the adults were placed in numbered glassine envelopes and stored frozen for subsequent analysis.

We could not gather equal numbers of larvae from each site since some sites were unproductive and larval mortality occurred after collection. To produce adequate sample sizes, we grouped the 27 collection sites into the 12 circled areas, labeled A–L in Figure 1 and Table 1. The basis of this grouping was a posteriori and involved proximity of sampling sites and a minimum sample size of eight plant–monarch pairs. In all but two cases less than 150 km separated the sites within each area, and more than 150 km separated the 12 areas. We also separately grouped the 27 sites by the five characteristics shown in Table 1 to explore cardenolide variation based on ecological as well as geographical differences.

Cardenolide Analyses

Spectroassay. The cardenolide content of 81 female and 77 male monarchs and the 158 samples of their respective host-plant leaves were determined by spectroassay as described in Brower et al. (1982), after Brower et al. (1972, 1975). Dried plant samples were ground to a powder and extracted with 95% ethanol in a 10-ml volumetric flask. Butterflies were similarly treated except that each dried individual was weighed, its right fore and hind wing lengths were measured, and it was then ground in ethanol with a Janke & Kunkel Ultra Turrax tissue mixer. The cardenolide concentration of each plant and butterfly extract was measured in micrograms (equivalent to the cardenolide standard, digitoxin) per 0.1 g dry weight of sample, and total cardenolide per butterfly was calculated by multiplying concentration by butterfly dry weight.

We made two changes in technique: (1) using a Perkin Elmer 559A spectrophotometer, digitoxin was found to absorb maximally at 622 nm and not 626 nm, as in Brower et al. (1972, 1975). Thus all cardenolide peak absorbances, when reacted with alkaline 2,2',4,4'-tetranitrodiphenyl (TNDP), were read at

622 nm. (2) Since the plant samples proved to have low cardenolide contents, 1 g dry weight was extracted in 10 ml instead of the 0.2 g of earlier studies.

Cleanup of Cardenolide Extracts. Some ketones, pregnane steroids, and plant pigments react with alkaline TNDP, resulting in overestimation of spectroassayed cardenolide content, especially in plant samples containing low to moderate amounts of cardenolide (Brown et al., 1979; Carolyn Nelson, personal communication). For example, the red tailing at the top of TNDP-sprayed TLC plates illustrated by Moore and Scudder (1985) is probably produced by the reaction of TNDP with pregnane glycosides. These compounds can interfere with TLC analysis by obscuring coincident cardenolides, and pregnane-3,20-dione steroids can add to colorimetric estimates of cardenolide content because they absorb light maximally at 555 nm, near the maximum absorbance wavelength of 622 nm for cardenolides (Carolyn Nelson, personal communication). Therefore, to make controlled comparisons between plant and butterfly extracts, both were spectroassayed, then cleaned by lead acetate pigment precipitation (Brower et al., 1982, 1984a), and spectroassayed again before TLC analysis. We modified the cleanup method for both plants and butterflies from that of Brower et al. (1984a) as follows: (1) The aqueous ethanol supernatant after pigment precipitation was partitioned with 2 ml hexane, the hexane fraction was back extracted with 2 ml 1:2 95% ethanol-water, and then the aqueous ethanol layers were pooled. The hexane extraction was used to remove noncardenolide contaminants since the discarded hexane layer extracts low-polarity lipids and pigments, but not cardenolides (Reichstein, 1967). (2) Instead of partitioning the aqueous ethanolic extract twice with 2:1 chloroform-95% ethanol, it was partitioned three times to ensure cardenolide extraction. The salt removal process with the dried extract was done once, and then plant and butterfly samples were resuspended in 95% ethanol and spectroassayed once again. The remaining cleaned extract was dried under N₂. Salts were removed once again, the extract dried under N₂, and then stored frozen in a 0.5-dram vial for TLC.

Before cleanup, the mean cardenolide concentration of the 158 plant samples was 20 $\mu\text{g}/0.1$ g dry weight (SD = 27, range = 0-187 $\mu\text{g}/0.1$ g). Following cleanup, the mean increased to 50 $\mu\text{g}/0.1$ g (SD = 39, range = 4-229 $\mu\text{g}/0.1$ g). Although the lead acetate cleanup procedure increased the mean plant cardenolide concentration, rather than decreasing it as in previous studies (*A. speciosa* decreased by 0.12 times; Brower et al., 1984a), the range of cardenolide concentrations in cleaned and unclean extracts changed very little. The change in mean concentrations is difficult to assess at such low cardenolide levels near the threshold for detection, particularly with such a strongly skewed distribution. We have less confidence in the accuracy of the unclean spectroassays because interfering pigments were concentrated by the necessity of extracting five times as much plant material in the same volume of solvent as earlier

studies. Thus we used the cleaned plant cardenolide estimates in our analysis, whereas earlier studies used data for unclean samples.

In contrast to the plant material, the cleanup process had little effect on the values of butterfly cardenolide concentrations. Prior to cleanup, the 158 butterflies had a mean cardenolide concentration of $234 \mu\text{g}/0.1 \text{ g}$ dry weight (SD = 148, range = 0–779 $\mu\text{g}/0.1 \text{ g}$) and after cleanup, the mean remained the same (SD = 150, range = 0–792 $\mu\text{g}/0.1 \text{ g}$). Since there was almost a one-to-one correspondence between clean butterfly concentration (CBC) and unclean butterfly concentration (UBC), according to the linear regression equation, $\text{CBC} = 1.02 (\text{UBC}) - 3.58$; $r^2 = 0.99$, only cleaned butterfly values are used for consistency with the plants.

Thin-Layer Chromatography (TLC). The cleaned plant and butterfly extracts were spotted, separated, and visualized on Merck Silicagel 60 F₂₅₄ plates. Each plate was developed four times at 20°C in the solvent system chloroform–methanol–formamide (90:6:1), as described in Brower et al. (1982). Extracts were spotted in chloroform so that 20 μl of solvent contained an estimated 100 μg of plant cardenolide and 75 μg of butterfly cardenolide, providing that sufficient cardenolide was available. If it was not, all of the sample cardenolide was added to the plate. Plant and butterfly paired samples were run side by side. To control for plate-to-plate variation, the paired samples were spotted to spread butterfly sex and collection sites across the 27 plates.

As in previous studies, digitoxin and digitoxigenin were spotted (10 μg of each) in three channels on each plate, along with two additional cardenolide standards known to occur in *A. syriaca*, desglucosyriaside (Cheung and Watson, 1980; Cheung et al., 1980) and aspecioside (Cheung et al., 1986; Seiber et al., 1986).

Visualized cardenolide spot mobilities, relative to digitoxin (R_d values), spot intensities (SI), and their probabilities of occurrence (PO) were measured and calculated as described in Brower et al. (1982) from projected 35-mm color slides of the TLC plates.

Statistical Analyses

Statistical analyses were performed with SAS (1985). All data were tested for normality before applying parametric statistics. Plant cardenolide concentrations were converted to a normal distribution by \log_{10} transformation. Analysis of variance was used where discrete variables only were investigated; however, where butterfly variation could also be influenced by variation among the plants, we applied analysis of covariance. Where appropriate, we used sequential retesting (Freund and Littell, 1985) and dropped insignificant interactions to assess the significance of remaining effects. For clarity and compactness, we omitted insignificant interactions from the tables.

RESULTS

Distribution of Monarch Larvae on A. syriaca

Monarch larvae were collected across the late summer range of *A. syriaca* from North Dakota (August 7, 1983), east to Vermont, and south to Virginia (September 2, 1983), at the 27 sites, grouped in 12 areas, (Figure 1, Table 1). A total of 245 patches of *A. syriaca* was searched, of which 70% had no monarch eggs or larvae. The numbers of immatures in the remaining 74 patches varied between 1 and 24 at the 27 sites.

Cardenolide Concentrations

Plant Variation. Following cleanup, the range of 158 plant cardenolide concentrations was 4–229 $\mu\text{g}/0.1$ g dry weight with a mean of 50 $\mu\text{g}/0.1$ g and SD of 39 (Figure 2). These concentrations ranged from 0.004% to 0.23% of plant dry weight, with a mean of 0.05%. Many plants contained extremely low quantities of cardenolide, and 63% contained less than the mean concentration, producing a positively skewed distribution (Figure 2, moment of skewness = 1.53; mean/median = 50/42; $D = 0.16$, $P < 0.01$). Since \log_{10} -transformed data were normally distributed, they were used for all subsequent analysis of plant cardenolide concentration.

We tested for differences among plant cardenolide concentrations, with respect to the 12 regional areas, the sex, and the larval stage of the monarch that was collected from them, by analysis of variance (Table 2). Area had a significant effect on plant cardenolide concentration. Duncan's multiple-range test split the plant samples into six overlapping groups (Table 3), of which the eastern *A. syriaca*, from Connecticut (I), New Jersey, Pennsylvania, and Maryland (J), the Thumb of Michigan, and Ontario (F) had significantly higher cardenolide concentrations than the western plants from North Dakota (A), Minnesota (B), and upper Michigan (C). Cardenolide concentrations of the plants from the other Michigan sites, New York, Vermont, and Virginia (areas D, E, G, H, K, and L) lay between these extremes.

The westernmost plant sample was also the most northern, as well as the earliest we collected. However, using Kendall's rank correlation coefficient (τ), we found the ranking of milkweed sites by cardenolide concentration fitted an east–west gradient ($\tau = 0.73$, $P = 0.0005$) better than either a north–south ($\tau = 0.57$, $P = 0.005$), or a temporal one ($\tau = 0.58$, $P = 0.005$), although the east–west effect does contain a significant north–south element ($\tau = 0.59$ for Kendall's partial rank correlation coefficient between plant cardenolide concentration and east–west position, with north–south position held constant).

There was no significant difference in plant cardenolide concentration according to the sex of the monarch larva feeding on them (Table 2). Larval

maturity at collection was also an insignificant main effect, but the interaction between area and larval stage was a significant determinant of plant cardenolide concentration. We think this interaction is significant because at some sites a particular instar predominated, causing instar and area effects to become compounded. This seems a more likely explanation than suggesting that larvae at different instars actively seek out plants of differing toxicity or are subject to differential mortality related to the host plant's cardenolide concentration, especially since larval instar at collection was not a significant main effect and had no significant effect on butterfly cardenolide concentration (see below).

Butterfly Variation. The 158 cleaned butterfly cardenolide concentrations were normally distributed over a range of 0-792 $\mu\text{g}/0.1 \text{ g}$ dry weight (Figure 2) with a mean of 234 $\mu\text{g}/0.1 \text{ g}$ (SD = 150, mean/median = 234/216, $D = 0.06$, $P = 0.13$). Three butterflies (1.9% of the sample) had no measurable cardenolide concentrations.

Variation in Butterflies as a Function of Plant Variation, with Geographical, Sex, and Instar Effects. The mean butterfly cardenolide concentration was 4.7 times that of the plants, and the butterfly cardenolide concentrations also had a considerably higher variance than the plants (Figure 2). For the whole data set pooled over sex, instar, and the collection sites, \log_{10} plant concentration predicted butterfly concentration with an r^2 of 0.61 ($P < 0.0001$; Table 4A, Figure 3). This logarithmic relationship means that butterflies store car-

denolides more efficiently from plants of lower cardenolide concentrations but approach an upper limit with increasing plant cardenolide concentration.

A significantly improved fit to the data was obtained by applying a full analysis of covariance model that included sample area, sex, and instar at collection, in addition to the plant concentration effect ($r^2 = 0.72$, $P < 0.0001$, Table 4B). The larval stage at which an individual was collected had no significant effect on adult butterfly cardenolide concentration. Females had significantly higher cardenolide concentrations than males, with mean values of 262 $\mu\text{g}/0.1 \text{ g}$ and 204 $\mu\text{g}/0.1 \text{ g}$, respectively. The sexes had similar cardenolide concentration slopes, but the intercepts were significantly different, hence male cardenolide concentration = 329 (log_{10} plant concentration) - 300, and female cardenolide concentration = 329 (log_{10} plant concentration) - 269. This ability of the females to convert a particular plant concentration to a higher butterfly concentration has been found for monarchs reared on several other *Asclepias* species (Brower et al., 1972, 1975, 1982; Brower and Glazier, 1975; Brower

FIG. 3. Cardenolide concentrations of monarch butterflies reared on *A. syriaca* plotted against the cardenolide concentrations of their larval food plants.

and Moffitt, 1974; Cohen, 1985; Lynch and Martin, 1987; Martin and Lynch, 1988). Reasons for this difference between the sexes are considered in the discussion.

As expected, plant concentration remained the most significant determinant of butterfly concentration. However, the area from which the butterfly came had an additional significant main effect on butterfly cardenolide concentration that was independent of the influence of area on plant cardenolide concentration, and there was a significant interaction between plant concentration and area (Table 4B). Consequently, the variation due to location found in the butterfly concentrations is not entirely explained by variation in plant concentration with location, indicating that monarchs in some areas seem able to sequester more cardenolide than monarchs on equivalent plants in other areas. Duncan's multiple-range test split the butterfly sample into eight overlapping groups arranged in practically the same order as the plant samples except for minor reversals (Table 5). Thus the western monarchs from North Dakota (A), Minnesota (B), and upper Michigan (C) had considerably lower cardenolide concentrations than the eastern monarchs from Ontario and the Thumb of Michigan (F), Connecticut (I), and New Jersey, Pennsylvania, and Maryland (J).

Total Cardenolide Content of Butterflies

Since the total cardenolide content of butterflies is the product of cardenolide concentration multiplied by dry weight, we investigated variation in butterfly weight and size (the data are summarized in Table 6). Analyses of covariance of butterfly dry weights and wing lengths against plant cardenolide concentrations, area, sex, and instar collected indicated no growth-related detoxification cost associated with more toxic plants ($F_{1,157} = 2.03$, $P = 0.16$). In addition, there were no significant differences between sexes in their weights ($F_{1,157} = 1.58$, $P = 0.21$) or wing lengths ($F_{1,152} = 0.73$, $P = 0.39$). This is contrary to most earlier findings in which males were heavier than females (Brower et al., 1982; 1984a,b), although Lynch and Martin (1987) report a similar nonsignificant result for monarchs fed *A. viridis*. Only the instar at which butterflies were collected affected their dry weight ($F_{5,157} = 5.71$, $P = 0.0001$) and wing size ($F_{5,152} = 2.88$, $P = 0.0168$). Larvae that were collected at fifth instar produced significantly heavier dry weight adults than those collected in earlier instars ($\bar{X} = 0.19\text{ g}$, $\text{SD} = 0.03$ and $\bar{X} = 0.16\text{ g}$, $\text{SD} = 0.02$, respectively).

Total cardenolide per butterfly (Table 6) was normally distributed and ranged from 0 to 1480 μg (mean = 415 μg , $\text{SD} = 279$). The overall regression, pooling sex, instar, and geographic region, indicates that the total cardenolide per butterfly is significantly dependent on the plant cardenolide concentration

($F_{1,157} = 211$, $P = 0.0001$). Since butterfly weight and size were unaffected by area or sex, the analysis of total cardenolide per butterfly mirrors that of cardenolide concentration. Hence analysis of covariance showed that area had a significant direct effect on total butterfly cardenolide content ($F_{11,157} = 2.75$, $P = 0.003$) that was in addition to its influence on plant cardenolide concentration (as was described for butterfly cardenolide concentration above), and there was a significant plant concentration \times area effect ($F_{11,157} = 3.49$, $P = 0.0003$). Once again butterflies from Ontario and the Thumb of Michigan (F), Connecticut (I), New Jersey, Pennsylvania, and Maryland (J) had higher mean total cardenolide contents (Table 7) than those from western areas (North Dakota, Minnesota, and upper Michigan, areas A, B, and C, respectively).

Although adult weight was affected by the larval stage at collection, this did not result in a significant difference in the total butterfly cardenolide content ($F_{5,157} = 0.49$, $P = 0.8$). Thus, although captive early instar larvae were probably given insufficient food, this did not significantly affect adult cardenolide concentrations.

^aSee Figure 1 and Table 1. Areas with the same numbers are not significantly different by Duncan's multiple range test at $P < 0.05$.

Despite the similar weight and size of male and female butterflies, females had a significantly higher mean total cardenolide content than males (Table 6; $F_{1,157} = 9.22$, $P = 0.003$). Females were more efficient than males at converting plant cardenolide concentration to total butterfly cardenolide content, since our analysis showed slope homogeneity but a significantly lower intercept for the males [female total cardenolide content = $614 (\log_{10} \text{ plant cardenolide concentration}) - 526$, male total cardenolide content = $614 (\log_{10} \text{ plant cardenolide concentration}) - 596$].

Ecological Effects on Plant and Butterfly Cardenolides

To investigate whether plants and butterflies from different ecological environments have significantly different cardenolide concentrations that might cause the observed regional differences in plant and butterfly cardenolide concentrations, we subdivided the original 27 collection sites in five different ways, according to the ecological characteristics shown in Table 1 and described below. We performed separate ANOVAs for each ecological effect because there were too many empty cells to perform a simultaneous multiway analysis. In all the subsequent groupings, plant cardenolide concentration was not significantly determined by the sex or instar of the associated larvae or by the interactions of these factors with the main effect of primary interest.

Plant Patch Size. *A. syriaca* grows in patches of stems, and each patch

usually represents a single clone (Wilbur, 1976). We searched 245 *A. syriaca* patches that ranged in size from 4 to an estimated 25,000 stems, with a mean of 345 (SD = 1608). The density of monarch eggs and larvae in these patches ranged from 0 to 0.357/stem, with a mean of 0.0077/stem ($N = 245$, SD = 0.0304). Both plants and monarchs were strongly skewed towards smaller patch sizes and lower densities, with 87% of plants in patches of 4–500 stems. Of the total sample, 70% of the plant patches had no monarchs at all, 22% had 0.0009–0.02, and 8% had 0.02–0.36 monarchs per stem. There was no correlation between plant patch size and immature monarch density (Kendall rank correlation coefficient, $\tau = 0.017$, $P = 0.35$).

Plants from small patches had higher cardenolide concentrations than those from large patches ($P = 0.04$). Patches of less than 500 plants had a mean plant cardenolide concentration of 46 $\mu\text{g}/0.1$ g, and those with between 500 and 1000 plants had 44 $\mu\text{g}/0.1$ g, whereas patches of more than 1000 plants had a mean value of 33 $\mu\text{g}/0.1$ g cardenolide. We used these values to calculate the expected mean plant cardenolide concentration of each regional area based on the patch sizes that the plants came from. Referring to Table 1, the mean for each region was weighted to reflect the relative contribution of plants from each patch type to the sample. The rank order of the regional sites predicted by patch size showed no association with their geographical rank order in Table 3 (Kendall $\tau = 0.22$, $P = 0.30$). Hence the regional plant cardenolide differences were not simply caused by differences in patch size. Moreover, patch size was not a significant determinant of butterfly cardenolide concentration, either by analysis of variance, $P = 0.31$, or analysis of covariance, $P = 0.82$. Thus the patch-size differences in plant cardenolide concentration were not sufficiently large to remain detectable in the resultant butterflies after their concentration and storage process.

Plant Maturity. The leaves of young flushing plants had a significantly higher cardenolide concentration than did those of mature plants with ripe seed pods (means = 51 $\mu\text{g}/0.1$ g, and 34 $\mu\text{g}/0.1$ g respectively, $P = 0.004$). The rank order of sites based on plant maturity, weighted for subsample size, showed no association with the rank order of regional plant cardenolide concentrations (Kendall $\tau = 0.24$, $P = 0.27$). Butterflies that were collected from young flushing plants had significantly higher cardenolide concentrations than those on mature plants (273 $\mu\text{g}/0.1$ g compared with 217 $\mu\text{g}/0.1$ g, $P = 0.046$). Analysis of covariance indicates that the butterfly differences were adequately explained by the plant cardenolide concentration differences according to the relationship shown in Figure 3. The rank order of sites determined by plant maturity did not correspond with the observed butterfly cardenolide concentration rank order (Kendall $\tau = 0.19$, $P = 0.38$). Thus differences in plant maturity among sites do not explain the observed regional differences in plant and butterfly cardenolide concentrations.

Plant Habitat. There was a marginally significant difference in cardenolide concentrations of plants from open, shaded, and edge habitats ($P = 0.05$). Duncan's multiple-range comparison showed that the cardenolide content of plants was significantly higher at habitat edges ($49 \mu\text{g}/0.1 \text{ g}$) than in shaded habitats ($30 \mu\text{g}/0.1 \text{ g}$), while the open habitat cardenolide concentration lay between these two values ($39 \mu\text{g}/0.1 \text{ g}$). The rank order of sites by plant habitat did not conform to the regional rank order of sites by plant cardenolide concentration (Kendall $\tau = 0.29$, $P = 0.19$). Differences in butterfly cardenolide concentration between shaded, open, and edge habitats were marginally insignificant by analysis of variance ($P = 0.058$), but Duncan's multiple-range test indicated that at the 5% level butterflies from habitat edges had a significantly higher mean value ($267 \mu\text{g}/0.1 \text{ g}$) than those from shaded habitats ($180 \mu\text{g}/0.1 \text{ g}$), with open habitats intermediate ($242 \mu\text{g}/0.1 \text{ g}$), i.e., similar differences to those of the plants. However, analysis of covariance indicated the butterfly differences were not entirely explained by the plant differences, but differences between habitats directly affected the butterflies ($P = 0.015$). There was no significant association between the expected rank order of sites based on their habitat characteristics and the observed butterfly cardenolide concentration order (Kendall $\tau = 0.29$, $P = 0.19$). Hence these habitat differences do not explain the regional plant and butterfly cardenolide concentration differences.

Other Ecological Effects. There were no significant differences ($P = 0.24$) among plant cardenolide concentrations when subdivided on the basis of site topography into flat sites ($36 \mu\text{g}/0.1 \text{ g}$), Great Lakes sites ($37 \mu\text{g}/0.1 \text{ g}$), or hilly sites ($46 \mu\text{g}/0.1 \text{ g}$). Similarly, there was no significant difference between roadside ($39 \mu\text{g}/0.1 \text{ g}$) and pasture ($39 \mu\text{g}/0.1 \text{ g}$) populations ($P = 0.99$). None of these factors had significant effects on butterfly cardenolide concentration.

TLC Cardenolide Fingerprint of Plants and Butterflies

The means and standard deviations of the R_d , spot intensity (SI) and probability of occurrence (PO) values for all visualized cardenolide spots in the 146 paired plant and butterfly samples are given in Table 8, and their overall pattern is illustrated in Figures 4 and 5 (12 of the original 158 paired samples had insufficient cardenolide to produce a cardenolide fingerprint). Several spots were frequently weak or absent in plants and butterflies but the standard deviations of the R_d values of all spots were low, once again indicating consistent separation and resolution of spots (cf. Brower et al., 1984a).

A total of 28 cardenolides were identified, of which 27 appeared in the plants and 21 in the butterflies. Spot 20, which corresponded with the mobility of the desglucosyrioxide standard, did not appear in any of the plants, and spots 19, 21, and 24–28 did not appear in any butterflies. Thus there were 20 spots in common. The migration distance of the digitoxigenin standard is based on

81 spotted samples (three per 27 plates), giving an R_d value of 2.75 (SD = 0.31). Spot 8, the most concentrated and characteristic cardenolide present in both *A. syriaca* plants and the monarchs that fed on them (see Figures 4 and 5), always corresponded with the aspecioside standard. By inference with published data on the mobilities of known cardenolides in the same TLC solvent system, spots 3 and 4 are likely to be syrioxide and uzarin, respectively, spot 9 is syriobioside, 16 is probably syriogenin, 24 or 25 is uzarigenin, 26 may be labriformidin, and 27 may be labriformin (Nelson et al., 1981; Seiber et al., 1983, 1986; Brower et al., 1984a).

Plants. Of the 27 spots, 17 were often absent, resulting in PO s of less than 0.40 (Table 8). This left 10 diagnostic spots, seven below digitoxin, one at this level, and two between digitoxin and digitoxigenin. Seventeen of the 27 plant spots (63%) occurred between the origin and level of digitoxin, seven (26%) between digitoxin and digitoxigenin, and three (11%) above digitoxigenin.

Butterflies. All the butterfly spots had mean SI values greater than 1.25, and they were generally greater than their corresponding plant SI values (Table 8). This probably accounts for the higher PO values of the butterfly spots (Table 8); 17 of the 21 butterfly spots occurred with a $PO > 40\%$. Seventeen spots (81%) occurred below digitoxin, and four (19%) occurred between the digitoxin and digitoxigenin levels. No butterfly had cardenolides with R_d values above digitoxigenin. The butterflies stored cardenolides within the more polar 46% of the plant R_d range (R_d spot 23/ R_d spot 28).

FIG. 4. TLC cardenolide patterns, in the chloroform-methanol-formamide (90:6:1) solvent system at 20°C, of monarch butterflies and their *A. syriaca* larval host plants, drawn from plotted R_f and SI values of TNDP-positive spots. The spot sizes of the 28 cardenolides are drawn to correspond with those on photographs of the original 27 TLC plates (see Figure 5). The four cardenolide standards (digitoxin, digitoxigenin, aspecioside, and desglucosyrioside) were spotted on each plate (see Figure 5). Remaining cardenolide identities (syrioside, uzarin, syriobioside, syriogenin, uzarigenin, labriformidin, and labriformin) were inferred from their published R_f values in the same solvent system.

FIG. 5. Photographs of four TLC plates showing the fingerprint pattern of TNDP-visualized cardenolide spots in extracts of monarch butterflies and their *A. syriaca* host plants, separated in chloroform-methanol-formamide (90:6:1) at 20°C, from North Dakota east to Vermont and south to Virginia. Each plate shows six plants and their corresponding monarch butterflies. The four cardenolide standards run on the plates are: ASP = aspecioside; DIG = digitoxin; DGN = digitoxigenin; DSG = desglucosyrioside. Each plant-butterfly channel pair is labeled with the state, site number (see Figure 1 and Table 1), plant (P), butterfly sex, sample pair number, and the respective amount of cardenolide spotted (μg , equivalent to digitoxin). Plant channels showing weak resolution resulted from pigment interference in the original spectroassay (see text). Spots 4, 12, 16, 24, and 28 correspond to those in Figure 4. Spots 8 and 20 always coincided with the mobilities of the cochromatographed standards aspecioside and desglucosyrioside, respectively.

Variation in Plant R_d and SI Values. Plant R_d values were significantly influenced by the regional area from which they derived ($F_{11,1557} = 2.13$, $P = 0.016$) and the TLC plate on which they were run ($F_{26,1557} = 1.72$, $P = 0.013$), but they showed no significant association with larval sex ($F_{1,1557} = 0.64$, $P = 0.42$) or any interactions of these main effects. We investigated whether this

R_d variation resulted from particular spot occurrences (and hence patterns) being peculiar to specific areas using a 12 (areas) by 27 (spots) contingency table, with a similar analysis for the plates (27 plates \times 27 spots). We found very high uniformity among the different treatments, spots having the same POs across areas ($\chi^2 = 241$, $df = 286$, $P = 0.98$) and across plates ($\chi^2 = 670$, $df = 676$, $P = 0.56$). This indicates that the variation in plant R_d values does not reflect significant pattern differences among areas or plates, but is the cumulative result of variation around the mean R_d value of each spot.

Plant spot intensity values varied with area ($F_{11,1557} = 3.49$, $P = 0.0001$), but not with plate ($F_{26,1557} = 1.34$, $P = 0.12$), the sex of the larva associated with the plant ($F_{1,1557} = 1.31$, $P = 0.25$), or any interactions of these variables. Generally, the more northern and western samples had more intense spots than the more southern and eastern ones.

Plant-Butterfly Spot Relationships: Effects of Area, Sex, and Plate on R_d and SI Values. We used analysis of covariance to test simultaneously for the dependence of the R_d and SI values of all the butterfly spots on their respective plant spots and for the effects of the 12 areas, butterfly sex, the 27 plates, and interactions between these terms. The analysis could only use observations where both plant and butterfly spots were represented, i.e., 981 of the possible 2920 (146 \times 20) spots in common.

The butterfly R_d values were strongly dependent on those of the plant ($F_{1,980} = 50111$, $P = 0.0001$). The simple regression model that examined the dependency of butterfly R_d on plant R_d alone showed a correlation of $r^2 = 0.98$. (The TLC spot comparison methodology largely predetermines the correspondence of the respective plant and butterfly spots.) The full model improved the fit slightly ($F_{174,980} = 597.76$, $P < 0.0001$, $r^2 = 0.99$) and indicated significant area ($F_{11,980} = 7.70$, $P = 0.0001$) and plate ($F_{26,980} = 11.48$, $P = 0.0001$) effects with significant interactions between plant R_d and area ($F_{11,980} = 6.25$, $P = 0.0001$), plant R_d and plate ($F_{26,980} = 12.83$, $P = 0.0001$), and plant R_d and sex ($F_{1,980} = 3.91$, $P = 0.05$), although butterfly sex was not a significant main effect ($F_{1,980} = 2.14$, $P = 0.14$). Although this analysis indicates significant variation in butterfly R_d , contingency table analyses of spot by area and of spot by plate showed remarkable uniformity in spot occurrences over the different locations ($\chi^2 = 120$, $df = 220$, $P = 1.0$) and plates ($\chi^2 = 291$, $df = 520$, $P = 1.0$), indicating a consistent *A. syriaca* fingerprint pattern. Rather than substantial pattern differences, it appears that the variation in butterfly R_d reflects variation around the mean R_d of each spot. The information in Table 8 indicates these differences are very small, but they are detectable because so much of the variation in butterfly R_d is explained by variation in plant R_d .

There was a weak, but significant, correspondence of butterfly SI values with plant SI s ($F_{1,980} = 400.90$, $P = 0.0001$). The main effects, plate ($F_{26,980}$

= 2.28, $P = 0.0003$) and area ($F_{11,980} = 3.30$, $P = 0.0002$), also had significant effects on butterfly *SIs* but the butterfly sex did not ($F_{1,980} = 0.25$, $P = 0.62$), and none of the interactions were significant. There was substantial overlap in *SI* values over the different areas, with no consistent pattern of division into clearly defined geographical zones.

DISCUSSION

Late Summer Breeding Distribution of Monarch Butterflies

Our field sampling corroborates previous unsubstantiated assumptions that by late summer monarchs breed across the entire range of *A. syriaca*. Since we found this milkweed growing abundantly in old fields, pastures, disturbed areas, and along roadsides and railways across the entire sampled range in August, and found no other milkweed host species approaching this range and abundance, it is probable that *A. syriaca* is in fact the principal milkweed host of overwintering monarchs that begin their southward autumn migration to Mexico in September (Urquhart and Urquhart, 1978; Brower, 1985). Other widely distributed milkweed species, like *A. incarnata*, *A. verticillata*, and *A. tuberosa* (Woodson, 1954), may also be used (Malcolm and Brower, 1986), but it is unlikely that they approach the significance of *A. syriaca* in the life history of monarch butterflies.

Quantitative Cardenolide Storage

Plants. We found that the mean cardenolide concentration of *A. syriaca* leaves is low, but, like other *Asclepias* species, there is considerable variation among plants. Previous investigations of *A. syriaca* leaf material cite low cardenolide concentrations, from immeasurable to 264 $\mu\text{g}/0.1\text{ g}$ (similar to our range of 4–229 $\mu\text{g}/0.1\text{ g}$), and a 40-fold variation among 16 samples from one site (Feir and Suen, 1971; Roeske et al., 1976; Isman et al., 1977; Nelson et al., 1981; Seiber et al., 1983). In-depth studies have yet to establish the ranges of cardenolides in the other widespread, eastern North American milkweeds recorded as monarch food plants, including *A. verticillata*, *A. tuberosa*, *A. incarnata*, *A. viridiflora*, *A. hirtella*, *A. exaltata*, *A. variegata*, *A. purpurascens*, and *A. amplexicaulis* (Malcolm and Brower, 1986), but preliminary evidence suggests that all these plants are at least as low, or lower in cardenolide than *A. syriaca* (Roeske et al., 1976; Seiber et al., 1983). Of the eight *Asclepias* species that have been analyzed in a similar manner to the present study, the variation in cardenolide concentration of *A. syriaca* is most like *A. speciosa* (Brower et al., 1984a), *A. californica* (Brower et al., 1984b), and *A. cordifolia* (Brower et al., in preparation). All four species have low plant cardenolide

concentrations with positively skewed distributions, such that most plants contain very little cardenolide.

We found plants on the eastern side of *A. syriaca*'s range to have a higher cardenolide concentration than those in the west. There was an almost fivefold difference in mean plant cardenolide concentration across the 12 areas we sampled. This compares with an approximate threefold difference among the California populations of *A. speciosa* (Brower et al., 1984a) and *A. californica* (Brower et al., 1984b), and an approximately twofold difference for *A. cordifolia* (Brower et al., in preparation). The *A. syriaca* variation is greater, but we sampled a much wider area both latitudinally and longitudinally, and the total sample size was larger. Because the variation in plant cardenolide concentration appears continuous, with no obvious regional discontinuities, we do not think it suggests different *A. syriaca* races. Instead, the high regional variance in cardenolide content of *A. syriaca* may simply be a characteristic feature of those *Asclepias* species with low mean levels of cardenolide.

Following Rosenthal and Janzen (1979), Brower et al. (1982) suggested that, aside from genetic factors, a host of environmental factors, such as temperature, altitude, nutrient availability, plant competition, and herbivore pressure may influence the production of defensive secondary chemicals in plants. Any or all of these might result in the regional variation we report. Thus we grouped our data in five different ways that we thought might reflect how such environmental factors could be acting on the plant sample.

Our analyses show a substantial north-south element to the east-west regional difference. Nelson et al. (1981) and Brower et al. (1982) suggested that the north-to-south increase in the cardenolide concentrations of their *A. eriocarpa* samples was a temporal rather than geographic phenomenon since the sample with the highest concentration was collected in June, while the lowest was collected in September. However, difference in sampling date is unlikely to explain the geographic variability of *A. syriaca*, since our total sampling period spanned only four weeks compared with their four months. More significantly, as in Nelson et al. (1981) and Brower et al. (1982), our data indicate independently that plants have higher cardenolide concentrations when they are younger than when older. Hence, we would expect the western plants to be *more* concentrated than the eastern plants, rather than the reverse as we found, because the western *A. syriaca* plants were not only sampled earlier in the season but were also younger by virtue of their more northerly location. The geographical differences we have found thus appear robust.

Young flushing plants had higher cardenolide concentrations than mature individuals, and plants in small patches had higher concentrations than those in large patches. In both cases this may reflect lower production or degradation of cardenolides in older plants (assuming that large clones have been established for longer than small ones). Overall, quantitative plant cardenolide defenses

appeared most in evidence in young, flushing, prereproductive individuals, and along habitat edges. However, none of these ecological groups accounted for the observed regional difference in plant cardenolide, and the ecological variation was never as great as the regional variation.

Abundant milkweeds, like *A. syriaca*, with high variance, low mean and skewed cardenolide distributions may lower the impact of specialist herbivory by reducing the availability of defensive chemicals to aposematic herbivores, like the monarch, for use in their own chemical defenses against predators. Thus we speculate that *A. syriaca* may be at a threshold of reduced specialist herbivore fitness and enhanced ability of generalist herbivores to exploit the weakly defended plant resource. The east-west gradient of cardenolide content could then be the result of higher generalist herbivory in the east and higher specialist herbivory further west by insects like the monarch.

Butterflies. The monarchs stored cardenolides more efficiently from plants of low, than from plants of high, concentrations. Similar logarithmic relationships occur in monarchs reared on *A. speciosa* (Brower et al., 1984a), *A. californica* (Brower et al., 1984b), and *A. cordifolia* (Brower et al., in preparation; Nelson, 1989), all of which have low mean plant cardenolide concentrations of less than 100 $\mu\text{g}/0.1\text{ g}$, and also for the southern *A. viridis* with 245 $\mu\text{g}/0.1\text{ g}$ cardenolide (Lynch and Martin, 1987). Indeed, it seems likely that a logarithmic curve applies to the uptake and storage of cardenolide from all milkweed species. However, in individual plants or species that have high concentrations, the butterfly concentration becomes constant because it reaches storage capacity and is thus operating at the curve's asymptote. Examples include the apparently linear conversion relationships for *A. eriocarpa* (Brower et al., 1982), *A. asperula* (Martin and Lynch, 1988), *A. vestita* and *A. erosa* (Brower et al., in preparation), all of which have mean plant cardenolide concentrations above 400 $\mu\text{g}/0.1\text{ g}$ (Nelson, 1989).

Because most plants had low cardenolide concentrations, logarithmic storage by monarchs resulted in considerably higher mean butterfly, than mean plant, concentrations, and an expanded range of butterfly concentrations. These trends are again consistent with those of other milkweeds with low cardenolide concentrations, although the *A. syriaca* data show the widest range and some of the highest concentrations of milkweed-derived cardenolide storage by monarch butterflies reported to date.

Although a logarithmic uptake curve is a good model of cardenolide storage across a range of milkweed species, butterflies were more efficient at storing cardenolides from *A. syriaca* than they were from *A. speciosa*, *A. californica*, or *A. cordifolia*. Nelson (1989) suggests that the storage of cardenolides from mixtures by larvae is, at least in part, additive. Since cardenolide storage is affected by cardenolide structure, the structure of *A. syriaca* cardenolides must facilitate storage by monarchs (Seiber et al., 1980; Nelson, 1989). For exam-

ple, the nonpolar plant cardenolide labriformin is readily converted by monarch larvae to the more polar desglucosyrioside, and cardenolides with doubly linked sugars, or those with C-3 hydroxyls, appear prevalent in *Asclepias* species and are selectively stored by monarch butterflies (Seiber et al., 1980; Nelson et al., 1981; Brower et al., 1982, 1984a; Nelson, 1989). Perhaps this indicates a special evolutionary relationship between the monarch butterfly and *A. syriaca*, in which the wide range and abundance of *A. syriaca* has resulted in strong selection for efficient storage of *A. syriaca* cardenolides to enhance the monarch's chemical defense. Indeed, if we are correct in speculating that the low cardenolide content of *A. syriaca* is a selected response to monarch herbivory, which reduces the effectiveness of monarch chemical defenses, then efficient cardenolide storage by monarchs on *A. syriaca* may indicate some reciprocity in their diffuse coevolution.

Female monarchs had significantly higher cardenolide concentrations than males, in agreement with prior studies. Previously, where females were significantly smaller than males (Brower et al., 1982, 1984a,b) this might have resulted simply from the higher surface area to body volume ratio of females since cardenolides are stored primarily in the exoskeleton (Parsons, 1965; Brower and Glazier, 1975; Nishio, 1980; Brower et al., 1988). However, in the present study, where there was no significant size difference between the sexes, the data suggest that females are more efficient at cardenolide storage than males. Hence females from *A. syriaca* also had significantly more total cardenolide than males, while earlier studies found no significant difference in total cardenolide content between the sexes, where it was suggested that the smaller female size canceled out the effect of higher female cardenolide concentrations.

The ability of butterflies to store cardenolides logarithmically from *A. syriaca* compensated for the relatively small differences among milkweeds from different sized plant patches, so there were no discernible differences among the monarchs that derived from them. However, there were significant differences in the cardenolide concentrations of butterflies from plants of differing maturity, from edge compared with shaded habitats, and from different collection areas. These butterfly differences were not entirely explained by the differences in plant cardenolide concentration, but they indicate a direct effect on the butterflies themselves. In particular, the cardenolide concentrations of butterflies from the Ontario region were higher than expected on the basis of plant cardenolide concentration, while those of butterflies from northern Virginia were lower than expected, although area still significantly effected butterfly cardenolide concentration even when these extreme cases were removed from the analysis. Brower et al. (1982) suggested that abiotic environmental influences could produce such an effect. For example, slower larval development at cooler temperatures might allow more time for cardenolide accumulation and result in

higher cardenolide butterflies in shaded conditions, or from a colder, more northerly area such as Ontario, compared with a warmer, more southerly area like Virginia.

Qualitative Cardenolide Storage: A. syriaca TLC Fingerprint

We found a remarkably consistent *A. syriaca* plant fingerprint among all our sites, contrary to earlier reports of variable numbers of cardenolides in different North American and European populations of *A. syriaca* (Brower, 1969; Duffey, 1970; Rothschild et al., 1975; Roeske et al., 1976; Brown et al., 1979; Brower et al., 1982, 1984a; Moore and Scudder, 1985). It seems likely that different methodologies and variable extraction efficiencies in the earlier studies are responsible for these disparities. Moreover, when cardenolide concentration was low, or the original sample weight was small, spots may have been missing from the cardenolide profile when the cardenolide was in fact present. Like us, Duffey and Scudder (1972) and Moore and Scudder (1985) found that the TLC cardenolide patterns of *A. syriaca* leaf and seed samples from different locations were very similar, with only a minor difference in seeds from Connecticut. The geographical variability in quantitative cardenolide storage that we describe above is probably produced by quantitative variation in the amounts of individual cardenolides. Thus area significantly influenced cardenolide spot intensities but did not result in qualitative differences in the presence or absence of particular cardenolides within the entire fingerprint.

Given the high consistency of the plant's cardenolide fingerprint, together with the monarch's logarithmic storage capacity, it is not surprising that the butterfly cardenolide fingerprint was also remarkably consistent across the sampled range of *A. syriaca*. The most diagnostic cardenolide of the *A. syriaca* monarch fingerprint is spot 8, corresponding with the cardenolide aspecioside. Aspecioside is also the most concentrated cardenolide in the plant, but even so, monarchs increase its relative concentration. Large amounts of aspecioside may accumulate slowly during larval feeding because monarch Na^+, K^+ -ATPase is insensitive to polar cardenolides (Vaughan and Jungreis, 1977), and the low permeability of tissues to polar cardenolides may make their storage in the monarch's exoskeleton (Brower and Glazier, 1975; Nishio, 1980) physically simpler than more readily mobilized nonpolar cardenolides (Yoder et al., 1976; Duffey, 1977; Duffey et al., 1978; Scudder and Meredith, 1982). The presence of large amounts of polar cardenolide may also explain the low emeticity of *A. syriaca*-derived monarchs, as discussed below.

Estimation of Emetic Toxicity of Monarchs Reared on A. syriaca

Brower and Moffitt (1974) determined the 50% blue jay emetic dose (ED_{50}) of monarch butterflies captured during their autumn migration through western Massachusetts in 1971, and from their data Fink and Brower (1981) calculated

the ED₅₀ as 398 μg of cardenolide/85 g bird (Table 9). Fingerprints of 24 of these same butterflies proved uniform (Roeske et al., 1976) and are consistent with the *A. syriaca* pattern described in the present study. Given the extensive breeding on *A. syriaca* by the late summer generation of monarchs in north-eastern America, together with these fingerprint determinations and the paucity of other *Asclepias* species at this time of year, it is virtually certain that these butterflies had fed on *A. syriaca*.

In an attempt to verify this ED₅₀ value of the wild-collected autumn migrants, a group of monarchs was reared in the laboratory on wild-collected *A. syriaca* plants from western Massachusetts in August 1969 (L.P. Brower and S.C. Glazier, unpublished data). It was found that 83 monarchs had a mean cardenolide concentration of 278 $\mu\text{g}/0.1$ g (SD = 76; range = 108–453; males, $N = 37$, mean = 263, SD = 76, range = 108–402; females, $N = 46$, mean = 291, SD = 74, range = 137–453). Note that these monarchs had cardenolide concentrations very similar to our field-collected monarchs, particularly those from New York and Vermont (areas G and H, Figure 2; Table 5).

After spectroassay of these *A. syriaca* monarchs, 19 blue jays were force fed between 0.111 and 0.257 g of the dry, powdered butterfly material. Two of the jays vomited when given 395 and 581 μg cardenolide/85 g bird. However, contrary to expectation, none of the nine birds given more cardenolide (587–1021 $\mu\text{g}/85$ g bird) vomited, and none of the eight birds given less cardenolide (261–564 $\mu\text{g}/85$ g bird) vomited. The failure of these freshly hatched *A. syriaca* monarchs to elicit emesis at cardenolide doses exceeding 1000 $\mu\text{g}/85$ g bird, compared to a clear ED₅₀ of 398 $\mu\text{g}/85$ g bird, for the *A. syriaca*

TABLE 9. TOTAL CARDENOLIDE CONTENTS AND ESTIMATES OF EMETIC POTENCIES OF MONARCH BUTTERFLIES PRESUMED OR KNOWN TO HAVE FED ON *A. syriaca* IN NORTHEASTERN U.S.A.

butterflies from the wild requires explanation. One possibility is that the chemical structures of the sequestered cardenolides change in the butterflies as they age in a way which increases their emetic toxicity. In support of this possibility, Nishio (1980) observed chemical modification as well as shifts in the proportion of polar and nonpolar cardenolides during the development of *A. humistrata*-reared monarchs. Such a postulated process in aging monarchs may also be accompanied by gradual cardenolide excretion or catabolism. Evidence for this is the fact that the mean total cardenolide of overwintering monarchs in Mexico (128 μg) is lower than the means for monarchs reared from all 12 of our sites and for both autumn migrants and laboratory-reared monarchs in Massachusetts (Tables 7 and 9).

The cardenolide storage pattern of *A. syriaca* butterflies is extremely similar to that of *A. speciosa* and, like it, has a preponderance of more polar cardenolides (Brower et al., 1984a). We therefore should expect monarchs reared on the two species to have a comparable blue jay ED_{50} assay. However, the ED_{50} of *A. speciosa* monarchs was only 192 μg cardenolide/85 g bird (from Brower et al., 1984a), i.e., their emetic toxicity was about twice that of the migrant *A. syriaca* monarchs ($\text{ED}_{50} = 398 \mu\text{g}/85 \text{ g bird}$, Table 9). We hypothesize that this lower emeticity is based on quantitative differences in proportions of the shared cardenolides of their two very similar TLC patterns (Brower et al., 1984a; Seiber et al., 1986). Since lower, compared to higher, polarity cardenolides can cross epithelial tissues more quickly (Wright, 1960; Duffey and Scudder, 1974; Yoder et al., 1976; Duffey, 1977; Duffey et al., 1978; Scudder and Meredith, 1982), the higher concentrations of lower polarity cardenolides, such as desglucosyrioxide in *A. speciosa*-reared monarchs, may trigger stronger emetic contractions in smooth muscles of a vertebrate predator's gut than extracts of *A. syriaca*-reared monarchs.

Based on the above findings, it is reasonable to consider 323–398 μg cardenolide as the approximate ED_{50} value for autumn migrant and overwintering monarchs of the eastern population. Hence butterflies from different regions would be expected to have different degrees of protection. In fact, four of our 12 collection areas (Table 7) produced butterflies that, on average, are substantially below the required ED_{50} dose. These are the western group, including North Dakota, Minnesota, and western Michigan.

Implications of A. syriaca Fingerprint for Understanding Annual Cycle of Monarch Butterflies

What are the implications of this variation in cardenolide content and emetic potency for the contribution of *A. syriaca* to the pool of Mexican overwintering butterflies? Wild Massachusetts monarchs (Table 9) have a similar, but narrower total cardenolide range of 34–850 μg , compared with our *A. syriaca*-

derived monarchs' range of 0–1480 μg and, like ours, it is normally distributed, although with a lower mean of 384 μg , compared to 472 μg . Yet both of these distributions differ considerably from the Mexican sample (Table 9), which has a similar ED_{50} value to the Massachusetts sample but has a positively skewed cardenolide distribution with a greater proportion of less protected, low cardenolide butterflies. This shift towards lower cardenolide values with time is contrary to expectations if predators take less protected butterflies (Fink and Brower, 1981; Brower et al., 1985). It seems highly unlikely that the earlier Massachusetts sample contains considerable numbers of toxic southern butterflies, as suggested by Martin and Lynch (1988), since it was not collected until September (Brower and Moffitt, 1974), by which time we would expect a huge preponderance of *A. syriaca*-derived butterflies resulting from as many as three northern generations (Borkin, 1982; Malcolm et al., 1987), and the butterflies were in mint condition, suggesting recent eclosion (L.P. Brower, personal observations). Furthermore, the variation that Brower and Moffitt (1974) and Fink and Brower (1981) cite for the Massachusetts sample lies within the range we have determined for *A. syriaca*-reared butterflies, and they have the same fingerprint as our *A. syriaca*-reared butterflies (compare the TLC fingerprint patterns of the same wild Massachusetts butterflies in Figure 7 of Roeske et al., 1976, with Figures 4 and 5 of this paper and plate 2D of *A. syriaca* monarch parts in Brower, 1985). Thus there is no need to suggest the influence of non-*syriaca*-derived butterflies.

Nevertheless, the overwintering cardenolide distribution does change with time, and consideration of monarch overwintering biology suggests four possible explanations. First, low cardenolide butterflies could be represented in greater numbers at the Mexican overwintering sites because more monarchs are produced from areas with milkweeds of lower cardenolide content and proportionately more of these butterflies reach Mexico. Second, there may be an aging effect related to energy expenditure in flight, or preferential excretion and metabolism of certain cardenolides over time. Third, there may be greater mortality of higher cardenolide monarchs with time because of a physiological cost of cardenolide storage. Fourth, apparent cardenolide loss through time may be an artifact of differential size mortality, unrelated to cardenolides per se. For example, predators may take larger monarchs, carrying more cardenolide, simply because they provide most food. Further work is needed to explore these hypotheses.

Since *A. syriaca* is the preeminent summer larval host plant of monarch butterflies in eastern North America, and because we have established the consistency of the *A. syriaca* TLC fingerprint, this paper provides the basis to tackle a number of pressing ecological and physiological questions. We will now be able to determine (1) the proportion of autumn migrants that fed on *A. syriaca*; (2) the proportion of Mexican overwintering monarchs that fed on *A.*

syriaca; (3) the temporal change of overwintering monarch cardenolides and its impact on predation and subsequent remigration; (4) whether overwintered monarchs with the *A. syriaca* fingerprint do return north to breeding sites and how far north they migrate; and (5) the proportion and timing of *A. syriaca*-bred monarchs that reach different breeding latitudes in the spring. Thus we will be able to describe the overall temporal and spatial pattern of the monarch's spring remigration. Answers to these questions will address some of the most consequential and topical issues in our understanding of monarch migration and the ecological chemistry of milkweed-monarch-predator interactions.

Acknowledgments—We are grateful to James Seiber at the University of California, Davis, for samples of the cardenolide standards desglucosyrioxide and aspecioside, Tonya Van Hook at the University of Florida for extensive help with the cardenolide analyses, Carolyn Nelson for advice on the spectroassay, and Susan Glazier and Christine Moffitt for the earlier assays performed at Amherst College. The comments of Murray Isman and an anonymous reviewer are also much appreciated. The research was supported by NSF grants BSR 8119382.A01 and BSR 8500416.

INSECTICIDAL ACTIVITY OF HYPERICIN TOWARDS *Manduca sexta* LARVAE

RICHARD SAMUELS and PAUL KNOX¹

Claverton Down, Bath Avon BA2 7AY, U.K.*

(Received December 28, 1987, accepted March 9, 1988)

Abstract—The toxic effect of hypericin (HYP), a photodynamic quinone that occurs in certain species of the genus *Hypericum*, towards *Manduca sexta* third-instar larvae was investigated. The LD₅₀ of purified hypericin was 16 µg/g larval initial fresh weight in constant light (22 W/m²). Reduced irradiance resulted in decreased mortality. Sublethal applications retarded larval growth (body fresh weight) in a dose-dependent manner. Toxicity had an absolute light dependence at the dose levels used, the active wavelengths being >500 nm. The phototoxic effect was rapidly lost when larvae were maintained in darkness (>8 hr) prior to irradiation. However, the potential for light-dependent mortality was retained if larvae were starved prior to irradiation.

Key Words—Hypericin, *Hypericum perforatum*, photodynamic quinone, photosensitizer, singlet oxygen, *Manduca sexta*, Lepidoptera, Sphingidae.

INTRODUCTION

It is increasingly apparent that interactions of species occur via subtle chemical mechanisms. Indeed, the ecological interactions between insects and plants mediated by photodynamic compounds are an important developing field (Towers, 1984; Downum and Rodriguez, 1986).

Hypericin (HYP), a naturally occurring photodynamic compound (Knox and Dodge, 1985a), causes photosensitization of grazing animals following ingestion of certain species of *Hypericum* (Giese, 1980). However, the evolutionary significance of these types of secondary plant compounds appears to be

¹Current address: John Innes Institute, Colney Lane, Norwich NR4 7UH, U.K.

related to phytophagous insect-host plant interactions. Photodynamic compounds may constitute a chemical defense against phytophagous insects by acting as feeding deterrents (McLachlan et al., 1982; Champagne et al., 1986). This role for secondary plant compounds has been well documented (e.g., Rosenthal and Janzen, 1979).

Differences in susceptibility to phototoxic compounds may be dependent upon rates of sequestration and metabolism, or cuticle sclerotization and depositions of melanin in the cuticle, i.e., a "black" mutant strain of *Manduca sexta* larva is more resistant to the effects of photosensitizers than normally pigmented larva (Berenbaum, 1987).

The toxic action of photodynamic compounds can be mediated by light activation of oxygen, notably singlet oxygen (1O_2), which can react at high rates with certain lipid, nucleic acid, and protein components of cells to cause disruption (Foote, 1976). HYP isolated from *Hypericum hirsutum* has been found to produce singlet oxygen (Knox and Dodge, 1985b).

Certain insects are capable of utilizing plants containing phototoxic compounds. Larvae of *Polia assimilis* (Lepidoptera: Noctuidae) feed on *Hypericum*, avoiding the phototoxic effects of HYP by adaptive behavior (Berenbaum, 1987), and it has been stated that *Chrysolina brunsvicensis* (Coleoptera: Chrysomelidae) may actually utilize HYP as a feeding cue (Rees, 1969).

The potential of synthetic photodynamic compounds for insect pest control has been reviewed (Heitz, 1982; Robinson, 1983; Lemke et al., 1987). However, the possibility of using natural photodynamic compounds for pest control programs has not been considered. Thus, insecticidal activity of HYP isolated from *Hypericum perforatum* towards a model pest species, larvae of the tobacco hawk moth *Manduca sexta* (Lepidoptera: Sphingidae), was investigated. Preliminary results from this report were presented at the ACS symposium "Light-activated pesticides" (Knox et al., 1987).

METHODS AND MATERIALS

Isolation of Hypericin. The HYP utilized in these experiments was isolated from *Hypericum perforatum*, which has HYP-containing glands on its leaves and stem. *H. perforatum* was grown from seed. The dried shoots were ground to a powder and extracted exhaustively in light petroleum ether with 5% (v/v) acetone to remove chlorophylls and carotenoids. The residue was allowed to dry, and the hypericin was extracted with 90% (v/v) aqueous acetone. The acetone fraction was washed repeatedly with light petroleum ether to remove the remaining photosynthetic pigments. The aqueous phase was acidified by addition of HCl. After 48 hr the dark precipitate was collected and washed with water. When dissolved in ethanol, the precipitate displayed the characteristic

absorption spectrum of HYP. *H. perforatum* contains pseudohypericin, which is indistinguishable from hypericin by means of absorption spectroscopy. For purposes of this study, no attempt was made to separate pseudohypericin from hypericin; the two compounds have equal $^1\text{O}_4$ -generation potential (data not shown). All concentrations of HYP were based on the compound's extinction coefficient in ethanol, $E_{592} = 41,600$.

Treatment of Manduca sexta Larvae. Larvae were reared at 25°C, 16 hr light–8 hr dark on artificial diet, using standard procedures (Bell and Joachim, 1978). Third-instar larvae that were actively feeding and weighed ca. 60 mg were used in all experiments, except the weight gain investigation, in which initial larval weight was ca. 150 mg, and larval development was monitored until the fourth instar.

HYP, in 5 μl of acetone, was applied to leaf disks of tobacco (7 mm diameter). The acetone was allowed to evaporate before feeding the disks to the larvae, which were maintained without illumination while consuming the disks (ca. 1 hr). Where appropriate, larvae were then fed artificial diet and exposed to light supplied by white fluorescent tubes (8 \times 40-W Thorn Warmlite tubes). Light levels were measured using a Li-Cor Radiometer with a pyranometer sensor. Irradiance was modulated by neutral (Kodak neutral density) and cutoff (Rank cinemoid) filters.

At least 15 larvae were used per dose of HYP. Larvae were weighed before treatment and, for certain experiments, at intervals following irradiation. Larvae were classified as dead by a lack of response to tactile stimulation. The LD_{50} was calculated by probit analysis.

RESULTS

HYP was phototoxic to *M. sexta* larvae. At the moderate radiance level used, the LD_{50} was 16 $\mu\text{g/g}$ larval initial fresh weight (fd. lmts. 14.37–18.05), which represents approximately a 1 μg dose to a third-instar larva. This dose was equivalent to HYP contained within four sepals of *H. hirsutum* (Knox and Dodge, 1985b). *H. perforatum* has an even higher shoot content of HYP.

It was noted that HYP-poisoned and then irradiated larvae stopped feeding and remained immobile until subjected to tactile stimulation, which induced irritability. The end result of hypericin poisoning is shown in Figure 1; growth of light-exposed larvae was retarded, and a characteristic discoloration, possibly due to oxidation of the tissues, was noted. The HYP-fed but dark-maintained controls and HYP-free irradiated controls attained normal body weight. These larvae continued development and pupated successfully.

The effect of HYP on weight gain was further investigated (Figure 2). Third-instar larvae were fed three low doses of HYP and then exposed to con-

FIG. 1. *Manduca sexta* larvae following hypericin poisoning. (A) Hypericin-fed dark-maintained control larvae. Hypericin-fed but irradiated larvae show characteristic discolorations (scale: mm).

stant light (22 W/m^2). Body weight was monitored over the following 76 hr. During the active feeding stage of the third instar the difference in body weight between $0.5 \mu\text{g}$ HYP-fed dark controls and $0.5 \mu\text{g}$ HYP-fed irradiated larvae was only 0.05 g. However, at 76 hr there was a significant difference in body weight (t test; $P < 0.01$). The lowest dose of HYP used ($0.12 \mu\text{g}$) also disrupted the normal growth pattern. There was no difference in body weight between HYP-fed dark-maintained controls and HYP-free irradiated controls (HYP-free data omitted in Figure 1 for clarity).

Reduced levels of irradiance resulted in reduced mortality (Table 1), and modulation of light quality by a cutoff filter (allowing irradiation with wavelengths $> 500 \text{ nm}$ only) reduced the mortality rate by only 20%, indicating that absorbance by HYP in the area of 500–600 nm was the major active region of the HYP action spectrum (for spectrum, see Knox and Dodge, 1985b). The fact that a 20% reduction did occur suggests that absorption of wavelengths $< 500 \text{ nm}$ could also elicit phototoxicity.

The phototoxic effect of HYP diminished rapidly when treated larvae were maintained in darkness for periods prior to irradiation (Figure 3). Mortality was reduced to 6% if irradiation was delayed for 8 hr after treatment. However, if

FIG. 2. The effect of sublethal doses of hypericin on larval weight gain. Controls were hypericin-fed ($0.5 \mu\text{g}$) and maintained in darkness and hypericin-free irradiated (not shown). Each data point was the mean of at least 15 individual larval body weight determinations.

TABLE 1. Phototoxicity of Hypericin toward *Manduca sexta* Larvae

Hypericin dose ($\mu\text{g}/\text{larvae}$) ^a	Irradiation (W/m^2)	Time in darkness between treatment and irradiation (hr)	Mortality at 48 hr (%) ^b
2.5	0	0	0
2.5	4	0	0
2.5	10	0	15
2.5	22	0	100
0	22	0	0
2.5	22	1 ^c	62
2.5	22	3 ^c	58
2.5	22	4 ^c	72

^a Mean initial fresh weight third-instar larvae approximately 60 mg.

^b Minimum of 15 larvae per data point. Data representative of two replicate experiments.

^c Larvae starved after hypericin treatment then retained in dark for stated time periods (hr) prior to irradiation and subsequent feeding on artificial diet.

FIG. 3. Reduction in rate of mortality when larvae were retained without illumination for periods following hypericin poisoning. Larvae irradiated at 0, 2, 4, and 8 hr (15 insects in each group). Mortality recorded 48 hr after irradiation. No mortality seen for controls (HYP-fed and HYP-free).

larvae were not supplied with artificial diet following HYP treatment and retained without irradiation for short periods, the potential for a high mortality rate upon subsequent irradiation was retained (Table 1).

DISCUSSION

These studies demonstrate that orally administered HYP was highly toxic to *Manduca* larvae, an oligophagous herbivore unaccustomed to feeding on plants containing this compound. Photodynamic insecticidal activity of HYP has been noted previously only for mosquito larvae *Aedes atropalpus* (Arnason et al., 1983) and larvae of *Platynota flavedana* (Lepidoptera: Tortricidae) (Berenbaum, 1987).

Toxicity of HYP was entirely due to photodynamic action as there was a dependence upon light at the dose levels used in this study. Other photosensitizers may additionally act as light-independent toxins. Rose bengal adversely affects body weight gain in the boll weevil *Anthonomus grandis* without irradiation (Callahan et al., 1977). No effects on larval development were detected in hypericin-fed dark-maintained insects.

Growth retardation, an effect of HYP documented here, is one of the more common symptoms associated with photosensitized insects (Weaver, 1987). Ingestion of alpha-terthienyl was also found to affect *Manduca* larval development (Downum et al., 1984). However, alpha-terthienyl may possess antifee-

dant properties (Champagne et al., 1986), although this has yet to be fully established. Observations indicated that *Manduca* larvae were not deterred from feeding on HYP-poisoned tobacco leaf disks.

Hypericin-poisoned larvae remained completely immobile prior to death. However, if subjected to tactile stimulation, they became highly irritable. These behavioral abnormalities were indicative of disruption to the nervous system, one of the possible target sites of light-activated pesticides (Callaham et al., 1975).

Exposure to visible irradiation (500–600 nm) was a prerequisite for HYP toxicity, contrasting with other plant metabolites capable of photosensitizing lepidopteran larvae, such as alpha-terthienyl, which was toxic to *Manduca* orally and topically by subsequent exposure to UV-A irradiation (320–400 nm) (Downum et al., 1984). It is of interest to note that the maximum radiance levels used here for LD₅₀ studies (22 W/m²) were considerably less than normal daylight levels (> 200 W/m²), indicating a much lower effective dose requirement for insecticidal activity in a natural environment.

The rapid loss of toxic activity found when HYP-dosed larvae were allowed to feed in darkness prior to irradiation indicated either rapid breakdown or excretion. If fecal pellet production was prevented (larvae starved) so that ingested hypericin remained within the insect's body, the light-dependent toxicity was essentially retained. The slight reduction in toxicity observed was probably due to detoxification.

Secondary plant compounds may act as insecticides by deterring an insect from feeding, poisoning per se (independent of irradiation), or by the production of toxic molecules such as ¹O₂ in the presence of light. Hypericin is capable of the photodynamic generation of ¹O₂ in vitro (Knox and Dodge, 1985b). However, the role of ¹O₂ in its phototoxicity towards *M. sexta* is uncertain, and other radical mechanisms, possibly involving superoxide anions, may be important.

The precise reactions of hypericin and the sensitive sites of its phototoxic action at the tissue, cellular, and biochemical level have yet to be determined. Hypericin acts as a true phototoxin by producing highly damaging singlet oxygen in the presence of visible irradiation. Compounds such as hypericin provide an insight to the toxic mode of action of photodynamic compounds and also have potential as a new class of insecticides.

COMPARATIVE ANALYSIS OF SEX-PHEROMONE-RESPONSE ANTAGONISTS IN THREE RACES OF EUROPEAN CORN BORER

T.J. GLOVER,¹ N. PEREZ, and W.L. ROELOFS

*Department of Entomology
New York State Agricultural Experiment Station
Cornell University

(Received December 29, 1987; accepted March 11, 1988)

Abstract—Behavioral responses of males from three New York races of European corn borer, *Ostrinia nubilalis* (Hübner), to various suspected sex-pheromone-response antagonists were investigated with a flight tunnel protocol. Males from a bivoltine (Z) race and from a univoltine (Z) race utilizing a natural pheromone blend of 98:2 (Z)-:(E)-11-tetradecenyl acetates and males from a bivoltine (E) race utilizing a 1:99 (Z)-:(E)-11-tetradecenyl acetate ratio were flown to their natural blends and to blends containing 1% of one of the following additional compounds: Z9-12:OAc, E9-12:OAc, Z9-14:OAc, and E9-14:OAc. In each race, the added components lowered significantly the number of individuals completing the behavioral sequence. The only exception was bivoltine E males flown to a blend with E9-12:OAc added. The number completing the sequence in this case was statistically not significantly lower than the number that completed the sequence to the standard blend. In all three races, the Z9-14:OAc produced the most dramatic reduction in completed flights, and in the univoltine Z race, this added component was significantly more effective in reducing completed flights than any other added component. The response to the Z9-14:OAc is understandable given recently published findings of an electrophysiological study of single sensilla in the European corn borer.

Key Words—European corn borer, *Ostrinia nubilalis*, Pyralidae, Lepidoptera, (Z)-9-tetradecenyl acetate, pheromone, flight tunnel.

¹ Present Address: Hobart and William Smith Colleges, Geneva, New York.

INTRODUCTION

Three European corn borer (ECB), *Ostrinia nubilalis* (Hübner), races have been defined in New York (Roelofs et al., 1985). These include bivoltine and univoltine populations whose sex pheromone is a 98:2 mix of (Z)- and (E)-11-tetradecenyl acetates (Z11-14:OAc and E11-14:OAc) (Z races) (Klun et al., 1973; Glover et al., 1987), and a bivoltine population that uses a 1:99 blend (E race) (Kochansky et al., 1975; Glover et al., 1987). Although the Z races use a similar pheromone blend, males from these two races can be differentiated in the flight tunnel by their response to mixtures containing only 0.5% of the E isomer (Glover et al., 1987). Bivoltine males exhibited good flight responses to the 0.5% E blend (80% completing their flights compared to 100% completing their flights to the natural 3% E blend), whereas univoltine males responded poorly to this off blend (17% completing their flights compared to 90% completing their flights to the 3% blend). Thus, all three ECB races exhibited different behavioral response profiles to the set of pheromone blends used in the flight tunnel.

Recently, Struble et al. (1987) reported that the presence of 0.1% of (Z)-9-dodecenyl acetate (Z9-12:OAc) or (Z)-9-tetradecenyl acetate (Z9-14:OAc) can greatly reduce the capture of male ECB by the natural 100:3 Z/E blend in three areas of Canada. Some reduction also was observed with (E)-9-tetradecenyl acetate (E9-14:OAc), which previously had been shown to be effective at ca. the 3% level in reducing trap catch of Z-responding males in Iowa and cage bioassay responses of Iowa (Z) and New York (E) males (Klun et al., 1979). A number of other closely related isomers and homologs did not have any significant effect on the capture of male ECB. Since the trapping studies could not reveal the behavioral response effects of the added compounds, Struble et al. (1987) suggested that behavioral studies should be conducted with these compounds. Therefore, the present flight tunnel study was carried out to determine the behavioral effects of adding low amounts of Z9-12:OAc, Z9-14:OAc, E9-12:OAc, or E9-14:OAc to the natural blend of the three ECB races presently cultured in our laboratories and to determine if differential effects of these compounds on the male's response would allow us to discriminate further among the three ECB races.

METHODS AND MATERIALS

Insect Cultures. The univoltine Z culture was started from field-collected larvae, pupae, and adults from corn stubble near Paris, New York, during July 1984. The bivoltine Z culture was started from field-collected larvae, pupae, and adults from corn stubble near Eden, New York, during August 1984. The

bivoltine *E* culture was started from adults emerging from corn stubble collected near Geneva, New York, during May 1985. These three cultures have been reared continuously using the techniques and diet described previously (Roelofs et al., 1985), which were modified from Reed et al. (1972). Male pupae were isolated individually in 1.25-oz plastic creamers with a 2-cm piece of dental wick soaked with tap water. They were kept in continuous light at $30 \pm 1^\circ\text{C}$ until eclosion. After eclosion, all insects were entrained to a 16:8 light-dark photoperiod at $25 \pm 1^\circ\text{C}$ for two or three days in the absence of females before being used in the bioassays, with all insects acclimated to the flight tunnel room for 4–6 hr before being tested.

Pheromone Blend Sources. The *E*11–14:OAc was TLC-purified material and the *Z*11–14:OAc was purchased from Dr. S. Voerman (The Institute for Pesticide Research, The Netherlands). Both the *E*11–14:OAc and *Z*11–14:OAc were >98.6% pure by GLC analysis and both contain <0.05% of the opposite isomer. The *E*9–12:OAc, *Z*9–12:OAc, *E*9–14:OAc, and *Z*9–14:OAc were purchased from Farchan Division of ChemSampCo, Inc., Willoughby, Ohio. The standard *Z* blend consisted of 97% *Z*11–14:OAc and 3% *E*11–14:OAc, and the standard *E* blend consisted of 1% *Z*11–14:OAc and 99% *E*11–14:OAc. These blends were made in concentrations of 1 mg/ml using redistilled Skellysolve B (Skelly B) as solvent. The additional components (*E*9–12:OAc, *Z*9–12:OAc, *E*9–14:OAc, and *Z*9–14:OAc) were made up in 100 ng/ μl solutions using redistilled Skelly B as solvent. Ten microliters of each of these solutions was added to different solutions containing 100 $\mu\text{g}/100 \mu\text{l}$ of either the *Z* or *E* standard solutions. Capillary GLC analysis (30-m Supelcowax 10 column) verified that these blends contained 0.96–1.20% of the additional component. Thirty microliters of the standard blend or the standard blend plus an additional component was applied to 5×9 -mm rubber stoppers (Thomas Scientific, Swedesboro, NJ, catalog No. 8753-D22) so that the final amount was ca. 30 μg . Each stopper was allowed to stand in a hood 2–4 hr before its initial use in the flight tunnel. Thereafter each stopper was stored in a screw top glass vial at -20°C . Before each use a stopper was warmed to room temperature in its vial prior to introduction into the flight tunnel.

Flight Tunnel. The flight tunnel has been described previously by Glover et al. (1987). The wind speed during all flights was 0.25 m/sec and the illumination was 11 lux of red light at the tunnel floor. The distance from the pheromone source to the insect release site was 1.2 m. All flights were conducted at $18 \pm 1^\circ\text{C}$ and 3–5 hr into scotophase.

Flight Tunnel Protocol. Individual naive male insects were placed in 3-cm \times 6-cm screen cylinders, which in turn were placed on a 10-cm-high release platform with the open end of the cylinder upwind. Each insect was allowed 30 sec to initiate flight. Insects that did not activate within that time period but later demonstrated the ability to fly were recorded as not responding (NR). For

each responding insect, the final behavioral response was recorded using the following sequence of criteria: ACT = activation, rapid wing beating, and walking within the screen release cylinder; TF = taking flight; CAST = casting or looping flight near the release stand; OR = orientation flight in the pheromone plume; MID = flight in the plume to the midpoint of the tunnel; 30 cm = flight in the plume to within 30 cm of the pheromone source; 5 cm = flight in the plume to within 5 cm of the pheromone source; TS = touching the source, landing on the pheromone source stand, and/or touching the rubber stopper; DIS = display, clasper extrusion with wings held vertically, and abdomen waving slowly from side to side. Any insect touching the source or displaying was considered to have completed the behavioral sequence, so these two categories have been combined for the analyses.

For each culture, at least 41 insects were flown to each blend containing an additional component and at least 61 insects were flown to the standard blend. Data were collected on a minimum of four different days for each blend tested. The standard blends were utilized at the beginning of each flight day to check the tunnel conditions. Only on days when at least 70% of the insects completed the behavioral sequence to the standard blends were the additional component blends tested. Not all additional component blends were tested every day, and the order of the tests was randomized each day. The data summaries presented in this article include final behavioral responses for only those days on which both standard and additional component blends were tested.

Statistical Analysis. For each culture, the distribution of final behavioral responses to each blend containing an additional component was compared to the distribution of final behavioral responses to the standard blend for that culture using a one-tailed Kolmogorov-Smirnov two-sample test for large samples, n_1 and n_2 both > 40 (Siegel, 1956). This two-sample test is concerned with the agreement between two cumulative distributions and is sensitive to any kind of difference in the distributions. The test of significance for this test approximates a chi-square (χ^2) distribution with two degrees of freedom. In addition, within each culture, the percentages completing the behavioral responses, i.e., touching the source and/or displaying, to each of the five blends were compared using the simultaneous $\sqrt{\chi^2}$ procedure to generate confidence intervals for the simple contrasts. The general formula for these confidence intervals is

$$(\hat{p}_i - \hat{p}_j) \pm \sqrt{\chi_{k-1; 1-\alpha}^2} \sqrt{\frac{\hat{p}_i \hat{p}_i}{n_i} + \frac{\hat{p}_j \hat{p}_j}{n_j}}$$

where \hat{p}_i and \hat{p}_j are the proportions of samples i and j , respectively, completing the behavioral sequences. This calculation allows the overall probability of a type 1 error to be fixed for the entire set of confidence intervals. This post hoc

multiple comparison procedure for proportions is outlined more fully in Marascuilo and McSweeney (1977).

RESULTS

Univoltine Z. The univoltine Z males responded extremely well to the standard blend of 97% Z11-14:OAc and 3% E11-14:OAc, with 58 of 61 (95.1%) of the insects completing the behavioral sequence (Table 1, Figure 1A). In contrast, blends containing 1% of any of the additional components elicited very different response profiles (Table 1, Figure 1A). In all four cases, the profile (Figure 1A) was significantly different ($P < 0.005$) from the profile to the standard blend according to Kolmogorov-Smirnov two-sample tests (E9-14:OAc, $\chi^2 = 18.14$; Z9-14:OAc, $\chi^2 = 81.13$; E9-12:OAc, $\chi^2 = 30.54$; and Z9-12:OAc, $\chi^2 = 21.35$). Although the behavioral response profiles to

^aThe standard Z blend consisted of 97% Z11-14:OAc and 3% E11-14:OAc. Blends with additional components contained 99% standard blend and 1% additional material. All septa had a total of 30 μ g of material.

^bPercentages followed by the same letter are not significantly different at the 1% level using the post hoc multiple comparisons procedure of simultaneous $\sqrt{\chi^2}$ to generate confidence intervals for simple contrasts.

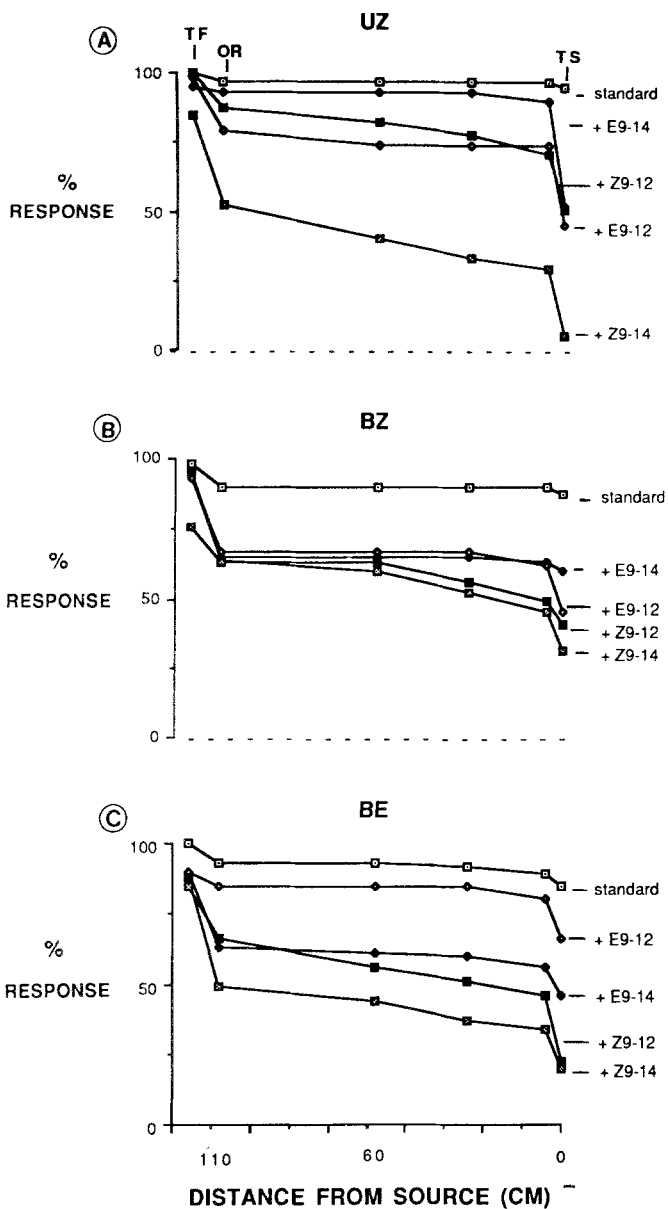

FIG. 1. Percentage response of male ECB from three races tested individually in the flight tunnel to 30- μ g dosages of standard pheromone blends and blends with 1% of an additional component. Behaviors are: taking flight (TF), orientation flight (OR), upwind flight to 60, 30, and 5 cm from the source, and touching the source (TS). Within each race, the response profiles to additional component blends were compared to the response profile to the standard blend via a Kolmogorov-Smirnov two-sample test. All response profiles to additional component blends were significantly different from the response profiles to the standards ($P < 0.005$) except the +E9-12:OAC in the BE race ($P > 0.1$).

the blends with 1% *E9-14:OAc*, 1% *E9-12:OAc*, and 1% *Z9-12:OAc* were similar (Figure 1A), they deviated dramatically from that of the standard blend by showing considerable arrestment at close range (5 cm). The insects flown to the blend with 1% *Z9-14:OAc* showed this same arrestment, but also had a significant proportion (48%) that failed to lock on the signal and therefore terminated flight before orienting to the blend plume (Figure 1A).

The percentage of insects completing the behavioral sequence, i.e., touching the source and/or displaying (Table 1), was significantly lower ($P < 0.01$) with any additional component than the 95.1% to the standard blend according to the post hoc multiple comparison procedure described earlier. The addition of *Z9-14:OAc* reduced the number of insects completing the behavioral sequence to 4.8%, whereas the addition of other components reduced the number completing this sequence to between 45.2 and 52.4%. This reduction with *Z9-14:OAc* compared with the other additional components is significant ($P < 0.01$).

Bivoltine Z. Fifty-four of 62 (87.1%) bivoltine males completed the behavioral sequence to the standard blend of 97% *Z11-14:OAc* and 3% *E11-14:OAc* (Table 2, Figure 1B). Again, blends containing 1% of any additional component elicited response profiles (Figure 1B) that were very different ($P < 0.005$) from the standard blend response profile according to Kolmogorov-Smirnov two-sample tests (*E9-14:OAc*, $\chi^2 = 12.30$; *Z9-14:OAc*, $\chi^2 = 35.94$; *E9-12:OAc*, $\chi^2 = 30.52$; and *Z9-12:OAc*, $\chi^2 = 20.53$). With all additional component blends, approximately one third of the insects did not orient to the blend plume. For *E9-14:OAc*, *Z9-12:OAc*, and *E9-12:OAc*, the number of insects terminating the behavioral sequence this early is markedly higher than in the results reported in Table 1 and Figure 1A for the univoltine *Z* population. The blends containing *Z9-14:OAc* and *E9-12:OAc* again elicited some close-range arrestment, with ca. 21% of the moths terminating flights at 5–30 cm from the blend source. This arrestment was less dramatic with *Z9-12:OAc* added to the standard blend.

The percentage of the insects completing the behavioral sequence (Table 2) was significantly lower than 87.1% for all additional component blends ($P < 0.05$ for *E9-14:OAc*, $P < 0.01$ for all others; post hoc multiple comparison procedures). Although the blend with *Z9-14:OAc* again yielded the lowest number completing the behavioral sequence (31.0%), this number was not significantly ($P > 0.05$) lower than those for the other additional component blends.

Bivoltine E. The behavioral responses of the bivoltine *E* strain to various blends are summarized in Table 3 and Figure 1C. The standard blend of 99% *E11-14:OAc* and 1% *Z11-14:OAc* elicited a complete behavioral sequence from 52 of 61 (85.2%) males exposed to it. According to the Kolmogorov-Smirnov two-sample test, the behavioral response profile for the blend contain-

ing an addition of 1% E9-12:OAc is not significantly different ($\chi^2 = 3.65$, $P > 0.1$) from the response profile for the standard blend (Figure 1C). However, the profiles for blends with the addition of E9-14:OAc, Z9-14:OAc, and Z9-12:OAc (Figure 1C) were all significantly different ($P < 0.01$) from the standard blend profile according to the same statistical procedure (E9-14:OAc, $\chi^2 = 14.84$; Z9-14:OAc, $\chi^2 = 42.34$; and Z9-12:OAc, $\chi^2 = 39.17$). The profiles in Figure 1C again demonstrate both the failure of a portion of the insects to lock on to the blend signal with Z9-12:OAc, E9-14:OAc, and Z9-14:OAc and some close-range arrestment (5-30 cm), most dramatically with Z9-12:OAc.

Whereas all blends with additional components elicited fewer completions of the behavioral sequence than did the standard blend (Table 3), the 65.9% completing the sequence with the E9-12:OAc additional component was not significantly lower ($P > 0.05$). All others were significantly lower ($P < 0.01$) with the response to the blend containing Z9-14:OAc again being the most markedly reduced. All contrasts for completion of the behavioral sequence were by the post hoc multiple comparison test described earlier.

DISCUSSION

Behavioral analyses of males from three New York ECB races flown to pheromone blends containing 1% of additional components showed that there are significant differences in the antagonistic effects of these components among the races. In every case, except with E9-12:OAc effects on bivoltine *E* males, the additional component significantly lowered the percentage of individuals completing the behavioral sequence as compared to the natural blend. Blends with Z9-14:OAc added were the most active in all races and Z9-14:OAc was significantly more active than the other three additional components in tests of the univoltine *Z* race. Although we investigated these antagonists at somewhat higher ratios than were generally used in field studies by Struble et al. (1987), our results further confirm the antagonistic nature of Z9-12:OAc, Z9-14:OAc, and E9-14:OAc when added to standard blends of ECB pheromone. Further, we have demonstrated antagonism with the addition of E9-12:OAc. We, therefore, agree with the warning issued by Struble et al. (1987) about the possible

effects of contamination by small amounts of these compounds in commercial batches of pheromone used for monitoring of ECB populations.

A response to Z9-14:OAc in both the Z and the E races is understandable in view of the finding (Hansson et al., 1987) of a specialized olfactory cell in all three races that responds only to Z9-14:OAc. They did not find any specialized olfactory cells for the other antagonists utilized in this study, but Struble et al. (1987) did report a positive EAG response to both Z9- and E9-14:OAc. Olfactory cells that are very sensitive to trace amounts of a specific compound and that, when activated, adversely affect the male moth's normal behavioral responses to the sex pheromone blend also have been found in other species. It has been suggested that this phenomenon allows male moths to discriminate between heterospecific blends that contain the same major component (Linn et al., 1988). For example, both the cabbage looper moth (CL), *Trichoplusia ni* (Hübner), and the soybean looper moth (SBL), *Pseudoplusia includens* (Walker), utilize Z7-12:OAc as a major component in their six- and five-component blends, respectively (Linn et al., 1984, 1987b). Grant et al. (1987) found that SBL males possess an antennal olfactory receptor neuron that is specifically sensitive to low dosages of Z5-12:OAc. This compound is a minor component of the CL blend and is not found in the SBL blend, but it adversely affects the upwind flight response of SBL males in the flight tunnel (Linn et al., 1988). Additionally, O'Connell et al. (1983) found a neuron on male CL antennae that responds specifically to Z7-12:OH. This alcohol is not part of the six-component blend for CL, but it does cause significant levels of arrested upwind flight in the flight tunnel when present in the CL blend in amounts as low as 0.5% of the major component (Linn et al., 1984). Relative to this case, it is known that a related noctuid, *Autographa californica*, utilizes the same major component as CL, but apparently also uses the alcohol as an additional pheromone component (Steck et al., 1979).

Thus, there is increasing evidence that specific pheromone blends act as a unit in mediating the complete sequence of behavioral responses to a calling female (Linn et al., 1987a) but that an individual component of that blend can be detected specifically by and have an adverse affect on the male moths of another species.

Acknowledgments—We thank Dr. C.J. Eckenrode, Jr., P.S. Robbins, and M.L. Hessney for generously supplying ECB adults from the three distinct populations. In addition, we thank G.S. Rule for preparing and checking the blends utilized in the flight tunnel. This research was supported in part by NSF grant BSR-8500234.

LEAF-TYING BY TORTRICID LARVAE AS AN
ADAPTATION FOR FEEDING ON PHOTOTOXIC
Hypericum perforatum

SHERRI L. SANDBERG and MAY R. BERENBAUM

Department of Entomology
University of Illinois, Urbana-Champaign
Urbana, Illinois 61801

(Received December 30, 1987; accepted March 11, 1988)

Abstract—Hypericin, an anthrone dimer in *Hypericum perforatum* (Guttiferae), is shown for the first time to be phototoxic to generalist lepidopteran larvae; survivorship was reduced and development prolonged for *Heliothis zea* (Noctuidae) and *Platynota flavedana* (Tortricidae) that consumed hypericin diets in the presence of light. Survivorship for both species is enhanced when photoactivating wavelengths are excluded by filters. In nature *P. flavedana* successfully survives on *H. perforatum* by tying together leaves and feeding inside the ties. Shielded from light, the larvae are protected by their mode of feeding from phototoxic compounds.

Key Words—*Hypericum perforatum*, phototoxicity, hypericism, *Platynota flavedana*, Tortricidae, *Heliothis zea*, Noctuidae, Lepidoptera.

INTRODUCTION

The phototoxicity of St. John's-wort, *Hypericum perforatum* (Guttiferae), to sheep, cattle, and horses is attributable to the presence of the phototoxin hypericin (Scheme 1). Localized in glands of the plants' flowers, leaves, and stems (Blum, 1941; Giese, 1980), hypericin is an anthrone dimer and is classified as a primary photosensitizing agent (Clare, 1952). As such, hypericin is a highly active photodynamic pigment that reacts with light at the surface of the skin, causing hemolysis of red blood cells at concentrations as low as 10^{-7} M (Pace and MacKinney, 1941; Pace, 1942). Ingestion of the plant followed by exposure to sunlight results in the irritation of unpigmented skin, a condition known as hypericism, leading in severe cases to blistering, sloughing of necrotic areas,

HYPERICIN

SCHEME 1.

and, occasionally, death (Blum, 1941; Pace, 1942; Giese, 1980). Accordingly, hypericin appears to confer some protection for the plant since livestock generally avoid St. John's-wort, unless other forage is scarce (Harris and Peschkin, 1974). Little is known, however, as to whether hypericin also deters potential insect herbivores. To test this, bioassays were conducted with larvae of the corn earworm, *Heliothis zea* (Noctuidae), a polyphagous lepidopteran not known to feed on *H. perforatum* in nature.

A number of insects do utilize *H. perforatum* in its indigenous range, Eurasia (Currie and Garthside, 1932; Wilson, 1943; Johansson, 1962), but there are few records of native North American insects adopting *H. perforatum* as a host plant (Tietz, 1972; Hodges, 1974; Kingsolver et al., 1984). Thus, it was of interest to encounter larvae of several species of native North American tortricids (Lepidoptera) feeding within leaf ties on *H. perforatum* in central Illinois (Sandberg and Passoa, 1988). All tortricid species have broad host ranges and, for each, *H. perforatum* represents a new host record. Bioassays were conducted on one of these species, *Platynota flavedana*, to examine possible mechanisms that allow the development of a generalist feeder on a plant containing a phototoxin.

METHODS AND MATERIALS

Extraction and purification of hypericin from *Hypericum perforatum* were based on a modification of a procedure developed by Knox and Dodge (1985).

Flowers, upper leaves, and stems were immersed into a series of beakers containing 90% aqueous acetone, until the intense red color was no longer produced. The acetone extracts were combined and filtered through Whatman No. 1 filter paper to remove flower and leaf material. Chlorophyll and carotenoids were removed by partitioning the aqueous acetone solution with petroleum ether (bp 30–60°C). The aqueous solution was then brought to dryness by rotary evaporation followed by lyophilization. This formed the crude extract in one of the bioassays.

The hypericin extract was further purified using a gravity column 40 mm in diameter with a 10 cm layer of 32- to 63- μm silica on the bottom and a 1- to 2-cm layer of sand on top. The dried *Hypericum* extract was then resolubilized in 100% acetone, loaded on top of the layer of sand, and the column was run with ether-acetone in a 1:1 ratio. After the pink-red fractions were collected, they were combined, brought to dryness, and purified by thin-layer chromatography on a 2-mm, 20 \times 20-cm silica gel 60 F254 plate. The solvent systems used consecutively were ether-acetone at a ratio of 1.5 : 1.0 and ether-methanol at a ratio of 9 : 1 with R_f s of 0.88 and 0.17, respectively. The red band was scraped from the plate and eluted with ethanol. The solution was brought to dryness, and the resulting dry powder was used in artificial diet studies. Throughout the extraction and purification procedures, a spectrophotometer was used to monitor the presence of hypericin by using hypericin's characteristic absorption peaks between the region of 450–600 nm of the visible light spectrum (Schiebe and Schontag, 1942; Giese, 1980). The possibility exists that some pseudohypericin, a closely related pigment with an absorption spectrum identical to that of hypericin, may have been present in the hypericin preparation, although thin-layer chromatography did not indicate its presence. Nonetheless since pseudohypericin is also a photosensitizer, its presence would not adversely affect the bioassays or their interpretation (Giese, 1980; Knox and Dodge 1985).

In order to bioassay hypericin for insecticidal activity, a modified Vanderzant-wheat germ artificial diet (Waldbauer et al., 1984) was developed for *Heliothis zea* and *Platynota flavedana*, with wheat germ as the only undefined ingredient for the *H. zea* diet. The foliage of strawberry, one of the hosts of *Platynota*, is not reported to contain phototoxins (no phototoxic effects to survivorship were observed in the controls in subsequent experiments) and was added to the *Platynota* diet to stimulate larval feeding.

An initial bioassay of hypericin tested for insecticidal activity towards *Heliothis zea*, a generalist insect not known to feed on *Hypericum*. Larvae were reared to second instar on control diets and diets containing 0.1% fresh weight under two different light treatments. The first light treatment, fluorescent lights (Sylvania Cool White 40 watt) with a clear filter, simulated sunlight, and the second, fluorescent lights with a red acetate filter, filtered out wavelengths below

600 nm, the activating range of the light spectrum for hypericin (Schiebe and Schontag, 1942; Giese, 1980).

The second bioassay examined the response of *Platynota flavedana*, a generalist insect known to feed on *Hypericum*. The larvae were subjected to three artificial diet treatments: a control, one with *Hypericum perforatum* leaves (0.075% fresh weight), and one containing a crude extract from the equivalent weight of *Hypericum* leaves. The extract was prepared as described in the purification procedure of hypericin. As it was already known that *P. flavedana* is able to utilize *Hypericum*, the leaves and a crude extract containing hypericin were assayed to determine if either could be toxic to *Platynota* if larvae were constrained to feed on the diets under conditions simulating sunlight (i.e., outside of a leaf-tie).

In three subsequent experiments, purified hypericin from *H. perforatum* was bioassayed against *P. flavedana*. Larvae were exposed to the same light treatments and reared to the second instar on three different levels of hypericin (0.02, 0.04, and 0.20% hypericin/fresh weight diet). Levels of hypericin in the flowers and leaves of *H. perforatum* have been reported to be approximately 0.03% (Brockmann and Sanne, 1957), 0.04% (Pace and MacKinney, 1941), and 0.05% (Brockman et al., 1942) fresh weight. Larvae were reared from egg hatch to the second instar as the previous experiment had shown the first instar to be the most vulnerable stage.

The survivorship data were analyzed as nonparametric three-way contingency tables by the log likelihood statistic G^2 . In each of the experiments, an equal number of larvae were exposed either to the control diet or the hypericin diet under the conditions of either "sunlight" or filtered light. Thus, by necessity, the totals of one margin of the contingency analyses were fixed, presetting the two-way interaction between diet and light at zero. Of interest in these experiments, however, is how survivorship is affected by diet, light, and both parameters conjointly. In the contingency analyses, the interaction between diet and light [DL] is present in all models, leaving only four possible models (instead of the usual eight) to explain the observed data (Fienberg, 1977).

RESULTS

The first experiment monitored the survivorship of the generalist *H. zea* on control diets vs. diets containing 0.10% hypericin. Survivorship was 100% on control diet in both light treatments and on the hypericin diet in filtered light. On the hypericin diet under nonfiltered light simulating sunlight, however, survivorship dropped to 8%. The first model of the three-way contingency analysis, [S] [DL], tests for independence of survivorship from diet and light treatment. The extremely large G^2 of 129.11 indicates that there is a large

amount of variability in the data not explained by the first model (Table 1). Models 2 and 3 test for the interactions of survivorship with diet and survivorship with light, respectively. Neither of these two-way interactions by themselves suffice to explain the data, although subtraction of their G^2 values from that for the initial [S] [DL] model indicates that both [DS] and [LS] are highly significant two-way interactions. The final model (4) tests for the sufficiency of these two-way interactions as descriptors of the data, acceptance of this model implying that no three-way interaction need be inferred. In this instance, the remaining G^2 is conventionally significant, so that the existence of a three-way interaction is inferred. In other words, light affects the survivorship observed on each diet; i.e., high mortality is dependent on exposure of the larvae to both the hypericin diet and nonfiltered light simultaneously, whereas low mortality is observed on the hypericin diet and filtered light.

In the bioassay of the *Hypericum* leaves and extract on *Platynota flavedana* (Table 2), the large G^2 of 23.38 again indicates that there is a large amount of variability in the data not explained by the first model. The two-way interactions of survivorship and light and survivorship and diet obtained by subtraction in models 2 and 3 were again both significant. The low G^2 of 3.79 in model 4 indicates that the two two-way interactions by themselves suffice to describe the data and that a three-way interaction need not be inferred, although this inference (that light and diet act jointly to affect toxicity) hinges on a borderline ($p = 0.15$) probability.

In the final series of experiments, larval survivorship of *P. flavedana* was independent of light and diet at the lower two dosages of hypericin, although there was higher mortality of larvae on the 0.04% hypericin diet under nonfiltered light than under filtered light (Table 3). The highest dosage of 0.20%

hypericin yielded similar results as the initial experiment with *H. zea*. A significant two-way interaction was found between survivorship and diet but not between survivorship and light. The G^2 of 4.30 in model 4 again indicates that the two-way interactions are not sufficient to describe the data and that a three-way interaction must be inferred; that is, high mortality results from exposure to hypericin and sunlight conjointly.

Mean development time (in days) of *P. flavedana* larvae to second instar was analyzed by two-way analysis of variance in each of the three experiments bioassaying the purified hypericin (Table 4). Light consistently prolonged larval development time. On the control diets, development time ranged from 0.7 to 1.2 days longer in simulated sunlight versus filtered light. Similar results were obtained on the lower two dosages of hypericin. On the 0.20% hypericin diet, however, larvae that survived required an additional four days to molt to second instar under "sunlight" as compared to larvae under filtered light. In addition, at this hypericin level, the factor of diet and the interaction of diet \times light also significantly contributed to longer larval development time. Under the clear filter, larval development to second instar was delayed by nearly five days on the hypericin diet compared to the control diet. Larvae on the hypericin diet under the red filter, however, were only two days behind the control diet and only one day longer than those on control diet in "sunlight."

DISCUSSION

The mortality observed for both *P. flavedana* and *H. zea* on hypericin diets exposed to visible light provides evidence that hypericin is phototoxic to insects. The results were particularly dramatic for *H. zea*, a polyphagous lepidopteran not known to feed on *Hypericum perforatum*. Yet despite the toxicity of hypericin to *P. flavedana*, this species commonly utilizes *H. perforatum* as a host plant (Sandberg and Passoa, 1988). In the presence of simulated sunlight on diets containing *Hypericum* leaves, extract, or 0.2% hypericin, larvae either died or experienced significantly longer development time. When reared under filtered light, however, in which the activating wavelengths of hypericin were excluded, there was no difference in survivorship compared to the controls, and only a slightly longer development time. These results suggest that leaf-tying in nature may serve the same function as do the red filters in the laboratory. Leaves are essentially opaque to visible wavelengths (Gates, 1980), and a leaf-tie would therefore protect the larvae from the activating wavelengths of hypericin. The longer development times observed in nonfiltered light on both control diets and hypericin diets by *P. flavedana* may further reflect the fact that these larvae normally feed sheltered from light.

These experiments provide the first experimental evidence that a behavioral preadaptation may allow an insect to exploit a phototoxic plant. Berenbaum (1978) first suggested leaf-rolling as a means of protection from phototoxins for oecophorid specialists on furanocoumarin-containing plants. Champagne et al. (1986) also hypothesized concealed feeding as a means of protection for the larvae of the European corn borer, *Ostrinia nubilalis*. A polyphagous lepidopteran species, *O. nubilalis* may protect itself from the phototoxic polyacetylenes of its host plants in the Compositae by boring into stems or spinning profuse amounts of silk. Avoidance of the phototoxic effects of hypericin by feeding within a shelter may not be an uncommon ploy of other lepidopteran larval feeders on *H. perforatum*. Three other leaf-tying polyphagous tortricids were collected in association with *P. flavedana* on *H. perforatum* in Illinois (Sandberg and Passoa, 1988). Moreover, of 44 lepidopteran species recorded on *Hypericum* (principally from its native range in Eurasia), 25 are concealed feeders, protected from light; of these, 15 are leaf-rollers or tiers, three are case-makers, two are leaf-miners, two are stem-borers, two are seed-borers, and one is a flower-tier (Table 5) (Currie and Garthside, 1932; Wilson, 1943; Johannson, 1962; Hodges, 1974; Bradley et al., 1973, 1979; Sandberg and Passoa, 1988). Since *H. perforatum* was introduced into North America in the grass and grain seeds of early colonists (first recorded in 1785 in Essex County, Massachusetts; Marsh and Clawson, 1930) native Lepidoptera (including the four species of tortricids currently found feeding on *H. perforatum*) have

had only a brief period of association with *H. perforatum* and hence little opportunity to coevolve with the plant. Leaf-tying, leaf-rolling, leaf-mining, and stem-, root-, fruit-, and seed-boring, however, are all characteristic feeding modes of tortricid larvae (Roelofs and Brown, 1982). These larval feeding behaviors initially may have been responses to pressures inflicted by predators and parasitoids (Weed, 1930; Price, 1980; Powell, 1980) and/or mechanisms to optimize the microclimate of the developing larva (Chauvin, 1967). Irrespective of the evolutionary forces that may have selected for their internal feeding habits, some microlepidopteran larvae with broad host ranges may be preadapted for feeding on plants containing phototoxins.

EXPERIMENTAL HABITAT SCENTING INHIBITS COLONIZATION BY BEAVER, *Castor canadensis*

R. GREGORY WELSH and D. MULLER-SCHWARZE

*College of Environmental Science and Forestry
State University of New York
Syracuse, New York 13210*

(Received January 20, 1988; accepted March 21, 1988)

Abstract—Unoccupied beaver (*Castor canadensis*) sites in New York State were for two years experimentally scented with a mixture of beaver castoreum and anal gland secretion. These sites were colonized less often than unscented control sites. The beaver is the first mammal to have been shown experimentally to use intraspecific odor cues when settling in vacant habitat. Territorial pheromones may be useful as repellents for beaver or other rodents.

Key Words—Adirondacks, beaver, *Castor canadensis*, castoreum, nuisance beaver, odors, pheromone, repellent, scent marking, territory, wildlife damage.

INTRODUCTION

Beaver maintain family territories year round and in spring and summer mark them with small scent mounds at the water's edge. With their front paws, the beaver scoop up mud and sticks from the pond, place them on land, and then deposit a mixture of castoreum from the castor sacs and secretion of the anal glands (AGS) on the mound (Aleksiuk, 1968; Hodgdon, 1978; Butler and Butler, 1979; Bollinger et al., 1983; Muller-Schwarze and Heckman, 1980; Svendsen, 1980; Muller-Schwarze et al., 1983).

Beaver scent marks most likely serve several different functions, such as advertisement of territory, orientation within the territory, sex recognition, sex attraction, advertising colony size or composition, or marking food. Aleksiuk (1968) proposed a territorial function, specifically to decrease conspecific contact. Indeed, colonies with closer neighbors constructed more scent mounds than more isolated colonies (Butler and Butler, 1979; Muller-Schwarze and

Heckman, 1980). A scent mark may provide an intraspecific warning signal ("no trespassing") or even a "psychological fence," both decreasing the probability of an agonistic encounter with its risk of injury or even death. As proposed for other mammals (Ewer, 1968) and experimentally demonstrated for rabbits (Mykytowycz et al., 1976), Svendsen (1980) suggested that scent marks affect the motivational state of beaver: They strengthen confidence and reduce anxiety in territory owners, but decrease confidence and increase the readiness to flee in all other beaver. Since beaver place their scent mounds at strategic points within their territories, such as trailheads, feeding sites, or dams (Muller-Schwarze and Heckman, 1980), they may also use them as orientation beacons (Collins, 1976). Finally, beaver discriminate between male and female gland secretions (Hodgdon, 1978; Bollinger et al., 1983). This suggests that this species' scent marks carry individual and sexual information.

The castoreum of the castor sacs consists of numerous compounds, of which over 40 have been identified in the Eurasian beaver, *C. fiber*. These include alcohols, ketones, phenols, aldehydes, and amines, notably "castoramine" (Lederer, 1949). Some major constituents are assumed to be derived from the diet and may vary greatly in concentration, including total absence. The other component of the scent mark is the oily secretion from the anal glands (Døving, personal communication). Gronneberg (1979) found over 60 different wax esters in the AGS of the *C. fiber*. The biological roles of these compounds from either source remain unknown. Recent bioassay experiments showed that several chemical fractions of castoreum release scent marking in resident beaver if the samples are placed in their territories (Muller-Schwarze et al., 1986).

Current beaver population expansion in the American Northeast causes increasing damage to developed land by flooding and destruction of valuable trees. Beaver already had been declared a "major nuisance" in five southern states (Larson and Gunson, 1983) and have also been a problem in several northern states (Parsons, 1978; Peterson and Payne, 1986). Each spring, 2-year-old beaver leave their parental territories and try to establish new colonies, either nearby or by dispersing to sites as far as 320 km away (Libby, 1957). They may settle in any suitable, but increasingly more marginal, site and typically modify it by impounding water. Agricultural or forest lands are often flooded, and roads or railroads damaged by softening of the soil. "Nuisance beaver" traditionally have been removed by live-trapping and transplanting. This, however, has become more expensive and available sites for new introductions are hard to find. Hence a need arose to find new, and more economic means of managing beaver, especially by manipulating their behavior.

This study examines the responses of transient beaver to artificially scented vacant beaver sites. It extends an earlier pilot experiment in Acadia National Park in Maine (Muller-Schwarze and Heckman, 1980) to a managed beaver population of lower density. We asked the question whether beaver are deterred

by artificial scent mounds that mimic site occupancy by an adult pair of beaver. If so, such a territorial demarkation signal may be a potential repellent, in principle, also for other rodents.

METHODS AND MATERIALS

Study Area. The study area was 1287-km² Fulton County, located in the southern foothills of the Adirondack Mountains in New York State. The county-wide beaver population is maintained at 30% maximum occupancy through a controlled trapping program by the New York State Department of Environmental Conservation. Sixty-six percent of the active colonies were located between 0.5 and 2.325 km from their nearest neighbors, with a median density of 0.5 colonies per stream kilometer (Welsh, unpublished observations). Compared with the estimated saturation density of 1 colony/km in northeastern hardwood forests (Nordstrom, 1972), this population is well below saturation level.

Woody vegetation was varied and consisted mainly of northern hardwoods such as beech (*Fagus grandifolia*), maple (*Acer* spp.), and yellow birch (*Betula lutea*), with hemlock (*Tsuga canadensis*), and balsam fir (*Abies balsamea*), on poorer sites. Almost all beaver sites contained some willow (*Salix* spp.), and alder (*Alnus* spp.). Stream gradients were low ($0.90 \pm 0.16\%$) and considered optimal for beaver. The county in general consists of numerous lakes, forests, developed towns and associated rural communities.

Experimental Procedure. The experiment took place in 1983 and 1984. The actual scenting occurred between May 2 and August 24, 1983, and between April 28 and July 31, 1984, the time of the year when transient beaver are most prevalent. Potential study sites were selected during the winters before the two field seasons. Sites were rated according to their resources, including woody vegetation as potential food, water supply, presence and condition of old beaver lodges and dams, and proximity to active beaver sites. Potential sites that were most similar in these categories were paired for two treatments: one site was scented, the other left as control. To keep the sample size large enough for statistical evaluation, we decided not to add a control odor as a third treatment. Care was taken that scented and control sites alternated on any given stream system, so that transient beaver always had a choice between two roughly equivalent sites that differed only in their treatment. Such a pair of sites could be located up- and downstream of an active colony, or on both arms of a stream fork. Fifty sites were chosen for study (24 experimental and 26 control) in 1983, and 46 sites (23 experimental, 23 control) in 1984.

The scent used in the experiment consisted of homogenized castor sacs and anal glands from adult beaver trapped the previous winter from areas in New York State that were well outside the study area. Ten pairs of glands, from five

males and five females, were blended to mimic a "mated pair odor." The resultant paste was transferred to Teflon bottles and stored at -10°C .

At the onset of the field season, six artificial scent mounds were constructed at each site along the water's edge by transferring stream substrate with a 1-liter plastic tub onto the shoreline. Experimental mounds then received 1 g of the castoreum-AGS mixture; the control mounds remained unscented. Two mounds each were placed beside the old lodge if one existed, on the shoreline opposite the lodge, and on either side of the main dam (or remnants of a dam), as well as 20 m both upstream and downstream of the center of the site, covering the potential immigration routes.

Every 14 days, each site was examined for signs of beaver occupancy such as fresh cutting, dam or lodge building, feeding, tracks, feces, or scent mounds. All mounds were rebuilt and sites rescented. When water levels dropped, old mounds were destroyed and new ones placed near the new waterline. We compared the results by a 2×2 test for independence with the G statistic.

RESULTS AND DISCUSSION

During the two years of the study, more control sites than scented sites were colonized ($P < 0.05$; G test; Table 1). This result is striking if one considers the many potentially intervening variables, notably a severe drought in summer 1983 and localized heavy fur-trapping. The drought affected the study by completely drying up 20% of the sites. In another 16% the water dropped to a level that probably hampered a beaver's foraging in the surrounding woodland.

Since only 30% of the county's suitable beaver sites were occupied, the beaver had a wide choice of alternative sites and could afford to avoid many of

TABLE 1. NUMBERS OF SCENTED AND CONTROL SITES COLONIZED BY BEAVER, *Castor canadensis*, DURING EXPERIMENT IN ADIRONDACK FOOTHILLS, FULTON COUNTY, NEW YORK^a

our study sites. If, on the other hand, the population density were very high, even less attractive sites would likely be colonized, including those with beaver scent. In fact, an unexploited beaver population in a similar Eastern hardwood ecosystem in Allegany State Park, Cattaraugus County, New York, reached a density of 1.03 colonies/km of stream (Muller-Schwarze et al., 1986). There beaver colonized marginal habitat with stream gradients of up to 6.44%. In this case an attempt to prevent colonization of four sites by artificial scenting failed (Muller-Schwarze, unpublished observations). Thus, if competition for space is intense, scenting will not prevent transients from settling. However, if colonizing beaver have a choice, we believe a conspecific odor can be effective as a repellent.

The results of the present study together with its precursor (Muller-Schwarze and Heckman, 1980) demonstrate for the first time that experimentally used conspecific odor cues, the putative "territorial marks," will affect colonization by a free-ranging wild mammal. In birds, an experiment with auditory cues has shown that conspecific song from loudspeakers can delay the moving of male great tits (*Parus major*) into empty territories (Krebs, 1976).

Our study suggests that pheromones can deter beaver and possibly other rodents or larger mammals from entering areas where they may become a nuisance. To consider pheromones for practical applications, several biological conditions must be met: First, the animals should not habituate to the odor during the period of application, usually a complete breeding season. The avoidance response is most likely stronger if reinforced by encounters, particularly hostile, with conspecifics and would wane over time if odor alone were applied. A repellent, however, could still be effective for short periods of time. Second, it is important to know how different age and sex classes respond to the odors being considered for application. The same odor may attract one sex or age and repel the other. For example, in muskrats (*Ondatra zibethica*) adults of both sexes avoided live traps scented with male musk during the breeding season, but immature muskrats did not discriminate between scented and unscented traps (Berk and Muller-Schwarze, 1984). Third, the odor has to be sufficiently species-specific to not attract other animal species, notably predators, that could interfere with the samples.

Once suitable odors have been found for practical application, it is important to emphasize that measures other than scenting should be taken. First, odors should be but one component of a comprehensive wildlife management program. Second, the odor should be formulated so that it is long-lasting in any weather, cost effective to manufacture, and easy to apply. This requires chemical identification of the active constituents, and embedding them into a slow-release matrix. Third, there should be a choice of scented and unscented sites. This is possible only in populations that are not too dense.

In summary, beaver pheromones hold promise as repellents that may prevent colonization of certain sites under well-understood ecological circumstances, but further studies are required to develop an efficient method of their application.

Acknowledgments—This study was funded by the New York State Department of Environmental Conservation. We thank Gary Parsons and Dr. Paul Bishop for providing aerial survey data and other help; James Oakes and Douglas Lansburg for beaver glands; Kathryn Fessenden for volunteer field work; Robert Cotter for assistance in the field; and Dr. Robert M. Silverstein for critically reading the manuscript.

FEEDING AND OVIPOSITION PREFERENCES OF
SWEET POTATO WEEVIL, *Cylas formicarius
elegantulus* (SUMMERS), ON STORAGE ROOTS
OF SWEET POTATO CULTIVARS WITH
DIFFERING SURFACE CHEMISTRIES

Abstract—Cores from sweet potato [*Ipomoea batatas* (L.) Lam.] storage roots (Centennial, Jewel, Resisto, and Regal cultivars) were presented to sweet potato weevils [*Cylas formicarius elegantulus* (Summers) (Coleoptera; Curculionidae)] in multiple-choice, limited-choice, and no-choice bioassays. Centennial, a susceptible cultivar in field-plot experiments, was preferred for feeding and oviposition by female weevils in choice bioassays, and for oviposition in no-choice bioassays, compared to three other cultivars. Analysis of root surface chemistry showed a tentatively identified triterpenol acetate in Centennial, which was not found in the more resistant cultivars; another root surface component was found in higher concentrations in the more resistant cultivars.

Key Words—Sweet potato weevil, *Cylas formicarius elegantulus*, Coleoptera, Curculionidae, *Ipomoea batatas*, feeding, oviposition, host-plant preference, host-plant resistance, root surface chemistry.

INTRODUCTION

A major constraint to sweet potato production worldwide is the sweet potato weevil, *Cylas* spp. (Edmond, 1971; Schalk and Jones, 1985; Sutherland, 1986), which causes substantial losses both in the field and during postharvest storage (Pillai and Nair, 1981; Talekar, 1982; Mullen, 1984). All parts of the plant are consumed, while eggs are laid singly in the storage roots (Reinhard, 1923; Cockerham et al., 1954). The development of insect-resistant sweet potato lines is seen as a viable component in the integrated management of this pest (Martin and Jones, 1986). Varying levels of resistance to *Cylas formicarius elegantulus* (Summers) have been shown for sweet potato cultivars in the field, in small field-plot tests (Cockerham and Deen, 1947; Cockerham and Harrison, 1952; Waddill and Conover, 1978; Rolston et al., 1979; Mullen et al., 1980b, 1981, 1982), and in laboratory bioassays (Mullen et al., 1980a; Barlow and Rolston, 1981; Nottingham et al., 1987). Resistance in the field studies may have been due to escape, for example, by having long thin storage roots set deep in the soil and scattered within growing hills (Cockerham et al., 1954; Jayaramaiah, 1975), tolerance (Velusamy and Heinrichs, 1986), antixenosis (nonpreference) (Kogan and Ortman, 1978; Singer, 1986), antibiosis (Painter, 1951), or a combination of any of these. The latter two types of plant resistance, which involve modification of insect behavior and metabolism, may have a chemical basis. Host-plant chemistry can potentially modify any stage of the weevil's host-location and utilization behavior from host finding (volatiles) through feeding and oviposition (surface chemicals) to larval development in the roots (internal root chemistry).

A methylene chloride root surface extract (Centennial cultivar) has been shown to stimulate oviposition in female weevils (Wilson et al., 1988). Two cultivars, Centennial and Jewel, known to be susceptible to the weevil in the field (Mullen et al., 1981) were used in these bioassays, along with two more recently developed cultivars having moderate levels of resistance, [Resisto (Jones et al., 1983) and Regal (Jones et al., 1985)]; methylene chloride extracts of these cultivars were analyzed using gas chromatography techniques (Son et al., 1987). The objective of this study was to compare the levels of feeding and oviposition on root cores with root surface chemistries in order to identify which chemical components might be responsible for the root extract modifying weevil behavior.

METHODS AND MATERIALS

Insect Rearing. Sweet potato weevils [*Cylas formicarius elegantulus* (Summers)] were reared in the laboratory on sweet potato storage roots in cages

held at 28°C and 65% relative humidity. Sweet potatoes used for rearing and bioassays were grown on the University of Georgia Horticulture Farm in 1986, harvested, cured, and stored at 15°C. Roots used in this study had been in storage five to seven months. Adult weevils were transferred to fresh potatoes every seven days; old potatoes were then incubated at room temperature until the new generation emerged. Emerging weevils were collected weekly and held in cages with potatoes until required for bioassays, between the ages of 20 and 35 days.

Bioassays. The bioassay used was an adaptation of one previously described by Mullen et al. (1980a) (Nottingham et al., 1987). Forty-eight male or female sweet potato weevils of known age were placed in plastic cages (32 × 24 × 10 cm) under experimental conditions (28°C, 90–100% relative humidity and 0:24 light–dark) 2 hr prior to treatments being introduced. Cores of sweet potato storage roots were taken with a cork borer (No. 11) and placed in 24-well Falcon tissue culture plates, such that the cores fitted in the wells (diam. 1.6 cm, depth 2 cm, area 2 cm²) with only the root periderm exposed. Four sweet potato cultivars were used: Centennial, Jewel, Resisto and Regal. These were presented in three different arrangements to the weevils:

(1) In the multiple-choice bioassay, the four cultivars were randomized within a 24-well plate (Nottingham et al., 1987). One plate was exposed to either 48 males or 48 females in each of four cages. (2) In the limited-choice bioassay, a choice of two cultivars, one cultivar in a block in each half of a 24-well plate, was presented to 48 females in each of six cages, such that all six combinations of the four cultivars occurred. (3) In the no-choice bioassay only one cultivar was presented in a 24-well plate in each of four cages to 48 females. For each type of bioassay, all weevils were taken from the same age batch and treatments were run at the same time.

After 24 hr, feeding punctures were counted. Beyond this time, the punctures tended to merge and reduce counting efficiency. After 48 hr, the plugged oviposition punctures were counted (Nottingham et al., 1987). Data were analyzed by analysis of variance, with orthogonal contrasts between treatments.

To obtain root periderm extracts, whole roots were submerged in a beaker containing methylene chloride and extracted for 9 min in an ultrasonic bath (Son et al., 1987). After solvent reduction on a roto-evaporator, a portion was taken down to dryness under nitrogen and treated with a silylation reagent, trimethylsilylimidazole-pyridine (1:3), for 1 hr at 76°C. After cooling, samples were analyzed by capillary gas chromatography on a 0.3-mm-ID × 25-m thin-coated SE-54 fused silica capillary column (temperature program 150–290°C at 4°C/min). Gas chromatograph profiles of all four cultivars were obtained, and extract component levels were calculated using an internal standard method (hexacosanol) and root surface area data, obtained by peeling periderm from storage roots and passing it through a LI-COR 3000 area meter.

RESULTS

In the multiple-choice bioassay, Centennial was preferred by female weevils for both feeding and oviposition, compared to the other three cultivars, which had similar levels of feeding and oviposition (Table 1). Males were found to have low levels of feeding on the roots (between 2.2 and 3.5 feeding punctures per 24 hr on average), compared to females, and no differences in feeding levels for males occurred between the four cultivars. Centennial was preferred by female weevils to each of the three other cultivars in the limited-choice bioassays for feeding and oviposition (Table 2). Jewel and Resisto were preferred to Regal for feeding and oviposition. A hierarchy of preference would place Centennial first, Jewel and Resisto intermediate, and Regal last, for both feeding and oviposition.

Female weevils had higher levels of feeding on Centennial and Regal than on Resisto in no-choice bioassays (Table 3). Weevils had higher levels of oviposition on Centennial than all three other cultivars in no-choice bioassays, while higher levels occurred on Resisto than Regal.

The gas chromatograph profiles of the root surface extract components of the four cultivars showed qualitative (Figure 1) and quantitative differences (Table 4). Centennial had a major component (peak 5), a triterpenol acetate, that was not present in the other three cultivars. Peak 2, which only occurred for Centennial, was the corresponding free alcohol of this compound (Son et al., 1987). Additionally, Centennial had a lower level of the component in peak 4 than the other three cultivars.
