There are two types of chemical assays for tannin and other phenolics: General phenolic assays and specific functional group assays. These assays can be used to determine the amount of tannin and the chemical nature of the tannin in a sample. When interpreting data from chemical assays for tannin, it is essential to fully understand the specificity of each assay. Several of these assays have been reviewed (Tempel, 1982; Mole and Waterman, 1987a,b).

Redox Assays. The general phenolic assays measure properties of phenols, such as their redox potential or their ability to complex various metals. Redox assays such as the Folin (Folin and Denis, 1915; Swain and Hillis, 1959) or Prussian blue (Price and Butler, 1977) assays are used to determine total phe-

nolics. It must be recognized that these methods do not discriminate between tannin and nontannin phenolics or between phenolics and other easily oxidized material such as ascorbic acid. The two assays are similar in sensitivity; both require timed addition of several reagents, and both are susceptible to interferences from redox active compounds including ascorbic acid and thiol reagents. The nonprotein imino acid *N*-methyl-*trans*-4-hydroxyl-L-proline gives a large response with the Folin assay (Figliuolo et al., 1987), as do some common purine bases (Ikawa et al., 1988). The Folin assay was modified by Lowry (Pederson, 1979) to enhance its sensitivity to protein; both proteins and phenolics, including tannin, respond in the Lowry assay. Protein does not give a significant response in the Prussian blue assay, although purine bases do interfere (Hagerman and van Pottelsberghe, unpublished). We recommend that the Prussian blue assay be used for general phenol analysis because it is less susceptible to interference from proteins than is the Folin assay.

Metal Complexing. Assays based on the formation of colored phenolic-metal ion complexes are more specific than the redox assays since the color of the complex depends on the pattern of substitution on the phenolic ring (Wesp and Brode, 1934). Although nonphenolics such as protein do not react in these assays, nontannin phenolics respond positively. Ferric chloride reacts with phenolic compounds in alkali to form complexes with the general formula $\text{Fe}(\text{OR})_6^{3-}$, where (OR^-) represents the ionized phenol (Wesp and Brode, 1934). Various phenolics, including condensed and hydrolyzable tannins, form violet complexes with ferric ion in solutions containing sodium dodecyl sulfate and triethanolamine (Mole and Waterman, 1987a). This method is appropriate for determining total phenolics in samples containing materials that interfere with the redox methods.

In neutral solution, condensed and hydrolyzable tannins form ferric ion complexes with distinctive colors. Mole and Waterman (1987a) found that condensed tannin yields green complexes with ferric ion, while hydrolyzable tannin yields blue complexes. However, Grove and Pople (1979) point out that the color of phenolic-ferric ion complexes does not provide an unambiguous means of discriminating substitution patterns of various phenolics, so this method must be used with caution. We recommend that the more specific functional group assays described below be used to distinguish condensed from hydrolyzable tannins.

Methods for assaying and for isolating phenols based on the formation of phenol-metal ion complexes have been suggested but are not suitable for general use. A gravimetric method for total phenols based on precipitation of the phenolic by ytterbium has been described (Reed et al., 1985), but it has not been widely adopted. Although it has been suggested that lead selectively pre-

precipitates tannin, other phenols form complexes with lead (Robinson, 1980), and therefore we do not recommend that precipitation by lead be used as a criterion for distinguishing tannin from other phenols.

Functional Group Assays. The functional group assays detect and measure specific molecular structures. With functional group assays, the structural differences between condensed and hydrolyzable tannin are exploited to obtain selective methods of analysis. Although chromatographic methods have been used to detect and differentiate condensed and hydrolyzable tannins (Howard, 1987), the methods described here provide more convincing evidence for the presence of specific types of tannin.

The acid butanol assay is specific for proanthocyanidins (condensed tannins) if the optimized reaction conditions described by Porter et al. (1986) are used. This method is generally the best assay for selective determination of condensed tannins. In this assay, the flavonoid subunits of the condensed tannin polymer are oxidatively cleaved to yield the anthocyanidin; the reaction does not involve hydrolysis, and color development is decreased by water. Because color yields are dependent on the solvent, standards must be dissolved in the solvent to be used for the final analysis. Acid butanol can also be used to detect leucoanthocyanidins (flavan-3,4-diols, flavan-4-ols) by using different reaction conditions (Watterson and Butler, 1983).

The vanillin assay (Price et al., 1978) is specific for flavanols (Sakar and Howarth, 1976) and thus can be used to selectively determine condensed tannin in the presence of hydrolyzable tannin or other phenolics. Widely distributed flavanols such as catechin and epicatechin respond to this assay and could compromise the results unless an independent assay is used for confirmation. Although analogs of vanillin can be used in the assay to increase sensitivity (Putnam and Butler, 1985), the assay as described by Price et al. (1978) is adequately sensitive for most applications. The correction for "blank" color (Price et al., 1978) is essential to this method.

The vanillin and proanthocyanidin assays can be combined to provide a measure of the degree of polymerization of condensed tannin (Butler et al., 1982). This approach to determining the molecular weight of condensed tannin is feasible in situations where methods (Foo et al., 1982) relying on sophisticated spectroscopic techniques are impossible. It is particularly useful for comparing the condensed tannin from materials at different stages of plant maturity (Butler, 1982).

The recently developed rhodanine assay (Inoue and Hagerman, 1988) is specific for gallic acid esters and can be used to determine gallotannin-type hydrolyzable tannins. This assay is not subject to the ambiguities of the iodate assay previously used to determine hydrolyzable tannin (Bate-Smith, 1977; Mole

and Waterman, 1987a), and we recommend that it be adopted instead of the iodate assay. The method is not specific for tannin, since any esterified gallic acid, including low-molecular-weight, nontannin species, will react.

An appropriate assay for ellagitannin-type hydrolyzable tannins has not been devised (Bate-Smith, 1972; Mole and Waterman, 1987a). Ellagic acid can be chromatographically identified (Haddock et al., 1982).

PROTEIN-BINDING ASSAYS

Protein-binding assays can be used either to determine the amount of tannin in a sample or to determine the biological activity of the tannin. To quantitate tannin via protein binding, the amount of tannin precipitated by a standard protein is measured. For biological activity assays, either the amount of protein precipitated by the tannin in a sample is determined, or the nature of the complexes formed between tannin and protein is established. Some authors suggest use of an alkaloid, such as caffeine, instead of protein as the precipitating agent (Wall et al., 1969), but protein binding methods have been better characterized and are preferable. Several protein binding methods have been reviewed by Mole and Waterman (1987b).

Each of the protein-binding assays gives rather different responses with different preparations of tannin. The tendency of tannin to form insoluble complexes with proteins is a complex function of factors including features of the tannin (molecular weight, structure heterogeneity) and the protein (degree of glycosylation, amino acid composition, molecular weight) and the reaction conditions (pH, temperature, reaction time, relative concentrations of reactants). The complexity of the reaction between tannin and protein means that results of protein precipitation assays can be compared directly only to results obtained under virtually identical conditions. In addition, the results of those assays must be interpreted cautiously.

Tannin precipitated by protein can be measured directly in a reaction that depends on the formation of the ferric ion-phenol complex in alkaline, detergent-containing solution (Hagerman and Butler, 1978). This assay is simple to perform, gives excellent results with either condensed or hydrolyzable tannin, and is recommended as a reliable assay for most situations. However, if the procedure is modified so that a large excess of protein is used, soluble tannin-protein complexes form and complicate the data treatment (Hagerman and Robins, 1987).

The radial diffusion method (Hagerman, 1987) is a very simple assay suitable for determining insoluble tannin-protein complexes. The amount of precipitated complex is proportional to the amount of tannin in the sample. Both

condensed and hydrolyzable tannin can be determined with the method. The radial diffusion assay is particularly suitable if a large number of samples are to be analyzed or if laboratory facilities are limited.

The amount of protein precipitated by tannin-containing samples can be used to estimate the biological activity of the tannin (Robbins et al., 1987). Protein precipitated by tannin can be measured radiochemically (Hagerman and Butler, 1980a) or colorimetrically (Bate-Smith, 1973; Schultz et al., 1981; Martin and Martin, 1983; Asquith and Butler, 1985). Of these methods, the blue BSA method (Asquith and Butler, 1985) is probably the easiest to perform, but it is not very sensitive. If colorimetric methods such as the Lowry assay (Pederson, 1979) or Bradford (Coomassie blue) assay (Martin and Martin, 1983) are used to determine protein in mixtures of tannin and protein, special effort must be made to ensure that all tannin is removed from the mixture before it is assayed, since these assays respond positively to tannin as well as to protein. The radiochemical assay is the most sensitive and least susceptible to interference but requires sophisticated instrumentation and techniques.

The amount of protein precipitated is proportional to the amount of tannin present in the sample if the tannin-to-protein ratio has been set properly to control the formation of soluble tannin-protein complexes (Calderon et al., 1968; Mole and Waterman, 1987b; Hagerman and Robbins, 1987). Excess protein in the reaction mixture decreases the amount of precipitable complex that forms, resulting in an apparent decrease in the amount of tannin present. Methods like the blue BSA (Asquith and Butler, 1985) or hemoglobin precipitation assay (Schultz et al., 1981) can be used to determine the amount of tannin in a sample only under carefully controlled conditions.

The biological activity of tannin is not dependent on the formation of insoluble tannin-protein complexes. Assays that detect both soluble and insoluble complexes are therefore necessary for estimation of biological activity of tannin. Formation of soluble or insoluble tannin-protein complexes can be detected using competitive binding assays (Hagerman and Butler, 1981; Asquith and Butler, 1985), immobilized tannin (Oh et al., 1980; Austin et al., 1988), electrophoresis (Austin et al., 1988), or enzyme inhibition (Goldstein and Swain, 1965). The competitive binding assays are the most generally applicable methods for detecting soluble complexes.

The biological activity of tannin is mediated by the affinity of tannin for proteins; tannin has a high affinity for some proteins and lower affinity for other proteins. Competitive binding methods can be used to determine the affinity of protein for tannin (Hagerman and Butler, 1981; Asquith and Butler, 1985). These assays can be used to determine affinity both in systems in which soluble complexes form and in systems in which insoluble complexes form. The procedure used by Asquith and Butler (1985) is simple and recommended for most

situations. Other methods of determining binding constants include equilibrium dialysis (Barbeau and Kinsella, 1983) or ultrafiltration (Artz et al., 1987); however, it is difficult to completely eliminate possible artifacts arising from interaction between the phenolic material and the dialysis or ultrafiltration membrane. Calorimetry has been used to investigate soluble tannin-protein complexes, but it is applicable only to conditions quite unlike physiological conditions (McManus et al., 1981).

COMBINED ASSAYS

By combining chemical and protein-binding assay data, diverse tannin samples can be compared. For example, tannin-specific activity (Hagerman and Butler, 1980b) has been defined as the amount of protein precipitated by a tannin sample (Hagerman and Butler, 1980a) divided by the total phenol content of that sample (Price and Butler, 1977). That parameter can be used to compare the contamination of tannin preparations, since the tannin-specific activity increases, as nontannin phenolics are removed from the preparation (Hagerman and Butler, 1980b). The tannin-specific activity can also be used to compare preparations from different plants (Mole and Waterman, 1988).

A somewhat different parameter, the tannin-phenol ratio, has been devised to allow comparison of various tannin samples. This ratio is obtained by dividing the amount of protein precipitable phenols (Hagerman and Butler, 1978) by total phenols (Price and Butler, 1977). This ratio has been used (Butler, 1982) to establish the amount of nontannin phenolics in crude plant extracts, but was incorrectly called tannin-specific activity in that paper.

For condensed tannins, the precipitation-size ratio, or amount of protein precipitated (Hagerman and Butler, 1980a) divided by the flavan-3-ol end units (Butler et al., 1982), can be used to determine how activity changes as the molecular weight of the tannin changes (Table 1). It is generally believed that moderate-sized condensed tannin polymers precipitate protein more efficiently than either very small or very large polymers (Haslam, 1979).

TANNIN STANDARDS

It is a practical impossibility to devise a simple extraction procedure that yields chemically pure tannin, so the analyst must devise a way to determine tannin in crude extracts that contain tannin, tannin-complexed proteins, and nontannin phenolics. The crude extracts must be compared with standard tannins in order to make estimates of the tannin content of the samples, expressed in terms of the chosen standard. Selection of a suitable standard is critical if meaningful

TABLE 1. PROTEIN PRECIPITATED PER FLAVANOL END GROUP^a

Tannin	Chain length	BSA ppt/ flavanol end group ^b (mg/A520)
Pinto bean	2.9	257

results are to be obtained from the analyses. Two types of tannin standards can be used: absolute standards and relative standards.

Suitable tannin standards for determining the *absolute* amount of tannin in a given plant could be obtained only by purifying the standard from the plant of interest, a procedure recommended by Wisdom et al. (1987). However, that approach is not simple. Most plants contain several chemically distinct types of tannin, often including both condensed and hydrolyzable tannins (Haslam, 1979). Not only may the ratio of the chemical species change with environmental, physiological, and seasonal changes, but also the extractability of the various molecular forms may change (Hatano et al., 1986; Baldwin et al., 1987; Hagerman, 1988). Adequate characterization of the pure tannin obtained is necessary to ensure that it is truly pure and to identify all the chemical species present. Even in simple systems containing only condensed tannin (e.g., *Sorghum* grain) obtaining pure tannin is laborious (Hagerman and Butler, 1980b). For more complex plant systems, obtaining a representative pure tannin standard for the absolute determination of tannin may well be impossible.

Using commercially available standards, relative amounts of tannin can easily be determined. The assay is standardized with the commercial standard, and the tannin in the plant extracts is then reported in terms of the weight of the selected standard. Nontannin phenolics are sometimes adequate standards. For example, the rhodanine assay and the various total phenol assays can be standardized with reagent-grade gallic acid, and the vanillin assay can be standardized with commercial catechin. The acid butanol assay can be standardized with commercial cyanidin, although that standardization would be most appropriate for procyanidin, not for prodelphinidins or other proanthocyanidins.

Tannic acid is probably the best commercially available tannin standard,

but ideally the commercial material should be purified. A simple purification using Sephadex LH20 (Hagerman and Klucher, 1986) yields an appropriate standard for the rhodanine assay, for any of the redox assays, or for any precipitation assay. Tannic acid cannot be used to calibrate the acid butanol assay. Unpurified commercial preparations of tannic acid contain variable amounts of low-molecular-weight galloyl esters and of nontannin material (Table 2). Each of these preparations is a unique mixture of galloyl esters, and each has a different ability to precipitate protein (Weerasuriya, Wilson and Hagerman, unpublished). If unpurified commercial tannic acid is used as a standard, its source must be indicated clearly because the preparations are so variable in composition.

Although tannic acid is an appropriate standard for analysis of tannins, it may be an inappropriate material to use for *in vivo* tests of the biological activity of tannin. Recent work (Robbins and Hagerman, unpublished) suggests that tannic acid does not affect nitrogen utilization in ruminants, whereas other hydrolyzable tannins diminish nitrogen utilization. It is not surprising that a material might be appropriate as a chemical standard but quite inappropriate for bioassay.

Sorghum tannin is an appropriate standard condensed tannin, but it is not available commercially and is rather tedious to purify (Hagerman and Butler, 1980b). Quebracho tannin is the only readily available condensed tannin. It must be purified (Asquith and Butler, 1985) because it contains large amounts of nontannin materials. There are probably substantial differences among the materials provided by various suppliers and even among various lots from a single supplier. Since a single commercial standard is not available, we suggest that all workers start to use purified quebracho standard prepared from a single

TABLE 2. GALLIC ACID IN VARIOUS PREPARATIONS OF TANNIC ACID^a

Tannic acid source	Total GA (mg/mg TA)	Ester GA (mg/mg TA)
Sigma (pfs) ^b	0.633	0.546
MCB reagent	0.689	0.598
Mallinckrodt technical ^c	0.691	0.610
Mallinckrodt reagent	0.449	0.413
Mallinckrodt purified ^d	0.809	0.766

^aTotal gallic acid and free (unesterified) gallic acid were determined with the rhodanine assay (Inoue and Hagerman, 1988) in triplicate for each sample of tannic acid, and esterified gallic acid was calculated by difference. TA = tannic acid, GA = gallic acid.

Abstract—The lubber grasshopper, *Romalea guttata*, is a generalist feeding on a broad diet of many herbaceous plant species and has a metathoracic defensive secretion normally containing phenolics and quinones synthesized by the insect. When insects were reared on a restricted diet of wild onion, they sequestered sulfur volatiles from the plant into their defensive secretions. These compounds were not detected by gas chromatography–mass spectroscopy in secretions of insects on an artificial diet or a natural, generalist diet of 26 plants that included wild onion as a component, nor were they present in secretions from field-collected insects. Defensive secretions of insects reared on wild onion were significantly more deterrent, by as much as an order of magnitude, to two species of ant predators than secretions from insects on either of the other two diets, despite a reduction in the concentration of autogenous defensive chemicals in secretions of insects on the onion

diet. Sequestration of plant chemicals that increased defensive efficacy occurred when diet breadth was reduced. We suggest that this occurs because under conditions of specialization, plant secondary metabolites are more likely to be ingested and bioaccumulated in sufficient concentrations to have biological activity against predators. What we define as casual bioaccumulation of bioactive plant chemicals following dietary specialization may lead to evolution of sequestered defense syndromes in insects, and this process may not necessarily require specific adaptation to or coevolution with a toxic host plant.

Key Words—Lubber grasshopper, *Romalea guttata* (microptera), Orthoptera, Acrididae, onion, generalist diet, artificial diet, sulfur volatiles, ant predation, casual bioaccumulation, specialization, evolution of defenses.

INTRODUCTION

Many herbivorous insect species use chemical defenses against predators (Duffey, 1976; Blum, 1981; Pasteels et al., 1983a). In some cases, autogenous defensive chemicals are made by the insect from dietary precursors. Alternatively, chemicals from the diet may be sequestered into the body tissues, fluids or glands with or without modification by the insect. Examples of sequestered defenses include cardenolides in the monarch butterfly (Brower, 1984), milkweed bug (Duffey and Scudder, 1972), and pyrogomorphid grasshoppers (Rothschild and Parsons, 1962); salicylaldehyde in some chrysomelid beetles (Pasteels et al., 1983b); and cardenolides and pyrrolizidine alkaloids in some arctiid moths (Rothschild and Aplin, 1971).

The ecological factors that initiate or constrain evolution of the sequestered defense syndrome are of considerable interest but poorly understood. It has been suggested that sequestered defenses initially evolved as a special insect adaptation for avoiding toxicity of specific chemicals in the host plant, by placing these chemicals out of harm's way in tissues or fluids. Storage of these compounds then subsequently conferred a selective advantage against predators (Brower and Brower, 1964; Rothschild, 1973). An alternative possibility is that the sequestered defense syndrome may arise as a consequence of what we term initial casual sequestration or bioaccumulation of ingested chemicals in body tissues (Duffey, 1976, 1980). The chemicals may not necessarily be toxic to the insect, and specific adaptation to a host plant may not be necessary. Bioaccumulated compounds might then deter predators if they were sequestered in sufficient concentrations. In this article we present evidence that two key characteristics of a sequestered defense syndrome—incorporation of plant chemicals into defensive secretions, and a concomitant increase in defensive efficacy against predators—can arise in an insect when there is no evidence for specific adaptation to a plant species, when the plants are not toxic to the insect, and in

a manner best described as casual sequestration. Furthermore, we show that diet breadth is the major ecological variable that determines whether or not sequestration of at least one class of plant chemicals occurs in sufficient amounts to have effects on predators.

The lubber grasshopper, *Romalea guttata* (Houttuyn) [Orthoptera; Romaleidae = *R. microptera* (Beauvois)] (Kevan, 1980), is a large, flightless, generalist grasshopper with a local host range of over 80 species of herbaceous and woody plants. Many of these plants will be eaten within the lifetime of an individual insect (C.G. Jones, D.W. Whitman, M.S. Blum, unpublished data). Adult *Romalea* have an impressive defensive armory, including warning coloration, a pink wing-flashing display and sharp spines on the legs. Most notable is the odoriferous, frothy, glandular secretion produced with an audible hiss from modified metathoracic spiracles (Eisner et al., 1971). This secretion is deterrent to ants and other predators (Eisner et al., 1971; D.W. Whitman, C.G. Jones, M.S. Blum, unpublished data). The major components of the secretion of wild insects are various phenolics and quinones, including hydroquinone, catechol, *p*-benzoquinone, phenol, guaiacol, and 4-methoxybenzaldehyde (Eisner et al., 1971; Jones et al., 1986, 1987). These compounds are presumably autogenous because they are found in the secretions of insects reared on an artificial diet that does not contain any of these chemicals (Jones et al., 1987). The autogenous defensive components are markedly affected by diet breadth. Restricting *Romalea* to a single host plant or artificial diet results in a reduction in the number and concentration of compounds, and thus alters the composition of the secretion, compared to lubbers reared on a generalist diet or collected in the field (Jones et al., 1987).

Eisner et al. (1971) showed that *Romalea* collected from an area sprayed with the herbicide 2,4-D had 2,5-dichlorophenol in the defensive secretion. We therefore wondered if *Romalea* was capable of sequestering natural plant products into the defensive secretion. In our studies on the effects of diet breadth on autogenous defenses (Jones et al., 1987), we noticed that the secretions of insects reared on a single host plant diet of onion appeared to have an onionlike odor. Here, we evaluated the possibility that sequestration of onion compounds might have occurred. We reared *Romalea* from first instar to adult on three different diets: (1) a restricted single plant species diet of wild onion, *Allium canadense* L., that we have observed is one of a number of favored food plants of *Romalea* (C.G. Jones, D.W. Whitman, M.S. Blum, unpublished data); (2) a "natural" generalist diet of plant species used by *R. guttata* in the field, which included wild onion as a component species; and (3) a restricted artificial diet known to lack any of the insects' autogenous phenolics and quinones and lacking any plant secondary metabolites. We compared the chemistry of secretions from insects reared on the different diets. We then bioassayed the secretions against a known ant predator of *Romalea*, the red imported fire ant, *Solenopsis invicta*

Buren (Formicidae: Myrmicinae), and a less aggressive ant species, *Tapinoma melanocephalum* F. (Formicidae: Dolichoderinae). Our findings are relevant to the ecology and evolution of chemical defense in insects.

METHODS AND MATERIALS

Rearing of Insects. Lubber grasshoppers were reared under the same conditions as used by Jones et al. (1987). The first of the three diets consisted of freshly cut leaves of *Allium canadense* in water. The second diet consisted of 26 species from 15 families of shrubs, herbs, forbs and grasses known to be eaten by *Romalea* in the field (C.G. Jones, D.W. Whitman, M.S. Blum, unpublished data). Plants were collected daily and the petioles or stems placed in water. The species list was as in Jones et al. (1987) and included wild onion, *Allium canadense*. The third diet was an artificial diet (Dadd, 1960) containing cellulose, sucrose, dextrin, mineral salts, cholesterol, linoleic acid, casein, pectone, egg albumin, ascorbic acid, and B vitamins and was fed as a water-moistened cake. Ten males and 10 females were also collected from the field for chemical analysis of their secretions.

Secretion Collection. Secretions were collected from adults at the eighth day after the terminal molt, by gently squeezing the thorax while applying a 10- μ l microcapillary to the metathoracic spiracule orifices. A single milking removes all the secretion produced since the last molt. Molting insects discard all previous secretions. The volume collected (range 1–8 μ l) was recorded and the secretion sealed in the microcapillary and stored at -10°C . Secretions from insects reared in the same batch on the different diets were randomly allocated for: (1) separately pooled secretions of males and females for mass-spectral analysis, (2) secretions from individual females and pooled secretions of females for quantitative analysis of sequestered compounds, (3) secretions from individual females for quantitative analysis of autogenous compounds, and (4) pooled secretions of females for bioassays. In addition, separately pooled secretions of wild male and female insects were subjected to mass-spectral analysis.

Qualitative Analysis of Secretions. Compounds were identified from splitless injection (10 psi) of undiluted secretion on a Finnigan 4021 gas chromatograph-mass spectrometer (GC-MS) using a 30-m \times 0.3-mm-ID DB-5 fused silica bonded phase column (J&W), programmed at 50°C for 1.5 min, then $100\text{--}250^{\circ}\text{C}$ at $15^{\circ}\text{C}/\text{min}$. The GC-MS was operated in electron impact mode (70 eV, 1400 V, 10^{-7} amp/V; scanning 45–350 amu, 1.5 sec/scan) with acquisition commencing at sample injection. Compounds were identified by using the molecular ions and characteristic mass fragments, by comparison with library spectra (*r* fit), and by GC-MS of authentic standards. Pooled secretions col-

lected from 10 individual males and females reared on each of the three diets and 10 males and females collected in the field were analyzed by GC-MS.

Quantitative Analysis of Sequestered Compounds. Diethyl ether extracts of secretions were analyzed by subambient, capillary gas chromatography (GC) (Varian 6000), using a 30-m \times 0.32-mm-ID fused silica bonded phase column (J&W, DB-5), helium carrier (2 ml/min) splitless injection (200°C, purge at 0.7 min), and flame ionization detection (300°C, 1×10^{12} sensitivity). Initial column temperature was 20°C, ramped to 40°C at 10°C/min, then 40°C/min to 200°C and held at 200°C for 2 min. Secretions from eight individual females and the pooled secretions of three females reared on the onion diet were each extracted with 10 μ l redistilled diethyl ether and immediately analyzed by GC. The 2.5- μ l aliquots were injected, and exact volumes of ether recovery and reproducibility were determined by addition of *dl*-alpha pinene to the ether as an internal standard, prior to extraction (325 μ mol/liter). We determined the concentration of eight sulfur-containing volatiles as the mean of three replicate injections: 1-propanethiol (minimum detectable quantity per microliter, 14 pg), methylthiirane (5 pg), methyldisulfide (21 pg), isopropylsulfide (11 pg), 2,5-dimethylthiophene (30 pg), methylpropylsulfide (13 pg), isopropylsulfide (28 pg), propylsulfide (25 pg). Retention times were accurate to $\pm 1\%$ ($P = 0.05$); peak heights with tangent baseline correction were accurate to $\pm 10\%$ ($P = 0.05$), based on analysis of standards and replicate injections of pooled samples, and were measured on a Varian 402 integrator. Retention times and concentrations of compounds were determined by calibration against authentic standards and confirmed by using coinjection and independent injection. Standards were commercially available, except for methylpropylsulfide, which was synthesized by the method of Carson and Wong (1959). Combined concentrations were determined from the sum of the concentrations of each compound.

Quantitative Analysis of Autogenous Compounds. Secretions were analyzed for six phenolics and quinones (hydroquinone, *p*-benzoquinone, phenol, catechol, guaicol, 4-methoxybenzaldehyde) using tertiary gradient reverse-phase high-performance liquid chromatography (HPLC) on a C_{18} bonded-phase silica column with a water-methanol-1% H_3PO_4 convex elution gradient, according to the method of Jones et al. (1986, 1987). Secretions from 10 individual females reared on each diet were diluted to 1% in 18 mohm deionized water, and triplicate 10- μ l aliquots were analyzed. Combined concentrations of phenolics and quinones were determined from the sum of the concentrations of each compound.

Bioassay of Secretions. In preliminary binary choice experiments, we determined that ants preferred pure sucrose solutions to those containing wild *Romalea* defensive secretions (D.W. Whitman, C.G. Jones, M.S. Blum,

unpublished data). We therefore decided that relative deterrence of the three different secretions was best determined by simultaneously comparing the secretions against one another, when they were made up in sucrose solution. Five laboratory colonies of *Solenopsis invicta*, varying in size from 1000 to 4000 individuals, were each presented with a 45 × 75-mm glass slide containing three separate 50- μ l droplets of 4% sucrose. Each separate droplet contained 1 μ l of *Romalea* metathoracic secretion pooled from individual females reared on either the natural, the onion, or the artificial diet. Ants foraged down a common trail to this comparative bait station. The common foraging trail prevented recruitment to one bait from affecting the total number of foragers approaching the bait station and reduced any biases due to the deterrence of a given bait. The number of ants feeding on each droplet was recorded every 4.5 min, up to the time that the first of the sucrose baits with secretion was completely consumed. Trials were repeated three times for each colony, with the order of the three droplets on the slide being changed for each trial. It was determined that the number of ants visiting the station initially increased, stabilized by 10 min, and remained more-or-less constant for over 30 min. Therefore the number of ants at each bait at 40 min was recorded for each colony and trial. These data were analyzed using ANOVA followed by multiple comparisons (least-significant-difference tests).

Two laboratory colonies of *Tapinoma melanocephalum* (colony size no more than 3000 individuals) were tested using the above procedures. Ten percent sucrose solution containing secretions was used because this species of ant did not recruit sufficient numbers to 2% pure sucrose solution to permit adequate evaluation of deterrence. Trials were repeated twice. In addition, pairwise comparisons of artificial diet secretion (1 μ l) + 10% sucrose versus natural diet secretion + sucrose, and natural diet + sucrose versus onion diet + sucrose were also carried out using the glass slide technique. Three lab colonies were used with five repeated trials each. Again, the number of ants visiting the baits at 20 min was recorded. Data in these trials were analyzed as above.

RESULTS

Sequestration of Plant Compounds. The secretions of insects reared on the wild onion diet lacked the characteristic color and odor of secretions from insects on the natural diet and had a marked onionlike odor. GC-MS of the volatile fraction of pooled secretions from males and females showed the presence of a large number of sulfur-containing compounds (C.G. Jones and P.J. Silk, unpublished data). Eight compounds were unambiguously identified (isopropylsulfide, methylpropylsulfide, isopropylsulfide, methylsulfide, propylsulfide, propanethiol, methylthiirane, and 2,5-dimethylthiophene) and were

identical to those previously isolated and identified from onion (Carson and Wong, 1961; Brodnitz et al., 1969; Boelens et al., 1971). The total concentrations of these eight onion sulfur volatiles that were generally the most abundant in the secretions were quantified in the defensive secretions of eight adult female individuals reared on the onion diet. Mean concentration of all eight of these compounds combined was 0.5 ng/ μ l (Figure 1a). None of these sulfur volatiles, nor any other sulfur-containing compounds, were detected in GC-MS analyses of pooled secretions from male or female insects reared on the natural or artificial diet (pooled from 10 of each sex on each diet), or from secretions pooled from 10 individuals of each sex of field-collected insects occurring in an area where a diversity of plant species grow, including wild onion. In a separate rearing experiment, sulfur volatiles were detectable by odor and GC-MS in defensive secretions of insects within five days of transfer from artificial to onion diets.

Autogenous Compounds. Secretions from insects raised on either onion or the artificial diets contained significantly lower concentrations of all autogenous phenolics and quinones than secretions from insects on the generalist, natural diet. Combined phenolic and quinone concentrations were depressed fivefold on the artificial diet and 37-fold on the onion diet (Figure 1b). The concentrations of autogenous compounds in secretions of insects on onion diets were also significantly lower than concentrations in artificial diet secretions (t tests, $P < 0.0001$). These new data agree with our previous findings for autogenous compounds (Jones et al., 1987).

Efficacy of Defensive Secretions. To determine whether changes in the secretion chemistry affected biological activity, we bioassayed secretions against two ant species. The imported fire ant, *Solenopsis invicta* Buren, is a very aggressive predator of insects (Lofgren et al., 1975). This ant species did not evolve in the same habitat as *Romalea guttata*, but we have observed predation by *Solenopsis* on *Romalea* in the field (D.W. Whitman, C.G. Jones, M.S. Blum, unpublished data). *Tapinoma melanocephalum* F. is a less aggressive, omnivorous scavenger sympatric with *Romalea* in Florida (Creighton, 1950). We estimated the relative deterrence of the defensive secretions. With *Solenopsis invicta*, significantly more ants visited and fed at the artificial diet secretion bait compared to the natural diet secretion bait, and significantly more ants visited and consumed both of these baits compared to the onion diet secretion bait (Figure 1c shows means \pm 1 SE). Overall effect of treatments was significant: ANOVA: $F = 16.42$, $df = 44$, $P = 0.0001$. All means in multiple comparisons were significantly different from each other, LSD t tests, $\alpha = 0.05$.) Approximately 63, 30, and 7% of all foraging ants visited and fed at the artificial, natural, and onion diet secretion baits, respectively.

The less aggressive ant, *Tapinoma*, showed even greater differences between treatments. In trials where all three secretion baits were presented

together, the proportion of ants visiting and feeding at the baits was approximately 70 (artificial diet), 29 (natural diet), and 1% (onion diet) (mean \pm 1 SE number of ants at bait at 20 min for two colonies and two trials was: artificial 13.3 ± 3.4 ; natural 5.0 ± 1.6 ; onion 0. ANOVA: $F = 9.55$, $df = 11$, $p = 0.006$. All pairs of means in multiple comparisons were significantly different from one another, LSD t tests, $\alpha = 0.05$). In comparisons with *Tapinoma*, where pairs of secretions were tested together, the number of ants at artificial diet secretion baits at 40 min (mean \pm 1 SE = 14.9 ± 1.7) was significantly greater than the number at natural diet secretion baits (mean \pm 1 SE = 7.0 ± 1.4 ; ANOVA: $F = 8.43$, $df = 49$, $p = 0.007$). Numbers at 40 min at natural diet secretion baits (mean \pm 1 SE = 45.1 ± 4.4) were significantly greater than numbers at onion diet secretion baits (mean \pm 1 SE = 0.3 ± 0.16 ; ANOVA: $F = 35.49$, $df = 49$, $p = 0.0001$).

DISCUSSION

Diet clearly affects the quality and quantity of the chemical components of the defensive secretion of *Romalea* and the efficacy of the defensive secretion against these predators. Sequestration of measurable quantities of sulfur compounds occurred only when *Romalea* specialized on the onion diet. The natural diet also included wild onion as a component species, and yet secretions from insects reared on this diet did not contain any detectable sulfur-containing compounds, nor were these compounds found in field-collected insects that fed on a large number of plant species. Since these compounds were not present in the artificial diet, their absence from secretions of insects specializing on this diet was to be expected. In addition, specialization on either artificial or onion diets again caused a reduction in the concentrations of autogenous phenolics and quinones, as has been previously reported (Jones et al., 1987).

The response of ants to baits containing these secretions is consistent with the chemical differences resulting from the presence of sequestered compounds and the depression of autogenous compounds. Sequestration of sulfur com-

FIG. 1. (a) Mean combined concentrations of eight sulfur-containing volatiles (ng/ μ l secretion, \pm 1 SE) in defensive secretions of individual adult female *R. guttata* ($N = 8$), reared on an onion diet. Pooled secretions of females ($N = 10$) on the other diets did not contain detectable levels of sulfur volatiles. (b) Mean combined concentrations of six autogenous phenolics and quinones (ng/ μ l secretion, \pm 1 SE) in defensive secretions of adult female *R. guttata* ($N = 10$), reared on three diets. (c) Mean number of *Solenopsis invicta* ants (\pm 1 SE, five colonies, three trials each) visiting and feeding at 20 min on sucrose baits containing defensive secretions of *R. guttata* females reared on three diets.

pounds in onion diet secretions is associated with an increase in defensive efficacy compared to natural diet secretions, despite depression of the concentrations of autogenous phenolics and quinones. Reduction of autogenous phenolic and quinone concentrations in artificial diet secretions is associated with a reduction in the efficacy of defense compared to natural diet secretions. The deterrent activity of components sequestered on the restricted onion diet appears to be much greater than the activity of the autogenous compounds. The combined sequestered sulfur compounds occurred at concentrations about 10^4 lower in onion diet secretions than combined concentrations of phenolics and quinones in the natural diet, and yet the onion diet secretion bait was visited and fed on by *Solenopsis* at about one quarter the rate of the natural diet secretion bait.

Dietary specialization in *R. guttata* therefore led to rapid and simultaneous changes in two attributes important to its chemical defense: acquisition of compounds directly from the diet and a reduction in autogenous compounds. This led to a concomitant increase in defensive efficacy. Experimental specialization in *Romalea* produces results strikingly similar to many specialist insect herbivores where chemical defense against predators depends upon sequestration of host-plant chemicals (Brower, 1984; Rothschild, 1973; Roeske et al., 1976; Duffey, 1976, 1980; Blum, 1981).

Why should specialization result in sequestration in *Romalea*? We propose that the degree of sequestration of plant chemicals in this insect is primarily a function of the concentration of compounds ingested in the diet. When a generalist diet is consumed, compounds from an individual plant species may be too dilute to be detectable or biologically active against predators in comparison to the autogenous compounds. Conversely, specialization results in the ingestion of sufficiently high concentrations of compounds from one plant species such that these compounds may be sequestered in detectable levels that have biological activity. Interestingly, data from Eisner and coworkers (1971) may be relevant to our contention. They reported 2,5-dichlorophenol in the defensive secretion of *R. guttata* collected in herbicide-sprayed areas and suggested that this compound was derived from the herbicide 2,4-D. 2,5-Dichlorophenol was not present in secretions of insects from unsprayed areas. Although in this case *Romalea* was consuming a generalist diet, it may have been, in effect, specializing on a halogenated phenol diet because all of the plants were sprayed with herbicide.

Our results may have important implications for understanding the evolution of plant-derived chemical defense in insects. What we term casual bioaccumulation of plant chemicals active against predators may be an important process that initiates selection toward the plant chemical-based defenses found in many insects. Bioaccumulation of natural and synthetic chemicals is a widespread phenomenon (Duffey, 1980). A large number of plants contain high levels of biologically active compounds, and a general relationship between

concentration of such compounds in the diet and subsequently in the body does exist for many organisms (Duffey, 1980). It follows that situations in which a high concentration of compounds are ingested may be more likely to lead to concentrations of plant compounds in herbivorous insects that are active against predators. Our data on *R. guttata* suggest that the ecological equivalent of this dose relationship is diet breadth. Generalist consumers may be less likely to sequester chemicals in bioactive concentrations than their specialist counterparts because the generalist diet dilutes the concentrations of specific compounds ingested from each plant. It is possible that initiation of the evolution of sequestered defenses may arise when an insect feeds on a single host plant or limited numbers of species because casual sequestration of chemicals occurs in sufficient amounts for these compounds to be active against predators. If so, evolution of sequestered defenses may not necessarily initially require a high degree of adaptation or coevolution with a toxic host plant, as has been previously suggested.

JUGLONE REDUCES GROWTH, NITROGENASE ACTIVITY, AND ROOT RESPIRATION OF ACTINORHIZAL BLACK ALDER SEEDLINGS

(Received July 27, 1988; accepted August 31, 1988)

Abstract—European black alder trees [*Alnus glutinosa* (L.) Gaertn.] fix nitrogen with nodular symbionts and are interplanted with valuable black walnut trees (*Juglans nigra* L.) to increase soil nitrogen fertility. However, on some soils interplanted alder can be killed by black walnut's allelochemical juglone. In order to better understand the effects of juglone directly on the growth, nitrogen fixation, and root respiration of black alder, we grew nodulated alders hydroponically in a nitrogen-free nutrient solution at juglone levels of 2×10^{-6} , 2×10^{-5} , and 0 molar (M). Results indicate that nitrogenase activity (acetylene reduction) of alders growing in 2×10^{-5} M juglone was reduced relative to alders without added juglone after one day, and in 2×10^{-6} M juglone after five days. Root respiration (CO_2 evolution) and the relative increase of plant fresh weight were reduced in the 2×10^{-5} M juglone treatment. In a related experiment, black alder germinants were grown in Flanagan silt loam soil dosed with 10^{-3} , 10^{-4} , and 0 M juglone. The inhibitory effects of 10^{-3} M juglone on radicle elongation ceased 22–37 days after juglone treatments were started, suggesting that this soil can readily detoxify juglone.

Key Words—Acetylene reduction, allelopathy, *Alnus glutinosa*, black walnut, *Frankia*, *Juglans nigra*, juglone, nitrogen fixation, root respiration.

INTRODUCTION

Black walnut (*Juglans nigra* L.) is able to inhibit the growth of many plant species (Cook, 1921; Strong, 1944; Gabriel, 1975) through its allelochemical juglone (5-hydroxy-1,4-naphthoquinone). In living tissue this compound is in

a reduced, nontoxic form called hydrojuglone (Gries, 1943; Lee and Campbell, 1969), but when plant tissue is incorporated into the soil, hydrojuglone is oxidized and toxic juglone is released (Rietveld, 1983).

Plant species show varying responses to the presence of juglone (Funk et al., 1979; Rietveld, 1983). The effect of juglone on black alder trees [*Alnus glutinosa* L. (Gaertn.)] is of particular interest because of its use as a nitrogen-fixing intercrop with commercially valuable black walnut. Of 16 herbaceous and woody species tested for juglone sensitivity, black alder was one of five most inhibited in seedling shoot elongation and dry weight accumulation, showing depressed growth at a concentration as low as 10^{-6} M juglone (Rietveld, 1983). Rietveld et al. (1983) also reported the sudden decline and death of black alder as a result of juglone toxicity in four mixed plantings with black walnut 8–13 years after planting.

Juglone also affects the nitrogen-fixing endophyte of black alder. A concentration of 10^{-4} M juglone inhibited in vitro growth of the symbiotic actinomycete *Frankia* (Dawson et al., 1981; Dawson and Seymour, 1983; Vogel and Dawson, 1985, 1986). Nodulation of black alder by *Frankia* was also significantly depressed by the addition of 10^{-4} M juglone to soil (Vogel and Dawson, 1985).

One mechanism by which juglone is thought to affect plant growth is through a reduction in respiration. Perry (1967) reported the inhibition of oxygen uptake by leaf disks of tomato (*Lycopersicon esculentum* Mill.) and bean (*Phaseolus vulgaris* L.) at juglone concentrations greater than 10^{-5} M. Similarly, juglone concentrations as low as 5×10^{-5} M reduced O_2 uptake in excised corn roots (Köeppe, 1972).

Edaphic conditions may influence the toxicity of juglone. On well-drained soils, red and white pine (*Pinus resinosa* Ait. and *P. strobus* L.) did not exhibit any adverse allelopathic effects when interplanted with walnut, but on imperfectly and poorly drained soils, pines growing with walnut showed poorer survival and growth than pines without adjacent walnut (Fisher, 1978). In the same study, a bioassay of "wet" and "dry" soils dosed with juglone showed that inhibition of radicle extension in red pine and detection of juglone (using thin-layer chromatography) occurred for a substantially longer period of time in the "wet" soil. Fisher considered this evidence that microbial degradation of juglone is determined by the moisture regime and, hence, aeration of the soil. He thought it less likely that differences in soil moisture had affected the sorption of juglone by the soil. Microorganisms that break down aromatic and phenolic substances similar to juglone are aerobic heterotrophs (M. Alexander, 1977). Schmidt (1988) isolated a bacterium (*Pseudomonas* J1) from soil beneath black walnut trees that could grow rapidly using juglone as its sole source of carbon and energy.

As well as possibly limiting microbial degradation of juglone, a wet soil will reduce the O_2 available for root respiration. What effect the presence of

juglone may have on root respiration of trees, in particular trees growing under reduced-oxygen conditions as occur in wet soils, is unknown. But given that O_2 uptake of other plants and plant tissues is reduced in the presence of juglone, it is likely that reductions in root respiration will occur in soil or other substrates as oxygen levels decrease. In nature, low oxygen conditions in wet soils may both slow juglone degradation and compound the inhibitory effects of juglone on plant respiration.

We hypothesized that the toxicity of juglone to black alder germinants would decline over time after dosing a fertile soil suitable for walnut culture and that the rate of that decline would be lower in wet soil. We also hypothesized that growth, acetylene reduction, and root respiration of nitrogen-fixing black alder grown hydroponically would be reduced when juglone is added and when the level of oxygen available to the roots is reduced.

The first experiment was designed to assess the rate at which a fertile soil detoxifies added juglone. The second experiment in hydroponics excluded the effects of microbial degradation and soil sorption of juglone and examined the direct effects of juglone and oxygen level on nitrogenase activity in alder root nodules and respiration in alder roots.

METHODS AND MATERIALS

Experiment 1. An experiment to measure the changes in juglone toxicity over time in wet and dry soils was carried out in a temperature-controlled environment, based on a completely randomized design with two juglone levels and a control, two soil moisture regimes, five replications, and four time intervals.

Soil for the experiment was a Flanagan silt loam (Aquic Argiudoll), somewhat poorly drained, with an average surface organic matter content of 4.5% and high available water capacity (J.D. Alexander et al., 1974). It was taken from a site close to Urbana, Illinois, and was collected using a soil coring device 1.6-cm in diameter. The cylindrical soil cores of length 10 cm and volume 80.5 cm³ were placed over 2 cm³ of glass beads inside test tubes of the same internal diameter and incubated at 27°C. Air dry weights of soil cores ranged from 20 to 26 g.

The three soil treatments consisted of a control of distilled water without juglone, 10^{-4} M and 10^{-3} M juglone. A 10^{-3} M solution is at the limit of juglone solubility in water. After determining the field capacity of the soil, soil cores were allowed to dry to 30% of their field capacity, after which 6 ml of the appropriate juglone or control solution were added. This brought the moisture in the soil up to field capacity.

Two soil moisture treatments were used. In the "wet" regime, there was a cycle in which the soil was dried to 90% of field capacity and was rewet with distilled water to field capacity. In the "dry" regime, soil was dried to 50% of field capacity and was rewet with distilled water to 70% of field capacity. Loose-

fitting caps were used for both treatments, allowing gas exchange while maintaining a high relative humidity inside the test tubes.

At intervals of 4, 22, 37, and 52 days after treatment, a bioassay of the soil was performed using black alder seedlings three days after germination with radicles about 1 mm in diameter. Soil was removed from the test tubes and placed in Petri dishes 5 cm in diameter. After measuring their initial radicle lengths, seven black alder germinants were sown in each dish, and the dry soil was brought up to field capacity. Dishes were kept in a growth chamber at 27°C for 48 hr, after which radicle length was measured again. Radicle elongation in the bioassay was statistically analyzed using three-way analysis of variance, the factors being level of juglone applied, moisture, and time.

Experiment 2. An experiment to measure the response of black alder seedlings to juglone and aeration was carried out under ambient temperature conditions and artificial lighting in a laboratory. A randomized design with three juglone levels, two aeration levels, and three replications was employed. A hydroponic medium was chosen rather than a soil medium so that aeration levels could be controlled and to minimize or eliminate microbial degradation and sorption of juglone that normally occur in soil.

The three treatments were a control lacking juglone, 2×10^{-6} M and 2×10^{-5} M juglone. These concentrations were chosen on the basis of the results of a hydroponic study of the sensitivity to juglone of several woody species including black alder (Rietveld, 1983). In this study, 10^{-6} M juglone did not cause a significant reduction in shoot and root dry weight production of black alder, but 10^{-5} M did. Juglone was dissolved in 1 liter of water and added to the nutrient solution.

The air flow rates for the low and high aeration treatments were 5–10 ml/min and 350 ml/min, respectively.

The experiment was conducted on a bench top under a combination of fluorescent and incandescent light, using a 16-hr photoperiod. Depending on the height of the plant, the light intensity at the terminal leaf ranged from 300 to 600 $\mu\text{mol}/\text{m}^2/\text{sec}$ of PAR (photosynthetically active radiation, 400–700 nm in wavelength). The temperature in the room ranged between 10 and 25°C.

Black alder seed was sown in a medium containing peat and Perlite. Thirty-seven days after germination, seedlings were transplanted to 12-cm-deep pots containing sterile sand. Ten cm^3 of complete nutrient solution (Hewitt, 1952) were applied biweekly. After 56 days, all seedlings were inoculated with 0.4 cc packed cell volume (1000g for 15 min) of *Frankia* isolate ArI3 obtained from Berry and Torrey (1979). Twenty-five days later, the seedlings were transferred to aerated 1-liter Erlenmeyer flasks containing an aerated nitrogen-free nutrient solution (Hewitt, 1952). The solution pH was 6.0, and solutions were changed weekly. Quarter-strength Hoagland's solution was used for 16 days, after which full-strength solutions were used. Eighteen and 19 days after transfer to hydro-

ponic culture, pretreatment measurements were made of acetylene reduction and CO₂ evolution. The juglone and aeration treatments were imposed on the following day. Measurements of acetylene reduction and CO₂ evolution were made every day for three days, every second day for eight days, every fourth day for 12 days, and finally 61 days after treatments were started. Bud set in all seedlings occurred between the second to last and last measurement dates.

At each measurement date, acetylene reduction and CO₂ evolution were assessed on two replicates of each treatment. Plants that had the greatest nodule development at the start of the experiment were chosen. Measurements were also made on control plants lacking nodules.

Gas-impervious Saran bags were used for assaying acetylene reduction and CO₂ evolution. A plant was removed from the nutrient solution and the base of the stem was wrapped in Plastilina (modeling clay). A length of hollow glass tubing with a rubber serum stopper attached to the outside end was embedded in the Plastilina to allow gases to be injected and withdrawn from the bag. The root system of the plant was placed inside the bag, and string was drawn tightly around the bag and Plastilina to form a gas-tight seal.

At the start of the assay, air was evacuated from the bag, and 400 ml of air from well-ventilated space in the laboratory was injected using a 50-ml syringe. Injected air samples had CO₂ concentrations similar ($\pm 5\%$) to that of ambient atmospheric air in the autumn in central Illinois. After an incubation of 30 min, duplicate 10-ml samples were withdrawn from the bag and placed in separate Vacutainer tubes (Becton Dickinson, Rutherford, New Jersey) for subsequent analysis of CO₂ concentration. Air in bags without plants was also sampled to determine the ambient CO₂ concentration. Immediately, another 20 ml of air was withdrawn from each bag, and 40 ml of pure acetylene was injected to give a 10% concentration surrounding the root. After an incubation of 1 hr at $20 \pm 1^\circ\text{C}$, duplicate 10-ml samples were withdrawn directly through the wall of the Saran bag and placed in Vacutainer tubes for determination of ethylene and acetylene concentrations.

A gas chromatograph (Hewlett Packard 5890) equipped with flame ionization detector (FID) was used to measure the concentration of ethylene and acetylene. A nickel column 1.5 m long \times 3.175 mm OD was packed with 100–120 mesh Porapak N. Acetylene was used as an internal standard when calculating acetylene-reduction activity (McNabb and Geist, 1979). The same gas chromatograph with a thermal conductivity detector was used to measure the concentration of CO₂ (Dean and Harper, 1986). A stainless-steel column 6 m long \times 3.175 mm OD was packed with 100–120 mesh Porapak N for CO₂ analysis.

Because acetylene reduction and CO₂ evolution were assessed repeatedly on the same plants, it was not possible to determine either nodule or root dry weight at each measurement date. To overcome differences in activity due to

differences in plant size, acetylene-reduction and CO₂-evolution activity are expressed per gram of plant fresh weight at the start of the experiment. Furthermore, acetylene reduction and CO₂ evolution varied widely from one day to the next, although all treatment responses tended to follow the same pattern. Variation in the temperature of the growth room on nights prior to the assays probably caused the fluctuations in plant activity (Table 1) (Dixon and Wheeler, 1983). To eliminate the effects of daily temperature fluctuation on acetylene-reduction and CO₂-evolution rates for the two juglone treatments, values are expressed as a percentage of control plant activity on each particular day.

Before juglone was added, plants randomly chosen for the 2×10^{-6} M treatment had higher acetylene-reduction and CO₂-evolution rates than plants chosen for the 2×10^{-5} M treatment. Therefore, between-treatment comparisons are not valid. The test of least significant difference (LSD) was used to determine whether acetylene reduction and CO₂ evolution of plants within a treatment changed over the period of the experiment relative to the control plants. Aeration level did not detectably influence activity and data were combined to provide a greater sample size.

Acetylene reduction on a nodule dry weight basis was calculated for the final measurement date.

^a Means based on four plants.

^b Acetylene reduction and CO₂ evolution expressed on the basis of plant fresh weight at the start of the experiment.

At the start of the aeration and juglone treatments and at the end of the experiment, plant fresh weight was measured. Because of differences in plant size, growth during the experiment is expressed in relative terms. Mean relative growth rate (RGR) is the change in plant size per unit time per unit growing material (Sestak et al., 1971).

RESULTS

Experiment 1. Results of analysis of variance for the bioassay (Table 2) indicate that the effects of juglone treatment and time were highly significant ($P < 0.0001$). Radicle elongation of alder germinants exposed to soil dosed with 10^{-3} M juglone averaged 7.9 mm, significantly ($P < 0.05$) less than mean values for radicles exposed to soil dosed with 10^{-4} M (8.4 mm) or no juglone (8.7 mm). At each time period, root elongation was significantly different, although the response pattern cannot be interpreted in terms of an effect of treatments over time. The alder germinants grew least in treated soil at time 1 and grew best at time 2; times 3 and 4 had intermediate values for radicle elongation. Differences in the soil moisture regime apparently did not affect juglone's ability to inhibit radicle elongation.

The response of alder germinants to different juglone levels with increasing time following dosing is illustrated in Figure 1. In the bioassay four days after treatments were started, radicle elongation in soil dosed with 10^{-3} M juglone was significantly ($P < 0.05$) less than in soils dosed with 10^{-4} M juglone or the control treatment. By day 22, radicle elongation in the 10^{-3} M treatment was again significantly smaller than those in the control, although the difference was much less marked. The bioassay on day 37 showed that radicle elongation

in the control and 10⁻³ M treatments did not differ, although seedlings in the 10⁻⁴ M grew less. There were no differences on day 52.

Experiment 2. There was a significant ($P < 0.0005$) effect of juglone on the relative rate of plant fresh weight accumulation over the period of the experiment (Table 3). Seedlings grown in 2×10^{-5} M juglone had a growth rate of -0.014 g/g/week, significantly less than seedlings in 2×10^{-6} M juglone and the control, which had rates of 0.042 and 0.047 g/g/week, respectively. The aeration treatments and the interaction between juglone and aeration levels did not significantly affect relative growth rates of alder seedlings.

The acetylene-reduction activity of seedlings (Figure 2) decreased after five days of exposure to both 2×10^{-5} M and 2×10^{-6} M juglone. Activity remained low in these plants throughout the rest of the experiment. For example, prior to treatment, seedlings that were subsequently exposed to 2×10^{-5}

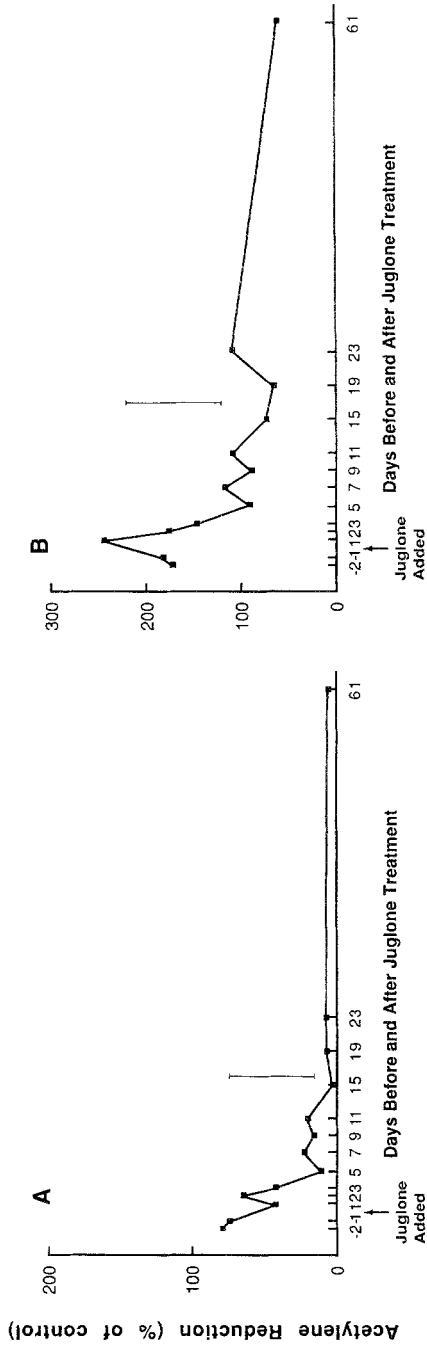

FIG. 2. Rate of acetylene reduction of black alder seedlings treated with 2×10^{-5} M juglone (A) and 2×10^{-6} M juglone (B) expressed as a percentage of the control acetylene reduction rate. Bars are LSD ($P < 0.05$).

M juglone had acetylene-reduction rates 79 and 74% that of control seedlings. After five days of exposure to juglone, the rate had declined to 11% of the mean control rate and remained depressed for the rest of the experiment, yielding a final value 5% that of the control. Seedlings grown in 2×10^{-6} M juglone solutions had pretreatment rates 173 and 182% that of the control mean, and after five days, the rate had declined to 90% of the average value for control seedlings. At the final measurement date, these seedlings were reducing acetylene at a rate 61% that of control seedlings.

When expressed on a nodule dry weight basis, plants in the control, 2×10^{-6} M, and 2×10^{-5} M treatments had acetylene-reduction rates of 32.58, 23.10, and $3.46 \mu\text{mol/g}$ (dry weight)/hr, respectively, at the final measurement date.

The relative rate of CO_2 evolution of seedlings in the two juglone treatments is shown in Figure 3. In the 2×10^{-5} M juglone treatment, seedlings had pretreatment CO_2 -evolution rates 119 and 112% that of control seedlings. After one day of exposure to juglone, the rate had declined to 76% that of control seedlings, and after seven days to 45% of the rate of control seedlings. From day 11 onward, the specific rate of CO_2 evolution relative to that of control plants steadily increased, yielding a final rate of 109% that of control seedlings after 61 days. There was much fluctuation in CO_2 evolution in the 2×10^{-6} M juglone treatment, and no pattern could be discerned.

DISCUSSION

The results of the bioassay of soils dosed with juglone differ markedly from those reported by Fisher (1978). In his study, using a Brant sandy loam, red pine (*Pinus resinosa* Ait.) seedlings subjected to different soil moisture regimes were inhibited by 50 ppm of juglone on an air-dry soil weight basis. In the drier soil, inhibition declined over time but was still apparent after 45 days, while in the wetter soil, inhibition also declined over time, but was still apparent after 90 days. Fisher proposed that the decrease in juglone toxicity over time was due primarily to microbial degradation rather than soil sorption, and microbial activity could be affected by the moisture regime of the soil.

In our study, 10^{-3} M juglone (equivalent to a mean of 45 ppm by soil air-dry weight, and therefore similar to the treatment concentration in Fisher's study) ceased to inhibit radicle elongation between 22 and 37 days after treatments began and 10^{-4} M juglone had no effect. Moreover, the wet and dry treatments had no effect on the seedling response. The more rapid detoxification of juglone in our study compared to that in Fisher's study may be due to the different soils used for the bioassay. Fisher used a fine sandy loam that had been planted to pine, whereas our soil was an organically rich, prairie-derived soil

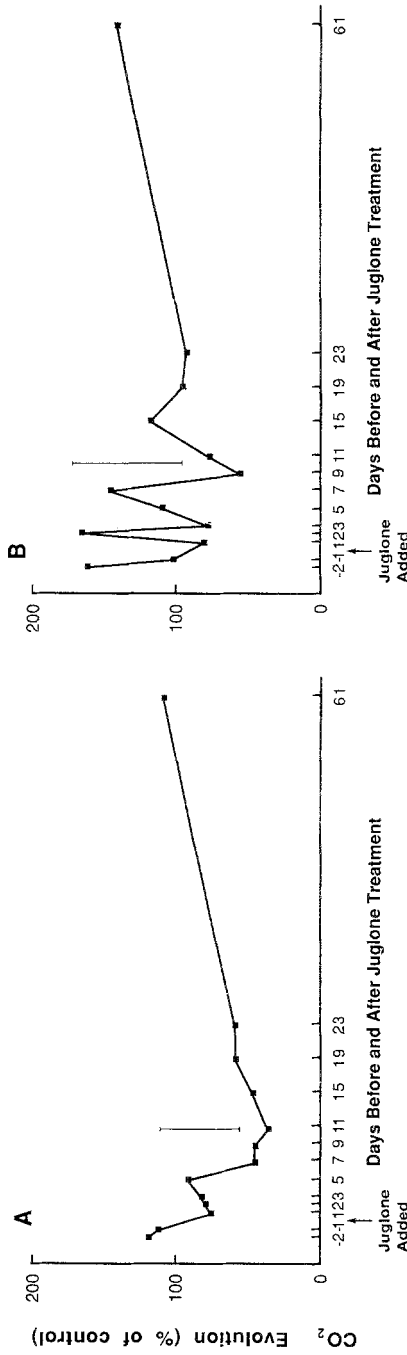

FIG. 3. Rate of CO₂ evolution of black alder roots treated with 2 × 10⁻⁵ M juglone (A) and 2 × 10⁻⁶ M juglone (B) expressed as a percentage of the control CO₂ evolution rate. Bars are LSD (P < 0.05).

that is used extensively for crop production. Native black walnut trees occurred close to the abandoned agricultural field from which our soil samples were taken. Microbial activity would probably be higher in the rich prairie soil, and therefore breakdown of juglone would be more rapid. Alternatively, juglone may be adsorbed more readily in a soil high in organic matter (Ponder, 1987). The absence of a moisture effect in our bioassay indicates that soil sorption may be more important than microbial degradation in detoxifying juglone in the rich prairie soil, or that juglone is subject to anaerobic attack by microbes (Schmidt, 1988).

An attempt was made to quantify the concentration of juglone in the soil at the end of each bioassay using a chloroform extraction technique (Ponder and Tadros, 1985) together with gas chromatography (FID and a 25-m fused capillary column). This proved unsuccessful due to the high diversity and quantity of soil organic materials that apparently prevented the segregation of juglone peaks in the chromatographs.

The hydroponic experiment, by eliminating the effects of soil microbial degradation and soil sorption of juglone, allowed us to measure the direct effect of juglone on plant growth, acetylene reduction, and root respiration without the complicating factors inherent in soils. Rietveld (1983) found that a concentration of 10^{-6} M juglone did not significantly affect the root and shoot growth of black alder in hydroponic culture, but that 10^{-5} M juglone caused a significant inhibition. In our study, 2×10^{-5} M juglone also caused a significant reduction in growth; however, 2×10^{-6} M juglone did not affect growth, confirming Rietveld's findings.

Prior to this work, there had been no studies of the effect of juglone on nitrogen fixation of plant species that have *Frankia* as their symbiont; however, the growth of *Frankia* cultures in vitro has been shown to decrease as juglone concentration increases (Dawson et al., 1981; Dawson and Seymour, 1983). Vogel and Dawson (1985) found that the in vitro growth of four of five *Frankia* isolates was inhibited by 10^{-5} M juglone and that all isolates were inhibited by 10^{-4} M juglone. In addition, nodulation of black alder in soil by *Frankia* isolate ArI3 was reduced at juglone concentrations of 10^{-3} and 10^{-4} M. In our study, the same *Frankia* isolate ArI3 was used to nodulate the black alder seedlings. Acetylene reduction activity in both the 2×10^{-5} and 2×10^{-6} M juglone treatments was reduced in vivo. The reduction in respiration reported in this experiment may explain black alder's reduced nitrogenase activity as estimated by acetylene reduction, since nitrogen fixation is an energy-demanding process.

Black alder is generally regarded as a species that improves the nitrogen fertility of soils (Dawson et al., 1983; Rietveld et al., 1983) via the incorporation of fixed nitrogen in sloughed root tissue and litter into the soil. In a study of juglone allelopathy, total soil nitrogen to a depth of 61 cm under black alder-black walnut interplantings, in which alder was visibly injured, and under wal-

nut alone, did not differ (Ponder, 1987). Perhaps juglone in soil under the mixed planting could have both directly suppressed the ability of black alder to fix atmospheric nitrogen and indirectly suppressed nitrogen fixation by damaging the host plant.

The level of oxygen in the hydroponic solution did not significantly affect the parameters measured in this experiment. It is possible that an airflow rate of 5–10 ml/min was sufficient to satisfy the oxygen demand of the seedling roots. It is also possible that two replications may have been insufficient to detect differences due to aeration.

The rate of root respiration (measured as CO₂ evolution) in seedlings in the 2×10^{-5} M treatment initially declined relative to that in the control treatment. Juglone has been shown to inhibit the oxygen uptake by leaves of tomato and bean plants at concentrations above 10^{-5} M (Perry, 1967). Köeppe (1972) suggested that juglone-induced reduction of respiration is due to the inhibition of some of the coupled intermediates of oxidative phosphorylation, resulting in a slowing of electron flow to O₂ (i.e., an affect on aerobic respiration). It is possible that the initial decline in relative CO₂ evolution in the juglone-treated black alder seedlings was due to inhibition of aerobic respiration. Subsequent increases in CO₂ evolution per unit of initial plant fresh weight relative to the control respiration rate may be due to a partial recovery of respiratory activity after prolonged exposure to juglone. It is more likely that the increase in respiration of roots exposed to juglone relative to root respiration of control seedlings is a function of the decline in respiration of the control seedlings reflected in Table 1.

HOST PLANT IRIDOID-BASED CHEMICAL DEFENSE OF AN APHID, *Acyrtosiphon nipponicus*, AGAINST LADYBIRD BEETLES

RITSUO NISHIDA and HIROSHI FUKAMI

*Pesticide Research Institute
Faculty of Agriculture, Kyoto University
Sakyo-ku, Kyoto, 606, Japan*

(Received April 25, 1988; accepted September 6, 1988)

Abstract—A Rubiaceae-feeding aphid, *Acyrtosiphon nipponicus*, is seldom attacked by the ladybird beetle, *Harmonia axyridis*. A potent deterrent against the beetle was isolated from the aphid and identified as paederoside, an iridoid glycoside originating in the aphid's host, *Paederia scandens*. The iridoid content was as high as 2% of the intact body weight, and a large portion was found in the cornicle secretion.

Key Words—Defense, deterrent, sequestration, iridoid glycoside, paederoside, *Acyrtosiphon nipponicus*, Homoptera, aphid, Aphididae, *Harmonia axyridis*, Coleoptera, Coccinellidae, *Paederia scandens*.

INTRODUCTION

A ladybird beetle, *Harmonia axyridis* (Pallas), feeds on a variety of aphids during its larval and adult stages. However, a monophagous aphid, *Acyrtosiphon nipponicus* (Essig et Kuwana) (synonym: *Aulacophora paederia* Takahashi), which feeds exclusively on *Paederia scandens* Merrill (Rubiaceae), is seldom attacked by the ladybirds. When a hungry adult of *H. axyridis* bites into the aphid, it immediately drops the aphid, salivates, and quickly escapes from the aphid colony. Usually this is accompanied by a persistent grooming of its mouthparts. The aphid frequently secretes droplets from a pair of cornicles (Figure 1) when attacked by ladybirds and quickly smears the fluid onto the predator's mouthparts. The cornicle fluid strongly deters feeding of the ladybirds. Such feeding deterrence in the ladybirds was found to be due to a chemical

FIG. 1. *Acyrthosiphon nipponicus* secreting the cornicle fluid after disturbance. Usually the aphid quickly smears the fluid onto the forceps if picked up gently. The droplets contain paederoside in high concentration.

sequestered by the aphid from its host plant, *P. scandens*. We describe here the isolation and identification of the feeding deterrent of *A. nipponicus* against *H. axyridis*.

METHODS AND MATERIALS

Bioassay. Pupae of *H. axyridis* were collected from the field in Kyoto City. After adult ecdysis, they were regularly fed with drone honeybee powder (Matsuka and Nijima, 1985) and water for at least three days and then used for feeding bioassay. An aphid dummy similar in size to an aphid was made by dipping the round tip (2 mm id) of the glass rod in hot sucrose-agar solution (12% sucrose and 3% agar). *H. axyridis* adults usually feed on the dummy more than 5 sec (Figure 2). When the dummy surface was coated with an extract of *A. nipponicus*, the ladybirds stopped feeding immediately after the first bite. The test samples of known concentration were applied on the dummy surface as a 1- μ l solution (in acetone or methanol) and brought into contact with the predator's mouthparts after evaporating the solvent in an air current. The bioassay was carried out at about 25°C (16:8 light-dark photoperiod) in a chamber (50 × 50 × 50 mm) which is open in front and illuminated by a fluorescent

FIG. 2. Feeding deterrence bioassay against *Harmonia axyridis* using an aphid dummy.

lamp (15 W) placed behind a screen at the rear. The deterreny of each sample was obtained as a percentage of the number of ladybirds that stopped feeding on the sample dummy within 5 sec of exposure after the first bite was observed.

Instruments. Optical rotatory dispersion spectra were measured with a Jasco ORD J-5 spectropolarimeter at 30°C, and the ultraviolet (UV) spectrum was recorded with a Shimadzu UV-360 recording spectrophotometer. Field desorption mass spectrum was measured with a Hitachi M-80 mass spectrometer using a carbon emitter at 5.5 kV. Proton and carbon-13 magnetic resonance (PMR and CMR) spectra were measured with a JEOL JNM FX-200 spectrometer (200 MHz) using tetramethylsilane for CD₃OD or sodium 3-trimethylsilyl-1-propane sulfonate for D₂O solvent, respectively, as the internal standards. The letters s, d, t, q, and m represent singlet, doublet, triplet, quartet, and multiplet, respectively (*J*-values in Hz).

Isolation of Compound I (Paederoside). *A. nipponicus* feeding on the vine of *P. scandens* was collected in the campus of Kyoto University during July 1982. The aphids were homogenized in acetone (10 ml), and the residue was extracted twice with acetone (10 ml × 2). The combined extracts (0.20 g), after filtration (Toyo Filter Paper, qualitative No. 2) and evaporation, were fractionated into hexane, ethyl acetate, and water layers by solvent extraction (hexane layer = 47 mg, ethyl acetate layer = 4 mg, water layer = 143 mg). The deterrent activity was recovered from the water layer, which was chromatographed on a reverse-phase column (Sep-pak cartridge C₁₈, Waters Associates), by elut-

ing successively with each 4 ml of water, 20% methanol, 40% methanol, 60% methanol, and 100% methanol (Figure 3). The 20% methanol eluate (24 mg) was subjected in part to high-performance liquid chromatography (HPLC) with a reverse-phase column (Radial Pak liquid chromatography cartridge, μ Bondapak C₁₈, 10 μ m, 100 mm \times 8 mm ID, Waters Associates) eluting with 30% methanol (2 ml/min). The eluate was fractionated into eight fractions, monitored by refractive index (differential refractometer, model R 401, Waters Associates) as shown in Figure 4A. Pure compound I, isolated from fraction 6 [retention time (*Rt*) = 12.0 min, yield = 20 mg from 1.3 g of the intact aphids], was then crystallized from acetone to yield colorless needles (mp 118°C). $[\alpha]_D = -44^\circ$, $[\alpha]_{233} = -3720^\circ$ ($c = 0.36$, methanol). UV: $\lambda_{\max} = 233$ nm ($\epsilon = 11,500$, methanol). PMR (CD₃OD): δ 7.30 (1H, d, $J = 2.2$), 5.94 (1H, d, $J = 1.8$), 5.73 (1H, m), 5.56 (1H, broad d, $J = 7$), 4.85 (2H, m), 4.68 (1H, d, $J = 8.0$), 3.92 (1H, double d, $J = 12.0$ and 1.9), 3.74 (2H, m), 3.19 (1H, double d, $J = 8.0$ and 8.5), 2.34 (3H, s).

Isolation of Compound III (Methyl Paederosidate). Compound III was isolated as an artifact when methanol was used for extraction instead of acetone. The compound was eluted with 40% methanol on a Sep-pak cartridge C₁₈, and purified by preparative HPLC (*Rt* = 39.6 min, under the same condition for compound I). $[\alpha]_D = +13^\circ$, $[\alpha]_{271} = +680^\circ$ ($c = 1.67$, methanol). PMR (CD₃OD): δ 7.66 (1H, d, $J = 1.2$), 6.02 (1H, m), 5.10 (1H, broad d, $J = 15$), 5.06 (1H, d, $J = 8.4$), 4.94 (1H, broad d, $J = 15$), 4.72 (1H, d, $J = 7.6$), 3.86 (1H, double d, $J = 12.0$ and 1.2), 3.74 (3H, s), 3.62 (1H, double d, $J = 12.0$ and 6.0), 3.04 (1H, m, $J = 7.8$, 6.0, and 1.2), 2.63 (1H, double d, $J = 8.4$ and 7.8), 2.34 (3H, s). CMR (D₂O): δ (off-resonance C-H splitting pattern) 15.64 (q), 42.81 (d), 47.24 (d), 54.61 (q), 63.61 (t), 68.09 (t), 72.27 (d), 72.58

FIG. 3. Separation scheme of the aphid extract and the deterrent activity of each fraction; [−]: less than 10%, and [+++]: more than 90% detergency were observed at a dose of 300 μ g aphid equivalent/dummy ($N = 20$).

(d), 76.74 (d), 78.40 (d), 78.89 (d), 101.70 (d), 103.02 (d), 109.27 (s), 134.39 (d), 146.31 (s), 157.72 (d), 172.37 (s), 176.53 (s).

RESULTS

Deterreny of Aphid Extracts. The deterrent component of *A. nipponicus* against the ladybirds was efficiently extracted with acetone. The crude acetone extract at various doses was tested on *H. axyridis* adults using the aphid dummy in the manner as shown in Figure 2. Figure 5 shows the dose-response curve of the crude extract. The mean deterreny at the 50% dose-response was approximately 50 μg aphid equivalent per dummy.

Isolation and Identification. An acetone extract of *A. nipponicus* was frac-

Fig. 5. Dose-response curve of the acetone extract of *Acyrthosiphon nipponicus* in the feeding test using *Harmonia axyridis* ($N = 30$).

tionated into hexane, ethyl acetate, and water layers by solvent extraction. The water layer showed the activity, which was chromatographed on a C_{18} reverse-phase cartridge column. The deterrent activity was recovered from a fraction eluted with 20% methanol (Figure 3). The active fraction was then subjected to preparative HPLC (Figure 4A), and the deterrent activity was found solely in fraction 6 (Figure 4B). The active compound I was isolated as colorless crystals (mp 118°C) from fraction 6. The yield of compound I was 15–20 mg from 1 g of intact aphids.

Compound I was characterized as paederoside, an iridoid glucoside known from aphid's host plant, *P. scandens* (Inouye et al., 1968, 1969), the structure of which has been revised by Kapadia et al. (1979). Field desorption mass spectrometry was employed in order to obtain an unequivocal assignment of the molecular weight (M : m/z 446), in which prominent peaks m/z 447 ($M+H$) and 469 ($M+Na$) were observed along with other fragment peaks, as shown in Figure 6. The dose-response of authentic paederoside provided by Dr. H. Inouye (from *P. scandens*) also coincided with that of compound I, as shown in Figure 7. The mean detergency at the 50% dose-response was approximately $1\ \mu\text{g}/\text{dummy}$, comparable to detergency of the original aphid extract (see Figure 4, a $50\text{-}\mu\text{g}$ aphid equivalent extract contains approximately $1\ \mu\text{g}$ of paederoside).

Activity of Iridoid Analogs. Paederoside is a tricyclic iridoid with an unique thiocarbonate group, OCOSCH_3 , which might be indispensable for detergency. However, asperuloside (II), an acetate analog of the iridoid glucoside, also

FIG. 6. Field desorption mass spectrum of paederoside (I).

FIG. 7. Dose-response of paederoside (I) (solid line: from aphids, *Acyrtosiphon nipponicus*; broken line: from the host plant, *Paederia scandens*), asperuloside (II) and methyl paederosidate (III) in the feeding deterrence bioassay using *Harmonia axyridis* ($N = 30$).

deterred the ladybirds, while methyl paederosidate (III), a bicyclic analog with the sulfur-containing moiety, was shown to be inactive (Figure 7).

DISCUSSION

It has been clearly demonstrated that *A. nipponicus* is chemically protected from the predatory attack of a ladybird beetle, *H. axyridis*, by possessing a potent deterrent, paederoside (I), which originates from its host plant, *P. scandens*. Paederoside is an iridoid glucoside with a methyl-thiocarbonate moiety that is a very rare functional group in nature. It is suggested that methyl mercaptan may be formed through enzymatic hydrolysis of paederoside when the ladybirds contact the compound with their mouthparts. According to our preliminary observations, a dilute methanolic solution of methyl mercaptan repelled the ladybirds when applied as an air puff. However, an analogous compound III was inactive, whereas the acetyl derivative II was moderately deterrent against *H. axyridis*, suggesting the importance of the tricyclic structure rather than the thiocarbonate moiety. Although the host plant contains a few other iridoid glucosides, including asperuloside (II) (Inouye et al., 1968, 1969), the aphid appears to selectively sequester paederoside in the body tissues. The iridoid content was as high as 2% of the intact body weight of the aphid. Microanalysis of the cornicle fluid revealed that the water-soluble material was pure paederoside (approximately 1 $\mu\text{g}/\text{droplet}$). The aphid appears to promote its chances of surviving because of the deterrent effectiveness of the secreted droplets from the cornicles in response to predatory attacks. Similarly, a nymphalid butterfly, *Euphydryas anicia*, which feeds on *Besseyea* and *Castilleja* plants (Scrophulariaceae), is known to sequester iridoid glycosides (catalpol, aucubin, and macfadienoside) in the body tissues (Stermitz et al., 1986). Catalpol was also shown to be sequestered by two *Penstemon*-feeding geometrid larvae (*Meris alticola* and *Nepterpes graefaria*) (Stermitz et al., 1988).

Two other aphid species are known to accumulate host-plant products after feeding. *Aphis nerii* Fonscolombe sequesters cardiac glycosides from *Nerium oleander* (Rothschild et al., 1970), and *Aphis cytisorum* sequesters sparteine and some other analogous compounds from its host plant, *Cytisus scoparius* (L.) (Wink et al., 1982). Interestingly, nepetalactone and nepetalactol, two monoterpenes that are very stimulatory for cats and have been previously identified in *Nepeta* spp., have recently been characterized as the sex attractant pheromones of the vetch aphid, *Megoura viciae* (Dawson et al., 1987). However, in this case, the terpenes may not be directly derived from the aphid host plant, as is the case for other insects that produce iridoid pheromones and allomones (Blum and Hermann, 1978; Rowell-Rahier and Pasteels, 1986).

Iridoids are widely distributed secondary metabolites in the plant kingdom

and are considered to act as chemical barriers against herbivores. *A. nipponicus* seems to have gained an ecological advantage by selectively feeding on and sequestering the specific deterrent iridoid from its host plant, *P. scandens*.

Acknowledgments—We thank Dr. H. Inouye of Faculty of Pharmacology, Kyoto University, for the authentic samples of paederoside and asperuloside, and Drs. S. Uesato and T. Harayama of the same faculty for measurements of NMR spectra and for their valuable suggestions. We are also grateful to Drs. M. Matsuka and K. Nijjima of Tamagawa University for the supply of drone powder and to Dr. Y. Johki of Kyoto University for useful information on this study. We wish to thank Dr. M.S. Blum of the University of Georgia for reviewing the manuscript.

Abstract—When crushed, the leek, *Allium porrum* emits propyl propanethiosulfinate. The unstable thiosulfinate decomposes during GC analysis in numerous compounds, except on very short columns. The propyl propanethiosulfinate is the most attractive substance for the leek moth, *Acrolepiopsis assectella*. This thiosulfinate is not active on *Plutella xylostella* or *Plodia interpunctella* and seems to be repulsive on *Ephestia kuehniella*.

Key Words—*Allium porrum*, leek moth *Acrolepiopsis assectella*, *Plodia interpunctella*, *Ephestia kuehniella*, *Plutella xylostella*, Lepidoptera, Hyponomeutoidea, propyl propanethiosulfinate, propyl trisulfide monoxide.

INTRODUCTION

The biosynthesis of several sulfur compounds identified in the odor of *Allium* mainly involves relatively unstable thiosulfates (Boelens et al., 1971). Although preliminary analysis by thin-layer chromatography (TLC) pointed to their presence in leek odor (Auger and Thibout, 1981), no analysis by gas chromatography-mass spectrometry (GC-MS) had yet proven their existence (Schreyen et al., 1976).

We studied the stability of synthetic propyl propanethiosulfinate on gas chromatography columns in order to develop a technique that would avoid its breakdown. The resulting technique was then applied to leek odor (*Allium porrum*, Liliaceae), and the results obtained were compared for attraction of the

leek moth *Acrolepiopsis assectella* (Hyponomeutoidea) both for substances possibly existing in this odor (Lecomte and Thibout, 1981), and for closely related substances (Lecomte et al., 1987).

The attractiveness of these substances has also been studied on two generalist moths, *Ephestia kuehniella* and *Plodia interpunctella*, and on *Plutella xylostella*, specialist of Cruciferae, the odor of which also contains some of the substances studied (Bailey et al., 1961).

METHODS AND MATERIALS

Instrumentation. Analytical gas chromatography (GC) was performed with a Varian 3300 chromatograph equipped with Varian on-column injector, FID, and FPD (sulfur mode) detectors. Fused silica columns (SGE) (2.5 or 25 m \times 0.33 mm ID; $df = 0.5 \mu\text{m}$) coated with BP 20 were used for analysis. The carrier gas was N_2 at a flow rate 1 ml/min. The injector temperature program was $50^\circ\text{C}/\text{min}$ from 70 to 150°C .

Materials. Dipropyl disulfide and propanethiol were supplied by E. Merck (Darmstadt, West Germany). Dipropyl trisulfide was obtained according to Banerji and Kalena (1980). Propyl propanethiosulfinate and dipropyltrisulfide monoxide [Pr-S-S(O)-Pr] were synthesized by oxidizing the disulfide and trisulfide, respectively, with perbenzoic acid (Auger et al., 1985). Propyl propanethiosulfonate was obtained by oxidizing propanethiol with hydrogen peroxide.

The purity of these compounds was examined by NMR and IR spectroscopy (Auger, 1987).

Leek Volatiles, Trapping, Isolation, and Identification. Leek odor was emitted by cutting green leaves (1 kg) of the Malabare cultivar in a closed glass vessel (0.15 m^3), at room temperature.

Head-space volatiles were trapped during 1 hr on a glass cartridge (20 mm \times 4 mm ID) containing 30 mg of Tenax GC (Alltech Associates) 60–80 mesh directly connected to a Gillian LFS 113 pump (250 ml/min).

The trapped volatiles were eluted from the cartridge with 1 ml of peroxide-free diethyl ether (analytical grade) and immediately analyzed.

The volatiles were tentatively identified by comparing their GC retention times under various conditions to those of authentic samples.

Bioassay. The biological activity of some of the identified substances and analogs on the behavior of the four moth species was evaluated in an olfactometer as previously described (Lecomte and Thibout, 1981; Lecomte et al., 1987). Females of the four species were reared in the laboratory under identical conditions and tested once. For each odor, 30 mature females were placed individually in a glass tube (90 cm length \times 2 cm diameter) opposite the air flow (20

cm/sec) entry. The position of each female in one of three equal longitudinal sections was recorded after 1 min of observation in pure air, then after 1 min in air loaded with the odor being tested (10^{-2} mg of product evaporated/min). The χ^2 test was used to compare the distributions obtained in pure air and in odor. Only these values are given here in Table 1. Some previously published results on *A. assectella* (Lecomte et al., 1987) were used here for comparison.

RESULTS

Propyl propanethiosulfinate (90% pure), which contained only dipropyl disulfide by NMR analysis, when chromatographed on a 25-m column, revealed propanethiol, dipropyl disulfide, dipropyl trisulfide, and propyl propanethiosulfonate in varying proportions, depending on the temperature, and only a minimal amount of the injected substance, thus suggesting its decomposition on the column (Figure 1). The shorter the column, the greater the amount of the injected substance observed. On a 2.5-m column, propyl propanethiosulfinate appears to be accompanied only by dipropyl disulfide in the real proportion (90:10) and with no other compound present (Figure 2).

The chromatogram of leek volatiles obtained by using the same short column under identical conditions reveals mainly propyl propanethiosulfinate, although with a significant quantity of disulfide (Figure 3). However, on a 25-m column, under various temperature conditions, only a small quantity of thiosulfinate is found, although the corresponding thiol, disulfide, and trisulfide appear, accompanied by propyl propanethiosulfonate and, in minor quantities, methyl disulfide and trisulfide (Figure 4).

The attractiveness of the different sulfur compounds tested differs according to species (Table 1). In *A. assectella*, the four compounds are highly attrac-

TABLE 1. RESPONSE OF FOUR MOTHS TO LEEK VOLATILES AND ANALOGS^a

Dipropyl trisulfide monoxyde	20.36***	0.00	0.08	0.59

^aThe distributions of the females in the olfactometric tube are compared by the χ^2 test in the presence of pure air and substance-loaded air (***, $P < 0.001$; **, $0.001 < P < 0.01$; $2 df$). The χ^2 value is taken as a measure of the difference between the pure air and the odorous air distributions.

^bThe sole repulsive effect observed.

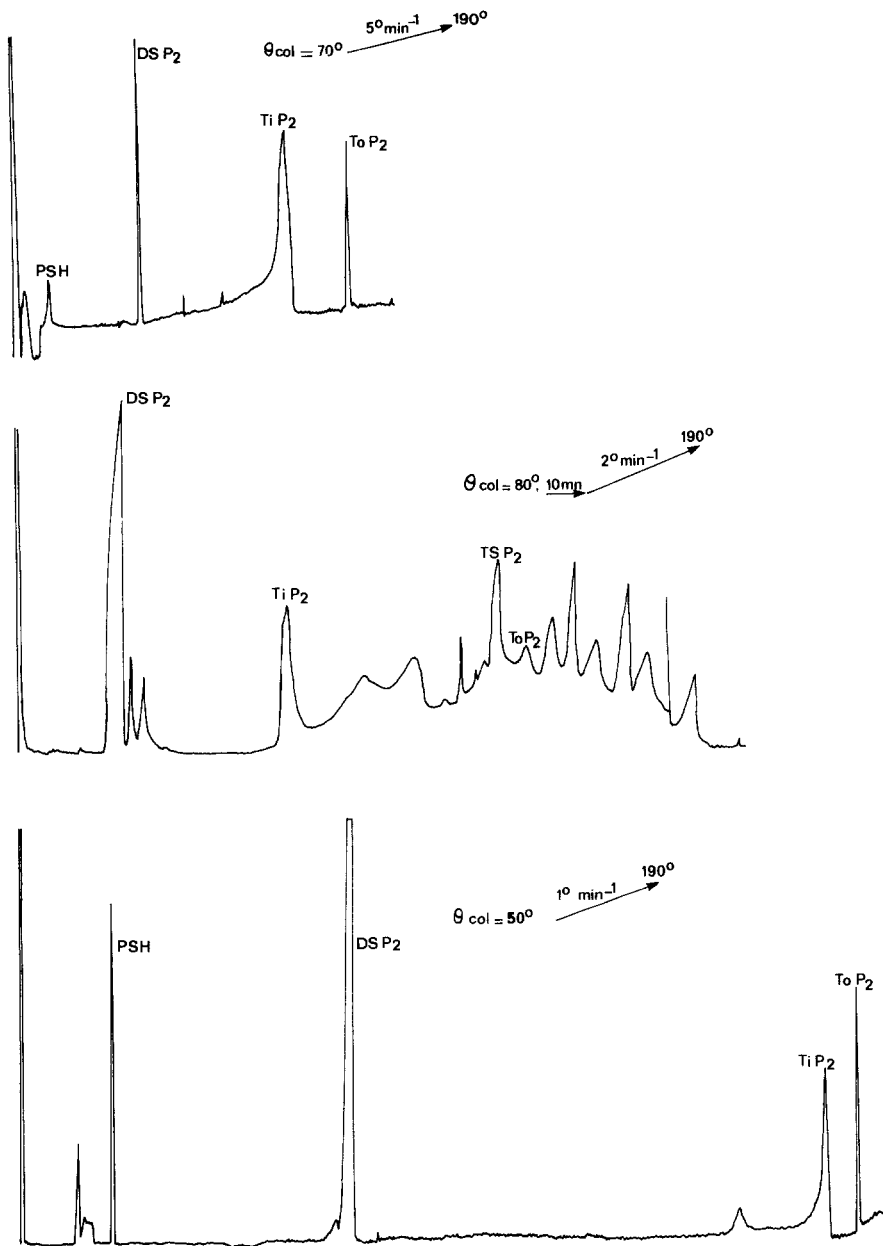

FIG. 1. Gas chromatogram of synthetic propyl propanethiosulfinate (TiP₂) containing 10% of dipropyl disulfide (DS P₂). Column = 25 m × 0.33 mm (ID); various temperature programs. On column injection. FP detector. PSH = propanethiol, ToP₂ = propyl propanethiosulfonate, TSP₂ = dipropyl trisulfide.

FIG. 2. Gas chromatogram of synthetic propyl propanethiosulfinate (TiP_2) containing 10% of dipropyl disulfide (DS P_2). Column = 2.5 m \times 0.33 mm (ID); temperature program = 70°C for 5 min, then 10°C/min to 100°C. On column injection. FP detector.

tive (highly significant χ^2 values), especially propyl propanethiosulfinate. In *P. xylostella*, dipropyl disulfide may be slightly attractive, while the other compounds are inactive (nonsignificant χ^2 values). In *E. kuehniella* and *P. interpunctella*, the tested compounds are inactive except for propyl propanethiosulfinate, which could act as a repellent of *E. kuehniella*.

DISCUSSION

On long gas chromatographic columns, propyl propanethiosulfinate is broken down, possibly by mechanisms other than simple disproportionation, into dipropyl disulfide since propanethiol and dipropyl trisulfide appear, apart from dipropyl disulfide and propyl propanethiosulfonate. In rapid chromatography

FIG. 3. Gas chromatogram of the leek volatiles, trapped on Tenax. Column = 2.5 m \times 0.33 mm (ID); temperature program = 70°C for 5 min, then 10°C/min to 100°C. On column injection. FP detector. DS P₂ = dipropyl disulfide, TiP₂ = propyl propanethiosulfinate.

(very short column), the thiosulfates do not break down. This technique allows one to conclude that leek odor just emitted contains primarily propyl propanethiosulfinate and perhaps a small amount of dipropyl disulfide. The majority of sulfur volatiles identified by GC-MS in *Allium* spp. are thus artifacts produced during the isolation of the sample and during chromatography.

It has been shown previously that sulfur compounds possibly existing in leek odor and their closely related analogs were attractive to the leek moth (Lecomte and Thibout, 1981; Thibout et al., 1982). Propyl propanethiosulfinate

FIG. 4. Gas chromatogram of the leek volatiles, trapped on Tenax. Column = 25 m \times 0.33 mm (ID); temperature program = (A) 2°C/min from 80°C to 150°C, (B) 1°C/min from 80°C to 150°C. On column injection. FP and FI detectors. DS M₂ = dimethyl disulfide, TS M₂ = dimethyl trisulfide; other compounds, see Figure 1.

is, however, more attractive than dipropyl disulfide, while dipropyl trisulfide monoxide is slightly more active than dipropyl trisulfide (Lecomte et al., 1987). Moreover, propyl propanethiosulfinate and other thiosulfonates are more stimulating than disulfides in *A. assectella* during oviposition (Auger, 1987).

These results confirm that the propyl propanethiosulfinate emitted when the leaves were crushed is one of the principal compounds that allow the moth to recognize *Allium* plants, particularly the leek.

The specificity of the action of this compound, unattractive to the other insects tested and even repellent for one of them, is much greater than in the disulfides that follow its breakdown in *Allium* extract and which, unlike thiosulfonates, also exist in other plant genera like Cruciferae. Moreover, these disulfides could be attractive to the adult *P. xylostella* moth, although less so than isothiocyanates, which are specific to Cruciferae (Auger, 1987).

In the light of these results, it seems necessary to reexamine GC analysis of other plant odors. Previously obtained results could be challenged if the identified compounds are produced by the breakdown of less stable precursors during analysis.

Acknowledgments—We are grateful to J.C. Landre for his technical help during this work.

ALLELOPATHIC POTENTIAL OF SORGHUM-SUDANGRASS HYBRID (SUDEX)¹

LESLIE A. WESTON, ROSELEE HARMON, and SARA MUELLER

*Department of Horticulture and Landscape Architecture
University of Kentucky
Lexington, Kentucky 40546*

(Received July 18, 1988; accepted September 14, 1988)

Abstract—Experiments were conducted under controlled conditions to investigate the apparent allelopathic effects of sudex [*Sorghum bicolor* (L.) Moench × *Sorghum sudanese* (P.) Stapf. cv. FFR 201] on weed and vegetable species. Allelopathic potential, as measured by radicle elongation of herbaceous indicator species, decreased with increasing sudex age. Greatest potential allelopathic activity of sudex shoot tissue was observed when sudex was collected at 7 days of age. Small-seeded broadleaf species were more inhibited in the presence of sudex shoot tissue than were grass species. Two major phytoinhibitors were isolated from aqueous extracts of sudex shoot material by partitioning with diethyl ether, followed by thin-layer and liquid column chromatography. Phytoinhibitors were identified as *p*-hydroxybenzoic acid and *p*-hydroxybenzaldehyde, potentially the enzymatic breakdown products of the cyanogenic glycoside dhurrin. The I_{50} values of these compounds using a cress (*Lepidium sativum* L.) seed bioassay were 140 and 113 $\mu\text{g}/\text{ml}$ for the acid and aldehyde, respectively. Sudex tissue collected at 7 days of age possessed a greater percentage of these phytoinhibitors on a per gram basis than did older sudex tissue. As sudex tissue age increased, the percentage of *p*-hydroxybenzaldehyde in ether extracts of tissue also increased, while the percentage of *p*-hydroxybenzoic acid decreased.

Key Words—*Sorghum bicolor* (L.) Moench × *Sorghum sudanese* (P.), Stapf. cv. FFR 201, sudex, allelopathy, shoot tissue, plant age, radicle elongation, *p*-hydroxybenzoic acid, *p*-hydroxybenzaldehyde.

INTRODUCTION

Cover crops are used to control soil erosion and reduce weed populations in nurseries and in agronomic crops. Between production cycles or seasons, cover crops are also used as a source of green manure for the improvement of soil structure and organic matter content (Martin et al., 1976). Sudex is commonly selected as a summer annual cover crop because of its rapid growth and ability to suppress weed biomass (Forney et al., 1985).

Both sudex and related sorghum species have shown possible allelopathic interactions with horticultural and agronomic species. Iyer et al. (1980) demonstrated that sudex incorporated into a container soil medium inhibited the growth of pine (*Pinus*) seedlings. Forney et al. (1985) obtained excellent suppression of broadleaf weed species when sudex was used as a green manure crop preceding alfalfa (*Medicago sativa* L.) establishment. Forney and Foy (1985) also discovered that root leachates from hydroponically grown sudex inhibited the growth of both monocot and dicot seedlings. Purification of collected sudex phytotoxins was not attempted.

Recently, we have found that the growth of selected woody and herbaceous seedlings was significantly reduced when seedlings were cocultivated with sudex and when sudex leaf material was incorporated into the growth medium (Weston and Geneve, 1987). In further studies with eastern redbud (*Cercis canadensis* L.), growth reductions could not be reversed with increased fertilizer rates. Additionally, redbud growth decreased linearly with increased amounts of fresh or dried sudex incorporated into the growth medium (Geneve and Weston, 1988).

Since sudex shows potential for use as a weed suppressive green manure crop, it is important to determine which stage of plant growth is associated with the greatest allelochemical production. Sorghum (*Sorghum bicolor* L. Moench), a closely related species, has been shown to inhibit germination and development of weed seedlings (Panasuik et al., 1986) and to contain greatest concentrations of the cyanogenic glycoside dhurrin in the seedling stages of growth (Conn, 1981; Haskins et al., 1984). In addition, Lehle and Putnam (1982) also found that Bird-a-Boo sorghum toxicity was greatest in herbage of 2-week-old plants.

Although recent laboratory, greenhouse, and field studies suggest that allelochemicals present in sudex tissue suppress weed growth, the potential phytotoxins have not been characterized. To further explore the possible allelopathic potential of sudex shoot tissue under controlled laboratory conditions, studies were undertaken to: (1) determine the influence of age of sudex tissue upon inhibition of seed germination and radicle elongation of broadleaf and grass species, (2) assess the effect of partitioned sudex shoot extracts on seed germination and radicle elongation, (3) isolate and identify the inhibitors

present in sudex shoot tissue responsible for the reduction in seedling root growth, and (4) determine the influence of age of sudex shoot tissue upon the levels of inhibitor(s) present in shoot extracts.

METHODS AND MATERIALS

Collection of Sudex Material. For all experiments, sudex cv. FFR 201 was seeded directly into plastic flats containing a nonpasteurized soilless growth medium [5 parts Promix BX (Premier Brands) to 1 part perlite, v/v]. Flats were placed in a glasshouse with temperatures maintained at 23–27°C day/20–24°C night. Supplemental lighting was provided by high-pressure sodium vapor lamps with photosynthetic photon flux density of approximately 500 $\mu\text{mol}/\text{sec}/\text{m}^2$ at a plant height of 30 cm. Flats were watered overhead as needed and fertilized with soluble fertilizer (Peter's) 14 N–6.5 P–13.3 K at 200 ppm N at each watering.

Sudex shoot tissue was harvested at several dates in April through July 1986 by cutting shoots 2 cm above the soil surface. In addition, sudex planted on September 29, 1987, was harvested at one, two, three, and four weeks after planting, at 7, 14, 20, and 30 cm in height, respectively. All sudex tissue was placed in a drying oven at 45°C for five to six days prior to analysis or bioassay. A small amount (15 g) of material was chopped into 1.5-cm pieces and saved for soil bioassays (described below). The remainder was ground separately in a Wiley mill (mesh screen size 1 mm). Powdered material was stored in tightly closed glass containers until used for extraction and quantification of sudex phytoinhibitors.

Bioassay of Sudex Shoot Tissue. A modified Parker (1966) bioassay was used for measurement of inhibition of seed germination and radicle elongation. Maury silt loam (Typic Paleudalf, fine, mixed, mesic) was sifted and combined with sand (1 : 1 v/v) and placed in a 45°C oven for seven days until dry. Treated soil (100 g) was placed in 100- × 15-mm² plastic Petri dish and topped with 1.0 g of chopped, dried sudex. A thin layer of the soil mixture (50 g) was spread over the residue and 35 ml of distilled water was added to the dish.

A 9- × 9-cm piece of filter paper (Whatman No. 1) was placed on the soil surface of each dish. Ten seeds of each of two indicator species were uniformly placed in two rows parallel to each other on the surface of the filter paper. Tomato (*Lycopersicon esculentum* Mill., Niagara), Burpee curly garden cress, foxtail millet [*Setaria italica* (L.) Beauv.] and barnyardgrass [*Echinochloa crus galli* (L.) Beauv.] were utilized as bioassay species. Dishes were covered, taped shut, and placed in a vertical position in a germination chamber to encourage downward root growth. Seeds were held in place by pressure of surrounding chamber upon dishes. Dishes were then placed in a 28°C incubator and radicle

length was measured for each seed four days later. Radicle length of nongerminated seeds was assumed to be 0. Treatments consisted of sudex shoot tissue aged 7, 14, 21, and 28 days, and a control consisting of paper toweling (1.0 g) cut into 1.5- × 1.5-cm pieces. Experiments were analyzed separately for each indicator species, as completely randomized designs with four replicates per treatment. Data were subjected to analysis of variance and means separated using Fisher's protected LSD (0.05) test.

Extraction of Sudex Shoot Material. Shoot tissue (400 g) was extracted for 48 hr with 7200 ml of distilled water on an orbital shaker in a 4°C coldroom (Figure 1). The mixture was filtered through four layers of cheesecloth and centrifuged for 20 min at 12,000g to remove particulate material. Finer particulates were removed by vacuum filtration through Whatman No. 4, 1, and 42 filter paper, respectively. The clear, aqueous extract was sequentially parti-

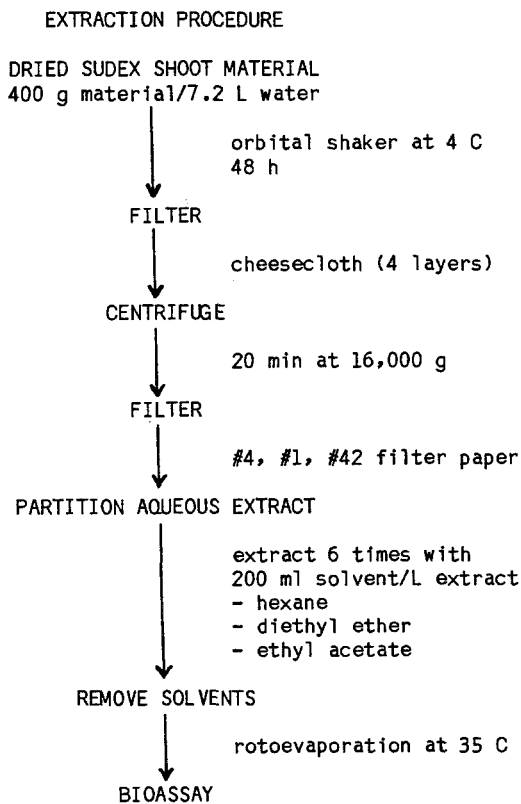

FIG. 1. Flow diagram of the procedure used for extraction and partitioning of dried sudex shoot residues.

tioned with hexane, diethyl ether, and ethyl acetate. Each liter of the aqueous shoot extract was partitioned six times with 200 ml of each of the three solvents. Solvent was removed from each fraction by rotary evaporation at 35°C. The entire process of extraction and partitioning was repeated twice and combined to gather enough material for experimentation.

Each fraction from the solvent extractions was weighed individually and redissolved in chloroform to form solutions at a concentration of 1.0 mg dry residue/ml chloroform. One half milliliter of each fraction was placed in separate glass Petri dishes (60 × 15 mm), which were lined with filter paper (Whatman No. 1). Chloroform was allowed to evaporate from each dish, and 1.5 ml distilled water was added to form a final concentration of 334 μg material/ml. The control consisted of distilled water applied to the filter paper after evaporation of 0.5 ml chloroform. Twenty seeds of Burpee curly cress were then added to each dish. Three replicates of each treatment were arranged in a completely randomized design and placed in a seed germination chamber maintained at approximately 26°C with relative humidity near saturation. Radicle length was measured at 72 hr. Radicle elongation of curly cress was consistently used as a bioassay throughout these experiments because of its sensitivity, uniformity, and availability. Data were subjected to analysis of variance and means were separated by Fishers protected LSD (0.05) test.

Isolation and Characterization of Phytotoxins. The ether extract from above was further separated initially using liquid column chromatography. The extract (380 mg) was loaded onto a silica gel (60 g Baker, 200–250 mesh) flash column (4 cm diameter × 40 cm). Pressure for the column was provided by a laboratory compressed air pump and was regulated to provide a solvent flow rate of 40 ml/min. The column was eluted with the following solvent series: 350 ml chloroform, 200 ml each of 19:1, 9:1 and 5:1 chloroform–methanol, followed by 250 ml methanol. Fractions (20 ml) were collected, examined by TLC (silica gel developed with 7:1 chloroform–methanol), and combined on the basis of similar TLC profile to provide 10 distinct fractions. The 10 fractions were bioassayed separately for inhibitory activity using 250 μg material/dish, or 166.7 μg/ml. Since activity was restricted to two consecutive fractions, these fractions were combined prior to further analysis.

The combined fractions (104.5 mg) were loaded onto a C₁₈ (60 g Baker Flash Octadecyl bulk packing; 40 μm) flash column and eluted as described above using the following solvent series: 350 ml 60:40, 250 ml 75:25, 250 ml 90:10 methanol–water, followed by 250 ml methanol and 250 ml chloroform. Fractions were collected and examined as described above and combined to provide 10 distinct fractions. Bioassay of fractions, using 200 μg material/dish or 133.3 μg/ml, revealed toxicity to be confined to fractions 1–3. These fractions were combined (42.7 mg) and chromatographed via silica gel TLC (Whatman LK5F plates) using a mobile phase of 7:1 chloroform–methanol.

Visualization under UV (254 nm) light revealed six distinct bands; similar bands were scraped off several plates and combined. Plate scrapings were eluted with 3:1 chloroform-methanol through a fritted glass filter, and the eluent from each zone was collected, dried, weighed, and bioassayed at 150 μg material/dish or 100 $\mu\text{g}/\text{ml}$. Strong inhibitory activity occurred in zones 2 ($R_f = 0.35\text{--}0.36$) and 5 ($R_f = 0.57\text{--}0.59$), each of which contained one major component only, visible under UV (254 nm) light. TLC plates were exposed to 5% vanillin in sulfuric acid for colorimetric characterization of active compounds. The migration of materials on silica gel TLC plates in various solvent systems was compared with that of standards of *p*-hydroxybenzaldehyde and *p*-hydroxybenzoic acid (Sigma) as visualized by exposure to UV (254 nm) light and to the vanillin sulfuric acid reagent. The chemical nature and the purity of the two unknown compounds were also examined using high-pressure liquid column chromatography (HPLC) using a Waters Bondapak, radial compression column (8 mm \times 10 cm). The UV detector (Waters LambdaMax model 481) measured absorbance at 254 nm. Solvent used was 50:50 methanol-water at a flow rate of 1.5 ml/min. Identity of compounds was further confirmed by coelution with known standards using TLC and HPLC. Dose-response curves were constructed to determine the concentration of these materials (compounds 1 and 2) required for 50% inhibition of cress seed radicle elongation (I_{50}).

Quantification of Phytotoxins from Sudex Shoots of Various Ages. Sudex shoots of various ages (7, 14, 21, 28 days) were collected and dried as described above. One hundred grams of dried shoot tissue of each age was extracted separately for 48 hr; the four extracts were then sequentially partitioned with hexane and diethyl ether. The diethyl ether extract was dried by rotary evaporation, weighed, and bioassayed as described above at levels of 0, 125, 250, and 500 $\mu\text{g}/\text{dish}$, or 0, 83.4, 166.7, and 333.3 $\mu\text{g}/\text{ml}$. The HPLC system described previously (50:50 methanol-water) was used to separate and quantitate compounds 1 and 2 in each fraction. Standard curves of each purified compound were generated and used to estimate the total amount of compounds 1 and 2 in each sudex tissue extract. This process was repeated, and data represent means of two replications.

RESULTS AND DISCUSSION

Bioassay of Sudex Shoot Tissue. As sudex age increased from 7 to 28 days, allelopathic potential of tissue decreased, as measured by radicle elongation of four indicator species (Table 1). Differential inhibition obtained with sudex tissues of various ages suggests that the concentrations of phytoinhibitors may be greatest in very young sudex tissue and gradually decrease with increasing maturity. Small-seeded broadleaf species were most sensitive to the presence

TABLE 1. INFLUENCE OF AGE OF SUDEX SHOOT RESIDUE UPON RADICLE ELONGATION IN 4 INDICATOR SPECIES AFTER 96 HOURS

Residue age (days)	Radicle length (mm)			
	Curly cress	Tomato	Foxtail millet	Barnyard grass
Control	10.2	9.1	35.8	38.0
7	2.6	0.7	19.5	23.9
14	3.5	2.4	21.2	31.0
21	7.8	7.7	26.4	39.6
28	6.7	7.8	36.4	36.7
LSD (0.05)	2.6	4.3	7.3	8.2

of the sudex tissue, whereas radicle elongation of grass species was less affected by the tissue. This was not unexpected, since several cover crop residues have also shown considerable selectivity in the inhibition of growth of both vegetable and weed seedlings in the field (Putnam and DeFrank, 1983). The modified Parker bioassay is particularly useful for uniform evaluation of tissue toxicity in a soil situation under controlled laboratory conditions. In additional studies performed using pasteurized soil and sudex tissue sterilized by exposure to propylene oxide, the presence of soil microorganisms was not required for the development of sudex tissue toxicity (data not presented). In fact, sudex tissue was generally more inhibitory to seedling indicators under sterile conditions, indicating that soil microorganisms may reduce tissue toxicity over time (Weston and Geneve, 1987). Greenhouse studies have also indicated that sudex toxicity diminishes over a period of eight weeks after incorporation in the growth media (Geneve and Weston, 1988). This may be due, in part, to microbial activity.

Extraction of Sudex Shoot Tissue. Greenhouse-grown tissue was used due to its uniform size obtained under growing conditions and its ready availability. Aqueous extraction of sudex shoot material was performed at 4°C to prevent the breakdown of secondary products by microorganisms. The greatest amount of material was removed from the aqueous shoot extract by partitioning with diethyl ether (Table 2). The greatest inhibitory activity was also associated with the diethyl ether fraction, as measured by the inhibition of cress radicle elongation at 72 hr. The ethyl acetate fraction was also quite inhibitory; however, this fraction was very similar in chemical composition to the diethyl ether fraction when examined using thin-layer chromatography. Very little toxicity remained in the crude aqueous extract after partitioning against the solvent series. Since the greatest toxicity and a comparatively large weight of material were concentrated in the ether fraction, the crude ether extract was used in

further separations and bioassays in an attempt to isolate sudex inhibitors responsible for the reduction in seedling growth.

Isolation and Characterization of Phytotoxins. Two toxic compounds were isolated from the ether extract of greenhouse-grown sudex material. It was necessary to extract fairly large amounts of dried sudex material (800 g) to obtain enough purified product for bioassay and comparison with synthetic standards. Since the ether extract was a complex mixture, the isolation of both compounds required the use of several chromatographic separation techniques.

After separation using both silica gel and C_{18} flash column chromatography, inhibitory activity, as measured by a cress seed bioassay, was concentrated in one fraction. Following separation via TLC, strong inhibitory activity was associated with zones 2 ($R_f = 0.36$) and 5 ($R_f = 0.58$). Based on similarity of R_f values, compound 1 ($R_f = 0.36$) was tentatively identified as *p*-hydroxybenzoic acid while compound 2 ($R_f = 0.58$) was tentatively identified as *p*-hydroxybenzaldehyde. Both compounds appeared colorless, were strongly visible under UV (254 nm) light, and turned pale yellow after exposure to vanillin and sulfuric acid spray reagent. Identity was confirmed by coelution with known standards on TLC and HPLC.

Dhurrin and *p*-hydroxybenzaldehyde have previously been isolated and identified as major inhibitors of seedling growth in the related species, Johnson grass (*Sorghum halepense* L.) and sorghum (Alsaadawi et al., 1986; Abdul-Wahab and Rice, 1967; Nicollier et al., 1983). Dhurrin is a cyanogenic glycoside that breaks down enzymatically to form *p*-hydroxybenzaldehyde, prussic acid (HCN), and glucose (Conn, 1981). Recently, Nicollier et al. (1983) also found that taxiphyllin, the epimer of dhurrin, was present in Johnson grass rhizomes. Although *p*-hydroxybenzaldehyde and HCN are known inhibitors of

seedling growth, dhurrin and taxiphyllin reduced seedling growth only minimally in tomato and radish bioassays (Nicollier et al., 1983).

Our extraction techniques and bioassays of sudex shoot tissue have shown major biological activity associated only with the presence of *p*-hydroxybenzoic acid and *p*-hydroxybenzaldehyde. It is very likely that *p*-hydroxybenzaldehyde is present as the breakdown product of the cyanogenic glycoside dhurrin. Evidence obtained from UV and NMR spectroscopy suggests that small quantities of dhurrin were also isolated in crystalline form, but possessed relatively little inhibitory activity using the cress bioassay (data not presented). HCN was not detected in the ether extracts of sudex tissue. At room temperatures, *p*-hydroxybenzaldehyde can be converted to *p*-hydroxybenzoic acid. The inhibitory activity of compounds 1 and 2, identified as *p*-hydroxybenzoic acid and *p*-hydroxybenzaldehyde, were nearly identical to the activity of the synthetic standards used in the cress seed bioassay (data not presented). The synthetic chemicals were utilized to develop dose-response curves for three small-seeded indicator species: cress, lettuce, and radish. The values representing 50% growth reduction (I_{50}) were calculated for each species (Table 3), and with the exception of curly cress, *p*-hydroxybenzoic acid inhibited radicle elongation of seed indicators slightly more than did *p*-hydroxybenzaldehyde. Some difference in sensitivity was also noted among indicators; I_{50} values obtained for lettuce were lower than those of radish and cress, indicating greater sensitivity for lettuce to these compounds. These I_{50} values using the various seed bioassays range from 70 to 140 $\mu\text{g/ml}$ (Table 3). These compounds are inhibitory to radicle elongation in cress, lettuce, and radish at concentrations comparable to other alleged allelochemicals (Rice, 1984). Both compounds are present in large proportions in the ether extracts or sudex shoot tissue.

Quantification of Phytotoxins from Sudex Shoots of Various Ages. Greenhouse-grown sudex residues collected at 7 days of age produced approximately

four times more dried ether extract per 100 g of dried shoot tissue than did tissue collected at 28 days of age (Table 4). The amounts of the two phyto-inhibitors (*p*-hydroxybenzoic acid and *p*-hydroxybenzaldehyde) in tissues of various ages were also compared by HPLC quantification (Table 4). Shoot tissue collected at 7 days of age contained approximately 17 times more *p*-hydroxybenzoic acid and twice as much *p*-hydroxybenzaldehyde than did tissue collected at 28 days of age. In all tissues, *p*-hydroxybenzoic acid was the major component present in the crude ether extracts of sudex tissue (15–59%), with considerably less *p*-hydroxybenzaldehyde present (0.01–0.03%). The figures shown are estimates of the quantities present in the ether extracts and may or may not reflect relative amounts of the two inhibitors present in the whole plant before extraction. However, partitioning with ether did remove the majority of these inhibitors from the aqueous extracts (as observed by TLC and the cress bioassay).

Sudex shoot tissue harvested at 7 days of age (< 10 cm in height) was most inhibitory to seedling growth and also contained the greatest percentage of the two inhibitors. As sudex shoot tissue matured to 28 days of age, both the activity associated with the tissue and the concentration of identified inhibitors decreased dramatically. This is in agreement with the findings of other researchers who note that dhurrin concentration (Conn, 1981) and tissue toxicity (Lehle and Putnam, 1982) are greatest in seedling sorghum. In sudex shoot tissue, the great majority of toxicity appears to be well correlated with the presence of the breakdown products of dhurrin, *p*-hydroxybenzaldehyde and *p*-hydroxybenzoic acid. Little direct evidence was previously available to indicate that identified sorghum phytoinhibitors were well correlated with observed inhibition of seedling growth. As Lehle and Putnam (1982) note, this may have resulted from a

lack of standardized methods or suitable bioassays used to quantify inhibitory responses reported.

Identified phenolic compounds may potentially be released from plant tissues by exudation or degradation and may play an important role in the alleged allelopathic activity of both living and dead sudex tissue. Although greatest toxicity was associated with the seedling stage of sudex, the competitive nature, large biomass production, and allelopathic properties exhibited by mature sudex may contribute to its potential role as a weed suppressive summer annual in agroecosystems.

ROOT-MEDIATED EFFECTS IN CARROT RESISTANCE TO THE CARROT FLY, *Psila rosae*

AMEL MAKI and M.F. RYAN

*Department of Zoology
University College Dublin
Belfield, Dublin 4, Ireland*

(Received March 21, 1988; accepted September 20, 1988)

Abstract—Field experiments on two different soil types in Ireland assessed the extent and mechanisms of resistance to *Psila rosae* (F.), the carrot fly, with emphasis on the role of the carrot root. Ten carrot cultivars gave consistent results in terms of resistant and susceptible cultivars. Nonpreference oviposition was confirmed as a mechanism, and the use of egg traps, providing differential exposure of the main root, showed this was regulated by root factors, probably chemical constituents. Independent main root resistance to the larva was also confirmed, and this effect was established as consistent with a chemically mediated nonpreference. Antibiosis by the root was demonstrated. Such effects in three different modes indicate that main root properties are crucial in carrot resistance to *Psila* and suggest a pervasive influence of root chemicals on such resistance.

Key Words—Carrot resistance, carrot fly, *Psila rosae*, Diptera, Psilidae, main root factors, nonpreference oviposition, root resistance to larvae, antibiosis, root chemicals.

INTRODUCTION

The first report of resistance in carrot (*Daucus carota* L.) against the carrot fly [*Psila rosae* (F.)] indicated nonpreference in egg-laying as a contributing factor (Åhlberg, 1944). Most subsequent investigations emphasized screening for resistance, which led to the formation in 1976 of a working group of the International Organisation for Biological Control (IOBC) with representatives from nine European countries. Their data from 12 sites demonstrated resistance as having sufficient effect and consistency to suggest a role for resistant cultivars in the integrated control of *Psila* (Ellis and Hardman, 1981); however, the

mechanisms of resistance were not ascertained. These were examined in this laboratory, where we also addressed the role of chemical factors using a range of cultivars different from those of the IOBC (Ryan et al., 1978).

Our field experiments confirmed nonpreference at the level of oviposition and detected a new effect in the form of root resistance to the larva that was independent of resistance to egg-laying (Guerin and Ryan, 1984); that is, two cultivars attracting equally few eggs could sustain widely different degrees of root damage. As such damage is the direct cause of crop losses, it follows that root resistance to the larva is a fundamental requirement in breeding resistance (Guerin and Ryan, 1984). It was not possible to decide if this operated through larval nonpreference or antibiosis, and this question is addressed in the present report. It was also clear that intact roots of resistant varieties released substantially less volatile material than susceptible ones as judged by comparison of steam distillates and of headspace vapors entrapped by Porapak Q (Guerin and Ryan, 1984).

We now report on field experiments with the IOBC range of cultivars. The results confirm nonpreference at the level of oviposition, independent root resistance to the larva, and show, in addition, that the latter is consistent with a chemically mediated nonpreference effect. The results unambiguously demonstrate antibiosis as independently elicited by the root, which also involves chemicals. Finally, and perhaps surprisingly, they indicate that root factors, as distinct from foliage ones, can govern nonpreference oviposition. Collectively, such data establish the root as capable of regulating carrot resistance to *Psila*, probably through its chemical constituents.

METHODS AND MATERIALS

A total of five field experiments were conducted over three years to assess both the extent of resistance to *P. rosae* in carrots and the underlying mechanisms, with special reference to chemical factors. In one we compared only two cultivars using egg-laying traps (details below). In the other four the design was similar to one already reported for use with IOBC cultivars (Ellis and Hardman, 1981). Essentially, there were three blocks each containing one replicate of each cultivar randomized within the block. Block dimensions were 5 × 5 m with 2 m between blocks. All carrot seed was hand-sown in 5-m rows spaced 40 or 50 cm apart within the blocks. Rows were perpendicular to a hedge and began 2 m away from it. Two guard rows terminated the layout of each trial.

Carrot seed of the following eight cultivars tested was supplied by the IOBC through the National Vegetable Research Station (NVRS), Wellesbourne, U.K.: Clause's Original Sytan (hereafter Sytan), Long Chantenay, Vertou L.D. (hereafter Vertou), Danvers Half Long 126, Gelbe Rheinische, Clause's Jaune

Obtuse Du Doubs, St. Valery, Royal Chantenay Elite. They represented a selection of European stocks ranging from susceptible to resistant (Ellis and Hardman, 1981). Caulfield Seed Merchants, Dublin, supplied seed of *Regulus Imperial* and *Chantenay-Red Cored-Elite* representing, respectively, the extremes of resistance and susceptibility previously reported from this laboratory (Guerin and Ryan, 1984).

Extent of Resistance

Two field experiments assessed the extent of resistance on contrasting soil types. All 10 cultivars were compared on peaty soil, comprising layered fen peat with *Menyanthes trifoliata*, non-*Sphagnum* moss and intermittent birch remains over wood fen, at the Peatland Experimental Station, The Agricultural Institute, Lullymore, County Kildare in 1982. The 1983 experiment was made on silty loam soil at University College Dublin, Belfield, using only the eight cultivars as supplied by the IOBC. Both experiments were harvested in late October and the roots graded for damage into five agreed categories of damage (Ellis et al., 1978): 0% (clean), <5%, 5–25%, 26–50%, and >50% of root surface damaged. Numbers and total weight of roots in each grade were recorded for each row. The data were subjected to analysis of variance as: number of roots; percentage unattacked roots; percentage of carrots with less than 5% of root surface damaged, i.e., percentage of marketable roots; and root damage index based on a grading system described by Ellis et al. (1978). These grades ranged from one for marketable roots to four for roots with more than 50% of the surface damaged. To allow for variations between cultivars in root density, the data were subjected to covariance analysis and derived means were compared by the least significant difference (LSD) test.

Mechanisms of Resistance

These were investigated by three experiments in 1981, 1982, and 1983, all on the peatland site of Lullymore. Essentially, the population densities of successive life stages were estimated to compare the mortality of each stage between cultivars.

Egg Sampling. Egg numbers were estimated on nine and 13 occasions for first and second generations of 1982 and on nine occasions for the 1983 experiment, from each of five plants, selected at random, in each row of the center block. Egg densities per cultivar were estimated from those in soil collected in a spoon (5 cm diameter) from the area surrounding the plant within a radius of 5 cm from the root and to a depth of 2.5 cm as previously described (Guerin and Ryan, 1984).

Larval Sampling. Six times during the 1981 experiment and 13 times in 1982, carrots were sampled by taking five random batches of two carrots per

row to give a total of 30 carrot plants for each cultivar (Guerin and Ryan, 1984). In addition to numbers of larvae, observations were made on numbers of attacked roots and mines. A mine is defined as an area of carrot 2 cm in diameter on the surface extending towards the core (Wright and Ashby, 1946).

Pupal Sampling. Pupal numbers were assessed on January 12, 1983, by collecting three soil samples per row from each block, or a total of nine samples per cultivar, using a square metal frame (25 × 25 × 15 cm deep). This was pushed into the soil surrounding the plants with the carrots centered in the frame. Then the soil sample was collected by pulling out the frame with the soil, which was poured into a plastic bag. Carrot roots were counted in the laboratory, and pupae were extracted from the soil by flotation using a saturated solution of magnesium sulfate. Pupae were collected with a paint brush, streaked on white filter paper, and counted. The number of roots per frame was not constant, so pupal numbers are expressed per root rather than per area.

Root Factors

The 1983 experiment differed from the usual design by concentrating on factors affecting egg numbers on only two cultivars, Vertou and Long Chantenay, representing the extremes of resistance and susceptibility, respectively. First, numbers of first-generation eggs were assessed by the spoon method on nine occasions at three-day intervals, from June 22 to August 16, on four plants selected at random from each plot.

Numbers of second-generation eggs were compared by the use of egg traps originally designed for use with cabbage root fly, *Delia radicum (brassicae)* L., (Freuler and Fischer, 1983). They were made of thin layers of felt material rolled down into a disk-shaped trap (5 cm diam. × 2 cm thick; Figure 1). Eggs are laid on the top surface of the traps between the felt layers. We used the traps in two forms: (A) those with a sponge centerpiece that encircled the stem of the plant on the soil surface such that the root was completely covered, and (B) those without such a centerpiece, thus exposing the top of the root. This comparison tested the hypothesis that manipulating the amount of root exposed, and presumably the quantity of root volatiles released, would affect the numbers of eggs laid.

It is generally accepted that larvae feed on the slender side roots before invading the main root (Gorham, 1934; Van't Sant, 1961; Whitcomb, 1938; Beirne, 1971; Städler, 1971; Jones, 1979; Guerin and Ryan, 1984); Overbeck (1978) reported that one third of larval development occurs in such side roots. We sought to compare the extent to which the first-instar larva of *Psila* feeds on side roots of resistant and susceptible cultivars before moving on to the main root. Accordingly, the surfaces of side roots in samples of 40 roots each from Vertou and Long Chantenay, taken at three-day intervals on each of seven occasions from August 4 to 19, 1983, were examined microscopically (×40). In

FIG. 1. Egg-traps used to assess the effect on oviposition of exposing the carrot root top. In A The sponge centerpiece completely covers the root top and in B the absence of the centerpiece exposes it. In both, the foliage is unaffected. With the root top covered, flies did not distinguish between Vertou and Long Chantenay in ovipositing, but when it was exposed significantly more eggs were laid on Long Chantenay as in regular field situations. Clearly, the foliage alone is inadequate to elicit this preference and must be supplemented by input from the root which, in the present comparison, is likely to be chemical.

addition, the cotton–blue lactophenol staining method, used to detect nematodes in plants (Souchev, 1970), was exploited in an effort to identify larvae of *P. rosae* in 175 side roots taken from each cultivar.

Statistical Analysis

All data for the experiments on resistance mechanisms relating to numbers of eggs, larvae, and mines were subjected to a square-root transformation ($X = \sqrt{n + 1}$) followed by analysis of variance; means were compared by the Duncan's multiple-range test (Duncan, 1955).

RESULTS

Extent of Resistance

The experiments on peat and mineral soil gave essentially similar results. All differences between cultivars reported below are statistically significant ($P < 0.05$) unless otherwise stated. On peat soil, Vertou had less damage, more unattacked roots, and more marketable roots than Regulus Imperial, St. Valery, and Long Chantenay (Table 1). On mineral soil, Clause's Original Sytan and Vertou had less damage than St. Valery, Danvers Half Long 126, Gelbe Rheinische, Long Chantenay, and Royal Chantenay Elite; more unattacked roots than all the other six cultivars, which did not differ significantly from each other; and more marketable roots than Danvers Half Long 126, St. Valery, Gelbe Rheinische, and Royal Chantenay Elite (Table 2).

We consolidated the results from each experiment into a single ranking system by assigning a value of 1 to the least resistant cultivar under each criterion; values of 10 and 8 were assigned to the most resistant cultivar in peat and mineral experiments, respectively, to take account of the different number of cultivars tested. This allows a possible maximum score of 30 and 24 for each cultivar in the peat and mineral soil experiments, respectively. For comparisons between experiments, cultivars were then rated by expressing their scores as a percentage of the maximum possible score (Tables 1 and 2). On peat soil, Vertou was the most resistant cultivar (100%), followed by Gelbe Rheinische (87%), and Regulus was the most susceptible (10%). On mineral soil, the two most resistant cultivars were Sytan (100%) and Vertou (88%), and Danvers Half Long 126 (17%) was the most susceptible.

Mechanisms of Resistance

In the 1981 experiment, when observations were confined to the second generation, more larvae and more mines per root were recorded on Long Chantenay than on all the other cultivars, which did not differ significantly from each other in either respect (Table 3).

In the 1982 experiment (first generation), fewer eggs were laid on Vertou, Sytan, and three other cultivars than on Royal Chantenay Elite, Regulus Imperial, and Long Chantenay (Table 4). There was, however, no significant difference between the numbers of larvae subsequently recorded on the roots of these cultivars (Table 4). Vertou, Clause's Jaune Obtuse Du Doubs, and Sytan had fewer mines per root than Long Chantenay, Chantenay-Red Cored-Elite, and Royal Chantenay Elite. The ratio of eggs laid to larvae established in main roots ranged from 7 (Gelbe Rheinische) to 11 (Long Chantenay) (Table 4).

Using the scoring system, Vertou was the most resistant (100%) followed by Clause's Jaune Obtuse Du Doubs (90%), St. Valery (77%), and Sytan (73%). In contrast, Long Chantenay was the most susceptible (27%).

Experimental results from the second generation were consistent with those from the first. Vertou had fewer eggs than Danvers Half Long 126 and Gelbe Rheinische. Furthermore, Vertou had fewer larvae than Gelbe Rheinische, Long Chantenay, Danvers Half Long 126, and Regulus Imperial. The ratio of eggs laid to larvae established in main roots ranged from 10 (Danvers half Long 126) to 12 (Sytan and Vertou) (Table 5). Vertou, Sytan, and three other cultivars had fewer mines per root than Gelbe Rheinische, Long Chantenay, Danvers Half Long 126, and Regulus Imperial (Table 5). Larval damage increased on all cultivars from the middle of September and peaked in November. A comparison between Vertou (resistant) and Long Chantenay (susceptible) showed that consistently more eggs, larvae, mines, and damaged roots were recorded on Long Chantenay than on Vertou. Percentage larval survival to the pupal stage ranged from 66% (St. Valery) to 98% (Vertou). The same scoring system showed Vertou again the most resistant cultivar (82%), followed by Clause's Jaune Obtuse Du Doubs (80%) and Sytan (78%). Long Chantenay was the third most susceptible cultivar (38%).

In the 1983 experiment (first generation) fewer ($P < 0.001$) eggs were laid on Vertou than on Long Chantenay as judged by the flotation method (Table 6). In the second generation, the use of egg trap A (root top enclosed) abolished this difference. But use of egg trap B (root top exposed) restored the significant difference between Vertou and Long Chantenay (Table 6). This unambiguously demonstrates that the root can regulate preference/nonpreference oviposition by the female fly.

The mean number of side roots per carrot root of the two cultivars Vertou and Long Chantenay was identical. Lactophenol staining did not detect *Psila* larvae inside such side roots. However, larval feeding areas were readily identified by examination with a binocular microscope. Each comprised a shallow pit in the epidermis (<2 mm long and 50–100 μ m deep), with a rust-colored perimeter. Alternatively this took the form of a narrow scar, more than 2 mm long. However, there was no significant difference between mean numbers of side roots infested on Vertou (1.3) and Long Chantenay (1.2) ($N = 7$).

^bTrap B was without centerpiece.

^cNot significant.

DISCUSSION

Vertou was consistently resistant: it was the most resistant cultivar on peat and the second most resistant on mineral soil. Sytan's ranking improved from sixth most resistant on peat to first place on mineral soil. At Wellesbourne, U.K., more sinuous mines but fewer nibbles were observed on carrots from fen or peaty soil than on those from mineral soil, suggesting that larvae mined more readily in tissues of peat-grown carrots (Ellis et al., 1978). Such a mechanism could contribute to Sytan's elevation to first place on mineral soil in our experiments. Similarly, Long Chantenay was the second most resistant cultivar in 1982 (peat soil) but the fourth resistant cultivar in 1983 (mineral). Overall, our data are quite consistent with the results of similar experiments in five European countries (Ellis and Hardman, 1981). Using the single criterion of percentage undamaged roots, they also rated Sytan and Vertou as the two most resistant cultivars. Their most susceptible cultivar was St. Valery, with Danvers in second place. Excluding *Regulus Imperial*, which was not considered by them, we found the most susceptible cultivars to be St. Valery and Long Chantenay in 1982 and Danvers and St. Valery in 1983. Thus, we confirm Sytan and Vertou as the most resistant cultivars and St. Valery as among the most susceptible.

In regard to mechanisms, highly significant differences in egg numbers were exhibited by different cultivars during the first ($P < 0.001$) and second ($P < 0.01$) generations of 1982. Resistant Vertou had 29% fewer eggs than susceptible Long Chantenay in the first generation of 1982. Such a response confirms nonpreference by the female *Psila* (Åhlberg, 1944; Guerin and Ryan, 1984). The experiment with egg-laying traps showed that exposing only the foliage was insufficient to reproduce differential egg numbers found between

Vertou and Long Chantenay; it was essential to also expose the respective root tops. This effect may be assignable to root volatiles, i.e., attractants and/or oviposition stimulants in root scent.

Significantly fewer eggs were laid on foliage of resistant Sytan than on that of susceptible Danvers in laboratory experiments (Guerin and Städler, 1982), which is consistent with the data from our field experiments. However, this preference was abolished when artificial leaves impregnated with leaf surface extracts from the two cultivars were compared in the laboratory. Furthermore, in a comparison of the effect of headspace vapor, Sytan attracted significantly more eggs than Danvers. Hence, the effect of contact with foliage was reproduced by neither extracts nor headspace volatiles of foliage. It was acknowledged that the observations took no account of root odor (Guerin and Städler, 1982). The present data indicate that input from the root contributes significantly to differential egg laying.

The second mechanism confirmed by our field data was resistance by the main root to larval attack as judged by numbers of larvae, mines, pupae, and damaged roots. This is exemplified by a comparison of Vertou with Long Chantenay and *Regulus Imperial* in the second generation of 1982. Cultivars Long Chantenay and *Regulus Imperial* had similar egg numbers to Vertou but sustained significantly more larvae, damaged roots, and mines (Table 5). Accordingly, these root effects reflect not only egg numbers but also indicate direct root resistance against the larva. This effect was first reported from a different set of cultivars by Guerin and Ryan (1984).

Present data indicate that the number of side roots would not affect root resistance in the two extreme cultivars (Vertou and Long Chantenay) as the mean number of side roots did not differ significantly between the two cultivars. Furthermore, detailed examination of the anatomy of the side roots gave no evidence of differential feeding or differential invasion. Thus, by elimination, root resistance to larval invasion must operate through the main root.

There was no evidence of more dead or stunted larvae immediately after establishment in any cultivar, eliminating antibiosis at that time as a mechanism. This suggests that decreased invasion, i.e., nonpreference exerted by the main root, governs larval establishment in such roots. At least five compounds, α -ionone, β -ionone, bornyl acetate, biphenyl, and 2,4-dimethyl styrene, attract larvae to roots (Ryan and Guerin, 1982). One compound, *trans*-2-nonenal, repelled and killed the larvae in laboratory experiments (Guerin and Ryan, 1980). Furthermore, combined concentrations of the attractants, but especially of 2,4-dimethyl styrene, were fivefold greater in the main root of the susceptible Chantenay-Red Cored-Elite as compared with resistant *Regulus Imperial* (Guerin and Ryan, 1984). Accordingly, it is reasonable to conclude that nonpreference, as influenced by chemical cues, affects root resistance to the larva.

Another possible resistance mechanism by the main root is antibiosis

against the feeding larva, i.e., if after prolonged feeding, larval growth, development, and survival were decreased (Campbell, 1983). In the second generation of 1982, larval survival in St. Valery and Sytan was 32% and 7% less, respectively, than in Vertou (100% survival). So antibiosis is another mechanism by which main root resistance operates, although it does not materially contribute to the resistance of Vertou and Sytan.

Antibiosis has previously been assigned to carrot on the basis of differential invasion of roots from inoculation with equal numbers of eggs (Guerin et al., 1981). However, the result did not preclude differential invasion due to non-preference behavior by the larvae in response to root chemicals. The present data provide an unambiguous demonstration of antibiosis. As this mechanism takes effect through physiological inhibitors, toxins, and decreased nutrient levels (Beck, 1965), it is reasonable to implicate root chemicals in its action against the *Psila* larva.

In summary, the present data identify root-mediated resistance as operating by: (1) eliciting fewer eggs (nonpreference by the female), (2) independently decreasing larval invasion (nonpreference by the larvae), and (3) antibiosis against the root-established larvae. Accordingly, root-mediated resistance has a pervasive role in carrot resistance to *Psila*. Root chemicals are already established as contributing to the second of these mechanisms (Guerin and Ryan, 1984), but it is now apparent that they also contribute to both the former and the latter. Accordingly, main root chemical constituents may be crucial in carrot resistance to *Psila*.

Acknowledgments—We thank Dr. P.R. Ellis, National Vegetable Research Station, Wellesbourne, U.K., for supplying seed and some statistical analyses.

Abstract—Roots of the carrot cultivars Vertou L.D. (resistant) and Long Chantenay (susceptible) were subjected to detailed chemical analysis to identify extracts and compounds influencing larval host-finding (preference/non-preference) behavior and to compare concentrations of these compounds in resistant and susceptible cultivars. Vertou yielded threefold less volatile material in headspace extracts of pureed roots. Extracts of chopped root in methanol, steam, hexane, and chloroform were inactive in behavioral assays. However, ether extracts were active and their hydrocarbon and carbonyl-rich fractions contained potent attractants. The principal constituent of the carbonyl-rich fraction of each cultivar was the carotatoxin complex comprising the neurotoxin falcarinol (carotatoxin), falcarindiol, and falcarindiol monoacetate, the latter compound here reported for the first time from carrot. Falcarinol (50 and 100 μg) was active in a behavioral assay, and all three ingredients of the complex were potent electrophysiological stimuli, eliciting maximum single unit responses to source concentrations of 10 ng. Furthermore, the complex was more abundant by about 1000 $\mu\text{g}/\text{root}$ in Long Chantenay. As this comprised extra amounts of 70, 862, and 110 μg of falcarinol, falcarindiol, and falcarindiol monoacetate, respectively, the observed differences seem both behaviorally and physiologically relevant. It is generally accepted that coevolution has transformed the role of many toxins into host-location cues, but this seems a relatively rare example of a neurotoxin (falcarinol) evincing, in decreased concentrations, nonpreference host resistance.

This evolved response to a toxin present in large concentrations is contrasted with that to *trans*-2-nonenal, which paralyzes and kills the larva and is present in only trace amounts in the root.

Key Words—Carrot *Daucus carota*, *Psila rosae*, Diptera, Psilidae, carrot-fly larva, root chemicals, carbonyl-rich fraction, falcarinol, falcarindiol, falcarindiol monoacetate, electrophysiology, neurotoxin, carrot resistance factor.

INTRODUCTION

The carrot root influences three principal mechanisms of carrot resistance to carrot fly, namely, nonpreference oviposition, independent nonpreference by the invading larva, and antibiosis against the feeding larva (Guerin and Ryan, 1984; Maki and Ryan, 1989). Of these, decreased oviposition is inadequate for plant protection, as cultivars with significantly fewer eggs nevertheless sustained significantly more root damage (Guerin and Ryan, 1984; Maki and Ryan, 1989). Thus, root resistance to the larva is critical for successful carrot resistance.

There is an association between increased carrot resistance and decreased release of root volatiles, as indicated both by solvent extraction and headspace entrapment. Specifically, the following five compounds significantly preferred by the larva were released in smaller concentrations by roots of resistant cultivars: bornyl acetate; biphenyl, α -ionone, β -ionone, and 2,4-dimethylstyrene (Guerin and Ryan, 1984).

This report further investigates the relationship between root chemistry and root resistance to the larva by examining larval responses to a variety of root extracts, fractions, and individual compounds using both behavioral and electrophysiological assays.

METHODS AND MATERIALS

Extraction and Quantification of Root Volatiles. Headspace extracts were derived from roots of Vertou and Long Chantenay by separate entrapment of their volatiles on the absorbents Porapak Q and Tenax GC (60–80 mesh). Weighed batches of each cultivar's roots, pureed in a food blender with periodic addition of ice, were placed in foil-covered glass tubes 62 cm long \times 9 cm diam. and simultaneously extracted. Air, purified over activated charcoal, diverged to pass over each puree, then through two flow meters set at 0.1 liter/min, and finally through two foil-covered tubes each containing 5 g absorbent. After 48 hr, the purees were discarded and replaced by fresh batches in the washed tubes. Thus ca. 1 kg of each cultivar was extracted for 70–80 hr. Pora-

pak was activated as previously described (Ryan and Guerin, 1982) and Tenax GC was activated by heating at 275°C for 5 hr in a nitrogen stream at 0.1 liter/min. Volatiles from each source were separately extracted in a Soxhlet apparatus for 24 hr in diethyl ether and for a further 24 hr in methanol, solvents of choice for nonpolar and polar compounds, respectively. After concentration by rotary evaporation and exposure to a nitrogen stream, such extracts were quantitatively examined by gas-liquid chromatography (details in Table 1).

The following extractions of chopped root were also made: steam-distillation, separation in water-hexane and water-chloroform mixtures, extraction in methanol followed by fractionation (Figure 1), and extraction in ether; only the latter yielded consistently active fractions (Figure 2). The active carbonyl-rich fractions from the ether extracts were further subdivided by repeated column chromatography on silica gel. The eluants were *n*-hexane-diethyl ether in the successive ratios 19:1, 4:1, 2:1, and 1:1. Eluant samples were monitored by TLC or GLC and isolates were identified by GC-MS (VG Analytical 7070E mass spectrometer, PYE 204 gas chromatograph; Finnigan-Mat INCOS 2400 data system) and [¹H]NMR (Perkin Elmer 12 RB), supplemented by high-field [¹H]NMR (Jeol GX 270). (±)-2-Methoxy-3-*sec*-butylpyrazine was an individual compound of particular interest as it has been claimed to produce the distinctive odor of carrot (Cronin and Stanton, 1976). It was not commercially available and has been recorded in concentrations too small for easy extraction (<1 ppm) (Cronin and Stanton, 1976). Accordingly, it was synthesised as a racemic mixture (F. Abe, In preparation).

TABLE 1. YIELD OF VOLATILES EXTRACTED WITH VARIOUS ADSORBENTS AND SOLVENTS FROM ROOTS OF CARROT CULTIVARS VERTOU (V, RESISTANT) AND LONG CHANTENAY (LC, SUSCEPTIBLE)^b

Adsorbent	Solvent	Volatile yield (μg/80 g pureed root tissue/24 hr) of cultivars ^a		Ratio of V to LC
		Vertou	Long Chantenay	
Porapak Q	Diethyl Ether	539	1410	1 : 2.6
	Methanol	18	21	1 : 1.4
Tenax G C	Diethyl Ether	1251	4019	1 : 3.2
	Methanol	273	503	1 : 1.8

^a80 g represents the mean weight of a mature root for carrots sown in June 1984 and harvested in March 1985. Values represent means of two replicates differing by less than 10%.

^bTypical operating conditions: Hewlett-Packard 5890 GC linked to automatic computing integrator 3380 Å; column, glass 10 m long, 530 μm diameter, coated with Carbowax 20 M, which gives superior resolution of carrot volatiles (Ryan and Guerin, 1982); injection port temperature 220°C, detector temperature 220°C; oven temperature 100°C for 1 min followed by a programmed rise of 10°C/min for 10 min to 170°C.

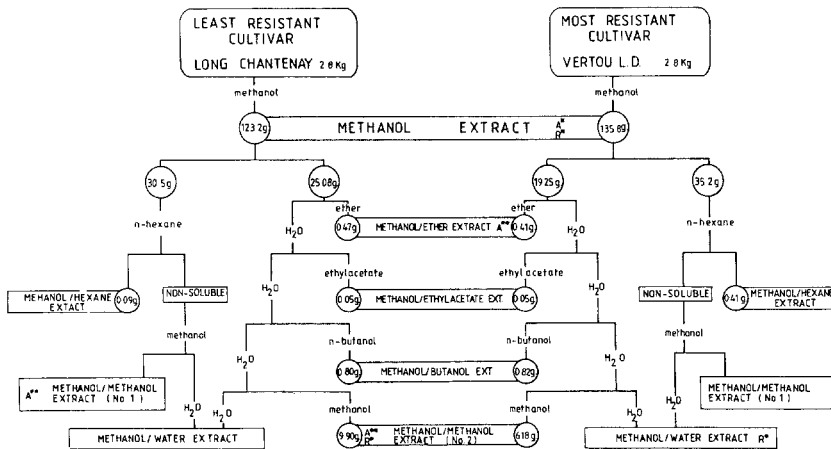

FIG. 1. Yields, effects, and potencies of fractions derived from methanol extracts of Long Chantenay and Vertou carrot roots. Typically, fractions were bioassayed by the box method in concentrations of 0.01, 0.5, and 1.0 mg/disk with some additional observations at 5.0 mg/disk. Encircled values are yields. Effects and potencies: A, attractive, R, repellent; * $P < 0.05$; ** $P < 0.01$. Corresponding values of $R(\%)$, derived from $(T - C/T + C) \times 100$ and rounded to the nearest integer (details in text), were as follows: methanol extract, Vertou, $R = 17\%$ at 0.1 mg/disk and -20% at 0.5 mg/disk; methanol-ether-extract, Vertou, $R = 38\%$ at 1.0 mg/disk; methanol-methanol extract No. 1, Long Chantenay $R = 29\%$ at 0.5 mg/disk; methanol-methanol extract No. 2 Long Chantenay, $R = 28\%$ at 1.0 mg/disk and -20% at 5.0 mg/disk; methanol-water extract, Vertou, $R = -26\%$ at 1.0 mg/disk.

Behavioral Assays. Root extracts were subjected to one of two behavioral assays. The first was based on the method used to observe larval responses of the onion fly, *Delia antiqua* (Meigan), to sulfur-bearing chemicals (Soni and Finch, 1979). It employed a Petri dish (10 cm diam.) lined with a 9-cm, damp, black filter paper (Schleicher and Schull No. 551), marked with a pencil into quarters designated test, control, upper neutral, and lower neutral, respectively. Typically, test chemicals were introduced by adding 100 μ l of stimulus solution onto an elderberry pith disk (1.5 cm diam. \times 0.3 mm thick, preextracted with solvent) (test) in concentrations of 0.05, 0.1, or 1 mg/100 μ l; another pith disk treated with 100 μ l solvent (control) was placed in the opposite sector. After evaporation of solvent, 20–30 third-instar larvae, deprived of food for 24 hr, were placed in the center of each test chamber using a soft paint brush. Five replicates (chambers) were used for each concentration. Test chambers containing larvae were kept in the dark for 15 min at $20 \pm 1^\circ\text{C}$, after which the number of larvae in each sector was counted and recorded.

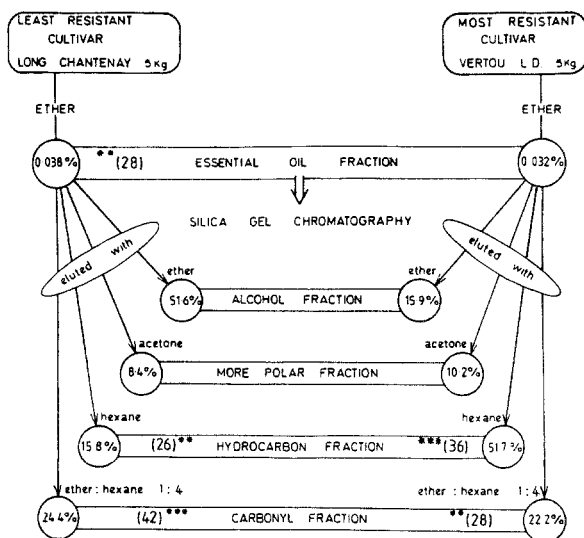

FIG. 2. Yield and potencies of fractions derived from ether extracts of Long Chantenay and Vertou carrot roots. Each batch of roots was extracted with ether and the solvent evaporated in vacuo at 40°C. Each ether extract was loaded on to a column of silica gel (Kiesel Gel 60, Merck, 20 times the extract weight) and eluted with the solvents indicated. Fractions at concentrations of 0.5, 1.0, 2.0, and 4.0 mg/disk were bioassayed by the box method (details in Methods and Materials). All significant responses were elicited at 1.0 mg/disk; ***P* < 0.01; ****P* < 0.001; values in parentheses are *R*(%), see text for details. The yields of ether-extracted oil are equivalent to 380 and 320 ppm for Long Chantenay and Vertou, respectively. On the basis of a mean root weight of 80 g, this is equivalent to an extra 4.80 mg oil from a Long Chantenay root.

The second method employed a lidded rectangular Perspex chamber (15 × 4 × 4 cm deep). The floor was lined with damp filter paper (Whatman No. 40) marked with pencil at the midline to give test and control halves. As before, a pith disk treated with the test chemical (usually 0.001, 0.01, 0.05, 0.1, and 0.5 mg/disk) was placed at the far end of the test half, a corresponding disk treated with solvent placed in the other end of the control half, and 20–30 unfed larvae were employed per replicate. Five lidded chambers were kept in the dark for 15 min, after which time the number of larvae in each half was recorded. Both methods gave essentially similar results when tested with the same compounds.

All data were subjected, first, to a χ^2 test for homogeneity and homogenous data were then further assessed by the *t* test. It was convenient to score larval responses in particular experiments according to the formula: $R(\%) = (T - C /$

$T + C) \times 100$, where T is the number of larvae on the test side of the chamber, and C is the number of larvae on the control side of the chamber.

Electrophysiological Assays. The experimental set-up was housed in an earthed Faraday cage into which ran a stimulus delivery system (Figure 3). Air flow was directed through three solenoids controlled by a timer switch opening one valve for 1 sec every 5 min; it could also be operated manually. The valve directed air over the stimulus chemical applied as 20 μ l to a folded piece of filter paper (12 cm) contained in a glass cartridge (54 mm long and 10 mm diameter) with ground glass end. The other two lines terminated in a control (solvent) cartridge and an empty cartridge, respectively, the latter providing a continuous flow of purified air to remove stimulus molecules from the vicinity of the preparation.

The principal electronic control unit was the WPI Micro-probe system model M-707 equipped with a probe, which was gold-plated, epoxy-sealed, and contained the first stage of amplification ($\times 1$). Plugged into this was a micro-electrode holder having a molded Ag-AgCl half cell into which the recording microelectrode was inserted through a rubber gasket. This microprobe system had the following features: current passing and low noise, drift-free performance, bandwidth limiting filter, notch filter, selectable bridge balance range, and a probe test. The system was connected to both a Phillips PM 8010 double pen recorder and to a Telequipment DM 64 storage oscilloscope. Recording and reference microelectrodes had tip diameters of 0.5 and 5.0 μ m, respec-

FIG. 3. A block diagram of the electrophysiological set-up. Inset: diagrammatic representation of the larval group B sensilla indicating the ampullaceous sensillum (a), from which recordings were made.

tively, and were loaded with Ringer solution identical in the following constituents to that of receptor lymph from *Antheraea polyphemus* (K.E. Kaissling, personal communication: glucose (22.50 mM/liter), KCl (171.90), KH_2PO_4 (9.17), K_2HPO_4 (10.83), MgCl_2 (3.00), CaCl_2 (1.00), NaCl (25.00), and HCl (1.50); pH 6.5 and 475 mosm).

Third-instar larvae, unfed for 4 hr at room temperature, were immobilized on a disk-shaped rubber stage (3 cm diam.) by knots of human hair. The larva bears on its cephalic lobes 24 sensilla arranged in three groups (A, B, and C), of which group B comprises six evident sensilla on each side of the ventral midline: one ampullaceous (3 μm diam.) and three basiconic on a cuticular projection; dorsolateral to this are two additional sensilla, one styloconic and one basiconic (Ryan and Behan, 1973) (see inset to Figure 3). This group of sensilla seems analogous to the terminal organ of the house fly larva and the anterior organ of the larvae of the onion and seed corn flies (Yamada et al., 1981; Honda and Ishikawa, 1987a). The latter organ has been associated, through electrophysiological recordings, with a gustatory function, but, because the capillary tip touched the whole organ, it was not possible to distinguish the functions of individual sensilla (Honda and Ishikawa, 1987b). In the *Psila* larva, the dome of the ampullaceous sensillum of group B is perforated by pores above branched dendrites (Behan, unpublished results), which is consistent with an olfactory function. The recording electrode just penetrated the cuticle of this ampullaceous sensillum (3 μm diameter) so the records obtained may be viewed as single unit responses, which we measured as DC changes; the primary electrical event in the response of a chemosensory neuron is the DC generator or receptor potential. The reference electrode was inserted into the hemolymph adjacent to the cephalic lobes.

As electrophysiological responses diminished throughout an experiment, the response amplitudes to the test compounds were expressed as a percentage of the responses to a standard: 0.1 μg limonene for carrot root fractions and 0.5 μg *trans*-2-hexen-1-ol for the single compounds.

Consistent physical conditions are necessary in order to obtain reproducible electroantennograms (Adler, 1971). Thus, the cartridge was always positioned at the same distance (2 cm) from the preparation, the size of the filter paper within the cartridge was always identical, all cartridges had identical dimensions, and the flow rate of air was always the same (1 liter/min).

RESULTS

Extraction and Behavioral Assays of Root Volatiles. In each of four comparisons of total volatiles released into the headspace, resistant Vertou yielded less than susceptible Long Chantenay (Table 1). Tenax was threefold more

efficient than Porapak as adsorbent, and washes with diethyl ether yielded 8.8-fold more volatiles than subsequent washes with methanol, so the ether wash of the Tenax extraction is the most appropriate one for comparison. In this, total volatiles released by Vertou were less than one third the quantity released by Long Chantenay (Table 1).

Behavioral assays were made with a range of extracts including steam distillates, hexane-water, and chloroform-water extracts derived from Clause's Original Sytan (resistant), Long Chantenay (susceptible), and Danvers Half Long 126 (intermediate in resistance) (0.05–0.1 mg/disk). The aqueous layers from these extracts of the cultivars were all inactive. Only the steam distillate of Sytan and Danvers (5 μ l/disk), the hexane extract of Long Chantenay (0.1 mg/disk), and the chloroform extract of Sytan (0.05 mg/disk) were significantly preferred to their corresponding controls. Batches of Vertou and Long Chantenay extracted and fractionated in methanol (Figure 1) elicited too few significant responses to merit further detailed investigation.

In contrast, ether extracts were quite active, especially at 1 mg/disk. Although the essential oil extract of Vertou was inactive, that from Long Chantenay elicited a highly significant positive response (details of subfractions, yields, and responses in Figure 2). Neither the alcohol nor more polar fractions, collectively representing 26% and 60% of Vertou and Long Chantenay extracts, respectively, elicited any significant responses. In contrast, the fractions rich in hydrocarbon and carbonyl compounds elicited significantly positive responses (Figure 2).

As α -ionone, β -ionone, and bornyl acetate are attractants (Ryan and Guerin, 1982) and contain a carbonyl group, we focused on the carbonyl-rich fractions that were further fractionated by repeated silica gel chromatography monitored by thin-layer and gas-liquid chromatography (Figure 4). Elution by hexane-diethyl ether 19:1 followed by 4:1 afforded falcarinol (carotatoxin); further elution with the same solvents in the ratios 2:1 and 1:1 afforded falcarindiol monoacetate and falcarindiol (Figure 4). These compounds are represented by

where for falcarinol (carotatoxin) $\text{R} = \text{R}^1 = \text{H}$; for falcarindiol monoacetate $\text{R} = \text{OH}$, $\text{R}^1 = \text{Ac}$; and for falcarindiol $\text{R} = \text{OH}$, $\text{R}^1 = \text{H}$ (Figure 4). Of the three compounds, falcarindiol monoacetate is newly recorded from carrot. For completeness, the foliage of the two cultivars was subjected to an identical extraction, which also afforded falcarindiol monoacetate and falcarindiol but not falcarinol (Figure 4). Quantitatively, these three compounds collectively

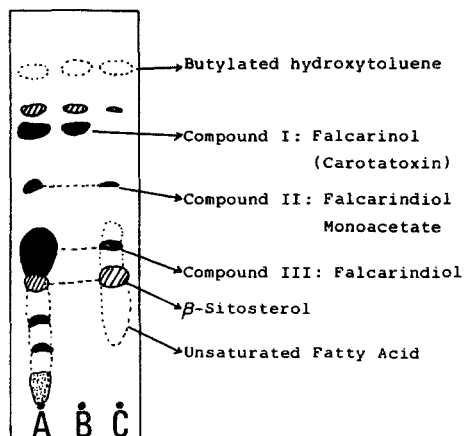

FIG. 4. Preparative thick-layer chromatography, developed in hexane-ethylacetate (1:1), of extracts of Long Chantenay roots with foliage included for completeness: (A) carrot root, ether extract; (B) carrot root, carbonyl fraction; (C) carrot foliage, ether extract. Compound I, a pale yellow oil, IR and [^1H]NMR values identical with those for falcarinol, carotatoxin (Crosby and Aharonson, 1967). Compound II, A colorless oil, falcarindiol monoacetate. [^1H]NMR CDCl_3 δ : 0.882 (3, t, $J = 6.7$, CH_3), 1.254 [2, s, $(\text{CH}_2)_6$],

2.105 (3, s, $-\text{OAC}$), 1.604 [2, 3 $-\text{C}_2$], 5.19–5.93 (5, m, $-\text{CH}=\text{CH}$, $-\text{CH}=\text{CH}_2$). Compound III, a pale yellow oil, falcarindiol, [^1H]NMR CDCl_3 δ : 0.9 (t, $J = 6.0$, CH_3), 1.30 [br, $(\text{CH}_2)_3$], 2.15 (m, OH), 5.0–6.2 (M) (olefinic protons).

represented 8.0% and 5.4% of the Long Chantenay and Vertou ether extracts, respectively, comprising 1.5 and 1.4% falcarinol, 5.9% and 3.6% falcarindiol, and 0.7 and 0.4% falcarindiol monoacetate, respectively. A check on the reliability of these values is provided by the measurement of the concentration of butylated hydroxytoluene, a commercial additive to stabilize ether, as 2.6% in the extract of both cultivars (mean of two replicates differing by less than 5%).

In behavioral assays, responses to falcarinol were significantly positive at 0.05 mg/disk and very highly significant at 0.10 mg/disk (Table 2). The positive response to β -sitosterol glucoside was significant at 0.01 mg/disk: scopletin and β -sitosterol were inactive. (\pm)-2-Methoxy-3-*sec*-butylpyrazine elicited highly significant positive responses at concentrations ranging from 0.05 to 10 mg/disk. As a check on the Petri dish method, bornyl acetate, established as an attractant following detailed behavioral observations including larvae-track records, was also assayed. It elicited very highly significant positive responses at 0.10 and 10.00 mg/disk (Table 2), thus confirming the utility of this method.

TABLE 2. RESPONSES OF CARROT FLY LARVAE TO INDIVIDUAL COMPOUNDS OCCURRING IN CARROT ROOT USING PETRI DISH METHOD

Electrophysiological Assays. The ether-extracted essential oil of chopped Long Chantenay root was a potent stimulus, eliciting a peak response equivalent in amplitude to 250% that of the standard (Figure 5); the corresponding oil from Vertou was not available for this assay. The carbonyl fractions from Vertou and Long Chantenay were also active electrophysiologically but never exceeded 150% of standard response and so were less potent than the essential oil of Long Chantenay. The carbonyl fraction of Vertou was consistently less potent than that from Long Chantenay, and the lowest source concentration evincing clear separation in their effect was 0.01 μ g (Figure 5). Here, the response to Vertou was 45% weaker than standard, whereas that to Long Chantenay was 17% stronger than standard, or the carbonyl fraction of Vertou was about one half as potent a stimulus as that from Long Chantenay (Figure 5). The major substituents of the carbonyl-rich fraction, falcarinol and falcarindiol, were potent stimuli, eliciting at 10 ng a maximum response more than fivefold more potent than that of the standard; falcarindiol monoacetate was about 3.5-fold more potent (Figure 6).

FIG. 5. Single unit responses (DC), from the group B ampullaceous sensillum of the *Psila* third-instar larva, to various concentrations of root extracts from Vertou and Long Chantenay. Responses are expressed as a percentage of the response to a standard, 0.1 μg limonene ($N = 5$; vertical bars here and in Figure 6 represent standard deviations).

DISCUSSION

The headspace comparison principally demonstrates a substantially decreased volatile release from pureed roots of resistant Vertou as compared with susceptible Long Chantenay. This is consistent with the earlier demonstration of decreased volatile release by the roots of resistant *Regulus Imperial*

FIG. 6. (a) Unretouched traces of single-unit responses (DC) to various source concentrations of falcarinol (carotatoxin) with limonene included as standard. (b) Single unit responses (DC) from the group B ampullaceous sensillum of the *Psila* third-instar larva to various concentrations of the three constituents of the carotatoxin complex. Responses are expressed as a percentage of the response to a standard, $0.5 \mu\text{g}$ *trans*-2-hexen-1-ol ($N = 5$).

as compared with susceptible Chantenay-Red Cored-Elite (Guerin and Ryan, 1984). Accordingly, such decreased release by carrot root may be a significant feature of *Daucus* resistance to *Psila*. The adsorbent superiority of Tenax over Porapak also seems noteworthy.

Ether extracts of chopped root were the most potent, and the principal component of their strongly preferred carbonyl-rich fraction was the carotatoxin complex comprising falcarinol, falcarindiol, and falcarindiol monoacetate. This seems to be the first report from carrot of the monoacetate, which we also identified in the extracted foliage of each cultivar; an earlier investigation of foliage did not detect this compound (Städler and Buser, 1984).

In quantitative terms, the larger yield of ether-extracted oil from Long Chantenay compounded by the larger percentage concentration represented by the toxin complex in Long Chantenay produces an increased amount of 13.07 ppm, or $1046 \mu\text{g}$ toxin complex per typical root of 80 g. In regard to individual constituents of the complex, the variation in the percentage concentration represented by falcarinol would seem to be close to error limits. However, the

additional yield of Long Chantenay oil would indicate additional amounts of 70 μg falcarinol per Long Chantenay root; corresponding increased amounts for falcarindiol and falcarindiol monoacetate are 862 μg and 110 μg , respectively.

The extra 70 μg falcarinol per Long Chantenay root exceeds the minimum source concentration of 50 μg falcarinol that elicited a significantly positive behavioral response from the larva. Increasing the source from 50 to 100 μg strengthened this response, so the 70 μg excess falcarinol seems behaviorally relevant. Furthermore, as the smallest of these additional amounts is 70,000 times larger than the source amount eliciting maximal electrophysiological response from the larva, the extra amount of toxin complex also seems relevant at the neurophysiological level. Given that the five individual compounds previously identified as larval attractants collectively constitute not more than 3 μg /root (Ryan and Guerin, 1982), they now seem less significant than the toxin complex as larval attractants and as resistance factors.

In a comparison of six carrot leaf substituents, falcarindiol was the most potent stimulus for oviposition by *Psila* and the only constituent active at concentrations equal to or less than those in the leaf surface (Städler and Buser, 1984). The estimated threshold concentration for egg laying was 100 ng falcarindiol and each 6 g of leaf contained about 3200 ng of this compound (Städler and Buser, 1984). We estimate that 6 g of the average root of Vertou and of Long Chantenay would contain 69 μg and 134 μg falcarindiol. Accordingly, the root moiety of this compound could surpass that in the leaf as an egg-laying stimulus. Furthermore, the additional amount in a Long Chantenay root (65 μg /6 g or 862 μg /root) seems more than sufficient to affect the differential egg laying we observed as influenced by root (Maki and Ryan, 1989). So there can be little doubt that falcarindiol is a crucial compound in the relationship between *Psila* and its host by serving as: (1) the principal reported stimulus for oviposition, (2) a potent neurophysiological stimulus for the larva, and (3) a contributing factor, through decreased concentrations, to the superior root resistance of Vertou.

When injected into mice, falcarinol (carotatoxin) evokes neurotoxic symptoms with an LD value of ca. 100 mg/kg body weight and is also toxic to the crustacean, *Daphnia magna* (Straus) (Crosby and Aharonson, 1967), effects that have been assigned to falcarindiol by Städler and Buser (1984) [antifungal properties have been demonstrated for falcarindiol (Kemp, 1978)]. Falcarinol was first given the trivial name "carotatoxin" by Crosby and Aharonson (1967), and subsequently the compound was confirmed as falcarinol (Bentley and Thaller, 1967), the polyacetylenic alcohol first isolated from *Falcaria vulgaris* Bernh. (Bohlman et al., 1966). Thus, a neurotoxin affecting vertebrates and invertebrates, and presumably capable of inhibiting feeding by them, would seem to have become a host-location cue for the *Psila* larva, which is consistent with the coevolutionary concept of plant-insect relationships. It is appropriate

to contrast this evolutionary response to the toxins with the failure of *Psila* to similarly evolve to another toxic ingredient of carrot root, *trans*-2-nonenal, which repels, paralyzes, and kills the larva (Guerin and Ryan, 1980). As *trans*-2-nonenal comprises only 40 μg /average carrot root, in contrast to 2394 μg represented by the toxin complex, the larger concentration of toxin might more readily elicit adaptation.

It has been reported that carrot cultivars more susceptible to root fly damage contain larger concentrations of chlorogenic acid, the principal phenolic constituent of carrot root peel (Cole, 1985). However, the fact that carrots overwintering in soil and subject to damage by frost also exhibited elevated levels of chlorogenic acid suggested that any damage to the root elicits this response (Cole, 1985). Subsequent observations did not experimentally separate "cause" and "effect" in this relationship (Cole et al., 1987).

The present data indicate that decreased levels of the carotatoxin complex confer resistance on carrot roots by making them less attractive to larvae. Although there are other examples of plant toxins employed as host-location cues of insect parasites, this seems a relatively rare example of decreased concentrations of a neurotoxin eliciting nonpreference resistance.

Abstract—Quaking aspen (*Populus tremuloides* Michx.) staminate flower buds and the extended catkins are primary food resources for ruffed grouse (*Bonasa umbellus*). Winter feeding observations indicate that ruffed grouse select specific trees or clones of quaking aspen to feed in. Flower buds and catkins of quaking aspen were analyzed for secondary compounds (tannins, alkaloids, and phenolics) that might cause ruffed grouse to avoid trees with high levels of these compounds. Coniferyl benzoate, a compound that has not been previously found in quaking aspen, exists in significantly higher concentrations in buds from trees with no feeding history as compared to ruffed grouse feeding trees. Aspen catkins were also significantly lower in coniferyl benzoate than buds from the same tree. Ruffed grouse feeding preference was not related to the tannin or total phenolic levels found in buds or catkins. Buds from feeding trees had higher protein levels than trees with no feeding history; however, catkins did not differ from buds in protein concentration. The high use of extended catkins in the spring by ruffed grouse is probably due to a lower percentage of bud scale material in the catkin as opposed to the dormant bud. Bud scales contain almost all of the nontannin phenolics in catkins and dormant buds. A feeding strategy where bud scales are avoided may exist for other bird species that feed on quaking aspen. Dormant flower buds are significantly lower in protein-precipitable tannins than catkins and differ in secondary metabolite composition from other aspen foliage.

Key Words—Coniferyl benzoate, *Populus tremuloides*, *Bonasa umbellus*, Fringillidae, feeding behavior, secondary metabolites, tannins, phenols.

INTRODUCTION

The importance of quaking aspen (*Populus tremuloides* Michx.) in the diet of ruffed grouse (*Bonasa umbellus*) has been recognized by numerous investigators (Svoboda and Gullion, 1972). Ruffed grouse rely on quaking aspen as a primary food source throughout the year; however, their dependence on this species is most evident during the winter and early spring when their alternative food sources are limited (Gullion, 1966; Vanderschaegen, 1970; Svoboda and Gullion, 1972; Doerr et al., 1974; Huempfer, 1981). The item that ruffed grouse consume most frequently during the winter is the staminate flower bud of quaking aspen (Vanderschaegen, 1970; Svoboda and Gullion, 1972; Doerr et al., 1974). Use of the staminate flowers continues in the spring, when, for a limited time, ruffed grouse exist on almost an exclusive diet of the extended catkins (Gullion, 1964; Vanderschaegen, 1970; Stoll et al., 1980).

Although quaking aspen is one of the primary food resources for ruffed grouse, feeding observations indicate that ruffed grouse normally feed only in certain trees or clones of quaking aspen and that preference for certain trees may change over time (Gullion, 1966; Huff, 1970; Schemnitz, 1970; Huempfer, 1981). Characteristically, ruffed grouse feed in older trees (30–50 years old) that are physiologically stressed (Huff, 1970; Svoboda and Gullion, 1972; Doerr et al., 1974). The preferential use of certain clones and trees can be explained partially by ruffed grouse selecting trees that have buds with higher nutrient levels; however, the periodic lack of use of quaking aspen buds by ruffed grouse cannot be readily explained by fluctuating nutrient levels (Huff, 1970; Doerr et al., 1974).

Long-term studies of ruffed grouse populations indicate that their populations cycle every 8–10 years, especially in the northern latitudes of their range (Keith, 1963; Gullion, 1970, 1984). Researchers in Minnesota and Alberta have noted that sharp declines in ruffed grouse populations and their periodic low population levels have coincided with the lack of use of aspen buds during the winter (Gullion, 1970, 1984; Doerr et al., 1974; Huempfer, 1981; D. Rusch, University of Wisconsin, unpublished data). Servello and Kirkpatrick (1987), sampling grouse crop contents during periods of depressed populations, found few aspen buds among birds coming from regions (e.g., Maine, Wisconsin, New York) where there has been heavy use of these buds at other times (Brown, 1946; Bump et al., 1947; Stollberg and Hine, 1952). This decrease in the use of quaking aspen can occasionally be attributed to a failure in the aspen bud crop; however, during many of these years the aspen bud crop has been ample (Doerr et al., 1974; Gullion, 1977, 1984, and unpublished data).

One possible explanation for the differential use of aspen buds during the ruffed grouse population cycle is that the overall nutritive value of the buds changes (Lauckhart, 1957). Studies on how the standard nutrients in quaking

aspen vary with cyclic animal populations indicate that nutrient levels do not track these cyclic populations (Pease et al., 1979; Batzli, 1983). However, the overall nutritional value of food is only partially determined by standard nutrients. Secondary compounds also play an important role in determining the value of a plant as a food source (Bryant and Kuropat, 1980; Bryant, 1981; Rhoades, 1983; Reichardt et al., 1984). Gullion (1977) attributed the lack of use of quaking aspen buds by ruffed grouse, during several consecutive years of abundant bud crops, to some type of "plant defensive mechanism." Additionally, he noted that the degree of aspen bud use by ruffed grouse was later reflected in their population levels. This periodic decrease in use of flower buds contrasts to the consistently high use of the catkins from these buds in the spring (Gullion, 1984). Previous investigations do not clearly indicate whether nutrient levels change significantly as aspen buds mature into catkins and how these changes are related to ruffed grouse selection for this item.

The objectives of this study were twofold. The first objective was to obtain preliminary information on the secondary chemistry of quaking aspen staminate flower buds and catkins, with the intent of identifying the compounds that would most likely act as primary feeding deterrents towards ruffed grouse. The second objective was to test the hypothesis that ruffed grouse feeding preference for quaking aspen catkins and certain flower buds is related to differential levels of specific secondary compounds.

METHODS AND MATERIALS

Sample Collection and Storage

Ruffed grouse feeding behavior was observed three times a week, from December to April (1985 and 1986), at the Mille Lacs Wildlife Management Area, in east-central Minnesota and at the Cloquet Forestry Center located near Duluth, Minnesota. Feeding observation methods are detailed in Svoboda and Gullion (1972). Quaking aspen that ruffed grouse were observed feeding in were designated as "preferred" trees and marked.

Quaking aspen buds were sampled from mid-January through the first week in March (1985 and 1986) at the Mille Lacs and Cloquet study sites. Samples were collected during the period when ruffed grouse normally make the heaviest use of quaking aspen buds and when physiological changes in these buds are relatively minor (Huff, 1970; Huempfer, 1981). When a preferred tree was sampled, an additional quaking aspen with no feeding history (nonpreferred tree) was sampled and treated as a paired tree. Trees were considered paired due to similar site characteristics and time of sampling. In order to minimize chemical variation between paired trees, nonpreferred trees were chosen from the same age class as preferred trees, and only the upper crowns of each tree

were sampled. To assure clonal separation of paired trees, nonpreferred trees were chosen at least 200 ft from preferred trees, and distinguishing characteristics of the preferred tree's clone were noted (Blake, 1963; Barnes, 1966). A total of 11 pairs of preferred and nonpreferred trees were sampled during the two field seasons.

After the branches were brought to the ground by shooting them with a small bore rifle, staminate flower buds were immediately picked, put into air tight plastic bags or Nalgene (Nalge 2007) bottles and stored at approximately -50°C on Dry Ice (Bielecki, 1964; Robinson, 1980; Bryant et al., 1983). Enzymes such as polyphenol oxidase can readily change phenolic compounds into quinones and other oxidation products (Takai and Hubbes, 1973; William Gordon, Howard University, personal communication; Mattes et al., 1987). Therefore, samples were kept on Dry Ice until they were lyophilized, after which they were ground with a mortar and pestle under liquid nitrogen and stored at -18°C (Swain, 1979; Martin and Martin, 1982).

Catkin sampling procedures were essentially the same as for dormant winter buds. Bud scales normally adhere to the base of the catkin after the catkins are picked from the branches. These scales were included in the catkin samples, since bud scales were seen in droppings from ruffed grouse that had been feeding on catkins. A total of 18 nonpreferred trees were sampled for their dormant buds and again in mid-April when their catkins had extended. Since ruffed grouse consistently utilize catkins, whether or not they have made use of the dormant winter buds, catkin samples were considered preferred food items. Therefore, bud and catkin samples from individual nonpreferred trees were treated as paired nonpreferred and preferred samples respectively.

Chemical Analyses

Tannins. Aspen bud and catkin samples were analyzed for both protein-precipitable tannins and condensed tannins. Protein-precipitable tannins were measured using the radial diffusion assay (Hagerman, 1987). Samples (100 mg) were extracted in acetone and water (70:30) (5.00 ml) for three days. A calibration curve was constructed using purified tannic acid (courtesy of A.E. Hagerman) and used to calculate the tannic acid equivalents in the extracts.

Condensed tannins were measured using a modified form of the proanthocyanidin assay of Watterson and Butler (1983). Samples (200 mg) were extracted in 2.00 ml of acidic methanol (1% HCl v/v) for 1 hr. The extract (0.20 ml) was dispensed into a test tube, and 2.00 ml of acidic butanol (30% HCl v/v) was added. This mixture was heated in a boiling water bath for 10 min, after which its absorbance was measured at 550 nm on a Beckman DB GT spectrophotometer (A.E. Hagerman, personal communication).

Alkaloids. Aspen bud samples were extracted following the methods outlined in Lindroth et al. (1986). Alkaloid content was analyzed by thin-layer chromatography (TLC) using silica gel plates (Kodak 13179) that were developed in toluene-chloroform-acetone (90:30:10) and visualized with Dragendorff Munier-Macheboeuf reagent or iodine-iodide reagent (Santavy, 1969; Touchstone and Dobbins, 1978). Isoniazid (Aldrich Chem. Co.), a pyridine alkaloid found in quaking aspen leaves, was used as a standard and cochromatographed with the bud extracts (Sunarjo, 1985). Visualization reactions were carried out both on TLC plates and standard filter paper due to an inverse reaction (light spot instead of dark) of the visualization reagents with isoniazid on the silica gel plates.

Phenols. Specific phenolic compounds and total phenolics were both investigated. Total phenolics were estimated using the Prussian blue assay (Price and Butler, 1977). Samples (0.20 g) were extracted in 2.0 ml of acidic methanol (1% HCl v/v) for 1 hr. Ferric ammonium sulfate was substituted for ferric chloride in the reaction, and potassium ferricyanide was added 20 min after the ferric ammonium sulfate addition (A.E. Hagerman, personal communication). Absorbance was measured at 720 nm on a Beckman DB GT spectrophotometer. A calibration curve was constructed using commercial gallic acid and was used to calculate gallic acid equivalents in the samples.

Bud samples that were qualitatively analyzed by TLC were extracted overnight (500 mg dry wt) in 3 ml of reagent grade methanol. The phenolic compounds that were analyzed by high-performance liquid chromatography (HPLC) were relatively nonpolar; therefore, ethyl ether was used as the extraction solvent. Bud and catkin samples (100 mg dry wt) were extracted for 24 hr in 5.0 ml of anhydrous ethyl ether, after which the eluent was drawn out of the plant material with a Pasteur pipet, and concentrated in vacuo to 1 ml. The extract was subsequently stored at -18°C until analyzed.

Initial qualitative and semiquantitative comparisons between preferred and nonpreferred samples were done using TLC. Silica gel (Kodak) plates were developed in either toluene-chloroform-acetone (40:25:35), toluene-acetone-formic acid (46:46:8), or chloroform-methanol-water (80:19:1), depending on the polarity of the compounds of interest (Egger, 1969; Lea, 1978). Aspen buds were tested for simple phenolics and phenolic glycosides including: salicortin, salicin, tremulacin, tremuloiden, *p*-coumaric acid, catechol, and benzoic acid. Compounds from aspen bud extracts that had similar R_f values as commercial standards were scraped from the TLC plate and rechromatographed with commercial standards on Merck reversed-phase, high-performance thin-layer plates (HPTLC) (Fried and Sherma, 1982). Plates were developed in aqueous 0.5 M sodium chloride-methanol (50:50) (Fried and Sherma, 1982).

Quantitative analyses were performed using HPLC. Pinosylvin dimethyl

ether (PDE) was used as the internal standard. Aspen bud and catkin extracts were diluted with 4.00 ml of methanol containing 150 μg of PDE. Samples were injected (20 μl) on an analytical column (25 cm \times 4 mm) packed with 10 μm Waters gamma bondapak C_{18} reverse-phase sorbent. The gradient program was: T1 = 0 min, 42% A, ramp time 1 min; T2 = 25 min, 60% A, ramp time 1 min; T3 = 40 min, 42% A, flow rate 1 ml/min; where solution A was acetonitrile and solution B 2% tetrahydrofuran in water. A Schoeffel SF770 and GM770 variable wavelength detector, set at 295 nm was used for detection of sample components. Peaks were quantified using peak height measurements that were standardized to peak areas of the internal standard and the compounds of interest. Reproducibility was within 1%.

Isolation of the suspected feeding deterrent was accomplished by extracting aspen bud samples (1 g) with reagent grade methanol (5 ml) for 24 hr. Methanol appeared to be equal to ether in its extraction efficiency, and its polarity made it superior to ether for large sample injections on the HPLC. Glass containers were used throughout the isolation procedure to prevent phthalate contamination. The suspected feeding deterrent was separated from the crude bud extract by HPLC. HPLC conditions were the same as previously mentioned with the exception that 50–100 μl of extract was manually injected, and detection was made with a diode array 1040M Hewlett Packard detector in conjunction with a HP9133 Analytical Chemstation. After a sufficient amount of sample was collected in a darkened test tube, the acetonitrile in the eluent was evaporated by vortexing the sample under a stream of nitrogen. The remaining sample was then extracted with HPLC-grade ethyl ether, dried (MgSO_4), and concentrated under a stream of nitrogen.

Mass spectra of the isolated compound were run on a Kratos MS25 with a Data General S/120 data system using direct probe insertion, at 70 eV. Samples for [^1H]NMR analyses were prepared by evaporating the ether from the isolation sample under a stream of nitrogen and redissolving the sample in D -chloroform. [^1H]NMR spectra were run on a Nicolet NT 300 MHz, wide-bore, Fourier transformer NMR. Nuclear Overhauser enhancer (NOE) and selective decoupling experiments aided in structure determination.

Nutrient Analyses. Methods for analyzing nutrients were chosen to duplicate those of Huff (1970), so that direct comparisons could be made between his study and ours. Buds and catkins were analyzed for Kjeldahl nitrogen content using the methods outlined in Bradstreet (1965) by the University of Minnesota's Department of Soil Science, Research Analytical Laboratory. Protein levels were calculated by multiplying the Kjeldahl nitrogen content by 6.25 (Huff, 1970). Crude fat, or ether-extractable material, was determined according to method 20.034 in the Association of Official Agricultural Chemists (1965).

RESULTS

The tannin and total phenolic content of the paired preferred and nonpreferred bud samples appear to have been affected by storage conditions (samples may have thawed). Relative comparisons between paired preferred and nonpreferred bud samples should be valid since storage conditions were identical for both preferred and nonpreferred buds, and any degradation that occurred should have occurred equally in both types of samples. However, true tannin and total phenolic levels for these samples may be underestimated. Paired catkin and bud samples were all collected the following year and do not appear to have suffered any sample degradation. The 1986 samples were compared to bud samples that were analyzed immediately after collection and were found to have condensed tannin and total phenolic values equivalent to samples that were analyzed immediately.

Tannins. Quaking aspen buds had significantly lower levels of protein-precipitable tannins than catkins from the same trees (Tables 1 and 2). Comparisons could not be made between paired preferred and nonpreferred dormant buds, since the majority of these samples were below the detection threshold.

TABLE 1. SUMMARY OF QUANTITATIVE TESTS COMPARING SECONDARY CHEMISTRY AND NUTRIENTS OF PREFERRED (P) AND NONPREFERRED (NP) QUAKING ASPEN BUDS AND CATKINS

Parameter measured	Sample comparison	Statistical tests	Sample size ^a	P value
Protein-Precipitable tannins	NP buds vs. catkins ^b	Paired <i>t</i> test	14	0.001
Condensed tannins	NP buds vs P buds	Paired <i>t</i> test	9	0.345
	NP buds vs. catkins	Paired <i>t</i> test	14	0.740
Total phenolics	NP buds vs P buds	Paired <i>t</i> test	9	0.184
	NP buds vs. catkins	Paired <i>t</i> test	14	0.224
Coniferyl benzoate	NP buds ^b vs. P buds	Paired <i>t</i> test	11	0.008
	NP buds ^b vs. catkins	Paired <i>t</i> test	18	0.006
Protein	NP buds vs. P buds ^b	Paired <i>t</i> test	9	0.062
	NP buds vs. catkins	Paired <i>t</i> test	10	0.647
Crude fat	NP buds vs. P buds	Welch <i>t</i> test ^c	10, 5	0.914
	NP buds ^b vs. catkins	Paired <i>t</i> test	10	0.042

^aSample size for paired *t* test indicates number of paired samples.

^bIndicates sample having the highest concentration for tests where the significance level was less than or equal to 0.1.

^cOtt (1984).

TABLE 2. MEAN TANNIN AND TOTAL PHENOLIC LEVELS IN PREFERRED (P) AND NONPREFERRED (NP) QUAKING ASPEN FLOWER BUDS AND CATKINS

Sample type	Total phenolics ^a (% dry wt)	Protein-precipitable tannins ^b (% dry wt)	Condensed tannins (A550/g)
P buds ^c	1.44 ± 0.22	ND ^d	3.10 ± 0.80
NP buds ^c	1.72 ± 0.18	ND	3.68 ± 0.64
Catkins	1.95 ± 0.15	2.68 ± 0.29	7.77 ± 0.91
NP buds ^e	2.30 ± 0.16	1.43 ± 0.088	7.39 ± 0.59

^aReported in equivalent units of gallic acid.

^bReported in equivalent units of tannic acid.

^cPhenolic and tannin levels are lower due to storage conditions.

^dNot determined due to low concentrations.

^ePaired with catkin samples.

Condensed tannin levels were not significantly different between paired preferred and nonpreferred buds, nor was there a significant difference between buds and catkins from the same tree (Table 1). The mean condensed tannin levels for buds and catkins were relatively low as compared to trees more noted for their "tannin defense" (Table 2). Using white oak foliage (*Quercus alba* L.) for a relative comparison, quaking aspen buds and catkins had approximately 13% of the condensed tannins found in *Q. alba* foliage (Martin and Martin, 1982).

Alkaloids. TLC analyses indicated that quaking aspen buds did not contain any detectable alkaloids. Fairly minute quantities of alkaloids should have been detected by TLC. Samples were concentrated to the point that if isoniazid was present at the same concentration as found in aspen leaves (0.036% fresh weight), each chromatographic spot would have contained approximately 2.16 µg of isoniazid, which is far above the detection limit for most alkaloids (Santavy, 1969; Lindroth et al., 1986).

Phenolic Compounds. The functional group assay for total phenolics did not indicate that aspen buds differ significantly from catkins in total phenolics (Table 1). Likewise, no significant difference was found between preferred and nonpreferred buds in total phenolics (Tables 1 and 2).

Thin-layer chromatographic analyses indicated that quaking aspen buds contained salicin (R_f 0.17) and salicortin (R_f 0.17–0.18) (chloroform–methanol–water 80:19:1) in relatively low concentrations and did not contain the phenolic glycosides tremuloiden and tremulacin, which have been reported in quaking aspen foliage (Pearl and Darling, 1971; Lindroth et al., 1987). Catechol (R_f 0.58) and *p*-coumaric acid (R_f 0.25) both appeared to be present when initially analyzed by TLC. However, only *p*-coumaric acid (R_f 0.49) was confirmed by

reversed phase HPTLC. It appeared that *p*-coumaric acid was present only in minute quantities after it was separated from its accompanying impurities by HPTLC. Benzoic acid could not be visualized by TLC; therefore, commercial benzoic acid and aspen bud extract were compared by HPLC. Benzoic acid eluted at 2.5 min, which matched the retention time of a compound in aspen buds. The UV spectra (analyzed by diode-array detector) of this compound was found to be identical to that of benzoic acid (Silverstein et al., 1974).

Preliminary TLC comparisons between paired preferred and nonpreferred bud and catkin samples indicated that there were three compounds that appeared to be present at higher levels in the nonpreferred samples. One of these compounds (R_f 0.52–0.54) (toluene–chloroform–acetone 40:25:35) appeared to be present at a higher concentration than any other secondary phenolic compound in quaking aspen buds and catkins. The other two compounds (R_f 0.34–0.38 and 0.74–0.78) were present in relatively small amounts. The high concentration of the compound at R_f 0.52–0.54 led to the assumption that this particular compound had the highest potential for exhibiting significant feeding deterrent properties.

Quantitative analyses using HPLC indicated that buds from nonpreferred and preferred trees had mean concentrations of the suspected feeding deterrent of 0.531 ± 0.086 (SE) and 0.251 ± 0.032 (SE) (% dry wt/PDE), respectively. Concentrations are expressed in relative amounts since a standard for the suspected feeding deterrent was not available. Buds from nonpreferred trees were significantly higher in concentrations of the suspected feeding deterrent than preferred trees (Table 1 and Figure 1). Likewise, analyses of paired bud and catkin samples indicated that buds had significantly higher amounts of the sus-

FIG. 1. Relative concentration (% dry wt/PDE) of conferyl benzoate for 1985 and 1986 preferred and nonpreferred staminate flower buds.

pected feeding deterrent than catkins (Table 1 and Figure 2). Mean concentrations of the suspected feeding deterrent in buds and catkins were 0.549 ± 0.59 (SE) and 0.355 ± 0.43 (SE) (% dry wt/PDE), respectively.

Structural analyses of the suspected feeding deterrent by $[^1\text{H}]\text{NMR}$ indicated that it is *trans*-coniferyl benzoate (Figure 3). Peak assignments were based on chemical shifts, double irradiation experiments, and comparison with spectra of authentic coniferyl benzoate (Kato, 1984). The location of the methyl was confirmed by a NOE experiment. Specifically, irradiation of the $-\text{OCH}_3$ at 3.91 ppm resulted in a large increase in the singlet located at 6.94 ppm but not

a.

b.

FIG. 2. Relative concentration (% dry wt/PDE) of coniferyl benzoate from 1986 buds and catkins collected from the (a) the Cloquet study site and (b) the Mille Lacs study site.

FIG. 3. $[^1\text{H}]$ NMR spectra of the suspected feeding deterrent (coniferyl benzoate).

in the apparent triplet located at 6.88 ppm, indicating that the methyl was nearest an unsplit aromatic hydrogen. The *trans* geometry was elucidated by coupling ($J = 15$ Hz) between the olefinic hydrogens. Finally, mass spectral analyses showed a molecular ion (284) in addition to fragment ions corresponding to benzoyl (105) and coniferyl (163) cations.

Nutrients. Protein levels were not significantly different between buds and catkins; however, preferred buds were found to have slightly higher levels of protein than nonpreferred buds (Tables 1 and 3).

TABLE 3. MEAN PROTEIN AND CRUDE FAT LEVELS IN PREFERRED (P) AND NONPREFERRED (NP) QUAKING ASPEN FLOWER BUDS AND CATKINS

Sample type	Protein (% dry wt)	Crude fat (% dry wt)
P buds	13.01 \pm 0.89	7.34 \pm 0.55
NP buds	10.66 \pm 0.63	
Catkins	9.88 \pm 0.65	5.21 \pm 0.53
NP buds ^a	9.49 \pm 0.48	7.46 \pm 0.83

^aPaired with catkin samples.

Crude fat levels were significantly lower in catkins than in nonpreferred buds, which is contrary to what would be expected for a preferred food item (Tables 1 and 3). Preferred and nonpreferred bud samples were not significantly different in their crude fat content (Tables 1 and 3).

The crude fat analysis (20.034 A.O.A.C.) gives only a rough estimation of the fat content of a sample, due to additional ether-soluble material being extracted along with the fat. This method is not well suited for aspen buds. The high drying temperatures and vacuum used in the procedure not only evaporate any residual water but also many of the volatile compounds. This results in wide variations in crude fat estimates, which are dependent on the exact drying time and conditions. Relative comparisons between samples are possible only if strict adherence to standardized drying conditions can be met. Comparing the crude fat analyses of aspen buds between different investigators, without knowledge of the specific drying conditions, would likely be meaningless.

DISCUSSION

Ruffed grouse feeding preference for both aspen buds and catkins was consistently related to the level of coniferyl benzoate found in these items. Although the overall mean concentration of coniferyl benzoate was lower in catkins as compared to buds, this pattern did not occur in every tree (Figure 2a). This apparent inconsistency may be due partly to differences in quaking aspen phenology at the time the catkins were collected. The ratio of bud scales to reproductive material in catkins is dependent upon the maturity of the catkin. A higher ratio of bud scales to reproductive material will effect the amount of coniferyl benzoate that is present in a gram of catkin material (see following paragraphs). Partially extended catkins coupled with within-tree variation of coniferyl benzoate levels may explain why some catkin samples had slightly higher levels of coniferyl benzoate than buds from the same tree. Even with these variations, catkins had significantly lower levels of coniferyl benzoate when compared with buds from the same tree. Similarly, a few nonpreferred trees had buds with lower levels of coniferyl benzoate than buds from preferred trees (Figure 1). All of these nonpreferred trees had relatively low levels of coniferyl benzoate, likely below the tolerance threshold of ruffed grouse for this compound, indicating that these trees were not selected as feeding trees for other reasons.

In order to assess why one food item is selected over another, the available nutrients in these items must also be taken into account. Ruffed grouse showed a preference for buds that were higher in protein in this study and in earlier investigations (Huff, 1970; Doerr et al., 1974). Although slightly higher protein levels may offer a partial explanation for the selection of aspen buds, protein

levels do not explain the general preference ruffed grouse have for aspen catkins. Aspen catkins do not differ significantly from buds in protein levels. This conclusion differs from those made by Huff (1970) on the nutritional differences between catkins and buds; however, Huff failed to test the significance of the differences he reported. He also did not compare buds and catkins from the same tree, which may have increased the amount of variance between samples.

One likely reason for the lower concentration of coniferyl benzoate in catkins is due to the relatively lower amount of bud scale material in the catkin as compared to the dormant bud. TLC analyses of bud scales and reproductive tissues of dormant buds and catkins indicate that virtually all of the nontannin phenolics are located in the bud scale material. The increased ratio of reproductive to bud scale material in the catkin would enable ruffed grouse to feed on a greater percentage of catkin material that is relatively free from coniferyl benzoate and other simple phenolic compounds. This would explain why ruffed grouse consistently feed on catkins even during years when they avoid the dormant buds.

The avoidance of flower bud scale material by an unknown species of bird has also been observed. While collecting bud samples, it was noted that branches from a particular tree had many staminate flower buds that had their centers removed (presumably consumed), yet the outer bud scales remained intact. A feeding strategy in which only the center portion of the bud was removed would allow a bird to avoid almost all of the simple phenolic compounds, particularly coniferyl benzoate, in the dormant winter bud. This method of feeding on quaking aspen buds cannot be attributed to ruffed grouse since ruffed grouse feed on quaking aspen buds by removing the entire bud. However, both the purple finch (*Carpodacus purpureus*) and evening grosbeak (*Coccothraustes vespertinus*), which feed on quaking aspen flower buds and are present in the study area during the winter, might exhibit this feeding behavior (Shaub, 1956; Bent, 1968; Gullion, 1985).

Huff (1970) compared levels of a number of other nutritional parameters between the buds of preferred and nonpreferred quaking aspen and concluded that buds from preferred trees had significantly lower levels of lignin and acid detergent fiber ($0.05 > P > 0.01$), along with higher levels of phosphorus, potassium, and moisture ($0.1 > P > 0.05$), than buds from randomly selected trees with no feeding history. Therefore, ruffed grouse feeding preference for buds from specific quaking aspen trees might be due to a combination of factors, including the levels of certain nutrients and allelochemicals. However, available data suggest that the level of coniferyl benzoate is one of the most significant differences between preferred and nonpreferred buds.

Servello and Kirkpatrick (1987) related the nutritional value of the natural foods of ruffed grouse, and their preference for these foods, to tannin and total phenolic levels in these items. Theoretically, total phenolics and tannins may

lower the nutritional value of foods; however, our study indicates that tannin content and total phenolics may not be reliable indicators of ruffed grouse feeding preference. Total phenolic concentration was not significantly related to ruffed grouse selection of aspen buds or to their general preference for aspen catkins. Total phenolic measurements were also not correlated with levels of coniferyl benzoate, even though coniferyl benzoate appears to be the primary simple phenol in aspen buds. Likewise, tannin levels (measured as protein-precipitable and condensed tannins) were not related to ruffed grouse feeding preference. Protein-precipitable tannins were significantly higher in aspen catkins, a preferred food item, as compared to nonpreferred buds. The level of tannins found in aspen catkins and buds (expressed in equivalent amounts of tannic acid) should have been sufficient to have a physiological effect on ruffed grouse (Vohra et al., 1966; Rostagno et al., 1973).

Several explanations can be postulated for this lack of correlation between tannin levels and feeding preference. Many herbivores are thought to have evolved adaptations to handle secondary compounds common in their diets (Rhoades, 1985; Robbins et al., 1987). The diet of ruffed grouse likely contains a number of items with tannin levels similar to the levels found in aspen catkins (Servello and Kirkpatrick, 1987). Ruffed grouse may have physiologically adapted to the tannin levels in their diet, which would account for the lack of correlation between tannin levels and ruffed grouse feeding preference. A second explanation for the lack of correlation between tannin levels (as measured by protein precipitation) and feeding preference is that the protein-precipitating property of tannins may not be the most important biological property of tannins to assay. The soluble tannin-protein complexes, or breakdown products of tannins, and their toxic effects may be biologically more important (Vohra et al., 1966; Rogler et al., 1985; Hagerman and Robbins, 1987). Consequently, one cannot infer that the adverse effects known to be caused by a given quantity of tannic acid are equivalent to those of the tannins found in quaking aspen, even though the protein precipitating ability of the tannins may be the same.

Coniferyl benzoate has not been previously reported as occurring in quaking aspen (see Sunarjo, 1985). Earlier investigations of the secondary chemistry of quaking aspen have primarily focused on the leaves, bark, and twigs (Pearl and Darling, 1959a,b, 1964, 1965, 1967a,b, 1971; Pearl et al., 1961; Thieme, 1965, 1967; Thieme and Benecke, 1970, 1971; Wollenweber, 1975; Sunarjo, 1985). It appears as if coniferyl benzoate production is rather specialized, in that coniferyl benzoate is primarily found in flower bud scale material and not in vegetative bud scales or in other quaking aspen tissues. Other studies have shown that different tissues (e.g., buds and internodes) from the same plant not only may vary in the concentration of secondary compounds they contain, but

also may contain secondary compounds from different metabolic origins (Pearl and Darling, 1971; Mattes et al., 1987).

A comprehensive comparison between the secondary chemistry of quaking aspen flower buds and leaves was not made; however, tremuloiden, tremulacin, catechol, and isoniazid, which are present in aspen leaves (Sunarjo, 1985), were not found in flower buds.

Differences were also found in the secondary metabolite composition of the various tissues in the flower bud. As reported above, the majority of non-tannin phenolics are located in the bud scale material. Conversely, the reproductive material of the catkin contains significantly ($P < 0.001$) more protein-precipitable tannins than bud scale material. The higher ratio of reproductive to bud scale material in the catkin would account for the higher level of tannins in catkins as compared to dormant buds. It is not known how this differentiation of secondary metabolites relates to the defense of the flower bud against herbivores or plant pathogens. It may be that the phenolic compounds in the bud scales protect the bud from herbivores, such as ruffed grouse or insects, as the bud develops from late summer until spring. The higher tannin content in the reproductive tissues may be important as a defense against fungal infection as the catkin emerges from its protective bud scales in the spring and is directly exposed to environmental conditions which may promote fungal infection.

The biological properties of coniferyl benzoate have only been investigated in relation to skin allergies that are caused by various natural products used in the cosmetic industry (Hjorth, 1961; Togano et al., 1983; Kato, 1984). These studies indicate that coniferyl benzoate is one of the principle allergens found in jasmine oil and gum benzoin Siam. Coniferyl benzoate would appear to be a good alkylating agent, which would enable it to react readily with nucleophiles, including some proteins. Coniferyl benzoate may not only bind to body proteins and act as a hapten, but may also bind to dietary proteins, affecting their digestion.

Related to the allergenic properties of coniferyl benzoate is its ability to cause hypersensitivity in individuals, after initial contact with coniferyl benzoate, to coniferyl benzoate or analogous compounds (Hjorth, 1961). This property of coniferyl benzoate increases the likelihood that it may act synergistically with other secondary compounds found in quaking aspen buds. Jung and Fahey (1983) demonstrated that synergism among phenolic monomers can play an important role in depressing the food intake in rats. It is not known at this time if the other secondary compounds in aspen buds (e.g., salicin and salicortin) react synergistically with coniferyl benzoate or how they are related to ruffed grouse feeding preference. Obviously the effect that coniferyl benzoate has on ruffed grouse physiology cannot be inferred from these studies. Only by

conducting feeding trials with ruffed grouse can the feeding deterrent properties of coniferyl benzoate be confirmed and information obtained on its effect.

Feeding trials with ruffed grouse are planned that would test the hypothesis that coniferyl benzoate deters ruffed grouse from feeding on foods that have relatively high levels of this compound. Additionally, investigations are underway on how coniferyl benzoate levels are related to the differential use of quaking aspen buds by ruffed grouse during their 8- to 10-year population cycle.

Acknowledgments—This research was supported by the University of Minnesota's Agriculture Experiment Station, the Ruffed Grouse Society, and Middlesex Mutual Assurance Co. We would like to thank Ann Hagerman, Miami University, Ohio, for her assistance with the tannin analyses; Mark Brenner, University of Minnesota, for the use of his HPLC laboratory; Tom Krick, University of Minnesota, for assistance with the MS and NMR analyses; and Otto Anderson, Paul Swedenborg, Ken Corbin, and Dave Ragsdale for their assistance with analytical procedures.

INHIBITION OF *Campoletis sonorensis* PARASITISM OF *Heliothis zea* AND OF PARASITOID DEVELOPMENT BY 2-TRIDECANONE-MEDIATED INSECT RESISTANCE OF WILD TOMATO

WILLIAM C. KAUFFMAN¹ and GEORGE G. KENNEDY

Department of Entomology
North Carolina State University
Raleigh, North Carolina 27695-7630

(Received June 20, 1988; accepted September 20, 1988)

Abstract—Field populations of *Heliothis* spp. were sampled for levels of naturally occurring larval parasitism on six tomato lines varying in levels of 2-tridecanone-mediated resistance to *Manduca sexta* (L.) and *Leptinotarsa decemlineata* (Say). Second and third instars were parasitized by *Campoletis sonorensis* (Cameron) (Hymenoptera: Ichneumonidae) and *Cotesia* (= *Apan-*tales*) marginiventris* (Cresson) (Hymenoptera: Braconidae) in 1984 through 1986 and by *Micropletis croceipes* (Cresson) (Hymenoptera: Braconidae) in 1986. Differences in parasitism by individual and multiple species among host plants were not demonstrated. However, levels of parasitism were low and variable among replicates. Total larval parasitism averaged across all plant lines was less than 6% in 1984 and 1986 and approximately 11% in 1985. In laboratory cage studies, *C. sonorensis* parasitized fewer *H. zea* larvae on tomato foliage with high levels of 2-tridecanone than on foliage with low levels. Rearing *H. zea* on diet containing 2-tridecanone and 2-undecanone did not alter incidence of parasitism by *C. sonorensis*; nor did rearing parasitized *H. zea* larvae on chemically treated host diets precondition the parasitoid to higher or lower mortality when transferred to foliage as a substrate for cocoon spinning, regardless of the foliage genotype. However, parasitoid survival during cocoon spinning on foliage varied significantly among plant lines in a manner corresponding to the level of 2-tridecanone-mediated resistance of the foliage. Parasitoid mortality was greatest on highly resistant foliage and lowest on susceptible foliage.

Key Words—*Camponotus sonorensis*, Hymenoptera, Ichneumonidae, *Heliothis zea*, Lepidoptera, Noctuidae, trichome, 2-tridecanone, allelochemical, plant resistance, *Lycopersicon hirsutum* f. *glabratum*, tomato.

INTRODUCTION

The resistance of the wild tomato *Lycopersicon hirsutum* f. *glabratum* C. H. Mull accession PI 134417 to the tobacco hornworm, *Manduca sexta* (L.), and the Colorado potato beetle, *Leptinotarsa decemlineata* (Say), is due, in large part, to the presence of a toxin, 2-tridecanone, in the tips of type VI (Luckwill, 1943) glandular trichomes, which abound on the foliage (Williams et al., 1980; Kennedy, 1986; Kennedy et al., 1987a; Fery and Kennedy, 1987). The level of resistance to both species is affected by both the amount of 2-tridecanone per trichome tip and the density of type VI glandular trichomes (Fery and Kennedy, 1987). Recently, it has been shown that the high densities of type VI trichomes found on PI 134417 foliage had a dramatic, adverse effect on parasitism of eggs of another herbivore species, *Heliothis zea* (Boddie), by *Trichogramma* spp. (Kauffman, 1987).

This study was undertaken to determine if 2-tridecanone-mediated resistance to *M. sexta* and *L. decemlineata* affected parasitoids attacking *H. zea* larvae. In addition to field experiments in which the incidence of larval parasitism by several parasitoid species was measured, we conducted detailed laboratory studies of the effects of 2-tridecanone, 2-undecanone (also a constituent of type VI trichomes on resistant foliage), and resistant foliage on the larval parasitoid *Camponotus sonorensis* (Cameron).

C. sonorensis oviposits in second- and early third-instar *H. zea* larvae. Following completion of development within the host, fifth-instar parasitoid larvae emerge through the host's integument and spin a cocoon on the foliar substrate of their host. This cocoon spinning involves extensive larval movement, which, on PI 134417, results in the destruction of large numbers of glandular trichomes.

METHODS AND MATERIALS

Larval Parasitism In Field Plots. In 1984–1986 *Heliothis* spp. larvae were collected from a 0.11- to 0.19-hectare tomato field in Clinton, North Carolina. The field was planted annually in a randomized complete block design with four to eight replicates. Individual plots were ca. 3–5 m × 1 row. Treatments consisted of the following six tomato genotypes, previously selected to provide a range of levels of 2-tridecanone-mediated resistance (Kauffman, 1987): *L. esculentum* (susceptible parental cultivar), *L. hirsutum* f. *glabratum* PI 134417

(highly resistant wild parent), F_1 (susceptible hybrid: *L. esculentum* \times PI 134417), and three backcross ($F_1 \times$ PI 134417) accessions BC17, BC2, and BC90, classified as having low, moderate, and high levels of 2-tridecanone-mediated resistance, respectively. The backcross lines were propagated vegetatively from individual plants selected from an F_1 backcross population. Each year the level of tobacco hornworm resistance of field-grown plants was verified by bioassay and gas chromatographic (GC) analysis of type VI trichome exudate to quantify 2-tridecanone and 2-undecanone levels. 2-Undecanone concentrations were of interest because, at concentrations associated with PI 134417 foliage, it causes pupal mortality of *H. zea* when ingested during the last larval instar. It has also been shown to synergistically enhance toxicity of 2-tridecanone to several species (Farrar and Kennedy, 1987a; Lin et al., 1987) but has no apparent effect on tobacco hornworm.

The hornworm bioassay consisted of two *M. sexta* neonates placed on the abaxial surface of a 78.5-mm² leaflet disk excised from the uppermost fully expanded leaf. The leaf disk was placed on moistened filter paper in a 5-cm plastic Petri dish, which was then sealed with Parafilm and held at 27°C. For each plant, this procedure was replicated with 6–10 disks obtained from separate leaflets. After 24 hr, consumption was measured to the nearest square millimeter by placing the leaf disk remnants on a 78.5-mm² circular grid divided in 1-mm² units and tallying the missing foliage. Walter and PI 134417 were included as susceptible and resistant controls, respectively. Type VI trichome density was determined by counting all type VI trichomes present on each of two to three 28.3-mm² leaflet disks taken from the uppermost fully expanded leaf of each plant. Concurrently, 1200 type VI trichome tips were collected from test foliage, using glass microcapillary tubes. Tip extracts were dissolved in HPLC-grade methanol and analyzed on a Hewlett-Packard 5880A gas chromatograph, using a Durabond 15-m \times 0.25- μ m fused silica capillary column with an injection volume of 10 μ l/sample and temperature program of 100–275°C increasing at 5°C/min.

The natural incidence of larval parasitism was determined by collecting larvae with a 60 \times 60-cm, beat cloth approximately 10 days after the ovipositional peak of second generation moths. *Heliothis* spp. larvae were categorized by instars, then placed individually into 30-ml plastic diet cups containing a corn-soya-milk (CSM) diet (Burton, 1970). Larvae were held at 27°C and 16:8 (light-dark) photoperiod and monitored daily for evidence of parasitism (i.e., cessation of growth at ca. 15 mm or less). Emerged adult parasitoids were identified to species. Host larvae collected from the same plant line were pooled prior to determination of parasitism. Percent parasitism (by parasitoid species and total parasitism) was analyzed by chi square for significant differences ($P \leq 0.05$) among plant lines.

Laboratory Studies. The levels of 2-tridecanone-based resistance and the

concentrations of 2-tridecanone and 2-undecanone were determined for all greenhouse-grown plants used in these studies by means of the aforementioned tobacco hornworm bioassay and GC analysis of trichome tips. The parasitoids came from a culture of *C. sonorensis* maintained on *H. zea* in the laboratory under conditions of 27°C and a light-dark cycle of 16:8. *H. zea* larval hosts were obtained from a laboratory colony maintained on CSM diet at North Carolina State University.

To test the hypothesis that, under constant conditions of host size and density, adult *C. sonorensis* would utilize all tomato lines equally well as substrates for parasitism of *H. zea*, we exposed mated adult female *C. sonorensis* to equal densities of *H. zea* larvae on foliage of each of the following plant lines in a no-choice experiment: *L. esculentum*, BC17, BC2, BC90, and PI 134417. Foliage from greenhouse-grown plants was arranged in bouquets consisting of five young fully expanded leaves with their petioles in a water-filled beaker. One bouquet (hence one plant line) was placed in each 30 × 30 × 30-cm Saran screen cage. Thirty second-instar, diet-reared *H. zea* larvae were placed on each bouquet and three 4-day-old, mated, adult, female *C. sonorensis* added to each cage. The infested cages were held at 27°C for 8 hr, after which the *H. zea* larvae were transferred to and maintained individually on CSM diet. Ten days later, larvae were classified as live and unparasitized, dead, or parasitized. Adult emergence and sex of *C. sonorensis* were recorded on day 20 for all parasitized hosts. Each plant line was replicated 20 times.

Data from this and all subsequent experiments were subjected to analysis of variance with mean separation using Duncan's new multiple-range test. All percentage data were based on numbers of larvae accounted for at the termination of the test and were transformed to arcsine $\sqrt{\text{percentage}}$ prior to analysis.

To determine if the presence of 2-tridecanone and 2-undecanone in the host's diet affected parasitism by *C. sonorensis* and if tomato foliage differing in levels of 2-tridecanone-mediated resistance to *M. sexta* differed in suitability as a pupation substrate for *C. sonorensis*, the following experiment was conducted. *H. zea* larvae were reared on three diets: (1) standard CSM diet (Burton, 1970), control; (2) CSM diet containing 0.3% and 0.055% (w/w) 2-tridecanone and 2-undecanone, respectively, concentrations which approximate those found in PI 134417 foliage; or (3) CSM diet containing 0.075% and 0.0137% (w/w) 2-tridecanone and 2-undecanone, respectively, concentrations approximating those found in BC2 foliage. The 2-tridecanone (Fluka Chemical Corp., Haulpauge, New York 11788) and 2-undecanone (Pfaltz and Bauer, Inc., Stamford, Connecticut 06902) were greater than 99% pure as determined by gas chromatography. Chemically treated diets were prepared as described by Farrar and Kennedy (1987).

H. zea larvae were reared to late second instar on the various diets, sub-

jected to parasitism by *C. sonorensis*, and returned to their respective diets and maintained at 27°C. Ten days later the larvae were classified as live and unparasitized, dead, or parasitized. Larvae were exposed to parasitism by confining them for 8 hr in groups of 10 in an inverted plastic cup (Sweetheart Plastics, Wilmington, Massachusetts) (9 cm diam. × 4.5 cm high) containing three cubes of CSM diet and one mated adult *C. sonorensis* female. Data were collected for 1002 larvae on the control diet and 985 and 823 larvae on the diets containing low and high concentrations of the test chemicals, respectively. Shortly before parasitoid larvae emerged from their hosts, indicated by pink coloration of the posterior third of host larva, the parasitized larvae from each diet were transferred in groups of five to the abaxial surface of excised foliage of *L. esculentum*, PI 134417, or BC2. This foliage was maintained at 27°C on moist filter paper in Petri dishes sealed with Parafilm. Twenty-one days following exposure of host larvae to adult *C. sonorensis*, the experiment was terminated and parasitized larvae were classified as producing a *C. sonorensis* larva that died prior to initiation of cocoon construction, a *C. sonorensis* larva that died during cocoon construction, or a complete cocoon. There were 15 replicates of 10 parasitized hosts for each diet-foilage treatment.

RESULTS

Larval Parasitism In Field Plots. Levels of resistance of field grown-plants varied somewhat from year to year, as indicated by hornworm foliar consumption and GC analysis of 2-tridecanone concentrations in trichome exudate. However, *L. esculentum* and F₁ were consistently highly susceptible, whereas BC90 and PI 134417 were consistently highly resistant (Table 1). Similar patterns of resistance and methyl ketone concentrations occurred in the glasshouse-grown plants used for laboratory studies with *C. sonorensis* (Table 2).

Second and third instars of *Heliothis* spp., which were the only stadia successfully parasitized, represented 77% ($N = 774$), 43% ($N = 325$), and 67% ($N = 791$) of the total larvae collected in 1984, 1985, and 1986, respectively. They were parasitized by *C. sonorensis* and *Cotesia marginiventris* (Cameron) in all three years and by *Microplitis croceipes* (Cresson) only in 1986 (Figure 1). Neither levels of parasitism by individual species nor total parasitism were significantly affected by tomato line (chi square, $P \leq 0.05$). Total parasitism averaged over all plant lines was less than 6% in 1984 and 1986 and ca. 11% in 1985. Data from 1985 was based on a relatively small number of hosts due to low *H. zea* oviposition (Kauffman, 1987). Also, the fewest *H. zea* larvae were collected on *L. esculentum* due to lower oviposition and higher egg parasitism by *Trichogramma* spp. than on the other plant lines (Kauffman, 1987).

Parasitism in Cages. Fewer *H. zea* larvae were parasitized by *C. sonorensis*

sis in laboratory cages on highly resistant (PI 134417 and BC90) plants than on BC2, BC17, or *L. esculentum* plants (Table 3). The percentage of dead host larvae was unaffected by plant line, suggesting that contact with and ingestion of resistant foliage by *H. zea* larvae during the brief period of exposure to adult parasitoids had a negligible influence on their survival. Furthermore, such exposure did not result in increased premature mortality of parasitized hosts, nor did it alter emergence success or sex ratio of adult parasitoids from parasitized hosts (Table 4). Since confinement of adult parasitoids in the cage with foliage did

not result in death of the parasitoids, it is possible that the adults were deterred from prolonged close-range aerial or tactile examination of resistant foliage for the presence of acceptable hosts, thus reducing parasitism.

The laboratory data appear to disagree with field parasitism data (Figure 1), which indicated no effect of plant genotype on parasitism by *C. sonorensis*. This inconsistency probably is due to the low and highly variable rates of parasitism observed in the field studies, but possible effects of confinement in relatively small cages cannot be discounted. Further field studies are warranted.

Effects of Host Diet and Pupation Substrate on C. sonorensis. Parasitism of *H. zea* larvae reared on diet containing 2-tridecanone and 2-undecanone at concentrations approximating those found in foliage of BC2 (low) and PI 134417 (high) plants did not differ from that on the control diet (Figure 2). Following

FIG. 2. Outcome of exposing *H. zea* larvae reared on chemically treated and untreated diets to *C. sonorensis*. Low and high refer to concentrations of 2-tridecanone and 2-undecanone in the diets. See text for details.

H. zea exposure to *C. sonorensis*, there were no differences in the percentages of dead hosts and live, unparasitized hosts due to diet consumed by *H. zea*.

The concentration of 2-tridecanone in the diet of the host larvae did not significantly alter survival of *C. sonorensis* either during larval development within the host or subsequently during cocoon spinning and pupal development. Thus, for any given plant line on which pupation occurred, there were no significant differences among host diets in percent parasitoid mortality (Table 5). The foliage type on which cocoon spinning and pupation occurred, however, had a profound effect on *C. sonorensis* larval and pupal mortality; this effect was independent of the 2-tridecanone concentration of the host's diet (Table 5). Parasitoid mortality during and after cocoon spinning closely paralleled the 2-tridecanone and 2-undecanone concentrations of the foliage that served as a substrate for cocoon spinning. Mortality was least on *L. esculentum*, which contained only trace quantities of 2-tridecanone and 2-undecanone, intermediate on BC2 foliage, which contained a mean of 31 ng 2-tridecanone and 4 ng 2-undecanone per mm², and greatest on PI 134417 foliage, which averaged 165 ng 2-tridecanone and 27 ng 2-undecanone per mm² (Tables 4 and 5).

DISCUSSION

Tomato genotypes possessing high levels of 4-tridecanone and 4-undecanone resulted in decreased parasitism of *H. zea* by *C. sonorensis* and interfered with successful cocoon spinning by the parasitoid in laboratory studies. During cocoon construction on the foliage of resistant plants, fifth-instar *C. sonorensis* disrupt numerous type VI glandular trichomes and directly contact the 4-tri-

decanone and 4-undecanone contained in their tips. Since 4-tridecanone is highly toxic to *C. sonorensis* larvae (Kauffman, 1987), it likely accounts for the observed mortality on resistant foliage during cocoon spinning. It is noteworthy that on foliage containing high levels of 4-tridecanone (PI 134417), virtually all parasitoid mortality occurred during cocoon spinning, whereas on foliage with intermediate levels of 4-tridecanone (BC4), a significant portion of the total parasitoid mortality occurred subsequently among pupae and unemerged adults. This may be attributable to the reduced dosages experienced on BC4 foliage. When incorporated into the host's diet, these two methyl ketones had no observable effect on the suitability of the host larvae for parasitism by adult *C. sonorensis* or for parasitoid development within the host. In the latter situation, the parasitoid larvae would contact the chemicals only if they were circulated or deposited within their host.

Selection of tomato lines for high levels of foliar 2-tridecanone could result in valuable resistance to both tobacco hornworm and Colorado potato beetle. In some situations, however, the advantages of this resistance may be more than offset by adverse effects on parasitism of *H. zea* eggs by *Trichogramma* spp. (peak percentage parasitism > 90% on *L. esculentum* vs. < 20% on highly resistant lines; Kauffman, 1987), and on larval parasitism by *C. sonorensis*, as

well as by the induction of elevated levels of cytochrome P-450 isozymes and associated elevated levels of tolerance to some insecticides in *H. zea*, which follows exposure to 2-tridecanone or resistant foliage (Kennedy, 1984; Kennedy et al., 1987b). Clearly, where *H. zea* is a potentially serious pest on tomato, it would be inappropriate to use tomato cultivars selected for high levels of 2-tridecanone-mediated resistance to other insect pests, unless those cultivars also possessed substantial levels of *H. zea* resistance attributable to other factors.

The ecological and practical consequences of the effects of 2-tridecanone-mediated resistance on parasitism by *C. sonorensis* will depend on the role of the parasitoid in suppression of *H. zea* populations on tomato. In the Coastal Plain of North Carolina, *C. sonorensis* seems to be of relatively minor importance in the population dynamics of *H. zea* on tomato, but in other areas it may play a much more important role.

(Received May 24, 1988; accepted September 26, 1988)

Abstract—Short-range attraction/feeding stimulation of male Mediterranean fruit flies [*Ceratitis capitata* (Wiedemann), (Diptera: Tephritidae)] to a stem extract of a host plant, *Litchi chinensis* Sonn. (Sapindaceae), and to milky exudates from stems of nonhost plants, *Ficus retusa* L. and *F. benjamina* L. (Moraceae), were attributed to the presence of the sesquiterpene α -copaene. The presence of α -copaene in the milky exudate from stems of *F. benghalensis* L. is also suggested as eliciting similar behavioral responses in male medflies. The presence of minor quantities of α -ylangene in the plants and its contributory effects to the behavioral response of male medflies is discussed. Short-range attraction/feeding stimulation of male medflies to equal amounts of α -ylangene-free α -copaene samples (94.5%+), prepared from α -copaene-enriched angelica seed oil and copaiba oil, respectively, showed no difference in intensity of response. α -Ylangene elicited a slightly less intense response for male medflies than α -copaene.

Key Words—*Litchi chinensis*, Sapindaceae, *Ficus retusa*, *Ficus benjamina*, *Ficus benghalensis*, Moraceae, *Ceratitis capitata*, Diptera, Tephritidae, Mediterranean fruit fly, medfly, α -copaene, α -ylangene.

INTRODUCTION

Naturally occurring attractants for *Ceratitis capitata* (Wiedemann) have been found in extracts and oils of many plants (Beroza and Green, 1963a). These include extracts of *Alpinia officinarum*, *Anaphalia margaritacea*, *Angelica* spp., *Berberis vulgaris*, *Chimaphila umbellata*, *Conioselinum chinense*, *Dendrobium superbum*, *Equisetum arvense*, *Fabiana imbricata*, *Festuca* spp., *Heracleum lanatum*, *Juglans nigra*, *Lycopersicon esculentum*, *Rhamnus frangula*, *Rosa centifolia*, *Tilia europaea*, and oils (Teranishi et al., 1987) of *Abies alba*, angelica seed (Steiner et al., 1957; Beroza and Green, 1963b; Fornasiero et al., 1969; Jacobson et al., 1987), copaiba, cubeb, cyste, gingergrass, grapefruit, hop, lemon, orange, Canadian pine needle, *Pinus pumilio*, *P. sylvestris*, sweet orange, orange peel, and ylang-ylang.

The present study extends this list of naturally occurring attractants for *C. capitata* to the host plant, *Litchi chinensis* Sonn. (Sapindaceae) (Back and Pemberton, 1918a,b), *Ficus benghalensis* L. (Moraceae)/*F. indica*, which has conflicting reports of host vs. nonhost classification (Quayle, 1938; Back and Pemberton, 1918a,b), and several nonhost *Ficus* spp.

L. chinensis, litchi or lychee, is a medium sized-tree that is native to the humid regions of southern China, where it has grown for several thousand years. Thousands of tons of the dried fruit are exported for use by Chinese people living abroad. These fruits are known as Chinese litchi nuts in the Western world. The trees are also cultivated in the American subtropics (Dahlgren, 1947).

McInnis and Warthen (1988) observed that the exudate from a stem of *F. benjamina* L., weeping fig, attracted male medflies and stimulated them to feed. Other species of *Ficus*, namely *F. benghalensis* L. (Indian banyan) and *F. retusa* L. (Indian laurel fig), produced the same behavioral responses (Table 1). We did not investigate *F. carica*, the common fig, which is a host for medfly. This plant is listed as being heavily or generally infested by medflies (Back and Pemberton, 1918a,b).

A detailed procedure was developed to isolate and identify the short-range attractants/feeding stimulants from *L. chinensis*; this same procedure was also applied to the *Ficus* spp. for isolation and identification.

METHODS AND MATERIALS

L. chinensis stems were collected and dried at two locations: the Tropical Agriculture Research Station, Mayaguez, Puerto Rico, and at the Subtropical Horticulture Research Laboratory, Miami, Florida. Leaves, small stems, and twigs of *F. retusa* and *F. benjamina* were also obtained and dried at Mayaguez.

TABLE 1. SHORT-RANGE LABORATORY MEDFLY ATTRACTANCY/FEEDING STIMULATION SCORING SYSTEM^a

Qualitative score	Quantitative score ^b
Negative (-)	No reaction above normal "passerby" activity.
Slight to negative (sl to -)	0-5 flies feeding or "sitting" on blotter within 5 min of start.
Slight (sl)	5-10 flies feeding, "mating," ^c or resting on blotter within 5 min.
+	10-20 flies feeding, etc., on blotter, within 2 min.
++	20-40 flies feeding, etc., on blotter within 2 min. Male "mating" activity heavy.
+++	40-60 flies feeding, etc., within 2 min. Male "mating" activity heavy.

^aMcInnis and Warthen, 1988.

^bApproximately 200 flies/sex for each test.

^c"Mating" by males consisted of attempted copulations by two or more individuals mounted in a row.

Leaf stem exudates were obtained from *F. benjamina* at the USDA Tropical Fruit and Vegetable Laboratory, Honolulu, Hawaii; from *F. retusa* on the east side of Oahu, Hawaii; and from *F. benghalensis* at the U.S. Botanic Gardens, Washington, D.C. A small sample of *F. benghalensis* fresh leaves was also obtained from the latter source.

Solvents and Sesquiterpenes. *n*-Hexane and isooctane were HPLC grade; all other solvents were reagent grade. The sources of sesquiterpenes, including enriched α -copaene samples from angelica seed oil and copaiba root oil, are listed in Table 2.

Extractions and Essential Oils. Dried stems (231.3 g) of Puerto Rican *L. chinensis* were ground in a Wiley mill and extracted with *n*-hexane for 24 hr in a Soxhlet apparatus; the marc was extracted with ethyl ether for 24 hr. Similar extractions of the dried stems of Miami *L. chinensis* were also performed. Fresh leaves (91.0 g) of *F. benghalensis* were ground in a Waring blender with *n*-hexane and extracted for 18 hr with *n*-hexane in a Soxhlet apparatus; the marc was extracted with ethyl ether for 18 hr. Dried leaves, small stems, and twigs (307.3 g) of *F. retusa* were ground in a Wiley mill and extracted with ethyl ether for 72 hr in a Soxhlet apparatus. Similar extractions of the dried leaves, small stems, and twigs (323.9 g) of *F. benjamina* were also performed. A steam distillate (collected in *n*-hexane, utilizing a continuous extraction head for 24 hr) was prepared from each of the following: 64.3 g ethyl ether extract of Puerto Rican *L. chinensis* (1498 g), 26.1 g ethyl ether extract of Miami *L. chinensis* (804 g), 48.9 g ethyl ether extract of *F. retusa* (307.3 g), and 40.6 g ethyl ether extract of *F. benjamina* (323.9 g).

^bSome tailing of the monounsaturated sesquiterpenes occurs with these analyses.

^cObtained from Professor V. Herout, Institute of Organic Chemistry and Biochemistry, Czechoslovak Academy of Science, Prague.

^dObtained from Professor Buchi, Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts. Also obtained from M. Jacobson; USDA-Retired, Collaborator (Jacobson et al., 1987).

^e(-)-Thujopsene and (-)- β -caryophyllene were separated on 3 μ m silica under the same HPLC conditions, giving 9.46 and 11.26 min retention times, respectively.

Each of the above extracts were dried (sodium sulfate) and concentrated in vacuo. The steam distillates were concentrated to 5.0 ml solutions.

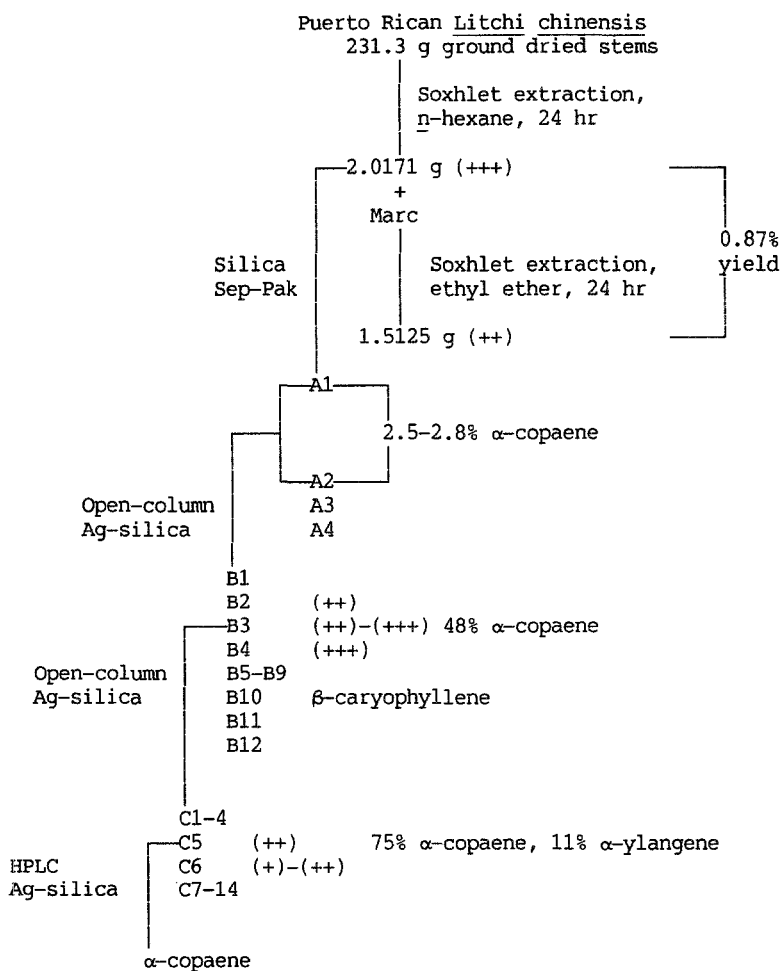

Exudates. Exudates of *F. benjamina* and *F. benghalensis* were collected with Pasteur pipets from snapped leaf stems. The exudates were refrigerated as such or mixed with distilled water (2 drops exudate/1.0 ml water) and refrigerated. Two of the latter *F. benghalensis* mixtures were extracted with 1.0 ml *n*-hexane and 1.0 ml ethyl acetate, respectively.

Leaf stem exudates of *F. retusa* were similarly collected, and trunk exudates were collected through a wound made in the trunk. These exudates were extracted with an equivalent volume of methylene chloride; the organic layer was stored under refrigeration.

Open-Column Chromatography. Millipore Waters Associates Sep-Pak sil-

ica cartridges were prewashed with 5.0 ml methylene chloride and then 10.0 ml *n*-hexane. The *n*-hexane extract (1–5 drops from a Pasteur pipet) of *L. chinensis* was placed on the Sep-Pak and eluted with three 5.0-ml portions of *n*-hexane followed by 5.0 ml methylene chloride; four 5.0-ml fractions (A1–4, Scheme 1) were collected.

To 437 g Bio-Rad Bio-Sil A (100–200 mesh) was added an aqueous, saturated solution of 109.25 g reagent-grade silver nitrate with shaking; the mixture was heated at 125°C overnight. The first two fractions, A1 and A2, were

SCHEME 1. See Table 1 for qualitative scoring (+, ++, +++) for short-range laboratory medfly attractant/feeding stimulation.

placed on a column (3.0 × 0.5 cm ID) containing 0.32 g of this adsorbent (20% silver nitrate) that was first wetted and prewashed with 2.0 ml *n*-hexane. Portions (0.7 ml each) of *n*-hexane, 1.0, 2.0, 2.5, 3.0, 3.5, 4.0, 8.0, 16.0, 32.0, 64.0% ethyl ether/*n*-hexane, and ethyl ether were added to the column and twelve 0.7-ml fractions (B1–12) were collected.

B3, concentrated to a 50- μ l volume, was placed on another prewashed silver nitrate–Bio-Sil A column of the same configuration and eluted with portions (0.7 ml each) of *n*-hexane, 0.5, 1.0, 1.5, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 10.0, 20.0, and 40.0% ethyl ether/*n*-hexane; each of the fourteen 0.7-ml fractions (C1–14) was concentrated.

A 4.1-ml methylene chloride extract of 4.0 ml *F. retusa* exudate was concentrated under nitrogen to 0.6 ml; three 0.2-ml aliquots of this concentrate were each placed on a prewashed silica Sep-Pak and eluted with *n*-hexane as previously described. The first fractions from each Sep-Pak were combined and concentrated under nitrogen to 0.2 ml. An aliquot (150 μ l) of this concentrate was placed on a 20% silver nitrate–Bio-Sil A column as previously described and eluted with portions (0.7 ml each) of *n*-hexane, 1.0, 2.0, 4.0, 8.0, 12.0, 18.0, 27.0, 40.0, 60.0% ethyl ether/*n*-hexane, and ethyl ether.

High-Performance Liquid Chromatography (HPLC). Analytical and preparative HPLC were carried out on a Waters Associates ALC-100 equipped with a model 720 system controller, a model 730 data module, two model 6000A pumps, a U6K injector, and a model 440 absorbance detector with an extended wavelength module at 214 nm.

Silver nitrate (20% w/w) on 3 μ m Hypersil (Shandon) was prepared by adding a solution of 2.5 g reagent grade silver nitrate in 70 ml acetonitrile to a mixture of 10 g 3 μ m Hypersil in acetonitrile (Heath et al., 1975). The mixture was concentrated in vacuo to dryness, and 4.0 g was added to 30 ml carbon tetrachloride and sonicated for several minutes. The mixture was added to a stainless-steel reservoir and topped off with carbon tetrachloride (Heath et al., 1977). The mixture was pumped into a 30 × 0.39 cm ID stainless-steel column followed by 50 ml *n*-hexane at 9000 psi air pressure. Then, the packed column was flushed with 5% ethyl ether–isooctane at 1.5 ml/min, until 400 ml was collected, and further flushed with isooctane until all traces of ethyl ether were removed.

Sesquiterpenes (50–100 μ g) in a volume of 5–100 μ l *n*-hexane solution were injected for analysis at a flow rate of 0.5 ml/min isooctane. After maintaining this flow rate for 15 min, a linear flow program was then initiated over 5 min to 1.0 ml/min isooctane followed by a linear gradient program over the next 10 min to 0.5% ethyl ether–isooctane. C5, containing about 12 μ g α -copaene in a 78- μ l volume of solvent, was also injected; α -copaene was collected and concentrated under nitrogen to a 100- μ l volume.

GLC. A Hewlett-Packard 5880A gas chromatograph equipped with a cap-

illary injector system and a flame ionization detector was used for GLC analyses. A Hewlett-Packard 12 m \times 0.2 mm ID dimethyl silicone (DMS) fused-silica capillary column was used for the analyses.

Temperatures employed for GLC were: injection port 200°C; detector 220°C; DMS column, 50°C for 5 min, then programmed at 20°C/min to 105°C, maintained at 105°C for 7.25 min, then programmed at 10°C/min to 125°C. Total run time was 22 min. A split ratio of 1:188 was used with a helium flow of 2.2 cm³/min plus an appropriate amount of helium makeup gas.

Standard sesquiterpene samples were dissolved in *n*-hexane to make 0.1% solutions, and 1 μ l of the solutions were injected for GLC analyses. The concentration of unknowns in solution for GLC analyses was adjusted to match that of standards in most cases.

Gas Chromatography-Mass Spectrometry (GC-MS). Mass spectra were recorded on a Finnigan GC-MS 4500 with a 6000 data system. The GC component was equipped with a 60 m \times 0.25 mm ID DB-1 capillary column (J&W Scientific) for sesquiterpene analyses in Figures 1A and 1B and a 50 m \times 0.25 mm ID Ultra 1 (100% dimethyl polysiloxane gum) capillary column (Hewlett-Packard) for analyses of α -copaene in Figures 1C and 1D. In the EI mode, 70 eV energy was used.

Bioassay. A rapid and efficient short-range laboratory bioassay was developed (McInnis and Warthen, 1988) to evaluate crude and fractionated plant extracts, purified phytochemicals, and standard sesquiterpenes as attractants/feeding stimulants for medflies, *C. capitata*. The bioassay's qualitative scoring system with a quantitative and behavioral basis appears in Table 1. Typically, 1- μ g samples of purified phytochemicals and standard sesquiterpenes were utilized. The concentrations of crude and fractionated plant extracts were adjusted according to the percentage of active substance present.

RESULTS

A Soxhlet extraction (2.5–5.1% yield) of Puerto Rican *L. chinensis* (Scheme 1) was also obtained with ethyl ether for 72–96 hr (the extract obtained during the last 24 hr gave a rapid +++ in the bioassay); extraction over 96 hr

FIG. 1. Structural formulae of (-)- α -copaene (A) and (+)- α -ylangene (B).

with *n*-hexane alone gave only a 1.7% yield with a slow +++ in the bioassay. The Miami *L. chinensis*, when extracted with ethyl ether in a Soxhlet for 72 hr, gave a yield ranging from 2.6 to 5.9% that elicited less biological activity than the Puerto Rican variety.

Biologically active A1 and A2 (Scheme 1) from the Puerto Rican *L. chinensis* *n*-hexane extract showed the possible presence of α -ylangene (Figure 1B), α -copaene (2.5–2.8%, Figure 1A), β -caryophyllene, α -humulene, longifolene, and eremophilene by retention time comparison with standard sesquiterpenes (Table 2) via GLC analyses. Chromatography of A1 and A2 revealed biological activity centered in B3, which appeared to contain α -copaene (48%) by GLC analyses. The presence of β -caryophyllene (95%) in B10 was confirmed by GC-MS with an NIH/EPA Spectral Library match. This substance was isolated and identified since it was listed as an insect attractant for medflies and Oriental fruit flies (Beroza and Green, 1963a). However, a Fluka β -caryophyllene sample (99.7% by GLC analysis) indicated no biological activity for medflies or Oriental fruit flies. K&K and Givaudan β -caryophyllene samples that were attractive to male medflies revealed the presence of 0.38–0.57% and 0.41% α -copaene, respectively, by GLC retention time comparison with standard α -copaene.

Chromatography of B3 revealed biological activity centered in C5, which appeared to contain 75% α -copaene and 11% α -ylangene by GLC analyses. HPLC of C5 effectively separated the two closely related sesquiterpenes (Table 2) to give a +++ biologically active substance (95.6% α -copaene by capillary GLC analysis), whose mass spectral fragmentation matched that of α -copaene in the NIH/EPA Mass Spectral Library. α -Copaene samples of 94.5% and 94.8% purity (capillary GLC analyses) prepared from α -copaene-enriched samples isolated from angelica seed oil and copaiba oil, respectively, were prepared by this method. Each of these three 94.5% + pure α -copaene samples exhibited the same biological response of the same intensity for equal treatments. Due to the small observed optical rotation of α -copaene and insufficient amounts of this sesquiterpene isolated from *L. chinensis*, it was not possible to obtain a specific optical rotation.

Although there was not a sufficient quantity of the substance in C5 whose GLC retention time coincided with α -ylangene for isolation, there was an adequate source of α -ylangene in the α -copaene-enriched samples from angelica seed oil and copaiba oil. α -Ylangene, free of α -copaene, was prepared by HPLC from these samples. This α -ylangene, as well as standard α -ylangene (Table 2, 98.9% pure by capillary GLC analysis), having identical GLC and HPLC retention times, initiated the same medfly biological response of the same intensity for equal treatments; this response (++ to +++) was slightly less than that (+++) for the α -copaene for equal treatments (McInnis and Warthen, 1988).

Steam distillates of Puerto Rican and Miami *L. chinensis* also contained 1.91–2.66% (Figure 2A) and 18.39–28.47% (Figure 2B) α -copaene (retention times, 8.96 and 8.97 min, respectively), the structure of which was confirmed by GC-MS with an NIH/EPA Mass Spectral Library match for α -copaene. The overall yields of α -copaene were 0.001% and 0.0003%, respectively, agreeing with the difference in biological activity for the two samples. The Miami *L. chinensis* seemed to be devoid of a GLC peak coincident for α -ylangene, whereas the Puerto Rican *L. chinensis* steam distillate had a 0.25% peak (coincident for α -ylangene) and a 2.01% α -copaene peak, roughly 1:8.

Crude leaf stem exudates (10–50 μ l) of *F. benjamina* and *F. retusa* (McInnis and Warthen, 1988), as well as *F. benghalensis*, were each shown to attract male medflies in the laboratory bioassay. Ethyl acetate and *n*-hexane extracts of fresh leaf stem exudates of *F. benghalensis* attracted male medflies, but solvent extracts of leaf stem exudate of *F. benjamina* that were processed after shipment from Hawaii showed less activity. Therefore, it was essential to extract the leaf stem exudates immediately upon harvest.

Capillary GLC analyses of *n*-hexane, ethyl ether, ethanol, and acetone extracts of small quantities of *F. benjamina* and *F. benghalensis* leaf stem exudate did not reveal useful data due to the low concentration of terpenes.

A larger quantity of exudate was then obtained from a large specimen of *F. retusa*; the leaf stem exudate was more attractive to medflies than the trunk exudate (McInnis and Warthen, 1988). The methylene chloride extracts of the fresh exudates were biologically active to medfly and maintained this activity over time. Open-column chromatography, via Sep-Pak (to remove latexlike materials) and 20% silver nitrate–Bio-Sil A, gave a fraction that showed medfly activity analogous to B3–B4 in Scheme 1 and that contained a real peak coincident with the retention time of standard α -copaene by comparison with a blank open-column chromatographic run.

To show the presence of α -copaene in *F. retusa* (307.3 g) and *F. benjamina* (323.9 g) and by inference in their exudates, the steam distillates (48.9 g and 40.6 g of material, respectively) were analyzed by GLC. Chromatograms of the distillates (Figures 2C and 2D) indicated the presence of 21.0% α -copaene in *F. retusa* and 11.0% α -copaene in *F. benjamina* (retention times, 8.95 and 8.96 min, respectively); structure was confirmed in each case by GC-MS with an NIH/EPA Spectral Library match for α -copaene. If α -ylangene were present in these distillates, it would be present at <0.6%, based on coincident retention times with standard α -ylangene. The yield, based on dried plant specimens, of α -copaene was 1.146 mg (0.0004%) from *F. retusa* and 0.802 mg (0.0002%) from *F. benjamina*.

Capillary GLC analysis did not reveal the presence of α -copaene in extracts of a small specimen of fresh *F. benghalensis* leaves; in all probability, this was

FIG. 2. Capillary GLC of the essential oils from Puerto Rican *Litchi chinensis* dried stems (A); Miami *L. chinensis* dried stems (B); *Ficus retusa* dried leaves, small stems, and twigs (C); and *F. benjamina* dried leaves, small stems, and twigs (D).

FIG. 2. Continued

due to the size of the specimen extracted. An adequate amount of this species could not be located for extraction; but, it is very likely that the attractiveness of its leaf stem exudate is also due to the presence of α -copaene.

DISCUSSION

Fornasiero et al. (1969) isolated α -copaene and α -ylangene (20:1) from angelica seed oil and demonstrated equal attractiveness to male medflies in lab bioassays (Guiotto et al., 1972); α -pinene and α -phellandrene from this oil were slightly attractive, and other sesquiterpenic fractions were more strongly attractive. The structure of α -copaene was resolved by de Mayo et al. (1965) and Kapadia et al. (1965), and the structure of α -ylangene was resolved by Motl et al. (1965) and Ohta and Hirose (1969).

α -Copaene was first isolated from African copaiba oil (Kapadia et al., 1965; Wenninger et al., 1967a,b; Lawrence, 1980); it was also isolated from *Cedrella toona* (de Mayo et al., 1965; Kapadia et al., 1965), chloranthus oil (de Mayo et al., 1965), ylang-ylang oil (Wenninger et al., 1966, 1967b), peppermint oil (Wenninger et al., 1967b), grapefruit and orange oils (Hunter and Brogden, 1964; Veldhuis and Hunter, 1968; Teranishi et al., 1987), and cubeb oil (Ohta et al., 1968; Teranishi et al., 1987). More recent reports indicate its presence in *Yucca gloriosa* (Wang and Kameoka, 1977), guava (MacLeod and de Troconis, 1982), juniper berry and oil of sage (Formacek and Kubeczka, 1982), pineapple fruits (Berger et al., 1983), leaves of *Siparuna guianensis* (Aubl.) (Antonio et al., 1984), corn leaf volatiles (Buttery and Ling, 1984), wheat (Buttery et al., 1985), cotton (Elzen et al., 1985), *Lippia nodiflora* (L.) Greene (Elakovich and Stevens, 1985), and *Heracleum dissectum* Ledeb. (Papageorgiou et al., 1985). α -Copaene usually exists as the levorotatory enantiomer; however, Jacobson et al. (1984) reported that α -copaene from angelica seed oil is dextrorotatory (Jacobson et al., 1987). Teranishi et al., (1987) also reported that the α -copaene from orange oil was dextrorotatory.

α -Ylangene has been isolated from *Schizandra chinensis* (Turcz) Baill by Motl et al. (1963) and Ohta et al. (1968), and traces have been reported in corn leaf volatiles (Buttery and Ling, 1984) and numerous other sources.

Racemic α -copaene was first synthesized via a 17-step route by Heathcock (1966) who, with Heathcock et al. (1967), reported the synthesis of racemic α -ylangene. Subsequently, Corey and Watt (1973) reported simpler syntheses of racemic α -copaene and α -ylangene.

The short-range attraction/feeding stimulation of male medflies to a host plant, *L. chinensis*, from Puerto Rico (McInnis and Warthen, 1988) was demonstrated and shown to be caused by 0.001% α -copaene in the dried twigs. Smaller amounts of a substance with a GLC retention time coincident to that of

α -ylangene, in the steam distillate (Figure 2A), also probably contributes to the behavioral response of male medflies since the α -ylangene standard (Table 2) elicits a similar response. The ratio of α -copaene to α -ylangene (retention times, 8.96 and \sim 8.83 min, respectively) in the steam distillate was 8:1. Through parallel bioassay/isolation of fractions from *Litchi* (Scheme 1), α -copaene (95.6%, α -ylangene-free) was isolated by HPLC as an active component. The behavioral response to this sample was identical to those produced by α -copaene samples (α -ylangene-free), each with a purity of 94.5% and 94.8%, prepared by HPLC of α -copaene-enriched samples from angelica seed oil and copaiba oil, respectively. No difference in behavioral response was noted to the purified α -copaene from copaiba and the purified α -copaene from angelica, each having opposing rotations, as reported by Jacobson et al. (1984, 1987); the implication is that optical rotation of these enantiomers is not relevant over short distances. α -Ylangene standard (98.9%) and α -ylangene (α -copaene-free) samples, the latter being prepared from α -copaene-enriched samples from angelica seed oil or copaiba oil, gave the same male medfly response but slightly less intense than with α -copaene. The presence of α -ylangene in *L. chinensis* from Miami was not detectable, even though there was 18.4% α -copaene (Figure 2B, retention time, 8.97 min) in the steam distillate as compared to 2.7% α -copaene (Figure 2A, retention time, 8.96 min) in the Puerto Rican sample. However, the overall yield of α -copaene was three times greater from the Puerto Rican sample than from the Miami sample. β -Caryophyllene in *L. chinensis* (B3, Scheme 1) was ruled out as a medfly attractant through bioassay even though it had been reported as an attractant (Beroza and Green, 1963a). Old samples of β -caryophyllene were probably attractive because of the presence of α -copaene as an impurity.

The short-range attraction/feeding stimulation of male medflies to the milky exudate of a nonhost plant, *F. retusa* (McInnis and Warthen, 1988), was also shown to be caused by α -copaene through a fractionation similar to Scheme 1. Fractions that would correspond to B3–4 showed a real GLC peak corresponding to α -copaene; and a steam distillate of leaves, small stems, and twigs revealed the presence of 21.0% α -copaene (Figure 2C, retention time, 8.95 min). A similar behavioral response to the milky exudate of the other nonhost plant, *F. benjamina* (McInnis and Warthen, 1988), was also probably due to α -copaene since a similar steam distillate revealed the presence of 11.0% α -copaene (Figure 2D, retention time, 8.96 min). If we had had a large enough sample of *F. benghalensis* to do a steam distillation, α -copaene would probably have been revealed as the component in the milky exudate responsible for eliciting a similar behavioral response of male medflies. If α -ylangene were present in *F. retusa* and *F. benjamina*, contributing to the medfly behavioral response, it would be present in the steam distillate (Figures 2C and 2D) at $<0.6\%$ based on coincident retention times.

The discovery of synthetics or phytochemicals as short-range attractants/feeding stimulants for the male medfly is an important area of research. Such materials may be useful in studying this short-range phenomenon and may even be used as an eradication tool when combined with a bait-toxicant system.

Acknowledgments—We thank the following USDA, ARS employees: Dr. Franklin W. Martin, Tropical Agriculture Research Station, Mayaguez, Puerto Rico, and Paul Soderholm, Subtropical Horticulture Research, Miami, Florida, for samples of *L. chinensis*; Francisco Vazquez, Tropical Agricultural Research Station, Mayaguez, Puerto Rico, for samples of *F. retusa* and *F. benjamina*; and Dr. James A. Duke, Narcotics Laboratory, Beltsville, Maryland, for arranging for these samples. The authors also thank USDA, ARS, Beltsville, Maryland, employees E. David DeVilbiss and Dr. Barbara A. Leonhardt, Insect Chemical Ecology Laboratory, for GC-MS data, M. Jacobson (retired; collaborator) for enriched α -copaene samples from angelica seed oil and copaiba root oil, and Dr. Charles W. Woods, Insect Reproduction Laboratory, for packing HPLC columns. We also thank Richard R. Barrett and Rayma Overton, U.S. Botanic Gardens, Washington, D.C., for leaves and leaf stem exudate of *F. benghalensis*; Professor V. Herout, Institute of Organic Chemistry and Biochemistry, Czechoslovak Academy of Science, Prague, for an α -ylangene sample; and Professor G. Buchi, Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts, for an α -copaene sample.

(Received July 27, 1988; accepted September 21, 1988)

Abstract—Soil from the chinampa agricultural system in the Valley of Mexico suppressed damage by plant-parasitic nematodes to tomatoes and beans in greenhouse and growth chamber trials. Sterilization of the chinampa soil resulted in a loss of the suppressive effect, thereby indicating that one or more biotic factors were responsible for the low incidence of nematode damage. Nine organisms were isolated from chinampa soil, which showed antinematodal properties in culture. Naturally occurring populations of plant-parasitic nematodes were of lower incidence in chinampa soil than in Chapingo soil.

Key Words—Nematode suppressive soil, false root knot nematode, *Nacobus aberrans*, *Meloidogyne incognita*, nematocidal microorganisms, reproduction suppression

INTRODUCTION

The chinampa agricultural system, which is based on land reclaimed from swamps and shallow lakes in the valley of Central Mexico, reached its greatest development during the reign of the Aztecs (Armillas, 1971). Records from the time of the Spanish conquest indicate that chinampas have been maintained continuously for about 2000 years (Coe, 1964); however, modern urban development has severely constricted the extent of these reclaimed farmlands. The high productivity of the chinampa system is well documented and is due to the large amounts of vegetation and sediments continuously dredged from the adja-

cent canals and added to the fields, the adequate supply of water from the canals, and the regular use of animal manures (Coe, 1964; Gliessman et al., 1981).

Casual observations indicating that root diseases were of low incidence in lands under chinampa management were confirmed through cooperative studies by Mexican and American scientists. This work demonstrated that damping-off caused by *Pythium* spp. was suppressed in chinampa soils as compared to Chapingo soils. (Lumsden et al., 1987). The Chapingo soils were used by Lumsden et al. (1987) and in the current work for comparison with the chinampa soils since disease suppression has been reported from chinampa but not Chapingo soils, yet both occur in the same geographical area. The current paper details experiments on the incidence of a nematode-induced disease as affected by the chinampa system, using for comparison soils from experimental fields located at the Postgraduate College, Chapingo, Mexico, and studies on the possible mechanisms underlying these effects.

METHODS AND MATERIALS

Greenhouse Trials. The influences of the chinampa and Chapingo soils on plant growth and root galling caused by the false root knot nematode *Nacobbus aberrans* and the root knot nematode *Meloidogyne incognita* were first evaluated in two greenhouse trials (see Tables 1 and 2). Host plants were tomato (*Lycopersicon esculentum* var. Ace) and bean (*Phaseolus vulgaris* var. Flor de Mayo) for the false root knot nematode experiment and tomato for the root knot

^aEach treatment was replicated eight times. Experiment duration was 63 days. Values for each treatment followed by different letters differ significantly ($P < 0.05$) from each other.

nematode experiment. Soils used were from the chinampa system and from Chapingo. Soils were sterilized by steam or were unsterilized. There were eight replicates of each treatment (the total number of pots in each experiment was 64). The ambient temperature was 20–27°C. These trials and others involving the processing of soil were performed in Chapingo.

The soils were the same as used by Lumsden et al. (1987). The physical and chemical characteristics of the chinampa and Chapingo soils were examined in detail by these workers, and their data are cited in the discussion of the current results.

Each pot contained 400 cc of soil and one plant. Three weeks after planting, a gram of nematode-infested roots was added to each pot. In the *N. aberrans* experiment, the plants were harvested after nine weeks and the wet weight of the plant roots and tops recorded. Growth of plant roots and tops was evaluated as dry weight in the *M. incognita* experiment. The number of galls on the roots were counted and were rated by a gall index as follows: no galls = 0; 1–2 galls = 1; 3–10 galls = 2; 11–30 galls = 3; 31–100 galls = 4; more than 100 galls = 5. Statistical analyses of results were by Duncan's multiple-range test.

Growth Chamber Trial. The influence of the chinampa and Chapingo soils on nematode attack was also evaluated in the growth chamber (see Table 3). Parameters were the same as for the greenhouse trial, with the following exceptions. Another category of chinampa soil was tested, specifically chinampa soil with fungicide and insecticide residues resulting from chemical pesticide treatment. The plant host tested was Ace tomato. Each treatment was replicated 10 times (total number of pots = 50). Growth chamber conditions were $23 \pm 1^\circ\text{C}$, 14 hr light and 10 hr dark. Duration of the experiment was 75 days.

Isolation of Soil Microorganisms. Chinampa soils were sampled at two separate dates 10 months apart. The soil was evaluated for bacteria, actinomycetes, and fungi following protocols detailed below. The procedure yielded a total of 466 pure cultures, many of which were undoubtedly the same species. No attempts at identification were made prior to determination of nematicidal or other antinematodal activity. Procedures were as follows: One gram of chinampa soil was shaken vigorously in 100 ml sterile 0.9% NaCl and further diluted to give concentrations of 1×10^{-6} , 1×10^{-7} , and 1×10^{-9} . An 0.2-ml aliquot of these three dilutions was then applied to four Petri plates each of (1) potato dextrose agar, (2) nutrient broth agar, (3) glucose-starch-asparagine agar, (4) glycerol-arginine agar, (5) glycerol-casein agar, (6) glycerol-starch-peptone agar, (7) glycerol synthetic agar, and (8) yeast starch agar (Anonymous, 1975). Isolates were subcultured at 3 and 15 days after plating to obtain pure cultures. Each isolate was spread in two thin lines across a 9-cm Petri plate containing the medium on which the original culture was isolated, so as to divide the plates into four equal quadrants. After three days of growth at 25°C, 30 μ l of broth containing *Escherichia coli* was placed in the center of three quadrants, and 20 μ l saline containing 30–50 of the nematode *Caenorhabditis elegans*, which had been axenically grown on heme soybean extract-yeast extract medium (McClure and Zuckerman, 1982), was added to the center of the fourth quadrant. Exudates of *E. coli* are strongly attractive to *C. elegans* (Jansson et al., 1986); thus the assay served to induce the nematodes to cross the barrier formed by the test isolate. The numbers of nematodes that had reached the *E. coli* were counted

at 3 and 24 hr, and a count was made of the numbers that stayed in the strip of the test isolate. Nematicidal activity was indicated when the nematodes died, and repellency when the nematodes lived but did not cross (or enter into) the barrier formed by the test isolate. Additional information on attraction and repellency was obtained using 3-day-old liquid cultures of bacteria in nutrient broth or 3- to 5-day-old liquid cultures of fungi in potato dextrose broth. Eight-microliter aliquots of culture extract were added to water agar plates, the plates equilibrated overnight and numbers of *C. elegans* migrating under the agar disks counted 60 min after addition of the worms as described by Jansson et al. (1984). In addition, where nematicidal activity occurred, tests included second-stage larvae of *M. incognita* collected by the method of Hussey and Barker (1973).

All isolates were then incubated for one week at 22°C and reexamined to determine if the nematodes were breeding normally or if reproduction was delayed or inhibited. A culture of *Streptomyces avermitilis* (ATCC 31267), which showed nematicidal activity, and a culture of *Aspergillus phoenicis* (ATCC 14332), which was both toxic and repellent, to nematodes, served as standards.

Incidence of Soil Nematodes. Samples of chinampa and Chapingo soils were examined to yield an estimate of the numbers of plant parasitic, bacteriophagous, and predaceous nematodes present. Each sample consisted of 100 cm³ of soil processed by sieving and use of the Baermann funnel. After 24 hr, an aliquot of water was drawn from the Baermann funnel and the nematodes counted and identified.

RESULTS

Greenhouse Trials. The greenhouse trial with the false root knot nematode *N. aberrans* showed significantly ($P < 0.05$) less root galling of both tomato and bean plants in nonsterilized chinampa soil as compared to nonsterilized and sterilized Chapingo soil (Table 1). The sterilized chinampa soil and the nonsterilized Chapingo soil showed significant differences in gall index, but the level of galling in the nonsterilized chinampa soil was much lower than that in the sterilized chinampa soil. Growth of the bean and tomato plants, as measured by the wet weight of the aboveground portions of the plants, was significantly enhanced, but there was no consistent difference in root growth. Sterilized chinampa soil had greatly reduced nematode suppressive activity, indicating that the reduction of nematode attack is related to biotic factors.

The root knot nematode *M. incognita* caused significantly less root galling ($P < 0.05$) on tomato in chinampa nonsterilized soil than in the other treatments (Table 2). These results support those of other experiments reported here that

biotic factors were responsible for the reduction in nematode damage. In this experiment root growth was enhanced in the nonsterile chinampa soil, but top growth was not significantly affected.

Growth Chamber Trial. The results of the growth chamber experiment supported those obtained in the greenhouse (Table 3). Root galling was significantly less ($P < 0.05$) and the vegetative growth of plants significantly greater ($P < 0.05$) in the nonsterilized chinampa soil than in the sterilized chinampa soil. The Chapingo soil, both sterilized and nonsterilized, showed no nematode suppression. Chinampa soil that was not sterilized but that was treated with agricultural pesticides was less suppressive to nematode attack and growth of plants was reduced. These results support a role for a biotic factor in enhanced plant growth and reduction in nematode attack associated with the chinampa agricultural system.

Antinematodal Organisms from Chinampa Soil. Of the 466 organisms from the chinampa soil, nine isolates were active against *C. elegans* (Table 4). The two fungi isolated on potato-dextrose agar were identified as belonging to the *Aspergillus niger* and *A. ochraceus* groups. Culture filtrates of the *A. niger* isolate that passed through a dialysis membrane with a 6000 mol wt cutoff, killed *C. elegans* within 10 min. These filtrates were toxic to newly hatched second-stage larvae of *M. incognita* within 60 min. Eight-microliter aliquots of

^bInhibited reproduction.

^cNematicidal.

filtrates from this culture, allowed to diffuse in water agar plates overnight, were highly repellent to *C. elegans*. The *A. ochraceus* group isolate was slower acting, but still highly toxic to *C. elegans*. A third fungus, isolated on medium 7, was also nematocidal to *C. elegans*. This organism has not as yet been identified, but the red pigment it produces suggests it may be a *Fusarium* sp. Six bacteria isolated on medium 1 and medium 2 inhibited reproduction of *C. elegans*. The criteria for inhibition of reproduction was that seven days after 30 nematodes were placed on a plate, either no reproduction had occurred or there were less than 50 nematodes/plate. By comparison, plates showing no inhibition of reproduction contained more than 1×10^5 nematodes.

Incidence of Soil Nematodes. The results of soil sampling of the chinampa and Chapingo soils demonstrated that numbers of both economically important plant parasitic nematodes and other plant nematodes were lower in chinampa soil than in Chapingo soil (Table 5). The large numbers of *Acrobeles* sp. and *Rhabditis* sp. agree with other observations (Sayre, 1971) that soils high in organic matter support high populations of these bacteriophagous nematode species.

DISCUSSION

Observations by Lumsden et al. (1987) on disease suppression in chinampa soil will be discussed in the context of the current study. An important observation was the increased incidence of disease caused when inoculum of *Pythium aphanidermatum* was added to both Chapingo and chinampa soils after the soil was subjected to gamma ray sterilization (Lumsden et al., 1987). This finding implicates a biotic factor in the disease suppression observed in chinampa soils. The present finding of enhanced susceptibility to nematodes in steam sterilized chinampa soil also suggests a crucial role for biotic factors in suppression of nematode damage in chinampa soil.

Lumsden et al. (1987) give a comprehensive analysis of the chemical and physical characters of the Chapingo and chinampa soils. They found that the chinampa soil was a silty, clay loam, pH 5.8, and was significantly higher in organic matter and P, K, Ca, Mg, NO₃, and NH₄ content than the Chapingo soil, as well as soluble salts. Chapingo soil, in addition to being lower in organic matter, was sandy and had a pH of 6.8. It is recognized that organic amendments to soil result in a shift in microbial populations, due to factors probably including more acid pH and the production of toxic materials. Sayre (1971) summarized the numerous observations that confirm significant reductions of phytonematodes in soils that conform to the chinampa profile. The high organic content of chinampa soil is probably partly responsible for the paucity of phytonematodes and the suppression of plant damage, but the importance of soil organisms in the reduction of injury by plant nematodes is also emphasized by the current experiments.

Of the nine organisms that showed antinematodal activity, the *A. niger* group isolate alone has been tested against a plant parasitic nematode. This fungus produced exudates that were highly nematocidal to both *C. elegans* and *M. incognita* at high concentrations and repellent to *C. elegans* at lower concentrations. Greenhouse tests to evaluate the efficacy of this organism against root knot nematodes are planned. Further evaluation will also proceed on the organisms that showed lower nematocidal activity or effects that retarded nematode development. Our interpretation of the current results is that the sum of effects of these nine organisms is probably large enough to account for the suppression of plant nematode damage observed in the chinampa soil.

Acknowledgments—The authors acknowledge grant 1-910-85 from the U.S.-Israel Binational Agricultural Research and Development Fund (BARD) and Northeastern Regional Research Project NE-133 for support of this work, and Dr. Margaret Bigelow for identification of the *Aspergillus* spp.

ALLELOPATHIC PROPERTIES OF *Polygonella myriophylla* Field Evidence and Bioassays

JEFFREY D. WEIDENHAMER¹ and JOHN T. ROMEO

Department of Biology
University of South Florida
Tampa, Florida 33620

(Received June 22, 1988; accepted September 29, 1988)

Abstract—*Polygonella myriophylla* is a perennial shrub endemic to the Florida scrub. Striking bare zones surround mature *Polygonella* stands. Quantitative measurements of root distribution show that few *Polygonella* roots extend into the bare zones, supporting the hypothesis that the bare zones result from chemical interference by *Polygonella* with the growth of other species. Bioassays of soils collected biweekly for one year from beneath *Polygonella*, the bare zone, and adjacent grassed areas confirm that the germination and growth of grasses is reduced in *Polygonella* soil and soil from the surrounding bare zone. Compared to adjacent grassed area soil, the average germination of bahiagrass (*Paspalum notatum*) was 71% in *Polygonella* soil and 81% in bare zone soil, and average shoot dry weight was 48% in *Polygonella* soil and 81% in bare zone soil. Seasonal variation in the inhibition of grass germination and growth was not pronounced.

Key Words—*Polygonella myriophylla*, *Paspalum notatum*, allelopathy, interference, sand pine scrub.

INTRODUCTION

The sand pine scrub community occurs on well-drained sandy soils along Florida's central ridge and coastal dunes. At many sites, sand pine, *Pinus clausa* (Chapm. ex Engelm.) Vasey ex Sarg., and oaks, including *Quercus chapmanii* Sarg., *Q. myrtifolia* Willd., and *Q. geminata* Small, form a dense canopy with little or no herbaceous understory. More open sites are dominated by widely

¹ Present address: Department of Chemistry, 232 Choppin Hall, Louisiana State University, Baton Rouge, Louisiana 70803.

spaced evergreen shrubs, such as *Ceratiola ericoides* Michx., *Conradina canescens* (Torr. & Gray) A. Gray, and *Polygonella myriophylla* (Small) Horton, with scattered young scrub oaks, sand pine, and scrub palmetto, *Serenoa repens* (Bartr.) Small. Few plants grow in the large open areas between shrubs. These include *Paronychia chartacea* Fern., a small plant less than 10 cm in height, and *Selaginella arenicola* Underw., a club moss. In many areas the soil is covered by a mat of lichens 2.5–15 cm thick.

Where open scrubs abut roads or abandoned fields, sharp boundaries between the scrub and neighboring vegetation often are evident (Figure 1). Grasses such as bahiagrass, *Paspalum notatum* Fluegge, and natalgrass, *Rhynchelytrum repens* (Willd.) C.E. Hubb., and the composites camphorweed, *Heterotheca subaxillaris* (Lam.) Britt & Rusby, and dog fennel, *Eupatorium capillifolium* (Lam.) Small, are common along roadsides but generally do not occur in the scrub.

In past years, similar sharp ecotones marked by a persistent bare zone 1–2 m wide were reported between the sand pine scrub and the sandhill, another community that occurs on well-drained sandy soils (Nash, 1895; Harper, 1921; Mulvania, 1931; Webber, 1935). Sandhills are dominated by longleaf pine,

FIG. 1. Patches of *Polygonella myriophylla* (left) dominate portions of a scrub near Sun Ray, Florida, which borders an abandoned citrus field that has been invaded by bahiagrass, *Paspalum notatum*, and other ruderal species. The bare zone is approximately 1 m wide.

Pinus palustris Mill., slash pine, *P. elliotii* var. *densa* Little & Dorman, and oaks, *Q. laevis* Walt. and *Q. geminata*. In contrast to the scrub, wiregrass, *Aristida stricta* Michx., other grasses and many herbs form a fairly dense herbaceous ground cover in the sandhill.

The possible role of allelopathy in the scrub is beginning to be explored (Richardson, 1985; Tannrisever et al., 1987; Richardson and Williamson, 1988). Richardson (1985) demonstrated that leaf washes of several plants, including *Polygonella myriophylla*, inhibited germination and growth of lettuce, *Lactuca sativa* L., and the native sandhill grasses *Andropogon gyrans* Ashe, *Schizachyrium scoparium* (Michx.) Nash and *Leptochloa dubia* (H.B.K.) Nees.

The experiments reported here were performed to test the hypothesis that the dominance of *Polygonella myriophylla* in certain areas of the Florida scrub is due in part to allelopathic interference. A study of the distribution of root mass around a mature *Polygonella* stand was carried out to determine whether the striking bare zone observed extends beyond the *Polygonella* root zone. Bioassays were conducted with soil collected biweekly for one year from beneath and around *Polygonella* shrubs to determine whether there is seasonal variation in the phytotoxicity of *Polygonella* soil.

METHODS AND MATERIALS

Root Mass Distribution Study

Site Description. South of Lake Wales, Florida, in a vacant field across from Warner Southern College on the west side of U.S. Route 27 (Range 27E, Township 30S, NW Quarter of Section 35), an area of open scrub was found that had been disturbed several years ago. Areas of scrub are now intermixed with patches of ruderal species, including bahiagrass (*Paspalum notatum*), natalgrass (*Rhynchelytrum repens*), and dog fennel (*Eupatorium capillifolium*). One large patch of *Polygonella myriophylla* is more than 4 × 9 m in extent. It borders an area of bahiagrass and is surrounded by a bare zone 0.6–1.0 m wide. Dead or dormant rhizomes of bahiagrass are found within the patch and in the bare zone.

Sampling and Root Mass Measurements. To measure the distribution of root mass across the bare zone, soil samples were taken in April 1985 from four areas: within the large *Polygonella* patch described above, at the edge of the patch, in the middle of the bare zone, and 1 m into the adjacent stand of bahiagrass. In each area, five soil cores (10 cm diameter × 20 cm depth) were obtained at random points. Roots were separated from the soil by sieving through a 2-mm screen, sorted by species, and dried for 48 hr at 80°C. Roots of *Polygonella myriophylla* and *Paspalum notatum* were easily distinguished from one another by their different color and morphology.

Study of Seasonal Variation of Soil Phytotoxicity

Site Description. The study area is located at the north end of the Lake Arbuckle scrub, approximately five miles southeast of Frostproof, Florida, off Rucks Dairy Road (Range 29E, Township 32S, south half of Section 8). The site is owned by the state of Florida and administered by the Division of Forestry. At this site, *Polygonella*-dominated scrub borders both sides of an old road cut for more than 250 yards. A dense bahiagrass cover 1–2 m on either side of the road does not extend into the scrub, producing sharp boundaries similar to that seen in Figure 1. Lichen cover (*Cladonia* and *Cladina* spp.) at the site is sparse.

Sampling Protocol. Samples of *Polygonella*, bare zone, and grassed area soils were collected biweekly from November 1984 to October 1985. The study area was initially mapped to determine the number of *Polygonella* patches suitable for sampling. There were over 200 patches greater than 1 m in diameter chosen, more than 100 on each side of the road. The patches were numbered, and at each sampling date, four patches, two on either side of the road, were randomly selected.

Collection of Soils. Soil samples were collected from directly beneath *Polygonella* patches, in the bare zones 0.6 m distant from the patches, and in neighboring grassed areas. Three 5-cm-diameter cores of the upper 5 cm of each soil type were collected at each of the four sampling sites. Soils collected at sampling sites 1 and 3 and sites 2 and 4 were combined to give two replicates of each soil type per sampling date.

A thin layer of litter (<0.5 cm) covers the soil beneath *Polygonella* stands. The texture of this litter layer was fine and difficult to separate from the underlying soil. Therefore, litter was not removed prior to sampling.

Storage and Preparation of Samples. All soil samples were stored frozen in polyethylene bags for a maximum of eight months (–20°C). Results of preliminary bioassays did not indicate any differences in the toxicity of freshly collected and frozen soils. Prior to the bioassays, soil samples were air-dried, passed through a 2-mm sieve to remove roots and other large debris, and mixed thoroughly.

Rainfall Measurements. Daily rainfall measurements were recorded within 1 km of the study site for the duration of the study.

Bioassay Methods. Bioassays were conducted in a large, walk-in growth chamber. Day length was 12 hr and light intensities at pot level were approximately 350 $\mu\text{mol}/\text{m}^2/\text{sec}$. Maximum daytime temperatures were 25–28°C, and night temperatures were 20–22°C. Humidity was not controlled. Fifty seeds of bahiagrass, *Paspalum notatum*, or the native sandhill grass little bluestem, *Schizachyrium scoparium*, were sown in 5 × 5-cm pots each containing 200 g soil. Each soil sample (two each of *Polygonella*, bare zone, and grassed area soil

per sampling date) provided soil for four pots, two replicates each of bahiagrass and little bluestem. Because of the large volume of soil involved, soil collected in October 1984 through mid-April 1985 and late April through October 1985 was assayed in separate experiments.

The arrangement of pots was randomized weekly. Pots were watered twice weekly to 12.5% moisture content, slightly below field capacity, to preclude leaching of phytotoxins from the soil. Moisture content of the pots was determined by weighing approximately 20 randomly selected pots before each watering.

Germination percentage was determined at three weeks. Plants were then thinned to two of the largest seedlings per pot by carefully pulling out the extra seedlings. This density was maintained by weekly thinnings until the plants were harvested at 6 weeks. At harvest, the number of leaves and length of the longest leaf of each seedling were recorded. Shoots were clipped at the point of the first root, and total shoot fresh weight per pot was determined. Shoot dry weight was measured after drying 48 hr at 80°C.

Soil and Data Analyses

Soil Mineral Analyses. Samples were sent to the Extension Soil Testing Laboratory of the University of Florida (Gainesville, Florida) for determination of soil pH, P, K, Ca, Mg, and organic matter content. Analyses for total, ammonium, and nitrate N were performed by the Soils Laboratory of Kansas State University (Manhattan, Kansas). All samples were air-dried before analysis. Soil texture determinations were made by water sedimentation rate using a soil texture kit from Forestry Suppliers, Inc. (Jackson, Mississippi).

Data Analysis. Data were subjected to standard analysis of variance procedures. In the seasonal study, the effects of soil type, sampling date, soil type \times sampling date, and sample (soil type) were tested for by this analysis. A significance level of 0.05 was used in the analysis and multiple comparison procedures.

RESULTS AND DISCUSSION

Root Mass Distribution Study

While some *Polygonella* roots extend across the bare zone, most of the root system and almost all of the fine roots are concentrated beneath the plant (Table 1). Compared to the root mass within the *Polygonella* patch, the root mass of *Polygonella* is 37% at the edge of the patch and only 3% in the bare zone. The root mass of bahiagrass is also greatly reduced in the bare zone. This strongly suggests a noncompetitive interaction between the two species

TABLE 1. ROOT BIOMASS OF *Polygonella myriophylla* AND *Paspalum notatum* WITHIN AND AROUND MATURE *Polygonella* STAND

Area sampled	Average root biomass (g) ^a			
	<i>Polygonella</i>	<i>Paspalum</i>	Other	Total
Within <i>Polygonella</i> patch	3.84 a ^b	1.25 b (100% dead)	0.00	5.09 b
Edge of <i>Polygonella</i> patch	1.43 ab	1.80 b (100% dead)	0.12	3.35 b
Middle of bare zone surrounding patch	0.13 b	4.36 b (50% dead)	0.16	4.63 b
Neighboring <i>Paspalum</i>	0.09 b	10.15 a	0.00	10.24 a

^aEach value is the average dry weight of roots in five randomly taken soil cores (10 cm diameter × 20 cm depth) from each area.

^bMeans in a column followed by the same letter are not significantly different at the 5% level by Duncan's multiple-range test. For *Polygonella* roots, $F = 9.69$, $Pr > F = 0.0007$, and for *Paspalum* roots, $F = 10.04$, $Pr > F = 0.0006$.

(see Dekker et al., 1983) and supports the hypothesis that toxins from *Polygonella* have played an important role in the displacement of bahiagrass at this site.

Soil properties across the *Polygonella*-bahiagrass ecotone are fairly uniform (Table 2). Given the evidence that *Polygonella* has displaced the bahiagrass stand over a period of years, the lower nitrogen levels beneath *Polygonella* appear to be a result rather than a cause of the observed vegetation patterning. This probably reflects differences in the nitrogen economies of the two species. Alternatively, this could be due to the influence of *Polygonella* allelochemicals on soil nitrification (Rice and Pancholy, 1974; Lodhi, 1978; Lodhi and Killingbeck, 1980) and nitrogen fixation (Rice et al., 1981). The possible influence of *Polygonella* allelochemicals on the soil nitrogen cycle needs to be investigated.

Animal activity, which has been demonstrated to contribute to bare zones around shrubs in the California chaparral (Bartholomew, 1970), is considered unlikely to cause the development of bare zones around *Polygonella* for several reasons: (1) Observations of some small mammal feces (possibly rabbit or armadillo) in grassed areas, as well as occasional diggings apparently to get at *Paspalum* roots, attest to the potential importance of animal herbivores in reducing growth of grasses. However, such activity has not been observed in the bare zones around scrub perennials. (2) Young patches of *Polygonella* at the same site, over 1 m in diameter and large enough to provide shelter for small mammals, have vigorous stands of bahiagrass growing within and around the patch.

^aData for the Lake Wales site are based on the average of three samples. For the Lake Arbuckle site, $N = 12$. For the soil nitrogen analyses, $N = 4$ for the Lake Wales site, and $N = 3$ for the Lake Arbuckle site. For each site, means within a row followed by the same letter are not significantly different at the 0.05 level by Duncan's multiple-range test. NS = not significant, n.a. = data not available.

(3) Late in the rainy season, some stunted *Paspalum* shoots appear in the bare zone from the apparently dormant rhizomes. These observations are consistent with the hypothesis that reduction of bahiagrass growth around *Polygonella* patches is due to the chronic toxic effects of *Polygonella* allelochemicals or their breakdown products. A gradual buildup of soil concentrations of allelochemicals, while a possibility, seems unlikely on these well-drained sandy soils.

Study of Seasonal Variation of Soil Phytotoxicity

Germination and Growth Bioassays. Analysis of variance showed a significant effect of soil type (i.e., *Polygonella*, bare zone, and grassed area soils) on germination and growth of grasses for all but little bluestem germination ("soil" term in Table 3).

Germination and growth of bahiagrass were reduced significantly in *Polygonella* soil compared to adjacent grassed areas (Figures 2 and 3). Reductions of germination and growth were intermediate in the bare zone soil. Average germination of bahiagrass for the year (expressed as percent of grassed area soil) was 71% in *Polygonella* soil and 81% in the bare zone soil (Figure 2).

^aThe sample (soil) term represents subsample variation.

FIG. 2. Germination of bahiagrass three weeks after planting in soil collected beneath and around *Polygonella myriophylla* and from adjacent grassed areas in November 1984–October 1985. For the six-month means, significant differences are indicated by letters.

The lower overall germination rates for the April–October samples were due to slightly lower (2–3°C) temperatures in the growth chamber during the period of the experiment. Average shoot dry weight of bahiagrass was more severely affected. For the year, growth (expressed as percent of grassed area soil) was 48% in *Polygonella* soil and 81% in the bare zone soil (Figure 3).

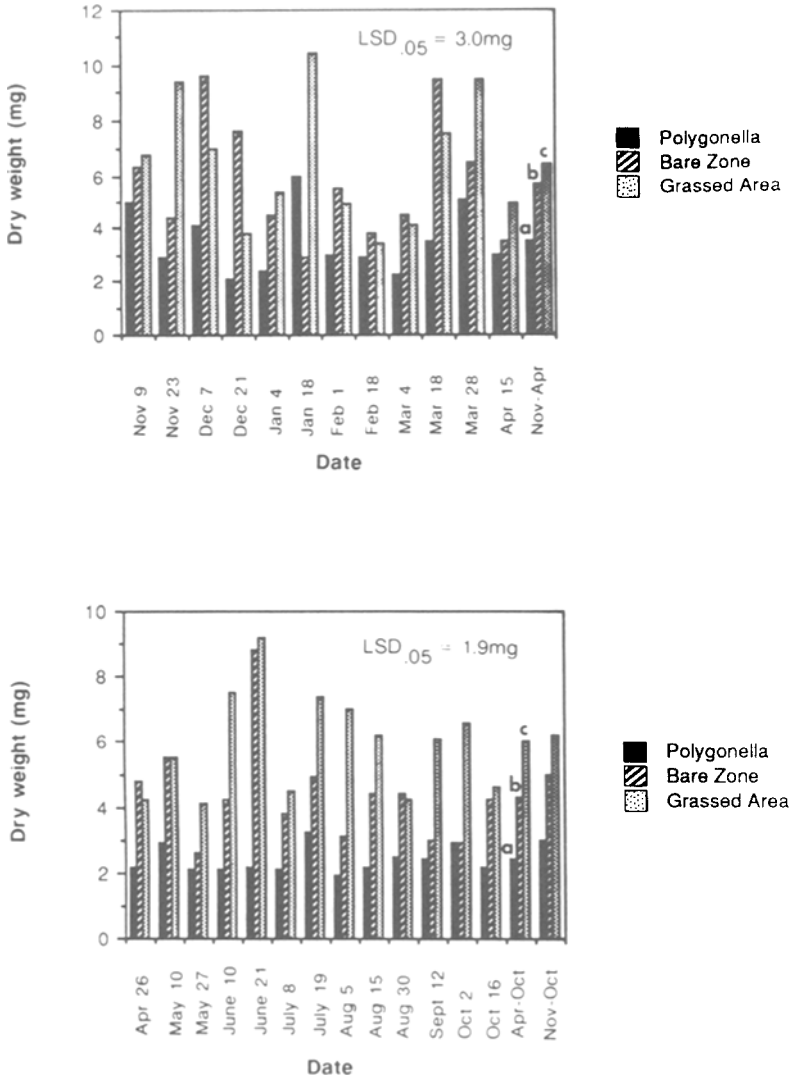

FIG. 3. Shoot dry weight of bahiagrass grown six weeks in soil collected beneath and around *Polygonella myriophylla* and from adjacent grassed areas in November 1984–October 1985. For the six-month means, significant differences are indicated by letters.

Little bluestem germination was unaffected by *Polygonella* soil (data not shown), and growth reductions were less than for bahiagrass (Figure 4). Average germination of little bluestem for the year (expressed as percent of grassed area soil) was 92% in *Polygonella* soil and 95% in bare zone soil. Average

FIG. 4. Shoot dry weight of little bluestem grown six weeks in soil collected beneath and around *Polygonella myriophylla* and from adjacent grassed areas in November 1984–October 1985. For the six-month means, significant differences are indicated by letters.

shoot dry weight of little bluestem for the year (expressed as percent of grassed area soil) was 80% in *Polygonella* soil and 94% in bare zone soil (Figure 4).

It was expected that the toxicity of *Polygonella* soil would vary during the year because of the influence of environmental factors such as rainfall and tem-

perature on the processes of phytotoxin production, release, accumulation, and breakdown. Richardson and Williamson (1988) reported strong seasonality of the effect of leaf soaks of several sand pine scrub plants on the germination and growth of native sandhill grasses. They found that inhibition was concentrated in the late spring and summer, at the onset of the summer rainy season.

In the present study, variation in inhibition observed in soils collected on different sampling dates, as measured by the date and soil \times date interaction terms of the analysis of variance model (Table 3), was not significant for bahiagrass germination but was for bahiagrass dry weight. There was a significant effect of sampling date for little bluestem germination and growth only in the November–April samples. There are no striking seasonal trends to this variation. For example, at some sampling dates, growth of bahiagrass was reduced in *Polygonella* soil compared to both the bare zone and grassed areas, with growth sometimes greater in the bare zone than the grassed area soil (see December 7 and 21, April 26, May 10, and June 21 in Figure 3). At other sampling dates, growth followed the average annual pattern of reduced growth in *Polygonella* soils and intermediate reductions in the bare zone soil (for example, November 23, January 4, June 10, and August 5). Regression analyses did not suggest a correlation of the amount of rainfall in the two weeks preceding each sampling date with grass germination and growth (data not shown). It was noted, however, that significant inhibition in *Polygonella* soil compared to grassed area soils occurred in a greater proportion of samples collected during the summer rainy season of June, July, and August. For little bluestem dry weight, the proportion of sampling dates on which significant inhibition in *Polygonella* soil occurred was significantly higher ($P = 0.03$, Fisher's exact test) in the summer months (five of seven sampling dates) compared to nonsummer months (four of 18 sampling dates). Similar trends are found with bahiagrass germination (inhibition five of seven sampling dates in summer, six of 18 in nonsummer months) and dry weight (inhibition six of seven sampling dates in summer, 11 of 18 in nonsummer months). There does appear, therefore, to be some evidence of a weak seasonal pattern in the inhibition of grass germination and growth.

It should be noted that because soils were assayed under similar environmental conditions, these bioassays measured seasonal variation in the presence and abundance of putative *Polygonella* phytotoxins. This is not necessarily the same as seasonal variation of phytotoxicity under field conditions. The effects of phytotoxins are known to be intensified by environmental stresses such as high temperature and nutrient limitation (Stowe and Osborn, 1980; Einhellig and Eckrich, 1984; Einhellig, 1987); therefore, the actual effects of equal soil concentrations of a phytotoxin may be quite different depending on the time of year. The white sands of the Florida scrub are low in available macronutrients (Table 2; also Kalisz and Stone, 1984), subject to soil surface temperatures in

excess of 50°C on sunny days (Richardson, 1985), and moisture stress is a significant factor in the dry season and during pauses in summer rains. It is likely that these environmental factors contribute to enhanced effectiveness of allelochemicals produced by *Polygonella* and other scrub perennials.

Soil Nutrient Analyses. Unlike the Lake Wales site, there was a higher clay content in the grassed area soils at the Lake Arbuckle scrub, which was the result of road construction. At the edges of the grassed area where samples were taken, these differences were slight (Table 2). Bare zone soil at the Lake Arbuckle site was lower in P, K, Mg, organic matter, and total N than the *Polygonella* and adjacent grassed area soils. *Polygonella* soil was slightly lower in P and K than the adjacent grassed area soils (Table 2). Levels of total and ammonium N were lower in *Polygonella* than grassed area soils (Table 2). Significantly, growth of bahiagrass and little bluestem was greater in bare zone soil than in *Polygonella* soil, which has higher nutrient levels. The reduced growth in *Polygonella* soil relative to the bare zone is thus attributed to the presence of higher concentrations of allelochemicals. The reduced growth in *Polygonella* soil relative to adjacent grassed area soils is attributed to the combined effect of phytotoxins and lower levels of P, K, and particularly N in the *Polygonella* soil. Seed germination is largely unaffected by soil nutrient levels, although it can be stimulated by relatively high concentrations (1–10 mM) of potassium nitrate (Mayer and Poljakoff-Mayber, 1982; Popay and Roberts, 1970). Given the low nitrate levels in these soils, the reduced germination of bahiagrass in the *Polygonella* and bare zone soils is attributed to *Polygonella* allelochemicals.

In summary, results of these studies provide strong evidence in support of the hypothesis that allelochemicals produced by *Polygonella myriophylla* can reduce the germination and growth of other species. Definitive proof awaits characterization of the putative inhibitors and evidence that they persist at concentrations sufficient to produce the observed effects. The involvement of disease organisms or subtle mycorrhizal effects cannot be ruled out, although an examination of *Polygonella*, bare zone, and grassed area soils at the Lake Wales site for mycorrhizal spores did not indicate any substantial differences in the amount or types of spores present. The reduced nutrient levels in the bare zone, along with allelochemical inhibition, may be important in reducing invasion and establishment by other species. An investigation of the phytochemistry of *Polygonella* has revealed the presence of high concentrations of several phenolic compounds in *Polygonella* foliage (Weidenhamer, 1987). The identification of these compounds and their quantification in leaf wash and soils is the subject of continuing work and will be reported separately.

Acknowledgments—This study was supported by grants-in-aid of research from The Conservation and Research Foundation and from Sigma Xi, The Scientific Research Society, and a scholarship from the Florida Federation of Garden Clubs to the senior author. Drs. D.C. Hartnett and G.B. Williamson made helpful critical comments on the manuscript.

ODOR PREFERENCES OF WILD STOCK FEMALE
HOUSE MICE (*Mus domesticus*) TESTED AT
THREE AGES USING URINE AND OTHER
CUES FROM CONSPECIFIC MALES
AND FEMALES

LEE C. DRICKAMER

*Department of Zoology
Southern Illinois University
Carbondale, Illinois 62901*

(Received July 8, 1988; accepted September 30, 1988)

Abstract—Urinary chemosignals from conspecific males and females can influence the physiological processes of sexual development in female house mice. The experiments reported here involved testing the odor and whole animal preferences of female mice presented with stimuli from male mice and grouped female mice. Mice were tested at three different ages. Five types of tests were performed: an olfactometer test using whole animals as stimuli, a second olfactometer test using urine stimuli, a soiled bedding substrate preference test, an animal association test, and a stick-chewing test. The results from all tests indicate that prepubertal females avoided male odors and prefer odors associated with grouped females. By about the age of puberty, the females exhibited a preference for male cues and generally avoided cues from grouped females. As adults, the females strongly preferred cues associated with males and avoided cues from grouped females. Thus, female mice appear to be exhibiting some control over their own physiological development and their reproductive condition by the nature of the stimuli with which they associate. Their stimulus preferences may have consequences for their fitness.

Key Words—House mouse, *Mus domesticus*, female odor preference, age effects, conspecific odors.

INTRODUCTION

Treating female mice with urine from male mice, female mice in estrus, and female mice that are pregnant or lactating all accelerate the onset on first vaginal estrus (Vandenbergh, 1969; Colby and Vandenbergh, 1974; Drickamer and Hoover, 1979; Drickamer, 1986a), whereas treatment with urine from grouped female mice delays the onset of first estrus (Vandenbergh et al., 1972; Drickamer, 1974, 1977). The urinary chemosignals that influence the development of the reproductive system have been explored with respect to a variety of factors pertaining to both the chemosignal donors and the female recipients (Vandenbergh, 1983; Drickamer, 1986b). The long-term consequences of accelerated and delayed puberty in terms of survival and reproductive output have also been investigated. Mice that have accelerated puberty have higher mortality rates and have, on average, smaller litters than females that are delayed in attaining the age of first reproduction (Drickamer, 1988).

Previous work on house mice indicates that they are capable of using olfactory cues, particularly those in urine, to recognize local population vs. strange population odors (Cox, 1984), kin (Kareem and Barnard, 1986; Winn and Vestal, 1986), sex (Hayashi and Kimura, 1974; Davies and Bellamy, 1974; Winn and Vestal, 1986), stress (Carr et al., 1970), and specific individuals (Bowers and Alexander, 1967).

Until recently, two types of questions regarding urinary chemosignals influencing reproductive physiology and the onset of puberty had not been investigated. These questions pertain to the deposition of the urine containing the chemical signals and the olfactory choices by the mice for urine and related cues from various sources, e.g., adult male mice. In a companion paper to this one (Drickamer, 1989), the patterns of urine deposition are reported. Here investigations are reported of selections by female mice for urine and other cues associated with male and female conspecifics.

METHODS AND MATERIALS

General Methods

The mice used for these experiments were third- and fourth-generation descendents of a stock of wild house mice (*Mus domesticus*) trapped near West Simsbury, Connecticut. All mice were maintained in opaque polypropylene cages measuring 28 × 15 × 15 cm deep with fitted wire lids containing food and water receptacles. A bedding of ground wood shavings was changed once each week. Pregnant female mice were given cotton squares for making nests. Wayne Lab Blox and water were provided ad libitum to all mice throughout the experiments, except for the time periods that mice were in the test apparatus.

All colony cages and the various test apparatuses were housed in the same two rooms throughout the 24 months during which the experiments were conducted. These rooms were maintained at 21–25°C and 30–60% relative humidity on a 12-hr dark–12-hr light daily regimen with overhead fluorescent lights on from 0600 to 1800 hr.

Female mice used as test subjects were produced by mating one adult male and one adult female. A total of 383 young females from 147 litters born to 77 different adult females were tested. These 383 subject females were used in a series of five experiments outlined below; mice were assigned at random to be tested at different ages and in different types of test apparatus with two restrictions: (1) no mouse was tested twice in the same apparatus, and (2) no mouse was used twice at the same age in two different types of tests. Mice were weaned from their parents at 25 days of age and housed in cages with two or three like-sex littermates until tested. They were maintained in these housing conditions until the conclusion of testing at about 110 days of age.

Five different types of experimental tests were performed, designed to assess the responses of the females at various ages to pairs of stimuli from males and grouped females involving different combinations of sensory modalities. Experiment I consisted of an olfactometer in which whole mice were used in the stimulus chambers, providing test females with a composite of volatile odor cues. Experiment II involved using the same olfactometer, but urine stimuli only were tested, providing the mice with volatile cues from urine. Experiment III was a substrate preference test wherein subject females were given choices between samples of soiled bedding, providing them with a variety of urinary and fecal odor cues and permitting them to have direct contact with the stimuli. Experiment IV involved test females associating with live mice as stimuli, with the possibility of visual and limited contact cues as well as olfactory cues. Experiment V was a test of the motivation of the test mice to chew through a barrier of balsa wood sticks to obtain access to cotton containing urine or water.

In each of the five experiments, mice of three different ages were tested: (1) 35–45 days of age (prepubertal); (2) 60–70 days (peripubertal); and (3) 100–110 days of age (adult or postpubertal).

For each age, mice were tested for their responses to six different pairs of stimuli: (1) adult male vs. adult male, (2) grouped adult female vs. grouped adult female, (3) blank vs. blank, (4) adult male vs. blank, (5) grouped adult female vs. blank, and (6) grouped adult female vs. adult male. The first three pairs in each instance were designed as control procedures. The nature of the blank varied with each experiment as outlined below. For each pair of test stimuli, 14 mice were tested. Thus, 84 mice were tested at each age in each type of test.

The data analyses for each age group of each experiment were similar. In every test of every experiment, the subject mouse was given a choice between

two alternatives. Ratios were computed for its selection for one alternative vs. the other alternative. (By the nature of the test procedures, neither the numerator or the denominator in any test could be zero.) Because the data were skewed and exhibited variance heterogeneity, they were transformed as the natural logarithm (Lenington, 1983). Because of the natural logarithm of 1, $\ln(1) = 0$, we would expect ratios with positive values to indicate selections of the alternative represented in the numerator and, conversely, negative ratios would indicate selections of the alternative represented in the denominator. Ratios of about 1 would mean equal selection of both alternatives. These ratios were used in one-way analyses of variance, followed by post hoc testing using Duncan's new multiple-range test with $P \leq 0.02$.

Experiment I. Olfactometer—Whole Mouse

Apparatus. The test apparatus for the first experiment consisted of a Plexiglas olfactometer based on that used by Lenington (1983). The two stimulus chambers consisted of Plexiglas cylinders measuring 9 cm in diameter by 20 cm long. The test chamber for the subject mouse was a Plexiglas cube 14 cm on each side with two side ports. Attached to each side port was a Plexiglas cylinder measuring 9 cm in diameter by 20 cm long. The pair of stimulus chambers was connected to the ports on the test chamber. Tygon tubing was used for all connections. The entire apparatus was dismantled and washed with detergent after each trial. The air flow through the apparatus was maintained at a rate that resulted in a turnover of the air in each stimulus chamber once every 20 sec.

Procedure. As outlined in the General Methods above, mice of three different ages were tested, six different pairs of stimuli were employed, and 14 mice were tested for each age-stimulus pair combination. The blank or control condition consisted of an empty chamber. The actual test procedure began by placing mice into the stimulus chambers, using a coin flip to decide randomly which mouse would be on which side of the apparatus. This coin flip was repeated for each separate test. The stimulus males were adults (ages 100–175 days) caged alone and stimulus females were adults (ages 85–180 days) caged in groups of eight for at least 30 days prior to being used as stimulus animals.

The air flow was turned on and allowed to run for 5 min. The female test mouse was then placed into the central chamber of the olfactometer and given a 5-min acclimation period. If, during the first 3 min, the test mouse had not visited each side port for at least 15 sec, the experimenter removed the wire mesh top of the test chamber and gently forced the mouse to spend 15 sec in each side port. For a mouse to be considered in the side port, either during acclimation or during the test that followed, the animal had to have all four feet and its head in the side tube.

Each test mouse was then given a 10-min test during which time the experimenter recorded the total time spent within the stimulus port on each side, and the total time spent in the central chamber. To be used in further analyses, the mouse must have spent at least 50% of its total test time in one port or the other and at least 15 sec must have been spent in each port during the test. Seventeen mice of various ages failed to meet these criteria; these animals were replaced by additional test subjects. The data were analyzed as described in the General Methods, using a ratio of the total time spent in one port versus total time spent in the other port.

Experiment II. Olfactometer—Urine

Apparatus. The apparatus used for this test was identical to that used in the preceding series of tests.

Procedure. The procedure used for this test was identical to that used for the preceding test, except that the stimuli consisted of 0.2-cc samples of urine placed on cotton located in the stimulus chambers leading to the two choice ports of the olfactometer. Male urine was collected from a battery of 25 individually caged adult males, 95–160 days of age. Female urine was collected from a battery of 40 adult females, 85–140 days of age, housed with eight females per cage for a period of at least 30 days prior to the start of urine collection. Fresh urine of each type was collected each day by holding appropriate mice over Petri dishes and gently squeezing the flanks. Urine was collected from at least 10 mice of each type each day. Separate Petri dishes were used for each urine type. Distilled water placed on cotton was used for the blank treatment. In this test 21 mice failed to spend 50 percent or more of the 10 min test period in one side port or the other and at least 15 sec in each during the test period; these mice were replaced by testing additional subjects. The results were analyzed using a ratio like that calculated for Experiment I.

Experiment III. Substrate Bedding Preference

Apparatus. The test apparatus consisted of a 35-liter aquarium with a Plexiglas partition cemented to the center of the floor. A wire mesh lid on top of the aquarium prevented the mice from escaping.

Procedure. Females of all three ages were tested with this apparatus using the six pairs of stimuli, with 14 mice tested for each age–stimulus pair combination. The test procedure involved first placing 100-cc samples of bedding on the two sides of the aquarium; a coin flip for each separate test was used to randomize placement of the bedding. New bedding samples were used for each test. A battery of 32 adult males (ages 100–170 days) and a battery of 10 cages each containing eight adult females (ages 80–145 days) served as donors of soiled bedding. The control condition consisted of clean bedding. For those

donor cages where bedding was removed, 300 cc of clean bedding was added every third day to ensure adequate bedding for the mice and a continuous supply of soiled bedding for the test procedure.

The test mouse was placed on the Plexiglas partition, and a 10-min test was begun during which the location of the mouse was recorded every 20 sec, providing a total of 30 position records. To be considered as being on one side of the apparatus or the other the mouse had to have all four feet and its nose on that side of the apparatus, and during the course of the test period the mouse must have spent at least one 20-sec interval on each substrate. For all mice, at least 27 of the 30 location records met the first criterion, and all mice met the second criterion. Thus, all were included in the data analyses. A ratio was generated consisting of the number of times the mouse was located on one side versus the number of times it was located on the other side of the apparatus. These ratios were analyzed using the procedure described in the General Methods.

Experiment IV. Association Test

Apparatus. The apparatus used to test whole animal associations consisted of a rectangular wooden box measuring 1 m long \times 50 cm wide \times 50 cm high with a wire mesh lid. The apparatus was divided into two halves by a wooden partition. The partition was broken at the bottom center where a wire cage (of 0.5-cm mesh hardware cloth) measuring 30 cm long \times 10 cm wide \times 8 cm high was located with equal portions extending into each half of the box. The wooden portions of the apparatus were covered with epoxy paint to facilitate washing the entire apparatus after each trial.

Procedure. Females of the same three ages used previously were tested with the six pairs of stimuli used in experiments I–III. Stimulus mice, selected from those maintained for use in experiment I were placed on either side of the main test chamber; a coin flip was used at each trial to determine on which side each stimulus mouse would be placed. The control condition consisted of a blank chamber. The test mouse was placed into the wire mesh alleyway at the center of the apparatus and the wire lids were placed on both the alleyway and the main chamber. A 5-min acclimation period ensued during which the observer made certain that the test mouse entered both sides of the alleyway to be exposed to the stimulus there for at least 15 sec; if the mouse had not been into both sides by the end of 3 min of the acclimation period, the observer carefully opened the main chamber and used a small probe to induce the test mouse to cross over to the other side of the test alleyway for at least 15 sec.

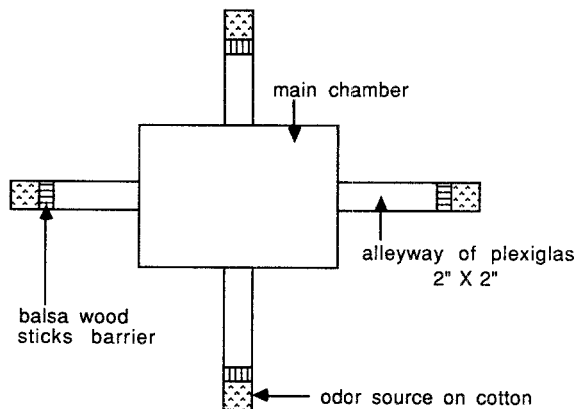

After the 5-min acclimation period, the mouse was observed for a 10-min test period during which the observer recorded the amount of time the mouse spent on each side of the apparatus. To be used in further analyses, the mouse

must have spent at least 30 sec of the total test period on each side of the apparatus. Only three mice failed to meet this criterion; additional test mice were used to replace these subjects. Ratios were generated of the time spent on one side versus the other of the apparatus, and the ratios were subjected to the same types of analyses used in previous experiments.

Experiment V. Stick-Chewing Behavior

Apparatus. The apparatus consisted of a 25-cm² central chamber with four alleyways radiating outward, one from each side of the square (Figure 1a). Each alleyway consisted of a 5-cm² made of Plexiglas (Figure 1b). At the end of each alleyway there were two small Plexiglas cubes; the one nearest to the central chamber contained a series of 14 balsa wood pegs arranged into three rows (5,

(a) overhead view of entire apparatus

(b) side view of alleyway

FIG. 1. Stick Chewing Apparatus. (a) A top view of the entire apparatus showing the main chamber where the subject mouse was placed and the possible four side alleyways ending with barriers of balsa wood sticks placed in front of a stimulus chamber with cotton containing urine. (b) A side view of just the alleyway illustrating the barrier of balsa wood sticks and the stimulus chamber.

4, 5), and the outer cube was used to provide urine test stimuli placed on small pieces of cotton. For the present series of tests, only two side alleyways, located on opposite sides of the central chamber were used. The entire apparatus was cleaned with soap and water after each trial.

Procedure. All three ages of test females and the six combinations of stimulus urine sources were used, with 14 mice tested for each age-stimulus pair combination. Fresh urine was collected for each test using the same batteries of donor mice described previously for experiment II. The test mouse was placed into the central chamber and, at the end of 6 hr, the mouse was removed and the numbers of sticks chewed in front of each of the two stimuli were counted. These stick counts were used to generate ratios, and analyses were performed on the ratios as in the other experiments.

RESULTS

For all five experiments at all three ages and the tests involving pairs of stimuli of the same type, there were no significant deviations from the expected value of 1.0. These data are graphed on the left-hand side of each of the five figures that display the results of the experiments.

Experiment I. Olfactometer—Whole Mouse

Prepubertal female mice avoided the whole body odors of males relative to the control condition, exhibited some preference for the odors from a grouped female relative to the blank and showed a marked preference for the odors from grouped females when tested against males ($F = 22.96$; $df = 5,78$; $P < 0.001$) (Figure 2). By 60–70 days of age, the females showed no significant deviations from equal choices in all stimulus pairs ($F = 0.46$; $df = 5,78$; $P = \text{NS}$) (Figure 2). Adult females showed a clear preference for the male odor when it was tested with either the blank or with a grouped female and avoided the odor from a grouped female relative to the blank condition ($F = 16.11$; $df = 5,78$; $P < 0.001$) (Figure 2).

Experiment II. Olfactometer—Urine

Female mice 35–45 days of age avoided male urine when it was paired with water, but preferred male urine compared to urine from grouped females, and exhibited no differential selection when presented with urine from grouped females and water ($F = 3.72$; $df = 5,78$; $P < 0.005$) (Figure 3). Peripubertal females spent more time near the odor of males than either grouped females or water and did not exhibit a selection preference between the blank and the odor

FIG. 2. Means of natural logarithms of ratios of seconds spent on two sides of the olfactometer (± 1 SEM = vertical lines) using live mice as stimuli. Female mice were tested at three different ages. Pairs of live mouse types that were placed into the two stimulus chambers of the olfactometer are indicated at the bottom of the histogram. The blank stimulus condition consisted of an empty chamber. Fourteen mice were tested for each stimulus pair at each age. Within an age group, those bars not marked with the same letter are significantly different at the 0.02 level by Duncan's new multiple-range test.

FIG. 3. Means of natural logarithms of ratios of seconds spent on two sides of the olfactometer (± 1 SEM = vertical lines) using mouse urine as stimuli. Female mice were tested at three different ages. Pairs of mouse urine types that were placed into the two stimulus chambers of the olfactometer are indicated at the bottom of the histogram. The blank stimulus condition consisted of water placed on the cotton. Fourteen mice were tested for each stimulus pair at each age. Within an age group, those bars not marked with the same letter are significantly different at the 0.02 level by Duncan's new multiple-range test.

of grouped females ($F = 11.51$; $df = 5,78$; $P < 0.01$) (Figure 3). Adult females preferred male odor to the water or the urine of grouped females, and they avoided the urine odors of grouped females when paired with water ($F = 22.02$; $df = 5,78$; $P < 0.001$) (Figure 3).

Experiment III. Substrate Bedding Preference

Prepubertal females chose the female-soiled bedding over the clean bedding or bedding soiled by males and avoided male-soiled bedding when it was paired with clean bedding ($F = 19.96$; $df = 5,78$; $P < 0.001$) (Figure 4). Females 60–70 days old preferred male-soiled bedding over clean bedding and over bedding soiled by grouped females and did not exhibit a selection preference between clean bedding and bedding soiled by grouped females ($F = 15.17$; $df = 5,78$; $P < 0.001$) (Figure 4). Adult females preferred soiled bedding when tested against either clean bedding or bedding soiled by grouped females, and they preferred clean bedding when tested with bedding soiled by grouped females ($F = 25.09$; $df = 5,78$; $P < 0.001$) (Figure 4).

Experiment IV. Association Test

Females 35–45 days old spent more time in association with the empty chamber or with the grouped female than with the male but did not exhibit a selection preference when tested with an empty chamber and a grouped female ($F = 25.173$; $df = 5,78$; $P < 0.001$) (Figure 5). At age 60–70 days, the females associated more with the male than with a grouped female, and more with the male than with a blank chamber, although this last mean was not different from that for the test involving a blank chamber vs. a grouped female, and the latter, in turn, was not different from the control values ($F = 6.791$; $df = 5,78$; $P < 0.005$) (Figure 5). Adult females spent more time in association with the male when that stimulus was paired with either the blank chamber or a grouped female, and they spent more time with the empty chamber than with the grouped female ($F = 27.997$; $df = 5,78$; $P < 0.001$) (Figure 5).

Experiment V. Stick-Chewing Behavior

Prepubertal females chewed through more sticks in front of the urine from grouped females than cotton with water, but chewed through more sticks with the water than male urine; they did not differentially chew through sticks when the test pair consisted of grouped female urine paired with water ($F = 13.08$; $df = 5,78$; $P < 0.001$) (Figure 6). Females 60–70 days old chewed through more sticks in front of the male urine than in front of grouped female urine but did not exhibit a selection preference in the other test pairs ($F = 7.42$; $df = 5,78$; $P < 0.001$) (Figure 6). Adult females chewed through more sticks to

FIG. 4. Means of natural logarithms of ratios of seconds spent on two sides of the substrate preference apparatus (± 1 SEM = vertical lines) using soiled mouse bedding as stimuli. Female mice were tested at three different ages. Pairs of mouse bedding types that were placed into the two sides of the aquarium are indicated at the bottom of the histogram. The blank stimulus condition consisted of clean bedding. Fourteen mice were tested for each stimulus pair at each age. Within an age group, those bars not marked with the same letter are significantly different at the 0.02 level by Duncan's new multiple-range test.

Female mice were tested at three different ages. Pairs of live mouse types that were placed into the two sides of the apparatus are indicated at the bottom of the histogram. The blank stimulus condition consisted of an empty chamber. Fourteen mice were tested for each stimulus pair at each age. Within an age group, those bars not marked with the same letter are significantly different at the 0.02 level by Duncan's new multiple-range test.

FIG. 6. Means of natural logarithms of ratios of the number of sticks chewed through at two alleyways of the stick-chewing apparatus (± 1 SEM = vertical lines) using mouse urine as stimuli. Female mice were tested at three different ages. Pairs of mouse urine types that were placed onto the cotton in the two alleyways are indicated at the bottom of the histogram. The blank stimulus condition consisted of an empty stimulus chamber at the end of an alleyway. Fourteen mice were tested for each stimulus pair at each age. Within an age group, those bars not marked with the same letter are significantly different at the 0.02 level by Duncan's new multiple-range test.

obtain access to cotton with male urine than either cotton with water or cotton with urine from grouped females and did not exhibit differential stick chewing when tested with urine from grouped females and water ($F = 14.50$; $df = 5,78$; $P < 0.001$) (Figure 6).

DISCUSSION

The foregoing series of five experiments supports the following three major conclusions: (1) Female mice of all three age classes tested exhibit differential selection of cues associated with male and grouped female conspecifics. (2) The differential selection is generally consistent within an age class, regardless of which cues are made available to the mice for use in making their selection. (3) The selections change considerably with the age of the female.

The first conclusion is supported by data from all but one of the analyses. I do not have any explanation to offer as to why there were no significant differences when females 60–70 days old were tested using whole mice as stimuli in the olfactometer apparatus. The lack of differences may be the result of the behavior of the mice; based upon the cues present, female mice of this age either cannot or do not exhibit any selection. Alternatively, the lack of differences may be the result of a statistical probability that out of 15 tests, at least one might be expected to fail to show any significant results. I also do not have any explanation to offer for the seemingly anomalous behavior of prepubertal mice tested with urine in the olfactometer. That these mice exhibited a selection for male urine over that of grouped females is not consistent with the results of the other four tests. Further testing would be required to substantiate and pursue further this potentially interesting result.

With the exception just noted, the patterns of preferences were quite similar across all five types of test apparatus used. The female mice are capable of using a variety of cues, either from a single modality or multiple modalities, to discriminate among the two stimuli presented in any given test. This may be significant in terms of the behavior of the mice; they can apparently respond to any of a variety of stimuli that signal the presence of a particular type of conspecific. One suggested explanation for these findings is, as suggested recently (Drickamer, 1989), that female mice are exhibiting some degree of control over their own reproductive physiology by the odor and related social cues with which they associate. If that is true, then the ability to make the selections based upon volatile body odors, volatile urine odors, nonvolatile odors in soiled bedding etc., could enhance the capacity for influencing their own physiology, including puberty, pregnancy, etc. An equally valid alternative explanation involves possible changes in the motivational state of the female with age. Young female mice may not be sexually motivated; their motivations may be

more directed toward familiar cues associated with maternal care, e.g., food, warmth. At about the time of puberty this pattern may change, resulting in increasing sexual motivation and attempts to locate potential mates. Further study of the behavior of the females and a better understanding of the internal changes associated with the observed behavior patterns will be necessary to distinguish between these alternative, although not mutually exclusive, explanations.

It is also noteworthy that in the final experiment the females not only exhibited selections similar to those observed in the general patterns from the other four tests, but in this last instance they were given the opportunity to work to gain access to the urine odor cues. They did so with the same selection pattern as the other four tests.

The last conclusion may be the most significant. As young mice, females avoided cues associated with male mice, generally preferring to associate with cues from grouped females. In most cases, females that were at about the age of puberty showed a shift in selection, being found more often near or in association with cues from males and either exhibiting an avoidance of, or no clear selection for, cues associated with grouped females. As adults, the females select male cues and avoid cues from grouped females. As has been shown recently (Drickamer, 1988), female mice that attain puberty at an early age, through the effects of either male urine or the presence of a male, have lower survival rates, smaller litters, and fewer pups in their lifetimes than females that are delayed in attaining puberty and/or first mating. Thus, there may be an explanation of the behavior of prepubertal females; they avoid male cues until after attaining puberty. Bronson (1979) proposed that females did not reach puberty until after dispersal, a suggestion that is consonant with the present findings and interpretations. Mice that avoid cues associated with males prior to puberty and until after dispersal would be effectively avoiding possible incestual matings with the father or male siblings and would also be ensuring a possible longer survival and greater reproductive output. Additional work will be needed to determine whether the higher mortality in females that commence reproduction very early is due to insufficient morphological development to properly maintain the pregnancy, other side effects from the early pregnancy, or factors not yet identified.

Beginning at about the time of puberty, female mice apparently seek out cues associated with males; the males represent potential mates. Given the short average lifespan of house mice (Bellamy, 1981), they must seek out potential mates at young ages, although not, apparently, until after the risks associated with early maturation have passed.

TOXICOKINETICS OF 2,4-DIHYDROXY-7-METHOXY-1,4-BENZOXAZIN-3-ONE (DIMBOA) IN THE EUROPEAN CORN BORER, *Ostrinia nubilalis* (HÜBNER)

(Received July 11, 1988; accepted September 30, 1988)

Abstract—2,4-Dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA), the major hydroxamic acid present in corn, and its tritiated derivative, were prepared synthetically for use in the determination of the toxicokinetics of this insect deterrent in the European corn borer (ECB), *Ostrinia nubilalis*. In growth studies with DIMBOA (0, 0.05, 0.2, and 0.5 mg/g diet), the mean time to pupation and adult emergence were significantly lengthened by an increase in concentration. Pupal and adult weights, for both female and male, decreased with an increase in concentration. Increased larval and pupal mortality occurred at the highest concentration of DIMBOA. DIMBOA, at concentrations of 0.2 and 0.5 mg/g diet, resulted in a decrease in the number of egg masses produced per female, and at 0.5 mg/g diet, in a decrease in the number of eggs per egg mass. Larvae fed from the neonate stage on a diet containing 0.2 mg [³H]- + [¹H]DIMBOA/g diet showed an increase in the content of label from fourth to fifth instar, but levels declined at pupation and emergence. A large amount of the labeled compounds was excreted by the insect in the pupal case. In dose-related studies, both uptake and excretion increased with an increase in concentration of DIMBOA (0.05, 0.2, 0.4 mg/g diet), while a body burden (concentration in the tissues/concentration in the frass) of approximately 0.25 was maintained for all concentrations. At the highest dose of DIMBOA (0.4 mg/g), the ECB increased consumption, possibly to compensate for the toxic effects of the compound. In topical application studies, elimination of the labeled compound in the frass was rapid, reaching 65% by 4 hr and 88% by 48 hr. Accumulation of label in tissues other than hemolymph was low. The results show that the ECB does possess adaptive mechanisms to deal with the effects of this host-derived compound.

Key Words—European corn borer, *Ostrinia nubilalis*, Lepidoptera, Pyralidae, corn, DIMBOA, 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one, tritiated DIMBOA, toxicokinetics, topical application, body burden, growth.

INTRODUCTION

Development of resistant lines of corn is one of the principal methods employed to control the European corn borer, *Ostrinia nubilalis* (Hübner) (Lepidoptera; Pyralidae), a major pest of corn in North America. Resistance to first brood leaf feeding has a phytochemical basis and has been found to be highly correlated with the level of 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA), the major hydroxamic acid present in corn (Klun and Brindley, 1966; Klun et al., 1970; Reed et al., 1972; Robinson et al., 1982; Zuñiga et al., 1983). DIMBOA is present in the uninjured corn tissue in the glucoside form, and only when the tissue is damaged is it converted to DIMBOA by the hydrolytic enzyme β -glucosidase. Subsequently, DIMBOA decomposes in a reaction that is pH and temperature dependent (Woodward et al., 1978; Perez and Niemeyer, 1986), to yield 6-MBOA (6-methoxybenzoxazolinone) and formic acid.

The level of DIMBOA in the corn varies with age, being highest in the leaves of the embryonic plant and 15-cm seedling (Klun and Robinson, 1969), giving most varieties of corn a high level of resistance at this stage. Levels of up to 4.1 mg DIMBOA/g dry tissue weight have been reported for seedlings (Guthrie et al., 1986). Although DIMBOA is biosynthesized and accumulated throughout the growth of the plant, the concentration decreases with plant height through dilution in growth (Klun and Robinson, 1969; Zuñiga et al., 1983). At a height of about 76 cm, the different cultivars of corn can be segregated into those with high, intermediate, and low concentrations of DIMBOA.

When ECB are fed diets containing DIMBOA at concentrations corresponding to levels in resistant cultivars, reduced larval development and weight at pupation, as well as reduced reproductive capability of the adult, which translates into a smaller number of egg masses, are observed (Reed et al., 1972; Robinson et al., 1982). MBOA has also been shown to have similar biological effects on the ECB, but these occur at much higher concentrations (Klun and Brindley, 1966; Argandoña et al., 1980; Campos et al., 1988).

The toxicokinetics of both of these compounds was examined to gain a greater understanding of the mode of action of DIMBOA and MBOA, and the insect's response to these toxicants derived from the host plant. Our work on MBOA is already published (Campos et al., 1988), and the present report examines in detail the fate of labeled DIMBOA in feeding trials and topical applications in the insect.

METHODS AND MATERIALS

ECB Rearing. The bivoltine strain was originally obtained from the Agriculture Canada Research Station (London, Ontario). The culture was maintained in our laboratory according to procedures and techniques of Guthrie et al. (1972). Diets used in experiments lacked corn cob grits so as to maintain textural uniformity. Compounds were added to the hot diet (55°C) before the agar solidified. All diets containing DIMBOA were changed every three days to ensure that the larvae were exposed to DIMBOA and not its degradation product, MBOA. Analysis of the persistence of DIMBOA in the diet were performed on diet containing a concentration of 5.0 mg DIMBOA/g. The diet cubes were placed in the incubator, under the same conditions as when presented to the larvae, and sampled at 0, 1, 4, 6, and 8 days. The diet cubes were extracted in methanol and DIMBOA content measured using the FeCl₃ method (Woodward et al., 1978). These results showed that approximately 70% of the DIMBOA remained in the diet after three days.

DIMBOA Synthesis. [³H]DIMBOA was synthesized (with some modifications) by the method of Jernow and Rosen (1975). The starting material, 5-methoxy-2-nitrophenol was tritiated using a dilute acid method (Werstiuk and Timmins, 1981) to a specific activity of 0.413 mCi/mmol. The tritiated hydrogens were located on the benzyl ring. The [³H]DIMBOA produced was a pink-tan solid, mp 160°C (rapid decomposition to a dark red tar). The specific activity of the [³H]DIMBOA was 0.443 mCi/mmol. [¹H]NMR (acetone-d₆, 300 MHz) δ 2.85 (bs, OH, D₂O exchangeable) 3.77 (s, 3H, 7-CH₃O) 5.72 (s, 1H, C-2) 6.61 (d, 1H, *J* = 2.6 Hz, C-8) 6.68 (q, 1H, δ_a = 6.70, δ_b = 6.67, *J*_{ab} = 8.8 Hz, C-6) 7.25 (d, 1H, *J* = 8.8 Hz, C-5). Complete synthetic details for DIMBOA and a variety of analogs will be published in the near future as part of a structure-activity investigation.

Growth Studies. Larvae were reared from the neonate stage on diets containing 0, 0.05, 0.2, and 0.5 mg DIMBOA/g diet. Seventy 8-day-old larvae (second instar) from the above diets were placed individually in vials plugged with cotton and provided with an appropriate diet cube and growth parameters measured.

Verification of [³H]DIMBOA as Tracer for DIMBOA. The doses used to determine if the uptake of the tritiated material by the insect was representative of the unlabeled DIMBOA in the diet and topical solutions were: 0.05, 0.10, 0.15, and 0.20 mg [³H]DIMBOA/g diet, to which sufficient unlabeled DIMBOA was added to bring the total concentration to 0.20 mg DIMBOA/g. Fourth-

instar larvae (five replicates with five larvae each) were fed on the above diets for a period of four days. To determine the total content of tritium, larvae and frass were recovered and digested using the tissue solubilizer Soluene-350 (Packard) with Hionic-Fluor (Packard) as the fluorescent medium. ^3H content was measured using a Packard 2000 CA Tri-Carb liquid scintillation counter.

Topical Application. In the topical application study, early fifth-instar larvae (five replicates with five larvae each) were topically applied on the dorsal area behind the head with [^3H]DIMBOA (83.3 ng/mg insect) dissolved in 5 μl of dimethyl sulfoxide (DMSO). The sampling times were 1, 2, 4, 6, 12, 24, and 48 hr. Levels of tritium were measured as described above. The method for the dissection of the larvae has been described in Campos et al. (1988). The concentration of DIMBOA chosen for this experiment did not produce any biological effects on the larvae.

Dose-Related Uptake and Excretion of DIMBOA. The concentrations of DIMBOA in the diets were determined from the growth studies. The concentrations chosen produced significant growth effects in the ECB with respect to controls, but they did not result in high mortality. The concentrations used in these experiments were: 0.05, 0.2, and 0.4 mg DIMBOA/g diet. All diets contained the same level of [^3H]DIMBOA (0.01 mg/g diet); thus a comparison of uptake (consumption) of the labeled parent compound and excretion of labeled compounds can be made as well as a comparison of the uptake of total DIMBOA and excretion of compounds. Larvae were fed from the neonate stage on these diets. The fifth-instar larvae and its frass were collected (five replicates with five larvae each), and the level of tritium was determined as described above. Since the [^3H]DIMBOA was a valid tracer for DIMBOA, the total adjusted radioactivity {counts in frass or insect \times (total DIMBOA/[^3H]DIMBOA)} represents the equivalents of DIMBOA that have passed into insect tissue and frass. Fifth-instar larvae (three replicates of 10 larvae each) fed on the above diets were dissected, as described in Campos et al. (1988), and the distribution of labeled compounds was determined. Larvae fed on the 0.2 mg DIMBOA/g diet were used to determine the accumulation of labeled compounds during the development of the ECB (three replicates of six). Fourth- and fifth-instar larvae were collected as well as pupae, adult, and pupal case.

RESULTS AND DISCUSSION

We have previously observed (Armason et al., 1985; Canney and Gardner, 1988) that the ECB has a greatly reduced antifeedant response to plant chemicals in artificial diets as compared to leaf disk. This phenomenon allowed us to examine the toxic effects of DIMBOA without considering the complication of the effects on feeding behavior on insect performance.

Growth Studies. Data from the growth studies showed that an increase in DIMBOA concentration did not affect the mean weight of the fifth-instar larvae, although it did result in a significant increase in the development time of the larvae (Table 1). Mortality of the larvae, which occurred throughout development, was significantly higher for the larvae on the 0.5 mg DIMBOA/g diet than for those on the control diet. A prolongation of development was not as clearly defined in the pupal instar as in the larval period, although pupal weights were significantly decreased by an increase in concentration (Table 2). Pupal mortality was significantly higher on the 0.5 mg DIMBOA/g diet than for those on the control diet, as was the case for larval mortality.

Total duration of the development of the ECB was increased only at the highest concentration of DIMBOA, for both male and female (Table 3). The weight of adult ECB was significantly decreased by an increase in DIMBOA concentration, especially for females. The presence of DIMBOA did not affect the sex ratio (F/total), indicating that neither of the sexes is more susceptible to the effects of DIMBOA. An increase in DIMBOA, however, did result in a significant decrease in the number of eggs masses produced by females as well as the number of eggs per egg mass (Table 4). Both effects result in a marked decrease in the number of eggs produced by the females. This decrease in fer-

tility has been observed with ECB fed on varieties of resistant corn (Reed et al., 1972).

Validation of [³H]DIMBOA as Biological Tracer. The amount of ³H isotope found in the fifth-instar larvae and its frass, after feeding on the diets with varying levels of [³H]DIMBOA but the same total level of DIMBOA (³H + ¹H) (0.2 mg/g), was directly related to the amount of ³H isotope in the diet ($P \leq 0.05$, $r = 0.89$, and $r = 0.97$ for the insect and frass samples, respectively) (Figure 1). This linear relation suggests that there was no preferential uptake and excretion of the [³H]DIMBOA over the unlabeled DIMBOA and that the [³H]DIMBOA thus was acting as a reliable tracer for the unlabeled DIMBOA.

Accumulation of Labeled Compound during Development and Dose-Related Uptake and Excretion of DIMBOA. As with MBOA (Campos et al., 1988), the level of label retained by the insect, after feeding from the neonate stage on a diet containing 0.2 mg [³H]DIMBOA/g, increased from fourth to fifth instar but decreased as the insect entered pupal stage and again at emergence. A high level of labeled compounds was excreted in the pupal exuviae at emergence (Figure 2). The level of tritium in the meconium was negligible. The body burden (concentration in the insect/concentration in the frass) at this dose for the fifth-instar larvae is 0.26. These results indicate that the ECB larvae has the ability to excrete a large percentage of the ingested compound and thus minimize the toxic effects of DIMBOA. By further excreting a large percentage of the retained compounds in the pupal exuviae, it minimizes the possible toxic effects to the adult. Metabolism studies have shown that the ECB is able to metabolize both MBOA and DIMBOA (in preparation), thus further minimizing the toxic effects of these compounds.

FIG. 1. Relationship between the concentration of labeled DIMBOA in the diet and that found in the fifth-instar larvae (▲) of *Ostrinia nubilalis* and the frass (●). Total DIMBOA was maintained at 0.2 mg/g diet by addition of cold compound. Bars indicate SE

FIG. 2. The level of tritium label in the ECB during its development when fed a diet of 0.2 mg DIMBOA/g diet containing 1.6×10^5 dpm/g diet. Bars indicate SE

A subsequent experiment examined the effect of dietary DIMBOA concentration on the distribution of label in insect and frass. The uptake and excretion of DIMBOA equivalents was found to be affected by concentration (Figure 3). The level of total adjusted DIMBOA (which is a measure of total DIMBOA equivalents that have passed into the insect and frass) increased linearly with an increase in concentration (Figure 3) ($r > 0.95$), resulting in a constant body burden (Figure 3, inset). If only the level of label is considered (Figure 3, inset), at the two lower concentrations used (0.05 and 0.2 mg/g) there was not much difference in the uptake and excretion of label by the insect. At the higher concentration (0.4 mg/g), there was an increase in the accumulation of label in the insect as well as an increase in the level in the frass. One explanation of these results is that the ECB larvae may be consuming more of the diet at the higher concentration than at the two lower concentrations. An increased consumption of food could be attributed to the antinutritional effects of DIMBOA. Argandoña et al. (1982) and Niemeyer et al. (1982) have postulated that the

FIG. 3. Dose-related uptake by the fifth-instar larvae of the ECB (○) and excretion in the frass (●) of labeled compounds in feeding trial with DIMBOA. All diets contained the same level of [³H]DIMBOA (4.66×10^4 dpm/g diet), but varying total concentrations of total DIMBOA (³H + ¹H). The total adjusted radioactivity was calculated from counts in frass or insect \times total DIMBOA/[³H]DIMBOA. Inset shows the relationship between concentration of DIMBOA in the diet and body burden (○) and the level of tritium in the insect (△) and frass (▲). Bars indicate SE

toxicity of DIMBOA is due to its ability to bind with enzymes. A reduction in digestive enzyme activity would result in a decrease in available nutrients to the larvae, and the larvae would compensate by increasing their consumption of food. With an increase in consumption, the larvae would be exposed to higher levels of the compound, and the toxic effects would become more noticeable.

Larvae from the above study showed that the ^3H compounds were not sequestered in any specific tissues (Table 5), although the level in the hemolymph (~50%) was higher than in the other body parts looked at. The log P value (the octan-1-ol-water partition coefficient) for DIMBOA [calculated to be approximately 0.8 by the shake flask method (Leo et al., 1971)] shows that this compound is relatively hydrophylic and therefore would not tend to be accumulated in specific tissues. The higher levels of ^3H compounds in the hemolymph indicate that any absorbed DIMBOA, or metabolites, are not sequestered in any specific tissue and are rapidly transported, which is a preliminary to rapid excretion of compounds. MBOA, with a log P value only slightly higher, 1.2 (Campos et al., 1988), shows these same characteristics.

Topical Application. Feeding studies with labeled DIMBOA make it difficult to distinguish between label passing directly through the gut and that which is excreted. To examine more closely the ability of the larvae to deal with the presence of DIMBOA, a topical application study was performed. The results of the topical application of DIMBOA are very similar to the topical application of MBOA (Campos et al., 1988). Absorption by the cuticle is very rapid, as can be seen by the decrease in the methanol rinse of the larvae (Figure 4). Excretion of labeled compounds is very fast. Four hours after application, 65% of the label appears in the frass, and by 48 hr, this has reached 88%. Tissue accumulation is low, as was the case for MBOA. The higher level in the hem-

olymph 2 hr after application points to the rapid transport and elimination of the compound.

In nature, highly resistant germ plasm may lead to behavior modification that significantly reduces consumption (Robinson et al., 1978). However, most cultivars are not highly resistant, and ECB larvae feed on them, ingest DIMBOA, and are subject to the toxic effects of the compound that are described in our laboratory study. Previous work has also shown that DIMBOA (Reed et al., 1972; Klun et al., 1967; Robinson et al., 1982) and MBOA (Klun and Brindley, 1966, 1980; Campos et al., 1988) are toxic to the ECB. The toxicokinetics of both compounds indicate that the ECB may have some adaptive mechanisms for handling these compounds. DIMBOA and MBOA are rapidly excreted both when topically applied and when placed in the diet. Tissue accumulation is maintained at a very low level, although this may well be a function of the hydrophilicity of the compounds. Further work on the metabolism of these compounds and their effects on digestive enzymes should give a better

FIG. 4. Toxicokinetics of topically applied $[^3\text{H}]\text{DIMBOA}$ (83.3 ng/mg insect) on the fifth-instar larvae of the ECB, *Ostrinia nubilalis*. Data are expressed as percent of total radioactivity recovered.

indication of the mechanisms of their toxicity and possible adaptive mechanisms the ECB larvae employ to reduce the toxicity.

(Received July 28, 1988; accepted October 3, 1988)

Abstract—Cuticular lipid components were examined from fourth-instar larvae of *Manduca sexta* reared on artificial diet or growing plants. The plants used were potato, tobacco, and tomato grown in pots in a greenhouse. Twenty-eight components made up the bulk of the lipids, but there were significant differences in the proportions of them present in insects reared on the different diets. In the case of some insect cuticular lipid components, there was an obvious relationship with the surface components of the plant, but generally this relationship was weak. Nonetheless, the differences may have ecological relevance, as indicated by preliminary work on predation.

Key Words—*Manduca sexta*, Lepidoptera, Sphingidae, insect cuticular lipids, plant cuticular lipids, plant-insect interactions, predator-prey interactions.

INTRODUCTION

The surface lipids of insects have a number of obvious physiological and behavioral roles, especially in relation to regulation of water loss and as a barrier limiting the entry of chemicals and microorganisms (Nelson, 1978; Blomquist and Dillwith, 1985; Lockey, 1988). It is possible that insect surface lipids are in a state of dynamic equilibrium with epidermal cells and that their composition is a reflection of the physiological state of the organism, as has been shown in plants (Cassagne and Lessire, 1975). This may, in turn, have ecological impor-

tance. The present work was initiated because recent results on the predation of caterpillars by ants indicated that prey acceptability was dependent upon the diet of the prey (Bernays, Cornelius, and Espelie, in preparation). Thus artificial-diet-reared larvae of *Manduca sexta* were found to be significantly more palatable to the Argentine ant, *Iridomyrex humilis*, than larvae reared on foliage of certain plant species, although the insect diet was not itself accepted. In addition, acceptability varied among caterpillars fed on different host plants. Ecologically, these differences may have great significance in determining differential mortality on different host plants.

In the course of the studies on Argentine ant, it was found that rejection often occurred after initial contact, suggesting that superficial chemistry of the caterpillars was influencing predator behavior. In preliminary experiments to see whether ants responded to insect cuticular lipids, beakers with or without cuticular lipid extracts of artificial-diet-reared *Manduca* were placed in alternating positions near worker trails of *Iridomyrmex humilis*. Over 5-min periods, there were significantly more ants in the beakers with the larval cuticular lipids than in control beakers with either plain paraffin wax or evaporated solvent only (sign test, $P < 0.01$). Thus, it is possible that predators may use chemical differences on the surface of the larvae as behavioral cues, and the present study is the first investigation of this chemistry.

METHODS AND MATERIALS

Insects. *Manduca sexta* larvae were obtained from a laboratory culture that has been kept on artificial diet for many generations. The artificial diet consisted of 240 g wheat germ, 108 g casein, 96 g sucrose, 36 g Wesson's salt mix, 48 g Torula yeast, 10 g cholesterol, 6 g sorbic acid, 3 g methyl paraben, 0.6 g streptomycin, 12 ml linseed oil, 48 g agar, and 0.4 g vitamin mixture in 2.2 l H₂O. Individuals were either kept on the artificial diet or placed on foliage during the first or second instar. With all foods, growth rates were variable, but individuals used for extraction were early fourth-instar larvae that had fed continuously on artificial diet or one plant species for at least one week at room temperature.

Extractions. Larvae were gently removed from their food source and placed on clean paper towels for 10 min, weighed, placed individually in test tubes (12 × 75 mm), and killed in the freezer at -20°C. Individual larvae were immersed in redistilled hexane for 60 sec at room temperature. A brief hexane extraction was utilized in an effort to remove primarily cuticular lipids and to minimize the extraction of internal components (Blomquist et al., 1987). The hexane was removed, and the larvae were then briefly rinsed with additional

hexane. The hexane extracts from each larva were combined and concentrated under a stream of N_2 .

Analysis. For chemical analysis, extracts were treated with *N,O*-bis(trimethylsilyl)acetamide at 110°C for 10 min. Excess derivatizing reagent was removed under N_2 , and the derivatized extract was resuspended in hexane. Aliquots (usually 1%) were analyzed by combined gas chromatography-mass spectrometry (GC-MS) (Hewlett Packard 5890A/5970). The capillary column (12.5 m cross-linked methyl silicone) was held at 55°C for 3 min after sample injection (splitless), and the oven temperature was then increased to 305°C at a rate of 25°/min and held at this temperature for 8 min. Individual peaks were identified by their mass spectra, which were recorded at 70 eV at intervals of 1.3 sec. Quantitation was based upon integration of total ion chromatograms. The cuticular extracts were analyzed for the presence of wax esters by reduction overnight with $LiAlD_4$ in refluxing tetrahydrofuran followed by $CHCl_3$ versus aqueous extraction and derivatization and analysis by combined GC-MS (Espelie et al., 1983).

The trimethylsilyl ether derivative of a standard sample of cholesterol was found to have identical retention time and mass spectrum to that recovered from the surface of the larvae and was matched by computer search with 40,000 spectra from the National Bureau of Standards Mass Spectral Library. 10-Nonacosanol was recovered from the epicuticular lipids of *Pinus taeda* needles and 4,8,13-duvantriene-1,3-diols from the leaves of *Nicotiana tabacum*. These compounds were converted to trimethylsilyl ethers and utilized as standards for retention time and mass spectral comparison (Holloway et al., 1976; Severson et al., 1984).

Fresh leaves of tomato, potato, and tobacco were dipped in hexane for 60 sec at room temperature, and the extracts were analyzed as described above. Components were identified by their mass spectra (Blomquist et al., 1976; Severson et al., 1984). The foliage extracts were not analyzed for the presence of wax esters. *M. sexta* larvae that had been extracted with hexane were subsequently extracted with redistilled $CHCl_3$ for 1 min at room temperature, and the extracts were derivatized and analyzed as described above.

RESULTS

The surface chemistry of *M. sexta* larvae was found to vary dramatically when the larvae were reared on different food sources (Table 1). All larvae had most of the same *n*-alkanes and methyl-branched alkanes in their cuticular lipids. Although these hydrocarbons were present in approximately equal amounts in the different larval extracts, the proportion that they comprised of the total

^b D: detectable, but less than 0.1%.

^c Elutes with *n*-nonacosane; estimated by integration of selected ion chromatogram.

surface lipids ranged from 35% from larvae reared on tobacco foliage to 76% from those insects reared on potato foliage. The hydrocarbons were dominated by *n*-heptacosane and *n*-nonacosane and by a series of mono-, di-, and trimethyl branched hydrocarbons where the backbone of the chain had an odd number of carbons, with C₃₅ and C₃₇ being the most prominent chain lengths. Several small peaks that eluted between *n*-nonacosane and methylheptatriacontane were

identified as hydrocarbons by their mass spectra, but these components were not present in sufficient quantities to allow complete characterization. The total amount of cuticular lipid recovered by hexane extraction from larvae reared on the same diet varied from one individual to another by as much as sixfold. However, the average amount of cuticular lipid per insect was almost identical for artificial diet and tomato-foilage-reared insects. Those larvae reared on potato foliage and those reared on tobacco foliage had less cuticular lipid (60% and 80%, respectively).

Derivatization of the larval extracts prior to GC-MS analysis allowed identification of components not previously found on the surface of an insect cuticle and the identification of several more components that have been reported only rarely. Variations in the proportion that these components comprised in each extract resulted in the observed diet-dependent differences in larval surface chemistry. The extracts from larvae reared on tobacco foliage were dominated by the diterpenes α - and β -4,8,13-divatriene-1,3-diol, which were identified as their trimethylsilyl ethers (Severson et al., 1984). These diterpenes comprised 46% of the cuticular extract from tobacco-reared larvae but were not found on any of the other larvae (Table 1).

Cuticular lipids from larvae reared on artificial diet contained large amounts of cholesterol and long-chain fatty alcohols, which were identified by the mass spectra of their trimethylsilyl ethers. Free cholesterol comprised 20% of the cuticular extract from artificial-diet-reared larvae, while it equaled only 1–2% of the extracts from larvae reared on the three types of foliage. Free fatty alcohols were approximately 8% of the hexane extract from artificial-diet-reared larvae, but these alcohols totaled only 1–3% of the components from the surface of the other *M. sexta* larvae (Table 1). Triacontanol (C_{30}) was the major fatty alcohol found on the surface of the larvae reared on artificial diet.

Larvae reared on tomato foliage had a high proportion (37%) of methyl-branched hydrocarbons in their cuticular lipids and small amounts of fatty alcohols and cholesterol (1% each). The lipids extracted from the cuticles of these larvae also included C_{29} and C_{27} secondary alcohols. The mass spectra of these components indicated that they were a mixture of positional isomers (Blomquist et al., 1972). The C_{29} secondary alcohols had the hydroxyl moiety on either C_8 (51%), C_9 (33%), C_{10} (10%), or C_7 (6%), while the C_{27} alcohols had the following distribution of isomers: C_7 (52%), C_6 (28%), and C_8 (19%). The amounts of these isomers are estimations based upon the relative intensity of the alpha-cleavage ions generated by cleavage on either side of the derivatized mid-chain hydroxyl. Although positional isomers of the secondary alcohols gave a single peak for each chain length in the total ion chromatograms, selected ion chromatograms (scanning for alpha-cleavage ions) indicated that there had been partial separation with the isomers eluting in decreasing order of carbon substitution number. Integration and comparison of these selected ion chromato-

grams was utilized to estimate the amount of the C_{27} secondary alcohols since they eluted with *n*-nonacosane.

The cuticular lipids of larvae reared on potato foliage were very similar to those isolated from larvae reared on tomato. However, those reared on potato had a higher proportion of methyl-branched hydrocarbons (46 vs. 37%) and slightly higher proportions of primary and secondary fatty alcohols (Table 1). The cuticular extract of potato-reared larvae also had the largest amount (albeit only 1%) of novel components, which appeared, from their mass spectra, to be C_{27} and C_{29} diols. The alpha-cleavage pattern indicated that the larger molecular weight components were a mixture of positional isomers: 8,9-nonacosanediol and 9,10-nonacosanediol (Figure 1). The mass spectra of the shorter chain length homologs indicated that they were 7,8- and 8,9-heptacosanediol.

The cuticular lipid compositions listed in Table 1 are those obtained by a 1-min hexane extraction of the larvae. In an effort to show that the hexane had

FIG. 1. Mass spectrum of the trimethylsilyl ether of 8,9-nonacosanediol, a minor component in the cuticular lipids of *Manduca sexta* larvae. Dominant ions at m/z 201 and 383 are due to cleavage between the adjacent hydroxyl moieties; the molecular ion is barely visible at m/z 584 and M-15 is seen at m/z 569. Fragments from the positional isomer 9,10-nonacosanediol are seen at m/z 215 and 369. These were the two dominant ions in the spectrum recorded 1.3 sec earlier.

removed most of the cuticular lipids, larvae previously extracted with hexane were immersed in CHCl_3 for 1 min, and the CHCl_3 extracts were derivatized and analyzed by combined GC-MS. With the exception of those larvae reared on tobacco, these extracts had the same cuticular lipid compositions shown in Table 1, but the amount of lipid extract was less than 5% of that obtained in the original hexane treatment. Analysis of the CHCl_3 extracts of hexane-extracted larvae reared on tobacco indicated that the hexane had efficiently removed the cuticular lipids from these larvae, except for the duvatatriene-1,3-diols that were present in the CHCl_3 in the same quantities found in the original hexane extracts.

Since wax esters would not have been detected with the procedure utilized above, the extracts from larvae reared on each of the diets were treated with LiAlD_4 , derivatized and analyzed by GC-MS. There were no changes in the composition or amount of the derivatized fatty alcohols in the total ion chromatograms, indicating that the cuticular lipids of these *Manduca* larvae do not contain significant amounts of wax esters.

Diet-dependent differences in the cuticular lipids were found for each insect examined. However, the values in Table 1 are averages obtained from the analysis of extracts from four to six individual insects reared on each food source. In each case, there were some variations among the components found on individual larvae. Figure 2 shows the total ion chromatograms of the derivatized extracts from larvae reared on artificial diet. Cholesterol (peak 19) was a dominant component in each case, but triacontanol (peak 21) was less than 1% in larvae 1–3 while it comprised 9–20% of the total extracts in larvae 4–6. Octadecadienoic acid (peak 3) ranged from 1% of the cuticular extract in larva 6 to 7% in larva 2 (Figure 2). All of the larval extracts contained unidentified components that eluted between 12 and 13 min. These components, which were identified only as derivatized carbohydrates by mass spectral computer search, comprised 1–5% of the extract from five of the larvae, but they totaled 42% of the total ion chromatogram of the extract from larva 5. Similar variations among individual larvae reared on the same food source were seen in the cuticular extracts from *M. sexta* reared on the three varieties of foliage.

Hexane extracts of tomato, potato, and tobacco foliage were derivatized and analyzed by GC-MS. The total ion chromatograms had very little similarity to those obtained from larvae reared on the respective foliage, with the exception of tobacco where the foliar extract was dominated (47% of total) by the 4,8,13-duvatatriene-1,3-diols as the larval cuticular extracts had been (Figure 3). The remainder of the tobacco leaf extract was a series of hydrocarbons with the major ones being 2-methyltriacontane (8%), 3-methylhentriacontane (7%), 3-methylnonacosane (6%), and *n*-hentriacontane (6%) (Table 2).

Unbranched alkanes were the major components in the hexane extract of

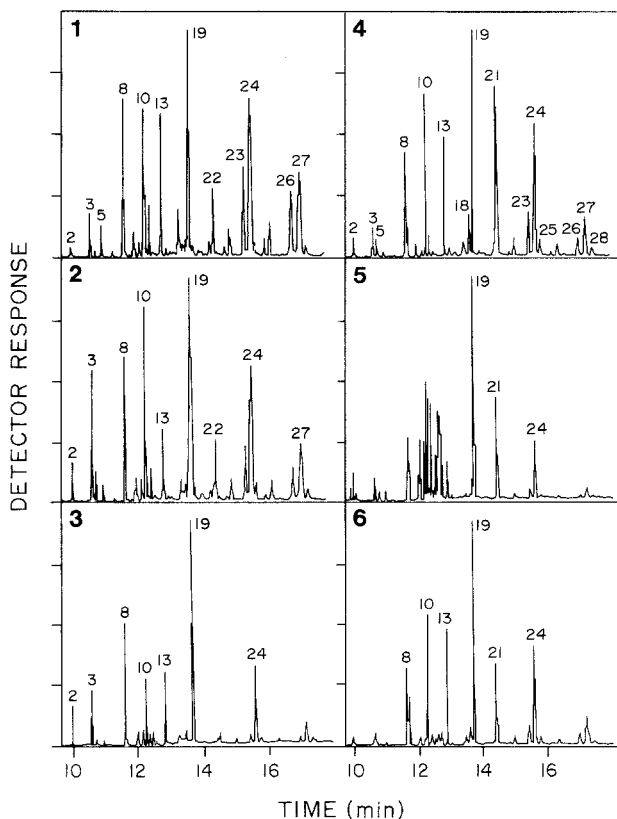

FIG. 2. Total ion chromatograms of the derivatized cuticular lipids isolated from six individual *Manduca sexta* larvae that had been reared on artificial diet. Numbered peaks are identified in Table 1.

tomato foliage. These homologs were *n*-hentriacontane (51%), *n*-tritriacontane (22%), and *n*-nonacosane (5%). Branched hydrocarbons included: 3-methylhentriacontane (9%) and 2-methyltriacontane (4%) (Table 2).

Unbranched alkanes were also the dominant components in the extract of potato foliage: *n*-hentriacontane (38%), *n*-nonacosane (15%), and *n*-heptacosane (12%). Free fatty alcohols were also present in potato leaf surface lipids, but with a different distribution of chain lengths than had been found on the surface of larvae reared on potato: C₂₆ (6% of total extract), C₂₈ (3%), and C₃₀ (0.1%). Fatty alcohols were not detectable in the cuticular extracts from either tomato or tobacco foliage.

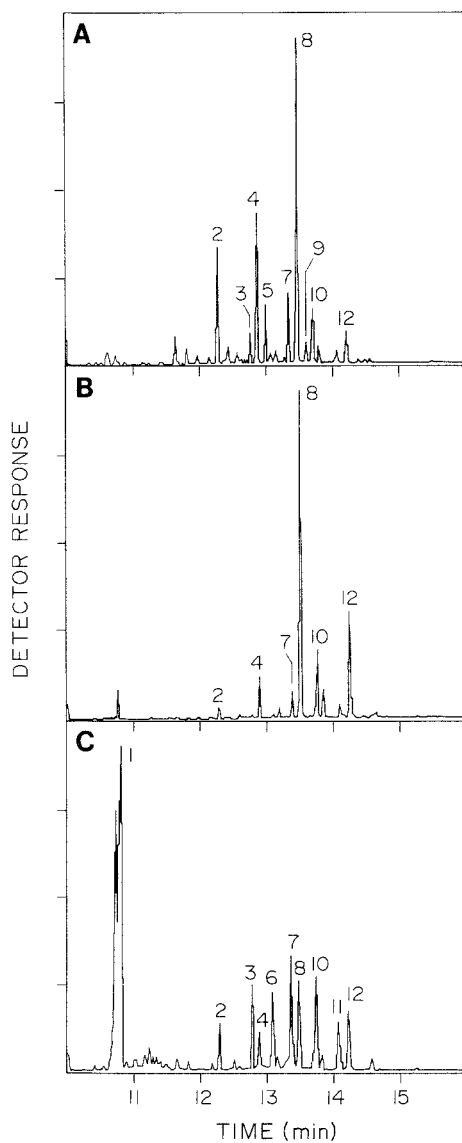

FIG. 3. Total ion chromatograms of the derivatized cuticular lipids isolated by hexane extraction from the foliage of potato (A), tomato (B), and tobacco (C). Numbered peaks are identified in Table 2.

TABLE 2. PERCENT COMPOSITION OF HEXANE EXTRACTS OF POTATO, TOMATO, AND TOBACCO FOLIAGE^a

^aComponents are listed in order of elution.

DISCUSSION

The results clearly show that the surface chemistry of *M. sexta* larvae varies with their food source. The addition of chemicals to the diet has been shown to alter insect surface chemistry (Baker et al., 1978; Brown, 1987), but the rearing of the Mexican bean beetle on different host plants resulted in only minor variations in the cuticular surface chemistry (Bordner et al., 1983; Danehower and Bordner, 1984). This is the first report that variation of the host plant utilized by an herbivore results in dramatic changes in that individual's surface chemistry. Although *n*-alkanes and methyl-branched alkanes were found in each larval cuticular extract, the major homologs were the same in each extract, and they occurred in approximately the same ratio one to another and in approximately the same amounts. The cuticular hydrocarbons of *M. sexta* have been analyzed in detail (Nelson and Sukkestad, 1970; Nelson et al., 1971, 1972), and our results agree very well with these previous reports.

The classes of cuticular compounds that seemed to distinguish which food source a larva had fed upon were the polar components (Table 3). Duvatriene-1,3-diols comprised almost half the cuticular extract from larvae reared on tobacco. Although these diterpenes have not been found on insect cuticles previously, they have been shown to be the dominant component in the cuticle of tobacco leaves (Springer et al., 1975). The duvatrienediols occur on the leaf as sticky globules (Chang and Grunwald, 1980), and some portion of this material

^aValues listed in bold face may be classes of compounds that serve to identify the food source of individual larvae.

was probably transferred directly to the surface of the browsing *M. sexta* larvae. Although these polar components would not be uniformly distributed on the insect cuticle, they could still give the larvae unique surface characteristics recognizable by a predator. For instance, spraying duvatrienediols onto the cuticular surface of different plants resulted in oviposition onto those leaves by moths that normally lay their eggs only on tobacco plants (Cutler et al., 1986).

The large amount of free cholesterol (20% of the cuticular lipid) that was found on the surface of *M. sexta* larvae reared on artificial diet (Table 1) may also have been acquired by the insects coming in contact with the food source. Previously, the highest reported levels of free cholesterol in insect cuticle had been 5–6% of the surface lipid of the fleshfly, *Sarcophaga bullata* (Jackson et al., 1974), and of the beetle, *Epilachna varivestis* (Daneshmand and Bordner, 1984). The presence of the long-chain fatty alcohols, which were dominant on some of the *M. sexta* larvae reared on artificial diet, might also result in a characteristic surface. When long-chain fatty alcohols are the dominant cuticular lipid of a plant, the leaf surface often has a characteristic plate morphology due to the crystallization of the alcohols (Jeffree et al., 1975). Two species of saturniid moth larvae, whose cuticular lipid is primarily triacontanol, and a sawfly larva, which has primarily hexacosanol for its cuticular lipid, have a characteristic appearance with the fatty alcohol deposited as a white powder, which may serve to reduce predation (Bowers and Thompson, 1965; Jones et al., 1982; Percy et al., 1983).

Free secondary alcohols comprised 6–7% of the cuticular lipids of potato- and tomato-reared *M. sexta* larvae. Asymmetrical secondary alcohols on the surface of plant cuticles (principally 10-nonacosanol) have been shown by scan-

ning electron microscopy to appear as hollow tube crystals (Holloway et al., 1976). If these secondary alcohols have a similar appearance on the surface of *M. sexta*, they could provide characteristics that would be very distinct to predators. Free secondary alcohols have been found only rarely in insects: as trace components in the cuticle of the grasshoppers, *Melanoplus sanguinipes* and *M. packardii* (Soliday et al., 1974), and as 2% of the cuticular lipids of a weevil, *Ceutorrhynchus assimilis* (Richter and Krain, 1980). The cuticular lipids from the grasshoppers also contained esters of secondary alcohols, with C₂₃ and C₂₅ being the most common chain lengths of both the esterified and free alcohols (Blomquist et al., 1972; Soliday et al., 1974). The hydroxyl moiety was most frequently located on C₁₁ or C₁₂ in both of these secondary alcohols, while the alcohols from *M. sexta* larvae were located on lower-numbered carbons (C₆-C₁₀). The C₂₇ and C₂₉ diols, which are found as minor components on the *M. sexta* larvae, probably originate from the secondary alcohols of the corresponding chain lengths. However, such diols have only been found on the larval cuticle of the beetle *Tenebrio molitor* where 8,9-pentacosanediol comprised 54% of the total lipid (Bursell and Clements, 1967). *M. sexta* is, therefore, the first insect in which long-chain secondary alcohols and diols have been reported to cooccur. Interestingly, the cuticle of *M. sexta* pupae also contains unique oxygenated lipids: oxoalcohols and oxoaldehydes of 26, 27, or 28 carbons that are found either free or esterified (Buckner et al., 1984).

Previous reports have shown a correlation between the chemical composition of the lipids from an insect's cuticle and that of the organic solvent-soluble lipids from the cuticle of its host plant (Blomquist and Jackson, 1973; Hendry et al., 1976; Richter and Krain, 1980). However, the duvatrienediols from tobacco were the only components from the leaf cuticles that were found on the *M. sexta* larval surfaces in proportions similar to those on the plant. *n*-Hentriacontane was the dominant *n*-alkane on all three leaf cuticles, but *n*-heptacosane was the most abundant *n*-alkane on each of the larvae. The 3-methyl- and 2-methylalkanes that were found in the tobacco and tomato leaf cuticles were not observed in the lipid extracts of the larvae that had fed upon either of those plants.

The basis of the variation in cuticular lipid composition among insects reared on the same diet is unknown, although individuals were at different stages in the instar and may have fed on leaves of different ages on the plant. In addition, there is the possibility of interplant variation. The significance of differences between larvae on different diets is unknown. Work is in progress on palatability to ants of larvae from different diets, and we know at present that artificial diet-reared insects are preferred to plant-reared insects (Bernays, Cornelius and Espelie, in preparation). Since the caterpillar diet is unacceptable to ants, we believe that the result is unlikely to be due to surface contamination. It is possible that high cholesterol in the cuticular lipids of diet-reared larvae is

important since this is the largest and most consistent difference from the cuticular lipids of plant-reared larvae. We also know that palatability varies with the host plant, but there seems little basis for any chemical crypsis due to cuticular lipid components among plant-reared larvae since the differences between insect surface lipids and their host cuticular lipids are so great. However, plant waxes are now known to play important roles in herbivore behavior (Bernays et al., 1975, 1976; Chapman, 1977; Woodhead, 1983; Woodhead and Chapman, 1986; Maloney et al., 1988; Varela and Bernays, 1988), and we believe it likely that insect cuticular lipids will be found to be similarly important for their natural enemies. This work is the initial study for a detailed examination of the role of the surface chemicals of *M. sexta* in relation to its predators.

Acknowledgments—This work was supported in part by a grant from the Office of the Vice-President for Research of the University of Georgia. We thank J. Weeks for insects and artificial diet, M. Cornelius for assistance with ant assays, and Darrell Ross and an anonymous reviewer for helpful comments.

CHEMICAL ECOLOGY OF THE LUNA MOTH Effects of Host Plant on Detoxification Enzyme Activity

RICHARD L. LINDROTH

*Department of Entomology
University of Wisconsin
237 Russell Laboratories
Madison, Wisconsin 53706*

(Received May 13, 1988; accepted October 10, 1988)

Abstract—The effects of food plant on larval performance and midgut detoxification enzymes were investigated in larvae of the luna moth, *Actias luna*. Neonate larvae were fed leaves of black cherry, cottonwood, quaking aspen, white willow, red oak, white oak, tulip tree, paper birch, black walnut, butternut, or shagbark hickory. First instar survival, larval duration, and pupal weights were monitored as indices of food quality. Midgut enzyme preparations from fifth instars were assayed for β -glucosidase, quinone reductase, polysubstrate monooxygenase, esterase, and glutathione transferase activities. Larval survival on seven of the 11 plant species, including several recorded host plants, was extremely poor. Larvae performed well, and quite similarly, on birch, walnut, butternut, and hickory. Activities of all enzyme systems except β -glucosidase were significantly influenced by larval host plant. Of the systems assayed, quinone reductase and glutathione transferase activities were especially high. Comparisons of these values with published values for other Lepidoptera support the hypothesis that these enzyme systems are involved in conferring tolerance to juglone and related quinones occurring in members of the plant family Juglandaceae. Results suggest that host plant utilization by luna is more specialized at the individual or population level than at the species level and that biochemical detoxification systems may play a role in such specialization.

Key Words—*Actias luna*, Lepidoptera, Saturniidae, detoxification enzymes, enzyme induction, glutathione transferase, Juglandaceae, juglone, nutritional ecology, plant–insect interactions, quinone reductase.

INTRODUCTION

The luna moth, *Actias luna* L. (Saturniidae), occurs from southern Canada to Texas and Florida (Baker, 1972). As a species, it is moderately polyphagous, feeding on trees from at least eight plant families (Baker, 1972; Tietz, 1972). Little is known, however, of the relative suitability of various tree species as larval food plants. The research reported here was conducted in part to assess the influence of known or potential host plants on performance (survival and growth) of luna larvae.

A second objective of this research was to investigate host plant alteration of allelochemical-metabolizing enzymes in luna larvae. Detoxification of plant allelochemicals by specialized enzyme systems is widely believed to be one of the most important forms of insect adaptation to plant diets. Yet few studies have documented the enzymatic detoxification capacities of tree-feeding insects, and fewer still have addressed potential host plant effects on multiple enzyme systems.

These studies provided the opportunity to test several predictions about evolutionary and ecological adaptations of enzymatic detoxification systems to particular food plants. Prior to the onset of this study, I had observed that luna larvae perform well on black walnut (*Juglans nigra*) and shagbark hickory (*Carya ovata*). The most distinguishing secondary metabolites of these and other members of the Juglandaceae are juglone and related 1,4-naphthoquinones, compounds that are generally deterrent or toxic to insects (Gilbert et al., 1967; Hedin et al., 1980; Norris, 1986). The enzyme systems most likely responsible for detoxification of juglone in Juglandaceae-adapted insects include quinone reductase, which catalyzes the reduction of quinones to hydroquinones (Yu, 1987a), and glutathione transferase, which conjugates allelochemicals containing α,β -unsaturated carbonyls (e.g., juglone) with reduced glutathione (Wadleigh and Yu, 1987). These enzyme systems can be induced by dietary exposure to various allelochemicals. Thus I predicted that quinone reductase and glutathione transferase activities would (1) be especially high in luna larvae in comparison to published values for other polyphagous Lepidoptera, and (2) be induced in larvae fed members of the Juglandaceae, in comparison to larvae fed members of other plant families.

METHODS AND MATERIALS

Insects. *Actias luna* eggs were obtained from a gravid female moth captured in Laurel County, Kentucky, in May 1987. Larvae were reared in plastic boxes at ambient temperature on leaves of black walnut or shagbark hickory. Newly eclosed adult moths were paired to provide larvae for this study. To

introduce more genetic variability into the laboratory culture, an attempt was made to pair laboratory-reared females with local males by placing tethered females in nearby woodlots; these attempts proved unsuccessful.

Feeding Trials. Neonate larvae were placed onto fresh leaves of 11 species of trees, including six genera on which luna are known to feed, and two genera for which no previous feeding records exist (Table 1). Each replicate consisted of 10–14 larvae, with leaves, in a ventilated plastic Petri dish (15 × 2.5 cm); leaf petioles were inserted into florist's Water Piks to maintain leaf turgor. Leaves were replaced at two- to three-day intervals. When larvae reached the fourth stadium, they were transferred to larger shoebox cages. Larvae were reared in a Percival environmental chamber at 24°C, on a 12:12 light-dark cycle. Measurements were made of first instar survival, duration from hatching to spin-up of the cocoon, and pupal weight (six to seven days following spin-up) as indices of food plant quality.

Enzyme Preparation. Because larval midguts are the major site for detoxification of plant allelochemicals, they were used as the enzyme source. Midguts (5–9 per enzyme replicate) were dissected from fifth instar larvae (3 to 7 days old) and gut contents removed. Midguts were then washed (0.2 M phosphate buffer, pH 7.8) and homogenized by 10 strokes in a Ten Broeck tissue grinder. The homogenate was centrifuged at 10,000g (10 min) and the supernatant removed and centrifuged at 100,000g (60 min), to separate soluble (cytosolic) and microsomal (membrane-bound) enzymes. The enzyme preparations

^aHost plant records compiled from Holland (1968), Baker (1972), and Tietz (1972). X = documented feeding; ? = probable feeding, not documented in preceding references.

were then processed according to Brattsten (1987a) for flash-freezing in liquid nitrogen and storage at -70°C . All procedures were conducted at $0-4^{\circ}\text{C}$.

Enzyme Assays. Assays were conducted for five different enzyme systems. β -Glucosidase activity was measured because these enzymes are involved in the metabolism of glycosidic allelochemicals (often activating rather than detoxifying them), and because little is known about host plant alteration of β -glucosidases (Lindroth, 1988). Quinone reductase (QR) and glutathione transferase (GT) activities were determined because they are likely to be especially important in the adaptation of luna larvae to members of the Juglandaceae. Polysubstrate monooxygenase (PSMO) and esterase activities were measured because these enzyme systems are generally important detoxification mechanisms in insects. Enzyme assays were optimized with respect to substrate and enzyme concentrations, incubation time, and buffer pH. Each enzyme assay for each enzyme solution was conducted in duplicate or triplicate. Specific activities were calculated relative to protein concentrations of the enzyme preparations, as determined by the Folin-phenol procedure of Schacterle and Pollack (1973).

β -Glucosidase activity was measured according to Lindroth (1988). Each 1 ml incubation solution contained 50–175 μg protein, 50 μmol salicin, and 0.1 M potassium phosphate buffer (pH 6.0). Solutions were incubated for 30 min at 35°C . Glucose liberated from salicin by β -glucosidase activity was quantified enzymatically (Sigma Diagnostic Kit 315).

Quinone reductase (QR) activity of soluble and microsomal fractions was measured using the juglone-dependent NADPH oxidation method of Yu (1987a). First, 40–70 μg protein, 160 μl NADPH (2.5 mM in phosphate buffer), and 0.1 M sodium phosphate buffer (pH 8.0) were mixed together for a total volume of 2 ml. From that solution, 995 μl were placed into a sample cuvette and mixed with 5 μl juglone (10 mM in methyl cellosolve). The remaining solution was placed into the reference cuvette. NADPH oxidation was determined as the decrease in absorbance at 340 nm over several minutes; a value of 6.22/mM/cm was used for the extinction coefficient of NADPH (Segel, 1976). Use of a double-beam spectrophotometer canceled out effects of endogenous NADPH oxidation because both cuvettes contained enzyme and NADPH. To confirm that the observed activity was due to a reductase rather than a microsomal oxidase, QR activities were compared between an untreated microsomal enzyme solution and a solution that had been bubbled with carbon monoxide (2 bubbles/min for 1 min). No difference was found in NADPH oxidation between the two samples.

Cytochrome *c* reductase and *O*-demethylase activities of microsomal fractions were measured as indices of PSMO activity. Cytochrome *c* reductase activity was quantified as the production of reduced cytochrome *c* with time, according to Brattsten et al. (1980). Assay solutions (1 ml) consisted of 20–50 μg protein, 200 μl cytochrome *c* (4 mg/ml in phosphate buffer), 100 μl NADPH

(1 mM in phosphate buffer), and 0.1 M potassium phosphate buffer (pH 8.0). Production of reduced cytochrome *c* was measured as the increase in absorbance (550 nm) over 1 min versus a blank containing everything but the enzyme. No significant endogenous reduction of cytochrome *c* was observed with this procedure. A value of 27.6/mM/cm was used for the extinction coefficient of reduced cytochrome *c* (Margoliash and Frohwirt, 1959). The assay for *O*-demethylase activity was adapted from Hansen and Hodgson (1971) and measured the PSMO-catalyzed formation of *p*-nitrophenol from *p*-nitroanisole. Each assay solution contained 0.5–1.0 mg protein; an NADPH-generating system consisting of 0.36 mM NADP, 3.6 mM glucose-6-phosphate, and 2 units/ml glucose-6-phosphate dehydrogenase (final assay concentrations); 0.15 M potassium phosphate buffer (pH 7.8, with 1 mM EDTA) to a total volume of 780 μ l; and 20 μ l *p*-nitroanisole (32 mM in methyl cellosolve) to initiate the reaction. Enzyme solutions were incubated at 32°C for 30 min; reactions were terminated with 200 μ l 1 M HCl. Acidified solutions were extracted with 1 ml dichloromethane, and these in turn were extracted with 900 μ l 0.5 M NaOH. Absorbance was read at 400 nm and converted to concentration of *p*-nitrophenol using a standard curve.

Soluble and microsomal esterase activities were quantified as described by Brattsten (1987a). Assay solutions contained 0.2–1.0 μ g protein and 0.05 M sodium phosphate buffer (pH 8.0) to a total volume of 495 μ l. Assays were initiated with addition of 5 μ l 1-naphthyl acetate (50 mM in ethanol). Reactions were run at 32°C for 10 min and terminated with addition of a 1 ml solution of fast blue B and sodium dodecyl sulfate (0.2 and 7.5 mg/ml water, respectively). After 10 min, absorbance was read at 600 nm and converted to concentration of 1-naphthol using a standard curve.

Soluble and microsomal glutathione transferase activities were measured as the conjugation of 1-chloro-2,4-dinitrobenzene (CDNB) with reduced glutathione, as documented previously (Lindroth, 1989). Reaction mixtures consisted of 4–15 μ g protein, 50 μ l glutathione (0.05 M in phosphate buffer), and 0.1 M potassium phosphate buffer to a total volume of 975 μ l. Reactions were initiated with addition of 25 μ l CDNB (40 mM in methyl cellosolve) and the increase in absorbance (340 nm) monitored for 1 min against a blank containing everything but enzyme. Again, use of a double-beam spectrophotometer automatically accounted for changes in absorbance due to nonenzymatic conjugation of CDNB. Concentrations of CDNB-glutathione were calculated using an extinction coefficient of 9.6/mM/cm (Cohen, 1986).

Statistics. Statistical analyses were performed with the SYSTAT statistical software package. One-way analyses of variance and multiple comparisons among means were conducted using a multiple general linear model (Wilkinson, 1987). For results from the survival trials, percentages were transformed ($\arcsin \sqrt{y}$) prior to analysis. For all other experiments in which Bartlett's test

of homogeneity indicated unequal distribution of variance, data were transformed ($\ln y$) prior to analysis.

RESULTS

Feeding Trials. Performance of luna larvae was exceptionally poor on seven of the 11 plant species tested (Table 2). For six of these species, no larvae survived through the first stadium. Survival of larvae fed willow was 33% for one replicate, but 0% for all others. Larvae fed quaking aspen or red oak consumed small amounts of leaf material prior to death, whereas larvae fed black cherry, cottonwood, or tulip tree showed few, if any, signs of feeding. In contrast, larvae fed birch or any of the three members of the Juglandaceae exhibited very high first instar survival.

Among the larvae that survived to pupation, those fed butternut had the shortest larval duration, but also the lowest average pupal weight (Table 2). Larvae fed birch required the longest time prior to pupation and had intermediate pupal weights. Luna reared on black walnut had the highest pupal weights (43% higher than those reared on the congeneric butternut) and intermediate larval development times.

Enzyme Assays. Survival of larvae was sufficiently high in only four of the 11 treatments to provide enough fifth instars for enzyme assays. Larval food plant did not affect activity of midgut β -glucosidases (Table 3), but it did influence activity of all the detoxification enzyme systems.

TABLE 2. PERFORMANCE OF *Actias luna* LARVAE ON VARIOUS FOOD PLANTS^a

Species	First instar survival (%)	Larval duration (days)	Pupal weight (g)
Black cherry	0.0 (5)		
Cottonwood	0.0 (5)		
Quaking aspen	0.0 (5)		
White willow	5.6 \pm 5.6(5)a	31.3 (1)	2.20 (1)

TABLE 3. SPECIFIC ACTIVITIES ($\bar{X} \pm 1$ SE) OF MIDGUT ENZYMES IN *Actias luna* LARVAE FED VARIOUS HOST PLANTS^a

Host plant	β -Glucosidase		Quinone reductase		Cytochrome c reductase	O-Demethylase		Esterase		Gluthathione transferase	
	Soluble	Microsomal	Soluble	Microsomal		Soluble	Microsomal	Soluble	Microsomal	Soluble	Microsomal
Paper birch (5)	98.6a ± 11.6	288.3b ± 17.3	47.0a ± 2.0	288.3b ± 17.3	169.9b ± 7.8	249.6c ± 30.0	1072a ± 48	1192.6c ± 86.7	1016a ± 86	160.4a ± 16.4	
Black walnut (5)	126.2a ± 10.7	195.9a ± 7.9	61.3c ± 2.7	195.9a ± 7.9	124.1a ± 4.2	179.9b ± 24.2	1940d ± 111	665.6a ± 30.8	2246b ± 82	258.3b,c ± 18.2	
Butternut (4)	108.4a ± 15.4	173.9a ± 9.6	53.1b ± 1.2	173.9a ± 9.6	139.1a ± 15.3	94.4a ± 16.6	1337b ± 28	691.3a,b ± 26.1	2867b ± 378	226.1b ± 13.0	
Shagbark hickory (5)	118.9a ± 9.3	255.0b ± 8.7	55.7b ± 0.9	255.0b ± 8.7	147.7a,b ± 10.0	145.2a,b ± 12.4	1619c ± 89	854.6b ± 37.3	2491b ± 86	282.4c ± 21.4	

^aSample sizes shown in parentheses. All specific activities except O-demethylase shown as nmol/min/mg protein. O-Demethylase activities shown as pmol/min/mg protein. Within a column, means followed by different letters are significantly different ($P \leq 0.05$).

Both soluble and microsomal quinone reductase activities were affected by larval host plant (Table 3). Soluble QR activity was lowest in larvae fed birch and highest in those fed walnut, a 1.3-fold difference. Microsomal QR activity, however, was lowest in larvae fed butternut and highest in those fed birch, a 1.7-fold difference. Specific activities (per unit protein) were three to six times higher in microsomal fractions than in soluble fractions. However, given that total soluble protein averaged six to eight times that of microsomal protein, total soluble QR activity was higher than total microsomal QR activity in larvae from all treatments.

Cytochrome *c* reductase and *O*-demethylase assays showed that highest PSMO activities occurred in larvae reared on birch (Table 3). Lowest cytochrome *c* reductase levels were in larvae fed walnut, whereas lowest *O*-demethylase activities were in larvae fed butternut. Host plant effects on enzyme activity accounted for a 1.4- and 2.6-fold variation in cytochrome *c* reductase and *O*-demethylase activities, respectively.

Activities of soluble esterases were significantly different among all treatments and were 1.8-fold higher in larvae fed walnut than in larvae fed birch (Table 3). Microsomal esterases exhibited an opposite trend in activity, with lowest values in larvae fed walnut, and highest in those fed birch. Specific activities of soluble esterases were higher than those of microsomal esterases in all treatments except birch. Considering the much larger quantity of soluble protein than microsomal protein in the enzyme preparations, a preponderance of midgut esterase activity is effected by soluble enzymes.

Glutathione transferase (GT) activities were strongly correlated with host plant genus (Table 3). There were no significant differences in soluble GT activities among larvae fed walnut, butternut, or hickory. Activities exhibited by these larvae were 2.2- to 2.8-fold higher than those of larvae fed birch. Similarly, variations in activities of microsomal GTs among larvae fed members of the Juglandaceae were small in comparison to the difference between those larvae and larvae reared on birch.

With respect to major among-treatment trends in enzyme activities, few patterns are evident among larvae fed species of the Juglandaceae. Clearly though, the enzyme profile of larvae reared on birch differed substantially from those of larvae reared on walnut, butternut, or hickory. Birch-fed larvae showed the lowest β -glucosidase, soluble QR, and soluble and microsomal esterase and GT activities, but the highest cytochrome *c* reductase, *O*-demethylase, and microsomal QR activities.

DISCUSSION

Larval performance on the trees tested in this study differed significantly from that expected on the basis of published food plant records (Holland, 1968; Baker, 1972; Tietz 1972). Survivorship values of 0% on white oak and red oak,

and of 5.6% on willow, were particularly surprising. Larvae performed quite well, and fairly similarly, on birch and the three species of Juglandaceae. These divergent results are best explained by the low genetic variability in the laboratory population. Although *Actias luna* feeds on a variety of plant families throughout its geographic range, local populations or individuals may specialize on particular plant families. Scriber and Feeny (1979) suggested that a similar situation exists for other species of saturniids. This study lends additional support to the notion of Fox and Morrow (1981) that insects exhibiting generalized diets at the species level are likely to have specialized diets at the population level.

Little is known about host plant alteration of midgut enzymes in deciduous tree-feeding insects. These data show that, with one exception, larval food plant strongly affects the activity of midgut enzymes. The single exception was β -glucosidase activity, which was not significantly affected by the plant species consumed. This lack of response contrasts with results from a similar study (Lindroth, 1988) in which strong host plant effects on β -glucosidase activity were found in the eastern tiger swallowtail (*Papilio glaucus glaucus*).

Although larval food plant significantly affected quinone reductase activities, the effects were not strong (1.3- and 1.7-fold maximum differences for soluble and microsomal QR activities, respectively). Similarly, Yu (1987a) found that individual allelochemicals induced QR activities in fall armyworm 1.3- to 2.5-fold. Quinone reductase activities in luna larvae were markedly higher than those found by Yu (1987a) in other lepidopteran species. Soluble QR activities in luna were up to 2.3-fold higher than those in the armyworm, and microsomal activities in luna were 5.6–6.2 times higher than those in four other species.

Plant alteration of PSMO-related activities was low to moderate in the luna larvae. Cytochrome *c* reductase activities and induced responses were similar to those reported for *Papilio glaucus glaucus* fed various host plants (Lindroth, 1989). *O*-Demethylase activities were also in the range reported for *P. g. glaucus* (Lindroth, 1989), for fall armyworm fed various crop plants (Yu, 1983), and for fall armyworm, corn earworm, tobacco budworm, and velvetbean caterpillar reared on artificial diets (Yu, 1987b).

Published studies of host plant alteration of insect esterase activities have typically shown small to moderate effects (Yu, 1986, 1987b; Brattsten, 1987b). In the present study maximum differences of 1.8-fold were found for both soluble and microsomal esterases. The range of esterase activities in luna larvae was similar to that of *P. g. glaucus* fed various host plants (Lindroth, 1989) and to the single value of 1004 nmol/min/mg protein reported for gypsy moth (*Lymantria dispar*) reared on an artificial diet (Kapin and Ahmad, 1980).

Soluble glutathione transferases exhibited the strongest apparent induction response of the enzymes assayed in this study, although the possibility exists that GT activity was simply inhibited in birch-fed larvae. In addition, the overall soluble GT activity of larvae fed members of the Juglandaceae was quite

high in comparison to that of other insect species. Midgut glutathione transferase activities (measured by the CDNB assay) for *P. g. glaucus*, the southern armyworm, fall armyworm, and corn earworm ranged from 600 to 970 nmol/min/mg protein (Gunderson et al., 1986; Brattsten, 1987a; Yu, 1987b; Lindroth, 1989).

Although this was a preliminary study, the results suggest that evolutionary and ecological adaptations of luna to particular food plants involve alterations in biochemical detoxification systems. Moreover, the enzyme systems of particular significance here have rarely demonstrated such importance in other plant-insect associations. Unusually high constitutive levels of quinone reductase and glutathione transferase activities in luna are probably an evolutionary adaptation to the presence of juglone and related quinones in their preferred food plants (Juglandaceae). The fact that soluble QR and soluble and microsomal GT activities appeared to be induced in larvae fed members of the Juglandaceae, relative to those fed birch, shows that biochemical alterations are involved in the adaptations of individual larvae to specific foods. These types of biochemical adjustments may well be involved in local feeding specialization of regionally generalist insects. Finally, this study illustrates that an understanding of the dominant allelochemicals in a plant-insect system can give clues as to the type of biochemical adaptations exhibited by the insects.

Acknowledgments—I thank Miel Barman for technical assistance, and Mark Evans for advice on rearing the larvae. (Received June 21, 1988; accepted October 13, 1988)

Abstract—A single compound with sex pheromone activity was isolated from the female soybean cyst nematode, *Heterodera glycines*, by a sequence of four high-performance liquid chromatographic steps and identified as vanillic acid by a combination of ultraviolet spectroscopy and chromatography. The structure was confirmed by gas chromatography-mass spectrometry. Both attractancy and coiling behavior in male soybean cyst nematode were elicited by authentic vanillic acid.

Key Words—Soybean cyst nematode, *Heterodera glycines*, Nematoda, sex pheromone, vanillic acid, attractancy, coiling, bioregulation, behavior.

INTRODUCTION

The identification of behavior-modifying compounds of free-living, animal- and plant-parasitic nematodes has been the subject of intensive study since the late 1960s. However, to date, no complete structures of any such compounds have been reported (for review see Bone, 1987; Huettel, 1986). Previous studies on nematodes generally have centered on sex pheromones, aggregation pheromones, or epideitic responses (Huettel, 1986).

Bone et al. (1979), in extensive studies of the animal parasitic nematode, *Nippostrongylus brasiliensis*, tentatively identified a long-chain polypeptide as the sex attractant of this nematode. In studies of the free-living nematode, *Caenorhabditis elegans*, compounds with physical and chromatographic properties

similar to hydroxylated, short-chain fatty acids and bile acids were partially characterized as a primer or epideitic pheromone that causes the dauer larval formation in this species (Golden and Riddle, 1982, 1984). Bone (1986) fractionated the sex pheromone of a plant-parasitic nematode of soybeans, *Heterodera glycines*, into two components of different solubility.

Our laboratory also has investigated pheromone production in *H. glycines*, the soybean cyst nematode (SCN). We have developed more sensitive bioassays than those used previously to detect responses by males to females of this species (Huettel and Rebois, 1986; Huettel and Jaffe, 1987). Unlike previous bioassays (Greet et al., 1968; Rende et al., 1982), which required at least 8 hr or more to complete, we developed a rapid bioassay based on a specific behavior that could be completed in several minutes. Furthermore, we demonstrated that this behavior could be induced in males only by the presence of females or their crude extracts (Huettel and Jaffe, 1987). This rapid method allowed us to screen large numbers of high-performance liquid chromatography (HPLC) fractions of female extracts.

We report here the isolation and complete structural identification of a compound (SCNP) from female soybean cyst nematode with sex pheromone activity. This is, to our knowledge, the first structure of this type to be reported from a plant-parasitic nematode.

METHODS AND MATERIALS

Soybean Cyst Nematode Culture and SCNP Extraction. *H. glycines* Ichinohe (Nematoda), race 3, was maintained on monoxenic soybean root explant cultures, as previously described (Huettel and Rebois, 1985). Female nematodes (1000), ca. 10–12 days old, were removed manually from the roots and placed in 15 ml Milli-Q water (Millipore). The nematodes were gently agitated in the dark at room temperature for 24 hr. The aqueous extract was then filtered through a 0.22- μ m Acrodisc filter (Gelman) and frozen at -80°C in a 20-ml polypropylene vial. Batches of extract from 20,000–40,000 females were lyophilized at $0-5^{\circ}\text{C}$.

SCNP Purification. The lyophilisate from 23,870 females was taken up in two 3-ml portions of the starting gradient mixture of HPLC step A (see below). The resulting solution was filtered through a 0.45- μ m Millex-HV filter (Millipore) prior to analysis by HPLC.

HPLC Step A. The filtered sample (5.3 ml) was divided into five equal parts (4774 female equivalents) each of which was chromatographed on a 4.6 \times 250 mm, 5 μ m Supelcosil LC-18DB column with a Pelliguard guard column (Supelco) on a model 840 liquid chromatograph with autosampler (Waters). The sample was injected onto the column and eluted with a concave gradient (Waters

curve 7) from 10 to 60% acetonitrile (0.1% v/v trifluoroacetic acid) against 0.1% aqueous trifluoroacetic acid (TFA) over 1 hr at ambient temperature and 1.0 ml/min. The eluent was monitored spectrophotometrically at 214 nm. Fractions were collected over 1-min intervals with both the autosampler and fraction collector cooled to 0–5°C. Fractions with the same retention times from the five runs were pooled in the fraction collector, and those fractions (17–19 min) with biological activity were lyophilized at 0–5°C.

HPLC Step B. Each of the pooled lyophilized 1-min fractions was purified further by reverse-phase HPLC on a 4.6×250 -mm, 7- μ m Zorbax C-8 150 SP column (Dupont) on a 1090 liquid chromatograph equipped with a photodiode array detector and Chemstation (Hewlett-Packard). The column was eluted with a linear gradient from 2 to 15% acetonitrile in 0.25 N triethylammonium phosphate (TEAP), pH 2.20, over 1 hr at 28°C and 0.4 ml/min. Fractions were collected at 1-min intervals, and the fractions (49–50 min) containing SCNP were processed in vacuo in a model SVC200H Speed Vac concentrator (Savant) to remove acetonitrile.

HPLC Step C. Fractions containing partially purified SCNP were purified further by reverse-phase HPLC using the same 1090 chromatograph and Zorbax column with a linear gradient from 2 to 20% acetonitrile (0.1% v/v TFA) against 0.1% aqueous TFA over 1 hr at 28°C and 0.4 ml/min. Fractions were collected at 1-min intervals and the fraction (46–47 min) containing SCNP was evaporated to dryness in the Speed Vac.

HPLC Step D. Final purification of the SCNP was achieved by reverse-phase HPLC of the partially purified SCNP fractions resulting from HPLC step C using the same 1090 chromatograph and Zorbax column, but using a linear gradient from 2 to 20% 2-propanol (0.1% v/v TFA) against 0.1% aqueous TFA over 1 hr at 28°C and 0.4 ml/min. The resulting fractions containing the SCNP peak were evaporated to dryness in the Speed Vac and stored at –80°C.

Control HPLC Isolation Experiments. Three control samples were prepared and analyzed by HPLC as follows: (1) Milli-Q water (200 ml) was lyophilized, taken up in starting gradient mixture of HPLC step A, and analyzed by HPLC step A. Fractions eluting between 17 and 20 min were pooled, concentrated, and analyzed by HPLC step B. (2) Sterile *Glycine max* (L.) CV Kent root (1 g) was stirred in 15 ml Milli-Q water at room temperature in the dark for 24 hr. The aqueous extract was filtered through a 0.22- μ m Acrodisc filter and lyophilized. The residue was analyzed by HPLC step A. Fractions eluting between 16 and 20 min were pooled, concentrated, and analyzed by HPLC step B. (3) Gamborg's B-5 medium Agar (Gibco) was prepared according to the manufacturer's instructions. A 1-g sample was stirred in 15 ml Milli-Q water at room temperature in the dark for 24 hr. The aqueous phase was filtered and analyzed by HPLC step A. Fractions eluting between 16 and 20 min were concentrated and analyzed by HPLC step B.

HPLC Analysis of Substituted Phenolic Acids. A group of commercially available substituted phenolic acids (Aldrich) was analyzed by the conditions of HPLC step D. The following absorbance maxima and retention times were observed: 2,3-dihydroxybenzoic acid, 206, 244, 247, 317 nm and 43.8 min; 2,4-dihydroxybenzoic acid (β -resorcylic acid), 208, 256, 295 nm and 43.0 min; 2,5-dihydroxybenzoic acid (gentisic acid), 212, 238, 330 nm and 34.5 min; 2,6-dihydroxybenzoic acid (γ -resorcylic acid), 208, 215, 247, 308 nm and 40.5 min; 3,4-dihydroxybenzoic acid (protocatechuic acid), 206, 217, 260, 294 nm and 23.4 min; 3,5-dihydroxybenzoic acid (α -resorcylic acid), 204, 220, 248, 307 nm and 23.4 min; 3,4-dimethoxybenzoic acid (veratric acid), 204, 219, 260, 293 nm and 56.0 min; 3-hydroxy-4-methoxybenzoic acid (isovanillic acid), 205, 218, 261, 294 nm and 40.4 min; 4-hydroxy-3-methoxybenzoic acid (vanillic acid), 205, 218, 261, 293 nm and 37.0 min.

Bioassay. Dried aliquots of HPLC fractions were taken up in Milli-Q water for bioassay by our previously described method (Huettel and Jaffe, 1987). The response of male SCN to various concentrations of vanillic acid (VA) was bioassayed as follows: male SCN were removed by hand from soybean root culture and aerated in 200 ml Milli-Q water to remove any effects of previous exposure to pheromone. For each concentration of VA in Milli-Q water, 10 males were removed from the water after aeration and placed in a 20- μ l drop of VA solution on a 1.5% Noble Agar plate (Difco). After 30 sec, the males were removed from the VA solution and observed for coiling behavior on the agar plate with a stereomicroscope (Nikon).

Derivatization Procedure for GC-MS Analysis of SCNP. A dried aliquot of the purified SCNP peak eluting at 37.0 min in HPLC step D (see Figure 4) was transferred by means of MeOH washes (2 \times 0.1 ml) to a 10-cm \times 1.6-cm-OD, Teflon-lined, screw-capped, glass culture tube for derivatization by a procedure adapted from the methods of Woolson and Harris (1967) and Metcalfe and Schmitz (1961). After the addition of 0.45 g BF₃-MeOH reagent (Supelco), the tube was tightly capped and heated in a boiling-water bath for 3 min. After cooling, 6 ml of 10% Na₂SO₄ was added to decompose excess reagent. The aqueous phase was extracted with 3 ml iso-octane-benzene (2:1). The organic extract was centrifuged for 5 min at 3500 rpm and the resulting supernatant transferred to a 15-ml conical flask for removal of solvents by rotary evaporation at 25°C. The residue was transferred by means of two EtOAc washes (0.15 and 0.10 ml) to a 0.3-ml glass, tapered-tip, HPLC autoinjector vial (Waters). After removal of solvent on the Speed Vac, the residue was dissolved in 30 μ l EtOAc and 2 μ l of the resulting solution was analyzed by GC-MS.

The following control samples were derivatized and analyzed by GC-MS: (1) dried fractions eluting before (35–36 min) and after (39–40 min) the SCNP peak, (2) authentic VA (200 mg), and (3) a solvent/reagent blank.

TABLE 1. GC-MS-SIM ANALYSIS OF METHYL ESTER DERIVATIVES OF SCNP ISOLATED FROM *Heterodera glycines* AND VANILLIC ACID

Compound	Average retention time of GC peak (min) ^a	Relative Abundance (%) at Indicated Ion			
		<i>m/z</i> 108.1	<i>m/z</i> 123.2	<i>m/z</i> 151.3	<i>m/z</i> 182.2
SCNP	5.00	13.93	27.27	98.57	96.77
Vanillic acid (VA)	4.99	14.07	28.27	100.0	94.17
Methyl vanillate (MEVA) ^b	5.01	13.41	26.69	99.82	94.86

^aFor SCNP, *N* = 3; VA, *N* = 3; MEVA, *N* = 11.

^bAuthentic sample (underivatized).

GC-MS Analysis. Samples were analyzed by GC-MS on a model 5985A GC-MS equipped with a model 18835 capillary inlet system, model 1000 computer, model 7920 and 7906 disk drives (Hewlett-Packard), and a DB5 30-m × 0.257-mm-ID fused-silica capillary (0.25 μm film) column (J&W), operated in the splitless mode and temperature programmed from 70 to 250°C at 18°C/min. For selected ion monitoring (SIM) experiments, the column was temperature programmed from 70 to 250°C at 30°C/min. The column was held at 250°C for 20 min between runs for column burn-off. GC-MS instrument parameters were: injection port, 250°C; carrier gas (He) inlet pressure, 8 psi; detector source temperature, 200°C; electron multiplier voltage 2800 V. Major ions (relative intensities >4.0) for methyl vallinate (MEVA) standard were observed at *m/z* 108 (12.6), 111 (5.3), 123 (23.5), 136 (4.8), 151 (base, 100.0), 152 (10.8), 167 (4.5), 182 (M+, 55.9), and 183 (4.4). For SIM analyses, the instrument was calibrated to monitor exact masses of the following ions: *m/z* 108.1, 123.2, 151.3, and 182.2. A total of 200-msec dwell time (50 msec/ion) was used for each SIM scan. The GC retention times and relative abundances of the selected ions (Table 1) were averaged for the SCNP (*N* = 3), VA (*N* = 3), and MEVA (*N* = 11).

RESULTS AND DISCUSSION

A single compound (SCNP) with sex pheromone activity in male SCN was isolated from aqueous extracts of females and purified by a four-step reverse-phase HPLC procedure. Biologically active 1-min fractions eluting between 17 and 19 min by HPLC step A (Figure 1) were each further purified by HPLC step B. As shown (Figure 2) for the fraction eluting between 18 and 19 min, the change of column and buffer from TFA to TEAP at this stage of purification

FIG. 1. Elution profile of extract of 4774 female soybean cyst nematodes by HPLC step A ($0.500A_{214}$ full scale) between 0 and 70 min (upper chromatogram) and 10–20 min (lower chromatogram). Bars indicate fractions with biological activity.

caused the fraction to resolve into several major peaks. The peak eluting between 49 and 50 min (later shown to be biologically active) was purified further by HPLC step C (Figure 3), where it eluted between 46 and 47 min. Although the change of buffer from TEAP to TFA at this stage of purification caused a co-eluting small peak in HPLC step B to shift to a lower retention time, satisfactory purification of the main peak was not achieved, as indicated by photodiode array UV spectroscopy. Final peak purification, however, was achieved in HPLC step D using the volatile TFA–2-propanol buffer (Figure 4). Superimposition

FIG. 2. Elution profile using HPLC step B ($0.100A_{220}$ full scale) of pooled fractions from HPLC step A eluting between 18 and 19 min from 23,870 females. Asterisk indicates peak with biological activity.

of the normalized upslope, apex, and downslope UV spectra (Figure 5) indicated peak homogeneity. Biological activity corresponded exactly with this peak.

The structure of SCNP was determined by a combination of UV spectroscopy and HPLC and confirmed by GC-MS. The UV spectrum of SCNP between

FIG. 3. Elution profile using HPLC step C ($0.200A_{220}$ full scale) of peak from HPLC step B eluting between 49 and 50 min. Asterisk indicates peak with biological activity.

200 and 500 nm displayed four distinct maxima, characteristic of substituted phenolic acids (Doub and Vandenberg, 1955; Scott, 1961). Analysis of a representative group of these compounds under HPLC conditions of step D (see Methods and Materials) revealed that VA and SCNP had identical HPLC retention times and UV spectra. In addition, in higher pH buffers, such as 0.01 M NH_4OAc , at pH 6.55, both SCNP and VA exhibited identical changes in UV

FIG. 5. Overlay of normalized UV spectra of the upslope, apex, and downslope of purified SCNP peak shown in Figure 4.

spectrum and shifts to lower HPLC retention times characteristic of substituted phenolic acids (data not shown). Based on these data, SCNP was identified as VA (4-hydroxy-3-methoxybenzoic acid) (Scheme 1).

SCHEME 1.

The total isolated yield of VA from 23,870 female SCN was 315 ng or 3.2 pg/female. In further support of the structural identification, the elution profile of a sample containing equal amounts of SCNP and VA (analyzed by the HPLC conditions of step C or D) displayed only one peak (Figure 6). In each case, superimposition of the normalized upslope, apex, and downslope UV spectra was observed, indicating peak homogeneity.

The identity of SCNP was confirmed by GC-MS. Because VA exhibited poor chromatographic behavior (broad, distorted peaks) on a variety of fused-silica capillary columns adaptable to GC-MS, it was converted by treatment with $\text{BF}_3\text{-MeOH}$ to its methyl ester (MEVA). As expected, MEVA eluted as a sharp symmetrical peak and was easily detectable by GC-MS in the low nanogram range (1–5 ng) when analyzed in the selected ion monitoring (SIM) mode.

Data in Table 1 show that $\text{BF}_3\text{-MeOH}$ reaction with the SCNP or an

FIG. 6. Elution profiles between 30 and 60 min of equal amounts of purified SCNP and vanillic acid by conditions of HPLC step C ($0.050A_{220}$ full scale, lower chromatogram) and HPLC step D ($0.050A_{260}$ full scale, upper chromatogram).

authentic sample of VA produced a GC peak with essentially identical retention time and SIM profile as that observed for MEVA. In addition, dried fractions eluting before and after the SCNP peak in HPLC step D were also derivatized and analyzed by GC-MS-SIM. MEVA was not detected in either of these control fractions or the reagent/solvent blank.

Since SIM experiments consumed a small portion of the derivatized SCNP sample, the remainder was concentrated and analyzed by GC-MS in the full spectrum mode. Peak I (Figure 7) in the total ion chromatogram was identified as MEVA based on a comparison of its retention time and mass spectrum to those of an authentic sample of MEVA. All major ions present in MEVA (mass spectrum B) were observed in the mass spectrum of peak I (mass spectrum A) in approximately the same relative intensity.

Because the yield in the BF_3 -MeOH derivatization reaction was 55%, we expected the presence of a significant amount of underivatized SCNP in the reaction mixture. Examination of spectra in the region (peak II, 5.85 min) in the total ion chromatogram where VA elutes as a broad, unsymmetrical peak (5.18–5.92 min) provided a spectrum (mass spectrum C) that contained all major ions observed for an authentic sample of VA (mass spectrum D), including the molecular ion m/z 168 and the base peak at m/z 153 corresponding to $\text{M} - \text{CH}_3$. Clearly, the GC-MS and GC-MS-SIM data confirm VA as the SCNP. Peaks other than I and II in the total ion chromatogram (Figure 7) resulted from HPLC column bleed and/or impurities in the reagents/solvents.

Male SCN displayed identical sex pheromone behavior to VA, i.e., the previously observed attractancy and coiling (Huettel and Rebois, 1986; Huettel and Jaffe, 1987) towards females or their extracts. Males responded to a concentration range of 10^{-5} – 10^{-7} M VA. At concentrations $>10^{-5}$ M VA, a paralytic-like effect was observed, resulting possibly from an "overload" of the pheromone receptor(s). It should be noted that VA is extremely active in our bioassay, with 60% of the males tested responding to 10^{-7} M VA or a total of 336 pg.

The phenolic acids including VA are ubiquitous compounds in nature, occurring in soil (Flaig et al., 1975) as products of plant lignin decomposition by fungi (Ishihara and Miyazaki, 1972; Ander and Eriksson, 1978). Although previous work (Harden and Stutte, 1980; Porter, 1983) had failed to detect VA in extracts of unhydrolyzed soybean leaf and root, it was considered essential nevertheless to conduct control experiments. These included the elimination of soybean root, Milli-Q water, and agar as a source of VA by our purification procedure. Both the weight of root and agar used in the control experiments were estimated to be substantially greater than the total weight of the females used in the SCNP isolation. The volume of Milli-Q water was about half that used in the SCNP isolation. Results of these control experiments were negative, confirming only the female SCN as the source of VA.

Although a recent report (Bone, 1986) suggested a two-component sex

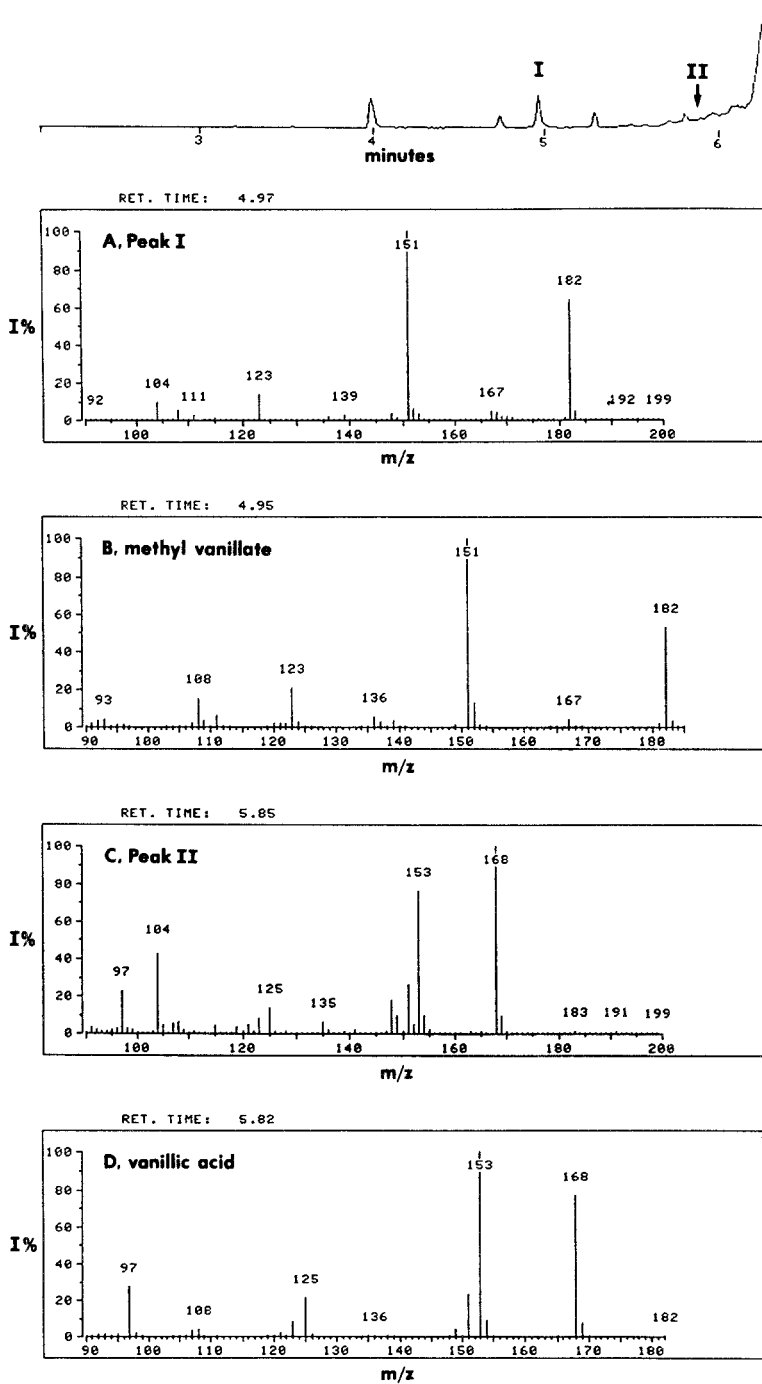

Fig. 7. Total ion chromatogram of derivatized SCNP (upper trace) and associated mass spectra: (A) peak I; (B) methyl vanillate; (C) peak II; (D) vanillic acid.

pheromone for SCN, our isolation procedure yielded only a single compound that elicited both aspects of SCN sex pheromone behavior, i.e., attractancy and coiling. We do not, however, rule out the possibility of other active compounds undetected by us.

To our knowledge, vanillic acid has not been previously identified as having sex pheromone activity in any species, although vanillin and vanillyl alcohol, the corresponding aldehyde and alcohol, have been identified (Aldrich et al., 1979) in gland secretions of male leaf-footed bugs (Hemiptera: Heteroptera) and vanillin has been identified (Ubik et al., 1975; Vrkoc et al., 1977) as a component of the sex pheromone of the bug *Eurygaster integriceps* (Heteroptera, Scutelleridae). With the present limited capabilities for chemical control of plant-parasitic nematodes (Feldmesser et al., 1985), we are hopeful the report here of the determination of the first structure of a compound with sex pheromone activity in nematodes might lead to development of future novel and environmentally safe control strategies for these pests.

MATING AND OVIPOSITION BY *Cotesia* (= *Apanteles*)
marginiventris (HYMENOPTERA: BRACONIDAE) IN
PRESENCE OF SYNTHETIC PHEROMONE OF
Spodoptera frugiperda (LEPIDOPTERA:
NOCTUIDAE)

(Received June 7, 1988; accepted October 18, 1988)

Abstract—Two blends of fall armyworm, *Spodoptera frugiperda* (J.E. Smith), pheromonal components were evaluated in the laboratory for possible close-range effects on mating and oviposition by *Cotesia marginiventris* (Cresson). Neither a two- nor a five-component blend had any significant effect on mating or parasitization of *S. frugiperda* larvae by this parasitoid. Dosages of 200, 400, and 800 μg were tested.

Key Words—Mating behavior, Parasitoids, *Cotesia* (= *Apanteles*) *marginiventris*, Hymenoptera, Braconidae, *Spodoptera frugiperda*, Lepidoptera, Noctuidae.

INTRODUCTION

Cotesia (= *Apanteles*) *marginiventris* (Cresson) is an important natural enemy of the fall armyworm (FAW), *Spodoptera frugiperda* (J.E. Smith), because it parasitizes first- and second-instar larvae that die when they reach the fourth instar (Ashley et al., 1982). Also, *C. marginiventris* is one of the most frequently recovered parasitoids from field-collected FAW larvae (Ashley, 1979). Thus, this parasitoid has the potential to reduce substantially FAW larval infestations that cause economic damage to agricultural crops throughout the southeastern and central United States.

Loke et al. (1983) suggested that *C. marginiventris* could be made more

effective through controlled management of its field activity. They reported that the presence of *C. marginiventris* and its searching activity were influenced more by FAW-damaged plants than by the presence of FAW larvae. Loke and Ashley (1984) demonstrated that this parasitoid responds to kairomones from frass of FAW larvae. Parasitization rates were increased 55 and 26% when they confined FAW larvae on filter paper and corn seedlings, respectively, that had been treated with a hexane extract of FAW frass. Nordlund et al. (1983) reported that the host-seeking behavior of *Telenomus remus* Nixon, a parasitoid of FAW eggs, was increased in laboratory and greenhouse bioassays by (Z)-9-tetradecen-1-ol acetate (Z9-14:Ac) and (Z)-9-dodecen-1-ol acetate (Z9-12:Ac), which were originally identified as the components of FAW sex pheromone (Sekul and Sparks, 1967). However, Mitchell et al. (1984) did not detect any significant effect on the level of parasitization of FAW larvae by *Chelonus insularis* Cresson and *Temelucha difficilis* Dasch. when these chemicals were evaporated in 1.1-hectare blocks of field corn. Earlier, Mitchell and McLaughlin (1982) reported significant reductions in FAW mating and oviposition when Z9-14:Ac was applied to a 12-hectare corn field, but Z9-12:Ac, an attractant for FAW but not a component of the FAW pheromone (Tumlinson et al., 1986), was ineffective as a disruptant of pheromone communication among FAW (McLaughlin et al., 1981). Tingle and Mitchell (1982) reported that applications of a four-component mixture of the *Heliothis virescens* (F.) sex pheromone that reduced mating and captures of moths in pheromone-baited traps did not adversely affect parasitization of *H. virescens* larvae in preharvest tobacco. Lewis et al. (1982) determined that the synthetic pheromone of *H. zea* (Boddie) increased the parasitization rate of *H. zea* eggs by *Trichogramma pretiosum* Riley. The study described here was undertaken to observe the close-range effects, if any, of two FAW synthetic pheromonal blends on mating and oviposition by *C. marginiventris* under laboratory conditions.

METHODS AND MATERIALS

The FAW host larvae and *C. marginiventris* used for testing were obtained from our laboratory colonies. Parasitoids and FAW larvae were reared in an environmentally controlled cabinet set at 27°C and 70% relative humidity with a 14-hr photophase. Virgin parasitoids were acquired by placing parasitoid cocoons individually into No. 00 gelatin capsules until eclosion. Upon emergence, females either were confined separately from males or paired with males (3-7 pairs/cage) in Plexiglas cages (25 × 25 × 25 cm) and provided with honey and water. Mating and oviposition tests were conducted 3-8 hr after the beginning of photophase at ambient laboratory conditions (ca. 27°C, 55% relative humidity) in an exhaust hood that was equipped with side and overhead flu-

orescent lighting. The light intensity inside the test chambers was ca. 150 foot-candles when measured with a Weston model 703-60 light meter.

Two blends of FAW pheromonal components were evaluated in both the mating and oviposition tests. One blend consisted of 0.5% (Z)-7-dodecen-1-ol acetate (Z7-12:Ac) and 99.5% (Z9-14:Ac), and the other blend contained five components: 1.0% dodecan-1-ol acetate (S-12:Ac), 0.5% Z7-12:Ac, 0.5% Z9-12:Ac, 79.0% Z9-14:Ac, and 19.0% (Z)-11-hexadecen-1-ol acetate (Z11-16:Ac). Tumlinson et al. (1986) reported that these blends and blends containing three and four components were equally attractive for capturing FAW males in traps; both Z7-12:Ac and Z9-14:Ac were essential for maximum catches.

Rubber septa were used as dispensers for the chemicals. All of the synthetic materials used for the formulation of the pheromone septa were obtained from commercial sources. Each pheromone component was purified by high-performance liquid chromatography on a 25 × 2.5-cm (OD) AgNO₃-coated silica gel column eluted with toluene (Heath et al., 1977). These compounds were then analyzed by capillary gas chromatography on a 50-m × 0.25-mm-ID fused silica CPS-1 (cyanopropyl methyl silicone, Quadrex Corp., New Haven, Connecticut) and a 50-m × 0.33-m-ID fused silica BP-1 (SGE, Austin, Texas). All compounds were determined to be >99% pure.

Dosages of 400 and 800 μg of the two-component blend were evaluated in the mating test, and three dosages (200, 400 and 800 μg) were evaluated in the oviposition test. The 800-μg dosage was used in both tests for bioassaying the five-component blend. In control treatments, septa that had been treated only with the solvent, hexane, were used. During testing, the chemicals were introduced continually into the upper portion of each plastic bioassay chamber by blowing air (300 ml/min) with an aquarium pump through a 1.6-cm-OD brass chamber containing the septum. The release rates of both the two- and five-component blends from the septa containing dosages of 200, 400, and 800 μg were ca. 15, 30, and 60 ng/hr, respectively. Exhaust holes were provided in the bottom of each chamber, and a single, stoppered hole in each top served as an entry for test insects.

In the mating test, four 1-day-old virgin *C. marginiventris* males were first released into a 14.0-cm × 11.5-cm-diam. test chamber and then four virgin females were introduced. The parasitoids were observed during the next 30 min for apparent matings (copulation) or unsuccessful copulation attempts, and data were compared to those in the control. In the oviposition test, 40 first- or second-instar FAW larvae were placed on four pieces of diet (Guy et al., 1985) in the bottom of a 7.0-cm × 9.5-cm-diam. test chamber. Then, one 4- to 7-day-old *C. marginiventris* female that had been confined with males for mating was introduced into the chamber and observed for 20 min for parasitization attempts (contacts with larvae with ovipositor). The parasitoid was then removed, and the FAW larvae were transferred with the diet into a similar container that had

an X-shaped metal grid to provide additional area to reduce larval cannibalism (Loke et al., 1983). Sufficient diet was provided as needed until pupation or emergence of parasitoids.

RESULTS AND DISCUSSION

At the dosages tested, neither the two- nor the five-component FAW pheromone blends had any significant effect on mating by *C. marginiventris* (Table 1). Due to undetermined factors, there were significantly more ($P < 0.05$, Duncan's multiple-range test) apparent matings (5.9 per pair) in the control treatment that was conducted simultaneously with the five-component treatment than in the other control treatments (1.2 and 1.6 matings per pair). However, the mean number of unsuccessful mating attempts (2.0–2.1 per pair) was similar in all of the control treatments. The numbers of apparently successful or unsuccessful matings did not change significantly (unpaired *t*-test) in the treatments with the FAW pheromonal components during the 30-min testing periods. Also, oviposition by *C. marginiventris* was not affected significantly (unpaired *t* test) by the presence of these chemicals (Table 2). During 20-min tests, female parasitoids made 13.0 to 17.8 contacts with FAW larvae in control treatments. These FAW larvae successfully yielded 2.7–5.8 progeny per female parasitoid. There was no significant (unpaired *t* test) difference between control treatments with the solvent (hexane) and treatments with either the two- or five-component FAW pheromonal blends.

Although the results of our tests with *C. marginiventris* indicate that the synthetic pheromonal components of its host, FAW, have no effect at close range on parasitism of FAW larvae, the potential value of semiochemicals for modifying insect behavior in pest management systems has been recognized and discussed (Mitchell, 1981, and papers therein; Lewis et al., 1985; Staten et al., 1987). Therefore, the effects that these chemicals may have on both target and nontarget insect species should be investigated, particularly if pheromones or related chemicals are used to disrupt mating and oviposition by the pest species.

Acknowledgments—We thank P.G. Hall for rearing the parasitoids and F. Adams for providing *S. frugiperda* eggs for larval hosts. Mention of a commercial or proprietary product does not constitute an endorsement by the USDA.

TOXICITY OF ALLELOCHEMICALS FROM WILD
INSECT-RESISTANT TOMATO *Lycopersicon*
hirsutum f. *glabratum* TO *Campoletis*
sonorensis, A PARASITOID OF
Heliothis zea

W.C. KAUFFMAN¹ and G.G. KENNEDY

Department of Entomology
North Carolina State University
Raleigh, North Carolina 27695-7630

(Received August 30, 1988; accepted October 24, 1988)

Abstract—Greenhouse-grown plants of five tomato lines varying in their level of 2-tridecanone-mediated resistance to *Manduca sexta* (L.) and *Leptinotarsa decemlineata* (Say) were found to adversely affect larvae of *Campoletis sonorensis* (Cameron), a larval endoparasitoid of *Heliothis zea* (Boddie), in a manner directly related to their level of resistance. The parasitoid larvae, which emerge as fifth instars from their host and construct a cocoon on the foliage of their hosts' host plant, suffered extensive mortality during cocoon spinning on highly resistant foliage. Mortality was greatest (82%) on the highly resistant plants of *Lycopersicon hirsutum* f. *glabratum* (accession PI 134417) and an F₁ backcross [(*L. esculentum* × PI 134417) × PI 134417] selection. Mortality was intermediate (40 and 28%, respectively) on backcross selections with moderate and low levels of resistance and least (8%) on susceptible *L. esculentum*. Removal of the glandular trichomes, which contain 2-tridecanone in their tips, from the foliage eliminated differences in parasitoid mortality among plant lines.

Bioassays of 2-tridecanone indicated that it is acutely toxic to fifth instar *C. sonorensis* larvae at the quantities associated with highly resistant foliage and produces symptoms identical to those observed on resistant foliage. 2-Undecanone, a second methyl ketone present in the glandular trichomes of resistant foliage, was also toxic to *C. sonorensis* larvae, but significantly less so than 2-tridecanone. The results support the hypothesis that 2-tridecanone is responsible for the observed mortality of *C. sonorensis* larvae during cocoon construction on resistant foliage.

INTRODUCTION

Accession PI 134417 of the wild tomato species *Lycopersicon hirsutum* f. *glabratum* Mull is highly resistant to a number of arthropod pest species normally attacking the cultivated tomato, *L. esculentum* Mill. (Dimock and Kennedy, 1983; Lin and Trumble, 1986; Lin et al., 1987). High levels of the methyl ketone 2-tridecanone associated with the type VI glandular trichomes of PI 134417 foliage have been shown to confer resistance to *Manduca sexta* (L.) and *Leptinotarsa decemlineata* (Say) (Fery and Kennedy, 1987; Kennedy and Sorenson, 1985; Kennedy et al., 1985). 2-Tridecanone plays only a minor role in the resistance of PI 134417 to *Heliothis zea* (Boddie) (Dimock and Kennedy, 1983; Kennedy, 1986; Kennedy et al., 1987b). Other factors, primarily associated with the foliar lamellae, appear to account for most of the resistance to *H. zea* (Farrar and Kennedy, 1987a).

Recently, Kauffman (1987) demonstrated that parasitism of *H. zea* eggs by *Trichogramma* spp. was reduced from a mean of 71% on *L. esculentum* to 18% on PI 134417. He further demonstrated that the high densities of type VI trichomes on the resistant foliage were responsible for the reduction in egg parasitism.

Larval parasitism of *H. zea* by *Campoletis sonorensis* (Cameron) is also adversely affected on PI 134417 foliage. Kauffman (1987) found, in cage studies, that the incidence of parasitization of *H. zea* larvae by *C. sonorensis* was significantly lower on plant lines possessing high levels of 2-tridecanone-mediated resistance to *M. sexta* than on susceptible lines or those with moderate to low levels of resistance. Fifth-instar *C. sonorensis* larvae kill their hosts, emerge through their host's integument, and spin a cocoon on the foliage of their host's food plant. Kauffman (1987) further found that *C. sonorensis* larvae attempting to construct cocoons on foliage of plant lines containing high levels of 2-tridecanone suffered extensive mortality (94–99% vs. 9–12% on *L. esculentum*). He demonstrated that consumption of 2-tridecanone by *H. zea* larvae parasitized by *C. sonorensis* had no effect on survival of the parasitoid and hypothesized that the mortality observed during cocoon spinning was due to intoxication resulting from direct contact of the fifth-instar parasitoid with 2-tridecanone contained in the tips of type VI trichomes of the resistant foliage. This study was undertaken to test that hypothesis by examining the toxicity of 2-tridecanone to *C. sonorensis*.

METHODS AND MATERIALS

Plant and Insect Rearing. The *C. sonorensis* stock colony was maintained at 27°C and 16:8 light–dark photoperiod on *H. zea* larvae reared on a corn–soya–milk (CSM) diet (Burton, 1970). Parasitoid progeny for our experiments were obtained by exposing late second instars of *H. zea* in lots of 10 for 8 hr to 4-day-old, mated *C. sonorensis* females. Parasitized larvae become immobilized after 10–12 days, shortly before the parasitoid larvae emerge from their host. Immobilized, parasitized larvae were collected for use in experiments. All experiments were conducted in 9 × 1.5-cm plastic Petri dishes with the above laboratory conditions.

Foliage Bioassays. A laboratory experiment tested the hypothesis that the glandular trichomes of resistant foliage do not adversely affect *C. sonorensis* larval survival and cocoon spinning, while a second experiment investigated the effect of removing type VI trichomes on the survival of *C. sonorensis* to adulthood. In both experiments, excised, fully expanded leaves from the upper third of the canopy of glasshouse-grown plants of each of the following five plant lines were used: *L. esculentum* cultivar Walter (susceptible), BC17 {backcross accession [(*L. esculentum* × PI 134417) × PI 134417], low resistance}, BC2 (backcross accession, moderate resistance), BC90 (backcross accession, high resistance), and PI 134417 (*L. hirsutum* f. *glabratum*, high resistance). These levels of 2-tridecanone-based resistance had been previously determined by gas chromatographic (GC) analysis to quantify the 2-tridecanone content of the type VI trichome tips and by bioassay with *M. sexta* (Kauffman, 1987). Where appropriate, glandular trichomes were removed by swabbing the foliage with cotton soaked in Triton X-155 (1 µl/500 ml water) and rinsed thoroughly with distilled water.

H. zea larvae were reared on diet and parasitized as described for the *C. sonorensis* stock colony. After 10–12 days, parasitized larvae become immobilized and take on a pink hue shortly before the parasitoid larva emerges to spin a cocoon and pupate on the foliage. These immobilized, pink, parasitized larvae were placed in groups of five onto the abaxial surfaces of 10–20 leaflets, which completely covered a moistened filter paper disk in the base of a 9 × 2.5-cm Petri dish. Petri dishes were sealed with Parafilm, held at 27°C, and checked on alternate days for proper moisture levels. The experiment was terminated 21 days after initial parasitization, and each parasitized larva was classified as producing one of the following: (1) a *C. sonorensis* larva that died prior to initiation of cocoon construction, (2) a *C. sonorensis* larva that died during the process of cocoon construction, or (3) a complete cocoon with or without an emerged adult. Petri dishes were set up in multiples of 10 *H. zea* (two groups of five larvae each per treatment) per day so that percentages of

each outcome for a given day (rep) were based on the combined data from two Petri dishes (10 larvae) containing similar foliage. The experiment was replicated 10 times for a total of 100 larvae/treatment.

Cocoon spinning by *C. sonorensis* fifth instars on *L. esculentum* and PI 134417 foliage was observed in detail to verify that the larvae were actually disrupting the glandular trichomes on the resistant foliage. The entire cocoon spinning process was observed for 20 larvae on *L. esculentum* and PI 134417 foliage, and for 19 larvae on moderately resistant BC2.

Toxicities of Methyl Ketones. 2-Tridecanone (Fluka Chemical Corp., Hauppauge, New York 11788) and 2-undecanone (Pfaltz and Bauer, Inc., Stamford, Connecticut 06902) were bioassayed to determine their effects on cocoon spinning by *C. sonorensis* larvae. Both compounds were determined to be greater than 99% pure by gas chromatography using a Durabond 15-m, 0.25-mm-ID DB-5 fused silica capillary column with a flame ionization detector. Analyses were run in triplicate using a 10 μ l injection volume, helium as a carrier gas, and a temperature program of 100–275°C increasing at 5°C/min. Acetone solutions covering a range of concentrations were prepared for each methyl ketone. To test each concentration, 0.5 ml of solution was pipetted on to 5.5-cm filter paper disks (Fisher Brand P-5 qualitative) and the solvent allowed to evaporate. Treated filter paper disks were placed in the bottom of a 60 \times 15-mm plastic Petri dish. Five immobilized, pink, parasitized *H. zea* larvae were placed on the filter paper in each dish and the dishes sealed with Parafilm. Fourteen days after initial parasitization of the host, parasitoid larvae were classified as having died prior to completion of cocoon spinning or as having successfully completed cocoon construction.

Concentrations were expressed as micrograms methyl ketone per square centimeter of treated filter paper. Six and eight concentrations of 2-tridecanone (range = 5.35–21.41 μ g/cm²) and 2-undecanone (range = 8.92–53.52 μ g/cm²), respectively, were tested, with each concentration replicated five times (total = 25 larvae/treatment). Controls consisted of confining larvae on acetone-treated filter paper. The number of parasitoid larvae that died following emergence but prior to completion of cocoon spinning was subjected to probit analysis using PROBIT procedure of SAS (SAS User's Guide, 1985) to determine LC₅₀ and LC₉₀ values and the corresponding 95% fiducial limits for each chemical. No mortality was observed in the controls.

Since type VI glandular trichomes of the highly resistant PI 134417 and resistant backcross accessions contain both 2-tridecanone and 2-undecanone, parasitoid larvae emerging from hosts encounter a mixture of these allelochemicals during attempted cocoon construction. Therefore, a second experiment was conducted to determine the effect of a combination of these chemicals on *C. sonorensis* survival. The general procedures were as described for the preceding experiment. A single concentration of 2-undecanone, at a level compa-

able to that found in the PI 134417 plant ($7.78 \mu\text{g}/\text{cm}^2$) was combined with the following three concentrations of 2-tridecanone: 8.75, 13.87, and $44.6 \mu\text{g}/\text{cm}^2$ treated surface. These represent the LC_{25} and LC_{50} values determined in the preceding experiment and the mean level found in the foliage of PI 134417 (Kennedy, 1986), respectively. In addition, each concentration of each chemical alone was bioassayed, and acetone-treated filter paper served as a control. On day 14 following parasitization, percentages of dead *C. sonorensis* larvae were calculated from the 10 parasitized hosts tested within each replicate of each treatment. Each treatment was replicated 10–12 times, and data were subjected to analysis of variance (ANOVA) with mean separation ($P \leq 0.05$) by Duncan's new multiple-range test.

RESULTS AND DISCUSSION

Mortality of fifth-instar *C. sonorensis* larvae during cocoon construction on normal foliage (i.e., with type VI trichomes intact) was greatly affected by tomato genotypes (Table 1). The percentage mortality following emergence of the parasitoid from its host larva but prior to completion of cocoon construction increased with increasing levels of 2-tridecanone-mediated resistance to *M. sexta*. The total mortality experienced by *C. sonorensis* larvae, pupae, and un-emerged adults was highest on the most resistant plant lines (PI 134417 and BC90), intermediate on lines with moderate and low levels of resistance (BC2 and BC17), and least on the susceptible *L. esculentum* cultivar. Kauffman (1987) reported the mean levels of 2-tridecanone in similarly aged plants grown concurrently with those used in this experiment, and under similar conditions in the same greenhouse, to be 1.0, 3.1, 20.1, and $16.5 \mu\text{g}/\text{cm}^2$ of abaxial leaf surface for BC17, BC2, BC90, and PI 134417, respectively. The latter value is considerably below the average of ca. $44 \mu\text{g}/\text{cm}^2$ abaxial leaf surface for PI 134417 reported by Kennedy and Dimock (1983) and observed in other studies (Kennedy, unpublished). We have found only trace amounts of 2-tridecanone associated with *L. esculentum* foliage (Fery and Kennedy, 1987).

Observation of *C. sonorensis* larvae following emergence from their hosts on PI 134417 and *L. esculentum* foliage revealed a rapid and pronounced effect of the PI 134417 foliage on cocoon spinning behavior (Figures 1 and 2). Characteristic weaving motions of the parasitoid's caudal end during cocoon spinning resulted in the rupturing of numerous type VI trichome tips and, hence, contact with the 2-tridecanone and 2-undecanone contained therein. Unlike on *L. esculentum* foliage, on PI 134417 foliage the parasitoid larvae manifested uncharacteristic periods of inactivity that increased in frequency and duration over time. Typically, only the loosely woven outer layers of the cocoons were completed before the larvae became completely moribund. On the PI 134417

FIG. 2. Incomplete cocoon and dead *C. sonorensis* larva on PI 134417 foliage.

foliage, death typically ensued within 2 hr of emergence from the host. However, parasitoid larvae transferred from PI 134417 foliage to untreated filter paper within 30 min of escape from the host were able to construct complete cocoons. On moderately resistant BC2 foliage, a larger proportion of the parasitoids survived to adult emergence (60% vs. 18% on PI 134417). Of those that died, many completed construction of the loose outer layers of the cocoon but died while weaving the tighter inner layers.

Differences in parasitoid mortality among plant lines were eliminated by removal of the type VI trichomes (Table 1). Although this trichome removal experiment was conducted following completion of the experiment involving foliage with intact trichomes, the plants used in both were grown concurrently under similar conditions. Thus, although the results of these experiments are not statistically comparable, they strongly suggest that the plant effects on *C. sonorensis* larvae are mediated through the glandular trichomes, which are known to contain significant quantities of the methyl ketones 2-tridecanone and 2-undecanone. These ketones are toxic to a number of insect species (Williams et al., 1980; Dimock et al., 1982; Kennedy and Sorenson, 1985; Farrar and Kennedy, 1987b; Lin et al., 1987).

Results of our bioassays of these methyl ketones indicate they are toxic to fifth-instar *C. sonorensis* larvae as well. In the probit analyses, the tests for heterogeneity gave chi-square values that were nonsignificant for both 2-tridecanone and 2-undecanone ($\chi^2 = 3.134$ and 3.237 , respectively; probability of greater $\chi^2 > 0.35$ for both). The LC_{50} and LC_{90} values indicate that 2-tridecanone is approximately three times more toxic to *C. sonorensis* larvae than is 2-undecanone (Table 2). These values for 2-tridecanone represent only 31 and

53%, respectively, of the 44.6 µg of 2-tridecanone per cm² of PI 134417 foliage reported by Kennedy and Dimock (1983), but 84 and 143%, respectively, of the 2-tridecanone levels found in PI 134417 foliage grown concurrently with the foliage used in this study (Kauffman, 1987). Bioassays of mixtures of 2-tridecanone and 2-undecanone provided no evidence for synergism in toxicity to *C. sonorensis* (Table 3). This is in contrast to the synergism observed in toxicity of the mixture to the lepidopterous species *H. zea* (Farrar and Kennedy, 1987b), *Spodoptera exigua* and *Keiferia lycopersicella* (Lin et al., 1987).

Our results support the hypothesis that 2-tridecanone is responsible for the observed mortality of *C. sonorensis* larvae on the resistant foliage. First, par-

asitoid mortality on foliage of the various plant lines was positively associated with their level of 2-tridecanone-mediated resistance to *M. sexta*. Second, removal of the 2-tridecanone-containing glandular trichomes from the foliage eliminated the detrimental effects of the various plant lines on *C. sonorensis*. Finally, the symptoms of intoxication manifested by *C. sonorensis* larvae in response to levels of 2-tridecanone on filter paper similar to those associated with PI 134417 foliage were identical to those manifested on PI 134417 foliage.

Although the toxicity of 2-tridecanone to *C. sonorensis* and *H. zea* is similar [$LC_{50} = 13.9$ and $17.1 \mu\text{g}/\text{cm}^2$ treated surface, respectively (Dimock et al., 1982)] in treated filter paper bioassays of the type used in this study, on resistant foliage *C. sonorensis* is affected to a much greater degree than its host, *H. zea*. Whereas 82% mortality was observed among *C. sonorensis* spinning cocoons on PI 134417 foliage, only about 20% of neonate *H. zea* larvae placed on or hatching from eggs incubated on PI 134417 foliage die. Many of the remaining larvae manifest symptoms of acute toxicity (convulsions, paralysis) but subsequently recover. Unlike fifth-instar *C. sonorensis* larvae, which disrupt numerous type VI trichomes and directly contact the 2-tridecanone contained therein, neonate *H. zea* are very small and rarely discharge type VI trichome tips before receiving a sublethal but narcotizing dose of 2-tridecanone from the fumes that surround the resistant foliage. These narcotized larvae subsequently recover, apparently completely, and are able to tolerate exposure to much higher levels of 2-tridecanone with no apparent ill effects (Dimock and Kennedy, 1983; Kennedy, 1984). This recovery appears to be related to the induction of elevated levels of cytochrome P-450, which results from exposure of *H. zea* eggs or larvae to 2-tridecanone or to PI 134417 foliage (Kennedy et al., 1987a).

The differential effects of 2-tridecanone-mediated resistance to *M. sexta* and *L. decemlineata* on *C. sonorensis* and *H. zea* are such that the suppressive effects of the parasitoid on the *H. zea* larval population will be reduced relative to those observed on tomato lines lacking 2-tridecanone-mediated resistance. In addition to a reduced level of parasitization of *H. zea* larvae by *C. sonorensis* on resistant foliage (Kauffman, 1987), few parasitoid larvae emerging from hosts and attempting to pupate on 2-tridecanone-laden foliage will survive to adult, thus precluding a population response by *C. sonorensis* to increases in *H. zea* larval populations on *M. sexta* resistant tomato lines. In areas where *C. sonorensis* is important in the natural biological control of *H. zea*, the use of 2-tridecanone-mediated resistance to *M. sexta* and *L. decemlineata* would be undesirable.

PATTERN OF VOLATILE COMPOUNDS IN DOMINANT AND SUBORDINATE MALE MOUSE URINE

SCOTT HARVEY, BOZENA JEMIOLO, and MILOS NOVOTNY

*Department of Chemistry
Indiana University
Bloomington, Indiana 47405*

(Received February 8, 1988; accepted October 24, 1988)

Abstract—The urinary volatiles from dominant and subordinate male mice were chromatographically compared, both immediately and seven days after dominant-subordinate relationships between pairs were formed. Statistical comparison of the peak areas of volatile constituents present in male urine revealed that 16 urinary compounds exhibited substantial concentration differences depending upon social status of the animals. Urinary dihydrofurans, ketones, and acetates exhibited a significant, long-term (seven-day) decrease in the urine of subordinates when compared to control and dominant males. Two sesquiterpenic compounds, α - and β -farnesene, were elevated only in the dominant urine one week after dominance was established. 2-(*sec*-Butyl)-4,5-dihydrothiazole was found in higher concentration in bladder or excreted urine of dominant males when compared to subordinates. Of the 16 compounds subjected to statistical analysis, four exhibited hormonal dependency: α - and β -farnesene, dehydro-*exo*-brevicommin, and 2-(*sec*-butyl)-4,5-dihydrothiazole. Neither dehydro-*exo*-brevicommin nor 2-(*sec*-butyl)-4,5-dihydrothiazole was present in the urine of immature and castrated males. Testosterone treatment restores their presence in male urine. Also, α - and β -farnesene were absent in the urine of immature males and significantly reduced in the urine of castrated males. The absence of α - and β -farnesene in bladder urine suggests that one of the sex-accessory glands may be the site of their origin.

Key Words—Pheromones, urinary volatiles, capillary gas chromatography, house mouse, social status.

INTRODUCTION

Mouse urine has been shown to be a rich source of olfactory cues that elicit changes in the reproductive behavior and physiology of recipient animals (Bronson, 1974). The male urinary pheromones induce the pregnancy block, estrus

synchronization, puberty acceleration, sexual attraction, and intermale aggression. These pheromones are androgen-dependent (Bronson and Whitten, 1968) and are not present in the urine of castrated mice (Bruce, 1965). Social subordination suppresses gonadal function in male laboratory mice (Bronson, 1973) and brown lemmings (Huck *et al.*, 1981), inhibits scent marking (Desjardins *et al.*, 1973), suppresses the ability of male urine to accelerate the onset of puberty in females (Lombardi and Vandenberg, 1977), and decreases the ability of the urine to cause pregnancy blockage (Huck, 1982).

Male mouse urine contains well over 100 volatile components; however, only a small number of these show a dependency on the male hormones (Novotny *et al.*, 1980). During our investigation of urinary volatiles by high-resolution, gas-phase analytical techniques, we observed that castration eliminates 2-(*sec*-butyl)-4,5-dihydrothiazole and dehydro-*exo*-brevicommin in male urine (Schwende, 1982; Novotny *et al.*, 1980). Testosterone supplementation can renew the normal concentrations of these compounds in castrate male urine (Novotny *et al.*, 1984). Both substances have been synthesized (Prodan, 1986; Wiesler *et al.*, 1982).

Studies of the behavioral activity of 2-(*sec*-butyl)-4,5-dihydrothiazole and dehydro-*exo*-brevicommin revealed that they elicit vigorous and persistent antagonistic behavior from male mice (Novotny *et al.*, 1985). When both compounds are added to castrate male urine, they create an olfactory signal that attracts females (Jemiolo *et al.*, 1985) and has the ability to abolish the suppressive effect of high caging density on the estrous cycle (Jemiolo *et al.*, 1986).

While it has long been assumed that urinary constituents, in a qualitative or quantitative sense, may signal the dominance status of male rodents, no chemical data on the subject have been reported at this date. The goal of the present study was to quantify urinary volatile constituents under various social conditions and rationalize these findings with respect to hormonal processes.

METHODS AND MATERIALS

The ICR/Alb albino mice used in the experiments were initially mated pairs purchased from Ward's Natural Science Establishment, Inc. (Rochester, New York), which were then randomly bred closed-colony. All animals were maintained at $21 \pm 0.2^\circ\text{C}$, 50–70% humidity, and a 12-hr light/12-hr dark daily regime (lights on at 0600 hr). Purina mouse chow and water were supplied *ad libitum* throughout the experiment. Bedding was changed weekly.

Prior to the social rank test, each male was maintained in social isolation from 25 days of age. At the time of the experiment, the animals were 90–100 days of age. The control urine (1 ml) was collected from each male prior to beginning the rank test. Next, dominance or subordination was established by

pairing two males in a neutral arena for 10 min on each of 10 consecutive days. Males were originally paired so that neither male weighed over 2 g more than his partner. An animal was classified as dominant if its daily chase-attack score was significantly higher (chi-square test; employing a 0.01 confidence interval) than that of the other member of the pair. Only males displaying a stable dominant-subordinate relationship during the 10 ranking tests were used. Eleven dominant and 11 subordinate males served as urine donors.

On the first day after completion of the social test, the first collection (collection 1) of urine from dominant and subordinate males took place. After first collection, the animals were kept in the home cage, undisturbed for the next six days. The second collection (collection 2) took place seven days after the social rank test was finished. One milliliter of urine was collected from each dominant and subordinate male during both collection periods. Two dominants and two subordinates served as bladder urine donors. Urine was collected directly from the bladder using needle and syringe. Two samples of bladder urine (1 ml of each) from dominant and subordinate males were analyzed. Subsequently, all tested animals were sacrificed, and the body, adrenal, and preputial glands, the seminal vesicle plus coagulating glands, and testes were dissected out and weighed.

Urine samples were also collected from immature and castrated males, as well as the castrates with testosterone. Three 1-ml urine samples were collected from 21 immature males when they were 21 days of age. In addition, nine immature males were castrated and housed in a group of three per cage until they reached the age of 90 days. At this time, three 1-ml samples of castrate urine were collected over three consecutive days. Four additional 21-day-old males were castrated and housed in a group of two per cage. At the age of 90 days, a testosterone capsule (4 mm in size) was implanted in each animal, using the technique described by Moore (1981) and Boyer *et al.* (1988). Ten days later, 4 ml of urine was collected from these testosterone-treated animals.

For a single chromatographic analysis, 1-ml urine samples were used. The number of chromatographic analyses for each type of urine corresponded with the number of milliliters for collected urine.

All urine samples were collected on a block of Dry Ice and immediately stored at -20°C . Each collection period lasted 6 hr and started the same time each day, *i. e.*, from 0900 to 1500 hr.

The urinary volatiles of all investigated samples were analyzed by capillary gas chromatography and identified by combined capillary gas chromatography-mass spectrometry, following the procedures described by Novotny *et al.* (1974) and Schwende *et al.* (1986). Additional verification of the chemical identity was based on methane and isobutane chemical ionization spectra. The identities of the sesquiterpenes were further confirmed by coinjections of the authentic compounds. *E,E*- α -Farnesene was synthesized (Negishi and Matsushita, 1984),

and *E*- β -farnesene was isolated from the oil of chamomile (Murray, 1969; Sorm *et al.*, 1949, 1951).

Statistical comparisons of the concentrations of excreted volatiles were made using one-way analysis of variance (ANOVA; *F* at $P < 0.05$) with post-hoc comparison by Duncan's new multiple-range test (*t* at $P < 0.02$) (Zar, 1974).

RESULTS AND DISCUSSION

The design of the experiment reported here was based on a series of our observations indicating that the concentrations of certain urinary volatile metabolites in male mouse urine were changed in response to testosterone levels (Novotny *et al.*, 1980). The observation of some authors that dominant animals tend to have higher levels of testosterone than subordinates (McKinney and Desjardins, 1973; Edwards and Rowe, 1975; Rose *et al.*, 1975) provided further incentive for this study. Laboratory evidence also indicates that male mouse urine has an odor indicative of social status (Jones and Nowell, 1973a). The above information has led to the present investigations of the urinary volatiles of trained fighters and subordinates.

The capillary gas chromatograms shown in Figure 1 are representative of the substance profiles obtained from bladder and externally voided urine of male mice. The list of compounds identified in these profiles is provided in Table 1. Sixteen volatiles exhibited statistically significant ($P < 0.02$) changes in concentration, depending on social status of animals or their endocrinological conditions. They have been subsequently identified as various dihydrofurans, ketones, acetates, dehydro-*exo*-brevicomine, 2-(*sec*-butyl)-4,5-dihydrothiazole, and the sesquiterpenes, α - and β -farnesene.

As seen in Figure 2A, the concentration of all selected dihydrofurans, ketones (except peak 10), and acetates are drastically decreased in the urine of subordinates collected immediately after social rank test (collection 1). Maintenance of all these volatiles at very low concentrations was still observed in the urines collected a week after the social rank test was completed (collection 2).

Urine of dominant males contained the dihydrofurans and acetates in concentrations similar to control animals, regardless of the time of collection (Figure 2B). A significant decrease of urinary ketones was observed only for peaks 7, 8, and 11, during either the first or second collection. While peak 10 exhibited no change of concentration in subordinate urine, it showed a trend to increase its level in dominant urine during both periods of collection.

The concentrations of α - and β -farnesene dropped significantly in both dominant and subordinate urine immediately after the social rank test (collection

1; Figure 2A,B). Only in dominant urine obtained during the second collection did both sesquiterpenes show a dramatic increase in concentration when compared to control and subordinate animals (Figure 2A,B).

Social status of the males did not influence the dehydro-*exo*-brevicommin concentration (Figure 2A,B). However, the concentration of 2-(*sec*-butyl)-4,5-dihydrothiazole dropped significantly in the urines of subordinates during both

collection periods (Figure 2A). The low level of this substance in dominant male urine was not found till some time after the social rank test (Figure 2B).

Our detailed chemical investigations of urine from immature males, adult intact males, castrate males, and castrated animals with testosterone implants clearly indicate that four of the selected volatile compounds are the most interesting with respect to hormonal function and social status of mice. These compounds are α -farnesene, β -farnesene, dehydro-*exo*-brevicommin and 2-(*sec*-butyl)-4,5-dihydrothiazole (Table 2). None of these four compounds were observed in the urine of immature males. The remaining 12 of the 16 selected compounds were always present in the urine from immature males, although at a low concentration. Castration reduced the levels of α - and β -farnesene and completely depressed the concentrations of dehydro-*exo*-brevicommin and 2-(*sec*-butyl)-4,5-dihydrothiazole (Table 2). Ten days of testosterone treatment reduced the levels of both sesquiterpenes in the male urine, when compared to intact and castrated males, and partially restored the presence of dehydro-*exo*-brevicommin and 2-(*sec*-butyl)-4,5-dihydrothiazole (Table 2). The decrease of α - and β -farnesene to the value below 1.0 (arbitrary units) was previously observed only for subordinate male urine at collection 1 (β -farnesene = 0.4 ± 0.2 , and α -farnesene = 0.7 ± 0.4).

Dehydro-*exo*-brevicommin was found at a similar concentration in both

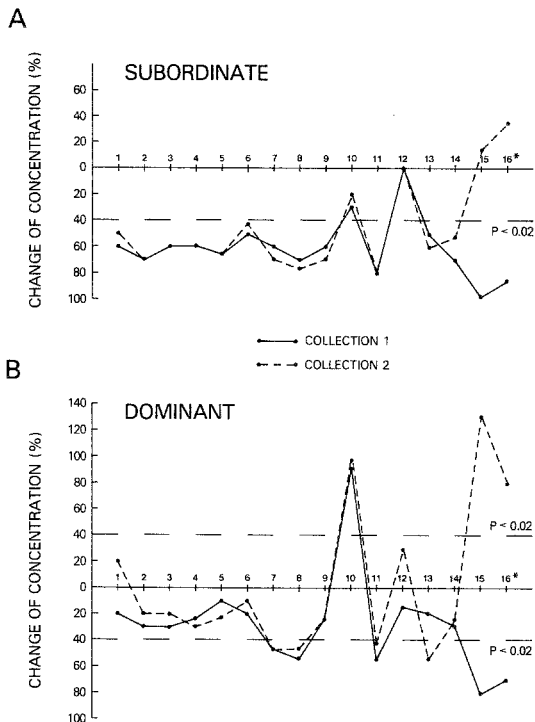

FIG. 2. (A and B). Effect of social status and the time of urine collection on the levels of urinary volatile constituents. Percentage differences in the peak areas of urinary dihydrofurans (peaks 1–3), acetates (peaks 5 and 6), ketones (peaks 4, 7–11, and 14), dehydro-*exo*-brevicomine (peak 12), 2-(*sec*-butyl)-4,5-dihydrothiazole (peak 13), and sesquiterpenes (peaks 15 and 16) are seen between collection 1 and collection 2 for (A) subordinate and (B) dominant males.

dominant and subordinate bladder urines, although at a significantly higher level when compared to control, excreted urine. 2-(*sec*-Butyl)-4,5-dihydrothiazole was present in the bladder urine of subordinate and dominant males at concentrations comparable to those found in excreted urine, but dominant bladder urine contained significantly more 2-(*sec*-butyl)-4,5-dihydrothiazole than did the bladder urine of subordinates (Table 2).

The bladder urine of neither dominant nor subordinate males contained α - and β -farnesene (Figure 1; Table 2).

There were no significant differences in the body weights and the weights of seminal vesicles plus coagulation glands between control, dominant, and subordinate males (Table 3). In marked contrast, the dominant animals had significantly greater preputial glands when compared to subordinate and control

reflect the circulation of FSH, LH, and corticosteroids in the plasma. Both FSH and LH were found to be depressed in the plasma of dominant and subordinate male mice after initial pairwise fights (Bronson, 1973). According to Bronson *et al.* (1973), FSH returned to the control level after several days in the dominant males, but remained depressed in the subordinate males. LH showed periodic, fluctuating circulation in the plasma of both dominant and subordinate animals.

The absence of α - and β -farnesene in bladder urine suggests that these sesquiterpenes may originate from the sex-accessory glands. The preputial glands have long been considered a possible site for the production of aggression and sex-related signals (Aron, 1979; Caroom and Bronson, 1971). Territorial marking is certainly of paramount importance for the establishment of social and/or sexual dominance. Territorial marking may be associated with aversive properties of the marker. It has been shown that the urine from dominant males possessed greater potency than that from subordinate males in aversion trials (Jones and Nowell, 1973a,b). The androgen-dependent aversive pheromones were shown to be absent in bladder urine (Jones and Nowell, 1973a,b, 1974). Testosterone treatment restored the aversive efficacy of urine in castrated males with a five-day latency, thus suggesting the involvement of some androgen-dependent tissue rather than that of an androgen-excreted metabolite (Jones and Nowell, 1974; Mugford and Nowell, 1970).

Since dehydro-*exo*-brevicommin and 2-(*sec*-butyl)-4,5-dihydrothiazole are clearly present in the bladder urine, we do not expect these compounds to be the aversion-eliciting compounds. We know that these two substances, when added to castrate urine, are sufficient to elicit increased aggressiveness of trained fighters (Novotny *et al.*, 1985). Interestingly, we find that 2-(*sec*-butyl)-4,5-dihydrothiazole has more than double the concentration in dominant bladder urine when compared to subordinate bladder urine (Table 2). The addition of preputial gland secretion to bladder urine is reported to induce further aggressiveness of fighter males (Jones and Nowell, 1973b). It is thus possible that α - and β -farnesene are the constituents that potentiate the known effectiveness of dehydro-*exo*-brevicommin and 2-(*sec*-butyl)-4,5-dihydrothiazole in eliciting aggression.

In agreement with observations by others (Bronson and Eleftheriou, 1964; Bronson, 1973; Lloyd, 1972), dominant males from our experiment exhibited larger preputial glands than did subordinates. The increase in concentrations of α - and β -farnesene that was established one week after dominance thus coincides with the increase in the weight of preputial glands. The low concentration or absence of these compounds in castrate or immature male urine might support the notion that production of these sesquiterpenes is androgen-dependent.

A significant decrease of α - and β -farnesene in castrated males with testosterone supplementation could have been caused by surgical stress or occa-

sional stressful encounters between castrated animals. The constant release of testosterone from the capsule for a period of 10 days and social interaction between testosterone-treated castrates could have a similar effect on the production of α - and β -farnesene to that observed for intact males (after the rank test was finished), when both sesquiterpenes dropped significantly in both dominant and subordinate males.

It is interesting that α - and β -farnesene are known in nature to elicit a variety of responses in insects (Bowers *et al.*, 1972; Edwards *et al.*, 1973; Vander Meer *et al.*, 1981). Based on the chemical data presented here, extensive behavioral testing of these terpenes in mice should be a subject of future studies.

EUPATORIOCHROMENE AND ENCECALIN, PLANT GROWTH REGULATORS FROM YELLOW STARHISTLE (*Centaurea solstitialis* L.)

GLORY B. MERRILL

Western Regional Research Center
United States Department of Agriculture
Albany, California 94710

(Received September 20, 1988; accepted October 27, 1988)

Abstract—Two chromenes, eupatoriochromene (1) and encecalin (2), have been isolated from yellow starthistle (*Centaurea solstitialis* L.). Both chromenes retard seed germination and reduce radicle and hypocotyl growth of weed and crop plant seedlings. In addition, 1 increases adventitious root formation of mung bean cuttings.

Key Words—Yellow starthistle, *Centaurea solstitialis*, chromenes, eupatoriochromene, encecalin, benzopyrans, allelopathy, plant growth regulator.

INTRODUCTION

Yellow starthistle (*Centaurea solstitialis* L.) is an aggressive noxious weed in the western United States and other parts of the world (Koehler, 1965; Sunderland, 1976; Maddox, 1981; Maddox et al., 1985; Maddox and Mayfield, 1985). Maddox et al. (1985) showed that the plant germinates during the winter rains and continues to grow and is plentiful until spring rain ceases. As soil moisture decreases, mortality increases, but even in the summer droughts of California, yellow starthistle is abundant. This annual herb spreads rapidly and, like many *Centaurea* spp., it is suspected of being allelopathic. *C. solstitialis* has been reported to contain alkaloids (Mamedov, 1956), polyphenols (Masso et al., 1979; Kamanzi and Raynaud, 1976), terpenoids (Cassady and Hokanson, 1978; Buttery et al., 1986), and sesquiterpene lactones (Theissen et al., 1969; Zarghami and Heinz, 1969; Mukhametzhonov et al., 1972; Cassady et al., 1979; Merrill and Stevens, 1985). This paper reports the first isolation from a *Cen-*

taurea spp. of the two chromenes, eupatoriochromene (**1**, desmethylencecalin, 2,2-dimethyl-6-acetoxy-7-hydroxybenzopyran, EUP) and encecalin (**2**, 2,2-dimethyl-6-acetoxy-7-methoxybenzopyran, ENC) (Figure 1).

Chromenes have been previously isolated from some members of the Asteraceae family (Bjeldanes and Geissman, 1969; Bohlmann and Grenz, 1970, 1977; Hegnauer, 1977; Wisdom and Rodriguez, 1982; Klocke et al., 1985; Proksch and Rodriguez, 1983, and references therein). They have been reported to be insecticidal (Proksch et al., 1983; Klocke et al., 1985; Wisdom et al., 1983), and they exhibit antifeedant (Wisdom et al., 1983) and antijuvenile hormone (Bowers et al., 1976) activity in insects. However, none have been reported to have plant growth regulatory activity. This paper reports the plant growth regulatory activity of eupatoriochromene (**1**) and encecalin (**2**).

FIG. 1. Structures of compounds **1-7**.

METHODS AND MATERIALS

Plant Material. Aerial parts of yellow starthistle were mowed, dried, and baled at the University of California at Davis, California. The air-dried plant was then ground in a hammermill through a $\frac{1}{8}$ -in. screen.

Isolation and Identification. The ground plant material was extracted in a large Soxhlet extractor with distilled hexanes for two days. After evaporation of solvent, the dark oily residue was then partitioned between petroleum ether, bp 40–60° (Skelly F)–benzene (1:1) and methanol–H₂O (4:1). The aqueous layer was concentrated *in vacuo* and chromatographed on silica gel column, eluting with Skelly F–ether (1:1). The first fraction was repeatedly chromatographed on a rotary preparative thin-layer chromatotron (Harrison Research) using Skelly F–ether (5:1) to give the two chromenes, eupatoriochromene (1) and enecalin (2). The chromenes were synthesized according to a procedure by Steelink and Marshall (1979). Physical properties (¹H]- and [¹³C]NMR, UV, MS, GC, and TLC) of the isolates were identical to those of the synthetic chromenes.

Seed Germination Bioassay. Twenty-five lettuce seeds (Black Seeded Simpson) were placed in Petri dishes containing 20 ml of 0.5% agar (Bacto-agar, Difco Laboratories, Detroit, Michigan) using 10, 50, and/or 100 ppm of test compound. All the test compounds had limited solubility in H₂O and 50 or 100 ppm was above saturation point. Seeds were incubated in the dark at 20–23°C and counted after three days. Seeds were considered germinated when the skin was broken and the radicle was greater than 1 mm long. Duplicates were run for each sample.

The effect of EUP and ENC on seed germination of red millet (*Panicum miliaceum*), alfalfa (*Medicago sativa*), barnyard grass (*Echinochloa crusgalli*), cucumber (*Cucumis sativus*, cv. Sumter), perennial ryegrass (*Lolium perenne* L.), and yellow starthistle was tested in a similar manner, but using 50 seeds per Petri dish in 50- and 100-ppm test solutions, respectively, and counted after three days. Where there was some effect, the dishes were read again after six days.

Seedling Growth Bioassay. For procedure A, the effect of test compound on radicle and hypocotyl growth of lettuce seedlings was tested at 0, 5, 10, 20, 40, 60, 80, 100, and 200 ppm in 20 ml of 0.5% agar solution. The appropriate amount of compound in ether was placed in each Petri dish. After ether was added to make 0.5 ml, the solvent was evaporated. Hot agar solution was added. The dish was heated on a hot plate to dissolve compounds, stirred, and cooled to room temperature. Twenty seeds were placed in each Petri dish containing test compound and grown in the dark at 20–23°C for three days. The lengths of the radicle and hypocotyl were measured to the nearest millimeter. Duplicates were run for each concentration.

For procedure B, the effect of some of the compounds on radicle and hypocotyl growth of barnyard grass, red millet, alfalfa, cucumber, yellow starthistle, green foxtail (*Setaria viridis*), annual morning glory [*Ipomoea purpurea* (L.) Roth] and soybean [*Glycine max* (L) Merr., cv. Lakota] was tested in a similar manner, but using pregerminated seedlings. Seeds were germinated to 1–3 mm on 0.5% agar in the dark at 20–23°C. Seedlings of equal length were then transferred into Petri dishes containing test compounds and grown as before for three to five days.

Mung Bean Cutting Bioassay. Mung bean (*Phaseolus aureus* Roxb) seeds were sterilized and grown in sterile soil for seven days in a growth chamber with a 16-hr day at 23°C and 8-hr night at 18°C. Cuttings were made 2½–3 cm below cotyledons and placed in vials containing 10 ml of distilled water, 100 µl acetone, and 0, 10, 20, 40, or 80 ppm eupatoriochromene. Two cuttings were placed in each vial. Three replicates of each concentration were made. Distilled water was added to each vial every 24 hr to maintain 10 ml. After 12 days in the growth chamber, the number of roots were counted and averaged over the replicates. A similar bioassay, but without acetone, was also done in duplicate.

RESULTS AND DISCUSSION

Seed Germination. The effect of eupatoriochromene, enecalin, and their precursors **4** and **5** and isomeric chromene **3** and its precursors **6** and **7** was tested on the germination of lettuce seeds. Eupatoriochromene inhibits germination at 100 ppm and enecalin at 10 ppm or above (Table 1). Compounds **3–7** do not retard germination at 100 ppm. The apparent inhibitory effect of chromenes **1** and **2** thus cannot be attributable to their precursors or to the chromene ring alone.

Germination of other seeds was also tested (Table 1). Germination of alfalfa and cucumber is not inhibited by either eupatoriochromene or enecalin at 100 ppm, but barnyard grass is slightly retarded at that concentration in ENC. In addition, red millet and perennial ryegrass are both inhibited at 50 ppm (three days). In each case where inhibition is observed, ENC is more effective than EUP. The initial inhibitory effect observed in red millet and barnyard grass, however, is reduced with increasing time until germination is equal (six days), within experimental error, to that of control. The effect of enecalin and eupatoriochromene is therefore retardation of rate of germination of seeds, not inhibition. The amount of retardation caused by compounds **1** or **2** is dependent upon seed species and amount of time elapsed.

Seedling Growth Bioassay. Preliminary testing of seedling growth was done on lettuce using procedure A. In these tests, EUP slightly increases radicle and

hypocotyl growth at low concentrations (1 and 5 ppm, Table 2) but reduces their growth at 20 ppm. This effect is similar to that previously shown by sesquiterpene lactones isolated from YST (Stevens and Merrill, 1985). EUP has limited solubility in aqueous medium; hence, it was tested in the presence of Tween 20, a surfactant. The inhibitory effect on lettuce growth is noticed at lower concentration (5 ppm vs. 20 ppm), consistent with the predicted greater solubility of **1** in water when Tween 20 is present. The effect of EUP thus is concentration dependent; inhibitory effect is observed at higher concentrations.

Germination experiments showed some retardation in the presence of com-

pounds **1** and **2**. Thus, to measure the effect of these compounds on seedling growth alone, further bioassays were performed using pregerminated seedlings of comparable length (procedure B). The effect of EUP on the growth of other weeds and crop plants is shown in Figures 2–6. The radicle growth of barnyard grass is reduced at 1 ppm; cucumber and green foxtail at 5 ppm, red millet at 10 ppm, annual morning glory at 20, and alfalfa at 80 ppm. The hypocotyl growth of cucumber and barnyard grass is retarded at 1 ppm; red millet and green foxtail at 5 ppm, soybean and alfalfa at 10 ppm, and annual morning glory at 40 ppm. The inhibitory effects on root and hypocotyl growth by eupatoriochromene above compare favorably with those exhibited by nordihydro-guaiaretic acid, an allelochemical from creosote bush (Elakovich and Stevens, 1985); radicle growth of alfalfa, barnyard grass, lettuce, green foxtail, and red millet is inhibited at 10 ppm, and hypocotyl growth of lettuce at 5 ppm and green foxtail at 80 ppm. The studies here thus show that EUP inhibits both radicle and hypocotyl growth of test plants, although not necessarily at the same rate.

Encocalin (Figure 7) seems to reduce radicle and hypocotyl growth of lettuce seedlings gradually, with the reduction being significant at 60 ppm. After factoring in its effect on germination by using pregerminated seedlings in the bioassay (Figures 7–9), ENC still retards radicle and hypocotyl growth, but at higher concentrations than EUP. For example, radicle growth of barnyard grass is reduced at 10 ppm (*vs.* 1 ppm in **1**) and red millet at 40 ppm (*vs.* 10 ppm in **1**). The effect of the methylation of the 7-hydroxyl group of chromene **1** to **2** thus is to lower the phytotoxicity of **1** towards seedling growth.

FIG. 7. Radicle growth in enecalalin.

FIG. 8. Hypocotyl growth in enecalin.

FIG. 9. Barnyard grass in enecalin.

Chromene **3** and chroman **5** were also tested to see what effect structural changes in the molecule has on biological activity. Again lettuce was used for preliminary testing. Red millet was also used because it was consistently one of the more sensitive seedlings among those previously tested. In these tests, both chromene **3** and chroman **5** (Figures 10 and 11) reduced hypocotyl growth as in tests with chromenes **1** and **2**, but at higher concentrations. However, chromene **3** and chroman **5** increase radicle growth for all concentrations tested. For example, at 80 ppm, radicle growth of red millet is 166% and 131% from compounds **3** and **5**, respectively. This is the reverse of the growth of retardation seen for EUP and ENC. The 7-hydroxyl (or 7-methoxyl) group and the double bond at the 3-position of EUP (or ENC) appear to be necessary for both hypocotyl and radicle growth retardation.

Root Formation. The enhancement of growth of some seedlings at low concentrations and the inhibition at higher concentrations seen in EUP is a characteristic growth pattern for auxins. Auxins are known to increase adventitious root formation. EUP was thus tested for this effect.

Mung Bean Cutting. EUP increases adventitious root formation of mung bean cuttings (Table 3). EUP increases the number of roots formed to over 200% of control at 20 ppm and above. When 1% acetone is used with the chromene, root promotion is observed at even lower concentrations (10 ppm).

FIG. 10. Lettuce in **3** and **5**.

FIG. 11. Red millet in 3 and 5.

As was noted previously, EUP is nonpolar and is very insoluble in water. Presumably, acetone improves solubility of the compound into water, making it more readily available to the cutting at lower concentrations, thus its effect is seen at lower concentrations. The root-promoting activity of EUP (287%, 20 ppm) is comparable to those of indoleacetic acid ($\approx 300\%$, 18 ppm; Goodwin, 1978) and dehydrocostus lactone ($\approx 340\%$, 25 ppm; Kalsi et al., 1981).

Another test for auxin activity is the lanolin paste method. A lanolin paste of an auxin applied to the side of young mung bean hypocotyl seedlings enhances growth and produces a pronounced curvature (Goodwin, 1978). Such a curvature was not observed upon application of 1 to mung bean hypocotyls. Thus, eupatoriochromene is not an auxin, but rather a plant growth regulator.

Effect of Eupatoriochromene and Encecalin on Yellow Starthistle (YST). The effect of EUP and ENC on YST is shown in Figure 12. Although germination is virtually unaffected by either EUP or ENC, both radicle and hypocotyl growth of seedlings are retarded by the two chromenes. In fact, YST is one of the most sensitive seedlings among those tested. Eupatoriochromene and encecalin affect its growth at 1 ppm and 10 ppm, respectively. Growth retardation increases with time.

When seedlings in the germination experiments were allowed to grow in the dark for several days, marked differences were noted in growth and mor-

TABLE 3. ADVENTITIOUS ROOT-FORMATION OF MUNG BEAN SEEDLINGS IN EUPATORIOCHROMENE

tality. The radicles and hypocotyls of seedlings in the control agar solution continued to elongate. There was one root per seedling. After a few days in the agar solutions containing test compounds, hypocotyl and radicle growth seemed to cease; the hypocotyl was short and fat; the radicle began to send out lateral roots (one to three per plant). These findings are consistent with previous experiments. For two weeks all seedlings lived. At 2½ weeks, the roots of seedlings in test solutions (50 ppm and 100 ppm) appeared to have darkened and some

FIG. 12. Yellow starthistle in 1 and 2.

seedlings were dying. At three weeks, all seedlings in the control and test solutions were dead. These experiments showed that the growth of YST is retarded in the presence of EUP and ENC, but that the plant can survive for an extended period in their presence.

The effects of eupatoriochromene (1) and enecalinalin (2) on the regulation of plant growth is the first report of chromenes having this type of activity. These compounds, together with the sesquiterpene lactones also found in YST and shown to possess plant growth activity (Stevens and Merrill, 1985), may play a key role in the allelopathic nature of these noxious weeds.

(Received August 1, 1988; accepted October 27, 1988)

Abstract—Electroantennograms (EAGs) were recorded from *D. ponderosae* to the enantiomers of the terpenoid bark-beetle pheromones *trans*-verbenol, *cis*-verbenol, verbenone, and the bicyclic ketals frontalin, *exo*-brevicommin, and *endo*-brevicommin. Male and female responses to enantiomers of the terpenoids differed significantly only at the two highest concentrations. No sex differences were seen in response to the bicyclic ketals. Significantly different responses to the enantiomers of all the chemicals, except frontalin, were noted over at least part of the dosage–response ranges tested. The negative antipode for all of the terpenoids elicited higher responses, while for the bicyclic ketals, the positive antipode effected the largest responses except for the two highest concentrations of *exo*-brevicommin.

Key Words—Olfaction, chirality, pheromone, semiochemical, enantiomer, bark beetle, electrophysiology, electroantennogram, mountain pine beetle, *Dendroctonus ponderosae*, Coleoptera, Scolytidae.

INTRODUCTION

Several species of pine trees in western North America are susceptible to the highly destructive attack of the mountain pine beetle (MPB) *Dendroctonus ponderosae* Hopkins. Colonization of the host tree depends on the beetles' responses to a complex blend of aggregation pheromones and host-tree kairomones (Vité and Gara, 1962; McCambridge, 1967; Pitman and Vité, 1969). *trans*-Verbenol, identified as the main female-produced pheromone (Pitman et al., 1968), is ineffective by itself (Pitman and Vité, 1969; McKnight, 1979), but when combined with the host-tree terpenes α -pinene or, especially, myrcene (Merrifield, 1972; Billings, 1974; Billings et al., 1976; Pitman et al., 1978), it becomes an effective aggregation pheromone. The addition of small quantities of *exo*-brevicommin to *trans*-verbenol plus myrcene (Borden et al., 1983a,b; Conn et al., 1983) produces a highly effective blend capable of attracting both sexes and mediating mass attack on several hard-pine species.

Investigations of chiral sensitivity in bark beetles began with *Scolytus multistriatus* when its aggregation pheromone was found to contain a three-component blend of (-)-enantiomers (Lanier et al., 1976). Since then, chiral discrimination has been shown in a number of other species of bark beetles, as well as in many other insects (Silverstein, 1979).

Research on optical isomers of pheromones of the mountain pine beetle began when significant differences were found in the behavior of the MPB to several semiochemicals, especially *trans*-verbenol (McKnight, 1979). Racemic verbenone and (-)-verbenone, but not (+)-verbenone, were found to have antiaggregative properties in both field and lab tests of beetles associated with lodgepole pine, *Pinus contorta* var. *latifolia* Engelmann (Ryker and Yandell, 1983). However, both enantiomers were active when tested on beetles from ponderosa pine, *Pinus ponderosa* Dougl. ex Laws. Male MPB from Oregon and British Columbia were found to produce predominantly (+)-*exo*-brevicommin and (+)-*endo*-brevicommin (Schurig et al., 1983). MPB in white pine in Idaho and lodgepole pine in Oregon responded best to (-)-*trans*-verbenol (Libbey et al., 1985).

Electroantennograms to racemic semiochemicals were recorded from MPB (Whitehead, 1986). The purpose of this paper is to report results of an investigation of antennal olfactory responses of the MPB to specific chiral pheromones, most of which have been determined to be important in the behavior of the insect.

METHODS AND MATERIALS

Adult beetles were obtained from infested bolts of lodgepole pine, *Pinus contorta* var. *latifolia* Engelmann, cut in Logan Canyon, Utah. After emergence, the beetles were sexed (Lyon, 1958) and placed on moist strips of filter

paper in Petri dishes at 5°C until use within 30 days after emergence. No differences in response were detected from beetles of different ages.

Electroantennogram (EAG) techniques were described previously (Whitehead, 1986) and were modified from those reported by Dickens et al. (1983). Briefly, EAGs were recorded with Ag-AgCl capillary electrodes filled with insect saline (Yamasaki and Narahashi, 1959). The recording electrode was placed into the distal end of the antennal club following prepuncture with an electrolytically sharpened tungsten needle. The indifferent electrode was placed into the head via the insect's mouth. EAG signals were amplified by a Grass P-16 amplifier and plotted on graph paper by an Apple II microcomputer. Chemicals were diluted in *n*-pentane in decade steps. A 10- μ l sample was placed on a 20- \times 6-mm filter-paper strip and inserted into an 80- \times 5-mm glass cartridge. The stimulus was made by orienting the cartridge toward the preparation, the tip being about 1 cm away, and by passing a 1-sec flow of air through the cartridge at 1.7 liter/min. Samples were presented from lowest to highest concentrations. Five replicates (different beetles) for each sex were made at each concentration. At least 4 min were allowed between stimuli, except at higher concentrations, when 5 min were allowed (Dickens et al., 1983; Whitehead, 1986). Racemic frontalin (10 μ g on filter paper) was used as a standard and was applied between every set of two stimulations of enantiomeric chemicals. EAGs were measured for negative amplitude and were shown as a percent of the mean of the two bracketing standards.

The semiochemicals used in this study are listed in Table 1. The optical purities of *trans*- and *cis*-verbenol and verbenone were determined using a chiral NEB column fitted gas chromatograph (Bradshaw et al., 1987). Optical purities of *exo*- and *endo*-brevicommin and frontalin were published by Mori (1974, 1975, 1985) and confirmed by chiral gas chromatography. The chemical purities of all the compounds were determined by gas chromatography. The temperature program initial value was set at 40°C for 2 min, increasing at a rate of 4°C/min until 150°C final temperature was reached (Whitehead, 1986).

Response to 10 μ l of *n*-pentane on filter paper was measured but not subtracted from the responses to the other chemicals. Responses to air were subtracted from the test-chemical reaction. We did a repeated-measures ANOVA (Myers, 1979) to control for the differences in measuring between beetles and across the same beetle.

RESULTS

EAGs obtained in response to the test chemicals were similar to those recorded previously from the MPB (Whitehead, 1986) and those from other species of beetles (Angst and Lanier, 1979; Grant and Lanier, 1982; Dickens, 1981; Dickens, et al., 1983). Increases in stimulus concentrations yielded increases in response amplitude (Figures 1-3). Saturation occurred at 100 μ g

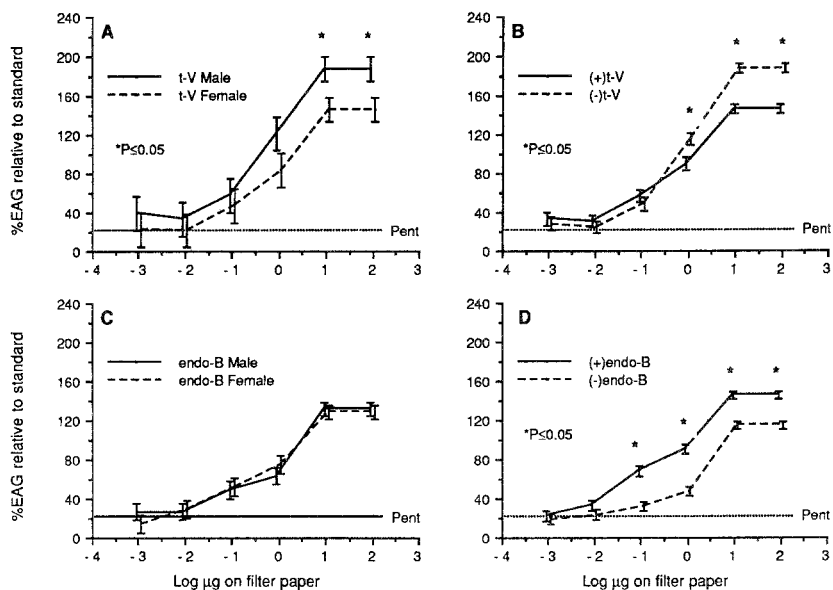

FIG. 2. (A,C) EAG-derived curves of MPB males (solid lines) and females (dashed lines) to serial dilutions of *trans*-verbenol and *endo*-brevicomin (enantiomeric responses averaged) and EAG-derived curves (responses from sexes averaged) to serial dilutions of (+)-enantiomer (solid lines) and (-)-enantiomer (dashed lines) of *trans*-verbenol (B) and *endo*-brevicomin (D). $N = 10$; error bars indicate \pm SEM. *Significant difference between responses at 0.05 level. t-V = *trans*-verbenol, endo-B = *endo*-brevicomin. Horizontal dotted line = pentane response.

for all chemicals except frontalin where, because of the limited amount of product on hand, the highest concentration tested was $10 \mu\text{g}$. The pentane control produced responses of $21.8 \pm 15.14\%$ (SE) of the frontalin standards (Figures 1–3). There were no significant differences between the male and female responses. The frontalin standard yielded 0.48 ± 0.01 mV (SE) from males and 0.49 ± 0.01 (SE) mV responses from females, which were also nonsignificant. Few responses to air were noted.

The analysis of the terpenoids showed that the males and females responded differently at each concentration level (Figures 1A,C and 2A). As the concentration of the terpenoids increased, there was usually a greater separation between the points on the curves. The analysis of the bicyclic ketals showed no differences by sex (Figures 2C and 3A,C) but did show a chemical by enantiomer interaction not found in the terpenoids.

Figures 1–3 indicate that the magnitude of the responses were dependent upon the chemical, its concentration, and its enantiomer. There were statistically different responses between the sexes at the two highest concentrations of all the terpenoids (Figures 1A,C and 2A). In all cases where sex differences were noted, the males showed the largest responses.

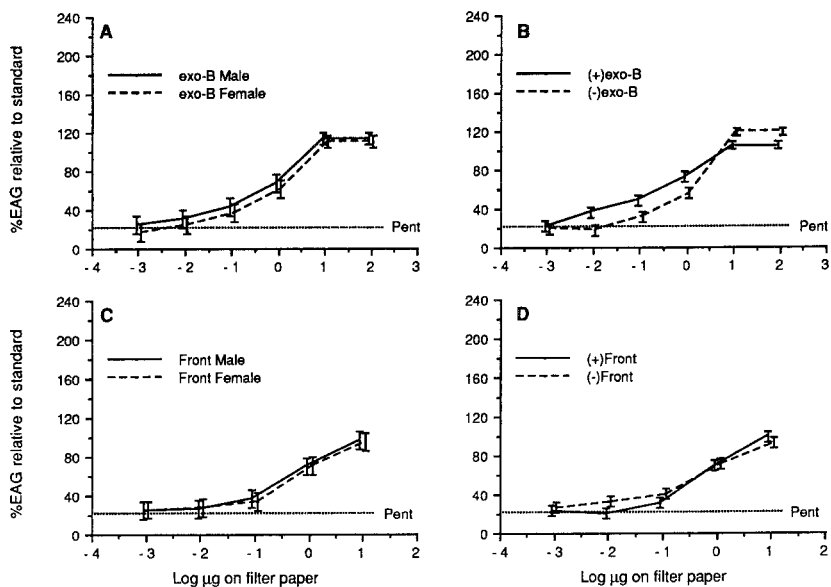

FIG. 3. (A,C) EAG-derived curves of MPB males (solid lines) and females (dashed lines) to serial dilutions of *exo*-brevicomin and frontalin (enantiomeric responses averaged) and EAG-derived curves (responses from sexes averaged) to serial dilutions of (+)-enantiomer (solid lines) and (-)-enantiomer (dashed lines) of *exo*-brevicomin (B) and frontalin (D). $N = 10$; error bars indicate \pm SEM. *exo*-B = *exo*-brevicomin, Front = frontalin. Horizontal dotted line = pentane response.

Figure 4A,B shows the values of the response averaged across concentration for sex, chemicals, and chirality. Figure 4A shows that frontalin was not significantly different from *exo*-brevicomin; however, both compounds were different from *endo*-brevicomin. The responses to the bicyclic-ketal enantiomers were statistically different from each other. Figure 4B, on the other hand, shows that both the sex and chirality factors for the terpenoids were different but that the overall responses to verbenone and *cis*-verbenol were not different from each other, while the response to *trans*-verbenol was different from those to verbenone and *cis*-verbenol when averaged across concentration. However, because of the interactions, these results could change for a given concentration level, e.g., in Figure 2B the responses to enantiomers were the same for the lowest concentrations but different for the highest concentrations.

Responses to the enantiomers of the terpenoids and the bicyclic ketals were more pronounced than the influence of the sex of the beetle. However, the analysis showed that no significant differences existed between responses to the frontalin enantiomers (Figure 3D). On the other hand, (+)-*exo*-brevicomin (Figure 3B), (+)-*endo*-brevicomin (Figure 2D) and (-)-verbenone (Figure 1B)

FIG. 4. Estimated means of the EAG responses by sex, chemicals, and enantiomers averaged over concentration. M = male, F = female, Fr = frontalinal, exo-B = *exo*-brevicommin, endo-B = *endo*-brevicommin, Verb = verbenone, c-Verb = *cis*-verbenol, t-Verb = *trans*-verbenol, (+) = (+)-enantiomer, (-) = (-)-enantiomer. $N = 180$ (sex), 120 (chemical), 180 (enantiomers). Vertical dashed lines indicate that the enclosed averaged responses should not be compared to the responses within the other dashed lines.

had the largest responses over most of their concentration ranges. (-)-*cis*-Verbenol (Figure 1D) and (-)-*trans*-verbenol (Figure 2B) showed significantly greater responses than their antipodes at the three highest concentrations. In general, responses to (-)-enantiomers were greater for the terpenes; while, by comparison, responses to (+)-enantiomers were greatest for the bicyclic ketals.

DISCUSSION

Our results confirm some of the findings of previous workers investigating the effects of chiral semiochemicals on the MPB both in laboratory and in field studies. McKnight (1979) found that the MPB responded significantly better to

(-)-*trans*-verbenol than to the (+)-antipode in white pine stands in Idaho and lodgepole pine stands in Oregon. This was supported by Libbey et al. (1985), who determined that males responded better to the (-)-antipode while females were attracted equally. Borden et al. (1987) indicated that both (\pm)- and (-)-*trans*-verbenol caused significant attraction of both sexes, while the (+)-enantiomer did not, and they determined by gas chromatographic analysis that females from British Columbia contained 65–87% of (-)-*trans*-verbenol.

Ryker and Yandell (1983) determined in field trapping that both sexes of the MPB showed significantly reduced attraction to the attractive mixture of *trans*-verbenol, myrcene, and α -pinene when exposed to either (-)- or (\pm)-verbenone in both ponderosa and lodgepole pine stands. However, their laboratory bioassay demonstrated that (\pm)-verbenone was effective in reducing the arrestment of male MPB and the number emitting attracting chirps, while either enantiomer would reduce arrestment. On the other hand, only the (-)-antipode was effective in reducing arresting chirps. They concluded that the antiaggregative effect of (-)-verbenone is not changed by the presence of its antipode in the racemic mixture. Verbenone is now recognized as an inhibitor of aggregation behavior in several bark beetle species (Borden, 1982). Borden et al. (1987) confirmed that verbenone was inhibitory to MPB males at several release rates in field studies.

The role of *cis*-verbenol is unclear in the biology of the MPB. Pitman et al. (1969) failed to find major quantities in either sex; however, it has been identified in female frass (Ryker and Rudinsky, 1982; Pierce et al., 1987). It was significantly more effective in eliciting EAG responses in male MPB than was *trans*-verbenol but not in females (Whitehead, 1986); however, in our current study, the opposite occurred, wherein males were slightly more sensitive to *trans*-verbenol than to *cis*-verbenol. The reasons for this disparity are unclear. Possibly the relative impurity of compounds (90%) used in the previous study (Whitehead, 1986), the low numbers of test animals ($N = 5$), or errors in recording in both studies could be contributing factors. In *Dendroctonus pseudotsugae*, *cis*-verbenol stimulates more generalized synergist cells (Dickens et al., 1984). The MPB may have similar cells, and if *cis*-verbenol fills the receptor sites on these cells in a similar fashion to *trans*-verbenol, then more or less equal responses may be expected from both compounds.

exo-Brevicomin is a female attractant at low concentrations (Conn et al., 1983; Rudinsky et al., 1974), but high release rates resulted in inhibition of male responses while intermediate doses yielded partial inhibition (Borden et al., 1987), thus suggesting that *exo*-brevicomin may be a multifunctional pheromone (Rudinsky et al., 1974). Analysis of male MPBs from Oregon and British Columbia showed that they produce predominantly (+)-*exo*-brevicomin and (+)-*endo*-brevicomin (Schurig et al., 1983). Their findings correlate positively with our observations that MPB antennal sensilla are more sensitive to (+)-*exo*-brevicomin than its antipode. However, field tests showed that the beetles seem

to be insensitive to chirality, in that they responded to racemic *exo*-brevicomin in a similar fashion as to the enantiomers (Borden et al., 1987).

The role of *endo*-brevicomin in the biology of the beetle is also unclear. It has been reported as a male-produced pheromone that acts as an antiaggregant similar to *exo*-brevicomin (Rudinsky et al., 1974). Ryker and Rudinsky (1982) suggested that high levels of both racemic *exo*- and *endo*-brevicomin may act as antiaggregative pheromones in lodgepole pine infestations. However, Borden et al. (1987) report that their unpublished experiments have failed to confirm any attractive or antiaggregative properties for *endo*-brevicomin in lodgepole pine forests. Our results showed that the (+)-enantiomer elicited significantly higher EAGs than its antipode and the enantiomers of *exo*-brevicomin. No other known field or laboratory studies have been carried out to date on the effects of *endo*-brevicomin enantiomers.

At low release rates, frontalin has been implicated recently as an aggregation pheromone in females, and at high release rates as an antiaggregative pheromone; furthermore, neither enantiomer was attractive at low rates, but they were inhibitory at high rates compared to the racemate (Borden et al., 1987), suggesting an additive effect of both enantiomers (Dickens et al., 1985). However, our results suggest that the beetle is incapable of detecting differences between the enantiomers at any concentration, and also, contrasting with the field data, both sexes had about the same sensitivity to frontalin (Whitehead, 1986) (Figure 3C).

A new series of experiments, being undertaken using extracellular recordings from individual antennal sensilla, may clarify some of the unanswered questions regarding semiochemical detection by the MPB.

Acknowledgments—We thank the following: Drs. J.C. Dickens and E.A. Dixon for their critical reviews of the manuscript, Dr. H. Wieser for supplying and analyzing some of the chemicals, and Dr. C. Rouse for verifying the chiral purity of the compounds. This project was supported in part by funds from the USDA-Forest Service, Intermountain Forest and Range Experiment Station, Ogden, Utah 84401; and from a Professional Development Grant (ATW), College of Biology and Agriculture, Brigham Young University.

CHARACTERIZATION AND ECOLOGICAL
IMPLICATIONS OF MIDGUT
PROTEOLYTIC ACTIVITY
IN LARVAL *Pieris rapae*
and *Trichoplusia ni*

ROXANNE M. BROADWAY

(Received September 20, 1988; accepted November 1, 1988)

Abstract—In their larval luminal midgut fluid, *Trichoplusia ni* (Lepidoptera: Noctuidae) and *Pieris rapae* (Lepidoptera: Pieridae) contain endopeptidases as their primary proteases. Neither species has detectable exopeptidase activity. Studies using enzyme-specific substrates and inhibitors demonstrate that the endopeptidases are serine proteinases (both trypsinlike and chymotrypsinlike) with histidine at the active site. Optimal pH for the tryptic and chymotryptic activity is 8.5 and 8.0, respectively, for *T. ni*. and 8.0 and 9.0, respectively, for *P. rapae*. The efficiency of proteolytic digestion (as measured by the rate of in vitro digestion of a standard protein by the midgut luminal fluid) is positively correlated with the larval dietary protein requirement and is significantly influenced by the ratios of tryptic to chymotryptic activity present in the gut lumen of these two species of Lepidoptera.

Key Words—*Pieris rapae*, *Trichoplusia ni*, Lepidoptera, Pieridae, Noctuidae, proteases, digestive enzymes, proteinase inhibitors, dietary protein requirement.

INTRODUCTION

One determinant of the success of herbivorous insects on specific host plant(s) is the ability to acquire essential nutrients in appropriate amounts. The digestive system in herbivores has adapted to specific food sources by (1) synthesizing

specific classes of digestive enzymes (Baker, 1981), (2) regulating the level of secretion of those enzymes (Broadway and Duffey, 1986a; Baker, 1977), and (3) maintaining the pH of the gut lumen within a relatively narrow range (Berenbaum, 1980) for optimal enzyme activity. For example, the cowpea-eating bruchid beetle has an acidic gut that secretes a thiol enzyme as its primary protease (Gatehouse et al., 1985), whereas the detritus-feeding larval caddisfly has a mildly basic midgut containing extremely high proteolytic activity (Martin et al., 1981), and larval *Heliothis zea*, a generalist herbivore, has a strongly alkaline midgut with relatively low proteolytic activity contributed primarily by a serine (trypsinlike) protease (Broadway and Duffey, 1986a). The general condition of the gut lumen (i.e., pH, ionic strength), and the class(es) and quantity of the intestinal digestive protease(s) determine: (1) the quantity and quality of protein that can be digested and, therefore, the level of nutrients available to the insect (Broadway and Duffey, 1986a, 1988); (2) the ability of naturally occurring inhibitors (common in plants) to block proteolytic digestion (Hilder et al., 1987; Broadway et al., 1986; Gatehouse et al., 1985); and (3) the susceptibility of insects to pathogens (Espinoza-Fuentes and Terra, 1987; Cha-Yun and Chen, 1982; Narayanan et al., 1976) and plant natural products (Mole and Waterman, 1987; Martin and Martin, 1984; Meisner et al., 1978; Goldstein and Swain, 1965). Thus, characterization of the midgut luminal milieu of herbivorous insects is necessary to gain insight into the acquisition of essential nutrients and to determine the physiological effects and limitations of phytochemicals that may modify digestion (e.g., phenolics, saponins, and proteinase inhibitors).

One group of phytochemicals that can significantly influence insect digestive physiology is the proteinase inhibitors. Plant proteinase inhibitors can effectively reduce proteolytic activity *in vitro* and significantly inhibit the growth of specific herbivorous insects (Hilder et al., 1987; Broadway and Duffey, 1986b). However, these inhibitors are only effective when susceptible digestive enzyme(s) and appropriate physiological conditions (i.e., pH, ionic strength) are present (Gatehouse et al., 1985).

Trichoplusia ni (Hübner), the cabbage looper, and *Pieris rapae* (L.), the imported cabbageworm, are major pests on a number of economically important agricultural crops. *T. ni* is a polyphagous herbivore, feeding on a broad spectrum of crops including cotton, cabbage, soybean, and tomato, whereas *P. rapae* is oligophagous, restricting its herbivory to plants in the family Cruciferae (Metcalf et al., 1962). All of these crops contain proteinase inhibitory activity, but the level of activity is highly variable (Broadway, 1988; Whitaker, 1981; Chen and Mitchell, 1973). Although there are extensive reports on behavior and host distribution of both of these species of Lepidoptera (Renwick and Radke, 1988; Maguire, 1984a,b; Gothilf and Beck, 1967; Shorey et al., 1962), no detailed information has been published on the digestive physiology of either species. This study presents information about the physiological condition and

protease profile of the larval midgut lumen of these two species of herbivorous Lepidoptera. The larval dietary protein requirement and the ability of specific proteinase inhibitors to reduce the activity of larval digestive enzymes *in vitro* are also described.

METHODS AND MATERIALS

Insects

All the insects used for this study were provided by Dr. A.M. Shelton, NYS Agricultural Experiment Station, Geneva, New York. The colony of *Trichoplusia ni* was established with individuals collected in the field in 1987. Larvae were reared to pupation on a pinto bean-based artificial diet (Shorey and Hale, 1965) in groups of 15–20 individuals per 8-oz wax-coated paper cup. The cups were placed in an environmental chamber maintained at 27°C, 70% relative humidity, with a photoperiod of 16:8 light–dark, until the larvae pupated. Groups of 60–100 pupae were placed in a $\frac{1}{4}$ -in. wire-mesh cylindrical cage (30 cm high \times 20 cm diameter), maintained in the environmental chamber. After eclosion, the adults were provided with 10% sugar water for food and waxed paper for oviposition. The waxed paper containing eggs was collected daily, divided into sections containing 15–20 eggs, and each section was stapled to the top of a diet cup. The neonates were provided with artificial diet *ad libitum*.

The laboratory colony of *Pieris rapae* was established from adults collected in the field in 1982 and was maintained as described by Webb and Shelton (1988). Larvae were reared to pupation on a high wheat germ-based artificial diet in groups of 30–40 individuals per 16-oz styrofoam cup. The cups were placed on their sides in an environmental chamber maintained at 21°C, 40% relative humidity, with a photoperiod of 16:8 light–dark, until the larvae pupated. Groups of 500 pupae were placed in a fine mesh cage (92 \times 70 \times 106 cm), in a greenhouse (25°C, 3200 lux light provided by a 2000-W metal halide lamp). The adults were provided with 10% sugar water containing 0.15% yellow food coloring for food and parafilm baited with a broccoli leaf for oviposition. The parafilm containing eggs was collected after a 1-hr oviposition period, surface-sterilized with 10% formalin, rinsed with sterile water, and air-dried. The parafilm was then cut into sections containing 50 eggs, and each section was placed in a cup containing artificial diet.

Isolation and Characterization of Proteolytic Enzymes

Proteolytic enzymes were isolated from the midgut lumen of fifth-instar larvae that were actively feeding on artificial diet to ensure optimal enzyme activity (Broadway and Duffey, 1986a). Whole midguts of 50–60 actively feeding fifth-instar larvae per species were quickly removed, wiped dry (to remove

external hemolymph), then placed in an ice-cold centrifuge tube. The midguts were gently homogenized to release all luminal fluid, then centrifuged at 20,000g, 4°C for 10 min, and the supernatant was analyzed for protease activity.

The survey of proteolytic activity in the midguts of fifth instar larval *P. rapae* and *T. ni* included assays for general protease activity, exopeptidase (carboxypeptidases A and B), and endopeptidase (chymotrypsin and trypsin) activity. Enzyme-specific substrates were used for activity determination of each enzyme.

General protease activity was measured using azocoll (Sigma Chemical Co., St. Louis, Missouri), a proteolytic substrate (Martin et al., 1981). A 50- μ l aliquot of insect enzyme (diluted 1:3 with 0.1 M phosphate buffer, pH 8) was mixed with 10 mg of azocoll in 167 μ l 0.1 M phosphate buffer, pH 8, and incubated at room temperature for exactly 15 min. The reaction was stopped by the addition of 1 ml 10 mM HCl. The solution was centrifuged for 30 sec in a microcentrifuge, then measured spectrophotometrically at 520 nm. Each test solution was replicated 10 times.

Exopeptidases. For the determination of carboxypeptidase A activity, 1 mM HPLA (hippuryl-L-phenylalanine, Sigma) in 0.05 M Tris buffer, pH 7.5, containing 0.5 M NaCl was used (McClure et al., 1964). A 100- μ l aliquot of supernatant from the gut homogenate (diluted 1:3 with buffer) was added to 2.9 ml substrate-buffer mixture, and activity was monitored spectrophotometrically at 254 nm for 3 min. Carboxypeptidase A from bovine pancreas (Sigma) was used as a standard. The assay was replicated three times.

Carboxypeptidase B activity was measured using 1 mM HA (hippuryl-L-arginine, Sigma), in 0.05 M Tris buffer, pH 7.5, containing 0.1 M NaCl (Folk et al., 1960). A 100- μ l aliquot of supernatant from the gut homogenate (diluted 1:3 with buffer) was added to 2.9 ml substrate-buffer mixture, and activity was monitored spectrophotometrically at 254 nm for 3 min. Carboxypeptidase B from porcine pancreas (Sigma) was used as a standard. The assay was replicated three times.

Endopeptidases. The determination of chymotrypsin activity required the use of 1 mM BTEE (benzoyl-L-tyrosine ethyl ester, Sigma; molar extinction coefficient of 964) (Hummel, 1959) in 50% MeOH mixed 1:1 with 0.04 M Tris buffer, pH 8.1, 0.01 M CaCl₂ (Walsh and Wilcox, 1970). A 25- μ l aliquot of supernatant from the gut homogenate (diluted 1:20 with buffer) was added to 2.9 ml of the substrate mixture, and enzyme activity was monitored spectrophotometrically at 256 nm for 3 min. Chymotrypsin from bovine pancreas (Sigma) was used as a standard. Each test solution was replicated at least three times.

For tryptic activity determination (Walsh, 1970), a 25- μ l aliquot of supernatant from the gut homogenate (diluted 1:20 with buffer) was added to 2.9 ml buffer (0.04 M Tris, pH 8.1, 0.01 M CaCl₂) containing 1.04 M TAME (*p*-

toluene-sulfonyl-L-arginine methyl ester, Sigma; molar extinction coefficient of 540) (Hummel, 1959). Tryptic activity was monitored spectrophotometrically at 247 nm for 3 min. Bovine trypsin (Sigma) was used as a standard. Each test solution was replicated at least three times.

Effect of Protease Inhibitors on Larval Proteolytic Activity. Inhibitors used for this study include: phenylmethylsulfonylfluoride (PMSF), which indicates the presence of serine at the active site (Gold, 1965); soybean trypsin inhibitor (STI), a naturally occurring trypsin inhibitor; *N*-tosyl-L-lysinechloromethyl ketone (TLCK), which indicates histidine at the active site of trypsin (Shaw, 1967); and L-1-tosylamide-2-phenylethyl-chloromethyl ketone (TPCK), which indicates histidine at the active site of chymotrypsin (Schoellman and Shaw, 1963). Solutions of individual inhibitors were prepared in 0.1 M phosphate buffer (for azocoll assays), or 1 mM HCl, and preincubated with an enzyme solution for 10 min at room temperature. Following this preincubation, the mixture was assayed for specific enzyme activity, using the appropriate substrate and buffer mixture (described above). Each assay was replicated at least three times.

Effect of Dietary Protein Concentration on Larval Growth

The effect of the concentration of dietary protein on the weight gain of larval *T. ni* and *P. rapae* was determined by allowing newly emerged neonate larvae to feed on control or test wheat germ-based diets until the majority of larvae feeding on the control diet developed to the second day of the fifth (ultimate) instar. Then all larvae, both controls and tests, were individually weighed. Each bioassay (20–40 larvae/cup; 3 cups/protein concentration; 4 protein concentrations/bioassay) for both species was replicated three times.

Statistics

All data were analyzed by the computer package SYSTAT (Systat, Inc., Evanston, Illinois) using the paired *t* test or ANOVA followed by orthogonal comparisons to determine the statistical significance at the 95% level.

RESULTS

General protease activity was readily detectable using a 1:3 dilution of the larval enzyme solution mixed with the substrate, azocoll. The rate of hydrolysis of azocoll by the diluted enzyme solution was significantly higher ($P < 0.001$, $r = 0.97$) for *P. rapae* than for *T. ni* (Table 1). [There was also a significant difference ($P < 0.001$, $r = 0.998$) between the rate of hydrolysis of azocoll by 80 $\mu\text{g/ml}$ of bovine trypsin and chymotrypsin (Table 1).]

There was no detectable exopeptidase (carboxypeptidase A or B) activity

TABLE 1. PROTEOLYTIC ACTIVITY IN MIDGUT LUMINAL FLUID FROM LARVAL *Pieris rapae* AND *Trichoplusia ni*

Enzyme	Substrate ^a	Activity
<i>P. rapae</i> (1:3 dilution)	Azocoll	104.4 ± 0.09 ^b
<i>T. ni</i> (1:3 dilution)	Azocoll	83.9 ± 0.04 ^b
Trypsin (80 µg/ml)	Azocoll	203.9 ± 0.2 ^b
Chymotrypsin (80 µg/ml)	Azocoll	165.1 ± 0.4 ^b
<i>P. rapae</i> (1:20 dilution)	TAME	13.5 ± 0.5 ^c
<i>P. rapae</i> (1:20 dilution)	BTEE	12.5 ± 2.8 ^c
<i>T. ni</i> (1:20 dilution)	TAME	26.3 ± 2.0 ^c
<i>T. ni</i> (1:20 dilution)	BETT	7.7 ± 0.7 ^c

^aSubstrates: azocoll = general proteolytic substrate; TAME = trypsin-specific substrate; BTEE = chymotrypsin-specific substrate.

^bActivity reported as mean change in OD/min ± SEM.

^cActivity reported as millimoles substrate hydrolyzed/min ± SEM.

in the guts of larval *T. ni* or *P. rapae*. However, the substrates for the endopeptidases, trypsin and chymotrypsin, were rapidly hydrolyzed by the midgut homogenates (diluted 1:20) prepared from these two species of insects (Table 1). Based on the rates of hydrolysis of the enzyme-specific substrates, the ratio of tryptic to chymotryptic activity for *T. ni* was 76:24, while the ratio for *P. rapae* was 52:48.

Enzyme activity relative to pH is shown in Figures 1 and 2. These data are reported as the rate of hydrolysis of substrate (millimoles per minute). For larval *T. ni* (Figure 1), optimal tryptic and chymotryptic activity occurs at pH 8.5 and 8.0, respectively. The optimal tryptic and chymotryptic activity from the luminal fluid of larval *P. rapae* (Figure 2) occurs at pH 8.0 and 9.0, respectively.

The ability to inhibit larval tryptic and chymotryptic activity was tested using specific inhibitors and was compared to the levels of inhibitor required to inhibit the activity of standard bovine trypsin and chymotrypsin. A 1 mg/ml solution of either STI or PMSF completely inhibited an 80 µg/ml solution of bovine trypsin (the uninhibited level of activity was 69 mmol TAME hydrolyzed/min), as measured by the TAME and azocoll assay (Table 2). However, the inhibition of tryptic activity from the guts of larval *T. ni* required 5 mg STI/ml to inhibit a 1:20 dilution of the enzyme solution by 92%, and 10 mg PMSF/ml inhibited the same enzyme solution by only 69% (Table 3), as measured by the TAME assay (uninhibited activity level was 33 mmol TAME hydrolyzed/min). When the 1:20 dilution of enzyme solution (tryptic activity producing

ity of the selected inhibitors to inhibit larval tryptic activity with that of the inhibition of bovine trypsin, even 5–10 times the amount of inhibitor that would result in 100% inhibition of bovine tryptic activity does not completely eliminate larval tryptic activity.

Bovine chymotryptic activity (80 μ g/ml resulted in hydrolysis of 30 mmol BTEE/min) was inhibited by 95.9% by the addition (1:1 mixture) of 1 mg TPCK/ml (azocoll assay) (Table 2). The mixture of *T. ni* (uninhibited activity was 54.5 mmol BTEE hydrolyzed/min) or *P. rapae* (uninhibited activity was 145 mmol BTEE hydrolyzed/min) enzyme solution (diluted 1:3) with a similar concentration of TPCK resulted in a 72% or 77% reduction in activity, respectively (Tables 3 and 4). A 10 mg/ml preparation of PMSF completely inhibited the chymotryptic activity for the two test species of insect (Tables 3 and 4).

For both species of Lepidoptera, there is a significant positive linear relationship between the concentration of dietary protein and larval weight (*P. rapae* slope = 27.2, $r = 0.93$, $P < 0.001$; *T. ni* slope = 30.4, $r = 0.70$, $P < 0.001$) (Figure 3). In addition, larval *P. rapae* shows a significantly greater reduction in weight gain with the reduction of dietary protein concentration than *T. ni* ($P < 0.001$).

DISCUSSION

Larval lepidopteran digestive physiology is generally characterized by an alkaline midgut and the secretion of endopeptidases for luminal midgut proteolytic degradation (Broadway and Duffey, 1986a; Sasaki and Suzuki, 1982; Law

FIG. 3. The effect of dietary protein concentration on the weight gain of larval *Pieris rapae* and *Trichoplusia ni*. The solid diamonds indicate growth of larval *T. ni*; the open squares indicate growth of larval *P. rapae*. The vertical lines indicate the standard error of the means. Each data point represents at least three replicates with a total of 170–350 larvae.

et al., 1977; Ward, 1975; Miller et al., 1974; Ishaaya et al., 1971). Larval *Trichoplusia ni* and *Pieris rapae* follow this general trend, exhibiting alkaline midguts (Broadway, unpublished data; Berenbaum, 1980), and proteolytic activity dominated by serine endopeptidases (trypsin- and chymotrypsin-like activity) (Table 1), with optimal enzyme activity at pH 8–9 (Figures 1 and 2). There was no detectable exopeptidase activity in the larval midguts of either species.

The results of the general in vitro protease assay (Tables 3 and 4) demonstrated that 86–89% of the larval enzyme activity could be eliminated by the addition of tryptic or chymotryptic inhibitors, indicating that trypsin and chymotrypsin are the major, if not sole, enzymes responsible for protein digestion. The data from enzyme-specific assays indicated that the chymotryptic activity in the midgut fluid from both species of Lepidoptera could be completely inhibited with selected inhibitors, but the insect tryptic activity could not be completely eliminated, even at extremely high concentrations of appropriate inhibitors (Tables 3 and 4). This inability to completely eliminate larval tryptic activity suggests that (1) the inhibitors form a weak bond with the insect trypticlike enzyme and/or (2) the insect trypticlike activity originates from more than one protein, resulting in complete inhibition of the enzyme(s) susceptible to the inhibitor and reduced or no inhibition of the less sensitive enzyme(s).

Although the digestive physiology of larval *P. rapae* and *T. ni* are similar

in many respects, there are striking differences when comparing the results from the in vitro digestion assays. One difference is the relative proportion of tryptic to chymotryptic activity in the midgut fluid (Table 1). The midguts of larval *P. rapae* contain a 1 : 1 mixture of tryptic and chymotryptic activity, whereas larval *T. ni* have more than three times as much tryptic activity compared to chymotryptic activity. This information suggests that these two species of Lepidoptera have different strategies of digestion of dietary protein. Trypsins are serine proteinases that cleave intact protein chains on the carboxyl side of basic L-amino acids such as arginine or lysine, whereas chymotrypsins cleave intact protein chains on the carboxyl side of aromatic amino acids (Walsh and Wilcox, 1970). Broadway and Duffey (1988) have shown that, for lepidopterous larvae in which trypsin is the primary protease, there is a significant positive correlation between larval growth and the relative amount of arginine + lysine residues in the dietary protein. Conversely, one may surmise that a mixture of different proteases (each acting at different sites on a protein) will digest dietary protein more efficiently and/or rapidly than a single protease. Following this line of reasoning, the relative proportions of different proteases in the gut will determine the relative number of amino acid sites at which proteins can be cleaved (or the extent of digestion) and, ultimately, the availability of proteinaceous nutrients. This line of reasoning is supported by the data demonstrating that the level of general protease activity in the midgut fluid (as measured in vitro by the rate of hydrolysis of azocoll) is significantly higher in larval *P. rapae* than *T. ni* (Table 1). This ability of larval *P. rapae* to digest protein more efficiently than *T. ni* may be related to the higher level of dietary protein required by *P. rapae*, as demonstrated by the protein bioassays (Figure 3).

Thus, for the two species of Lepidoptera examined in the current study, the protease activity profile (the total tryptic + chymotryptic activity, and the relative proportion of each enzyme), and the rate of in vitro digestion of azocoll provide an insight into the strategy and efficiency of proteolysis during the initial (luminal) phase of digestion. *P. rapae* and *T. ni* have equivalent total tryptic + chymotryptic activity; however, the proportions of enzymes are different. Using this equivalent amount of total enzyme activity, *P. rapae* digests azocoll at a significantly faster rate than *T. ni*, suggesting that *P. rapae* digests protein more efficiently than *T. ni*. In addition, the tryptic and chymotryptic activity from the midgut fluid of *P. rapae* is less sensitive to specific enzyme inhibitors than is *T. ni*. This suggests that *P. rapae* would digest a natural protein-proteinase inhibitor mixture more effectively than *T. ni*. This is physiologically adaptive, since the oligophagous larval *P. rapae* has a significantly higher dietary protein requirement than polyphagous larval *T. ni*.

Acknowledgments—I wish to thank Dr. A.M. Shelton and W.T. Wilsey for providing insects, D.L. Misurelli and K.T. Conklin for technical assistance, and Drs. W.L. Roelofs and D.M. Sod-

erlund for critically reviewing this manuscript. This research was supported, in part, by Hatch funds.

(Received June 17, 1988; accepted November 7, 1988)

Abstract—Heritable cuticular hydrocarbon patterns of *Solenopsis invicta* workers are consistent within colonies for a given sampling time but vary sufficiently from colony to colony to distinguish the colonies from each other. In addition, cuticular hydrocarbon patterns change within colonies over time. Nestmate recognition cues found on the individual's cuticle, can be from heritable or environmental sources, and are a subset of colony odor. The cuticular hydrocarbons can be used as a model for heritable nestmate recognition cues. We propose that because potential nestmate recognition cues, both environmental and genetic, are dynamic in nature rather than static, during its lifetime a worker must continually update its perception (template) of colony odor and nestmate recognition cues.

Key Words—*Solenopsis invicta*, Hymenoptera, Formicidae, cuticular hydrocarbons, nestmate recognition, colony odor, temporal changes.

INTRODUCTION

Cuticular hydrocarbons serve several purposes in insects, such as prevention of desiccation and regulation of cuticular permeability (Hadley, 1980). In addition, this class of chemically inert compounds can have many semiochemical

functions, such as alarm, recruitment, defense, sex attractants, and host attractants (see Howard and Blomquist, 1982, for review).

Solenopsis invicta Buren cuticular hydrocarbons constitute the largest lipid class (over 70%) on the cuticle (Lok et al., 1975) and are species specific (Nelson et al., 1980; Vander Meer, unpublished). *S. invicta* and *S. richteri* have the same cuticular hydrocarbons, identified as normal, monomethyl, and dimethyl branched alkanes (Lok et al., 1975; Nelson et al., 1980). However, quantitative patterns for the two species are distinctly different (Nelson et al., 1980; Vander Meer et al., 1985). Their species specificity has been used as a reliable chemotaxonomic tool to attack several problems (Vander Meer, 1986). The heritable nature of these compounds has been clearly demonstrated in studies of hybridization between *S. invicta* and *S. richteri* (Vander Meer et al., 1985; Ross et al., 1987).

It is generally accepted that nestmate recognition in social insects involves the detection of specific odiferous cues on the cuticle (Wilson, 1971). Heritable (Mintzer and Vinson, 1985) and/or environmental (Jutsum et al., 1979) odors can be operational in ant nestmate recognition. Odors under genetic control or resulting from genetic-environment interactions are termed heritable odors. It has been demonstrated that *S. invicta* uses both heritable and environmental nestmate recognition cues (Obin, 1986; Obin and Vander Meer, 1989). Cuticular hydrocarbons have been implicated in species and caste recognition in termites (Howard et al., 1982a), and several species of termitophiles have been shown to have cuticular hydrocarbons identical to their host, which was associated with their integration into the host colony (Howard et al., 1982b). Hydrocarbons have also been implicated in nestmate recognition of the ant *Camponotus vagus* (Bonavita-Cougourdan et al., 1987).

Although there is no direct evidence for the use of cuticular hydrocarbons in nestmate recognition in *S. invicta*, we have used the cuticular hydrocarbons as a model to study the quantitative variation of heritable components of colony odor. We report here that individual colonies have distinguishable cuticular hydrocarbon patterns; however, these patterns change with time. The implications of the dynamic nature of these heritable characters in relationship to nestmate recognition mechanisms are discussed.

METHODS AND MATERIALS

Source of Colonies. Laboratory colonies of *S. invicta* were reared from newly mated queens collected near Gainesville, Florida, or Gulfport, Mississippi, and reared in the Gainesville laboratory by the procedures described by Banks et al. (1981). Workers from monogynous field colonies were sampled

from the Gainesville, Florida, area. *S. invicta* workers undergo age-related polyethism and have been categorized as nurses, reserves, and foragers (Miranda and Vinson, 1981). Only reserve workers were used in this study. Reserve workers were defined in laboratory colonies as those workers that were inactive and clustered together at the outside of the colony cell (Sorensen et al., 1981). For field colonies, reserve workers were obtained by placing a beaker (50 ml), coated on the inside lip with Fluon, partly into the surface of a mound. If any workers were observed carrying brood, the sample was discarded. In the laboratory, the collected ants were anesthetized with CO₂, and three replicate samples of 50 or 100 reserve workers were placed in a vial and weighed on a Mettler H51Ar analytical balance. Worker ants within a range of 1.5–4.0 mm in length, readily determined by visual inspection, were used for the analysis of cuticular hydrocarbons.

Analysis of Cuticular Hydrocarbons. Cuticular hydrocarbons were obtained by soaking the ant samples for 7 min in hexane (ca. 2 ml HPLC grade, Baker Chemical Co., Phillipsburg, New Jersey). The samples were gently shaken for the first and last 15 sec of the soak period. Immediately after the rinses were complete, 9 μ l of a 0.1% hexane solution of *n*-pentacosane was added for quantitation as an internal standard. Samples were evaporated to a small volume under a stream of nitrogen and the residue applied to a Pasteur pipet silicic acid HA column (325 mesh particle size, Bio Rad, Richmond, California). Hydrocarbons were isolated by eluting the column with hexane (Christie, 1973). The hexane eluate was evaporated to ca. 50 μ l and an aliquot was analyzed on a Varian 3700 gas chromatograph (Varian Associates, Sunnyvale, California) equipped with a flame-ionization detector. A 1.8-m \times 2-mm-ID glass column packed with OV-17 on 120–140 mesh Gas Chrom Q (Applied Science Laboratories, Deerfield, Illinois) was used to separate the hydrocarbons. The oven was programmed from 175°C to 235°C at 3°C/min. Qualitative and quantitative data were obtained for the five major hydrocarbon peaks (Figure 1) using a Varian Vista 401 data processor (Varian Associates).

Quantitative Influence of Soak Time. Three replicates of 100 workers each from the same colony were weighed and allowed to soak in hexane, containing *n*-pentacosane as an internal standard, for the following time periods: 3, 5, 7, 10, 15 min, and overnight. Aliquots of the hexane were removed at the indicated time periods, and hydrocarbons were isolated and analyzed as described above.

Analysis of Data. The individual peak areas were quantitated using the internal standard and digitalized as the number of nanograms per sample. The data were normalized using the weight of the corresponding ant sample. We used principal component analysis, a pattern recognition technique (Wold, 1976), to establish relationships between the GC profiles of the ants and several

FIG. 1. Gas chromatogram of cuticular hydrocarbons from *Solenopsis invicta* workers. Peak a: n-heptacosane, b: 13-methylheptacosane, c: 13,15-dimethylheptacosane, d: 3-methylheptacosane, and e: 3,9-dimethylheptacosane.

variables, such as colony source and time. The principal component projections were made without the use of information about the class assignment of the samples.

Hydrocarbon Time Study. Four laboratory colonies were selected for a study to determine whether hydrocarbon patterns varied with time. These colonies were sampled, as described above, three to six times during a four- to eight-month period. The hydrocarbons were isolated, separated by gas chromatography, and the data analyzed as described in the previous sections.

RESULTS

The quantitative results for the removal of cuticular hydrocarbons over several soak times is shown in Table 1. The percent composition of the five hydrocarbon peaks under consideration varied most for time periods of 3 min and overnight. Consistent results were obtained for time periods 5, 7, 10, and

TABLE 1. EFFECT OF SOAK TIME ON EXTRACTIONS OF HYDROCARBONS FROM *S. invicta* WORKER ANTS

Soak time	Percent hydrocarbon peak ^a					Hydrocarbon (μ g)	
	A	B	C	D	E	Per mg ant	Per 100 ants
3 min	12.4 \pm 0 ^b	27.6 \pm 0.2	18.6 \pm 0.0	15.4 \pm 0.0	25.9 \pm 0.2	0.62 \pm 0.02	31.8 \pm 1.0
5 min	11.6 \pm 0.6	27.8 \pm 0.2	19.2 \pm 0.1	15.2 \pm 0.0	26.1 \pm 0.3	0.76 \pm 0.11	38.7 \pm 6.7
7 min	10.4 \pm 0.2	27.3 \pm 0.2	19.1 \pm 0.3	15.6 \pm 0.1	27.7 \pm 0.6	0.76 \pm 0.04	37.3 \pm 2.5
10 min	10.3 \pm 0.3	27.8 \pm 0.2	19.8 \pm 0.2	15.2 \pm 0.1	27.0 \pm 0.2	0.80 \pm 0.01	39.8 \pm 2.5
15 min	10.0 \pm 0.0	27.1 \pm 0.3	19.8 \pm 0.0	15.4 \pm 0.2	27.8 \pm 0.0	0.88 \pm 0.04	46.4 \pm 4.2
Overnight	8.7 \pm 0.4	26.0 \pm 1.0	22.4 \pm 2.4	15.6 \pm 0.4	27.2 \pm 0.6	2.91 \pm 0.27	138.8 \pm 14.2

^bMean \pm standard deviation (N = 3).

15 min. However, the quantity extracted, whether expressed as micrograms per milligram of ant or micrograms per 100 ants, was most consistent for the 5-, 7-, and 10-min soak periods. Consequently, all subsequent samples were soaked for 7 min.

The inter- and intracolony variations in cuticular hydrocarbon patterns were monitored from samples collected within two weeks of each other. A principal component analysis of a set of 27 ant samples from nine different laboratory and field colonies (three replicates each taken at the same time) was performed using the five major hydrocarbon GC peaks as descriptors (Figure 1). A plot of the first two principal components is shown in Figure 2. The first two eigenvectors account for 85.9% of the total cumulative variance.

Pattern groupings according to each individual colony are evident. As determined by inspection (Figure 2), within-colony variation is less than the between-colony variation. There were no obvious principal component plot separations based on a colony's geographic origin (Mississippi and Florida), nor was there a separation of field versus laboratory colonies.

Cuticular hydrocarbon patterns of laboratory colonies sampled at several

FIG. 2. A plot of the first two principle components of the five major hydrocarbons for nine *S. invicta* colonies. Colonies 1-4 are field collected from Florida; colonies 5-7 are lab-reared in Gainesville, Florida, but originated from newly mated queens from Gulfport, Mississippi; colonies 8 and 9 are lab-reared in Gainesville, Florida, collected in Florida from newly mated queens.

FIG. 3. A plot of the first two principle components of the five major cuticular hydrocarbons collected from field colony 3 (Figure 2) over four time periods. The letters A, B, C, and D represent collections in November 1982, January 1983, February 1983, and April 1983, respectively.

time periods were not static. Principal component maps of the first two principal components developed from the five GC peaks showed pattern groupings according to the date of collection in all four cases. The variation in replicates within a time period was less than that between time periods. An example of one colony sampled at four different times is shown in Figure 3. The first two eigenvectors account for 90% of the total cumulative variance. Use of an internal standard and careful attention to the proper peak integration baselines minimized instrument variation. When a single principal component plot was made of several colonies at several times, the pattern fluctuation of a colony with time caused overlap with other colony patterns.

DISCUSSION

Hydrocarbon Variability. It is not possible to obtain a rinse or soak of whole ants that does not contain compounds from a variety of sources other than the cuticle (Vander Meer, 1989). For example, species-specific fire ant venom alkaloids and hydrocarbons are routinely obtained by simply soaking

worker ants in hexane (Vander Meer et al., 1985; Ross et al., 1987). In this study, hydrocarbons were isolated by column chromatography to avoid contamination from other classes of chemicals. Quantitative analysis of the hydrocarbons from worker ants soaked for various times showed a dramatic increase in material when samples were soaked overnight. This probably reflects leaching of the large amount of hydrocarbon found in the postpharyngeal gland (Vander Meer et al., 1982). This material can exit the gland via the pharynx and mouth parts. A 7-min soak time was used for all subsequent analyses because of the consistent results from 5–10 min and to provide the best approximation of a cuticular hydrocarbon profile.

The separation of nine *S. invicta* colonies from diverse locations at a single collection time (Figure 2) is indicative of the quantitative intercolony variability possible in the cuticular hydrocarbons. These data also suggest that cuticular hydrocarbon variation is random throughout the distribution of *S. invicta* in the United States, since there was no obvious separation of colonies based on whether they were derived from Florida or Mississippi. Nestmate recognition studies (Obin, 1986) support this data.

The lack of separation of field-collected colonies from laboratory-maintained colonies in the principle component plots suggests that diet and other environmental factors do not have a noticeable influence on the phenotypic expression of cuticular hydrocarbon patterns (no gene–environment interaction). Similar results for hydrocarbon analysis of laboratory and field colonies were obtained by Obin (1986). The genetic origin of these compounds has been confirmed by the concordance of hydrocarbon profile data and genetic data (isozymes) in differentiating hybrid fire ants from their *S. invicta*–*S. richteri* parents (Ross et al., 1987).

It should be noted that the principal component projections (Figures 2 and 3) were made without the use of information about the class assignment of the samples. Therefore, distinct separations are a strong indication of real differences in the GC profiles of the ants.

The analysis of colony hydrocarbons over time demonstrated that individual colony profiles (reserve worker temporal subcaste) are dynamically changing, although for any given time period the profiles for the three replicates of a given colony are consistent (Figure 3). This is in part because the social interactions of the colony workers ensure the efficient transfer of cuticular chemicals (environmental and genetic) throughout the worker force of a colony. The transfer of compounds on the cuticle of several ant species has been clearly demonstrated by: (1) the mixing of species-specific cuticular chemical components on individuals from laboratory colonies composed of two different species (Errard and Jallon, 1987; Vander Meer, unpublished), (2) the rapid distribution of radiolabeled markers in fire ant colonies (Sorensen et al., 1985), and (3) the transfer of species-specific fire ant hydrocarbons to a myrmecophilous beetle

(Vander Meer and Wojcik, 1982). These interactions decrease the variability of all chemicals found on the worker surface and confound studies aimed at the investigation of individual variation. Although in this study we cannot address the mechanism of profile change, we can definitively state that heritable cuticular hydrocarbon profiles undergo continuous quantitative changes during the life of a colony. The magnitude of the temporal changes creates overlap with the clusters of other colony patterns.

Nestmate Recognition. Nestmate recognition occurs in ants when a worker distinguishes between workers of another colony and its own colony following a pause and sweep of the antennae over the others' body (see Breed and Bennett, 1987, for a review). The odor on the surface of a worker is a composite of environmentally and genetically derived components. In general, the odors used by a particular species or colony for nestmate recognition are a subset of all possible odors and may be composed of any combination of components (Vander Meer, 1988). *S. invicta* uses both environmental and heritable nestmate recognition cues (Obin, 1986; Obin and Vander Meer, 1988). Studies with *S. invicta* have investigated the effects of environmental components on nestmate recognition (Obin and Vander Meer 1988, 1989). However, although cuticular hydrocarbons are strongly correlated with nestmate recognition in *Camponotus vagus* (Bonavita-Cougourdan et al., 1987) and associated with the integration and survival of a myrmecophilous beetle in fire ant nests (Vander Meer and Wojcik, 1982), the composition of the heritable part of the cues has not been determined. In any event, cuticular hydrocarbons are a part of the heritable component of colony odor and can be used as a general model for heritable nestmate recognition cues. This paper establishes the dynamic nature of these compounds.

Nestmate recognition cues are only half of the nestmate recognition process. It is generally considered that colony-specific chemical patterns or templates (Breed and Bennet, 1987) are learned by workers soon after eclosion (Morel, 1983; Errard, 1984; Morel et al., 1988). Although newly eclosed workers may not be completely olfactorally naive in terms of nestmate recognition (Isingrini et al., 1985), they learn to recognize the first odors they experience, whether from their own colony or, in the case of laboratory adoption experiments, from another colony or species (Carlin and Hölldobler, 1983; Errard, 1986; Morel and Blum, 1988).

Our results indicate that early template formation must be modified by continuous updating. The dynamic nature of the environmental part of colony odor is obvious. The variation in cuticular hydrocarbons demonstrates that the heritable component of colony odor is not fixed either. Because of the dynamic nature of colony odor and, by implication, nestmate recognition cues, we propose that workers are not hard-wired to a specific chemical or pattern of chemicals but have a great deal of flexibility through a process of continuous, iterative

learning that provides a mechanism for colony members to cope with a constantly changing chemical environment, as well as within-colony individual genetic variations (hydrocarbon patterns vary temporally as widely as between colony patterns). This concept was alluded to by Wallis (1963), who likened the recognition process to odor habituation and suggested that an ant "is continuously habituating to the slight variations in the odour of its nest-mates." Our work supports the necessity for such a process in nestmate recognition.

EFFECT OF JUGLONE ON FRESHWATER ALGAL GROWTH

CARL T. KESSLER¹

*Department of Life and Health Sciences
Bloomsburg University
Bloomsburg, Pennsylvania 17815*

(Received August 29, 1988; accepted November 7, 1988)

Abstract—Allelopathic growth inhibition of various freshwater algal species was observed upon the addition of juglone to culture medium under laboratory conditions. Juglone is a phenolic chemical compound common to most parts of the black walnut (*Juglans nigra* L.). Growth inhibition of all species occurred at a juglone concentration of 10^{-3} M. Three of the five species were inhibited by a concentration of 10^{-4} M juglone, while no inhibition occurred at 10^{-5} M juglone. The results of this study indicate that juglone is less toxic to algae than fish. Therefore, the potential of juglone for aquatic management purposes is limited. Algal biomass will increase at natural juglone concentrations from 10^{-8} to 10^{-4} M due to the elimination of secondary producers. Algal biomass will decrease at natural juglone concentrations between 10^{-4} and 10^{-3} M. Species richness will decrease at juglone concentrations of 10^{-5} and higher.

Key Words—Juglone, allelopathy, black walnut, *Juglans nigra* L., freshwater algae, algal biomass.

INTRODUCTION

Allelopathy is any direct or indirect harmful effect by one plant on another through the production of chemical compounds that escape into the environment (Rice, 1974). Allelochemicals belong to a few major groups of compounds among secondary plant substances, including terpenoid substances, steroids,

¹Present address: Department of Biological Sciences, Rutgers University, Piscataway, New Jersey 08855-1059.

alkaloids, organic cyanides, flavonoids, phenolic acids, and other aromatic compounds (Whittaker and Feeny, 1971). Many instances of allelopathy have been reported for a variety of plants (reviewed in Rice, 1974; Waller, 1987). Both Putnam and Duke (1978) and Rice (1979) suggested that allelopathic compounds could be utilized for biological weed control. Many studies have since examined the potential for agronomic weed control by allelopathic crops (Alsaadawi et al., 1986; Lodhi et al., 1987; Leather, 1987).

Robson (1977) suggested that allelopathy be used for the control of aquatic weeds. Many studies have examined the effects of allelochemicals from aquatic plants upon other aquatic plants. Eelgrass, *Zostera marina* L., was found to inhibit epiphytic and nearby algae and bacteria (Harrison and Chan, 1980). Similarly, marsh grass, *Spartina alterniflora*, and water shield, *Brasenia schreberi* Gmelin, were each shown to possess some allelopathic agent against various species of algae (Valiela et al., 1979; Elakovich and Wooten, 1987). Elakovich and Wooten (1987) suggested that water shield may, therefore, be useful for aquatic plant management.

Allelopathic interactions existing between diatoms and cyanobacteria were found to be one of the most significant controlling factors in the determination of their bloom sequence (Keating, 1977). Based upon these interactions, Keating (1977, 1978) discussed the potential of allelopathy for lake management. She described how the use of algicidal allelopathic species would be extremely advantageous in comparison with the undesirable application of copper sulfate to the lake environment.

However, Szczepanski (1977) suggested that the simple replacement of aquatic weeds with other strongly allelopathic plants would simply replace one problematic species with another. Therefore, allelopaths must be used that will not become weedy themselves. Plants that are not located within the immediate aquatic environment, yet would release allelochemicals into the system, would be ideal for this purpose.

Armstrong and Boalch (1961) and McLachlan and Cragie (1964) showed that phenolic compounds accumulate in marine waters. Three phenolic compounds released from three species of marine algae (*Polysiphonia morrowii*, *P. lanosa*, and *Monostroma fuscum*) were subsequently found to be highly toxic to several species of unicellular marine algae (McLachlan and Cragie, 1966). This suggests that phenolic compounds possess qualities that may be useful for the control of eutrophyng algae.

Black walnut (*Juglans nigra* L.) is known to cause allelopathic effects in a wide variety of organisms (Rice, 1974). Stickney and Hoy (1881) were the first to report that vegetation under black walnut is very sparse compared with that under most shade trees. The phenolic compound, juglone (5-hydroxy-1,4-naphthoquinone), was suggested by Massey (1925) to be the toxic constituent of black walnut. This was later confirmed by Davis (1928). Many studies have

since described the allelopathic effects of this chemical upon a variety of both plant and animal species (Brooks, 1951; Westfall et al., 1961; MacDaniels and Pinnow, 1976).

Juglone is present in the greatest quantities very near the tree (Ponder and Tadros, 1985). The concentration decreases with both soil depth and distance from the tree. Thus, the formation of a range of the presence of juglone must result. Should either a lake or stream be located within this range, the dispersal of juglone into the aquatic system will occur.

The majority of studies of the inhibitory effects of juglone have involved examinations upon terrestrial organisms. Furthermore, of the studies that have been performed upon aquatic organisms, only the effects upon animal species have been examined (Westfall et al., 1961; Marking, 1970). There have been no studies examining the effects of juglone upon aquatic plant species.

The purpose of this study was to determine the effects of juglone concentration upon the growth of freshwater algae.

METHODS AND MATERIALS

The effect of varying concentrations of juglone upon the growth of five species of freshwater algae was examined. Chlorophytes were chosen due to their large distribution and tremendous production capabilities in the natural environment. The species chosen were *Closterium acerosum* (Schrank), *Pandorina morum* Bory, *Micrasterias thomasiana* Arch., *Spirogyra grevilleana* (Hass.), and *Eudorina californica* (Shaw). All were easily obtainable (Carolina Biological Supply, Burlington, North Carolina) and common to the lakes and streams of North America.

The algae were cultured in Alga-Gro Freshwater Medium (Carolina Biological Supply) containing juglone (Aldrich Chemical Co., Milwaukee, Wisconsin) in concentrations of 0, 10^{-5} , 10^{-4} , and 10^{-3} M. The cultures were maintained in 500-ml Erlenmeyer flasks at $25 \pm 1^\circ\text{C}$ with a 16-hr light to 8-hr dark cycle under a lighting bank of Sylvania 40-W cool white fluorescent lights providing an intensity of ca. 300 foot-candles.

To ensure an even distribution of cell concentration before sampling, each culture was mechanically shaken at 350 rpm for 10 min. Two replicate samples of 5 ml each were taken from each culture daily for two weeks. These were pipetted into centrifuge tubes and centrifuged at 3000 rpm for 10 min. The pellets were placed into preweighed crucibles, dried overnight at 100°C , and weighed to 0.001 g. Dry weight (biomass) per volume was determined for each sample. Statistical analysis of treatment biomasses from control biomasses at each juglone concentration was performed using ANOVA.

RESULTS

Biomasses of all algal species tested were significantly reduced by a juglone concentration of 10^{-3} M (Table 1). In contrast, a concentration of 10^{-5} M juglone was not inhibitory to any species tested. A juglone concentration of 10^{-4} M was inhibitory to three of the five species tested. This indicates that the concentration of juglone within a natural aquatic system must reach approximately 10^{-4} M for algal inhibition to occur. No correlation existed between the taxonomic position of the algal species within Chlorophyta and the degree of inhibition observed. In addition, no correlation existed between the condition of the aquatic system to which the alga is most common (i.e., oligotrophic, mesotrophic, or eutrophic) and the degree of inhibition.

A juglone concentration of 10^{-3} M caused growth reductions of 83–89% (Table 2). Table 2 also illustrates that the reduction in growth caused by a 10^{-4}

<i>S. grevilleana</i>	1.03	0.791	0.122

M juglone concentration ranged from 13 to 30%. Although *Eudorina* and *Micrasterias* were not significantly inhibited by a juglone concentration of 10^{-4} M in this study, continual exposure to juglone may result in an increased inhibitory effect. Rietveld (1983) suggested that allelopathic effects observed in the field are most likely the result of longer-term exposures to moderate juglone concentrations, such as 10^{-4} and 10^{-5} M. Thus, all species examined here may be inhibited to a greater degree by long-term exposure to juglone than is indicated by this study.

DISCUSSION

Ponder and Tadros (1985) reported that the concentration of juglone under black walnut ranged from 2.27×10^{-5} M within the top 8 cm of the soil and 0.9 m from the tree to 0 M at an increased distance and soil depth from the tree. This concentration would be adequate to cause previously described allelopathic inhibition in terrestrial systems (Rietveld, 1981). However, in aquatic systems, dilution of the compound delivered from the organism will occur. Thus, in order for allelopathy to occur in aquatic systems, additional mechanisms must exist for the accumulation of juglone to high enough concentrations to result in the allelopathic inhibition reported in this study and others such as those by Westfall et al. (1961) and Marking (1970).

Fisher (1978) reported that pines (*Pinus* spp.) often suppressed black walnut growth under dry soil conditions, while black walnut suppressed and often killed pine under poorly drained soil conditions. Fisher (1978) also showed that juglone was extractable and remained inhibitory for long periods from soil that was kept moist, while juglone of dry soil quickly disappeared and lost its inhibitory activity. It should be noted that the soil collected by Ponder and Tadros (1985) was dried for 24 hr before juglone was extracted. This may have considerably reduced the amount of juglone present within the samples.

Rietveld (1981) suggested that moist soil conditions limit the degradation of juglone. Therefore, it is likely that juglone will remain more stable and inhibitory in aquatic than terrestrial systems. This may allow an increased concentration to accumulate within aquatic systems. In addition, Ponder and Tadros (1985) sampled soil from a moderately well-drained site. Thus, a greater concentration of juglone than that measured by their study may be possible under an extremely wet moisture regime, such as in the soil near a lake and the lake water itself.

In addition to the build-up of juglone as a result of rainwash and runoff, fruit and leaf deposition within the lake will also occur. Juglone will become available from these by both leaching and decomposition within the sediment and hypolimnion. Phenolic compounds have been shown to accumulate in the

aquatic environment (Armstrong and Boalch, 1961; McLachlan and Cragie, 1964), and allelochemical accumulation was shown to occur within intertidal crevice sediments (Evans, 1986). Therefore, juglone may accumulate in the sediment of lakes located near black walnut. Little decomposition of juglone will likely occur in these sediments since juglone has been shown to inhibit bacteria and microorganisms (Shcherbanovskii et al., 1971; Sokolov et al., 1972; Didry et al., 1986).

Since spring turnover results in an abundance of available minerals and nutrients for algae, tremendous growth normally occurs. However, with turnover, the juglone accumulated within the sediment from the fall also will be dispersed. Should juglone concentrations be elevated at this time of year to levels shown by this study to inhibit algal growth, the annual algal production will be decreased substantially. This will result in reduced secondary production at all trophic levels.

Westfall et al. (1961) reported that fish were sedated, but not killed, by juglone concentrations between 6.2×10^{-6} and 1.3×10^{-5} M. Marking (1970) found that various fish were killed by concentrations ranging from 2.4×10^{-8} to 7.8×10^{-8} M juglone. The difference between results may have resulted in differences between the juglone obtained from extracts of black walnut by Westfall et al. (1961) and the juglone obtained from Aldrich Chemical Co. by Marking (1970). In either case, it appears that fish are more sensitive than algae to juglone present in the environment. Thus, should juglone be concentrated within the aquatic environment from 10^{-8} M to 10^{-5} M, fish toxicosis will occur in the absence of algal inhibition. An increase of algal biomass within the aquatic environment will result due to the removal of the higher trophic levels from the aquatic food web.

Intermediate concentrations of juglone, such as from 10^{-5} to 10^{-4} M, will be toxic to both fish and many algae species. However, some algae may persist, particularly those little affected by such juglone concentrations (i.e., *Micrasterias* and *Eudorina*). The species diversity of the lake under these conditions will be reduced, since it has been shown that most organisms are inhibited by juglone (Westfall et al., 1961; Marking, 1970). However, it is likely that an increase in algal biomass will occur at these intermediate concentrations, resulting from the fish toxicity. Should juglone accumulate to concentrations of 10^{-4} – 10^{-3} M, all organisms would be inhibited. Extreme reduction of both primary and secondary production within the lake environment will likely result.

It would be difficult to examine the effects caused specifically by the presence of juglone within the natural aquatic system. This is due to the occurrence of other interactions between organisms, i.e., competition and allelopathic interactions such as those described by Keating (1977, 1978). Thus, the initial step for the determination of the effects of juglone within aquatic systems is to analyze the effects of juglone upon a variety of organisms. Potential ecological

situations may then be deduced from the responses of aquatic organisms to various concentrations of juglone.

Additional work is required to locate the presence of juglone within the aquatic environment. A continuum of concentrations likely exists, depending upon such varying conditions as lake topography, nearby soil moisture levels, and number and size of nearby black walnut trees. An assay of juglone levels found within the natural environment would then allow for the correlation of laboratory and field observations. The effects of juglone within the aquatic environment may then be conclusively determined.

(Received December 28, 1987; accepted November 14, 1988)

Abstract—Settling of the potato aphid, *Macrosiphum euphorbiae*, on feeding membranes was deterred by methanolic leaf rinses of *Lycopersicon pennellii*, or of its F₁ with tomato, *L. esculentum*. The active compounds in the *L. pennellii* rinsates were identified as 2,3,4-tri-*O*-acylglucoses bearing short to medium chain length fatty acids. These compounds are localized in the glandular exudate of the type IV trichomes and may accumulate to levels in excess of 400 $\mu\text{g}/\text{cm}^2$. In choice assays, purified glucose esters from *L. pennellii* reduced aphid settling at concentrations as low as 25 $\mu\text{g}/\text{cm}^2$; at concentrations of 150 $\mu\text{g}/\text{cm}^2$ or more, all aphids avoided treated areas. Glucose esters were also active in deterring aphid settling in no-choice assays. At 100 $\mu\text{g}/\text{cm}^2$, these esters resulted in increased levels of mortality after 48 hr.

Key Words—Aphid resistance, fatty acids, glucose ester, insect resistance, *Lycopersicon esculentum*, *Macrosiphum euphorbiae*, potato aphid, Homoptera, aphididae.

INTRODUCTION

Genetic diversity within the cultivated tomato has been seriously depleted by intensive selection pressure for agronomic traits. Wild germplasm is a potential source of resistance to 30 different diseases and 16 known arthropod pests of tomato (Rick, 1982). Currently, resistance to at least 15 different diseases has

³Present address: Ecogen Inc. 2005 Cabot Blvd, Langhorne, Pennsylvania 19047.

been incorporated into adapted cultivars utilizing this exotic germplasm (Rick, 1984). Incorporation of insect resistance into tomato has not been as successful because of the complex nature of resistance and a lack of understanding of its biochemical and genetic basis.

Lycopersicon pennellii Corr. (D'Arcy), a wild relative of the cultivated tomato, *L. esculentum* Mill, is resistant to many arthropod pests of tomato including the potato aphid, *Macrosiphum euphorbiae* Thomas; carmine spider mite, *Tetranychus cinnabarinus* Boisduval; two-spotted spider mite, *T. urticae* Koch; glasshouse whitefly, *Trialeurodes vaporariorum* Westw.; cotton bollworm, *Heliothis armigera* Hübner; and potato tuberworm, *Phthorimaea operculella*, Zell. (De Ponti *et al.*, 1975; Gentile and Stoner, 1968; Gentile *et al.*, 1968, 1969; Juvik *et al.*, 1982). These authors have suggested that the resistance in *L. pennellii* is due to the entrapment of these pests in the viscous glandular exudate of the type IV trichomes, which are not present on the cultivated tomato (Luckwill, 1943).

However, aphid resistance in *L. pennellii* cannot be completely attributed to entrapment in the sticky glandular exudate. Although potato aphid mortality in leaf cages is significantly higher on *L. pennellii* and its F₁ than on *L. esculentum*, few adult aphids become entrapped in the glandular exudate (Goffreda *et al.*, 1988). Aphid settling is dramatically reduced on *L. pennellii*, suggesting that starvation may contribute to the high aphid mortality.

We recently characterized aphid feeding behavior on *L. pennellii*, *L. esculentum*, and F₁ plants using electronic monitoring techniques (Goffreda *et al.*, 1988). Feeding behavior on *L. pennellii* and F₁ plants is characterized by an increase in preprobe time, a reduction in the number of probes per unit time, and a decrease in the total time spent probing, relative to tomato. The transfer of *L. pennellii*'s glandular exudate to *L. esculentum* results in feeding behavior resembling that on *L. pennellii* and F₁ plants. Conversely, removal of the type IV glandular exudate from *L. pennellii* and the F₁ with various solvents decreases preprobe time and increases the number of probes and total time spent probing. These results suggest that the chemistry of the glandular exudate of *L. pennellii* also deters aphid feeding.

Although previous work associated *L. pennellii*'s type IV trichome exudate with resistance to aphids and other insects, relatively little is known about the chemical basis of this resistance. In this study we show that application of *L. pennellii* type IV glandular exudate to artificial feeding surfaces deters aphid settling, and we identify the chemical constituents responsible for this activity.

METHODS AND MATERIALS

Plant and Aphid Culture. Plants of *L. esculentum* cv. New Yorker, *L. pennellii* (LA 716), and their F₁ were grown from seed in soilless media, a modification of Cornell mix (Boodley and Sheldrake, 1973), supplemented with

a slow-release fertilizer. Plants were not treated with pesticides. All plants used for chemical extraction were grown to maturity (*ca.* 3 months old) in a growth chamber maintained at 29°C day and 27°C night with a relative humidity of *ca.* 65%. The chamber was illuminated with *ca.* 1300 $\mu\text{E}/\text{m}^2/\text{s}$ of fluorescent and incandescent light for a 16-hr photophase.

Aphids were obtained from a colony established from a single apterous potato aphid (*Macrosiphum euphorbiae*) collected from tomato in Ithaca, New York, in September 1985 and maintained on tomato plants cv. New Yorker in a growth chamber at 20°C. The chamber was illuminated with diffuse fluorescent light of *ca.* 55 $\mu\text{E}/\text{m}^2/\text{s}$ intensity. Apteræ were gently shaken from the foliage and starved for *ca.* 3 hr prior to bioassays.

Aphid Settling Assays. Potato aphid settling behavior was assayed using a modification of the procedure described by Avé *et al.* (1987). Each feeding chamber was constructed by cutting two 1-cm² feeding ports in a hollow polyethylene stopper (Nalgene No. 7). A circular disk of unstretched Parafilm (American Can Company) was placed on top of the stopper and secured with another layer of Parafilm (Figure 1). A 0.9-ml volume of 20% sucrose was supported atop the feeding apparatus with another layer of stretched Parafilm, and yellow transparent disks of cellulose acetate were placed over each of the feeding ports. Tested compounds and extracts were applied to the exposed surface of the unstretched Parafilm, which was directly encountered by the aphids.

Choice Bioassays. A solution of the test material was applied to the surface of one of the two feeding ports, designated as the test port, and an equivalent volume of solvent was applied to the other feeding area (control port). Control feeding chambers were constructed by applying solvent alone to both the test and control feeding ports. Four aphids were placed in each chamber, and the distribution of aphids between the test and control ports was recorded at 2, 6, and 24 hr.

FIG. 1. Schematic diagram of aphid feeding chamber utilized in choice and no-choice assays.

Since aphids are gregarious (Dixon, 1973), each chamber was analyzed as a single experimental unit. Chambers in which there was either an equal aphid distribution between both ports or more aphids settled on the test port were scored as showing no response (NR). Chambers in which there were more aphids settled on the control port were scored as showing a response (R). Since chambers with equal aphid distributions were scored NR, the proportion of control chambers scored NR was expected to be greater than 50% on average. If a compound or extract strongly deters aphid settling, the proportion of chambers scored NR will be significantly lower than that of the control.

No-Choice Bioassays. A solution of the test material was applied to both feeding ports, and only a single aphid was placed in each chamber. Aphid settling was recorded at 2, 6, and 24 hr in short-term no-choice assays. In long-term no-choice studies each chamber was scored for whether or not the aphid was alive, and, for those still living, whether it was settled on a feeding port at 24, 48, and 72 hr.

Bioassay of Leaf Rinses. Since previous work (Goffreda *et al.*, 1988) has demonstrated that the feeding deterrent activity of *L. pennellii* can be removed by washing the leaf in alcohols, leaf rinses were assayed for activity in choice bioassays. Approximately 200 cm² of leaflets of *L. esculentum* cv. New Yorker, *L. pennellii* (LA 716), or their F₁ were briefly (1–3 sec) dipped in two 15-ml volumes of methanol (Fisher HPLC Grade). Microscopic examination of treated leaves revealed that the methanolic dip effectively removed the type IV trichome exudate droplets with no apparent damage to the membrane-enclosed type VI trichomes. A number of solvents are capable of efficient removal of type IV trichome exudate droplets. Alcohols such as methanol cause the least disruption of leaf and trichome metabolism; within 48 hr, leaflets treated with methanol regenerate exudate droplets. However, halogenated solvents cause wilting and death of the leaflet within a few hours after exposure.

The first and second rinses were combined and concentrated so that 10 μ l of this extract represented half the exudate obtained from 1 cm² of leaf surface. In choice bioassays, 10 μ l of the concentrated rinse was applied to the test port and allowed to dry as described above. There were 24 replicates per genotype arranged in a completely randomized design. Data were analyzed by partitioning of the likelihood ratio chi-square (*G* statistic) as described by Shaffer (1973).

Identification of Feeding Deterrents in L. pennellii Type IV Trichome Exudate. The glandular exudates of several hundred type IV trichomes were individually collected with a finely drawn capillary tube and injected into a Varian 3740 gas chromatograph equipped with a flame-ionization detector and a 25-m BP-5 fused silica narrow-bore capillary column (5% phenyl, methyl silicone, bonded phase, 0.25 μ m) (SGE, Australia). The injection port temperature was maintained at 260°C, and the column was held at 50°C for 5 min and programmed to 250°C at 4°C/min. Identity of fatty acids in the exudate was con-

firmed by comparison of retention times and by coinjection with both free and methyl esters of fatty acid standards. Methyl ester derivatives were prepared by treatment with BF_3 -methanol (Pierce Chemical Co). GC-MS of fatty acids was carried out on a Finnigan 3300 gas chromatograph-mass spectrometer in electron impact and chemical ionization modes.

Thin-layer chromatography (TLC) analysis of sugars in hydrolyzed and untreated trichome exudates was carried out on silica gel TLC plates (DC Fertigplatten Plate-Kieselgel 60 F-254) eluted twice with *n*-butanol, glacial acetic acid, ether, and distilled water (9:6:3:1) (Harborne, 1973). The plate was stained by heating with aniline-diphenylamine-phosphoric acid (Schwimmer and Bevenue, 1956).

Preparative isolation of *L. pennellii* glucose esters was achieved by a brief (1–3 sec) dip of 300 leaves in 1 liter of methanol to collect the polar epicuticular lipids; 12.5 ml of water was added to a 37.5-ml subsample of the leaf rinse and partitioned against hexane. The aqueous fraction was concentrated to a yellowish oil using a rotary evaporator equipped with a vacuum pump. The sample was taken up in a minimal volume of chloroform and purified over a Florisil column (30 × 2.5 cm) eluted with a 1.2-liter gradient of 100% chloroform to 50% chloroform-acetone. Glucose esters eluted as a clear viscous oil at approximately 20% acetone. Individual glucose esters were purified for characterization by reverse-phase HPLC (210 nm, Waters 5-micron C18 radial compression column). Authentic *L. pennellii* glucose ester standards were graciously provided by Dr. Basil Burke of Plant Cell Research Institute Inc. (Dublin, California).

Fatty acid compositions were identified as described above. Positions of esterification on the glucose esters were established by [^1H]NMR spectra recorded in CDCl_3 using a Varian XL-400 spectrometer. Spectra were referenced to CDCl_3 at $\delta 7.26$. High-resolution positive ion desorption chemical ionization MS spectra of purified glucose esters were recorded on a Kratos MS 890 spectrometer.

Bioassay of Purified Glucose Esters. Biological activity of purified glucose esters was assayed using choice and both short- and long-term no-choice assays as described. To ensure even coverage of glucose esters on the Parafilm, 2.5 μl of a solution of glucose esters dissolved in a mixture of acetone, chloroform, and paraffin oil (15:3:1) was applied onto the feeding membrane surface and allowed to dry. All treatments were arranged in a completely randomized design. In choice assays, glucose esters were tested at 0, 25, 50, 100, 150, and 200 $\mu\text{g}/\text{cm}^2$, with 22 replicates per concentration. In short-term no-choice assays, glucose esters were tested at 0, 50, 100, and 200 $\mu\text{g}/\text{cm}^2$, with 20 replicates per concentration. To determine if there was a relationship between the concentration of sugar esters applied and aphid settling, data were analyzed for homogeneity and tested for linearity by regression of the arcsine square root of the

proportion on the concentration of purified total glucose esters (Snedecor and Cochran, 1980). Long-term no-choice assays were conducted at two levels, 0 and 100 $\mu\text{g}/\text{cm}^2$, and analyzed by partitioning of the likelihood ratio chi square (Shaffer, 1973).

RESULTS

Leaf Rinse Bioassays. Leaf rinses from both *L. pennellii* and its F_1 with *L. esculentum* strongly deterred aphid settling on treated feeding ports in choice assays (Figure 2). Aphid response to the *L. esculentum* rinse did not differ significantly from the control chambers (Table 1). Aphid response to *L. pennellii* and F_1 leaf rinses also did not differ significantly. The chi square from the pooled data (*L. esculentum* and control vs. *L. pennellii* and F_1) was highly significant and accounted for over 90% of the total variation at each time period (Table 1).

Identification of Deterrents in Type IV Glandular Exudate and Leaf Rinses. TLC and HPLC analyses of both type IV trichome exudate and methanolic leaf rinses showed that the primary constituents of *L. pennellii* trichome exudate are glucose esters of branched short and medium chain length (C_4 to C_{12}) fatty acids. TLC analysis showed that *L. pennellii* leaf rinses, hydrolyzed by treatment with weak base, contained free glucose, which was not present in unhydrolyzed samples, suggesting esterification. Similarly, fatty acids were also not detected by GC unless injection port temperatures exceeded 150°C. The predominant fatty acids, identified by GC and GC-MS of the free acids and methyl

FIG. 2. Aphid settling response to leaf dip rinsate from *L. esculentum*, *L. pennellii*, and their F_1 hybrid in choice assays at 2, 6, and 24 hr. ²Expressed as percent of the chambers scored as NR. Chambers in which there was either an equal distribution of aphids between both ports or more aphids settled on the test port were scored as showing no response (NR).

TABLE 1. APHID SETTLING RESPONSE TO LEAF DIP RINSATES OF *L. pennellii* (L.p.), *L. esculentum* (L.e.), AND F₁ AS ANALYZED BY ORTHOGONAL PARTITIONING OF LIKELIHOOD RATIO CHI SQUARE FROM CHOICE STUDIES

Time (hr)	Likelihood ratio chi square ^a			
	Total (df = 3)	L.p. vs. F ₁ (df = 1)	Control (C) vs. L.e. (df = 1)	(L.p. and F ₁) vs. (C and L.e.) (df = 1)
2	8.36 ^b	0.03	0.22	8.11**
6	17.62***	0.03	0.26	17.33***
24	21.72***	0.36	1.55	19.81***

^aLikelihood ratio chi square was obtained from analysis of frequency tables of chambers scored as NR and R for the different treatments.

^b*, **, ***: $P < 0.05, 0.01, \text{ and } 0.001$, respectively.

esters, include 2-methylpropanoic, 3-methylbutanoic, 8-methylnonanoic, *n*-decanoic, and *n*-dodecanoic acids. GC analysis of individually collected, type IV droplets possessed high levels of these esterified fatty acids in the same proportions as they occur in the glucose esters from the leaf rinses. Individually collected type VI trichomes did not contain detectable quantities of the esterified fatty acids.

The [¹H]NMR spectrum of total glucose esters from *L. pennellii* showed, in agreement with Burke *et al.* (1987), that fatty acid esterification was at positions 2, 3, and 4 of glucose for all members of the complex: δ 4.92, *dd*, $J = 9.8, 3.7$ Hz; δ 5.69, *t*, $J = 9.8$ Hz; and δ 4.95, *t*, $J = 9.8$ Hz for H-2, H-3, and H-4, respectively, of the α anomer. As the glucose esters are hygroscopic, and in the field are constantly exposed to moisture, it is likely that the esters exist as an anomeric mixture both on the plant as well as *in vitro*. We were unable to assign precise positions of each fatty acid on individual glucose esters by either NMR or MS. High-resolution MS of a purified ester identified by GC as composed of di-2-methylpropanoic, *n*-decanoic fatty acids gave a mass of 457.2799, satisfying the formula for C₂₄H₄₁O₈ (M + H - H₂O; calc. 457.2801).

Activity of L. pennellii Total Glucose Esters. In choice assays, there were highly significant deviations ($P < 0.001$) in the proportion of chambers scored as showing no response (NR) at different levels of glucose ester application for the 2-, 6-, and 24-hr time periods (Table 2). The test for linear trend was also highly significant at each time period ($P < 0.001$), indicating that there was an increase in aphid deterrence with increasing levels of glucose ester application. Aphids completely avoided the test port at concentrations of 150 $\mu\text{g}/\text{cm}^2$ and higher.

no-choice assays, the proportion of living aphids settled at 24 and 48 hr was significantly lower in chambers in which $100 \mu\text{g}/\text{cm}^2$ of total glucose esters were applied to the feeding area than in control chambers (Figure 4; Table 3). At 48 and 72 hr, the proportion of dead aphids in treated chambers was significantly higher than in control chambers ($P < 0.001$).

DISCUSSION

Settling of the potato aphid, *Macrosiphum euphorbiae*, is deterred in artificial feeding chambers by methanolic leaf rinses of *L. pennellii* and its F_1 with *L. esculentum*. In contrast, *L. esculentum* methanolic leaf rinses have no effect on aphid settling behavior.

Active compounds in the *L. pennellii* leaf rinses are 2,3,4-tri-*O*-acyl glucoses comprised of short to medium chain length fatty acids (C₄ to C₁₂). Individual collection of type IV trichome exudates confirms that these compounds are localized in the glandular exudate of this trichome. Sugar esters of short and medium chain length fatty acids are the predominant compounds in the leaf rinses of *L. pennellii* and the F₁. Few other components are detectable in either the leaf rinses or the type IV trichome exudate of these plants.

Our structural identification of these glucose esters in the trichome exudate of *L. pennellii* is in agreement with that published by Burke *et al.* (1987) and with the properties of authentic *L. pennellii* glucose ester standards (kindly supplied by B.A. Burke). Sucrose esters of similar fatty acids have been isolated from the trichomes of other insect-resistant species within the family Solanaceae, including *Nicotiana tabacum*, *Solanum berthaultii*, and *Lycopersicon hirsutum* (Severson *et al.*, 1985; King *et al.*, 1986, 1987).

Insecticidal properties of free decanoic and dodecanoic acids and their derivatives have been known for over 50 years (Siegler and Popenoe, 1925; Shepard, 1951). The biological effects of endogenous fatty acid esters have only recently been studied within the family Solanaceae. Johnson and Severson (1984) characterized the leaf surface chemistry of nearly 30 tobacco accessions and found one accession with high sucrose ester levels and low docosanol levels that was resistant to damage from the tobacco budworm, *Heliothis virescens*. Other research indicates that 3-methylvalerate-substituted sucrose esters of tobacco also inhibit gram-positive bacteria, including *Bacillus subtilis*, *B. cereus*, and *Mycobacterium thermosphaerium* (Cutler *et al.*, 1986). Recent work with *Solanum berthaultii* also implicates the involvement of sucrose esters in this species' resistance to aphids (Neal *et al.*, in press) and potato late blight, *Phytophthora infestans* (Holley *et al.*, 1987).

L. pennellii glucose esters are perceived by aphids at concentrations of 25 µg/cm² in choice bioassays (Table 2). It is unlikely that the aphid is responding to the viscous properties of the glucose ester since these compounds only form a microscopic film at this low concentration. It is possible that abiotic or biotic conditions may hydrolyze the ester linkage, thereby liberating free short and medium chain fatty acids. Fatty acids with chain lengths of C₉ to C₁₃ are disruptive to settling of the green peach aphid, *Myzus persicae* Sulzer, at concentrations of 1–100 µg/cm² (Greenway *et al.*, 1978). In our assays, *n*-decanoic or *n*-dodecanoic acids repel potato aphid settling at concentration of 50 µg/cm² (unpublished data).

L. pennellii glucose esters are also active in no-choice assays, although the threshold level of activity is higher than in choice assays; between 50 and 100 µg/cm² was required to detect a deterrent response at 24 hr (Figure 3). In long-term no-choice assays, there was significantly higher mortality in chambers treated with 100 µg/cm² than control chambers at 48 hr and 72 hr, probably

because the aphids died from starvation since they would not settle and feed (Table 3; Figure 4). There was no evidence of aphid habituation to glucose esters because the proportion of aphids that were settled on the treated feeding area remained constant through the course of the experiment. This high level of aphid deterrence possessed by glucose esters may be of practical significance in reducing the rate of virus transmission because, in many cases, aphids cease to be viruliferous minutes after acquiring a nonpersistent virus (Bradley, 1959; Harris, 1977).

The activity of individual glucose esters is not different from that of the total glucose esters, suggesting the absence of either synergistic or antagonistic interaction between individual glucose esters. Furthermore, there was little variation in deterrent activity among individual glucose ester fractions, suggesting that fatty acid chain length is not critical for deterrence (data not shown).

Polar epicuticular lipids can accumulate to concentrations exceeding $400 \mu\text{g}/\text{cm}^2$ on *L. pennellii* foliage (Fobes *et al.*, 1985). Data presented here suggest that glucose esters may be active deterrents of aphid settling at concentrations far lower than those reported on mature *L. pennellii* plants: total avoidance was observed at concentrations as low as $150 \mu\text{g}/\text{cm}^2$.

This high level of deterrent activity of glucose esters at relatively low concentrations should facilitate the transfer of aphid resistance into the cultivated tomato in an applied breeding program. Our research has determined that the presence of the type IV trichome is relatively simply inherited (Lemke and Mutschler, 1984), but we have had difficulty in retaining high densities of type IV trichomes bearing large exudate droplets in hybrid populations. Since fatty acid chain length on *L. pennellii* glucose esters may not be critical to the activity of these compounds in choice assays, screening plants for total epicuticular glucose esters should be effective in the development of resistant hybrids. We have developed a rapid colorimetric assay to evaluate sugar ester accumulation in large segregating populations. We are in the process of evaluating this assay as a selection technique for the development of insect-resistant tomato cultivars.

Acknowledgments—The authors are especially grateful to Dr. Basil Burke who provided us with preparative quantities of HPLC-purified glucose esters and Dr. T. Wachs for acquiring G.C./M.S. spectra. This research was supported through Hatch project numbers 149484 and 149411, U.S.D.A. and by U.S.D.A. competitive grant number 8800683.

ALLELOPATHIC RESEARCH OF SUBTROPICAL
VEGETATION IN TAIWAN. IV.
Comparative Phytotoxic Nature of Leachate from Four
Subtropical Grasses^{1,2}

CHANG-HUNG CHOU

*Institute of Botany, Academia Sinica
Taipei, Taiwan 11529, Republic of China*

(Received June 23, 1988; Accepted November 14, 1988)

Abstract—The phytotoxicity of plant leachates was evaluated from four subtropical grasses: *Brachiaria mutica*, *Digitaria decumbens*, *Imperata cylindrica* var. Major, and *Panicum repens*. The aqueous leachate of each grass was used to water the growth of the four grasses in pots. The leachates exhibited variable inhibition of grass growth as compared to the tap water control. By the 41st day after treatment, the leachate of *D. decumbens* significantly suppressed the growth of itself and retarded that of *B. mutica* and *P. repens*. The growth of *B. mutica* was inhibited by its own leachate, but that of *I. cylindrica* was not affected by any of the grass leachates. In crop growth rate (CGR) analysis, the four grass leachates exhibited a similar inhibition pattern. In laboratory bioassays, the leachates showed a significant phytotoxic effect on the radicle growth of ryegrass and lettuce. Six phytotoxic phenolics were quantitatively compared by high-performance liquid chromatography, and the amount of compounds varied with species. The highest total amount of phytotoxic phenolics occurred in *D. decumbens*, followed, in decreasing order, by *P. repens*, *B. mutica*, and *I. cylindrica*. These findings show that the leachates of four grasses possess phytotoxic compounds that may play a significant role in grass dominance in the field.

Key Words—Allelopathy, phytotoxicity, phytotoxic phenolics, grass leachate, *Digitaria decumbens*, *Brachiaria mutica*, *Panicum repens*, *Imperata cylindrica*.

^{1,2}Paper No. 344 of the Scientific Journal Series of the Institute of Botany, Academia Sinica, Taipei, Taiwan, R.O.C. The study was supported in part by a grant to C.-H. Chou by the Academia Sinica and the Council of Agriculture, the Executive Yuan of the Republic of China.

INTRODUCTION

Organic and inorganic substances are commonly leached out from the above-ground plant parts by rainfall, mist, fog, and dew through ecological processes (Tukey, 1969, 1970, 1971; del Moral and Muller, 1969; Chou and Muller, 1972). This phenomenon was described by Stephen Hales and de Saussure (see Tukey, 1971) in the early 18th century, and subsequent studies were conducted in many parts of the world (Tukey, 1970). Phytotoxic metabolites in leachates often play an important role in the regulation of plant dominance, succession, stability of plant communities, and agricultural productivity (Muller, 1969; Chou, 1987; Rice, 1984). The leaching phenomenon in the humid region of Taiwan is of particular importance because of the substantial amount of annual precipitation there. Chou and coworkers studied the ecological functions of plant leachates in various vegetations (Chou, 1975; Chou and Chen, 1976) and found that some leachates exhibited allelopathic properties. Chou and Young (1975) evaluated the phytotoxicity of 12 subtropical grasses and found at least seven phytotoxic substances present in the aqueous extracts of the grasses. This led us to further investigate the phytotoxic nature of leachates from four subtropical grasses, *Brachiaria mutica*, *Digitaria decumbens*, *Imperata cylindrica*, and *Panicum repens*, in order to clarify biochemical interference both intra- and interspecifically.

METHODS AND MATERIALS

Four subtropical grasses, *Brachiaria mutica*, *Digitaria decumbens*, *Imperata cylindrica* and *Panicum repens*, were selected for study. Plant material of *B. mutica* and *I. cylindrica* was collected at the farm of the Institute of Botany, Academia Sinica, Taipei, and the other two species were obtained from the Hsinchu Experiment Station of the Taiwan Livestock Research Institute. Fresh grass leaves were collected and allowed to air dry. The soil used for pot experiments was obtained from the field of the Institute of Botany, Academia Sinica, and the visible plant residues were removed before placing into the pots.

Each grass leachate was obtained by using a leaching apparatus (Figure 1), consisting of a steel frame with three layers (A, B, and C). Layer A was a 55 × 40 × 15-cm plastic tray with numerous needle-sized holes (2 cm between holes), which was filled with 3 liters of tap water. The tap water dripped through the holes as an artificial rain and 1 kg of chopped leaves of each grass was placed on a similar tray of layer B. The leachate from layer B was collected in layer C. About 800 ml of each leachate was collected daily, and the leachate was returned to tray A and recirculated for another 48 hr. The leachate was then stored in a cold room at 5°C prior to analysis. The grass was replaced by fresh

FIG. 1. The leaching apparatus system: A = a plastic tray, $55 \times 40 \times 15$ cm with numerous needle-sized holes (2 cm between holes) was filled with tap water, which dripped through the holes to make an artificial raindrip; B = the same as tray A was filled with chopped plant material to receive the artificial raindrip from tray A; C = a plastic tray, like that of A and B, without holes to receive plant leachate from tray B. The pump recirculated the water from tray C to tray A.

material every week. Of the 800-ml leachate, 200 ml was filtered through a Whatman No. 42 filter paper and used for bioassay or chemical analyses. The remaining leachate was used for watering the grasses grown in pots in the greenhouse of the Academia Sinica, Taipei.

Laboratory Analyses. The grass leachate was bioassayed to determine phytotoxicity (Chou and Young, 1975). Seeds of lettuce (*Lactuca sativa* var. Great Lakes 366) and ryegrass (*Lolium multiflorum*) were used as test species. Distilled water served as the control. Each bioassay included three replications and was incubated at 25°C for 72 hr. After incubation, the radicle length of each seedling was measured and the phytotoxicity expressed as percent inhibition as compared with the control.

The cation content of each leachate was determined by an atomic absorption spectrophotometer (Perkin-Elmer, model 300) following the techniques described in Analytical Methods for Absorption Spectrophotometer (Perkin-Elmer, 1971).

The techniques for isolating phytotoxic substances present in the leachates were described by Chou and Young (1975). The identification of phytotoxic substances was performed mainly by means of paper chromatography using two solvent systems and four detecting methods (Chou and Lin, 1976). The amount of phytotoxic phenolics present in each grass leachate was determined by a high-performance liquid chromatograph (HPLC) (LDC model 1203) and co-chromatographed by using authentic phenolics for comparison (Chou and Kuo, 1986).

Pot Experiment. Each pot, 25 × 30 cm size, was filled with 10kg fresh soil and then planted with 15-cm long stolons or rhizomes, with four replications. The pots were placed in a greenhouse at Nankang and were irrigated with tap water until the grass grew healthily. The pot was then irrigated with the grass leachate obtained from laboratory; a similar pot was irrigated with tap water as a control. The length of the main leaf of the grasses was measured on two successive dates, days 11 and 41 after irrigation, to detect the effect of leachates. In addition, on days 59 and 119 after irrigation, the aboveground part of the grasses was harvested and the dry weight measured. The crop growth rate (CGR) of each grass in every treatment was compared in order to see the effect of leachates on the grass growth. The crop growth rate is defined as follows:

$$\text{CGR} = \frac{\text{Difference of biomass in weight between two measured times (g)}}{\text{Length of time between two measured times (day)}}$$

RESULTS

Effects of Grass Leachates on Grass Growth. The growth of grasses in pots was measured 11 and 41 days after watering with leachate or tap water to see the effects of each grass leachate on grass growth. Results of the leaf length measurement are shown in Table 1, which indicate that the grass growth, at the early stage, was noticeably suppressed by leachates compared to tap water. The leachates obtained from *Digitaria decumbens*, *Brachiaria mutica*, and *Panicum repens* inhibited leaf growth of *D. decumbens*. At the 41st day after treatment, the leachate of *D. decumbens* inhibited its own growth and also suppressed the growth of *B. mutica* and *P. repens*. The leachate from *B. mutica* was also autotoxic. However, the growth of *Imperata cylindrica* was not significantly affected by the leachates.

The crop growth rate (CGR) was calculated based on the dry weight of

grasses harvested at days 59 and 119 following irrigation with leachates (Table 2). The leachate of *D. decumbens* significantly suppressed the growth of itself and that of *B. mutica* in both cuttings but stimulated the growth of *P. repens* and *I. cylindrica* at the second cutting. The leachate of *B. mutica* exhibited a pattern similar to that of *D. decumbens*, but the inhibition of the former was significantly lower than that of the latter. The leachate of *P. repens* was toxic to the growth of *B. mutica* in both cuttings and to that of *I. cylindrica* at the second cutting. Finally, the leachate of *I. cylindrica* suppressed the growth of *D. decumbens*, but stimulated the growth of *P. repens*. In conclusion, *D. decumbens* and *B. mutica* exhibited relatively high phytotoxic effects on the growth of themselves and appeared to be an autointoxicating phenomenon. However, *P. repens* was shown to be tolerant to the leachates of the aforementioned species.

Comparison of Phytotoxic Effects of Grass Leachates on Lettuce and Ryegrass. To further confirm the phytotoxic effect of the leachates on plant growth, bioassays were conducted using lettuce and ryegrass as test species. Leachates from *Digitaria decumbens*, *Brachiaria mutica*, and *Panicum repens* inhibited radicle growth of lettuce but had no effect on ryegrass (Table 3). Among them, the leachate of *D. decumbens* showed the highest phytotoxicity, which agreed with the findings in Table 2. The phytotoxicity of leachate obtained at different times of leaching was not significantly different, suggesting that the phytotoxic substances might continuously leach out within two weeks.

Identity of Phytotoxic Phenolics in Grass Leachate. By paper chromatography, six phytotoxic phenolics were identified. They include ferulic, *p*-coumaric, 2,4-dihydroxybenzoic, vanillic, *p*-hydroxybenzoic, and *p*-hydroxyphenylacetic acids, and three unidentified compounds. Of the three unknowns, one is a flavonoid and two are phenolic acids (Table 4). In addition, by using a HPLC analysis, the quantity of each of the identified phenolics was compared. The amount of phenolics present in the leachate of *D. decumbens* was the highest, *P. repens* was next, and *I. cylindrica* was the least (Table 4). The findings agreed with the bioassay results, in which the leachate from *D. decumbens* was the most phytotoxic.

Cation Contents of Leachates. The leachates were analyzed for cations by an atomic absorption spectrophotometer. The data were the average of cation contents from at least 30 leachates. The quantity of Cu, Zn, and Fe was as low as 0.3 ppm, and the content ranged from 39 to 170 ppm for K, 32 to 63 ppm for Na, 15 to 18 ppm for Ca, and 22 to 28 for Mg. Only the amounts of K, Na, and Mn were significantly different between species, but those of the remaining cations were not significantly different. Therefore, the cations present in the leachates of the grasses may not play a significant role in their growth performance.

pH and Osmotic Concentration of Grass Leachates. The pH of grass leachates ranged from 7.19 to 7.65. The osmotic concentrations were as low as 17.4,

at which concentration or below the plant growth would not be suppressed (Chou and Young, 1974). Thus, the previous findings of plant growth inhibition by the grass leachates were evidently due to phytotoxic inhibition rather than osmotic effect.

DISCUSSION

In previous studies, Chou and Young (1975) identified seven phytotoxins present in the aqueous extract of 12 subtropical grasses, and among these species *Digitaria decumbens* was the most phytotoxic to test plants. Moreover,

Chou (1977) presented further evidence that potentially phytotoxic substances were present in the aqueous fraction of the grass extracts. These unidentified phytotoxic compounds were tentatively identified as nitrogenous compounds of low molecular weight. In this study a phytotoxic flavonoid was found but the amount of the isolate was too small for structural identification. The physiological function and inhibition model on seed germination of 15 phytotoxins, including the aforementioned six phenolics, were studied, and findings will be presented in a subsequent report, which will interpret the role of phytotoxins in biochemical inhibition among plants. Compounds produced during the decomposition of grass residues in soil were also phytotoxic to the radicle growth of several test species (data are not shown). However, under natural conditions, the interactions among the aforementioned grasses have not been clearly demonstrated. The grass leachates obtained by the present leaching apparatus could not be the same but were very similar to those obtained in the field. One may argue that recirculated leachates do not occur in nature, and the concentration of the artificial grass leachate was also not the same as in the field. The author makes no argument about this; however, the present findings provide the evidence that under comparable conditions the grass leachate of *D. decumbens* clearly showed phytotoxicity. Since the productivity of *D. decumbens* declined several years after planting, Liang et al. (1983) found that the decline was due in part to biochemical inhibition of the grass. Thus, the present study is an attempt to answer the question by using grass leachate to test the growth of grasses inter- and intraspecifically. Because the pH and osmotic concentration were such that they did not affect plant growth (Chou and Young, 1974), the inhibition was thus surely due to the phytotoxic effect. In conclusion, the phytotoxic mechanism, therefore, plays an appreciable role in the formation of dominance and in the decline of productivity of *D. decumbens* in the field. The decline was overcome by a pangola grass-watermelon-pangola grass rotation management.

Black et al. (1969) proposed that the mechanism of plant dominance could be due in part to biochemical competition, in that some plants possess high efficiency in photosynthesis resulting in better growth. This phenomenon is particularly pronounced in C_4 plants, such as *D. decumbens*, which exhibit highly efficient photosynthesis, higher biomass production, and are aggressive against associated weeds grown nearby. According to the data of crop growth rate (CGR), the rate is higher in the *D. decumbens* than in the other three grasses (data were not shown). Chou and Lee (1987) found that the more nitrogen fertilizer was applied to the grass, the greater was the quantity of phytotoxins produced; this suggests that the increased growth of *D. decumbens* cultivars may produce more phytotoxins and may suppress the growth of competitors such as *P. repens* and *I. cylindrica*. Whittaker and Feeny (1971) and Putnam and Duke (1974) suggested that allelopathy could be used in agriculture by

breeders who can select cultivars that produce natural phytotoxins and thus lessen the use of herbicides and environmental pollution. Chou et al. (1987) have demonstrated such a case study by using kikuyu grass as a cover grass in deforested land, in which kikuyu suppresses the growth of weeds but not the growth of *Cunninghamia lanceolata*, a coniferous plant.

The amount of phytotoxins present in the aqueous leachate of *I. cylindrica* var. Major was the lowest of the species tested. Eussen and Niemann (1981) had identified eight phytotoxic phenolics, *p*- and *o*-coumaric, gentisic, vanillic, benzoic, and *p*-hydroxybenzoic acids, vanillin, and *p*-hydroxybenzaldehyde, from leaves of *I. cylindrica* (L.) Beauv. Of them, *o*-coumaric, gentisic, and benzoic acids, *p*-hydroxybenzaldehyde, and vanillin were not found in the leachate of *I. cylindrica* in the present study, due primarily to the difference of leachate and extract: the leachate contains less phytotoxin. The correlation between the phytotoxins and habitats and the real mechanism of interaction between the dominant and inferior grasses in the field still remain unclear.

Acknowledgments—The author expresses his great appreciation to Mr. Chia Huang, senior specialist of the Council of Agriculture, Executive Yuan of the R.O.C. for the encouragement during this study.

CHEMICAL CONSTITUENTS OF *Erysimum cheiranthoides* DETECTING OVIPOSITION BY THE CABBAGE BUTTERFLY, *Pieris rapae*

J.A.A. RENWICK, C.D. RADKE, and K. SACHDEV-GUPTA

*Boyce Thompson Institute
Cornell University

(Received September 1, 1988; accepted November 16, 1988)

Abstract—Avoidance of *Erysimum cheiranthoides* for oviposition by *Pieris rapae* has been attributed to the presence of water-soluble deterrents. The active material was extracted into *n*-butanol and isolated by a series of HPLC separations. TLC of the active fraction and visualization of individual constituents with Kedde's reagent indicated that cardenolides are responsible for deterring oviposition. UV spectra were also characteristic of cardenolides. Bioassays of selected known cardenolides revealed a general lack of activity, except for cymarins, which was as strongly deterrent as the most prominent cardenolide isolated in pure form from *E. cheiranthoides*. The results suggest that cardenolides in this plant can explain its escape from cabbage butterflies, but specific structural features of the glycosides are necessary for oviposition-deterrence activity.

Key Words—Cabbage butterfly, *Pieris rapae*, Lepidoptera, Pieridae, *Erysimum*, oviposition deterrent, cardenolides.

INTRODUCTION

The cabbage butterfly, *Pieris rapae* L., oviposits primarily on members of the Cruciferae and a few related plant families that are linked by the presence of glucosinolates (Verschaffelt, 1911; Ma and Schoonhoven, 1973); however, some crucifers are rejected by gravid butterflies and may be unsuitable for feeding by the larvae (Feeny, 1977; Rodman and Chew, 1980). These plants may contain specific groups of chemicals that offer a second line of defense against herbivores and other invading organisms (Feeny, 1977; Nielsen, 1978). However, representative cardenolides, cucurbitacins, and alkaloids, which have been

suggested as defensive compounds, failed to affect feeding and development of *P. rapae* larvae in the laboratory (Usher and Feeny, 1983). Nevertheless, the involvement of chemical constituents in deterring oviposition on nonhost plants has been clearly demonstrated. Polar extracts of the crucifers, *Erysimum cheiranthoides* L. and *Capsella bursa-pastoris* (L.), were particularly effective (Renwick and Radke, 1985). Further work on these unacceptable crucifers has shown that *E. cheiranthoides* contains oviposition stimulants as well as deterrents (Renwick and Radke, 1987), so the deterrents must be potent enough to outweigh the effects of the stimulant(s).

Despite the known presence of oviposition deterrents in nonhost plants, specific chemicals responsible for rejection of these plants have not been identified. In this report, we describe the systematic isolation and partial characterization of active compounds in *E. cheiranthoides* that deter oviposition by *P. rapae*.

METHODS AND MATERIALS

Insects. Butterflies used in bioassays were from a laboratory colony maintained on cabbage plants at ca. 22°C under fluorescent lights providing a photoperiod of 16 : 8 hours light-dark. The colony was originally started from field-collected butterflies and had completed 20–30 generations in the laboratory. No change in discriminatory behavior had been noted in this time. Pupae were separated by sex (Richards, 1940) and kept in screen cylinders (15 cm × 15 cm diam.) closed at the top and bottom with plastic Petri dishes. After eclosion, five pairs of butterflies were transferred to each bioassay cage in the greenhouse. Each cage was supplied with a vial of 10% sucrose solution containing yellow food coloring and a cotton wick to facilitate feeding.

Plants. *Erysimum cheiranthoides* plants were grown in artificial soil mix (Cornell Mix A) (Boodley and Sheldrake, 1977) from seeds originally collected by Dr. Frances S. Chew in Vermont. Supplemental lighting in the greenhouse was supplied by 400-W multivapor, high-intensity-discharge lamps, and the temperature was maintained at ca. 25°C. Foliage was harvested after four to five weeks, just before flowering began. Cabbage plants, *Brassica oleraceae* (var. Golden Acre), grown under the same conditions in 10-cm-diam. pots, reached a suitable size for bioassays after about six weeks.

Bioassays. Oviposition assays for deterrent activity were conducted in screen cages (48 × 48 × 48 cm) in a greenhouse, with supplemental lighting from 400-W multivapor lamps. For each replication, one treated and one control cabbage plant were placed in opposite corners of each cage for a period of 5 hr from 10:00 AM to 3:00 PM, and the eggs laid on each plant were counted. The positions of control and treated plants were alternated between cages to

eliminate possible positional effects. Dead butterflies were replaced daily to maintain five pairs in each cage. Extracts of fractions to be tested were applied to test plants in methanol or water using a Freon-propelled chromatographic sprayer. Both upper and lower leaf surfaces were sprayed with a total of 7 ml of test solution, and control plants were sprayed with an equal volume of solvent alone. The oviposition deterrent index (ODI) was calculated for each test material according to the formula: $ODI = [(C - T)/C + T] \times 100$, where C and T are the numbers of eggs laid on control and treated plants, respectively (Lundgren, 1975). The ODI was calculated for each replication, and a paired t test was used to analyze the results for each compound tested.

Extraction and Isolation of Active Material. Fresh foliage of *E. cheiranthoides* was added to boiling ethanol, and after ca. 5 min the mixture was cooled and homogenized in a Waring blender. After filtration through glass wool, the ethanolic extract was evaporated to dryness, and the residue was sequentially extracted with hexane and water. The aqueous deterrent material was then extracted into *n*-butanol (Renwick and Radke, 1987) and, after evaporation of the butanol, the total residue was taken up in water for HPLC. Separation into fractions for bioassays was accomplished with a C_{18} reversed-phase column (Varian MCH-10, 30 cm \times 8 mm) at a flow rate of 3 ml/min. A water-acetonitrile gradient was used throughout and was adjusted to provide better resolution of active fractions as the isolation progressed. Chromatograms were initially obtained with UV detection at 254 nm, and later a diode array detector was used to monitor the eluate at 219 nm, based on the absorption maximum of active compounds.

Thin-layer chromatography (TLC) of active fractions was carried out on 10 \times 20 cm, 250- μ m thick, Whatman K6 silica gel plates. The solvent system consisted of ethyl acetate-methanol-water (8 : 1 : 0.8), and spots were visualized with ceric sulfate for glycosides or with Kedde's reagent for cardenolides (Krebs et al., 1969). Purification of individual compounds in the active HPLC fractions required separation on an open column of Woelm silica gel, 32-63 mesh, eluted with a gradient of ethyl acetate saturated with water and 0-15% methanol.

UV spectra of isolated compounds were obtained from the diode array detector (Hewlett Packard model 1040A) in water-acetonitrile and with a Perkin Elmer model Lambda 5 spectrophotometer in methanol solution.

RESULTS

Bioassays of extracts of *E. cheiranthoides* as oviposition deterrents to *P. rapae* confirmed our previous observation that the activity can be removed from aqueous extracts by *n*-butanol (Renwick and Radke, 1987). When tested in this

FIG. 1. Initial HPLC separation of butanol extract of *E. cheiranthoides*. Deterrent activity indicated by double arrow. UV monitoring at 254 nm.

study at 3 gram leaf equivalents (GLE) per plant, butanol extracts gave an ODI of 84.7. In 10 replications, a total of 108 eggs were laid on treated cabbage plants, whereas 1302 were laid on the controls ($P < 0.001$, paired t test).

Initial HPLC runs using a rapid solvent gradient resulted in isolation of the active material as a relatively nonpolar fraction eluting with 50–70% acetonitrile (Figure 1). Subsequent runs used a slow solvent gradient from 15 to 33% acetonitrile to further separate constituents of the active fraction (Figure 2).

FIG. 2. HPLC separation of active fraction of *E. cheiranthoides* collected from initial HPLC run (as shown in Figure 1). UV monitoring at 254 nm.

TABLE 1. MEAN OVIPOSITION DETERRENT INDICES (ODI)^a OF *E. cheiranthoides* FRACTIONS COLLECTED FROM HPLC (FIGURE 2), IN BIOASSAYS WITH *P. rapae*

Fraction No.	ODI	Fraction No.	ODI
1	14.1	8	62.0
2	1.1	9	35.0
3	-20.2	10	53.0
4	27.0	11	44.0
5	78.0	12	25.0
6	96.0	13	26.0
7	73.0	—	—

^aOviposition deterrent index = $(C - T/C + T) 100$. *C* = eggs laid on control plant; *T* = eggs laid on treated plant. Mean values were obtained from two replications at 10 gram leaf equivalents/plant.

Several fractions from these separations were deterrent (Table 1), but most of the activity was concentrated in fractions 5–8. Better resolution in the region of high activity was obtained from the same material using a different solvent gradient that increased slowly from 15 to 28% acetonitrile (Figure 3). UV monitoring of the eluate at 254 nm showed little absorption for the active fractions, but when a wavelength of 219 nm was used, three prominent peaks were obtained (Figure 3).

FIG. 3. Final HPLC separation of *E. cheiranthoides* deterrent fraction with UV monitoring at 254 and 219 nm. Active region indicated by double-headed arrow.

The UV spectra of the isolated prominent compounds (1, 2, and 3) were almost identical, with a λ_{max} at 216–219 nm, which is typical for a butenolide ring. TLC of the individual compounds collected from HPLC indicated the need for further purification (Figure 4), but visualization of spots with $\text{Ce}(\text{SO}_4)_2/\text{H}_2\text{SO}_4$ indicated that all the compounds were glycosides. Visualization of the spots with Kedde's reagent gave an intense purple color, which is typical for cardenolides.

Purification of the individual compounds on an open silica gel column and a final clean-up by HPLC resulted in the isolation of milligram quantities of pure compound 2 for bioassays and further characterization. The deterrent activity of compound 2 was compared with that of commercially available cardenolides at 2 concentrations (Table 2). Digitoxin, ouabain, and helveticoside were completely inactive, but compound 2 was deterrent at both 0.1 and 0.01 mg/plant. Cymarín was the only known cardenolide among those tested to show similar deterrent activity.

FIG. 4. TLC of active fraction (A) and individual peaks (1, 2 and 3) isolated in final HPLC separation.

TABLE 2. OVIPOSITION BY *Pieris rapae* ON CABBAGE TREATED WITH KNOWN CARDENOLIDES OR COMPOUND 2 FROM *E. cheiranthoides*

DISCUSSION

The results show that avoidance of *E. cheiranthoides* by ovipositing cabbage butterflies can be explained by the presence of specific cardenolides in the foliage. Cardenolides have been reported in *Erysimum* species (Singh and Rastogi, 1970; Rodman et al., 1982), but their possible role in the defense of these plants against insects was not demonstrated until recently. Rothschild et al. (1988) isolated and characterized a cardenolide from Siberian wallflower, *Cheiranthus allionii*, that deters oviposition by *Pieris brassicae* in Europe. The host ranges of *P. rapae* and *P. brassicae* are very similar, and our results along with those of Rothschild et al. (1988) suggest that the two cabbage butterfly species rely on similar cues to reject unsuitable crucifers.

The idea that atypical secondary compounds in crucifers serve to protect certain species from herbivory provides a popular explanation for the escape of those plants from insect feeding (Feeny, 1977). Many attempts have been made to test this idea, usually by adding known compounds to insect diet (Nielsen,

1978; Usher and Feeny, 1983). Other studies have aimed to show the positive effects of typical compounds such as glucosinolates in the process of host finding and acceptance, often using relatively high concentrations of known compounds (reviewed by Schoonhoven, 1972). Our approach in studying the oviposition deterrents from *E. cheiranthoides* has been to isolate systematically the active material by solvent extractions and chromatographic separation, using bioassays to monitor the progress.

Our bioassays of known cardenolides as oviposition deterrents indicate that activity is likely to be restricted to a few specific members of the group. The four compounds tested along with compound 2 represent different groups of cardenolides based on the aglycones as well as type and number of sugars. Cymarín was active but is not known to be present in *E. cheiranthoides*. However, the results should pave the way for studies on structure–activity relationships. The final identification of the three major cardenolides in *E. cheiranthoides* is almost complete and will be reported separately.

Acknowledgments—This research was supported in part by a grant from the Cornell University Biotechnology Program and by USDA contract 86-CRCR-1-2007.

CHEMICAL CONSTITUENTS AND INHIBITORY ACTIVITIES OF ESSENTIAL OILS FROM *Cyperus brevifolius* and *C. kyllingia*

KOICHIRO KOMAI¹ and CHUNG-SHIH TANG

Department of Agricultural Biochemistry
University of Hawaii
Honolulu, Hawaii 96822

(Received October 8, 1988; accepted November 21, 1988)

Abstract—*Cyperus brevifolius* and *C. kyllingia* are two common weeds in Hawaii. The underground parts, including the rhizomes and roots, contain allelopathic essential oils, which may contribute to the aggressive spread of these weeds in grasslands and lawns. Although morphologically similar, *C. kyllingia* contains more essential oils than *C. brevifolius*. Also, the former is rich in terpenes, including α -cyperone, β -selinene, and α -humulene, while the latter is rich in C₁₇ to C₂₅ *n*-paraffins. These chemical differences agree with their inhibitory activities against indicator species and the general observation that *C. kyllingia* is the more prevalent weed of the two.

Key Words—*Cyperus brevifolius*, *Cyperus kyllingia*, weeds, allelopathy, inhibition, essential oils, terpenes, *n*-paraffins.

INTRODUCTION

Cyperus brevifolius (Ruttb.) Hassk (synonym, *Kyllingia brevifolius* Rottb.) is a perennial weed widely distributed in tropical and subtropical regions. It is found in open waste areas, grasslands, and lawns, and has long been established in Hawaii. Another weed species, *C. kyllingia* f. *Humulis*, which presents persistent problems in lawns and gardens, has been considered as a dwarf form of *C. brevifolius* (Neal, 1965). According to our observations, however, *C. kyllingia* is more commonly distributed than *C. brevifolius* on Oahu, Hawaii, and the height of *C. kyllingia* is variable, depending on various environmental fac-

¹On leave from the Department of Agricultural Chemistry, Kinki University, Osaka, Japan.

tors. While similar in many morphological characteristics, a distinctive difference between the two species is that *C. brevifolius* has green globular flower heads, and *C. kyllingia* has white ones. Common names for these two weeds, therefore, are "green head" and "white head" kyllingia, correspondingly.

Both *C. brevifolius* and *C. kyllingia* have been observed to make spot invasions upon grasslands and lawns followed by circular spread, and establish patches or colonies (Sakai and Kawanabe, 1981; Barnes and Chandapillai, 1972). These aggressive and persistent characteristics are similar to those of purple nutsedge (*C. rotundus*), whose underground rhizomes and tubers contain several phytotoxic sesquiterpenes. Composition of the terpene oils in tubers has been examined, and four major chemotypes has been reported so far (Komai, et al., 1977; Komai and Ueki, 1981; Komai and Tang, 1988). Neither *C. brevifolius* nor *C. kyllingia* forms any tubers. However, their rhizomes and roots have a strong terpenelike aroma, and their underground parts have been used as perfume and herbal medicine in some countries (Neal, 1965).

Many terpenoids are phytotoxic and have been suggested to be allelopathic or inhibitory to the growth of nearby plants or microorganisms (Putnam and Tang, 1987). In this report, the essential oils from *C. kyllingia* and *C. brevifolius* were obtained from the fresh rhizomes and roots. The chemical characteristics and plant growth inhibitory activities of the two morphologically similar weeds were compared.

METHODS AND MATERIALS

Isolation and Identification of Essential Oils. Two kilograms each of roots and rhizomes of mature, flowering *Cyperus brevifolius* and *C. kyllingia* were collected on the Manoa campus, University of Hawaii. After removal of soil and debris, the fresh tissues were crushed and extracted with 8 liters of *n*-hexane. The extract was dried over anhydrous sodium sulfate and the bulk of the solvent evaporated with a rotary evaporator under reduced pressure. Further concentration was carried out under a stream of N₂. Both concentrates from the two species had a strong, typical terpene aroma and were used for instrumental analyses.

GC was performed on a Spectra-Physics SP-7100 gas chromatograph equipped with a flame ionization detector and a 20-m × 0.25-mm-ID, DB-5 fused silica capillary column (J&W Scientific). The oven temperature was programmed from 90 to 250°C at 4°C/min. For GC-MS analysis a model HP-5730 gas chromatograph-mass spectrometer was used. Conditions for GC of the GC-MS were similar to those of the GC analysis. For the MS, 70 eV and 300 mA electron energy were used. The ion-source temperature was 200°C.

Compounds were identified by the comparison of GC retention times and mass spectra with those of the authentic compounds.

Inhibitory Activities of Essential Oils. Inhibition of lettuce (*Lactuca sativa* L. Anuenue) seed germination was performed in a Petri dish containing a Whatman No. 1, 5-cm-diameter filter paper. Two mls of the *n*-hexane solution with a known concentration of the essential oils was added to the paper and the hexane evaporated in a hood. The paper was moistened with 2 ml of distilled water, and 20 lettuce seeds were placed in the covered Petri dish in the dark at 23°C. The rate of germination was determined after 48 hr.

Inhibition of the lettuce seedling growth (Table 2) was performed by transplanting 10 pregerminated seeds to a Petri dish containing a filter paper and 2 ml of the aqueous suspension of a known quantity of essential oil. Hypocotyl and radicle length were measured four days after incubation, and the inhibitory activity was expressed as percent growth of those of the control (i.e., without essential oil).

Methods for determining inhibition of oat (*Avena sativa* L.) seedlings (Table 3) were similar to those of the lettuce except that a 9-cm Petri dish with filter paper and 4 ml of aqueous suspension of the essential oils were used instead. The lengths of leaf sheath and radicle were measured after four days. Inhibitory effects were also tested using fumigation (Table 4). A 3-cm-diameter center well containing 5 ml of an aqueous suspension with known amounts of the essential oils was used as the source of the volatile inhibitors. Distilled water was added to the filter paper disk for the germination of seeds. All experiments were performed in the dark at 23°C in covered Petri dishes.

RESULTS AND DISCUSSION

Composition of Essential Oils and Chemotaxonomy. Yield of the essential oils from underground parts of *C. kyllingia* was substantially greater than that from the *C. brevifolius* (0.72% vs. 0.15%, on fresh weight basis). Table 1 shows the qualitative and quantitative data of the *n*-hexane extracts using capillary GC and GC-MS.

The essential oils of both species had a typical terpene aroma. *C. kyllingia* contained mainly sesquiterpenes; the two major ones were β -selinene (28.1%) and α -cyperone (30.9%). *n*-Paraffin content accounts for less than 7% and the most abundant one was C₁₉H₄₀ (6.7%). In contrast, the essential oil from *C. brevifolius* contained mainly C₁₇ to C₂₅ *n*-paraffins (ca. 58%). Only a trace of β -selinene was detected, and there was no α -cyperone. Thus, the two species can be easily distinguished by their gas chromatograms in case the flower heads are not present.

^aPercent of the total volatile compounds as determined by GC analysis. t = trace; n = none detected.

^bMethods used for identification: 1 = retention time on GC; 2 = GC-MS; 3 = cochromatography with the authentic compound.

Earlier, a survey by Komai (1982) reported that the essential oils from six *Cyperus* species, i.e., *difformis* L., *haspan* L., *polystachyos* Rottb., *globosus* All., *sanginolentus* Vahl., and *brevifolius* Rottb. were rich in paraffins (C_nH_{2n+2}, N = 19–27). These were wetland or paddy species without tubers. Except for *C. brevifolius*, which is perennial, all the others are annual sedges.

Comparing *Cyperus* spp. of dryland habitat, such as *C. rotundus* and *C. kyllingia*, it is apparent that the paraffin content is higher in the above-mentioned wetland species. This striking difference is of interest from both biochemical and ecological standpoints. Biochemically, paraffins are synthesized from the fatty acid pathway while terpenes are from the mevalonic acid pathway. Therefore, the paraffin-rich and the terpene-rich *Cyperus* species differentiated biochemically at an early stage of acetate utilization, suggesting basic genetic differences in photosynthate utilization as well as adaptation strategy. These differences may serve as chemotaxonomical bases for the division of these two types of *Cyperus* spp.

Plant Growth Inhibitory Activities of Essential Oils. The essential oils were not inhibitory to the germination of either lettuce or oat seeds; even at the high concentration of 1000 ppm, 100% germination was observed. However, the

TABLE 2. INHIBITION OF LETTUCE (*Lactuca sativa* L.) SEEDLING GROWTH BY AQUEOUS SUSPENSION OF ESSENTIAL OILS OF *Cyperus brevifolius* AND *C. kyllingia*^a

250	73.2*	67.2*	47.4*	39.8*
500	66.2*	60.2*	(32.3)*	34.4*
1000	64.2*	61.3*	(29.4)*	27.4*

^aExpressed in Percent Length of radical (R) and hypocotyl (H) of the treated in comparison to those grown in distilled water control. Average of three treatments; measured after four days. For distilled water control, the hypocotyl length = 18.6 mm; radicle length = 23.4 mm. *Significantly different from the control at more than 95% confidence level.

^bData in parentheses indicate that radicles withered after browning.

lettuce seedling growth rate (Table 2) was reduced by more than 50% of that of the water control when treated with 50 ppm essential oil from *C. kyllingia*. *C. brevifolius* showed a much weaker effect, reducing only to less than 10% of the control. Even at the high concentration of 1000 ppm, the growth reduction was less than 40%, while severe inhibition causing browning and withering of the radicles was observed in seedlings grown in a suspension of *C. kyllingia* oil at 500 ppm. The higher activity of the essential oil from *C. kyllingia* is expected since it has a high ratio of terpenes. The essential oil from *C. brevifolius* has a high ratio of paraffins, which, unlike the terpenes, are nontoxic in general. Less severe effects were observed when lettuce seedlings were treated with the volatiles released from the aqueous suspension of the essential oils (Table 3), confirming the presence of volatile inhibitors under the treatment conditions.

TABLE 3. INHIBITION OF LETTUCE SEEDLING GROWTH BY FUMIGATION USING AQUEOUS SUSPENSION OF ESSENTIAL OILS OF *Cyperus brevifolius* AND *C. kyllingia*^a

1000	71.6*	68.6*	8.9*	12.4*

^aExpressed in percent length of radicle (R) and leaf sheath (S) of the treated in comparison to those grown in water (control). Average of three treatments; measured after four days. For distilled water control, the leaf sheath length = 18.5 mm; radicle length = 32.4 mm.

^b*Significantly different from the control at more than 95% confidence level.

Similar differences were shown in the inhibition of oat seedling growth (Table 4). The oat radicle showed a higher susceptibility than the leaf sheath to the toxicity of the essential oil of *C. kyllingia*. For example, at 250 ppm, the growth of radicle was reduced by 65% but the growth of the leaf sheath by only 25%. In general, roots are more susceptible to the inhibition of these essential oils, showing reduction of root hairs and browning in addition to growth.

CYANOGLYCOSIDE GYNOCARDIN FROM *Acraea horta*
(L.) (LEPIDOPTERA: ACRAEINAE)
Possible Implications for Evolution
of Acraeine Host Choice

DAVID RAUBENHEIMER¹

*Department of Zoology
University of Cape Town
Cape Town South Africa*

(Received April 25, 1988; accepted November 23, 1988)

Abstract—All stages in the life cycle of *Acraea horta* (L.) (Lepidoptera: Acraeinae) were found to release hydrogen cyanide (HCN) from their crushed tissues, and the source of cyanogenesis was present in the hemolymph of adults and larvae. Comparison with standards on thin-layer chromatograms (TLC) revealed the presence in adults of gynocardin, a cyclopentenyl cyanoglycoside also produced by the larval food plant, *Kiggelaria africana* L. (Flacourtiaceae). Analysis of adults reared on plant species (Passifloraceae) containing gynocardin and/or other cyanoglycosides suggested selective uptake of gynocardin by the larvae. This is the first demonstration of a cyanoglycoside, other than the acyclic linamarin and lotaustralin, occurring in Lepidoptera and the first evidence for the storage by *Acraea* butterflies of a plant-produced allelochemical. Possible implications for the understanding of the evolution of acraeine host choice are discussed.

Key Words—*Acraea horta*, Lepidoptera, Acraeinae, cyclopentenyl cyanoglycoside, gynocardin, *Kiggelaria africana*, sequestration, evolution.

INTRODUCTION

Unpalatable herbivorous insects that store the same toxic chemicals as their hosts often obtain these from the plants they eat (Brower and Brower, 1964; Rothschild, 1972). It was therefore surprising when evidence emerged sug-

¹Present address: Department of Zoology, University of Oxford, South Parks Road, Oxford, OX1 3PS, U.K.

gesting that all three groups of Lepidoptera known to contain cyanoglycosides are an exception in this regard: the Zygaenidae and the nymphalid groups, Heliconiini and Acraeinae, feed selectively on plants containing cyanoglycosides and yet synthesize these compounds themselves.

This was first reported by Jones *et al.* (1962), who found that *Zygaena filipendulae* (L.) and *Z. lonicerae* (von Schev.) (Zygaenidae) release hydrogen cyanide (HCN) from their crushed tissues even when reared on acyanogenic plants. Davis and Nahrstedt (1979) subsequently identified the chemical basis of cyanogenesis in *Z. filipendulae* to be the cyanoglycosides linamarin and lotaustralin. Thereafter, one or both of these compounds were detected in the adults of five species of *Acraea* (see Table 3) and three species of *Heliconius* (Nahrstedt and Davis, 1981) and subsequently in *A. violae* (Fabricius) and in six additional genera of the Heliconiini (Nahrstedt and Davis, 1983). The major food plants of the Heliconiini and Acraeinae, the Passifloraceae and related families (Smiley, 1985; Ackery, 1987), produce cyanoglycosides with a cyclopentenyl moiety, suggesting that the acyclic linamarin and lotaustralin are synthesized by these butterflies. Nahrstedt and Davis (1983) confirmed this for *Heliconius melpomene* (L.) by demonstrating that larvae and adults incorporate radioisotope-labeled amino acids into linamarin and lotaustralin.

The question thus arises, why do cyanogenic Lepidoptera feed selectively on cyanogenic plants if not to obtain defensive chemicals? The recent discovery that *Zygaena trifolii* (Esper) and probably *Z. filipendulae* are capable, in addition to their *de novo* synthesis, of sequestering linamarin and lotaustralin (Nahrstedt and Davis, 1986), indicates that the association of these insects with cyanogenic plants does indeed involve the uptake and storage of plant-produced allelochemicals. Since there had been no demonstration of sequestration by the Heliconiini and Acraeinae, it was suggested that these groups originally colonized the largely competitor-free cyanogenic plants because their already established ability to synthesize cyanoglycosides preadapted them to cope with the toxicity of these compounds (Rothschild, 1972; Davis and Nahrstedt, 1985; Ackery, 1988). However, this hypothesis fails to explain why several species of *Acraea* show the patterns of host utilization typical of insects that obtain defensive chemicals from the plants they eat. These patterns include: (1) families and subfamilies of insects being more or less confined to a single group of plants with taxonomic and/or chemical affinities, and (2) different groups of insects having a similar pattern of host preference across several families of plants (Rothschild, 1972).

Acraea horta (L.) is one such species showing the patterns of herbivory typical of insects that sequester defensive chemicals from their hosts. With reference to the first of these patterns listed above, the larvae are monophagous on *Kiggelaria africana* L. (Flacourtiaceae) in their natural habitat and are also known to feed on introduced garden plants in the taxonomically related Passi-

floraceae (Pennington, 1978). Several *Acraea* species feed exclusively on one or both of these families and additionally, where available in their distribution range, on a third related family, the Turneraceae (Ackery, 1988). The Flacourtiaceae, Passifloraceae, and Turneraceae have biochemical affinities in that it is only from this group of plants that cyanoglycosides with the unusual cyclopentenyl structure are known (Seigler, 1975). With reference to the second of the patterns listed above, the Heliconiini show a similar pattern of host specificity to the Acraeinae, in which the larvae feed only on the Passifloraceae and Turneraceae (Smiley, 1985).

The circumstantial evidence therefore suggests that *A. horta* may obtain defensive compounds from their larval food plants. This would have implications for our understanding of how acraeine butterflies came to be associated with cyanogenic plants, and the purpose of the present study was therefore to investigate the source of cyanogenic compounds in *A. horta*.

METHODS AND MATERIALS

Test for Cyanogenesis. Eggs, larvae, pupae, and adults were collected from *Kiggelaria africana* trees in Newlands Forest, Cape Town. Larvae, pupae, and adults were tested for cyanogenesis by crushing the individual organisms in 3 ml of distilled water in a glass vial (50 × 10 mm) in which a strip of picrate paper was suspended before stoppering (Steyn, 1934); eggs were tested in the same way in batches of approximately 50. For larvae, the digestive tract was first dissected out in order to remove any residual plant tissue. In addition, the hemolymph of adults and larvae and the dissected wings, head, thorax, and abdomen of adults were tested separately. Hemolymph was extracted from the wing veins of adults and the body spines of larvae using 2- μ l glass pipets and the full pipets were crushed in vials containing picrate paper. The presence of hydrogen cyanide (HCN) was indicated by a change in the picrate paper from yellow to purple-brown. The time taken for this change to begin and the final intensity of the coloration are roughly proportional to the quantity of HCN released (Jones *et al.*, 1962; Gibbs, 1974). In all cases the test was conducted at 25°C and allowed to run for 24 hr. Each test was replicated at least 10 times on both male and female insects.

Identification of Gynocardin in A. horta. Gynocardin was identified from *A. horta* adults using correlative chromatography on thin-layer plates (TLC) (silica gel 60F, 254) and Whatman No. 1 paper (descending). Reference standards were pure gynocardin isolated from the leaves of *Kiggelaria africana* (Raubenheimer and Elsworth, 1988) and linamarin supplied by Professor A. Nahrstedt and Dr. R. H. Davis. The sandwich technique (Tantisewie *et al.*, 1969) was used to monitor cyanoglycosides on paper chromatograms, incor-

porating a crude enzyme extract from leaves of *K. africana* as a hydrolytic agent (Spencer and Seigler, 1982). On TLC, glycosides were visualized by spraying with cerium (IV) sulfate in 1.5 M H₂SO₄ followed by heating for 1–2 min on a hot plate; the cyanogenic nature of the glycosides was confirmed using the sandwich technique modified for use with TLC. The cyanoglycosides were applied to chromatograms as methanolic solutions. Solvent systems used are shown in Table 1.

Extraction of Gynocardin. To isolate the cyanogenic substance from *A. horta*, 235 (16 g fresh weight) adults were collected, frozen, and later macerated in boiling 96% ethanol. Since the test for cyanogenesis (see above) revealed no differences between the sexes, this sample contained approximately equal numbers of males and females. The resulting slurry was filtered and the filtrate defatted using petroleum ether, then dichloromethane, and dried under vacuum to a syrup (1.2 g). This was adsorbed onto 1.5 g silica gel (Merck 35–70 mesh), placed on a silica gel column (Merck 70–230 mesh, 60 g), and eluted using acetone–water (5:1). Fractions (15 ml) were collected and monitored for cyanoglycosides using cerium (IV) sulfate reagent and the modified sandwich method on TLC (see above). The cyanogenic fractions were combined, dried to a syrup,

TABLE 1. MOBILITY OF CYANOGLYCOSIDE EXTRACTED FROM *Acraea horta* ADULTS COMPARED WITH LINAMARIN AND GYNOCARDIN STANDARDS

Chromatographic system	Mobility (R_f)		
	Linamarin standard	Gynocardin standard	Extracted from <i>A. horta</i>
TLC

and partially purified using preparative plate chromatography (silica gel 60, Merck; ethyl acetate-acetone-methanol 4:4:1). The cyanogenic front ($R_f = 0.38-0.62$) was located by spraying a 1-cm-wide strip of the chromatogram with crude enzyme extract from *K. africana* and overlaying this with medicinal gauze and picrate paper (Steyn, 1934). The chromatogram, picrate paper, and gauze were enclosed between glass sheets and incubated at 30°C until a red band appeared on the yellow picrate paper, indicating the cyanoglycoside front. The cyanoglycoside was eluted using methanol.

Test for Sequestration. To investigate the possible sequestration of cyanoglycosides, *A. horta* were reared from eggs to the adult stage on the leaves of plants containing gynocardin and/or other cyanoglycosides. These plants, *Passiflora caerulea* L., *Tacsonia mollissima* Kunth., and *Tacsonia manicata* Juss. (Passifloraceae), were selected as those most readily eaten by fifth-instar larvae in a previous experiment (Raubenheimer, 1987). The butterflies were then extracted in ethanol and the resulting extracts compared for cyanoglycosides using TLC with the extracts of the respective food plants on which each batch of butterflies had been reared and with a gynocardin standard.

Owing to low survival rates on these plant species, extractions were limited to three butterflies per batch. It was thus not practical to purify the butterfly extracts chromatographically, as had been done to establish the presence of gynocardin in the wild butterflies (see above). The crude extracts were, therefore, filtered, dried under vacuum, and made up to equal concentration (weight/volume) in methanol before application to TLC for comparison. Cyanoglycosides were monitored using the sandwich method (Tantisewie et al., 1969). Hydrolysis of the cyanoglycosides was achieved by spraying the chromatograms with a mixture of crude enzyme extracts from *K. africana*, *P. caerulea*, *T. mollissima*, and *T. manicata*. This ensured that a negative result was due to the absence in the organism under test of cyanoglycoside and not of an appropriate hydrolytic enzyme (Nahrstedt et al., 1981).

RESULTS

Test for Cyanogenesis. All stages in the life cycle gave a strong positive result for cyanogenesis, with a color change beginning within 5 min and resulting in dark purple-brown within 30 min. The dissected wings, head, thorax, and abdomen of adults all gave a positive reaction with picrate paper, as did the hemolymph of adults and larvae. For hemolymph, however, the reaction took up to an hour to begin, resulting in a dark orange after 24 hr. This was suspected to result from the small quantities tested. There were no apparent differences between the sexes.

Identification of Gynocardin. Table 1 shows the mobility on various chro-

matographic systems of the cyanogenic compound extracted from *A. horta* adults, together with that of gynocardin and linamarin standards. These results indicate that the butterflies contained gynocardin, the same compound produced by their larval food plant.

Test for Sequestration. The results of the experiments to test for sequestration are presented in Table 2. *Tacsonia manicata* contained only gynocardin, as did the butterflies reared from the egg stage on this species. While the leaves of *Passiflora caerulea* contained gynocardin as a minor component (as gauged by intensity of development on TLC) as well as a second, less polar cyanoglycoside as a major component, the insects reared on this species contained only gynocardin. No cyanogenic activity resulted when the enzyme extract from the leaves of this species was added to the frass of larvae, suggesting that the major glycoside was not excreted. Neither this nor the cyanoglycoside extracted from *T. mollissima* (see below) were hydrolyzed by the enzyme extract from *K. africana*. Gynocardin was not detected from extracts of the leaves of *Tacsonia mollissima*, but a less polar cyanoglycoside, which ran concurrently with the major glycoside in *P. caerulea* (using TLC in butanol-acetic acid-water, 2:1:1), was present. No cyanogenic substance was detected on TLC plates from the extracts of *A. horta* adults reared from the egg stage on this species. When four intact adults reared from the egg stage on *T. mollissima* were crushed in separate vials containing picrate paper, two gave a slight positive reaction, with the color change beginning after 1 hr and resulting in a light orange after 24 hr, and two gave no reaction. This demonstrates that there was some potential for cyanogenesis even in insects reared on plants that, in other cases, resulted in acyanogenic butterflies. Controls reared on *K. africana*, *T. manicata*, and *P. caerulea* caused a color change within 5 min, resulting in dark purple-brown after 24 hr. Adults of larvae transferred from *K. africana* to *T. mollissima* in their second instar gave a final color change after 24 hr to a dark orange, indi-

<i>Tacsonia mollissima</i>	0.43		nd

^a Figures refer to R_f values (TLC, butanol-acetic acid-water 2:1:1); nd = not detected.

^b Identified as gynocardin using the chromatographic systems listed in Table 1.

cating levels of HCN intermediate to those discussed above. Addition of the enzyme extract from *T. mollissima* caused no further color change, thus confirming that the results reflected the levels of cyanoglycoside rather than the absence of appropriate hydrolytic enzymes. The low survival rates of insects reared on these plant species precluded any further quantification of these results.

DISCUSSION

Selective Sequestration of Gynocardin. Results of this study demonstrate that all stages in the life cycle of *Acraea horta* are cyanogenic. The chemical basis of this in the adults is gynocardin, which is biogenetically unrelated to linamarin and lotaustralin (Conn, 1979), the cyanoglycosides previously detected in several *Acraea* species (Table 3). It cannot, however, be ruled out that trace amounts of linamarin and lotaustralin were also present, and more sensitive techniques are needed to investigate this.

Gynocardin is also the cyanoglycoside produced by the larval food plant *Kiggelaria africana* (Raubenheimer and Elsworth, 1988), and the present results demonstrate that cyanogenesis in *A. horta* is dependent on the diet of these

TABLE 3. *Acraea* SPECIES INVESTIGATED FOR IDENTITY OF CYANOGLYCOSIDES CONTAINED, CYANOGLYCOSIDES DETECTED, AND GROUPS OF PLANTS ON WHICH LARVAE ARE KNOWN TO FEED^a

insects. Thus, adults reared on *Tacsonia mollissima*, which did not contain gynocardin, showed, at the most, low cyanogenic activity. It is unlikely that this was a result of some general dietary inadequacy due to *T. mollissima* being alien to the evolutionary history of *A. horta*, since adults reared on *Passiflora caerulea* and *T. manicata*, neither of which occur naturally in the distribution range of *A. horta*, were strongly cyanogenic; these plants however contained gynocardin. Similarly, those that fed as larvae on *K. africana* prior to being transferred to *T. mollissima*—and had thus been exposed to a dietary source of gynocardin—showed higher cyanogenic activity than those transferred as eggs. Together, this evidence suggests that *A. horta* obtains gynocardin from the larval food plants.

The glycoside responsible for cyanogenesis in *T. mollissima* did not appear in adults reared on this species, suggesting that the uptake of cyanoglycosides by *A. horta* is selective. Similarly, of the two cyanoglycosides produced by *P. caerulea*, adults reared on this species contained only gynocardin. Interestingly, crude enzyme extract of *K. africana* did not hydrolyze the second of these glycosides or the sole cyanoglycoside in *T. mollissima*. Therefore, assuming that the hydrolysis of gynocardin in *A. horta* is catalyzed by a similar enzyme system to that in *K. Africana* absorption of these compounds would not contribute to the cyanogenic capability of *A. horta*. Neither of these cyanoglycosides appeared in the frass of larvae fed the leaves of *P. caerulea* or *T. mollissima*, and it must therefore be concluded that they were metabolized by the insects.

There are interesting similarities in these results and those of von Euw et al. (1967). The tissues of *Poekilocerus bufonius* (Klug), an aposematic grasshopper, were found to contain two of the six cardenolides produced by their asclepiad food plant, suggesting that the remaining four were either excreted, metabolized, or converted in vivo by these insects. Hoppers reared on nonpoisonous plants contained approximately 10 times less cardenolide than those reared on toxic plants, and these levels were further reduced by a factor of about seven in their offspring. That these offspring contained the toxins at all suggests that cardenolides are carried over from the adult to the egg stages, and from eggs to the larvae. However, von Euw et al. (1967) contend that cardenolide levels in both generations were unexpectedly high for storage in the egg alone and postulate that additional factors such as de novo synthesis or bioaccumulation through cannibalism must contribute to these. Similarly, the residual cyanogenic activity in *A. horta* adults reared on *T. mollissima* in the present study may have been due to any one or a combination of these factors. Answers to such questions must, however, await detailed quantitative analyses.

Evolution of Host Choice. The demonstration of gynocardin in *A. horta* raises some interesting questions regarding the colonization of cyanogenic plants by acraeine butterflies. Rothschild (1971) first predicted, on the basis of their patterns of host choice, that acraeine butterflies would sequester cyanoglyco-

sides from the larval food plants. The subsequent evidence that cyanogenesis in these insects is based on de novo synthesis (see Introduction), led to the suggestion that ancestral Acraeinae initially synthesized cyanoglycosides and were thus preadapted to cope with the toxic effects of these compounds in plants (Rothschild, 1972; Davis and Nahrstedt, 1985; Ackery, 1988). With the discovery of gynocardin in *A. horta*, Rothschild's (1971) hypothesis may now be vindicated. Perhaps the original diversification of *Acraea* butterflies on cyanogenic hosts was based on sequestration of cyanoglycosides and the capability to synthesize linamarin and lotaustralin evolved subsequently.

Table 3 lists those species of *Acraea* that have been investigated to determine the identity of the cyanoglycosides they contain, together with the known feeding preferences of the larvae. While it is clear from this that the *Acraea* species for which we know the chemical basis of cyanogenesis are too few to allow any firm conclusions, the data presented nonetheless suggest some interesting patterns. *Acraea horta* is associated exclusively with the Violales, considered the ancestral larval food plants of the Acraeinae (Ackery, 1987). The larvae are only known to feed on the Flacourtiaceae and Passifloraceae (Pennington, 1978) and, by inference from several other *Acraea* species sharing a similar pattern of host choice (e.g., see Raubenheimer, 1987), it seems likely that the closely related Turneraceae would also be accepted as hosts if available. These families have strong biochemical affinities in their production of cyanoglycosides with a cyclopentenyl moiety. Furthermore, this biochemical similarity is probably an important factor in larval host choice, since *A. horta* larvae feed selectively on cyanogenic species from among a range of plants in the Flacourtiaceae and Passifloraceae (Raubenheimer, 1987). It may be significant that Nahrstedt and Davis (1983) failed to detect linamarin or lotaustralin in *A. andromache*, a species that is also only known to feed on the Violales (Table 3), despite the fact that the insects were cyanogenic; it would be interesting to analyze these insects for the presence of cyclopentenyl cyanoglycosides. There therefore exists in *A. horta* an interesting link among acraeine butterflies between primitive patterns of host choice, cyclopentenyl cyanoglycosides, and the storage of plant-produced allelochemicals.

Acraea encedon L., by contrast, is believed to synthesize cyanoglycosides since the adults contain linamarin and lotaustralin, which do not occur in their larval food plants (Nahrstedt and Davis, 1981). This species is also, as far as is known, unique among acraeine butterflies and, indeed, unusual among Lepidoptera, in that the larvae feed on a monocotyledonous family, the Commelinaceae (Table 3). Since, in the words of Ehrlich and Raven (1965), "All utilization of foods other than dicotyledons by butterfly larvae . . . is assumed to be the result of changes from an earlier pattern of feeding on dicotyledons," there exists good reason to consider as derived this singular choice of host plant. Similarly, *A. eponina* contains linamarin and lotaustralin and is not known to

feed on the Violales, but is strongly associated with the Malvales [only known to feed on a single family outside this order (Table 3)]. Of the three groups into which most *Acraea* species fall on the basis of host-plant selection—the Violales group, the Utricales group and the Malvales group,—the Malvales group is considered the most recently evolved (Ackery, 1987).

There is additional evidence linking de novo synthesis of cyanoglycosides by *A. encedon* to derived features. In 1969 Owen and Chanter (1969) reported that no cyanogenic activity was detected from the tissues of *A. encedon* adults but suggested that an analysis of the yellow foam produced from a gland in the thorax may yield different results. Owen (1970) subsequently reported that HCN is indeed released from this exudate. Such localization of toxic substances in insects is considered to be specialized (Brower and Brower, 1964) relative to the state in *A. horta*, which contain cyanoglycoside throughout their bodies. It might also be significant in this context that *A. encedon* was found by Nahrstedt and Davis (1981) to contain an appreciably higher concentration of cyanide than the other *Acraea* species analyzed. Interestingly, *A. eponina*, the only other species analyzed that does not feed on Violales, contained the second highest concentration.

Acraea horta and *A. encedon* represent two extremes in the possible “sequestration-as-ancestral” evolutionary sequence considered for the Acraeinae: those that feed exclusively on the Passifloraceae and related families (Violales) and contain cyanoglycosides of the structural group characteristic of these families, and those that feed on monocotyledons and synthesize linamarin and lotaustralin. *Acraea caldarena* Hewiston and *A. natalica* Boisduval—both of which contain linamarin and yet are only known to feed on Passifloraceae and related families (Table 3)—may represent an intermediate stage in this sequence. These butterflies have possibly evolved the biochemical machinery for synthesising linamarin without having evolved the sensory or ecological changes necessary for a switch to unrelated host plants. Indeed, there is good reason to believe that among Lepidoptera such a host change may be genetically conservative. Wiklund (1975), for example, has shown that choice of host plant by adult and larval *Papilio machaon* is controlled by separate genes, and a successful host switch would therefore rely on the unlikely event of two simultaneous and independent mutations. Either of these mutations occurring singly would result in eggs being deposited on plants on which the larvae do not feed, and thus would be rapidly selected out of the population.

We might nevertheless expect to find species intermediate in pattern of host utilization between *A. caldarena* and *A. natalica* on the one hand and *A. encedon* on the other, i.e., species that produce linamarin and/or lotaustralin and feed on Violales as well as on unrelated families. Indeed, *A. violae* feeds on the Passifloraceae as well as members of the Malvales and *A. onacaea* Hopffer feeds on the Passifloraceae, Turneraceae, and the disparate family, Vitidaceae (Ackery, 1988). Both species contain linamarin (Table 3).

If the ability to synthesize cyanoglycosides is indeed a recently evolved trait, derived from ancestral species that sequestered these compounds from plants then the following questions need consideration: (1) what was the evolutionary impetus for such a switch from sequestration to de novo synthesis; and (2) why did this switch involve a change from sequestering cyanoglycosides with a cyclopentenyl moiety to synthesizing the acyclic glycosides linamarin and lotaustralin? Concerning the first question, Bernays and Chapman (1978) have shown that acridoid grasshoppers that sequester toxins from their food plants, have significantly longer developmental times than others, and this they consider to be a result of the considerable metabolic expenditure involved in the uptake of toxic chemicals. However, little is known about the cost of de novo synthesis of cyanoglycosides, and a full answer to this question must therefore await further research. Regarding the second question, it is interesting that linamarin and lotaustralin are also the cyanoglycosides synthesized by the Heliconiini (Nahrstedt and Davis, 1981, 1983) and by the taxonomically distant Zygaenidae (Davis and Nahrstedt, 1979, 1982). These are also the most widespread cyanoglycosides among plants (Conn, 1979). Such convergence may be the result of some factor that lowers the cost or increases the benefit of manufacturing these relative to other cyanoglycosides. For example, valine and isoleucine, the respective precursors of linamarin and lotaustralin (Seigler, 1975), may be more freely available in insects and plants than is cyclopentenyl glycine, the nonprotein amino acid precursor of the cyclopentenyl cyanoglycosides (Conn, 1981).

On the other hand, *A. horta* emerges from Piere's (1984) cladistic analysis as one of the most recently evolved of the recognized *Acraea* species, and it is therefore difficult to accept on the basis of this species alone that sequestration is the ancestral state. But then, according to Piere's cladogram, so are all the known cyanoglycoside-synthesizing species considered recently evolved.

The demonstration of gynocardin in *A. horta* has therefore reestablished the question of why acraeine butterflies came to be associated with cyanogenic plants. If this association is indeed a relic of ancestral species that sequestered cyanoglycosides from their passifloraceous hosts, this may explain the resemblance of acraeine patterns of host choice to those of insects that obtain defensive compounds from the plants they eat (Rothschild, 1972). However, this suggestion is currently based on insufficient evidence and must await further studies into the relationship between food choice and the chemical basis of cyanogenesis for a wide range of *Acraea* species.

Acknowledgments—I thank Professor G.N. Louw and Dr. J.F. Elsworth for their valuable contributions to this work; Professor A. Nahrstedt and Dr. R.H. Davis for their donation of linamarin; the Council for Scientific and Industrial Research, the Charles Dickson Research Grant and the Flora Conservation Committee of the Botanical Society of South Africa for financial assistance; and for reading and providing valuable comments on the manuscript, Mr. M. Cherry, Dr. C.R.

Johnson, Dr. P. Kelly, Dr. S. Nicholson, Dr. J. Scott, Dr. S.J. Simpson, and Mr. P. Stirling. I also thank two anonymous referees for their constructive comments and criticisms.

(Received August 15, 1988; accepted November 28, 1988)

Abstract—Chemical investigation of the Dufour gland contents of three species of *Myrmecia* by GC and GC-MS showed that *M. gulosa* and *M. nigriceps* contain predominantly linear hydrocarbons, whereas *M. pilosula* contains acetates, aldehydes, and propionates. The major components of *M. gulosa* and *M. nigriceps* are (Z)-8-heptadecene, pentadecane, and heptadecane. Their chemical profiles are similar to each other and to that of *Nothomyrmecia macrops*, the most primitive living ant, placed by itself in a separate subfamily. The major components of *M. pilosula* are hexadecyl acetate, (Z)-9-octadecenyl acetate, (Z)-11-eicosenyl acetate, and (Z)-11-eicosenal. Some geographical variation was observed in the relative proportions of the components. The chemotaxonomic significance for the primitive Australian ant subfamilies Myrmeciinae and Nothomyrmeciinae is considered. The possibility is discussed that 11-eicosenal or geranyl citronellol, minor components of the Dufour gland secretion of *M. gulosa*, may be responsible for the aggressive behavior released by the natural stinging secretions.

Key Words—Ant, Dufour gland, *Myrmecia*, Hymenoptera, Formicidae, hydrocarbons, acetates, eicosenal, chemotaxonomy.

INTRODUCTION

The Dufour gland is a saclike organ attached to the poison apparatus in all aculeate Hymenoptera. The function of its secretion remains unknown for many species, although in individual cases among ants it has been shown to contain a trail pheromone, a home-range or territorial marking pheromone, or to have

other pheromonal properties. Its contents have been examined in a number of ant species, and in every case they have been shown to be a mixture of hydrocarbons or oxygenated hydrocarbon derivatives (Attygalle and Morgan, 1984). These mixtures are species specific and can be used to separate morphologically similar species. The contents may therefore be a useful systematic and taxonomic indicator. Howse and Bradshaw (1980), in considering the phylogeny of Myrmeciinae and Ponerinae, pointed to the need for "chemical studies [of the exocrine secretions] of the more primitive subfamilies . . . to shed light on the interrelationships."

Ants of the subfamily Myrmeciinae are found only in Australia and New Caledonia, and the only living genus of the subfamily is *Myrmecia*. The genus contains some of the most primitive ants known (Clark, 1951; Greenslade, 1979). They are usually large (13–38 mm in length), very agile, aggressive when disturbed, and have a sting-delivered venom of a proteinaceous type (Cavill et al., 1964). Robertson (1971) studied the pheromones involved in the aggressive behavior of *Myrmecia gulosa*. She observed an alarm effect resulting from the natural stinging secretions and determined that the pheromone was produced in the Dufour gland. Cavill and Williams (1967) examined *M. gulosa* Dufour glands and identified six aliphatic hydrocarbons, including (*Z*)-8-heptadecene (62%), pentadecane (17%), and heptadecane (4%). Robertson (1971) concluded that the alarm pheromone was probably a minor component in the gland, not yet isolated. Other exocrine secretions of *M. gulosa* have been studied, including their behavioral effects (Cavill and Robertson, 1965; Robertson, 1971). Chemical investigations have shown that the head (mandibular gland) contains 2,5-dimethyl-3-*n*-propylpyrazine (Brophy and Nelson, 1985) and the cuticular wax contains C₂₆–C₃₄ monomethyl alkanes and C₁₉–C₂₉ normal paraffins (Cavill et al., 1970).

In the present work, the Dufour gland contents of *M. gulosa* are reexamined using GC-MS and those of *M. nigriceps* and *M. pilosula* are investigated for the first time.

METHODS AND MATERIALS

Insect Material. Workers of *Myrmecia gulosa* (Fabricius) from Sydney, *M. nigriceps* Mayr from Black Mountain, Australian Capital Territory, and *M. pilosula* (F. Smith) from Mongarlowe, New South Wales, and from Hobart, Tasmania, identified by Dr. R.W. Taylor, were collected during February 1987. They were taken to Canberra (CSIRO) and there anaesthetized and killed by placing for 3 min in a Biofreezer at -50°C . The Dufour glands were removed by dissection under water. They were immediately sealed, either individually or in groups, in soft-glass capillaries (2 cm \times 2 mm), and kept cool until brought by air to Keele.

Instrumentation. Gas chromatography was carried out on a Carlo Erba Fractovap 4160 series instrument with a flame ionization detector and a Shimadzu Chromatopac C-R3A data processor. A fused silica capillary column (25 m \times 0.32 mm) coated with OV-1 stationary phase of 0.4 μ m film thickness was used for the analysis. Helium was used as the carrier gas at a flow rate of 1.0 ml/min.

The capillary tubes containing the samples were kept in the solid injector (Morgan and Wadhams, 1972) in the injection port at 220°C for 2 min before crushing. The split vent was kept closed during the injection and opened after 1 min. The oven temperature was initially 100°C and increased at a rate of 6°C/min to 270°C. Seven single glands of *M. gulosa*, 13 of *M. nigriceps*, and 15 of *M. pilosula* (seven from New South Wales and eight from Tasmania) were analyzed in this way. The absolute quantity of each component was determined by using a solution of pentadecane in hexane as an external standard.

Two or three single glands and samples of three or five glands for each species were analyzed by GC-MS, on a Hewlett Packard 5890 gas chromatograph and 5970 mass selective detector with HP59970C ChemStation. A fused silica capillary column (12 m \times 0.2 mm) coated with HP-1 (cross-linked methylsilicone gum \cong OV-1) of 0.33 μ m film thickness was used. The carrier gas was helium at 10 psi column head pressure (\cong 1 ml/min flow rate). The samples were introduced by the solid injection method described above. The oven temperature was initially 60°C and increased at a rate of 4°C/min to 250°C. The mass selective detector was set to monitor m/z 35–350 in the scan mode (\cong 1.5 scans/sec) under "Autotune" conditions using 70-eV ionization.

Determination of Double-Bond Position. A hexane extract (15 μ l) of one Dufour gland of *M. nigriceps* or five glands of *M. pilosula* were placed with dimethyl disulfide (10 μ l, Aldrich) and ethereal iodine (2 μ l, 0.25 M) in the bottom chamber of a Wheaton-Keele microreactor vial (Wheaton Scientific, Millville, New Jersey). This was closed with a Teflon-lined cap and kept overnight at 40°C (Attygalle and Morgan, 1986; Buser et al., 1983). Analysis of the reaction mixture was performed by GC-MS as above with a syringe injection. The temperature program was initially 80°C and increased at a rate of 8°C/min to 270°C, and the mass selective detector was set to monitor m/z 35–450.

The same reaction was carried out on a hexane solution of oleyl acetate (Sigma) and on a mixture of (*Z*)- and (*E*)-9-octadecenyl acetate formed by shaking the oleyl acetate (20 mg) in hexane (1 ml) solution with 5 μ l of Poutet's reagent [mercury (0.5 ml) dissolved in concentrated nitric acid (8 ml)] (Griffiths and Hilditch, 1932).

To determine the double-bond position of eicosenal, the aldehyde group was first reduced to the alcohol. The secretion from nine Dufour glands of *M. pilosula* workers was extracted with hexane (25 μ l), and the hexane was evap-

orated by a gentle stream of nitrogen and replaced by ethanol (15 μ l). Sodium borohydride (5 mg) followed by water (3 μ l) was added and the mixture agitated. The product was extracted into hexane (15 μ l) in a Keele Microreactor (Wheaton Scientific) and the reaction with dimethyl disulfide performed as above.

RESULTS

M. gulosa. Analysis of a sample of three Dufour glands of *Myrmecia gulosa* by GC-MS revealed 27 identifiable components (Figure 1). The mixture comprises mainly unsaturated and saturated linear hydrocarbons in the range C_{13} -

FIG. 1. Total ion chromatograms (TIC) from the GC-MS analysis of three Dufour glands of workers of *Myrmecia gulosa*, showing the minor as well as the major components. The symbols give identification, e.g., C_{15} is pentadecane, $C_{17:1}$ is heptadecene, $C_{16:2}$ is hexadecadiene, $C_{20:1AL}$ is eicosenal, T_3 is geranylcitronellol. The glands were chromatographed, using a solid injection technique, on a 12-m \times 0.12-mm fused silica capillary column coated with HP-1. The oven temperature was increased from 60°C at 4°C/min to 250°C, then held at 250°C.

C₂₇ (odd numbers predominating). Four of the minor components are not linear hydrocarbons. These are 7-methylheptadecane, eicosenal [M⁺ 294(0.2), 276(0.4), 135(3), 121(5), 111(9), 109(7), 98(17), 97(18), 96(14), 95(17), 83(30), 81(28), 69(49), 67(39), 57(41), 55(100), 43(59), 41(89)], an unidentified unsaturated compound A [tr 26.6 min, KI 1840, M⁺ absent, 217(0.6), 189(1), 175(1), 162(2), 150(4), 133(4), 122(7), 119(9), 105(15), 95(11), 93(29), 91(34), 81(25), 80(63), 79(95), 77(25), 67(72), 55(52), 43(32), 41(100), 29(41)] and a diterpene T₃. The mass spectrum of T₃ shows good agreement with that of all-*trans*-geranylcitronellol found in *Bombus lapponicus* (Hymenoptera: Apidae), which itself was identical with a synthetic sample (Bergström and Svensson, 1973). Squalene is probably not part of the Dufour gland secretion and may arise from the tissue (see Billen et al., 1988).

The quantification of the major components by GC is summarized in Table 1. We frequently find the size of Dufour glands varies considerably between individuals in a species. Here the variation was particularly marked, with the

total amount of material in individual workers' glands varying from 6 to 55 μg . However, when the percentage composition is calculated for each individual, and the mean and standard deviation calculated for each component, it is seen that the proportions of the major components do not vary very much. The major components are heptadecene (50.5%), pentadecane (16.5%), heptadecadiene (7.0%), and heptadecane (6.6%).

M. nigriceps. A GC-MS total ion chromatogram of the Dufour gland contents of *M. nigriceps* is shown in Figure 2 and the quantification of the major components summarized in Table 2. Twenty-eight components have been identified, and the composition is very similar to that of *M. gulosa*. However, in addition to eicosenal, five other linear aldehydes (pentadecanal, hexadecanal, heptadecanal, octadecanal, and octadecanal) and two more terpenes, T₁ [tr 24.8 min, KI 1770, M⁺ absent, 219 (0.4), 191 (0.6), 149 (0.6), 136 (4), 123 (5),

109 (5), 95 (11), 81 (26), 69 (100), 55 (20), 43 (18), 41 (61)] and T₂ [t_r 31.7 min, KI 2050, M⁺ absent, 247 (0.3), 221 (0.4), 203 (0.5), 161 (1), 147 (1), 136 (6), 123 (7), 121 (5), 109 (9), 95 (10), 81 (33), 69 (100), 55 (19), 43 (14), 41 (64)] are present. The unknown compound A is found in this species as well as in *M. gulosa*. The major components are again heptadecene (37%) and pentadecane (15%).

The positions of the double bonds were determined in the unsaturated components by converting them into their α,β -di(methylthio)ethers and submitting these to GC-MS (Francis and Veland, 1981). Each adduct gives two intense peaks that indicate the location of the double bond in the parent molecule. Heptadecene gave an adduct with prominent ions of m/z 332(M⁺), 173 [CH₃(CH₂)₇CH=SCH₃]⁺ and 159 [CH₃(CH₂)₆CH=SCH₃]⁺, indicating 8-heptadecene. This is the same position as in *M. gulosa* (Cavill and Williams,

1967). The other double-bond positions are indicated in Table 2. The retention times of the alkenes correspond to the *Z*-isomers of synthetic standards.

M. pilosula. The Dufour gland contents of *M. pilosula* are very different from the other two *Myrmecia* species examined (Figure 3, Table 3). The components are all oxygenated compounds. Long-chain acetates (C_{12} – C_{20}) predominate and the remaining compounds are long-chain aldehydes and propionates.

Individuals show a large variation in the amounts of each component present, but considering the proportions, as before, they show a smaller variance. Differences in the glandular contents of the samples from the two different sites were observed. The two major components of the Tasmanian samples were always hexadecyl acetate followed by octadecenyl acetate. However, the major component of the New South Wales samples was eicosenyl acetate for four

FIG. 3. Total ion chromatograms from the GC-MS analysis of the Dufour gland of a *Myrmecia pilosula* worker. Symbols indicate identification, e.g., $C_{16}Ac$ is hexadecyl acetate, $C_{18:1}AL$ is octadecenyl, $C_{16}Pr$ is hexadecyl propionate. Conditions as in Figure 1.

^a Mean values and sample standard deviations for total sample (15 individuals), New South Wales (7), and Tasmania (8).

individuals, hexadecyl acetate for two, and eicosenal for another. The average proportion of octadecenyl acetate and eicosenal are approximately equal in the New South Wales sample, whereas the proportion of octadecenyl acetate is much higher than that of eicosenal in the Tasmanian samples.

The position of unsaturation of the major components was determined by GC-MS of their di(methylthio)ethers (Buser et al., 1983). The adduct of octadecenyl acetate gave prominent ions of m/z 404 (M^+), 231 $[\text{CH}_3\text{COO}(\text{CH}_2)_8\text{CH}=\text{SCH}_3]^+$ and 173 $[\text{CH}_3(\text{CH}_2)_7\text{CH}=\text{SCH}_3]^+$, and eicosenyl acetate gave derivative ions of 432 (M^+), 259 $[\text{CH}_3\text{COO}(\text{CH}_2)_{10}\text{CH}=\text{SCH}_3]^+$ and 173 $[\text{CH}_3(\text{CH}_2)_7\text{CH}=\text{SCH}_3]^+$. This identifies the compounds as 9-octadecenyl acetate and 11-eicosenyl acetate. The fragment ions of the eicosenal derivative, m/z 215 and 173, could arise from either 8- or 11-eicosenal. Therefore, a sequence of two nano-scale reactions was performed in which the eicosenal was reduced to eicosenol by sodium borohydride and then converted to the di(methylthio)ether. This adduct gave fragment ions at m/z 217 and 173, identifying the original compound as 11-eicosenal. Although micro-scale reactions of this kind have been used frequently by us and others (Attygalle and Morgan, 1988), we believe this is the first time a sequence of two reactions has been carried out on material at this small scale. The retention times of 9-octadecenyl acetate and its di(methylthio)ether correspond to those of oleyl acetate and its di(methylthio)ether and were shorter than those of the corresponding compounds with a *trans*-double bond, elaidyl acetate and its di(methylthio)ether. Therefore the Dufour gland component is (*Z*)-9-octadecenyl acetate, the product which would be expected as derived from oleic acid. The necessary synthetic compounds were not available for eicosenyl acetate and eicosenal, but these too may be presumed to have the *Z* configuration, and arise from (*Z*)-11-eicosenoic acid.

The amounts of propionates present generally mirrored the relative proportions of the corresponding acetates, but at less than a tenth of the amount of the acetates. Numerous minor components were observed, most of which are thought to be branched, saturated and unsaturated acetates, due to characteristic ions of m/z 43 and 61 in their mass spectra, although many of these remain to be fully identified.

In some of the samples analyzed by GC-MS, the minor components are present in relatively large amounts, although still much less than the four major components. In these samples, traces (< 10 ng) of linear hydrocarbons (heptadecene, nonadecene, hexadecene, octadecene, pentadecane, heptadecane, and hexadecane) were identified. A trace (< 5 ng) of more volatile acetates, including decyl acetate and nonyl acetate, was observed. A total of 80 components was detected.

DISCUSSION

The investigation of the Dufour gland contents of three species of *Myrmecia* by GC and GC-MS, using the solid injection technique of Morgan and Wadhams (1972), showed species-specific mixtures of hydrocarbons and oxygenated compounds.

M. gulosa has been examined before (Cavill and Williams, 1967), when six components were identified: (*Z*)-8-heptadecene (62%), pentadecane (17%), heptadecane (4%), hexadecene, tetradecane, and hexadecane. A further six components were not identified. The present study has identified 27 components, and the proportions of the major components are in good agreement with the published results, since heptadecene and heptadecadiene would have co-eluted in the earlier study so that the figure of 62% represents the total of these two compounds, which in the present work is 57.5%.

Robertson (1971) studied the pheromones involved in aggressive behavior in *M. gulosa*. Such pheromones are found in the rectal secretion, the mandibular glands, and the Dufour gland. An alarm pheromone, acting as an activation stimulus was found in the natural stinging secretions of the workers and is produced in the Dufour gland. Hydrocarbons tested for this effect gave a very weak response, and it was suggested by Robertson that the pheromone was a minor component not yet isolated. Three compounds that are not linear hydrocarbons were observed in this work among the minor components: (*Z*)-11-eicosenal, geranyl citronellol (3,7,11,15-tetramethylhexadeca-6,10,14-trien-1-ol, T₃ in Figure 1) and an unknown unsaturated compound A. Unsaturated aldehydes and terpenes are used as alarm pheromones by some species of ant, such as monoterpenes by *Myrmecaria eumenoides* and hexanal and 2-butyl-2-octenal in the complex alarm system of *Oecophylla longinoda* (Bradshaw and House, 1984). Aphids also use sesquiterpenes as alarm pheromones (Nault and Phelan, 1984). The collection or synthesis of these three minor components is now required for bioassay.

The Dufour gland secretion of *M. nigriceps* (Figure 2) is very similar to that of *M. gulosa* (Figure 1), except that more aldehydes and terpenes are present. Cavill and Williams (1967) noted that the Dufour gland secretion of *M. tricolor* (Mayr) workers showed a similar pattern of hydrocarbons to that of *M. gulosa*.

The composition of the Dufour gland contents of *M. pilosula* (Figure 3) is very different from the other species studied (Table 4), with acetates, aldehydes, and propionates being the only components. This species was collected from two different sites: in Tasmania and New South Wales. Differences were observed in the relative proportions of the major components, suggesting a geographical variation in the chemical composition of the Dufour gland of this

species. There is recent karyotypic and morphological evidence for several sibling species centered on *M. pilosula* (Crosland et al., 1988). The Dufour gland composition may reflect this.

Acetates and other oxygenated compounds are found with hydrocarbons in the Dufour glands of some formicine ants (Attygalle and Morgan, 1984), but this is the first observation in ant secretions of octadecenyl acetate, eicosenyl acetate, eicosenal, and geranylcitronellol. They have all been found in other aculeate Hymenoptera: octadecenyl acetate in the labial glands of male *Bombus muscorum* (Apidae), eicosenyl acetate and eicosenal in the Dufour glands of several *Perdita* species (Adrenidae), and geranylcitronellol in the labial gland secretions of three *Bombus* species and *Psithyrus rupestris* (Apidae) (Wheeler and Duffield, 1988).

While the size of the samples used here is smaller than we would prefer to use, the consistency of composition among individuals within samples, and the similarity of results obtained for *M. gulosa* between ourselves and Cavill and Williams (1967), make some tentative conclusions possible. There is some similarity between *M. pilosula* and the others, in that they all contain eicosenal, and also, in several glands of *M. pilosula*, there were traces of some of the

hydrocarbons found in the other species. However, the Dufour gland secretions indicate two distinct groups (Table 4). This reflects morphological considerations. Greenslade (1979) describes *Myrmecia* in terms of two groups: the "inch" or "bulldog" ants and the "jumpers." *M. pilosula* is classified in the latter group, and the other species studied are placed in the former. These groups have also been described as two separate genera, *Myrmecia* and *Promyrmecia* (Clark, 1951).

These *Myrmecia* ants are very large and that is reflected in the size of their Dufour glands. Those of *M. gulosa* (25 μg mean total contents, body length 15–20 mm) and *M. nigriceps* (30 μg , body length 20–25 mm) are the largest we have encountered in the examination of many species of ant. The glands from *M. pilosula* are proportionally smaller (14 μg , body length 12 mm), as are those of *Nothomyrmecia macrops* (6.5 μg , body length 10 mm) (Billen et al., 1988).

The Dufour gland contents reflect the relationships among species, in those of *Myrmecia* studied so far. This has been observed in a number of ant genera. For example, *Tetramorium impurum* and *T. caespitum* are morphologically very similar and have very similar Dufour gland contents, whereas *T. semilaeve* is different in both respects (Billen et al., 1986).

Nothomyrmecia macrops Clark is regarded as the most primitive living ant (Taylor, 1978) and has been placed in a subfamily on its own. Its Dufour gland contents have recently been investigated (Billen et al., 1988) and showed great similarity with *M. gulosa* and *M. nigriceps* (Table 4). *N. macrops* also contains trace amounts of acetates (hexadecyl, octadecenyl, octadecyl, and eicosenyl) and aldehydes (octadecanal and hexadecanal), indicating similar biosynthetic capabilities to those of *M. pilosula* as well. Also "unknown I" of *N. macrops* is found as a trace component of *M. pilosula*.

Nothomyrmecia is placed in a separate subfamily mainly because of anatomical differences of the petiole structure (Taylor, 1978). However, *Nothomyrmecia* shares many characteristics with *Myrmecia*, and the chemical evidence of the Dufour gland secretion may indicate a closer relationship than previously thought. Further work is required on other *Myrmecia* species to see if this chemotaxonomic indicator does separate the genus into two distinct groups, and examination of further colonies of *M. pilosula* should show whether there is a consistent difference between the species in mainland Australia and Tasmania.

Acknowledgments—We thank Dr. R.W. Taylor for his help in collecting and identification of the ants, the Belgian National Fund for Scientific Research for a travel grant to Australia for J.P.J.B., the British Council for a travel award to J.P.J.B. to visit Keele, the Royal Society and S.E.R.C. for the award of grants for equipment, and to the S.E.R.C. for a research studentship to B.D.J.

(Received June 23, 1988; accepted December 8, 1988)

Abstract—The behavior of captive male muskoxen was observed closely during their characteristic superiority display, the anatomy of the preputial region was studied in two adults and three calves, and preputial washings and preorbital gland secretion were subjected to gas chromatography and mass spectroscopy. During the superiority display, the prepuce was everted to form a pendulous tube tipped with a fringe of matted hair. Owing to the movement of the animal, the urine that dribbled from the preputial opening was liberally applied to the long guard hairs of the belly. The superiority display was almost exclusively confined to dominant males and apparently accounted for their odor. In the quiescent state, the hair seen around the preputial opening was drawn inside and formed an 8 cm-wide band on the lining of the prepuce. The preputial washings contained large amounts of benzoic acid and *p*-cresol. The infraorbital gland secretion contained cholesterol, benzaldehyde, and a homologous series of saturated γ -lactones ranging from 8 to 12 carbons. The latter compounds and the natural secretion smell similar to the human nose.

Key Words—Muskox, *Ovibos moschatus*, odor, preorbital gland, prepuce, rut, urine, behavior, gas chromatography, mass spectroscopy, lactone.

INTRODUCTION

The muskox has two particularly noticeable odors, the strong, rank smell of the rutting male, to which the species probably owes its name (Allen, 1913), and the light, sweetish, ethereal smell of the preorbital gland secretion. The origin

of the rutting odor has never been fully explained, although Teal (1959) recognized that it was associated with urine and was most noticeable in dominant bulls. An analysis of smegma (Teal, 1961, cited by Tener, 1965) indicated that cinnamaldehyde might be an important constituent.

The preorbital glands are well developed in muskoxen (Brinkman, 1911, cited by Schaffer, 1940; Lönnberg, 1900; Sack and Ballantyne, 1965), and they are used extensively for self-marking and scent marking in agonistic situations; this occurs during encounters between males and in both sexes when they are alarmed by predators or human activity (Gray, 1987; Gray et al., 1988). A preliminary analysis of preorbital gland tissue from a male muskox revealed the presence of cholesterol, cholesterol esters, and triglycerides but no volatile components were identified (M. Benn, footnote in Gray, 1987).

The muskox lacks discrete scent glands in other parts of the body (Schaffer, 1940), although apocrine sweat glands are widely distributed (Flood et al., 1988). There has been some confusion about the existence of interdigital glands in muskoxen (Haltenorth, 1963); our observations (unpublished) confirm Lönnberg's (1900) opinion that they are absent.

The object of the present study was to determine the source of the rutting odor and to make a preliminary investigation of the volatiles associated with the preorbital gland and the preputial region.

METHODS AND MATERIALS

Animals. The animals used in the investigation were from the research herd of muskoxen at the Western College of Veterinary Medicine, University of Saskatchewan. The herd originated from 13 hand-reared calves that were captured on Banks Island, Northwest Territories, at about 2 weeks of age in 1982 (Flood et al., 1984). At the time of sample collection, it consisted of six 3-year-old females, four entire males (two 3-year-olds and two juveniles) and four 3-year-old castrates. They were kept in a series of interconnecting pens totalling 1.5 hectares. They had free access to brome/alfalfa hay and water and were given 1.5 kg of supplemented oat pellets daily. The animals were thoroughly accustomed to human contact and could be handled without showing signs of distress.

General Observations. Day-to-day work with the research herd took 2–10 hr daily and provided a good opportunity for behavioral study. Relevant observations are reported in the results. We also report pertinent information on the anatomy and histology of the preputial region obtained from two adults and three calves that either died or were killed for various reasons.

Sample Collection from Preorbital Gland. Preorbital gland secretion was collected by placing pledgets of fine glass wool over the gland openings and

repeatedly squeezing and wiping the area. The glass wool was cleaned with methylene dichloride (CH_2Cl_2) before use and the fingers were wiped with CH_2Cl_2 before handling the glass wool. On June 27, secretion was collected from the entire herd and combined to form a single pooled sample.

Sample Collection from Prepuce. Preputial odorants were collected by instilling 60 ml of distilled water into the preputial cavity with a syringe, closing the preputial opening with finger and thumb, and massaging the preputial region for a few seconds. The contents of the preputial cavity were then collected in a wide-mouthed glass jar; this sometimes required further massaging of the prepuce. Washes were collected from all the males on June 27 and combined to provide a single sample, which was stored at -20°C until analyzed.

Extraction of Preorbital Gland Secretion. The glass wool pledgets were extracted with redistilled CH_2Cl_2 (BDH, Omnisolve, glass distilled, 3×125 ml). The combined extracts were evaporated in a rotary evaporator at 30°C and the residue redissolved in 1 ml CH_2Cl_2 prior to gas chromatography.

Extraction of Preputial Washes. Following acidification (pH 1, 10% HCl), the washes were extracted separately with redistilled CH_2Cl_2 (3×50 ml). The extract was dried (anhydrous sodium sulfate) and filtered, then treated as above.

Analysis. The preorbital and preputial extracts were treated in the same way. Gas chromatography was performed on a Varian 3700 instrument with a split injector and flame ionization detector. A DB5 column ($30 \text{ m} \times 0.32 \text{ mm ID}$) was used with helium as the carrier gas at a flow rate of $85 \text{ cm}^3/\text{sec}$. The samples were introduced at 50°C , then the oven temperature was increased at $5^\circ\text{C}/\text{min}$ to 200°C . Mass spectra were obtained on a Finnigan 4000 instrument linked to a model 2300 Inco Data Acquisition system. A DB5 column ($60 \text{ m} \times 0.32 \text{ mm ID}$) was used with a splitless injector and helium as the carrier gas at a flow rate of $45 \text{ cm}^3/\text{sec}$. The oven temperature was raised rapidly from 40°C to 90°C , then at $4^\circ\text{C}/\text{min}$ to 300°C . An electron impact of 70 eV was used scanning from mass 43 to mass 600 every second. Chemical ionization spectra were also obtained using methane as the reactant gas.

RESULTS

General. The characteristic superiority display known as "head-tilting" (Gray, 1987) was seen when the males entered their first rutting season: a bull showing this behavior walks slowly past his rival with his head tilted to display the horn boss; in doing so he uses a curious stiff-legged gait that emphasizes the height of the shoulder. Close observation revealed that during this process the prepuce was everted to form a pendulous tube about 12 cm in length tipped with a fringe of matted hair (Figure 1). The preputial tube swung about during the display and urine dribbled from its opening. As a result, the abdominal

portion of the skirt (the long, flowing, outer hairs that give the animal its characteristic appearance) became soaked with urine. This was clearly responsible for the rutting odor.

In the quiescent state the preputial tube was retracted to the level of the abdominal wall as in other ruminants and the hair previously visible at its tip was drawn inside. Dissection of the prepuce of a 3.5-year-old bull and a 4-year-old castrate showed that about 8 cm of the prepuce was lined with fine, crimped hair that was up to 3 cm in length. It covered the entire circumference of the preputial cavity and was encrusted with pale caseous particles (Figure 2). Histological examination of the prepuce of three calves less than 2 weeks old showed that the hairs were present at that age and that their follicles were directed proximally in the more distal part of the prepuce and distally in the deeper part. Sebaceous glands were associated with the hair follicles, but no sweat glands could be found (Figure 3).

Analysis of Preorbital Gland Secretion. Analysis of the methylene chloride extract of the pooled sample by gas chromatography–mass spectrometry allowed

FIG. 1. An adult male muskox with the preputial tube extended and the tuft of hair exposed at its tip. The coat has been trimmed in the area within the circle so that the prepuce can be seen. The inset shows the extended preputial tube in detail. (Composite drawing made from several photographs.)

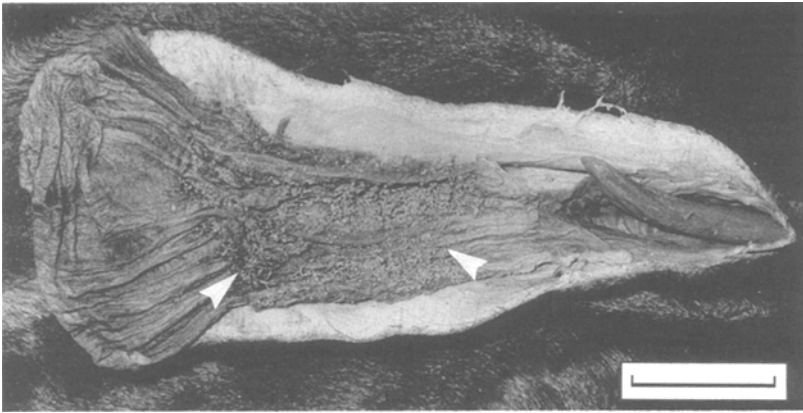

FIG. 2. The preputial cavity of a 3.5-year-old muskox opened longitudinally from the ventral side. The tip of the penis is visible on the right and the preputial opening is on the left. The hair-covered zone of the preputial lining is visible between the arrows. (Scale bar = 5 cm.)

FIG. 3. Longitudinal section of the preputial skin in the haired zone from a 1-week-old calf. The lumen of the prepuce is at the top. Parts of hair shafts and several follicles are visible and these are associated with sebaceous glands. Hematoxylin and eosin. (Scale bar = 100 μ m.)

positive identification of a number of components of the mixture. Assignments of structures were made on the basis of the mass spectral fragmentation patterns observed in both the electron impact and chemical ionization modes, as well as by coelution of authentic standards on gas chromatography.

Figure 4 shows the reconstructed ion chromatogram of the preorbital extract. Cholesterol and benzaldehyde were prominent components of the mixture together with a homologous series of straight-chain, saturated γ -lactones ranging from $C_8H_{14}O_2$ to $C_{12}H_{22}O_2$. The 10-carbon lactone was present in the greatest concentration. The lactones were readily identified in the electron impact mass spectrum by a common lactone fragment (base peak m/z 85), which resulted from cleavage at the ring. The chain lengths were obtained from the chemical ionization experiments and the structural assignments were confirmed by coinjection with commercially available (Aldrich) eight- and 10-carbon γ -lactones. There was a minor peak that eluted ahead of the 12-carbon lactone that also gave a base peak of m/z 85 and a molecular ion at 196 corresponding to a monounsaturated γ -lactone.

Analysis of Preputial Washes. The major components of the CH_2Cl_2 extract of the pooled preputial washes were benzoic acid and *p*-cresol. These assignments were confirmed by nuclear mass resonance. A series of saturated straight-chain hydrocarbons ranging from $C_{22}H_{46}$ to $C_{32}H_{66}$ was present, the C_{24} homolog being the most prominent. In addition, there was a series of unidentified compounds with longer retention times than cholesterol and with molecular weights and fragmentation patterns similar to those of steroids.

DISCUSSION

Rutting Odor. Self-marking with urine is common in ruminants during the rut. Urine may be applied directly to the neck and beard (goats; Coblenz, 1976), belly (red deer; Lincoln, 1971), or legs (blacktailed deer; Müller-Schwarze et al., 1978), or it may be applied indirectly as in the bison (McHugh, 1958) and moose (Geist, 1963), which wallow in urine voided onto the ground, and the camel, which urinates on its tail, then uses this to soak the hind quarters (Wemmer and Murtaugh, 1980). The method of urine self-marking employed by the muskox is apparently unique, and the presence of hair on the inner surface of the prepuce, which is equally unusual, seems to be an anatomical correlate of the urine sprinkling behavior. In the female muskox, a homologous patch of hair is present on the ventral aspect of the vestibule.

Teal's (1959) view that the strong rutting odor is most obvious in the dominant male is supported by our own observations on the captive animals in Saskatchewan. The superiority display which, among other things, leads to the application of urine to the belly hair is also largely a prerogative of the dominant

FIG. 4. The reconstructed ion chromatogram of an extract of pooled preorbital gland secretion. The numbered peaks have been identified as follows: (1) benzaldehyde, (2) nonenol, (3) decanol, (4) $C_8H_{14}O_2$, (5) $C_9H_{16}O_2$, (6) $C_{10}H_{18}O_2$, (7) $C_{11}H_{20}O_2$, (8) a monounsaturated γ -lactone, (9) $C_{12}H_{22}O_2$, (10) myristic acid, (11) $C_{16}H_{34}$, (12) $C_{19}H_{40}$, (13) palmitic acid, (14) $C_{20}H_{42}$, (15) $C_{21}H_{44}$, (16) oleic acid, (17) stearic acid, (18) $C_{22}H_{46}$, (19) $C_{23}H_{48}$, (20) $C_{24}H_{50}$, (21) $C_{25}H_{52}$, (22) phthalate, (23) $C_{26}H_{54}$, (24) $C_{27}H_{56}$, (25) $C_{29}H_{60}$, (26) cholesterol. The compounds shown by their formulas are straight-chain, saturated hydrocarbons or straight-chain, saturated γ -lactones. The peaks without numbers have not been identified.

male (Gray et al., 1988). It therefore seems likely that the characteristic odor of the dominant animal is due to his behavior rather than any profound metabolic change. Nonetheless, such a metabolic change cannot be excluded since changes in testosterone concentration are known to affect the volatile constituents of mammalian urine (Raymer et al., 1986; Schwende et al., 1986), and testosterone levels can influence and be influenced by social status (Bouissou, 1983). Further, it is known that mice (Jones and Nowell, 1974; Lombardi and Vandenberg, 1977), rats (Krames et al., 1969), and rabbits (Bell, 1984) respond differently to the urine of dominant and subordinate conspecifics.

The function of the rutting odor is unclear but a number of possibilities exist. It may advertise the presence of a dominant male and discourage interlopers. It may convey the identity of the dominant male to bulls that have challenged him previously and thereby reduce the number of fights. It may suppress reproductive activity in subordinate males (Perret and Schilling, 1987), permitting them to conserve energy. It may advance the onset of reproductive activity in the females of the herd, as does the fleece odor of the ram (Knight and Lynch, 1980) or the voice of the red deer stag (McComb, 1987), allowing the dominant male to minimize the risk that he will be deposed before the females of the herd are ready to mate. Subordinate males may be discouraged from mating with estrous females that already carry the odor of the dominant male.

The presence of phenolic compounds in the preputial washings of bull muskoxen is not unexpected since 0.5% of the content of the preputial gland of the musk deer is *p*-cresol (Sokolov et al., 1987). The preputial diverticulum of the boar is rich in *p*-cresol and also contains phenol, *o*- and *m*-methoxyphenol and *p*-ethylphenol (Patterson, 1967), and the urine-soaked belly hair of the rutting red deer contains phenol, *p*-cresol, and ethylphenol (Albone, 1984). We do not contend that the compounds identified fully account for the rutting odor of the male; clearly, some of the most volatile constituents would have been lost during concentration of the extracts and significant odorants remain unidentified. These considerations apply equally to the preorbital gland secretion considered below.

Volatiles were sought in preputial washings as opposed to urine because the odor is likely to be altered by bacterial action in the prepuce; we also believed it was important to collect some of the solids adherent to the preputial hairs. Further, the animals tolerate the procedure well; urine collection on the other hand requires prolonged restraint which causes serious distress, particularly in rutting males.

Preorbital Secretion. Perhaps the most characteristic behavior pattern of wild muskoxen is the self-marking sequence in which the preorbital region is rubbed on the outstretched foreleg (Gray, 1987; Gray et al., 1988). This results in the application of secretion to the hair of the leg and face and the release of the volatile constituents into the atmosphere. The preorbital gland may also be

rubbed on prominent objects in the environment, but this is less frequent. Use of the preorbital gland is associated with agonistic situations, but the nature of the encoded message is unknown. As in the case of rutting odor, many possibilities exist; it may betray individual identity like the inguinal glands of rabbits (Hesterman et al., 1984), and it may convey information about sex and reproductive status. The preorbital glands are much larger in males than females (Gray et al., 1988) and contain apocrine sweat glands and sebaceous components, both of which are influenced by gonadal hormones (Flood, 1985).

The presence of large amounts of cholesterol in the preorbital gland secretion is not surprising since this compound is widespread in cutaneous products; straight-chain hydrocarbons are less common, however (Albone, 1984). Benzaldehyde does not seem to be commonly identified in cutaneous secretions, but it is present in urine (Jorgenson et al., 1978) and vaginal secretion (Huggins and Preti, 1976).

The γ -lactones found in the preorbital secretion of the muskox are particularly interesting because related compounds are known to be behaviorally active in the black-tailed deer (Müller-Schwarze et al., 1978). The pure compounds also smell somewhat similar to the preorbital gland secretion. A compound that is probably isomeric with the "deer lactone," (*Z*)-4-hydroxy-6-dodecenoic acid lactone (Müller-Schwarze et al., 1978), was also found, although it was present in smaller amounts than the saturated lactones. γ -Lactones have been found in the occipital gland of the bactrian camel (Ayorinde et al., 1982), the pedal gland of the bontebok (Burger et al., 1977), and on human hair (Labows et al., 1979). We have made no attempt to determine the absolute stereochemistry of the muskox lactones.

Acknowledgments—The Research Herd at the Western College of Veterinary Medicine, Saskatoon, was established with the generous help of the Donner Canadian Foundation and is currently supported by NSERC grants A2759 and A2793. G.D.M. was the recipient of an NSERC Undergraduate Summer Research Award. We would like to thank Colleen Stevens for her dedicated care of the animals, Angela Shaw for expert technical assistance with the chemical analysis, Lawrence Hogge and Doug Olson for the mass spectra, and Juliane Deubner for the artwork.

ELECTROANTENNOGRAM RESPONSES OF
MEDITERRANEAN FRUIT FLY, *Ceratitis*
capitata (DIPTERA: TEPHRITIDAE) TO
TRIMEDLURE AND ITS *trans* ISOMERS

(Received September 22, 1988; accepted December 8, 1988)

Abstract—Electroantennograms (EAGs) of unmated laboratory-reared male and female *Ceratitis capitata* (Wiedemann) were recorded in response to the attractant trimedlure [*tert*-butyl 4(and 5)-chloro-*trans*-2-methylcyclohexane-1-carboxylate] and its four *trans* isomers. For both sexes, the magnitude of the EAG response was relatively low as compared to other previously tested compounds (i.e., plant volatiles). Dosage-response curves generated for all TML isomers revealed that flies responded to increasing dosages over a relatively narrow range (two to three log steps). Responses for both sexes peaked at ca. 10 μg dose for all isomers. Antennal response in males was greatest to the C isomer followed by the B₁, A, and B₂ isomers, while responses of females were greatest for the A isomer followed by B₁, C, and B₂. Both sexes exhibited a long recovery period for the response potential to return to baseline at doses above 1 μg for all of the isomers tested, except for B₂. The low EAG sensitivity to trimedlure and the apparent EAG selectivity to the C isomer in males are discussed in relation to the known field attractancy of males to the C, A, B₁, and B₂ isomers.

Key Words—*Ceratitis capitata*, medfly, Diptera, Tephritidae, trimedlure, electroantennogram, dosage-response.

INTRODUCTION

The Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann), is a serious economic pest of fruit and vegetable crops throughout the world. During the past 75 years, considerable effort has been put forth to devise and improve the trapping technologies for this and other tephritid fruit fly species. Of the many compounds that have been tested as attractants for *C. capitata* (Beroza et al., 1961; Keiser et al., 1975), trimedlure (TML) [*tert*-butyl 4(and 5)-chloro-*trans*-2-methylcyclohexane-1-carboxylate] is one of the best to date and is currently used as the de facto standard for survey and detection of adult male *C. capitata*. Unlike the many pheromones or host-plant odors reported as attractants in various insects, the biological rationale as to why trimedlure, a synthetic chlorinated molecule, is attractive to male flies has remained an enigma since the serendipitous discovery of its predecessor, siglure (1-methylpropyl *trans*-6-methyl-3-cyclohexene-1-carboxylate) (Gertler et al., 1958). Trimedlure attracts both mated and unmated male *C. capitata* and has also been reported to attract virgin females in the absence of males (Nakagawa et al., 1981).

Commercial TML is composed primarily of four *trans* isomers (McGovern and Beroza, 1966) and lesser quantities of the four *cis* isomers (Leonhardt et al., 1982). The four *trans* isomers, when tested singly, elicit varying degrees of attractancy ($C \gg A > B_1 \gg B_2$), which suggests that the stereochemistry of the molecule may be an important factor (McGovern et al., 1987). Recent studies have shown the *cis* configurations of TML to be less attractive than the *trans* counterparts (McGovern et al., 1986). Although much work has been done on the isomeric chemistry of TML (McGovern and Beroza, 1966; Leonhardt et al., 1982; McGovern et al., 1986) and its attractiveness in laboratory and field tests (Beroza et al., 1961; McGovern et al., 1966, 1987), little is known about antennal sensitivity or selectivity to TML or why it elicits such a strong behavioral response, primarily in males.

Electroantennogram (EAG) recordings have been widely used to investigate detection of chemical compounds by insect antennae, but have only recently been used to study olfactory reception in tephritid fruit flies (Fein et al., 1982; Guerin et al., 1983; Van Der Pers et al., 1984; Robacker et al., 1986; Light and Jang, 1987; Light et al., 1988). These previous investigations have studied the reception of either host-plant compounds (Fein et al., 1982; Guerin et al., 1983; Light and Jang, 1987; Light et al., 1988) or identified, or putative pheromone components (Van Der Pers et al., 1984; Robacker et al., 1986; Jang et al., 1989).

The purpose of this study was to investigate the selectivity and sensitivity of adult *C. capitata* to TML and its *trans* isomers. Of special interest in this study were the questions of whether or not females possessed antennal receptors

capable of detecting these compounds and whether antennae are selectively responsive to particular isomer configurations of the molecule.

METHODS AND MATERIALS

Insects. Pupae of *C. capitata* were obtained from a laboratory mass-rearing colony maintained at the USDA, Tropical Fruit and Vegetable Research Laboratory, Honolulu, Hawaii. Upon arrival, the pupae were segregated by sex, placed in separate cages, and maintained ad libitum on sugar and water. Adult flies were tested on the second to fifth day postemergence.

Olfactory Stimuli. Commercial TML (UOP 3702) was purchased from UOP Chemical Co., East Rutherford, New Jersey, and contained the following proportions of both *trans* and *cis* isomers; *trans*: 26.9% A, 7.1% B₁, 19.7% B₂, 42.1% C; *cis*: 1.2% V, 1.3% X, 0.3% Y and W. The *trans* isomers of TML, designated as A, B₁, B₂, and C (Figure 1) according to their chromatographic retention times (McGovern and Beroza, 1966), were purified according to McGovern et al. (1987) and found to be ca. 99%+ pure by capillary GC analysis (Leonhardt et al., 1982; McGovern et al., 1986). Compounds were dissolved in spectrometric grade hexane (that was additionally distilled to 100% purity and treated with Ionox, a nonvolatile antioxidant). Serial dilutions of 100 $\mu\text{g}/\mu\text{l}$ stock solutions of the TML blend, A isomer, and B₁ isomer were made to obtain a series of logarithmic concentrations from 1×10^2 to 1×10^{-4} $\mu\text{g}/\mu\text{l}$. Compounds were delivered by pipetting 1- μl aliquots onto 1×2 -cm pieces

FIG. 1. Structure of *trans* trimedlure isomers.

of glass-fiber filter paper inserted into individual Pasteur pipets, which served as cartridges for the odor delivery system. Solvent was allowed to evaporate off for ca. 30 sec prior to delivery of compound over the antennae. Due to the differences in volatility of the different *trans* isomers, the less volatile isomers, B₂ and C, were tested by applying the compounds over a greater surface area of the filter paper. Based on the work by McGovern et al. (1966) on the relative volatility of these isomers, the B₂ and C isomers evaporate ca. 6.6× and 3.5× slower than the A isomer. To compensate for this difference, these compounds were diluted to obtain stock concentrations of 15.2 μg/μl and 28.6 μg/μl, respectively, and serially diluted over seven log steps. The B₂ and C isomers were applied to the filter paper at the same microgram dose as the A and B₁ isomers (i.e., 100 μg to 1 × 10⁻⁴ μg), but spread over a proportionally greater surface area (i.e., ca. 6.6× and 3.5× the size of the A isomer). This procedure "equalized" the effective volatile dose of each isomer, which was subsequently presented to the antennae. Either 6.6 μl (B₂) or 3.5 μl (C) was aliquoted onto the filter paper to achieve this effect. The diluting solvent was allowed to evaporate for 2 or 3 min before testing as determined with hexane controls using the larger volumes. These controls were found to give no higher response than the previous 1-μl volume controls.

Electrophysiological Recording Technique. Electroantennogram (EAG) techniques used in this study were identical to previously published techniques utilizing glass capillary Ag-AgCl electrodes (Light and Jang, 1987). Intact flies were immobilized by a yoke in a Plexiglas block. The recording electrode was inserted into the apical region of the terminal antennal segment, the funiculus; the indifferent electrode was positioned into the hemocoel of the cranial cavity. The signal was amplified 100× by a Grass P-16 microelectrode preamplifier and viewed on a Nicolet model 4094 digital storage oscilloscope. EAG deflections were measured from the calibrated screen and stored on floppy disks.

Odor Delivery System. The odor delivery system and stimulation apparatus were essentially the same as that described by Light (1983). A constant flow (1.0 liter/min) of charcoal-filtered and humidified compressed air was passed over the antenna through a disposable plastic pipet tip positioned ca. 1 cm from the antenna. A three-way solenoid valve diverted the purified air to the stimulus cartridge where the test odor was purged from the pipet tip and over the antenna. Stimulation was for 1 sec. For each compound, the order of presentation was always from lowest to highest dosage. A minimum of 3-4 min of clean air preceded and followed each stimulation. This time period allowed for full recovery of the antenna at the highest (100 μg) dose tested.

Experimental Procedure. EAGs were recorded from at least five individual flies of each sex for the TML commercial blend and for each of the isomers over a seven log dose range. "Control" stimulations containing either 1, 3.5,

or 6.6 μl of the hexane solvent and "standard" stimulations containing fresh cartridges of 1 μl of 1% hexan-1-ol (100% purity, Aldrich Chemical Co.) dissolved in hexane were presented between each appropriate series of compounds. EAGs were normalized to the standard stimulation by measuring the maximal amplitude of the negative deflection ($-\text{mV}$) during the stimulation period elicited by a given stimulus, subtracting the amplitude of the response to the preceding hexane control, and then dividing by the mV response to the accompanying 1% hexan-1-ol standard (from which the hexane control was also subtracted) to obtain the percent of the standard response (the standard being a 100% response in each case). This "normalization" minimized the observed variability in: (1) absolute responsiveness among preparations, (2) the time-dependent variability in antennal responsiveness, and (3) allowed for relative comparison of responses between sexes (Payne, 1975; Light, 1983; Dickens, 1984). Hexan-1-ol was chosen as a standard based on its relatively constant response as measured on many individuals in previous studies (Light and Jang, 1987; Light et al., 1988; Jang et al., 1989). The mean mV responses to standard stimulations measured for each sex in this study were $1.09 \pm 0.08 \text{ mV}$ for males and $1.14 \pm 0.11 \text{ mV}$ for females. Mean normalized TML responses were statistically compared using t tests and the nonparametric Mann-Whitney U test (Snedecor and Cochran, 1967). A "threshold" EAG response (or the minimal effective dosage needed to produce a reliably detectable response) was arbitrarily defined as the stimulus dosage at which the lower limit of the standard error to the test stimulus did not overlap with the upper limit of the standard error for the response to control (Light, 1983; Dickens, 1984). The upper limit of the standard error to the hexane control was calculated as 9.3% of standard and 5.5% of standard, respectively, for males and females.

The period of time necessary for the EAG depolarization to return to the baseline trace level for a given stimulus was defined as the recovery period. To evaluate the effects of the stimuli on antennal recovery period, the percent recovery was calculated by measuring the positive mV recovery 3 sec after the end of the stimulus, and dividing it by the maximum depolarization (see Figure 3). Comparisons of the mean percent EAG recovery at three seconds post-stimulus were made using ANOVA and Duncan's multiple-range test (Duncan, 1955).

RESULTS

Sensitivity. Dosage-response curves of male and female *C. capitata* to the commercial mixture of TML and the *trans* isomers are shown in Figure 2. In general, flies responded to increased dosages of the commercial blend and isomers A, B₁, and C over a relatively narrow dosage range (two to three log

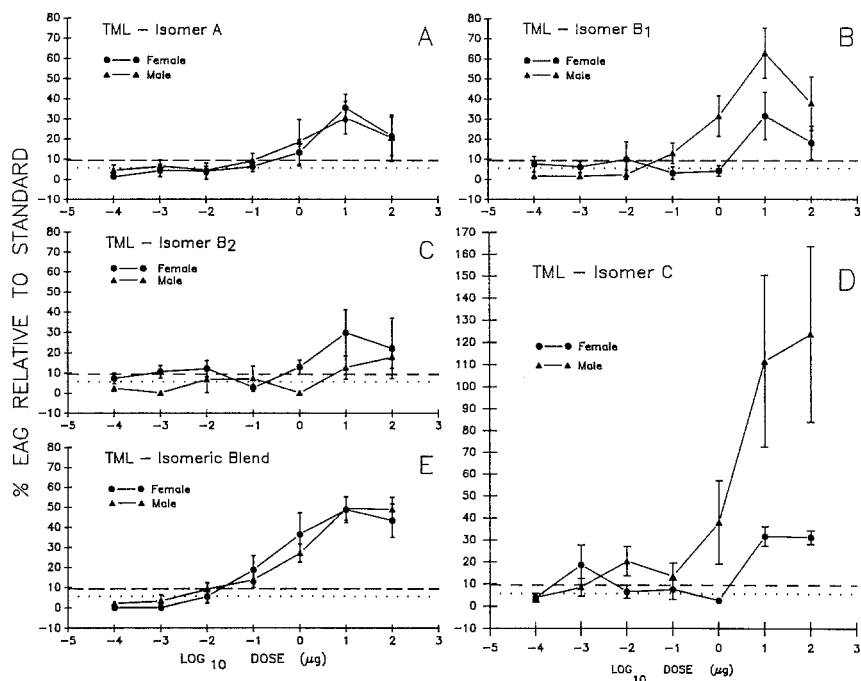

Fig. 2. Dosage–response curves of male (triangle) and female (circle) *C. capitata* to the commercial blend and individual *trans* isomers of trimedlure. Points represent the mean response \pm SE of at least five male and female flies relative to a standard (1 μ l dose of 1% hexan-1-ol), and the horizontal lines (dashes, males; dots, females) delineate threshold levels (one SE of control above zero, see Methods and Materials) above which responses are significantly greater than control ($P < 0.05$). (A) Isomer A; (B) isomer B₁; (C) isomer B₂; (D) isomer C; (E) commercial blend.

steps). Responses peaked at ca. 10 μ g for each of these isomers and for both sexes.

The antennae of both sexes showed similar EAG responses to the commercial blend (Figure 2E), with no significant differences between the sexes observed at any of the doses tested. Threshold responses appeared to occur at less than the 0.1- μ g dose for both sexes. Increased responses were evident over the dose span from above 0.01 μ g to 10 μ g, then plateaued at 100 μ g.

Isomer A of TML elicited similar EAG response curves for males and females (Figure 2A, Table 1). The threshold response occurred between 1.0 and 10 μ g for males and females. Antennae of both sexes showed a maximum response to the 10- μ g dose.

Dose–response curves to the B₁ isomer differed between the sexes in

TABLE 1. EAG THRESHOLD AND RESPONSE MAXIMA FOR MALE AND FEMALE *Ceratitis capitata*

	EAG threshold (μg)		Maximum EAG response \pm SE	
	Male	Female	Male	Female
Blend ^a (99+ %)	<0.1	<0.1	49.2 \pm 15.9	48.7 \pm 6.5
Isomer ^b A (99+ %)	>1.0	>1.0	30.5 \pm 8.2	35.6 \pm 6.8
Isomer B ₁ (97%)	>0.1	>1.0	62.9 \pm 12.6	31.6 \pm 12.2
Isomer B ₂ (99+ %)	>10.0	>10.0	17.9 \pm 5.6	29.8 \pm 11.4

^a Composition of commercial trimedlure (UOP 3702) *trans*: 26.9% A, 7.1% B₁, 19.7% B₂, 42, 1% C; *cis*: 1.2% V, 1.3% X, 0.3% Y and W.

^b Preparation of isomers as in McGovern et al. (1987).

threshold level, slope, and dynamic response range (Figure 2B, Table 1). Males had a lower threshold (>0.1 μg vs. >1 μg) and responses increased over a broader stimulus range than the female curve. Isomer B₁ elicited significantly greater ($P < 0.05$) responses to both the 1- μg and 10- μg doses from male than female antennae.

Neither sex responded significantly above threshold to the B₂ isomer over the majority of the dose range tested (Figure 2C). Only the females at the 10- μg dose and males at the 100- μg dose showed responses above threshold. However, relative responses were still quite low compared to the other isomers, even with compensations made for the low volatility of this isomer.

EAG responses of male *C. capitata* to the C isomer were significantly greater than those of females and were also the highest recorded among all the compounds tested (Figure 2D, Table 1). Male antennae responded above threshold at the >0.1- μg dose, while female antennae were a log step less sensitive. Maximum response was seen at the 100- μg dose for both sexes.

Selectivity. Comparing the responsiveness of both sexes to the four isomers, antennal response in males was greatest to the C isomer followed by the B₁, A, and B₂ isomers. Females exhibited maximum responses to the A and B₁ isomers followed by the C and B₂ isomers (Table 1). Differences between the sexes were most evident for the C and B₁ isomers, in both cases males having a greater response over a two to three log dose range than females (Figures 2D and B).

Recovery Period. The antennae tested exhibited a long recovery period to baseline after presentation of TML or its isomers at concentrations above 1 μg (Figure 3 and Table 2). The antennal recovery period at these higher doses was prolonged by all isomers except the B₂ isomer. Recovery periods considered

FIG. 3. Electroantennogram recording showing "normal" (hexan-1-ol standard) and "long" (isomer C, 10- μ g dose) recovery of antennal receptors. Recovery was analyzed by calculating the percent change between the maximum deflection (X) and the recovery of the stimulation trace towards baseline (dX) at 3 sec after stimulus.

"normal" were those in which the trace of the oscilloscope recording returned to the approximate baseline within ca. 3-4 sec of the end of the stimulus delivery. Stimulation traces exhibiting "long recovery" did not return to baseline within the field of view of the oscilloscope screen (ca. 10 sec). Most antennae exhibited "long recovery" at a concentration of 10 μ g, although a few were affected at lower doses. Analysis of the relative recovery rates for males after three seconds at the two highest doses tested showed significantly more long recovery for the blend, A, B₁, and C isomers than for the B₂ isomer (Table 2). Females responded similarly except for the C isomer, which was significant only at the highest dosage tested. EAGs showing long recovery did, however, return to baseline well within the minimum time period chosen between presentations of the compounds (3-4 min). The B₂ isomer and the hexan-1-ol standard exhibited "normal" recovery in all cases.

DISCUSSION

Both males and females exhibited EAG responses above threshold to the TML commercial blend and three (A, B₁, and C) of the four *trans* isomers of TML, indicating that *C. capitata* has receptor populations capable of detecting

these compounds. However, the relative magnitudes of these EAG responses to these compounds were relatively low compared to the hexan-1-ol standard and most plant volatiles previously tested, which elicit EAGs ranging from ca. 100% to 300% of standard at a 100- μg dose (Light et al., 1988). These plant volatiles include various monoterpenes, aliphatic esters, primary alcohols, and aldehydes; in particular, the general "green-leaf" volatiles, appear to be more potent EAG stimuli to *C. capitata* antennae. The exception was the male antennal response to the C isomer at the two highest doses, which elicited responses comparable to many of the plant volatile compounds and which elicited a significantly higher response than either the females to the same compound or

either sex's response to the A, B₁, or B₂ isomers. Significantly greater ($P < 0.05$) EAG responses between sexes were also evident in males for the B₁ isomer (at doses of 1.0 and 10 μg).

The magnitude of the EAG response is thought to be representative of the overall population size of the antennal receptors responding to a particular olfactory stimulus (Kaissling, 1971; Payne, 1975; Nagai, 1981, 1983; Mankin and Mayer, 1983; Mayer et al., 1987). Preliminary single-cell recordings (Dickens, Light, and Jang, unpublished observations) indicate the presence of cells responsive to the TML blend that are capable of detecting differences in relative doses. These TML-responsive receptor neurons were recorded from seven of the 23 cells in our preliminary sampling of sensilla distributed over various regions of the funiculus (Dickens et al., 1988). The low numbers of TML-responsive antennal receptor neurons compared to those responding to plant odors encountered in these preliminary single-cell recordings correlate with the relatively low EAG responses to most isomers, suggesting that there are low densities or small overall populations of TML receptors present. Therefore, we conclude that *C. capitata* antennae may possess small populations of receptors for the A, B₁, and B₂ isomers compared to those responsive to other semiochemicals such as selected plant volatiles. Males do, however, possess larger populations of antennal receptors responsive to the C isomer than for the other three *trans* isomers, while females may have similar numbers of receptors for the A, B₁, and C isomers. This difference suggests that males may possess specific receptors that are responding to the C isomer but are not part of the population that responds to the other isomers and may, in part, explain why the C isomer is the most active of the individual isomers in field tests. Males show a striking behavioral attraction to TML, whereas neither sex is attracted to most individual plant odors or green-leaf odors (Beroza and Green, 1963; Cunningham, unpublished observations). Primarily virgin females rather than mated females have been reported to be attracted to TML in the field (Nakagawa et al., 1981). Yet in preliminary EAG recordings to mated females (Jang, unpublished observations) we find little difference in EAG response to trimedlure or its *trans* isomers over that reported in this study to virgin females. This may indicate that other physiological states may influence perception and/or elicitation of a behavioral response to certain semiochemicals (Davis, 1984; Blaney et al., 1986).

The chemoreceptive basis for TML being a potent nonpheromonal attractant for *C. capitata* is due not only to the presence of populations of antennal receptors for these isomers, but also to the specificity and sensitivity of receptors and ultimately the CNS to specific configurations of the TML molecule. McGovern et al. (1987) suggested that the stereochemical configuration of the TML molecule was an important factor in its attractiveness based on extensive

field testing of the four *trans* isomers of TML, which showed the C isomer to be most attractive, followed by the A, B₁, and B₂ isomers, respectively. For maximal attraction in the field, they considered the axial positioning (isomers C and A) of the 4- or 5-position chlorine atom of TML to be more suitable than an equatorial conformation (isomers B₁ and B₂), and that the diequatorial position of the 1 and 2 substituents on the cyclohexane ring (*trans*) is preferable to an axial-equatorial position (*cis*). Electrophysiological evidence from this study suggests that the C and B₁ isomers are more potent antennal stimulants for males than the A or B₂ isomers at the same dose, while very little difference in EAG response to the TML isomers by the females was observed.

Although the precise significance is not known, the "long recovery" of the medfly antennal receptor neurons to high doses of TML suggests a strong interaction of the molecules with their receptors, which may be indicative of the relative "affinities" or "stickiness" of the compounds (Roelofs et al., 1969; personal communication), or slow "inactivation" of the receptor complex and/or the TML molecule (Kaisling, 1969, 1974). We found that isomers of TML that have been reported to be the most attractive (C, A, B₁) exhibited longer recovery than that of low attractancy (B₂) isomer or plant volatiles (Light et al., 1988). This difference in recovery as seen between behaviorally "active" compounds such as trimedlure and pheromones, and other more "general" odors may have a functional significance in how insects interpret chemical cues. An in-depth discussion of chemoreceptive recovery and inactivation is presented by others elsewhere (Kaisling, 1971, 1986).

We conclude from these studies that (1) both male and female *C. capitata* do possess populations of antennal receptors capable of detecting trimedlure, (2) there are differential population levels of antennal receptors responsive to different configurations of the TML molecule, and (3) based on these results, it appears that there is a relationship between differential population levels of receptors and previously published field attractancy to these same compounds. Single sensillum recordings have been initiated that may provide additional information useful in determining the precise structure-activity relationships of the TML geometric and optical isomers with antennal receptors and, perhaps, insights as to why particular isomers and/or enantiomers are more attractive than others. Future single-cell recordings on the sensitivity, specificity, and long recovery phenomena of receptor neurons from male and female *C. capitata* may reveal the mechanisms by which these isomers are detected. These studies may also reveal the neural basis of the observed behavioral differences between the sexes for both TML and host plant odors.

Acknowledgments—The authors wish to thank Dr. B.C. Campbell for the figure of trimedlure isomers, and Drs. H.T. Chan, R.T. Cunningham, D.O. McInnis and the journal reviewers for comments on the manuscript.

FEMALE SEX PHEROMONE COMPONENTS OF *Heliothis peltigera* (LEPIDOPTERA: NOCTUIDAE)
Chemical Identification from Gland
Extracts and Male Response¹

Bet Dagan 50 250, Israel

(Received August 9, 1988; accepted December 8, 1988)

Abstract—Ten compounds were found in the sex pheromone glands of *Heliothis peltigera* (Schiff) and identified as tetradecenal, (Z)-9-tetradecenal, (Z)-9-tetradecenol, (Z)-9-tetradecenyl acetate, hexadecenal, (Z)-7-hexadecenal, (Z)-9-hexadecenal, (Z)-11-hexadecenal, (Z)-11-hexadecenol, and (Z)-11-hexadecenyl acetate. Behavioral tests in a wind tunnel and subsequent trapping studies conducted in the field indicated that (Z)-11-hexadecenal and (Z)-9-tetradecenal are the main pheromone components of *H. peltigera*. Addition of (Z)-11-hexadecenol to the binary blend did not enhance the capture of males of *H. peltigera*, but it decreased the number of males of the sympatric *H. armigera*. Rubber septa impregnated with a mixture of 2 mg (Z)-11-hexadecenal + 1 mg (Z)-9-tetradecenal + 0.6 mg (Z)-11-hexadecenol are recommended for monitoring *H. peltigera*.

Key Words—Sex pheromone, Lepidoptera, Noctuidae, *Heliothis peltigera*, capillary chromatography, DMDS derivatization, behavioral tests, field work.

INTRODUCTION

Heliothis peltigera (Schiff) is a polyphagous insect distributed over central and southern Europe, the Canary Islands, Asia Minor, Syria, Iraq, and Iran. It infests ornamental plants, fodder crops, medicinal crops, safflower, tobacco, grapevine, stone fruit trees, and citrus (Avidov and Harpaz, 1969; Yathom, 1971).

¹Contribution from the Agricultural Research Organization (ARO), No. 2454-E, 1988 series.

In Israel it is also sometimes responsible for damage inflicted to young cotton plants and is abundant on chickpea and safflower. In order to monitor its population, particularly when adults and larvae resemble those of the sympatric *H. armigera*, work was undertaken to find attractants to be used in traps. There has been only one observation, from Sudan, on captures of *H. peltigera* in traps baited with pheromonal compounds (Outram, personal communication, in Nesbitt et al., 1979).

The purpose of the present study was to develop a specific sex pheromone blend for monitoring *H. peltigera*. To accomplish this aim, chemical identification of the pheromonal compounds in gland extracts was performed and the major components, which evoked male response in the flight tunnel, were tested in the field. The emphasis in this work was to obtain a bait, as good or better than a virgin female, that would be able to capture efficiently and specifically *H. peltigera* males. Despite the fact that 10 pheromone-like compounds were identified in the glands, there was no intention to perform a behavioral study of all the compounds. The development of sex pheromone traps for *H. peltigera* will enable monitoring and improvement of practical control procedures for this pest.

METHODS AND MATERIALS

Insects and Extracts. Females of *H. peltigera* were captured in light traps and kept for egg laying. Larvae were individually reared on a modified diet medium (Shorey and Hale, 1965). Pupae were sexed and placed in separate rooms with a dark-light regime of 10:14 hr, at $25 \pm 2^\circ\text{C}$. The insects used in the study were from this colony, which was 6–12 months old.

All ovipositors were excised from 2- to 3-day-old females, 7–8 hr into scotophase, which is the time of maximal mating in the laboratory. The ovipositors were immersed in redistilled hexane for 10–15 min, and the supernatant solution was pipetted into conical vials sealed with a Teflon-lined screw cap. Four pooled samples, each consisting of 20–30 glands, were prepared and 200 ng of Z8-13:Ac was added to each one as internal standard. The extracts were concentrated by letting them stand in a fume hood; they were stored at -18°C until use.

Chemical Identification. Capillary GC analysis was conducted using a Varian 3700 model equipped with a FID detector and a splitless injector system. A 30-m \times 0.25-mm DB 225 cyanosilicone column (J&W) was kept at 60°C for 2 min and then programmed to 150°C at $10^\circ/\text{min}$. The purge valve was opened 1 min after injection, and the helium (carrier gas) pressure was maintained at 15 psi. Quantification of peak areas was performed by a Varian 4270 electronic integrator.

Capillary GC-MS analysis was conducted on a Finnigan 5100 E1 machine at 70 eV, coupled with a Superincoss data system and interfaced with a Finnigan MAT 9610 GC. A 30-m \times 0.25-mm SE 54 (J&W) column was kept at 60°C for 2 min and then programmed from 60° to 250°C at 12°/min for pheromone components; for the dimethyl disulfide (DMDS) adducts, the column was kept at 60°C for 4 min and then programmed at 20°/min to 230°C. The column was operated in the splitless mode, the purge valve was opened 0.5 min after injection, and the helium (carrier gas) pressure was maintained at 10 psi.

DMDS adducts were prepared from several standards (Z9-14:Ald, Z9-14:Ac, Z11-16:Ald, Z11-16:OH, and Z11-16:Ac) and from a portion of the gland extracts. Samples in hexane were treated with DMDS and ethereal iodine as described by Buser et al. (1983) and Dunkelblum et al. (1985). The EI mass spectrometric analysis was conducted in the multiple ion detection (MID) mode searching for the characteristic RCHSCH_3^+ and molecular ions.

Flight-Tunnel Bioassays. The flight tunnel used ($2 \times 0.5 \times 0.5$ m) in these tests was of the same design as described by Snir et al. (1986). All tests were conducted with 4-day-old males, 6–8 hr into scotophase. The insects were kept in screen cages ($30 \times 30 \times 30$ cm) in the tunnel room. Individual males were transferred into small cylindrical cages (6 cm diameter, 6 cm high) and placed on a tripod in the center of the tunnel, approximately 20 cm from the downwind end. The tests were performed at $24 \pm 2^\circ\text{C}$, with a light intensity of 0.3 lux and a wind speed of 40–45 cm/s.

Baits were prepared by impregnating rubber septa (Maavit Products, Tel Aviv, Israel) with hexane solutions of the test compounds, and they were aged for 48 hr on a laboratory bench before use. The baits were kept in glass vials (2 cm diameter), fixed on top of a cork with a cut paper clip. The cork served as a stand for the bait in the tunnel and also enabled storage of the septa in the glass vials. They were stored in a refrigerator and kept at room temperature for 24 hr before use. Baits were positioned in the wind tunnel on a tripod approximately 20 cm from the upwind side. Ovipositor extracts from one female (1 FE), in hexane, were placed on a 1×1 -cm piece of filter paper. After evaporation of the hexane, the paper lures were fixed on a cork with a pin. Virgin females were tested as a group. Attempts to use one virgin female as a lure failed; therefore five females were placed in a screen cage and put in the tunnel. The number of calling females at a specific moment was not recorded.

Individual males were used for testing the attractancy of different blends, extracts, and live females. Four behavioral categories were recorded: (1) upwind flight (approximately half the length of the tunnel); (2) flight close to source (within 10 cm of the bait and hovering around it); (3) source contact, and (4) copulation attempts. Results were analyzed by the χ^2 2×2 test of independence using the actual number of insects and are presented as percentage of response. Only moths that responded within 2 min of release were scored.

Field Work. Tests were conducted in cotton, chickpea, and safflower fields in the Bet Shean Valley, and at Mai Ami and Bet Dagan during the 1987 and 1988 seasons. Rubber septa dispensers were loaded with hexane solutions of test compounds containing 10% of butylated hydroxytoluene (BHT) as antioxidant. The traps used consisted of a plastic ring (9 cm diameter) with a plastic roof fixed 3–5 cm above the opening; the dispenser containing the synthetic chemicals was hung under the protecting roof. A nylon bag was attached to the plastic ring to collect the trapped insects. Attractancy of virgin females was tested by hanging a small screen cage containing two virgin females under the protecting roof. Talcum powder was inserted into the nylon bag to prevent the escape of captured moths. The traps were fixed at a height of ca. 1.5 m above the ground; adjacent traps were located at least 30 m apart. Captured moths were collected and counted every one to three days. Positional bias was reduced by moving the different treatments one position whenever the traps were examined. In all experiments, three to five traps were used for each treatment. Duncan's new multiple-range test was used to analyze significant differences between treatments.

RESULTS

Chemical Identification. Capillary GC analysis of the ovipositor extracts revealed the presence of a large number of peaks (Figure 1). Comparison of the retention times with synthetic compounds enabled the tentative identification of 10 components: tetradecanal (14:Ald), (Z)-9-tetradecenal (Z9-14:Ald), (Z)-9-tetradecenol (Z9-14:OH), (Z)-9-tetradecenyl acetate (Z9-14:Ac), hexadecanal (16:Ald), (Z)-7-hexadecenal (Z7-16:Ald), (Z)-9-hexadecenal (Z9-16:Ald), (Z)-11-hexadecenal (Z11-16:Ald), (Z)-11-hexadecenol (Z11-16:OH), and (Z)-11-hexadecenyl acetate (Z11-16:Ac) (Table 1). The amount of the major component Z11-16:Ald in the pooled extracts was 23–42 ng/female. The polar DB 225 capillary column gave a fair separation of Z7-16:Ald, Z9-16:Ald, and Z11-16:Ald.

Additional information on the identity of the compounds present in the gland extracts was obtained from the GC-MS analysis on a SE 54 capillary column. The amount of some of the trace compounds, such as 14:Ald, was insufficient for a mass spectrum. Two of the minor unsaturated aldehydes, Z7-16:Ald and Z9-16:Ald eluted on the SE 54 column as one peak. The mass spectrometric data were in accordance with the proposed structures. Derivatization of a portion of the extracts with DMDS and subsequent GC-MS analysis enabled the separation of all unsaturated components. It confirmed the presence and established the position of the double bond in all these components. The mass spectrometric analysis in the MID mode enhanced the sensitivity of the

FIG. 1. Capillary GC trace of gland extracts of *Heliothis peltigera*: 1 = 14:Ald, 2 = Z9-14:Ald, 3 = Z9-14:OH, 4 = Z9-14:Ac, 5 = 16:Ald, 6 = Z7-16:Ald, 7 = Z9-16:Ald, 8 = Z11-16:Ald, 9 = Z11-16:OH, 10 = Z11-16:Ac, and I.S. = Z8-13:Ac.

analysis and enabled the detection of all the predicted DMDS adducts. The intense $RCHSCH_3^+$ ions as well as the molecular M^+ ions were diagnostic for the structure of all the adducts. The mass spectrometric data are summarized in Table 2.

Flight-Tunnel Bioassays. The flight-tunnel tests reported here concentrated on the components present in largest amounts: Z11-16:Ald, Z9-14:Ald, and Z11-16:OH. The best blends were compared with ovipositor extracts and with virgin females. In all flight tests, most males that reached the bait performed copulation attempts. This behavioral stage was readily recognized by the expo-

and compared with that of several binary blends consisting of these two components in different ratios (HP3, HP4, HP5). Subsequently, a blend of Z11-16:Ald + Z11-16:OH (HP6) and a ternary blend of the two aldehydes and the alcohol were examined. The results showed that both Z11-16:Ald and Z9-14:Ald induced only upwind flight. Addition of varying amounts of Z9-14:Ald to Z11-16:Ald caused a significant increase in attractancy of the blends. Mixtures containing 5% of Z9-14:Ald (HP4) or 50% of Z9-14:Ald (HP5) performed similarly, with approximately 60% of the males completing the whole courtship sequence. Addition of Z11-16:OH to Z11-16:Ald (HP6) had no influence on the performance of the bait. In further tests the binary blend, HP5, was compared with a ternary blend of Z11-16:Ald + Z9-14:Ald + Z11-16:OH (HP7). A slight increase in activity was observed, but the difference was not significant. The ternary blend HP7 was as active as virgin females and more active than the one-ovipositor extract (1 FE).

Field Tests. Most of the field tests were performed during 1987 at two locations on two different crops at the beginning of the season, and later on cotton alone (Table 4). Initial results (test 1) indicated that the mixture of Z11-16:Ald + 2.5% Z9-16:Ald (HA), the two major sex pheromone components of *H. armigera* (Kehat et al., 1980), did not attract *H. peltigera* males. The addition of 5% Z9-14:Ald to this mixture (HP8) resulted in trapping of *H. peltigera* on the one hand, and in a significant decline in captures of *H. armigera* on the other. Increasing the amount of Z9-14:Ald up to 20% (HP9) sig-

nificantly increased the captures of *H. peltigera* and further reduced the number of trapped *H. armigera* males (HP8 vs. HP9). Results presented in test 2 indicated that increasing the amount of Z9-14:Ald up to 50% (HP10) did not enhance captures of *H. peltigera* as compared with the addition of only 20% Z9-14:Ald (HP9) but drastically reduced captures of *H. armigera*. The minor component in HA, Z9-16:Ald, did not affect the captures of *H. peltigera*, as shown by the comparison of HP10 with HP5. Therefore, this compound was eliminated from additional field tests. In test 3, two binary blends of Z11-16:Ald and Z9-14:Ald (HP11 and HP5) were compared with a ternary blend of these components and Z11-16:OH (HP7). The results showed that all three lures captured the same numbers of *H. peltigera* males, but larger amounts of Z9-14:Ald (HP5 vs. HP11) resulted in a smaller trap catch of *H. armigera*. Addition of 30% of Z11-16:OH, which is a strong inhibitor to *H. armigera* (Kehat et al., 1980), resulted in complete elimination of males of *H. armigera* from the traps (HP5 vs. HP7).

Two field tests were performed in the spring of 1988, when the population density of *H. peltigera* was higher (Table 5). The first test again compared the efficiency of the best binary blend (HP5) with the ternary blend (HP7), and results indicated that they have the same attractancy in the field. The second test compared blend HP5 with two virgin females, and the synthetic lure attracted significantly more males than did the females.

DISCUSSION

The sex pheromones of several *Heliothis* species—*H. virescens* (Klun et al., 1980a), *H. zea* (Klun et al., 1980b), *H. armigera* (Nesbitt et al., 1979, 1980; Dunkelblum et al., 1980), *H. subflexa* (Teal et al., 1981; Klun et al.,

1982), *H. puntiger* (Rothschild et al., 1982), and *H. phloxiphaga* (Raina et al., 1986) have been investigated in recent years. For most *Heliothis* species, gland extracts were analyzed and multicomponent pheromones were found. Only in *H. virescens* was airborne pheromone from live females (Teal et al., 1986) and from gland volatiles (Pope et al., 1982) collected and analyzed. Gland volatiles were also analyzed from *H. zea* (Pope et al., 1984). In all the *Heliothis* species, the main pheromone component was Z11-16:Ald, accompanied by varying amounts of other C₁₆ aldehydes, acetates, and alcohols. Only in *H. virescens* was Z9-14:Ald found to be an essential component in addition to the C₁₆ components (Vetter and Baker, 1983; Teal et al., 1986).

Comparison of the content of the gland extract from *H. peltigera* (Table 1) with the pheromone components of the other *Heliothis* species showed that *H. peltigera* contains most of the compounds found previously in the other species. The composition of the gland extracts from *H. virescens* (Teal et al., 1986) is similar to that of *H. peltigera*, although the latter contains also the two acetates, Z9-14:Ac and Z11-16:Ac, not present in *H. virescens*. There is also some similarity to the composition of gland extracts of *H. subflexa* (Teal et al., 1981; Klun et al., 1982). However, the latter contains additional alcohols and acetates. Most important, *H. subflexa* contains relatively large amounts of Z9-16:Ald and only trace amounts of Z9-14:Ald, whereas in *H. peltigera* the opposite was found.

The gland extracts of *H. peltigera* contain a large number of pheromonal compounds, but probably only some of these compounds are emitted by the female; the rest of the components may be biosynthetic precursors and intermediates (Morse and Meighen, 1987). The different functional groups of aldehyde, alcohol, and acetate can be biosynthetically interconverted, as shown in *Choristoneura fumiferana* (Morse and Meighen, 1987) and in *H. virescens* and *H. subflexa* (Teal and Tumlinson, 1987). The presence of the three functional classes in *H. peltigera* may indicate the biosynthetic pathway of the formation of the pheromone components in the glands of this moth.

The principal goal of the present study was to identify the main pheromone components of *H. peltigera* and to develop a species-specific lure for monitoring *H. peltigera* in the presence of the sympatric species, *H. armigera*. Therefore, the major effort was directed at the identification of the compounds in the pheromone gland that are attractive to males in both the flight tunnel and field.

The flight tests were planned to find the main components that evoke maximal response from the males and eventually would be useful in the field. The tested lures were evaluated by comparing their activity with that of calling females. A relatively high load per septum, based on 2 mg of Z11-16:Ald, was used because this is the standard load of pheromones in use for monitoring other lepidopteran pests in Israel. In view of the information on the pheromone blends of other *Heliothis* species, the obvious choices to start these behavioral tests were the two most abundant aldehydic compounds, Z11-16:Ald and Z9-

14:Ald. The tests showed that these compounds initiated individually only upwind flight, but a mixture of the two evoked a strong response from the males, comparable to that of calling females. The fact that the binary blends of Z11-16:Ald + Z9-14:Ald evoked the whole courting sequence from the males was very encouraging. The alcohol Z11-16:OH, which was one of the more abundant compounds in the gland extracts of *H. peltigera*, is an inhibitor to the sympatric *H. armigera* males (Kehat et al., 1980). Therefore, it was important to evaluate the response of the *H. peltigera* males to this compound. Addition of 30% Z11-16:OH to the binary blend of aldehydes indicated that this alcohol has no inhibitory effect on *H. peltigera* males. Subsequent field tests showed that a 2:1 mixture of Z11-16:Ald and Z9-14:Ald is an efficient attractant for *H. peltigera*, better than two virgin females. The addition of Z11-16:OH did not enhance the trap catch, but produced a more species-specific lure for *H. peltigera* by reducing completely the capture of the sympatric *H. armigera* males. The minor component Z9-16:Ald, which is present in both *H. armigera* and *H. peltigera*, is an essential component in the pheromone blend of *H. armigera* (Kehat et al., 1980) but seems to have no effect on the trap catch of *H. peltigera*. Despite that fact that the present results are based on the composition of gland extracts, the data from both the flight tunnel and field tests indicated strongly that Z11-16:Ald and Z9-14:Ald are the essential pheromone components of *H. peltigera*. The alcohol Z11-16:OH might be a pheromonal component responsible for enhancement of the pheromone specificity. Therefore, the ternary blend of Z11-16:Ald + Z9-14:Ald + Z11-16:OH is recommended for monitoring *H. peltigera*.

Careful airborne collection from live females is necessary in order to determine which components, from the large pool of compounds in the gland, are emitted as pheromone components. Based on these findings, additional behavioral tests with synthetic lures emitting the same blend should be performed. At the present time, the major pheromone components have been identified and evaluated by flight and field tests. A lure has been developed that efficiently and specifically attracts *H. peltigera*, thus enabling monitoring of the pest and possibly leading to improved procedures for its control.

CHEMICAL MIMICRY IN A PARASITOID
(HYMENOPTERA: EUCHARITIDAE) OF FIRE ANTS
(HYMENOPTERA: FORMICIDAE)

(Received March 24, 1988; accepted December 9, 1988)

Abstract—A wasp (*Orasema* sp.) parasitic on the fire ant, *Solenopsis invicta* Buren, develops to the adult stage within the ant colony, where wasp larvae are ectoparasitic on ant pupae. This phase of the parasite's life cycle requires a mechanism of integration into the host colony. Gas chromatographic profiles of hexane soaks of various stages of the parasite and host suggest that during development within the ant colony the parasite acquires the colony odor of the host through a passive mechanism, based on simple contact and other social interactions. No parasite-specific components were observed. After leaving the host nest as adults, the parasite biosynthesizes a parasite-specific cuticular compound, while retaining residual amounts of the host acquired components. This complicated scenario is consistent with current knowledge of nestmate recognition and the preferential treatment of ant workers to their brood.

Key Words—Parasite, fire ant, *Solenopsis invicta*, *Orasema*, Hymenoptera, Formicidae, mimicry, nestmate recognition, cuticular hydrocarbons, Eucharitidae.

INTRODUCTION

The search for natural enemies of the fire ant, *Solenopsis invicta* Buren, has revealed a number of diseases, parasites, and inquilines (Jouvenaz, 1986; Wojcik et al., 1987). One of these is a wasp, *Orasema* sp. (Hymenoptera: Chalcidoidea: Eucharitidae), that parasitizes *S. invicta* in Brazil. Species of Eucharitidae only parasitize ants (Das, 1963; Johnson et al., 1986; Williams

and Whitcomb, 1974) and have an unusual life cycle. Female wasps oviposit in plants (leaves, buds, fruit) that are frequented by ants. The planidia (newly hatched larvae) attach themselves to foraging ants and are carried to the nest (Wheeler, 1907; Johnson et al., 1986). The planidia then make their way to ant brood and complete their development as ectoparasites (Wojcik, 1986).

The apparent inability of fire ants to distinguish between wasp brood and their own brood suggested that the *Orasema* sp. mask their odor in some way to confuse the ants' nestmate-recognition mechanism. There is ample precedence for chemical mimicry among myrmecophiles and termitophiles. Adults of the myrmecophilous scarab beetle [*Martinezia duterteri* Chalumeau = *Myrmecaphodius excavatiocollis* (Blanchard)] integrates into host colonies of fire ants, *Solenopsis* spp., by passively acquiring the colony odor of the host (Vander Meer and Wojcik, 1982). Integrated beetles move unmolested among host ants and obtain food directly from workers by trophallaxis, by predation on ant brood, and by feeding on dead ants (Wojcik, 1975). Chemical mimicry also occurs in syrphid flies (*Microdon* sp.) that live in ant nests (R. Howard, USDA, Manhattan, Kansas, personal communication). In addition, it has been proposed that myrmecophilous lycaenid larvae successfully associate with their hosts through mimicry of volatile secretions produced by the host ant and its brood (Henning, 1983). The termitophilous beetle, *Trichosenius frosti* Seevers, biosynthesizes the same cuticular hydrocarbons as its host, *Reticulitermes flavipes* Kollar (Howard et al., 1980). These compounds are believed to be important in termite nestmate recognition. Three other termitophiles have been shown to have a cuticular hydrocarbon profile identical to that of their hosts (Howard et al., 1982).

We report the results of studies that compare chemical profiles of cuticular washes of an *Orasema* sp. parasite and its host during parasite development within the host colony and of adult parasites captured away from their host colony.

METHODS AND MATERIALS

Source of Parasite and Host. Colonies of *S. invicta* were collected for biocontrol screening in the vicinity of Cáceres, Mato Grosso, and Campo Grande, Mato Grosso do Sul, Brazil, in 1985 and 1986, and the ants were separated from the soil by flotation (Jouvenaz et al., 1977). In addition to the adult and immature wasps and ants collected from nest soil (Cáceres), adult male and female wasps were captured with an insect net as they swarmed over fire ant nests (Campo Grande). Queenless, miniature laboratory colonies composed of conspecific adult and immature worker ants, with and without wasp parasites (wasps were always maintained with the host colony from which they

were collected), were maintained in soil-free nests for up to one week by methods described by Banks et al. (1981). To facilitate observation, colonies were limited to fewer than 200 individuals.

Sample Preparation. Pupae and adults of both wasps and ants were placed individually and in groups in 7-ml vials that contained ca. 0.5 ml HPLC-grade *n*-hexane (Merck, Darmstadt, West Germany). The vials were capped with aluminum foil-lined lids and allowed to stand at room temperature for 45 min or 24 hr. The hexane was transferred by Pasteur pipet to 2-ml vials. The vials were loosely capped and the hexane allowed to evaporate. The cap was then tightened. Great care was taken to avoid cross-contamination of the samples. All samples were externally labeled and shielded from sunlight and foreign matter. They were hand carried to our laboratory in Gainesville, Florida, where they were reconstituted with HPLC-grade hexane (Burdick and Jackson, Muskegan, Michigan) prior to analysis by gas chromatography.

Chemical Analysis. Gas chromatographic (GC) analyses were carried out on a Varian 3700 gas chromatograph (Walnut Creek, California) equipped with a flame ionization detector and a 30-m \times 0.032-mm-ID DB-1 fused silica capillary column (J&W Scientific, Inc., Rancho Cordova, California). Helium was used as the column carrier gas, and nitrogen was used as the makeup gas. The following two oven temperature programs were used: (1) 50°C for 1 min then increased to 285°C at 5°/min and held for a total run time of 70 min; (2) 150°C for 1 min then increased to 285°C at 4°/min for total run time of 35 min. The chromatograms were printed and peak areas calculated on a Vista 401 data processor (Varian). If injection of 1 μ l of the reconstituted samples gave a weak chromatogram, then they were concentrated under a stream of nitrogen and run again. The accuracy of peak integration was checked by replotting the chromatograms with integration baselines.

Quantitative Analysis of Orasema sp. Adults. Samples of evaporated hexane soaks of individual *Orasema sp.* adults were reconstituted with hexane. Three microliters of a 0.01% hexane solution of *n*-pentacosane was added as an internal standard. The samples consisted of three replicates of each of the following: (1) males collected from the host ant nest; (2) females collected from the host ant nest; and (3) males collected from outside potential host ant nests. Gas chromatograms were obtained for each sample as described above and the data quantified using the Varian Vista data processor. The quantitative data was statistically analyzed using the Newman-Keuls test.

Mass Spectral Analysis. Mass spectra were obtained on a Hewlett-Packard 5988A GC-MS (Hewlett-Packard Co., Palo Alto, California) that was operated in the EI mode (70 eV) and equipped with an HP 9000/300 Chemstation and interfaced with an HP 5890 GC operated in the splitless mode. An HP methyl silicone fused silica capillary column (12 m \times 0.20 mm ID) was used for the chromatographic separation. The GC oven was operated at 60°C for 1 min then

to 225°C at 25°/min and finally to 300°C at 7°/min. The mass spectra of GC-separated components derived from pooled samples of *Orasema* sp. pupae and host colony pupae were compared. Comparison of the chromatograms of *Orasema* sp. pupae and adults with the corresponding host ant chromatograms was accomplished using the Newman-Keuls test, comparing, one at a time, the percentages of the five dominant peaks in the chromatograms.

RESULTS

Parasitism in fire ant colonies by *Orasema* sp. (identified as *Orasema* sp. by L. de Santis, Universidad Nacional de La Plata, La Plata, Argentina) can be common, with up to 41% of the colonies sampled containing the parasites and 1–598 wasps per colony (Wojcik et al., 1987). Wasp larvae and pupae were visually distinguishable from host ant larvae and pupae. In the disturbed conditions of isolating ants and parasites by flotation (Jouvenaz et al., 1977), worker ants carried wasp larvae and pupae around in the same way ant brood was carried. Wasp pupae were readily adopted by conspecific colonies of fire ants. No aggressive behavior toward wasp pupae was observed. One female wasp eclosed in an observation nest. She did not move about the nest, but remained immobile and was tended with the ant brood. After two days, the adult wasp was presumed dead and was removed from the nest for examination, whereupon she immediately flew away.

Gas chromatograph (GC) traces of host worker ants show the characteristic venom alkaloid pattern of *S. invicta* (Figure 1A). These piperidine alkaloids are found in large amounts (10–20 µg) in the fire ant poison sac and are released into the solvent during the hexane soak period. They are composed of 6-methylpiperidine alkaloids with 2-substituted alkyl or alkenyl side chains (Brand et al., 1972). The structures are simply defined by the chain length of the 2-position side chain and whether or not it contains a double bond; i.e., $C_{13:1}$ = 2-tridecenyl-6-methylpiperidine; see Figure 1A. In addition, Figure 1A illustrates the species-specific hydrocarbon patterns characteristic of *S. invicta* (section A of Figure 1A) (Vander Meer, 1986). These components have been identified as a series of normal, monomethyl and dimethyl branched hydrocarbons (Lok et al., 1975; Nelson et al., 1980). The patterns and peak retention times were directly compared with authentic samples of *S. invicta* venom alkaloids and cuticular hydrocarbons.

Gas chromatograms of hexane soaks from male and female *Orasema* sp. adults collected from their host net (Figure 1B and C) showed an identical qualitative hydrocarbon pattern to that of its ant host (Figure 1A) established by comparison of retention times and mass spectra of the five major components. The mass spectra were completely in accord with published spectra (Lok et al.,

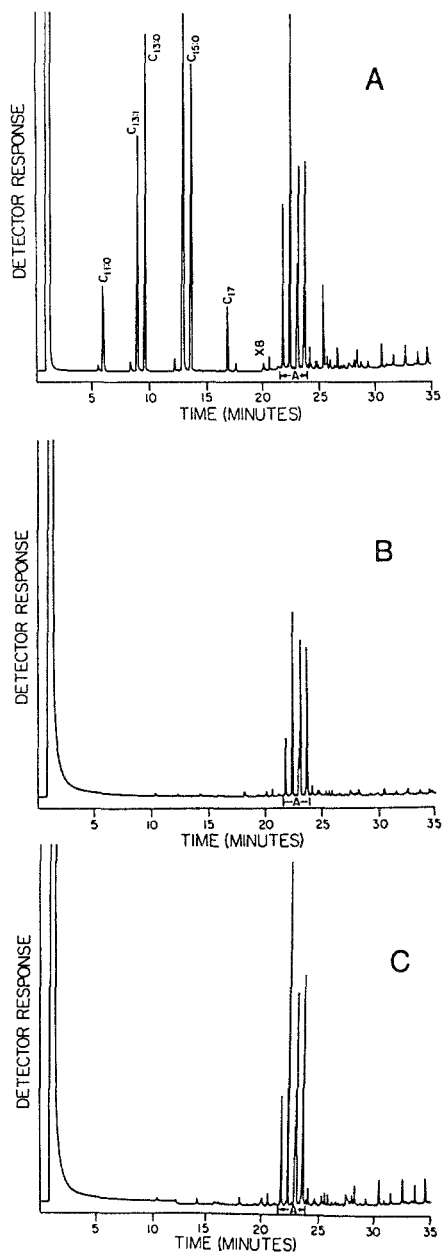

FIG. 1. Total gas chromatograph volatiles from hexane soaks of (A) host fire ant worker; (B) *Orasema* sp. female adult from host ant colony; (C) *Orasema* sp. adult male from host ant colony. Alkaloids are designated by their side-chain length and whether or not they contain a double bond. The five species-specific hydrocarbons associated with *S. invicta* are defined by chromatogram section A.

1975; Nelson et al., 1980; Thompson et al., 1981) of the five major *S. invicta* hydrocarbon components identified as *n*-heptacosane, 13-methylheptacosane, 13,15-dimethylheptacosane, 3-methylheptacosane, and 3,9-dimethylheptacosane. Venom alkaloids leached from the poison sac of the host during the hexane soak are evident. Although it is known that *S. invicta* aerosols venom on its brood (Obin and Vander Meer, 1985), the amount of alkaloids present on individuals is too small to measure (< 1 ng) by GC; consequently, alkaloid peaks are absent or not detectable from the *Orasema* sp. soaks. Volatile components were not found when the starting GC oven temperature was 50°C (temperature program 1) and no additional peaks were found on maintaining the maximum oven temperature for a prolonged period of time (285°C for 22 min).

Gas chromatographic analysis of host colony *S. invicta* pupae and parasite wasp pupae were qualitatively identical (Figure 2A and B) as demonstrated by comparison of retention times and comparison of the mass spectrum of each peak. As in the case of the parasite adults, no additional highly volatile or nonvolatile peaks were found when different chromatographic conditions were used.

Several replicates of individual *Orasema* sp. pupae and adults from one colony were analyzed by GC. The percentage of each of the five major GC peaks were compared for host pupae and adult workers, and parasite pupae and adults of both sexes. The results are given in Table 1. Host and wasp pupae were indistinguishable for all five peaks. Host pupae and adult workers were significantly different in four of five hydrocarbon peaks. The male and female adult wasps were identical in all but one hydrocarbon peak; however, they were both significantly different from adult ants and wasp and ant pupae in three of five hydrocarbon peaks (not all the same peaks).

Adult *Orasema* sp., collected flying above *S. invicta* colonies, were analyzed by GC. A representative chromatogram is shown in Figure 3. Peaks characteristic of *S. invicta* hydrocarbons are evident (defined by retention times A on the chromatogram). However, in contrast to the chromatograms of the parasite taken directly from the host nest (Figure 1B and C; Figure 2A and B), the *Orasema* sp. adults captured outside host nests had complex GC peak patterns of both lower and higher retention times.

The results of the quantitative analysis of male and female adults from the host nest and males captured outside of the nest are shown in Table 2. The total amounts of GC detectable compounds from female and male *Orasema* sp. adults collected in the host nest are not statistically different; however, *Orasema* sp. males collected outside host nests had significantly more material than their within-nest counterpart (male or female). When only the hydrocarbon peaks characteristic of the host, *S. invicta*, are considered, males and females col-

lected within the colony are indistinguishable; however, the *Orasema* sp. males collected outside the nest contain significantly less host hydrocarbon than the within-nest *Orasema* sp. The percentage of host-specific hydrocarbons to all GC components was 76.6% and 74.2% for the within-nest *Orasema* sp. females and males, respectively, and 14.5% for the *Orasema* sp. males collected outside the host colony.

The variance of the percentage of four new compounds (see Figure 3 and

Wasp male (5)	10.6 ± 0.3 (A)	29.3 ± 0.7 (B)	10.2 ± 0.3 (B)	23.8 ± 1.0 (B)	26.1 ± 0.5 (B)

^a Mean and standard error of the percent of each of the five hydrocarbon peaks.

^b Means with different letters are significantly different ($P < 0.05$), Newman-Kuels test. Comparisons are made only within each column.

FIG. 3. Total gas chromatograph volatiles from a hexane soak of an *Orasema* sp. adult collected outside the host colony. Chromatogram section A defines the species-specific hydrocarbons of the *S. invicta* host. Peaks 1–5 were used to compare the variance of host- and nonhost-derived components.

Table 3) and one host-specific compound were compared. The relative proportions of the four new components were not significantly different from each other; however, in all cases the variance of the host-specific compound was greater than the four new components and in two cases significantly so.

TABLE 2. QUANTITATIVE COMPARISON OF GC COMPONENTS DERIVED FROM *Orasema* SP. ADULTS COLLECTED FROM WITHIN AND OUTSIDE HOST NEST

<i>Orasema</i> sp. type	All components (ng) ^a	Host-specific components (ng) ^a
Female from nest	602.3 ± 122.5 a ^b	461.4 ± 101.6 a ^b
Male from nest	450.3 ± 62.1 a	334.2 ± 42.8 a
Female outside nest	1340.9 ± 198.1 b	194.4 ± 122.1 b

^a Mean ± SD (*N* = 3); see Figures 1 and 3 for GC profiles.

^b Column results with a different letter are significantly different. Newman-Keul's test (*P* < 0.05).

TABLE 3. COMPARISON OF PERCENT COMPOSITION OF FOUR NONHOST COMPONENTS AND ONE HOST-SPECIFIC COMPONENT FROM *Orasema* SP. CAUGHT OUTSIDE HOST NEST

Component ^a	$X (\%) \pm SD (N = 9)^b$	Variance
1	8.83 \pm 2.33	4.82
2	8.77 \pm 5.32	25.11
3	15.60 \pm 1.90	3.18
4	24.46 \pm 3.50	10.90
5	42.44 \pm 3.06	8.31

^a See Figure 3.

^b Comparison of variance showed no significant difference between components 1, 3, 4, and 5; however, two (host-specific compound) was significantly different from components 1 and 3 ($P < 0.05$).

DISCUSSION

A great diversity of myrmecophiles have evolved a wide range of mechanisms for survival among their ant hosts (Wilson, 1971). The release of appeasement substances used to mitigate ant attacks and to gain entrance to a host colony is common (Hölldobler, 1971, 1972). Repellent and other defensive secretions are also employed (Brand et al., 1973; Gnanasunderam et al., 1981). One staphylinid beetle even mimics the alarm pheromone of its hosts, which aids in eluding worker ant attacks (Kistner and Blum, 1971). All of the above integration methods involve the release of myrmecophile-produced exocrine gland products. There are no reports of defensive or appeasement secretions for *Orasema* spp. or Eucharitidae in general. All information on the biology of the parasite states that they are not aggressively treated by the ants (Arye, 1962; Clausen, 1940; Wojcik, 1989). Past studies and observations of *Orasema* spp. parasites in the laboratory indicate that there are no defensive or appeasement secretions involved in their acceptance into fire ant colonies. We assume that initial entry into the colony by planidia is facilitated by their extremely small size (0.12–0.20 \times 0.04–0.07 mm; Heraty and Darling, 1984).

Morphological mimicry is also used by certain myrmecophiles (Wilson, 1971); however, to the human eye *Orasema* sp. larvae, pupae, and adults are easily distinguished from their host. Current evidence indicates that integration involves the nestmate-recognition mechanism of their ant host.

Colony odor is composed of heritable and environmental odors. Nestmate-recognition cues are a subset of colony odor and may be any combination of the heritable and environmental factors (Vander Meer, 1988). Colony odors of all types are continually being transferred to and from the cuticle of an individ-

ual ant via simple movement within the colony and social interactions with other workers, queen, and brood. This has been demonstrated with *S. invicta* (Sorensen et al., 1985) and other ant species (Errard, 1986). *S. invicta* and probably all *Solenopsis* spp. utilize a combination of environmentally and heritably derived nestmate-recognition cues (Obin, 1986).

The surface of an insect's cuticle is coated with lipids (Blomquist and Dillwith, 1985), which are ideal for the absorption of both environmental and heritable odors. Thus, each ant is enveloped in chemicals that identify it at species and colony levels (Vander Meer, 1983). The cuticular hydrocarbons of *S. invicta* are species specific and have been used as chemotaxonomic markers in several studies (Vander Meer et al., 1985; Vander Meer, 1986). The hydrocarbons represent a heritable component of colony odor; however, there is no direct evidence that they play a role in *S. invicta* nestmate recognition (Obin, 1986). Most important, however, is the fact that these easily analyzed (by gas chromatography) cuticular components can be used as markers for the movement of odors in a colony (Vander Meer, 1988). Vander Meer (unpublished) used the technique to demonstrate the dynamic nature of nestmate-recognition cues. This is further exemplified by the ability of the myrmecophilous scarab, *Martinezia duterteri*, to integrate into the nests of several *Solenopsis* sp. (Vander Meer and Wojcik, 1982). The mode of initial entrance into a *Solenopsis* colony is unknown; however, the beetle uses its armored exoskeleton and thanatosis to survive worker attacks long enough to acquire the host's colony odor. The acquisition of colony odor was monitored by GC analysis of ant cuticular hydrocarbons transferred to the cuticle of the beetle.

Based on our knowledge of the life history of *Orasema* sp., and their cuticular chemistry, we can postulate two possible integration mechanisms, one of which is analogous to that of *M. duterteri*. In this case the tiny planidia are transported undetected to the host colony. By some mechanism (probably through worker transfer during trophallaxis) they find their way to a *Solenopsis* brood chamber where they proceed to parasitize fire ant brood and develop into adults. *Orasema* sp. brood are treated by host workers as ant brood and, through social interaction with host workers and contact with host brood, they acquire host colony odors, ergo nestmate-recognition cues. This scenario is supported by comparative GC analysis of *Orasema* sp. life stages with those of their host (Figures 1 and 2). The GC profiles of the parasite collected within host colonies are remarkable in that they contain only components found in the host. This is in contrast to *M. duterteri*, which, in addition to the host components, had its own characteristic profile (Vander Meer and Wojcik, 1982).

Perhaps the *Orasema* sp. does not produce cuticular hydrocarbons in sufficient quantity to be GC detectable and is masked by the copious amount of hydrocarbons transferred from the host (hydrocarbons comprise 75% of the total cuticular lipid for *S. invicta*; Lok et al., 1975). Cuticular lipids are known to

be important in preventing desiccation in insects (Blomquist and Dillwith, 1985). This function can be carried out by hydrocarbons, wax esters, or combinations of these or other lipid classes. The *Orasema* sp. may rely on nonhydrocarbon lipids for prevention of desiccation, or they may require the acquisition of host lipids.

An alternative possibility involves biosynthesis by *Orasema* sp. of the exact hydrocarbon profile of the host, as reported for the termitophile *Trichosenius frosti* (Howard et al., 1980). Mediating against this hypothesis is the fact that environmental odors play an important role in *Solenopsis* spp. nestmate recognition (Obin, 1986; Obin and Vander Meer, 1988). This detracts from the adaptive advantages of biosynthesis by *Orasema* sp. of genetically derived colony odor components. One would predict that in ant species where genetically derived nestmate-recognition cues dominate, i.e., *Pseudomyrmex ferruginea* (Mintzer and Vinson, 1985), the probability of finding myrmecophiles that biosynthesized host recognition cues would be much greater.

In addition, results of the colony study (Table 1) demonstrate that GC profiles of host workers and pupae are distinguishable within a given colony. Although the profiles of parasite pupae are identical to those of host pupae, the adult parasite corresponds to a profile between that of the host pupae and adult. This can be readily explained by a preponderant transfer of brood cuticular components to other brood or objects among the brood (i.e., *Orasema* sp. brood). After eclosure of *Orasema* sp. adults, their contacts are predominantly with host workers.

The thanatotic behavior on the part of adult *Orasema* sp. in the host nest fits well with the hypothesis that nestmate-recognition cues, along with the lack of bidirectional agonistic behavior, explain the preferential treatment of ant brood by workers and the successful interspecific adoption of brood (Morel and Vander Meer, 1988). Similarly, when ant callow workers are transferred to a conspecific colony, or that of a closely related species, they respond by taking on a nonaggressive posture (Morel and Vander Meer, 1988; Jaisson, 1985).

The GC profile of adult *Orasema* sp. captured outside host colonies still contains host-specific hydrocarbons; however, they now also have additional complex patterns at both higher and lower molecular weights (Figure 3). Quantitative analysis of adult *Orasema* sp. (Table 2) demonstrates that the total amount of detectable compounds increases for parasites collected outside the nest by more than a factor of two and that the host-specific compounds decrease significantly after the parasite leaves the host nest. The loss of host-specific compounds on parasite adults caught outside the nest supports our contention that they are acquired and not biosynthesized by the parasite while it is living in the host nest. As in the case of the within colony parasite, the additional compounds found in parasites captured outside the nest could be acquired or biosynthesized.

If the new compounds are biosynthesized, the relative ratios of the new components to each other should be consistent, whereas the ratio of new components to host-specific components (assuming they are acquired) should be more variable. Alternatively, after leaving the ant colony, the adult wasp may acquire the new components from its new environment. Since *Orasema* spp. are not host-plant specific (Lloyd R. Davis, Jr., USDA-ARS, Gainesville, Florida, personal communication), the sources and therefore the compounds acquired from the environment would be expected to be variable. Chemical analysis of 10 individual *Orasema* sp. collected with a sweep net outside a fire ant colony showed remarkable consistency, both qualitatively and in percent composition (Figure 3, Table 3). Given the two possibilities outlined above, this implies that the new compounds found on *Orasema* sp. outside the host nest are probably biosynthesized by the parasite. In addition, the greater variance in percentage of the host-specific compounds on *Orasema* sp. collected outside the nest supports our contention that these compounds are acquired from the host and diminish when the parasite leaves the nest.

The data support a complex scenario for parasite cuticular chemistry. The immature parasites appear to acquire the recognition-masking colony odors of the host. In contrast, the GC profiles of adults found outside the mound suggest that the biosynthesis of parasite-specific cuticular compounds commences with adult eclosion.

(Received June 23, 1988; accepted December 9, 1988)

Abstract—The semiochemicals verbenone (Vn), ipsenol (Ie), and ipsdienol (Id), present in late phases of host colonization, have been implicated as qualitative “shut-off” signals regulating attack density. Combinations of the three chemicals were released in pipe traps together with the aggregation pheromone components 2-methyl-3-buten-2-ol (MB) and *cis*-verbenol (cV) at different levels and in different ratios to MB + cV, and with two spacings of traps to test for possible effects on reducing catch at traps baited with aggregation pheromone. When they were released with the attractants Vn and Ie (alone or together) decreased the mean catch significantly at the higher release rates used (1 mg/day). Id alone or together with Vn at low release rates (0.1 mg/day), with the attractants, increased catch somewhat. A dose-response test of Vn, with the attractants held constant, showed a decline in catches, down to about <10% of the control, at ratios of Vn to cV between 1:1 and 150:1. A larger spacing (25 m) of traps gave a stronger response to change in doses of Vn and MB + cV than a smaller (6 m) spacing. The sex ratio was more skewed towards females when two or three inhibitors were present and at higher doses of Vn. It is suggested that Vn could be the most important density-regulating signal in the natural system, as release of Vn from galleries is larger and starts earlier than that of Id and Ie.

¹This study was made within the Swedish project “Odour signals for control of pest insects.”

Key Words—Aggregation pheromone, *Ips typographus*, Coleoptera, Scolytidae, density regulation, inhibitor, verbenone, ipsenol, ipsdienol.

INTRODUCTION

The eight-spined spruce bark beetle of Europe, *Ips typographus* (L.), regularly mass attacks standing, healthy host trees (Postner, 1974). In this respect, its population biology resembles the more aggressive Nearctic *Dendroctonus* species. The attack dynamics of the spruce bark beetle, i.e., the aggregation and density regulation process of initial attacks, mass attack, and then switching of attack focus to nearby trees, is only partly understood. The first part of the attack dynamics, where density is positively regulated by the attraction of both sexes to the aggregation pheromone released by the pioneering males, is empirically relatively well known (Bakke, 1976; Bakke et al., 1977; Bakke and Riege, 1982; Birgersson et al., 1984; Schlyter and Löfqvist, 1986; Schlyter et al., 1987a–c). A simple numerical model using these data (Schlyter and Anderbrant, 1989) described the first part of the process governed by the rapid release of 2-methyl-3-buten-2-ol (MB) and *cis*-verbenol (cV) from the males, up to and including the mass attack, but after this period the model was inadequate (Anderbrant et al., 1988).

The latter part of the dynamics includes a decline in attraction and the switch of attack focus in order to avoid the well-established negative effects of larval competition at high densities on the number and quality of offspring (Thalenhurst, 1958; Ogibin, 1973; Botterweg, 1983; Anderbrant et al., 1985; Mills, 1986). The mechanisms governing the latter part are much less known, but two mechanisms have been proposed in *Ips typographus* (Schlyter et al., 1987c): (1) the quantitative hypothesis based on sex-specific response of males to large amounts of pheromone (relative inhibition; Byers, 1983) and the decrease of pheromone quantity after mating (Byers, 1981; Birgersson et al., 1984; Schlyter and Löfqvist, 1986), and (2) the qualitative hypothesis based on male production in later "attack phases" of ipsdienol (Id) and ipsenol (Ie) (Birgersson et al., 1984, 1988; Schlyter et al., 1987c) as inhibitors of the attraction to the pheromone. These might function as a "shut-off" signal for the aggregation. Ie is more or less inhibitory at the doses tested (Bakke, 1981; Schlyter et al., 1987c). In contrast, Id is inhibitory only at higher doses, but slightly attractive (Bakke, 1976; Schlyter et al., 1987c) or neutral (Dickens, 1981) at lower doses.

The numeric model of attack dynamics (Schlyter and Anderbrant, 1989) indicated that production of Id and Ie may start too late to influence the dynamics of density regulation (limitation) and switching at the rate these processes proceed in nature. It is likely that other signals are present in the process. One such additional signal may be the release of verbenone (Vn), which (at an

unspecified release rate) alone or together with Ie, has been shown to reduce the catch of *I. typographus* (Bakke, 1981). Verbenone also inhibits response (lower the catch at attractant baits) of North American species (*Dendroctonus frontalis*, Payne et al., 1978; *D. brevicomis*, Bedard et al., 1980; Tilden and Bedard, 1988; *D. ponderosae*, Ryker and Yandell, 1983; *D. adjunctus*, Livingston et al., 1983; *Ips paraconfusus*, Byers and Wood, 1980). The amounts of oxygenated monoterpenes, such as Vn, are found to increase in gallery wall phloem during late attack phases of *Ips typographus* and are probably produced by microorganisms, such as yeasts, brought to the tree by the beetle (Leufvén et al., 1984, 1988; Leufvén and Birgersson, 1987). The release of Vn from beetle-infested logs (Schlyter et al., 1987a) or from male attacks on standing trees (Birgersson and Bergström, 1989) is relatively high, often of the same magnitude as cV. Since Vn may affect behavior of the beetle, but is produced mainly by associated organisms (Leufvén et al., 1984) and only in trace amounts by the beetle (Birgersson et al., 1984), we use the term "semiochemical" for Vn together with Ie and Id. The two later compounds may also be termed pheromone components.

In order to test the relative importance of these three semiochemicals as "inhibitors" of attraction, we have released them, in racemic form, in all the seven possible combinations at two levels of release rates with the attractants MB + cV. We have also quantified the response to three decadic steps of Vn dose with MB + cV at two levels and spacing of traps in a factorial experiment.

METHODS AND MATERIAL

Compounds, Dispensers, Traps, and Study Area. The three proposed "inhibitors," which are all chiral molecules, were tested in racemic or close to racemic mixtures. For verbenone (Vn), which is probably derived from the chiral precursor α -pinene, which has a very high between-tree variation in enantiomeric composition (Lindström et al., 1989), both enantiomers of Vn could be expected to be equally active, as was also indicated by Bakke (1981). The Vn used was not far from racemic as it had a rotation (measured by polarimetry) of only $[\alpha]_D^{25} = +93.9^\circ$ ($c = 0.82\text{g}/100\text{ ml}$, 99.5% ethanol) (corresponding to 34.9% ee of *R* or 67.5 : 32.5% *R/S*). The two compounds derived from the achiral precursor myrcene in nature, ipsenol (Ie) and ipsdienol (Id), could be produced by the beetle in nonracemic form (Francke et al., 1980), but were synthetic and racemic.

The attractants 2-methyl-3-buten-2-ol (MB) and (4*S*)-*cis*-verbenol (cV) and their dispensers were identical to those earlier used by Schlyter et al. (1987a,c) (Table 1). Release rates were estimated in a mini wind tunnel in the laboratory as described earlier (Schlyter et al., 1987a).

			1.0	1.2 ± 0.1		

^aMeasured in a mini wind tunnel at 20°C and 0.7 m/sec. Rate calculated as the slope \pm its 95% confidence limits of the regression of weight loss vs. time.

^bDispensers were polyethylene vials that were either closed or closed but with hole drilled through the cap (x -mm-diam. hole) or with a capillary through the lid (w. x - μ l cap.) or open. Vials were from Kartell, Italy, with the #730 being a 1-ml vial.

Traps were of type N79, i.e. black drainpipe traps without exterior funnel (Regnander and Solbreck, 1981; Bakke et al., 1983). These traps require beetles to orient, land, and enter holes to be caught. Tests were done in three old clear-cut felling areas (S, L, and J), all with relatively low beetle populations in Esum Forest District, Grib Skov, North Zealand, Denmark, in May-June 1985. Randomization was "without replacement" (in the probability statistics sense) and followed a Latin-square design, i.e., with eight treatments and positions, a trap was assigned a random position after each replicate, but was tested exactly once in each position during eight replicates.

Qualitative Test of Verbenone, Ipsenol, and Ipsdienol Combinations. Vn, Ie, and Id were released in all possible combinations (singly or in binary or

trinary combinations) with the attractants, which with the control included eight treatments. Traps were placed at 6-m spacings in a clear-cut (site S), and their positions randomized after each replicate. A replicate, which lasted one day or longer, depending on flight activity, was completed when at least one trap was judged to have caught ≥ 50 beetles or when all traps had caught ≥ 100 beetles. For the first period (May 18–26, eight replicates), the “inhibitory” compounds were released at about 0.1 mg/day and for the second period (May 27–June 6, nine replicates) at about 1 mg/day (Table 1). In both cases, the control was a “low” level of attractant, MB + cV, at a release of 5 + 0.1 mg per day (Table 1).

Dose-Response Test of Verbenone. A release dose range of approximately 0.1, 1, and 10 mg/day of Vn (exact laboratory rates in Table 1) was combined with two levels of attractant, MB + cV at 50 + 1 mg/day and 5 + 0.1 mg/day, giving, with the two levels of attractants alone as controls, eight different baits. A 6-m spacing between traps was used for the two first replicates at each of the two sites (L and J) but was changed to a larger spacing (25 m) at site J, as the difference in catch between the two levels of attractant control baits was smaller than found in earlier studies (Schlyter et al., 1987c). Replications and randomizations were as described above, with the exception that the two first replicates at each site lasted for only half a day.

Statistics. The mean catch (\bar{x}) of a bait (i) per replicate (j) is given as the proportion (p_{ij}) of the total catch per replicate (p_j) in Figures 1 and 2 below. To further facilitate comparisons between the different experiments, the proportion of total catch caught by a bait, p_i , is given in percent of the catch (100%) of the “low” control bait (release rate level MB + cV, 5 + 0.1 mg/day). This “low” control has been used in several earlier experiments (Schlyter et al., 1987a–c; Byers et al., 1989) and has about 10% of the release of commercial mass-trapping dispensers (Ipslure by Borregaard/Hercon; Schlyter et al., 1987a).

Following Perry (1986) and Jones and Matloff (1986), we have used factorial MANOVA for analysis of the dose-response test. The variable used in ANOVA (Perry, 1986) was p_{ij} transformed by $\arcsin p^{0.5}$, which was the transformation that gave the most homogenous variances as judged by Cochran’s C test.

RESULTS

Qualitative Test of Effects of Verbenone, Ipsenol, and Ipsdienol Combinations. The higher release rate (1 mg/day) of the three compounds, together with a constant release of the attractants, resulted in a reduced total catch for all combinations of “inhibitors” (Figure 1B). Except for Id alone, the reduction was significant. The pattern of qualitative influence by individual compounds

and their combinations on catch was quite similar between the two release rates of semiochemicals (Figure 1).

However, when the three compounds were released at their low rate (0.1 mg/day) alone or in any combination with attractant, only small and not statistically significant negative (inhibitory) effects on catch were seen (Figure 1A).

In all combinations and at both levels, addition of Id seemed to increase catch (low release rate) or at least not significantly decrease catch (high rate).

With the low rate of inhibitor candidates, all the binary and trinary combinations decreased the proportion of males down to around 22% at 6 m trap spacing (Table 2A), while the total catch was little affected (Figure 1A).

FIG. 1. Mean relative catches ($p \pm SE$) of *Ips typographus* in pipe traps at 6-m spacing with qualitative addition in all possible combinations of verbenone (Vn), ipsenol (Ie), and ipsdienol (Id) in separate dispensers to attractant pheromone (MB + cV at "low" release 5 + 0.1 mg/day). Catches expressed as percent of the catch of the control ("low" level of the attractants MB + cV). Bars with the same letter are not significantly different by ANOVA on arcsin $p^{0.5}$ followed by Duncan's multiple-range test. (A) Added semiochemical compounds (Vn, Id, Ie) released at approx. 0.1 mg/day, (B) semiochemicals released at approx. 1 mg/day (see Table 1 for exact laboratory estimated release rates). For sex ratios, see Table 2.

^aSignificantly different from the control (low level attractants) at $P < 5\%$.

^bValues for % males within parentheses are based on less than 20 individuals.

For the high rate of “inhibitors,” the proportion of males was very similar for both the control and addition of Id alone, while for the addition of Vn + Id, the male proportion was significantly lower (6% males, Table 2B). However, the absolute catches were low, making estimates of sex-ratio differences less reliable.

In contrast to the spruce bark beetle, its predator *Thanasimus formicarius* was mostly attracted only to the bait including Id + Id, which had 38% of the total 26 clerids caught.

Verbenone Dose-Response. Verbenone (Vn) decreased trap catch when released at 1 mg/day or more with both levels of attractants (Figure 2). At a 25-m spacing of traps, a significant inhibition began to occur at a ratio of Vn to cV of 0.1 : 1 (Figure 2B), corresponding to a ratio of Vn to Mb + cV as low as 0.002 : 1.

Of the factors (ANOVA) in the experiment, the level of attractant (MB + cV) had the largest main effect, followed by the dose of verbenone (Table 3). The factor spacing between traps had very little effect, as would be expected when relative catch, p_{ij} , per bait (i) per replicate (j), was the variable used in the analysis. The interaction of spacing with attractant level (Table 3) can be

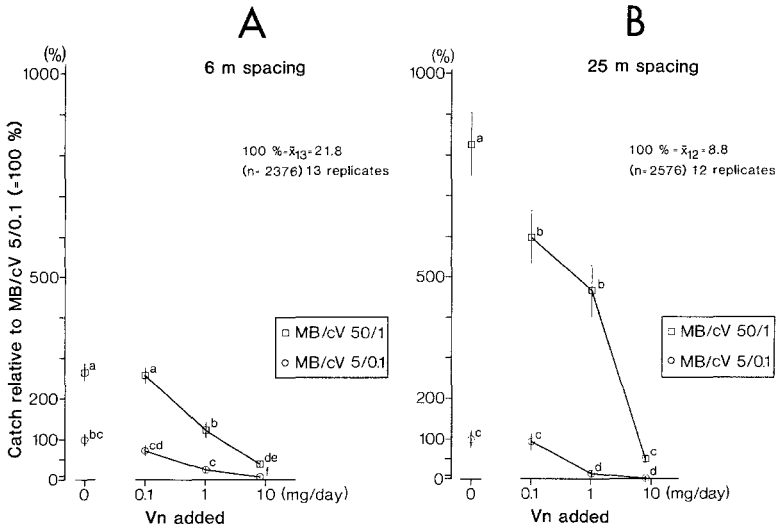

FIG. 2. Mean relative catches ($p \pm SE$) of *Ips typographus* in pipe traps with doses of verbenone (Vn) added to two levels of attractants (MB + cV) at (A) 6-m spacing, and (B) 25-m spacing of traps. Catches expressed as percent of the catch of the “low” control (MB + cV, 5 + 0.1 mg/day) (cf. Figure 1). Within each spacing of traps, values with the same letter are not significantly different at $P > 5\%$ by ANOVA on arcsin $p^{0.5}$ followed by Duncan’s multiple-range test.

TABLE 3. FACTORIAL MANOVA OF EFFECTS OF SPACING OF TRAPS, LEVEL OF ATTRACTANT (MB + cV), AND DOSE OF VERBENONE (0–10 mg/day) ON TRAP CATCHES OF *Ips typographus*, GRIB SKOV, DENMARK, 1985^a

^aCatch was transformed by $\arcsin p^{0.5}$ before analysis. Test of homogeneity of variances yielded Cochran's $C(11, 16) = 0.13$, $P = 23\%$ (approx.) after transformation.

^bTwo levels: 6 and 25 m spacing of traps. The factor SPACE was confounded with possible effects of location, as SPACE was not balanced between the two locations: there were two runs (replicates of each site) of 6 m at both sites before the change to 25 m spacing at one site. The total number of replicates was 2 + 11 for 6 m spacing and 0 + 12 for 25 m spacing. The results of the two first replicates at each of the two sites were very similar in absolute and relative catches ($P \gg 10\%$ in ANOVA), and the age, size, and proximity to naturally attacked trees (>500 m) was also similar for the two sites. Thus, it was judged appropriate to do a simultaneous statistical comparison and to include the factor SPACE in the ANOVA.

^cTwo levels: MB + cV 50 + 1 or 5 + 0.1 mg/day (see Table 1).

^dFour levels: 0, 0.1, 1, and 10 mg/day (see Table 1).

clearly seen when comparing Figure 2A and B, as the difference in catch levels between attractant levels is much larger in Figure 2B (25-m spacing). There was also a quite significant covariance between attractant level and verbenone dose (Table 3), graphically detectable as the different slopes for high and low attractant levels with increasing dose of Vn (Figure 2A and B) (cf. Tilden and Bedard, 1988). Also the third-order interaction was significant (Table 3), which can be seen graphically by the difference in slope between the attractant levels, which was not the same for the two trap spacings (Figure 2A and B). A direct test of the ratio between MB + cV and Vn as a factor was not possible as the ratio did not vary independently of Vn dose and attractant level.

The sex-ratio differences were large at the 6-m spacing of traps. At the low level of attractant (MB + cV, 5 + 0.1), the sex ratio decreased from 1:0.9 (male to female) at the control to 1:3 (24–31% males) at the higher Vn doses.

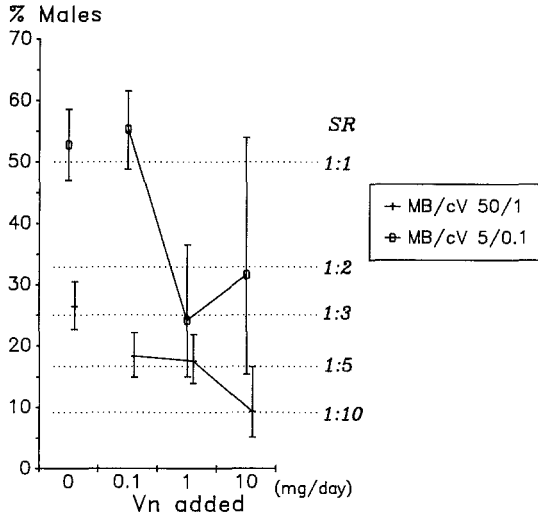

FIG. 3. Mean proportion of males ($p \pm 95\%$ C.I.) of *Ips typographus* in pipe traps with doses of verbenone (Vn) added to two levels of attractants (MB + cV) at the 6-m spacing. Values shown are retransformed from arcsin $p^{0.5}$, hence the asymmetric CI.

For the high level of attractant (MB + cV, 50 + 1), a threefold decrease in sex ratio, from 1:3.3 in the control to 1:10 (9% males) at the highest Vn dose, took place (Figure 3). At the 25-m spacing of traps, there was no effect on sex ratio by Vn dose alone (Table 2C).

DISCUSSION

The present study shows the inhibitory effects of ipsenol and verbenone on the attraction of *Ips typographus*. The effect is especially strong on the number of males, as both the total number of beetles and the proportion of males are reduced. The qualitative effects of Ie and Vn acting alone or in the pair Ie + Id were not unexpected as they agree with the findings of Bakke (1981) and Schlyter et al. (1987c). In the qualitative test Vn showed a negative effect on attraction, at both release rates (except in the binary combination with Id at the low rate). This agrees also with the effect of the binary combination of Ie + Vn with the attractants tested by Bakke (1981). Similar to previous reports (Dickens, 1981; Schlyter et al., 1987a, b), addition of Id to MB + cV had no significant effect on trap catches compared to MB + cV alone. Our current results do not show the effect shown in previous studies in which Id in combination with MB + cV was attractive at some dosages (0.005–0.04 mg/day,

Schlyter et al., 1987c; unspecified but relatively low doses, Bakke 1976; Bakke et al., 1977) but inhibitory at a high dose (0.58 mg/day, Schlyter et al., 1987c). Similar to the qualitative test, an increased dose of Vn (with both levels of attractant) decreased the trap catch linearly down to a level of 10% or less of the control (cf. Tilden and Bedard, 1988). The mechanism of this inhibitory effect of Vn is probably an inhibition of long-distance orientation, as the quantitative effect of verbenone dose was clearer at the 25-m than at 6-m spacing between traps (cf. Tilden and Bedard, 1988).

These experimental results must now be put into the framework of both how the semiochemicals (quantity and quality) are released from gallery systems in different attack phases (Birgersson et al., 1984; Leufvén and Birgersson, 1987; Birgersson and Bergström, 1989) and how they may affect the overall attack dynamics (Schlyter and Anderbrant, 1989; Anderbrant et al., 1988). The three compounds (Vn, Ie, Id) tested here were racemates or close to racemic, while their natural quality may be either as pure enantiomers or as mixtures with enantiomeric excess. For Vn, the racemate used is probably not a problem, as Vn chirality may depend on the pinan-skeleton of the α -pinene from which it is derived, and the chirality of α -pinene is known to vary widely between individual trees of Norway spruce (Lindström et al., 1989). Also, the activity of *R*- and *S*-enriched Vn tested by Bakke (1981) was equally high in reducing trap catch at the dose tested. For Id, however, it is possible that effects could have been distorted by the use of the racemate, because (1) the chirality of Id is known to be important in the behavior of *Ips* beetles (Birch et al., 1977, 1980; Wood, 1982), (2) Id produced by *I. typographus* has been reported as not racemic (Francke et al., 1980), and (3) it is known that a compound attractive in enantiomerically pure form may, as a racemate, show inhibitory effects at high release rates but attractive effects at low rates (Vité et al., 1985). However, we decided to test Id in racemic form as the compound was not available to us as pure enantiomers. In contrast, Ie seems to lack attractive effects at all rates tested both here and in a previous study (Schlyter et al., 1987c), and it would seem less likely that attractive properties of Ie were concealed by the racemic composition.

Estimates of the quantity of Ie, Id, and Vn released from logs (Schlyter et al., 1987a) and from galleries in attacked trees (Birgersson and Bergström, 1989) are now becoming available. These studies show that, although Ie and Id are undoubtedly present in beetle hindguts of males in late attack phases (Bakke, 1976; Birgersson et al., 1984, 1988), they are produced in such small quantities that they cannot be detected in the samples from airborne collections (Birgersson and Bergström, 1989). In contrast, Vn is readily detected and released in quantities similar to or larger than *cis*-verbenol from beetle infested logs and from galleries in trees (Schlyter et al., 1987a; Birgersson and Bergström, 1989).

The production mechanisms for the relatively large amounts of Vn, which

is found only in trace quantities in beetle hindguts (Birgersson et al., 1984, 1988), are not clear. Both autoxidation from α -pinene (Borden et al., 1986) and microbial mediated oxygenation of verbenols (Leufvén et al., 1984) have been shown. Irrespective of the relative and absolute release of the three semiochemicals (Id, Ie, and Vn), they could in theory all contribute to an odor message of an "old patch," as they are all produced in late attack phases by the beetle (Id, Ie) or by a sequence of oxidations of α -pinene in the defensive resin (Vn). At present, it seems that intraspecific attack density regulation by a qualitative change in the odor signal from a patch (such as a tree or a part of a tree) in *I. typographus* would be mostly dependent on Vn. The response of *I. typographus* to the beetle produced compounds (Id, Ie) may be more relevant in interspecific communication and competition, as Id and Ie are produced in larger quantities both by *Picea*-inhabiting sympatric *Ips* species such as *I. duplicatus* (Bakke, 1975) and *I. amitinus* (Francke et al., 1980) and by other sympatric species: *I. sexdentatus* (Vité et al., 1974), *I. acuminatus* (Bakke, 1978), *I. cembrae* (Stoakley et al., 1978), and *I. erosus* (Giesen et al., 1984). The attraction of the predatory *Thanasimus* beetles to baits with Ie and/or Id has been shown earlier (Bakke and Kvamme, 1981; Schlyter et al., 1987c).

An integration of the inhibitory effects of Vn and Ie into a quantitative model of attack dynamics (cf. Schlyter and Anderbrant, 1989) and into practical uses for forest protection would require more knowledge. Gathering of such data for time-dependent release (Birgersson and Bergström, 1988) and quantitative dose-response on attacks on logs (Schlyter et al., 1988) is now under way.

Acknowledgments—Reidar Lie, Borregaard A/S, Sarpsborg, Norway, supplied the Ie and Id used, and Peter Bäckström, KTH, Stockholm, supplied Vn. Marie Bengtsson, Organic Chemistry 2, Lund, checked optical purity of several batches of Vn under time stress. Olle Anderbrant provided field assistance in critical periods and commented on earlier drafts of this manuscript together with Drs. John Byers and Christer Löfstedt. Elisabeth Marling recorded release rates and Erling V. Jirle processed insect samples in the laboratory. Statskovvesenet in Grib Skov, Esrum forest district, and Strødam Ecological Field Station provided research facilities. Their professional help and commitment is gratefully acknowledged. Suggestions from two anonymous referees were helpful during preparation of the revised manuscript. Drs. Jan Löfqvist and Gunnar Bergström provided ample encouragement, discussion of manuscripts, and support from their grants from Swedish research councils (NFR, FRN, SJFR) to "Odour Signals for Control of Pest Insects."

Abstract—Caryophyllene and caryophyllene epoxide are two terpenoids found in neotropical plants and known to be deterrent to leafcutter ants. To estimate the variation in deterrent activity of these compounds toward the genera *Atta* and *Acromyrmex*, behavioral bioassays were conducted over a range of concentrations. The responses of four captive colonies of *Atta cephalotes* and two captive colonies of *Acromyrmex octospinosus*, all from a single locality in Costa Rica, were studied. Although specific patterns of deterrency differed in the two genera, in both cases caryophyllene epoxide concentrations of 0.70 mg/g or greater, and caryophyllene concentrations of 7.0 mg/g or greater, significantly deterred the harvest of potential substrates. Individual colonies within each genus did not differ significantly in their responses to caryophyllene epoxide. The mean response of the two genera to caryophyllene epoxide differed significantly, but responses to caryophyllene did not. *Acromyrmex octospinosus* was more sensitive to low concentrations and less sensitive to high concentrations of caryophyllene epoxide than was *Atta cephalotes*.

Key Words—*Atta cephalotes*, *Acromyrmex octospinosus*, leafcutting ants, Hymenoptera, Formicidae, terpenoids, deterrents, dosage-response studies, bioassays.

INTRODUCTION

Leafcutting ants of the genera *Atta* and *Acromyrmex* (Formicidae: Attini) are common generalist herbivores in neotropical forests. These ants harvest leaves from a variety of woody plant species in natural communities (Cherrett, 1968; Rockwood, 1976) and are significant pests throughout the Neotropics (Cherrett, 1986a). Current methods of chemical control are costly and may have undesirable effects on nontarget species (Cherrett, 1986a, b; Vilela, 1986). The search for improved methods of control has led us to study natural mechanisms of resistance in native plants.

Recent studies of the leafcutting ant *Atta cephalotes* in tropical deciduous forest of Costa Rica suggest that plant secondary chemistry is an important influence on the preferences of leafcutters for plants (Hubbell et al., 1984; Howard, 1987, 1988). These studies suggest that nonpolar compounds such as terpenoids strongly influence ant behavior. A number of hydrophobic natural products deter or repel *A. cephalotes* in laboratory bioassays (Wiemer, 1985), and at least some are toxic to the ants and/or to their fungal mutualist (Howard et al., 1988).

The bioassays done to guide the isolation of leafcutter ant deterrents were conducted using a single laboratory colony (*A. cephalotes* or *A. octospinosus*) for each plant studied. Such single-colony studies offer precise estimates of comparative chemical effects. All ants within these single-queen colonies are at least half sibs, and possibly full sibs, descendant from the same mother, and thus are genetically similar. However, there are valid reasons for studying colony-to-colony variation. Bioassay results from a single colony may not be representative of the species as a whole if genetic variation in ants or fungal strains produces significant colony-to-colony differences in response to chemicals. Estimates of colony-to-colony variation within and among habitats may offer insights into the structure of leafcutting ant populations. Finally, comparative dosage-response studies on leafcutter species and genera are important in determining the potential of natural products for chemical control of this economically important group of insects.

Here, we report a comparison of the deterrent activity of two terpenoids to colonies of the leafcutting ants *Atta cephalotes* L. and *Acromyrmex octospinosus* Reich. These species are widely sympatric in Central America, and the two genera are thought to forage on similar resources in their natural forest communities (Weber, 1972). Behavioral bioassays were used to measure the response of ant colonies to several concentrations of the two compounds. Our studies address the following questions: (1) Do colonies of a given species react similarly to these pure compounds? (2) Do different leafcutting ant genera react similarly? (3) What is the minimum concentration of these chemicals required to significantly deter substrate harvest by ants of these genera?

METHODS AND MATERIALS

Studies were conducted on four colonies of *Atta cephalotes* and two colonies of *Acromyrmex octospinosus*. All colonies were collected in July 1982 from a tropical deciduous forest in Santa Rosa National Park, Guanacaste Province, Costa Rica, and contained a single queen. Colonies of *Atta cephalotes* all possessed a single small entrance at the time of collection, indicating that they were approximately one year of age (Weber, 1972). Colonies of *Acromyrmex octospinosus* were of a similar size at the time of collection but are in general smaller than those of *Atta* and may have been older than one year (Weber, 1972). All colonies were maintained in Plexiglas boxes in an insectarium at the Department of Biology, University of Iowa. The room was maintained at 23°C and 40–60% relative humidity, on a 12:12 light–dark cycle. Colonies were fed fresh lilac leaves in season and frozen leaves during winter months. The colonies were maintained under these conditions for approximately one year prior to the start of bioassays. All experiments were conducted between July and October while colonies were being fed fresh, mature lilac leaves.

The two compounds selected for testing, caryophyllene and caryophyllene epoxide, are common secondary constituents of tropical plants (Arrhenius and Langenheim, 1983; Hubbell et al., 1983; Wiemer, 1985). Both compounds deter *Atta cephalotes* in laboratory bioassays, and are toxic to both ants and fungus (Howard et al., 1988). We obtained authentic samples from a commercial supplier (Aldrich) and tested five different concentrations of each compound on each colony. Although structurally similar, caryophyllene is 10–20 times less deterrent to leafcutting ants than caryophyllene epoxide (Hubbell et al., 1983). Accordingly, we tested caryophyllene epoxide at concentrations 10-fold lower than caryophyllene.

Standard behavioral bioassays were used to measure the deterrency of each concentration of the two chemicals on each colony (Hubbell and Wiemer, 1983). Prior to use in a bioassay, rye flakes were oven dried for 24 hr at 50°C and stored in a desiccator until needed. These rye flakes (0.6 g) were soaked for 1 min in a solution of the test chemical in methylene chloride (1.2 ml total volume), removed, air dried at room temperature, and presented to the colony on a computer-generated random grid. Rye flakes soaked in methylene chloride and dried in a similar fashion served as a control. Each bioassay included 60 test flakes and 60 control flakes. Ants were allowed to forage over the grid until 30 control flakes had been harvested; at this time the number of test flakes harvested was determined. The significance of differences between numbers of control and test flakes harvested ($C - T$) was determined using a modified binomial test (Hubbell and Wiemer, 1983).

We estimated the amount of test chemical actually deposited on rye flakes by measuring the amount of caryophyllene and caryophyllene epoxide remain-

ing in test solutions. After soaking the rye flakes, the remaining solution was returned to its original vial. The porcelain crucible used for soaking the flakes was rinsed with additional solvent and the rinse combined with the remaining solution. This was filtered to remove any particulate matter, and then dried and weighed (± 0.1 mg). The maximum amount deposited on test flakes was estimated by subtraction. In each case, analysis of the residual test solution by gas chromatography (OV-101, 50–270°C) revealed only a single peak corresponding to the test chemical, and quantification by GC agreed with the gravimetric analyses. This verified that methylene chloride did not extract significant amounts of material from the rye flakes.

Three replicate bioassays were carried out on each colony at each of the five concentrations of caryophyllene epoxide, totaling 90 bioassays. To avoid biases in response due to previous experience, the order of presentation was randomized for each colony and several days were allowed to elapse between consecutive tests on a single colony. A similar procedure was planned for caryophyllene. Unfortunately, an infestation of mites required suspension of experiments after completion of the first set of experiments (30 bioassays). Replicate assays were not possible because two of the *Atta* colonies died when mite infestations overwhelmed their fungus, bringing experiments to an end.

Data analyses were carried out using the SYSTAT (version 3.0) computer package for microcomputers. Data from the caryophyllene epoxide experiments were used to analyze the variation in response among colonies of each species, because these experiments were replicated at the colony level. An analysis of covariance was used because the concentrations tested were arbitrarily selected from a continuous range of possible concentrations. Concentration was treated as a continuous variable and each colony as a discrete class. Separate analyses were performed for *Atta cephalotes* and *Acromyrmex octospinosus*. The data were tested for homogeneity of variances among colonies and chemical concentrations and were found to require no transformation. Residuals from the analysis were examined for normality and influence.

The data from both caryophyllene epoxide and caryophyllene experiments were used to analyze differences in response between *Atta* and *Acromyrmex*. The response of each colony to each concentration of caryophyllene and the mean of the three replicates for each colony at each concentration of caryophyllene epoxide were treated as single observations in this analysis. Separate analyses of covariance were run for caryophyllene epoxide and caryophyllene experiments, treating chemical concentrations as continuous variables and treating ant species as discrete classes. Homogeneity of variance and residual analyses were conducted as previously described. A square-root transform was used to obtain homogenous variances in the caryophyllene analysis.

RESULTS

Slightly more than one third of the test chemical present in solution was deposited on rye flakes ($34.77 \pm 5.02\%$). Percent deposition of caryophyllene and caryophyllene epoxide on rye flakes did not differ ($T = 0.904$, $P > 0.2$, t test) and did not vary significantly with concentration ($r^2 = 0.043$, $P > 0.4$, simple regression). Accordingly, we applied a constant correction factor of 35% to all concentrations of caryophyllene and caryophyllene epoxide. We estimate that effective concentrations encountered by ants during bioassays were 0.07, 0.21, 0.70, 1.40, and 2.10 mg of caryophyllene epoxide per gram of rye flakes, and 0.70, 2.10, 7.00, 14.0, and 21.0 mg of caryophyllene per gram of rye flakes.

Under the conditions of our bioassay, the harvest of 16 or fewer test flakes was significantly different from control flake harvest ($P < 0.05$). Both *Atta cephalotes* and *Acromyrmex octospinosus* colonies harvested fewer test than control rye flakes at even the lowest concentrations of caryophyllene epoxide tested, although these differences were generally not significant (Figure 1). Mean test flake harvest by *Atta* colonies fell below 16 at caryophyllene epoxide concentrations of 0.70 mg/g or above. *Acromyrmex* colonies harvested 16 or fewer test flakes at all concentrations of 0.21 mg/g or above (Figure 1). A comparison of the overall responses of *Atta* and *Acromyrmex* to caryophyllene and caryophyllene epoxide showed that, as expected, caryophyllene epoxide produced responses similar to those produced by 10-fold higher concentrations of caryophyllene. Mean test flake harvest fell below 16 in both species when colonies were presented with caryophyllene concentrations equal to or greater than 7.0 mg/g (Figure 2).

FIG. 1. Response of individual colonies of *Atta cephalotes* and *Acromyrmex octospinosus* to caryophyllene epoxide.

FIG. 2. Overall response of *Atta cephalotes* and *Acromyrmex octospinosus* to caryophyllene epoxide and caryophyllene. Bars are ± 1 standard error.

Analysis of covariance indicated that variation in deterrent activity of caryophyllene epoxide among colonies was not statistically significant in either species (Table 1) and that the slope of the relationship between test flake harvest and concentration was similar in all colonies of a species (colony \times concentration effect, Table 1). The effect of caryophyllene epoxide concentration was highly significant in both analyses, explaining 68.1% of the variation in test flake harvest by *Atta cephalotes* and 53.8% of the variation for *Acromyrmex octospinosus* (Table 1).

Analysis of overall responses of *Atta* and *Acromyrmex* indicated that the two genera differed significantly in their responses to caryophyllene epoxide (Table 2). Although higher concentrations were always more deterrent than low concentrations, the slope of the relationship between test flake harvest and concentration differed significantly between genera (species × concentration effect, Table 2). *A. octospinosus* was more sensitive to low concentrations and less sensitive to high concentrations of caryophyllene epoxide than *A. cephalotes* (Figure 2). Although the same qualitative patterns were observed in caryophyllene bioassays (Figure 2), no statistically significant differences were found in responses of the two species to caryophyllene (Table 2).

DISCUSSION

The responses of insects to chemical stimuli may be affected by genetic differences and by prior experience. Although the colonies tested in this study may have encountered different plants and secondary chemical defenses prior to collection, individual workers live only four to six months (Weber, 1972). Because colonies were maintained under standardized conditions in our laboratory for one year prior to the study, all workers in all colonies had identical recent histories of exposure to plants and chemicals. Possible seasonal variation in colony responses was minimized by maintaining colonies under constant

environmental conditions and by feeding all colonies fresh, mature lilac leaves during the months of these experiments. Any differences in response observed in this study should be due primarily to genetic differences among colonies or between species.

We found no statistically significant variation in the responses of colonies to given concentrations of caryophyllene epoxide in either ant species. The relationship between concentration and test flake harvest was also similar for all colonies within a species. This is consistent with evidence from field experiments suggesting that ant colonies within a single habitat or locality respond similarly to plant characteristics (Howard, 1987). However, the colonies tested in this experiment may have all originated from a single nuptial flight of a few *Atta cephalotes* or *Acromyrmex octospinosus* colonies and may represent only a fraction of the total genetic diversity present within populations at Santa Rosa National Park. Further experimentation on colonies collected from this and other sites will be required to establish the extent to which patterns of deterrent activity may be generalized within and among attine populations and species.

Atta cephalotes and *Acromyrmex octospinosus* differed significantly in their responses to caryophyllene epoxide but did not differ in response to caryophyllene. This may be due in part to the higher variance inherent in the caryophyllene measurements (Figure 2). These measurements are based on a single observation per colony, while the caryophyllene epoxide measurements are the mean of three replicates. *Acromyrmex octospinosus* was more sensitive to low concentrations and less sensitive to high concentrations of both test chemicals (Figure 2), and the similarity of these results suggests that the two genera may, in fact, differ for both chemicals tested.

The biological significance of differences in the response of the two genera is not immediately clear from the whole animal bioassays reported in this study. Whatever the physiological or biochemical mechanism involved, it is reasonable to hypothesize that differences in perception may be related to differences in ecological relationships between ants and terpenoid-containing plants, and it may be that the ecological roles of *Atta* and *Acromyrmex* are less similar than is currently supposed. Few studies of diet selection and foraging in forest-dwelling *Acromyrmex* species have been carried out compared to *Atta* or grass-cutting *Acromyrmex* from the savannahs of South America. Comparative studies of sympatric forest-dwelling *Atta* and *Acromyrmex* would be of particular interest in determining if the subtle differences seen in this study reflect substantial differences in life-style.

Although specific patterns of deterrence differed in the two genera, effective concentrations of caryophyllene epoxide greater than 0.70 mg/g and those of caryophyllene greater than 7.0 mg/g significantly deterred the harvest of test flakes in both cases. By testing this range of concentrations, a minimum deterrent concentration has been established, and it is three- to fourfold lower than

deterrent concentrations previously reported (Hubbell et al., 1983). Thus the number of plant species containing concentrations of caryophyllene and/or caryophyllene epoxide meaningful to leafcutters may be greater than previously supposed.

Within the Attini, primitive genera culture fungus on feces and detritus, while more advanced genera show an increasing reliance on living plant tissues for fungus culture (Weber, 1972). In this study, the plant natural products caryophyllene and caryophyllene epoxide showed similar but not identical effects on the behavior of *Atta* and *Acromyrmex*, the two most advanced attine genera. It would be of great interest to know whether members of more primitive attine genera are equally deterred by these compounds or if deterrency is correlated with the use of plant material in fungus culture. Bioassays using these two compounds at constant concentrations may provide a useful standard for comparative studies of other attine genera and may offer insights into the evolution of fungus culture in this group of insects.

Acknowledgments—We thank the National Park Service of Costa Rica for permission to collect ant colonies at Santa Rosa National Park. S. Baldwin, J. Cerhan, R. Klemme, and T. Parker conducted the bioassays. The financial assistance of the National Science Foundation (grants DEB 80-10638 and BSR 83-07105) is gratefully acknowledged.

(Received August 12, 1988; accepted December 9, 1988)

Abstract—Greenhouse and laboratory experiments were conducted at the Agricultural and Water Resources Research Center Station, Baghdad, in 1985 and 1986 to investigate the possible allelopathic potential of alfalfa (*Medicago sativa* L.) and its decomposed residues on bladygrass (*Imperata cylindrica* L. Beauv.), a noxious weed in Iraq, and to isolate, characterize, and quantify possible allelopathic agents in alfalfa residues and root exudates. Results indicated that decomposed alfalfa roots and their associated soil produced a 51–56% reduction in bladygrass seed germination. Root and shoot length of bladygrass seedlings were reduced by an average of 88%. Decayed and undecayed mixtures of alfalfa roots and soil at 0.015:1 (w/w) inhibited bladygrass seedlings reproduced from rhizomes by 30 and 42%. It was found that root exudates of alfalfa seedlings caused significant reduction in shoot and root dry weights of bladygrass seedlings when alfalfa and bladygrass were grown together in nutrient culture. Caffeic, chlorogenic, isochlorogenic, *p*-coumaric, *p*-OH-benzoic, and ferulic acids were detected in alfalfa root exudates and residues. The highest amount (126 μ g phenolic acids/g soil) of these compounds was found in alfalfa root residues after six months of decomposition in soil.

Key Words—Allelopathy, *Medicago sativa*, *Imperata cylindrica*, root exudates, residues, decomposition.

INTRODUCTION

The term allelopathy includes the direct or indirect harmful and beneficial effects by one plant on another through the production of chemical compounds that escape into the environment (Rice, 1984). Studies concerning the manipulation of allelopathy of crops to control weeds have been increased recently. Al-Saa-

dawi et al. (1986) found that some *Sorghum bicolor* cultivars possess potential biological control of *Amaranthus retroflexus* by reducing its growth through root exudations. Root secretions of *Zea mays* L. inhibited the growth of common lambsquarters (*Chenopodium album* L.) and redroot pigweed (Dzubenko and Petrenko, 1971). Overland (1966) showed that allelopathy was involved in the mechanism of weed control by barley (*Hordium* spp.), wheat mulch, and rye (*Secale cereale* L.). Putnam and Duke (1974) found that some accessions of cucumber (*Cucumis sativus* L.) were able to inhibit proso millet (*Panicum miliaceum* L.) growth. Studies by Fay and Duke (1977) indicated that some accessions of (*Avena* spp.) contained scopoletin, an allelopathic agent. Germination and growth of wild mustard (*Brassica kaber*) were inhibited by aqueous leaf extracts of sunflower (*Helianthus annuus*) (Leather, 1983). Some soybean cultivars also possess the ability to inhibit growth of companion weeds by allelopathic exudates (Rose et al., 1984).

Bladygrass (*Imperata cylindrica* L. Beauv.), an upright rhizomatous grass, is widespread throughout the tropics and subtropics and is considered one of the worlds worst weeds (Holme et al., 1977). In Iraq, bladygrass is a noxious weed that spreads widely and infests almost all aspects of agriculture. Al-Juboory (1978) reported that some newly established citrus orchards have been abandoned by farmers due to heavy bladygrass infestation. Our preliminary field observations showed that alfalfa (*Medicago sativa*) was an excellent smother crop to bladygrass and in some instances was able to halt bladygrass seedling emergence for periods ranging between two and four years. The ability of alfalfa to smother bladygrass could be due mainly to physical competition (light and nutrients). However, alfalfa has been reported to contain water-soluble substances toxic to plants. Lawrence (1962) found that alfalfa roots contained water-soluble substances toxic to several grasses. Another study by Guenzi et al. (1964) indicated that extracts of alfalfa contained water-soluble substances that reduced shoot and root growth of corn seedlings. A recent study by Miller (1983) demonstrated the autotoxicity of alfalfa on the reestablishment of subsequent plantings. Therefore, the ability of alfalfa to compete strongly with bladygrass might not be due to physical competition only but also to allelopathy. This study was undertaken to (1) determine if residues of alfalfa roots in soil after different periods of decaying have allelopathic effects on bladygrass seedling growth, (2) determine the effects of alfalfa root exudates on bladygrass seedling growth, and (3) isolate and characterize possible allelopathic agents in alfalfa residues and root exudates.

METHODS AND MATERIALS

Effect of Decayed Alfalfa Roots on Bladygrass Seed Germination and Seedling Growth. A 1-year-old established alfalfa field was chosen to collect alfalfa roots and the surrounding soil in August 1985. The site was located 80 km north

of Baghdad at the Ishaki Research Station. The roots were separated from the soil, and both were air-dried for three days at an average temperature of 45°C, then ground to pass a 0.5-mm sieve, and mixed thoroughly at a ratio of 0.015:1 (w/w root to soil). The ratio was selected on the basis of actual weight of dead alfalfa secondary roots and the soil in their vicinity. The mixtures were placed in 30 × 10 × 10-cm plastic containers under greenhouse conditions and left to decay for 0, 3, and 6 months. The containers of the last two treatments (3 and 6 months decay periods) were watered with 500 ml of water every three days. Alfalfa-root-free soil collected from adjacent locations was used as a control. Ground peatmoss was mixed with the soil at a ratio of 0.015:1 (w/w peatmoss to soil) to substitute for alfalfa roots in the control pots. The average pHs of the root-soil and peatmoss-soil mixtures were 7.8 and 7.3, respectively.

Bladygrass inflorescence were collected from the same site during June 1985. The seeds were separated and stored at room temperature for germination tests. One hundred seeds were planted in 12-cm Petri dishes filled with a 100-ml volume of the previously prepared alfalfa root and peatmoss-soil mixtures. Ten Petri dishes were used for each treatment. Watering was done by adding 20 ml of tap water to each dish. After 10 days of incubation at 30°C, germination and length of radicles and shoots of bladygrass seedlings were recorded. Data were analyzed for significant differences by randomized complete-block design analysis of variance and Duncan's multiple-range test at the 5% level of significance.

Effect of Decayed Alfalfa Roots on Bladygrass Rhizomes Growth. To determine the effect of decayed alfalfa roots on bladygrass rhizome growth, the following planting media were prepared: (1) undecayed mixture of alfalfa roots with their planting soil at ratio of 0.015:1 w/w root to soil; (2) undecayed alfalfa-planted soil; (3) undecayed bare soil; (4) mixture of decayed alfalfa roots with their planting soil at a ratio of 0.015:1 (w/w roots to soil); (5) decayed alfalfa planting soil; and (6) decayed bare soil. Alfalfa-planted soil and roots were taken from a 1-year-old alfalfa field, while bare soil was collected from an adjacent field. All decayed planting media were prepared by placing 2 kg of ground and mixed soil mediums in 20-cm-diameter plastic pots and watered periodically to maintain them at field capacity for three months.

Bladygrass rhizomes were collected from heavily infested bladygrass sites located 80 km north of Baghdad in the fall of 1985. Rhizomes were cut into 4- to 5-cm segments with three nodes. Three uniform segments were selected and planted 3-4 cm deep in the planting mediums. Pots were placed in a greenhouse at an average 50-60% relative humidity and 25°C and watered periodically as required. Three replications of each treatment were used. After 20 days, all bladygrass nodes of the control treatment seedlings were counted, and the percent of seedling emergence was calculated based on that of the control treatment. Seedlings were counted, the lengths of roots and shoots were measured, and seedling dry weights noted. Data were analyzed for statistical differences by Duncan's multiple-range test with 5% level significant.

Effect of Alfalfa Root Exudates on Bladygrass Seedling Growth. This experiment was conducted to determine the ability of alfalfa seedlings to produce allelopathic inhibitors that may influence bladygrass seedling growth in the absence of physical competition. The procedure followed that described by Al-Saadawi and Rice (1982). Uniformly sized alfalfa and bladygrass seedlings were selected from seedlings grown in sand culture under greenhouse conditions at 25°C, 60% relative humidity, and 14 hr light. The average stem length of both seedlings was 7 ± 0.5 cm, with an average root length of 4 ± 0.5 cm. Roots were washed with tap water to remove sand. One seedling was placed in each end of a U-shaped Pyrex tube, 2.5 cm in diameter and 25 cm long. The seedlings were held in place by a stopper bored to admit the seedling stem, which was encased in cotton. The tube was wrapped with aluminum foil and filled with Hoagland's solution (Hoagland and Arnon, 1950). Three paired seedling treatments were used in this experiment: alfalfa-bladygrass, alfalfa-alfalfa, and bladygrass-bladygrass. Tubes were aerated daily by vacuum for 10 min, and the solutions were maintained at the same level by adding the required volume of solution. Each treatment was replicated 10 times. After 21 days, shoot and root dry weights of both seedlings were taken. Data were subjected to analysis of variance and LSD with a 5% level of significant.

Isolation and Characterization of Allelochemicals. Since phenolic compounds have been implicated in most allelopathic studies (Rice, 1984; Guenzi and McCalla, 1966; Putnam and Duke, 1974; Blum et al., 1985), we investigated their presence in alfalfa. The procedure used to isolate and identify the phenolic compounds was the same as described by McPherson et al. (1971). One hundred grams of the decomposed alfalfa-planted soil medium was mixed with 150 ml of 95% EtOH and sufficient 2 N NaOH to bring the pH to 11. The mixture was shaken for 48 hr using a mechanical shaker with periodic readjustment of pH to 11 and then the mixture was filtered under vacuum.

The filtrate was reduced to about 50 ml in vacuo at 50–60°C, centrifuged, and the supernatant brought to pH 7 with 2 N HCl. The resultant liquid was evaporated to dryness on a hot plate (60–65°C). The residue was ground to a powder, taken up into three washes of ether, acidified to pH 2 with 2 N HCl, and evaporated to dryness at room temperature under a fume hood. The residue was dissolved in 3 ml of 95% EtOH. The solution was applied to 2 × 30-cm strips of Whatman No. 1 chromatographic paper, developed in *n*-butanol–acetic acid–water (BAW, 63:10:27 v/v/v), and inspected with short- and longwave UV. Compounds were marked under UV light and eluted with 95% ethanol. The elutes were reduced to dryness, taken up in 3 ml absolute EtOH, and chromatographed on Whatman No. 1 paper in three solvent systems: BAW, 6% acetic, and IBW (isopropanol–*n*-butanol–water; 140:20:60 v/v/v). The R_f values in various solvent systems, colors under UV light, and colors in various reagents were determined for all detected compounds. Allelochemicals of alfalfa root exudates in the paired seedling experiment of alfalfa-alfalfa, alfalfa-blad-

ygrass, and bladygrass–bladygrass were isolated and characterized by collecting a total of 1750 ml of the growing solution in each U-tube after 20 days of growth, vacuum dried under 40°C, and then extracted and chromatographed by the previously mentioned procedure. Identification of the phenolic acids in the samples was made by comparing their R_f values and colors with those of known standards. Quantitative estimation of the total phenolic compounds for each decay period and exudate treatment was done using Folin-Dennis reagent according to Pearson (1970).

Biological Activities of Isolated Phenolic Compounds. The biological activity of all isolated allelochemicals was determined using bladygrass seeds. All distinctive bands resulting from the previous identification were cut out, placed on 9-cm-diameter Petri dishes containing 10 ml buffer, 6.8 pH, and 50 bladygrass seeds. Similar sized areas from blank chromatograms were used as a control. The Petri dishes were placed in a growth chamber with a 14-hr photoperiod and 30°C temperature. The test and control treatments were replicated three times. Seed germination and radicle and hypocotyl lengths were taken after 10 days of incubation.

RESULTS

Bladygrass Seed Germination and Seedling Growth. The percentage of bladygrass seed germination and seedling root and shoot length as affected by decomposed alfalfa roots and soil residue are summarized in Table 1. Germination percentages of bladygrass seeds were significantly decreased by incorporation alfalfa roots with planting soil and for the two periods of decomposition (3 and 6 months). As the time of decomposition increased, the germination decreased. The greatest reduction in seed germination (55%) resulted when a

mixture of alfalfa roots and soil were subjected to 6 months of decomposition prior to germination tests. This treatment resulted in 25% germination compared to 56% for the control (bare soil) treatment.

Bladygrass root and shoot lengths were significantly reduced by alfalfa root and soil residues. The percentage reduction in root length was 92 and 95% for the 3 and 6 months periods of decomposition, respectively. The same trend on shoot length was detected, whereas higher reductions resulted with the 6-month period of decomposition. Incorporation and decomposition of alfalfa roots with soil reduced shoot length to 7 cm compared to 52 cm for the control treatment.

Effect of Decayed Alfalfa Roots on Bladygrass Rhizomes Growth. The percentages of bladygrass seedling emergence, radicle and shoot length, and seedling dry weight as affected by decayed alfalfa roots and soil are summarized in Table 2. Seedling emergence was significantly reduced by undecayed and decayed alfalfa roots and soil planting mediums. Length of time seemed to have no significant effect on bladygrass seedling emergence, because no differences were detected between the 0- and 3-month treatments. Both periods inhibited emergence to 30–42% compared to the control treatment (bare soil).

Bladygrass radicle length was greatly inhibited by all treatments of decayed or undecayed alfalfa root–soil mixtures or by alfalfa residue. Percentage of inhibition was found to be 95 and 97% for the undecayed and decayed root–soil, respectively. Time of decomposition had no significant effect on the inhibition of radicle length. However, the 3-months alfalfa root–soil decomposition resulted in the shortest radicle (1 mm).

Similar trends of effect on bladygrass shoot elongation were noticed. A higher percentage of shoot length inhibition resulted from the 3-month decay

TABLE 2. INFLUENCE OF DECOMPOSED ALFALFA ROOTS AND SOIL RESIDUES AT DIFFERENT PERIODS OF DECOMPOSITION ON GROWTH OF BLADYGRASS SEEDLINGS PRODUCED FROM RHIZOMES^a

treatments than that of the undecayed. Incorporation of alfalfa roots with soil and decomposed for 3 months reduced shoot length to an average of 94% from that of the check treatment. The dry weight of bladygrass seedlings was also significantly reduced by alfalfa residues. The highest percentage of inhibition (90%) was obtained from the 3-month decayed of alfalfa root-soil planting medium.

Effect of Alfalfa Root Exudates on Bladygrass Seedling Growth. The influence of root exudates on the dry weight of alfalfa and bladygrass seedling shoots and roots is summarized in Table 3. Bladygrass seedling shoot dry weight grown with alfalfa was significantly reduced. The percentage of reduction in bladygrass shoot dry weight was 42% compared to its dry weight in the bladygrass paired seedling treatment. Great reductions in the dry weights of both alfalfa—seedling shoots resulted when they were grown together.

The root dry weight of bladygrass was less when grown with alfalfa. This was significantly different from that of the control treatment (bladygrass—bladygrass). The dry weight of alfalfa roots in the alfalfa—alfalfa paired seedling treatment was also inhibited by 20%; however, this reduction was less than that for the shoot dry weight.

Isolation and Characterization of Allelochemicals. Chromatography of alfalfa root residues and exudates (Table 4) showed the presence of phenolic acids: caffeic, chlorogenic, isochlorogenic, *p*-coumaric, *p*-OH-benzoic, and ferulic. In addition, quercetin, one of the flavinoid group, and four unknown compounds were present. The R_f values under different solvents, their fluorescences under long and short UV with and without ammonia, and their colors

2	3	32	49	81
3	6	72	54	126

with various reagents are shown in Table 4. The R_f values and colors of the unknown detected compounds 1, 2, 3, and 4 suggest that they might be flavinoids.

Quantitative estimation of the phenolic compounds in decomposed alfalfa residues is summarized in Table 5. The cumulative amounts of the phenolic acids in the ethanol and hexane extracts showed that longer periods of decomposition resulted in higher accumulation of phenolic compounds. The 6-month period of decay resulted in 126 μg of phenolics/g of soil in comparison to 81 $\mu\text{g/g}$ in the 3-month decomposition. Root exudates of alfalfa-bladygrass paired seedlings was found to contain 12 μg phenolics/ml of analyzed growing solution while that of alfalfa-alfalfa and bladygrass-bladygrass seedlings contained 2.1 and 1.4 $\mu\text{g/ml}$ of solution, respectively.

Biological Activities of Isolated Allelochemicals. Percentages of bladygrass seed germination and seedling root and radicle length as affected by isolated phytotoxins or their mixtures are summarized in Table 6. Bladygrass seed germination was significantly inhibited by all isolated compounds or their combinations in comparison to the control treatment. Isochlorogenic, chlorogenic, ferulic acids, and the mixtures of the isolated compounds from the 6-month decayed alfalfa residues resulted in inhibition. Shoot and radicle lengths of bladygrass seedlings were also inhibited by all isolated phenolic acids and their combinations.

DISCUSSION

The results of these experiments show that alfalfa soil residues reduced germination and seedling growth of bladygrass. It was found that the longer the period of decay, the higher the inhibition of seed germination. Decomposition of alfalfa roots for 6 months reduced seed germination by 55%. Seedling growth (shoot and root length) of bladygrass was also inhibited by incorporation and

decomposition of alfalfa roots. The reduced seed germination and seedling growth of bladygrass by alfalfa residues was apparently due to its allelopathic effect. This is supported by the fact that the decayed and undecayed bare soil (control) planting media did not inhibit the germination and growth of bladygrass (Table 1). No previous work has been published on the allelopathic effect of alfalfa on bladygrass. However, Nielsen et al. (1960) showed that alfalfa, among other crops, caused the greatest delay in seed germination and seedling growth of corn, soybean, peas, and oats. Another study by Guenzi et al. (1964) supports the previous observation of the allelopathic effect on corn. They demonstrated that this effect was due to saponins.

Bladygrass seedling growth emerging from rhizomes was also inhibited by alfalfa residues. Significant reduction occurred in percent of bladygrass seedling emergence, their radicle and shoot length, and their cumulative dry weights (Table 2) from alfalfa residues. Decomposing alfalfa roots appear to produce greater inhibition than undecomposed roots. This may be due to a higher release of phytotoxic substances. However, this conclusion may not be definite since

TABLE 7. AMOUNTS OF PHENOLIC ACIDS IN ROOT EXUDATES OF ALFALFA AND BLADYGRASS PAIRED SEEDLINGS

other factors such as microbial action might play a role (Kommedahi et al., 1959).

Inhibition of bladygrass seedling root and shoot dry weights by alfalfa root exudates in the absence of physical competition (Table 3) is another indication that the reduction is due to allelochemicals exuded from alfalfa. This is supported by previous work by Nielsen et al. (1960) and Guenzi et al. (1964), who demonstrated that alfalfa contains water-soluble materials that inhibit seedling growth of several crops. Miller (1983) has established the autotoxicity of alfalfa. He observed that phytotoxic factors released from alfalfa affect the reestablishment of alfalfa. A later study by Tsuzuki and Kawagoe (1984) showed also that root exudates from alfalfa reduced the dry weight of barley, alfalfa, and radish seedlings.

The isolation and identification of caffeic, isochlorogenic, chlorogenic, *p*-coumaric, *p*-OH-benzoic, and ferulic acids and quercetin flavinoid from alfalfa root residues and exudates also support the potential for allelopathic interactions of alfalfa on bladygrass. Most phenolic compounds have been reported as being strong allelopathic agents (Fay and Duke, 1977; Rice, 1984; Blum et al., 1985; Putnam and Duke, 1974; Abdul-Rahman and Al-Naib, 1986). Our results (Table 7) showed that these isolated phenolic acids were biologically active by reducing bladygrass seed germination and seedling root length. This indicates that the allelopathic effect of alfalfa on bladygrass may be due to the presence of these phenolic acids.

It is clear from these results that the reduction in bladygrass seedling growth was due to allelochemicals released from alfalfa. This probably explains the ability of alfalfa to act as a strong smother crop to bladygrass (personal field observations). However, the ability of alfalfa to compete strongly with bladygrass for light, space, and nutrients might enhance the smothering ability of alfalfa in the field. The results of this study could be an added support to previous studies by many researchers (Rose et al., 1984; Leather, 1983; Fay and Duke, 1977) to manipulate the allelopathic phenomenon of some crops to control weeds.

CUTICULAR HYDROCARBONS OF THE SCREWWORM,
Cochliomyia hominivorax (DIPTERA: CALLIPHORIDAE)
Isolation, Identification, and Quantification as a Function of
Age, Sex, and Irradiation¹

J. GEORGE POMONIS

Biosciences Research Laboratory
ARS-USDA
Fargo, North Dakota 58105

(Received September 1, 1988; accepted December 13, 1988)

Abstract—A novel series of 2,X-dimethylalkanes were isolated and identified. The nonpolar fraction of the surface lipids secreted by the adult (5-day-old) screwworm, *Cochliomyia hominivorax*, contains over 130 different hydrocarbons comprising normal alkanes (32% of the total hydrocarbon), branched alkanes (53%), and monoalkenes (11%). Branched alkanes included monomethylalkanes with substitution in all possible positions except for 4-methylalkanes, internally branched dimethylalkanes, and 2,X- and 3,X-dimethylalkanes. At emergence, adults of both sexes of the 009 strain have nearly identical gas chromatographic profiles, which diverge as the insect ages. Irradiation of pharate pupae does not affect the hydrocarbon produced.

Key Words—Insect, screwworm, *Cochliomyia hominivorax*, Diptera, Calliphoridae, cuticular hydrocarbons, mass spectrometry, 2,X-dimethylalkanes.

INTRODUCTION

The screwworm, *Cochliomyia hominivorax*, belongs to the family of blowflies (Diptera: Calliphoridae). The female oviposits in open sores and wounds of mammals, and the larvae, after hatching, feed on the living flesh surrounding

¹ Mention of a commercial or proprietary product in this paper does not constitute an endorsement of that product by the USDA.

the wound (myiasis). The insect has been a pest of the livestock industry in the United States since the turn of the century. A "barrier" of released radiation-sterilized insects is now located in southern Mexico at the isthmus of Tehuantepec. The insect is considered to be officially eradicated north of the barrier in Mexico. The screwworm was colonized at Fargo, North Dakota, in 1975 from a culture of the 009 strain from the screwworm facility in Mission, Texas. The 009 strain is a composite formed with screwworms collected from 28 different Texas locations.

The purpose of this study was to gather information of the screwworm's nonpolar surface lipid composition as a base for current and future studies in such areas as: the effect of sterilizing radiation on quantity and quality of hydrocarbon production, which may negatively affect the sterile release program, lipid biosynthesis, the role these lipids have on the behavioral functions (pheromone), and as a possible chemotaxonomic indicator for strains from various geographical locations.

We had earlier reported the gas chromatographic composition profiles of surface lipid extracts from screwworms from different geographical locations (Pomonis and Mackley, 1985). We now report, for the 009 strain, the isolation and characterization of the hydrocarbon fraction of the surface lipids, the quantification of the *n*-alkanes and methylalkanes, and the relationships of these quantities to age, sex, and effect of 6000 rads of gamma irradiation.

METHODS AND MATERIALS

Biological. Insects were reared as described by Hammack (1984) and were of the 009 strain, which had been in laboratory culture for nearly 10 years at Fargo. The insects were separated by sex 24 hr after emergence and reared separately for use at the appropriate age. Pupae were irradiated at four days preemergence in a cobalt-60 source with 6000 rads and separated by sex within 24 hr postemergence; experimental data were compared to those from nonirradiated pupae.

Extraction of Lipids. Flies, which were killed by freezing, were counted and weighed as a single mass with the number of flies as the denominator in the standardization of quantities (Jackson and Bartelt, 1986). The surface lipids were extracted with CH_2Cl_2 , 3×35 ml/45 insects for 1 min. For the screwworm, extraction periods greater than 5 min extracted internal lipids that appeared as a broad peak in the gas chromatogram at Kovats retention index (KI; Kovats, 1965) of about 1700–1900. The solvent was removed in vacuo, and 3-methylnonadecane and 3-methylheneicosane (KI 1975 and 2175, respectively, and 100 μg each per 45 insects) were added as internal standards for chromatography. Silica column chromatography separated the hydrocarbon fraction from the other lipids. The alkenes were separated from the alkanes by

argentation thin-layer chromatography (TLC) or argentation column chromatography. The methyl alkanes were separated from the *n*-alkanes by molecular sieving (O'Connor et al., 1962).

Alkene Derivatization. Alkenes were derivatized as the methoxy adducts for analyses by gas chromatography-mass spectrometry (GC-MS) using the methoxy-mercuration reaction described in the literature (Abley et al., 1970; Plattner et al., 1976; Blomquist et al., 1980).

Gas Chromatography (GC). Analyses were performed with a Varian model 3700 flame ionization instrument fitted with a multipurpose heated (225°C) variable split injector (100:1) and a cross-linked methylsilicone fused silica capillary column [Hewlett-Packard (H-P) 12 m × 0.20 mm ID, film = 0.33 μm, He carrier gas at 0.77 ml/min (30 cm/sec) at a head pressure of 12.5 psig]. The GC was programmed from 150 to 320°C at a variable rate (usually at 4 or 2°/min) with a 2-min initial and a 15-min final isothermal hold. Chromatographic data were reported by a H-P model 3390A integrator interfaced to the GC. For quantification and to determine the KI, a mixture of nearly equal and exactly weighed quantities of (ca. 1.0 μg) each of the normal alkanes: C₂₀H₄₂, C₂₄H₅₀, C₂₈H₅₈, C₃₂H₆₆, C₃₆H₇₄, C₄₀H₈₂, and C₄₄H₉₀ was used.

Gas Chromatography-Mass Spectrometry (GC-MS). The GC-MS analyses were performed by means of a modified Varian model 3700 packed column gas chromatograph coupled to Finnegan-Mat 112S mass spectrometer in the electron impact mode and fitted with a Carter-Cook jet separator. For chromatography, a 3.05-m × 0.635-cm (OD) glass column was packed with 3.5% OV-101 on Gas-Chrom Q, 100-120 mesh and temperature programmed from 150 to 324°C at 4°/min, using He carrier gas at 25 ml/min. Alternatively, for some GC-MS analyses, an H-P 5790 GC with a standard H-P cool on-column injector was used; this was fitted with a 12.5-m cross-linked methylsilicone fused silica capillary column whose exit inserted directly into the ionizing chamber of the 112S spectrometer. The GC was programmed with a 2-min initial isothermal hold at 60°C, heated to 150°C at 28°/min, then from 150 to 325°C at 3°/min with helium as carrier gas at 1 ml/min.

Mass spectra of the methylalkanes were interpreted according to the criteria proposed by McCarthy et al. (1968), Nelson and Sukkestad (1970), Nelson et al. (1972), and Pomonis et al. (1978, 1980). Mass spectra of the alkene methoxy derivatives were interpreted by criteria proposed by Blomquist et al. (1980).

RESULTS

Table 1 summarizes the effect of age, sex, and irradiation on the quantities of various cuticular lipid fractions produced by the screwworm. Total surface lipid increased as the fly aged for each type of treatment (column 1). Hydro-

carbons comprised a majority of the surface lipids for newly emerged (NE) adults (values discussed are for control female flies although values for both sexes are listed in Table 1). As the fly aged, the absolute amount of hydrocarbon increased from 34 to 50 to 74 μg , respectively, for the three ages. For all treatments in the hydrocarbon group, the quantity of *n*-alkanes remained nearly constant. The total quantity of the methylalkanes showed an increase as the insect aged for all treatments. The alkene fraction showed a high degree of variability and contained the lowest quantities of hydrocarbons of the three fractions considered. Irradiation of pharate pupae did not appear to affect synthesis of the lipids in adults. No significant differences in quantities or type of alkanes listed in Table 1 were observed between irradiated and nonirradiated insects and therefore are not included in the data of Table 2 (*t* test for paired observations with two degrees of freedom showed no significant difference; $n = 3 \times 45$).

Nearly 130 different alkanes were found (Table 2), including methylal-

^a Fargo 009 Strain, F₁₀₃ to F₁₀₉. Analyzed by gas chromatography (GC) and gas chromatography-mass spectrometry (GC-MS). Only data from nonirradiated flies is shown since irradiated insects had similar values. Blank indicates no peak or that the recorder did not integrate or sense peak. Values are means from pooled samples where *N* = 3 replicates of 45 individuals per sample and each sample injected once.

^b Data for males and females identical except for male KI 2537.

^c GC peaks were sensed by integrator for one of three replicates.

^d GC peaks were sensed by integrator for two of three replicates.

^e Capillary GC-MS does not always resolve all isomers of a homologous series; however, KI were determined by GC alone (see Pomonis et al., 1989).

kanes with branching at nearly all possible positions as well as three different types of dimethylalkanes. The dimethyl alkanes include the well-documented internally branched compounds with three methylene units separating the methyl branches as well as the novel 2,X- and the 3,X-dimethylalkanes where X signifies the carbon carrying the second methyl group at 3, 5, 7, . . . methylene units of separation (Blomquist et al., 1987). Interpretation of the spectra of the methylalkanes is straightforward (Pomonis et al., 1978, 1980), while the interpretation of the 2,X-dimethylalkanes was based on information obtained from synthetic 2,X-dimethylalkanes reported in the companion paper (Pomonis et al., 1989).

The hydrocarbons were characterized by GC-MS and their KI values, names, and quantified values (averaged, from triplicate runs) of the chromatographic peaks (such as in Figure 1) are given in Table 2 for each of the three age groups of flies. The values for the quantities discussed below are for the control groups, but the trends were similar for the irradiated groups. Sexual dimorphism is evident from the chromatograms shown in Figure 1 for the three age groups. The two peaks at KI 1975 (3-methylnonadecane) and KI 2175 (3-methylheneicosane) are the internal standards and represent the detector response equivalent to 1 μg of material. The standard peaks are not exactly aligned because of operator differences; however, the chromatograms are aligned on KI 2936.

The *n*-alkanes were the second most abundant group of hydrocarbons found (Table 1). They ranged in size from 22 to 33 carbons with the odd-numbered homologs present in greater quantities than the even-numbered ones (Table 2). The male produced greater quantities of *n*-pentacosane than the female. The female produced greater quantities of *n*-hentriacontane. Both sexes showed increases with age for the *n*-heptacosane and a steady-state quantity for *n*-nonacosane.

The chromatographic profile of NE males and females in Figure 1 are similar except for the peak at KI 2537 (9-, 11-, and 13-methylpentacosane), which showed an increase in the amount with age, while in the female KI 2537 appeared at 3 days and diminished at 5 days of age. In males, the methylnonacosanes (KI 2936) decreased in quantity with age, while the methylheptacosanes (KI 2735 and 2773) increased. In females, the methyltrtriacontanes (KI 3331), methylpentatriacontanes (KI 3530), and 5-methylpentatriacontane (KI 3558) peaks showed increases beginning with day 3 and showed a threefold increase in quantity over the male with age.

The 2-methylalkanes were found in homologous even-numbered hydrocarbons, whereas the 3-methylalkanes were in homologous odd-numbered hydrocarbons. The quantities of 2-methyloctacosane (KI 2864) and 2-methyltricosane (KI 3065) decreased as both sexes aged. In males, the 3-methyltricosane, 3-methylpentacosane, and 3-methylheptacosane (KI 2374, 2574, 2773, respectively) showed an increase in quantity with age. However, the amounts

FIG. 1. Comparison of representative capillary gas chromatograms of the methylalkane fraction from surface extracts of screwworm adults (009 strain) by sex and age. Slight differences in each chromatogram do not allow for perfect alignment of all peaks; however, they are arbitrarily aligned on KI 2936 (methylnonacosanes). Peaks at KI 1975 (3-methylnonadecane) and KI 2175 (3-methylheneicosane) are those from standards added to the initial extracts and represent the detector response to $1 \mu\text{g}$ of each standard.

of the 3-methylnonacosane (KI 2977) showed a decrease with aging to half the original amount in NE. Sexual dimorphism was evident by the presence of additional higher 3-methylalkanes in the female surface lipids. Thus, 3-methylpentacosane, 3-methylheptacosane, 3-methylhentriacontane, and 3-methyltriacontane (KI 2372, 2773, 3175, and 3375, respectively) showed slight increases with age, whereas 3-methylnonacosane (KI 2973) remained nearly constant.

It was important to the interpretation of the mass spectra of the unknowns to carefully measure the chromatographic retention indices. Figures 2-5 show examples of mass spectra obtained during sequential scans by the spectrometer of specific peaks eluting from the GC. The scan sequence number and nominal KI are shown with each spectrum (The nominal KI was used in the figures because, when the mass spectrometer scanned across a peak eluting from the GC, not all mixtures were separated into individual isomers; therefore the mass spectra from the leading edge of the peak may be different than those from the trailing edge).

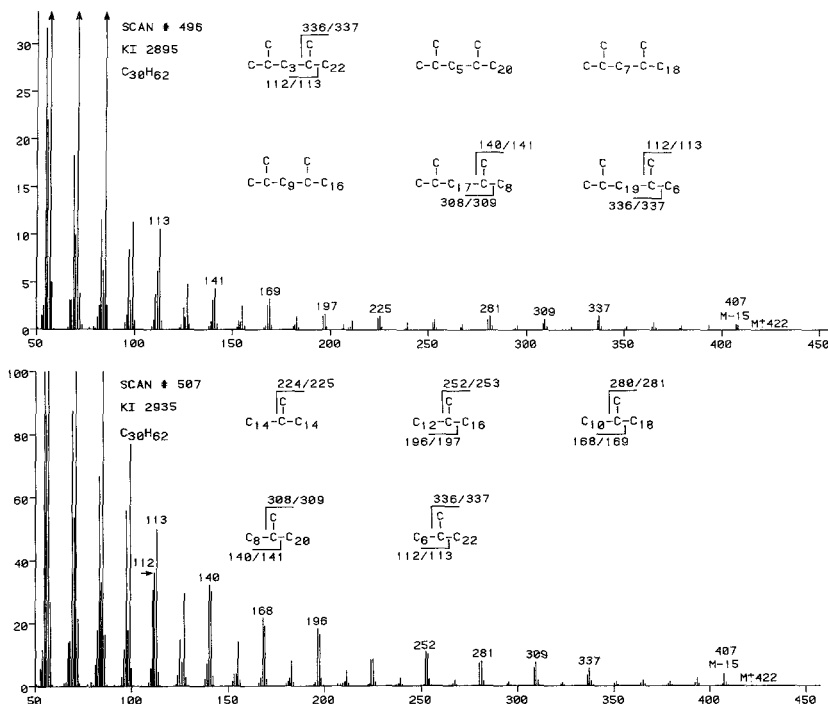

FIG. 2. Mass spectra of methylalkanes from screwworm: 2,X-dimethyloctacosanes (nominal KI 2895); methylnonacosanes (KI 2935).

FIG. 3. Mass spectrum of mixture of 2,X-dimethyltriacontanes (nominal KI 3095).

The spectra shown in Figure 2 are from peaks eluting at nominal KI 2895 and 2935 and represent mixtures of 2,X-dimethyloctacosanes and methylnonacosanes. The two mixtures are isomeric to each other, have identical molecular weights, and identical mass spectra. They differ only in their retention indices. An additional series of 2,X-dimethyltriacontanes (nominal KI 3095) was identified from the hydrocarbon fraction (Figure 3). The 2,X-dimethylalkane structures were proven by synthesis and careful measurement of the KI values of homologous compounds (Pomonis et al., 1989).

Figure 4 shows the MS scan for the peak with nominal KI 3005. This spectrum for the mixture of 3,X-dimethylnonacosanes is typical of dimethylalkanes. The mass spectrum of the synthetic 3,11-dimethylnonacosane (Pomonis et al., 1980; Pomonis and Hakk, 1984; Rosenblum et al., 1976; Nishida et al., 1974) (KI 3006; Pomonis et al., 1989) showed that fragmentation external to carbon 11 yielded two fragments at m/z 182/183 with an intensity ratio > 1 ,

which suggests that the methyl branch at carbon 3 has no influence on fragmentation ratios, similar to the 2,X-dimethylalkanes. However, the mass spectrum of the mixture (Figure 4), which contains naturally occurring 3,11-dimethylnonacosane, does not show significant even mass peaks for those fragments from external scission of the internal methyl branch for all compounds, e.g., at m/z 210/211, 182/183, 154/155, 126/127. It is assumed that because there is a mixture, other fragments at these same m/z values may confound the expected ratios. Also, it should be pointed out that the mass spectrum (Figure 4) has been amplified 4 \times , suggesting that the compounds are present in very small quantities (Table 2). The strongest evidence for the 3,X-dimethylnonacosanes is the KI obtained for this peak (Pomonis et al., 1989). No other 3,X-dimethylalkanes were identified.

The alkene fraction had the largest variability among the various treatments and also the smallest quantity of mass of the hydrocarbons (Table 1). The amount of total alkenes remained fairly constant as the insects aged. The alkenes that were characterized by GC-MS as methoxy derivatives are listed in Table 3. Infrared spectrometry of the alkene mixture gave no peak at 970 cm^{-1} , which suggested *Z* rather than *E* double bonds (Jackson and Bartelt, 1986). Those alkenes identified were straight-chain monoalkenes with double bonds in position 5 or 7 or 9 (Table 3). No attempt was made to quantify the individual alkenes.

DISCUSSION

The insect's cuticular lipids may serve to protect it from desiccation, penetration of microorganisms and pesticides, and often may have a role in chemical communication (Jackson and Blomquist, 1976; Nelson, 1978; Blomquist and Jackson, 1979; Howard and Blomquist, 1982; Blomquist and Dillwith,

1985). Studies to develop understanding and knowledge of these processes may result in ecologically safe methods of insect pest control.

In an earlier gas chromatography study of the screwworm, Louloudes et al. (1962) compared the hydrocarbon fractions of extracts of whole body sodium hydroxide digests of several dipteran species. Even-numbered alkanes accounted for over one third of the total compounds in the screwworm. While all four species had alkenes, the screwworm had only 6% of the total hydrocarbons as unsaturates. The quantities of alkenes we found present in the screwworm were nearly identical with those reported Louloudes et al. (1962). Those authors reported that the principal constituents of the alkanes from the hydrocarbons of the screwworm were the C_{29} as well as appreciable amounts of C_{30} and higher homologs (about 25% of the material).

We found that the absolute amount of hydrocarbon increased in the screwworm female and male with age and may also be strain dependent (Pomonis and Mackley, 1985). Conversely, the hydrocarbon fractions contribute a decreasing percentage to the total quantity of surface lipid. At emergence, both sexes had nearly identical profiles and quantities of individual groups of compounds. Individual methylalkanes varied in amount with age for both sexes, suggesting sexual priorities in synthesis of certain compounds.

Comparison of irradiated and nonirradiated flies showed no difference between treatments as no large differences in quantities or quality of the various hydrocarbon groups were found. Apparently, synthesis and/or secretion is not affected by irradiation, possibly because the synthesis enzymes are already programmed before irradiation of the pupae. Irradiation of 1-day-old adult stable flies has been found to have no effect on hydrocarbons produced by these flies when measured at five days (Harris et al., 1976).

Normal, methyl- and dimethylalkanes, but not trimethylalkanes were found by GC-MS. All possible isomeric methylalkanes were found in the screwworm

FIG. 5. Mass spectrum of 2-methyltriacontane (KI 3065).

except for 4-methylalkanes; however, not every isomer was found in every homologous series. In odd-numbered carbon backbone methylalkanes, the isomers were those in which the substitution was on odd-numbered carbons, e.g., 9-, 11-, and 13-methylpentacosane. In even-numbered carbon backbone methylalkanes, the isomers were those substituted on consecutive carbons e.g., 8-, 9-, 10-, 11-, . . . methyloctacosane.

Dimethylalkanes of several types were characterized from the screwworm surface hydrocarbon fraction. The ubiquitous dimethylalkanes with three methylene units between the branches (see Blomquist et al., 1987, for a recent review) were found also in the screwworm. The 3,X-dimethylalkanes have been previously reported in several species of insects (Nelson et al., 1980, 1981; Thompson et al., 1981; Lockey, 1982, 1984, 1985; Peschke and Metzler, 1987). In the screwworm, 3,X-dimethylnonacosanes (500 ng/fly) were detected only in the newly emerged female.

A group of novel compounds that eluted at KIs approximately equal to those of *n*-alkanes and whose spectra appeared to be those of monomethylalkanes in the next higher series were identified as belonging to a previously unreported class of dimethylalkanes, viz., 2,X-dimethylalkanes. Chromatographically, peaks KI 2895 and KI 3095 have KI values inconsistent for monomethylalkanes of their molecular mass, although their mass spectra appeared to be those of monomethylalkanes. Figure 2 compares mass spectra of the 2,X-dimethyloctacosanes and methylnonacosanes. These two groups of compounds give chromatographic peaks having a difference of about 40 units of KI. Identification was aided by synthesis and mass spectrometry of a series of 2,X-dimethylheptacosanes and careful measurement of the KIs (Pomonis et al., 1989). This group of compounds does not give the typical mass spectral fragmentation of dimethylalkanes. In previously reported spectra of dimethylalkanes (Nelson and Sukkestad, 1970; Nelson et al., 1972; Pomonis et al., 1978, 1980), characteristic fragments are found that are a result of scission about the methyl branch. This process yields an odd/even pair of ions of 1 amu difference for each methyl branch point. Additional characteristic fragment ions contain both methyl groups. However, the 2,X-dimethylalkanes do not give the typical spectra of the more frequently encountered internally branched dimethylalkanes. The methyl substituent on position 2 (the "iso" position) does not have an influence on fragmentation, so that the compound acts as if it has only one methyl group; that is, there is no significant peak indicating a loss of an isopropyl radical (very low intensity M-43, C₃H₇) so that the spectrum appears to be that of a monomethylalkane.

There was one ambiguity which was observed in the MS of these compounds: In Figure 2 there are groups of two compounds each, which may contribute the same fragments; for example, 2,10- and 2,18-dimethyloctacosane both yield ions at *m/z* 168/169 and 280/281 and 2,12- and 2,16-dimethylocta-

cosane yield ions at m/z 196/197 and 252/253, all of which result from fragmentation about the branch. Whether one or both isomers of each group are present in the natural products is not certain but must wait synthesis of examples of the 2,16- and 2,18-dimethylheptacosanes for comparison with the synthetic 2,10- and 2,12-dimethylheptacosanes (Pomonis et al., 1989).

This is the first report of the isolation and characterization of 2,X-dimethylalkanes from insects. The compounds may be present in other insect species and may have been overlooked because of their low concentration, their cochromatography with the *n*-alkanes that may not have been completely sieved out, and the similarity of their MS with the methylalkanes.

Current studies with carbon label suggests that quantitative differences exist in lipid content among different strains of screwworm. In contrast to the tsetse fly, where sexual dimorphism in the alkanes has also been shown and where mating activity has been found in the dimethylalkane fraction (Carlson et al., 1978), mating stimulant activity has not been found in the alkane or alkene fractions but is present in the more polar fractions of surface extracts. The results of these studies will be presented in future papers.

Acknowledgments—The author wishes to thank Mr. Heldur Hakk for his technical assistance in this work.

(Received September 1, 1988; accepted December 8, 1988)

Abstract—All possible isomeric mono-methylpentacosanes as well as 2,6-, 2,8-, 2,10-, 2,12-, and 2,14-dimethylheptacosane were synthesized. The [^{13}C]NMR shifts and the Kovats indices were determined, and the relationship to separation of isomeric mixtures of insect cuticular waxes are discussed. When several homologous series of hydrocarbon isomeric mixtures are to be separated, it is not practical to attempt complete gas-chromatographic separation of all possible isomers. The mass spectra of the 2,X-dimethylheptacosanes are presented and discussed.

Key Words—Insect hydrocarbon, methylpentacosane, 2,X-dimethylalkane(s), [^{13}C]NMR, mass spectra, Kovats index.

INTRODUCTION

Insect hydrocarbons and their role in the growth, development, and behavior of insects have been widely studied and reviewed (Howard and Blomquist, 1982; Lockey, 1985, 1988; Blomquist and Dillwith, 1985; Blomquist et al., 1987). Characterization of hydrocarbon structure has been accomplished by mass spectrometry with some ambiguity because of the lack of standard compounds for comparison. Several papers have described the synthesis and mass spectra of some dimethylheptacosanes (Pomonis et al., 1980), methylpentatriacontanes, methylheptatriacontanes, a dimethylpentatriacontane, and a dimethylheptatriacontane (Pomonis et al., 1978) for the purpose of corroborating the structure of

these compounds, which had first been isolated from the tobacco hornworm (Nelson and Sukkestad, 1970; Nelson et al., 1972). The structures were assigned solely on the interpretation of the mass spectra of the natural products.

Many hydrocarbon mixtures that are isolated from insects are blends of not only homologs but also of isomers. Separation of the component compounds from these mixtures is usually accomplished by gas chromatography (GC). Structural characterization is performed by determining their Kovats indices (KI) (Kovats, 1965) and combining GC with mass spectrometry (GC-MS). Although homologs may easily be separated by GC, separation of isomers is not so readily accomplished. Capillary GC provides the best resolution of the mixtures. However, because the natural product mixtures contain compounds that range from 23 carbons ($C_{23}H_{48}$) to greater than 40 carbons ($C_{40}H_{82}$), the GC conditions require temperature programming over a wide range to obtain a separation. Theoretical as well as technical considerations do not allow complete GC separations, even by the best capillary chromatography, of all isomers in a series, e.g., not all isomeric methylalkanes can be separated from each other. The reasons for these limitations will be shown and discussed.

Recent biosynthetic studies using ^{13}C -labeled precursors showed incorporation of the label into insect hydrocarbons (Blomquist et al., 1980; Dwyer et al., 1981; Dillwith et al., 1982). Analysis of the isolated hydrocarbons by ^{13}C nuclear magnetic resonance spectrometry ($[^{13}C]NMR$) enabled investigators to identify the exact location of the incorporated label by nondestructive analytical means. The above authors used $[^{13}C]NMR$ data obtained from our synthetic compounds to assign structure to their biosynthetic hydrocarbons.

All possible 12 monomethylpentacosanes ($C_{26}H_{54}$) were synthesized. The GC Kovats index and $[^{13}C]NMR$ for each isomer was determined and will be discussed. The spectra obtained from a tandem mass spectrometer (MS-MS) of each of the monomethylpentacosanes were reported elsewhere (Cerny et al., 1986). In addition to the methylpentacosanes, five 2,X-dimethylheptacosanes were synthesized, viz., 2,6-, 2,8-, 2,10-, 2,12-, and 2,14-dimethylheptacosane. This class of dimethylalkanes was recently reported for the first time and was isolated from the screwworm (Pomonis, 1989). This report verifies the structure of these natural products by synthesis, chromatography, and spectrometry of some analogs.

METHODS AND MATERIALS

Gas Chromatography. The purity of the synthetic intermediates and final products was evaluated by GC. Analyses were performed with a Varian model 3700 flame ionization instrument using a 12- or a 25-m \times 0.20-mm-ID fused silica capillary column [Hewlett-Packard (H-P) cross-linked methyl silicone 19091102, 0.33 μ m film]. A Varian multipurpose type injector in the split mode

with a glass frit insert was used for all capillary chromatography. Sample introduction was by injection using a 100:1 split ratio. The GC was programmed from 150 to 320°C at a variable rate (usually at 4 or 2°/min) with a 2-min initial isothermal and an 8-min final isothermal hold. Helium was the carrier gas at a flow rate of 0.77 ml/min (20 cm/sec) with a head pressure of 12.5 psig. Chromatographic data was reported by a Hewlett-Packard model 3390A integrator interfaced to the GC. The KI (Kovats, 1965) of each methylpentacosane or artificial mixtures of the methylpentacosanes were determined by isothermal gas chromatography at 210°C and *n*-C₂₅H₅₂ and *n*-C₂₆H₅₄ were used as the reference points. The KI of the dimethylheptacosanes were determined with *n*-C₂₇H₅₆, *n*-C₂₈H₅₈, and *n*-C₂₉H₆₀ as the reference points at an isothermal oven setting of 225°C.

Gas Chromatography-Mass Spectrometry. These analyses were performed on a Hewlett-Packard model 5790 GC fitted with a 12.5-m methylsilicone fused silica capillary column with the exit inserted directly into the ionizing chamber of a Finnigan MAT model 1125 mass spectrometer. The transfer line from the gas chromatograph to the spectrometer was at 320°C. Ionizing voltage was 70 eV. The GC was programmed with a 2-min initial isothermal hold at 60°C, then heated to 150°C at 28°/min, then from 150 to 325°C at 3°/min using helium as carrier gas at 1 ml/min. An MS scan was made every 4.8 sec. Data acquisition and storage were made with a PDP 11/34 RSX-11 3.2 version computer dedicated to the spectrometer.

Synthesis. The procedures for synthesis of thiophene intermediates and methyl alkanes via Raney nickel desulfurization have been reported earlier (Pomonis et al., 1976a, b, 1978, 1980) and have not been modified significantly. Infrared and proton magnetic resonance spectra were in agreement with those previously reported (Pomonis et al., 1976a).

Carbon-13 Magnetic Resonance. The spectra were determined in CDCl₃ as 15% solutions with chemical shifts assigned relative to added tetramethylsilane (TMS) using a Jeol FX90Q magnetic resonance spectrometer at 22.5 MHz. Frequency assignments to carbons were calculated from the Lindeman and Adams (1971) formula shown in Levy and Nelson (1972).

RESULTS

Synthesis. Synthesis of two of these methylpentacosanes is shown in Scheme 1. Friedel-Craft acylation of thiophene (**1**) with dodecanoyl chloride in benzene as solvent using stannic chloride as the Lewis acid gave 2-dodecanoylthiophene (**2**) in 82% yield. Modified Wolff-Kishner reduction of **2** gave the 2-dodecylthiophene (**3**) in 78% yield. Further acylation of **3** with nonanoyl chloride and stannic chloride gave **4** in near quantitative yield. Subsequent reaction of **4** with methyl Wittig reagent yielded the methylidene **5** (71% yield),

SCHEME 1.

which was desulfurized with Raney nickel and hydrogenated over palladium-carbon catalyst to give 9-methylpentacosane (**7**) in 61% yield from **5**. Compound **2** was also used to synthesize **13**. Methyl Wittig reagent, when reacted with **2**, gave **8** in 83% yield. To avoid desulfurization and/or poisoning of the heterogeneous catalyst during reduction of the methyldiene double bond, the homogeneous catalyst Tris-triphenylchlororhodium (Osborn et al., 1966; Harmon et al., 1969) was used to synthesize **9** from **8** (61%). Friedel-Crafts acylation, Wolff-Kischner reduction, desulfurization, and catalytic reduction (Pd/C) of **9** yielded **13** (**10**, 99%; **11**, 65%; **13**, 89%).

The 2,X-dimethylheptacosanes were synthesized as outlined in Schemes 2 and 3. Acylation of 3-methylthiophene (**14**) with eicosanoyl chloride gave a mixture of varying proportions of the two possible isomers: 2-acyl-3-methylthiophene (**15a**) and the 5-acyl-3-methylthiophene (**15b**). The ratio of 2-acyl to 5-acyl product was controlled by the type of Lewis acid used. Thus, when

aluminum chloride was used, greater than 98:1 yield of **15a**:**15b** was obtained, while a ratio of 66:44 (**15a**:**15b**) was obtained when stannic chloride was employed. The two isomers were easily separated by alumina column chromatography. Compound **15a** was reduced to **16** by the Wolff-Kischner reaction (73%) and then acylated with 3-methylpropanoyl chloride and stannic chloride to give **17** (90%). Reduction of **17** to **18** (80%) followed by desulfurization and hydrogenation provided the 2,6-dimethylheptacosane (**19**, 90%). Thiophene (**1**) was acylated with either eicosanoyl or octadecanoyl chloride and stannic chloride to provide **20** (99%) or **21** (Scheme 3). Compound **20** was purified by column chromatography through alumina. These acylthiophenes were reacted with methyl Wittig reagent to provide either **22** (62%) or **23**, and the methylene double bond was subsequently reduced in a hydrogen atmosphere with homogeneous catalyst to prevent premature ring desulfurization to give **24** (92%) or **25**. Compounds **24** and **25** were acylated with 2-methylpropanoyl chloride and 4-methylpentanoyl chloride to give **26** (99%) and **27**, respectively, which were then reduced to give **28** (79%) and **29**. Raney nickel desulfurization of the dialkylthiophenes **28** and **29** followed by catalytic reduction with hydrogen over palladium on charcoal gave 2,8- and 2,10-dimethylheptacosane (**30** and

31, 88%) respectively. The 2,12- and 2,14-dimethylheptacosanes were similarly prepared.

Gas Chromatography. Each of the methylpentacosanes were gas chromatographed using various parameters on capillary columns to determine the best conditions for optimum resolution of isomers. The Trenzahl number (separation number) for these compounds was determined also using various chromatographic conditions. Chromatograms of mixtures of groups of three methylalkanes are shown in Figure 1. The best separation for this series was achieved on a 12-m × 0.22-mm-ID column with 1.0 or 0.33 μm film thickness at 210°C isothermal using helium as carrier gas at 30 cm/sec. The KI values of all methylalkanes that were determined in this study are listed in Table 1.

13-Methylpentacosane	14.04	22.72	31.98	29.35	29.74	29.74	29.74	29.74	29.74

The KI values for the 2,X-dimethylheptacosanes show a trend toward decreasing values as the number of methylene groups between the methyl branches increases.

Carbon-13 Nuclear Magnetic Resonance Spectrometry (¹³C]NMR). The NMR spectra of all 12 methylpentacosanes as well as the five 2,X-dimethylheptacosanes were experimentally determined and the chemical shifts are listed in Tables 2 and 3, respectively. The tertiary carbon that bears the branched methyl group in the straight-chain portion has, as predicted by calculation (Levy and Nelson, 1972), a constant chemical shift for all possible isomers between 5- and 13-methylpentacosane. However, the tertiary carbons of 2-, 3-, or 4-methylpentacosane have chemical shifts that are significantly different from the more internally located tertiary carbons of the remaining isomers. This difference reflects the influence of the terminal methyl group at position 1. The branched methyl group, which is carbon-26 in all of the methylpentacosanes (Table 2), also has a fairly constant chemical shift in all possible isomers except for 2-methylpentacosane, in which the two ultimate methyl groups are equivalent. The chemical shift for carbon-26 (in 3-methylpentacosane also reflects the effect of the proximal carbons at positions 2 and 3.

Mass Spectrometry. The synthesis of the complete series of methylpentacosanes made compounds available for mass spectrometric fragmentation studies. These reactions were consistent with the well-known patterns of electron-impact-induced fragmentations for natural or synthetic methylalkanes (McCarthy et al. 1968; Pomonis et al., 1978, 1980). The spectra are not included in this paper.

The mass spectra of the 2,X-dimethylheptacosanes (Figures 2 and 3) reveal that a pair of peaks that are characteristic of fragmentation reactions typical of the more frequently encountered dimethylalkane compounds are missing. The spectra appear to be those of methylalkanes whose gas chromatographic KI values are about 40 units lower than those expected, i.e., very near the KI value of the *n*-alkane of one methylene unit less than the molecular ion mass of the experimental value.

DISCUSSION

Chromatography. In a companion paper (Pomonis, 1989) we described the isolation and characterization of a large number of hydrocarbons from the screwworm fly. We also attempted to quantify the individual hydrocarbons with some success. However, it is not always possible to separate an individual hydrocarbon component from all of its companion isomers even with capillary GC. Quantification of some individual hydrocarbons may therefore become difficult or impossible, causing ambiguity to be introduced; that is, only the mass of the mixture of hydrocarbons is represented by the chromatographic peak and measured.

The separation of two isomers on a GC column is a function of the col-

TABLE 3. CARBON-13 CHEMICAL SHIFTS (PPM) OF SOME SELECTED 2,X-DIMETHYLHEPTACOSANES^a

umnn's separation number (n_{sep}) also known as the Trennzahl number, TZ (Ettre, 1977; Grob, 1977; Jennings, 1980). The TZ number is a measure of the possible number of resolved peaks between peaks of two members of a homologous series differing by one CH_2 unit. The TZ is inversely related to temperature, i.e., the higher separation numbers occur at lower temperatures. Thus, at lower temperatures, the peaks are separated by greater distances, but there is a point beyond which peak shape and resolution suffer. This implies that for efficient separation of moderate to higher molecular weight hydrocarbons at lower temperatures and large retention coefficients, inordinately long analysis times are required.

Our column, under optimized conditions, gave a $\text{TZ} = 34$ for separation of $n\text{-C}_{25}\text{H}_{52}$ and $n\text{-C}_{26}\text{H}_{54}$ according to the equation shown (Jennings, 1980):

$$\text{TZ} = [t_{R(n+1)} - t_{R(n)} / w_{0.5n} + w_{0.5n+1}] - 1. \quad (1)$$

It is possible to calculate the separation number necessary to separate two compounds whose KIs are known and which fall between the two n -paraffins (Jennings, 1980). The TZ is related to KI by the equation:

$$\text{TZ} = [100 / (\text{KI}_2 - \text{KI}_1)] - 1 \quad (2)$$

thus for 4-methylpentacosane (KI 2557) and 2-methylpentacosane (KI 2562) at 210°C isothermal on a 12.5-m capillary column, the relationship becomes:

$$\text{TZ} = [100 / (2562 - 2557)] - 1 = 19$$

Thus, the efficiency of the column has to be 19 or greater to resolve the two isomers. An example of this separation is shown in Figure 1 and includes a

third isomer, 3-methylpentacosane. Other factors that improve column efficiency are (1) increasing the linear flow velocity with use of hydrogen in preference to helium as carrier gas since hydrogen has a flatter van Deemter curve and (2) increasing the length of the column since resolution is a square root function of the column length (Jennings, 1980). However, increasing the column length to 50 m (4×12.5) only doubles the resolution ($R_s = 4^{1/2} = 2$). It also increases the analysis time and, under isothermal conditions, causes peak broadening. From equation 2 and from the KI values (Table 1) for various methylpentacosanes, it is seen that in order to separate some isomers a TZ = 99 (10-methyl- vs. 11-methylpentacosane) would be required. However, 10-methylpentacosane may more easily be separated from 4-methylpentacosane (TZ = 3.4).

From the foregoing argument, it is seen that the analyst who is dealing with a mixture of homologous hydrocarbons composed of several isomeric series such as those isolated from the insect surface lipids faces a formidable task if it is desired to separate the mixture into its individual component parts.

Magnetic Resonance Spectrometry. Isotope-labeled precursors such as malonic, 2-methylmalonic, propionic, and succinic as well as tetracosanoic acids have been used in studies to determine the metabolic origin of the methyl branches in insect hydrocarbons (Blomquist et al., 1980; Dwyer et al., 1981; Dillwith et al., 1982; Pomonis and Hakk, 1987). When radiolabel is biochemically incorporated in a molecule, the position of that label in the product is

FIG. 2. EI mass spectra of synthetic compounds. Top: 2,10-dimethyl heptacosane (KI 2802). Middle: 2,8-dimethylheptacosane (KI 2802). Bottom: 2,6-dimethylheptacosane (KI 2808).

often determined by tedious and meticulous oxidative degradation. Alkanes are resistant to oxidative reactions, and the products of the oxidation are those of randomized cleavages leading to ambiguity as to the position of the label. However, ^{13}C -labeling allows the investigator to use nondestructive [^{13}C]NMR spectrometry to precisely observe the position of the incorporated label in the metabolic product. For example, [^{13}C]NMR analysis of the isolated hydrocarbon fractions from housefly surface lipids showed that the 2-methyl group in 2-[^{13}C]methylmalonic acid was the origin of the methyl branch in internally branched methylalkanes by isotope enrichment (Dillwith et al., 1982). The synthesis of all 12 methylpentacosanes permitted a systematic assignment of ^{13}C chemical shift values for each carbon in the molecules, with the experimental values (Table 2) being in very good agreement with the calculated values computed from an equation taken from Levy and Nelson (1972). A few of these experimentally determined chemical shift values were used in locating the position of the incorporated label (enrichment) in biosynthetic studies in the termite (Blomquist et al., 1980) and housefly (Dillwith et al., 1982).

Mass Spectra. In the companion paper (Pomonis, 1989) are described the isolation and characterization of a number of alkanes from the screwworm fly adult. Of special interest is the report of the characterization of 2,X- and 3,X-dimethylalkanes. The 2,X-dimethylalkanes are a new category of insect alkanes and were reported for the first time. Characterization of this group of alkanes was difficult because (1) they were present in very low concentration; (2) they were easily masked, chromatographically, under the *n*-alkane peak; and (3) most confounding of all, when all *n*-alkanes were removed by molecular sieving, two chromatographic peaks gave the same mass spectra. The unknown compounds were represented by a peak that chromatographed with a nominal KI of 2900 but presented mass spectra nearly identical to methylnonacosanes ($\text{C}_{30}\text{H}_{62}$), which are included in a peak with a nominal KI 2935 (Pomonis, 1989).

After considering several possible structures, the 2,X-dimethylalkane alternative seemed to fit the data but did not adhere to one of the several useful empirical rules of fragmentation for dimethylalkanes under electron impact (McCarthy et al., 1968; Nelson et al., 1972; Pomonis et al., 1980). Missing were those characteristically prominent single masses due to cleavage yielding fragment ions that include both methyl groups (Pomonis et al., 1980) and those due to loss of C_3H_7 (M-43). To test the 2,X-dimethylalkane hypothesis, several 2,X-dimethylheptacosanes were synthesized and the MS that were determined are shown in Figures 2 and 3. The fragmentation reactions of the synthetic compounds supported our earlier interpretations and assignment of structures as the 2,X-dimethylalkanes.

We have synthesized a number of 2,X-dimethylheptacosanes and determined and reported their mass spectra, [^{13}C]NMR, as well as their chromatographic retention indices (KI). These data corroborate the structures of a number of previously unreported compounds isolated from the screwworm fly (Pomonis,

1988). We also reported the synthesis, some spectral properties, and KI of the possible monomethylpentacosanes. The relationship of these physical properties to those of a few other methyl alkanes were compared and discussed.

Abstract—Simulated large aspen tortrix (*Choristoneura confictana*) herbivory of quaking aspen (*Populus tremuloides*) induces significant increases in concentrations of two phenol glycosides, salicortin and tremulacin, in leaves within 24 hr. Crushing of leaf tissue, as must occur when aspen leaves are eaten by chewing insects such as the large aspen tortrix, results in conversion of salicortin and tremulacin to 6-hydroxy-2-cyclohexenone (6-HCH). Salicortin, tremulacin, 6-HCH, and its degradation product, catechol, are all toxic to the large aspen tortrix when fed on an artificial diet. These damage-induced chemical changes provide a plausible mechanism for short-term resistance induced in aspen leaves by insect herbivory.

Key Words—Chemical induction, phenol glycosides, salicortin, tremulacin, 6-hydroxy-2-cyclohexenone, quaking aspen, *populus tremuloides* large aspen tortrix, *choristoneura confictana*, Lepidoptera, Tortricidae, chemical defense, short-term induction.

INTRODUCTION

Real or simulated insect herbivory can change the secondary chemistry of leaves and reduce their food value for insects within 24 hr (Rhoades, 1979, 1983; Haukioja, 1980; reviews in Raupp and Tallamy, 1989). These changes have

been attributed to a short-term induced defense (STID) response targeted by the plant at the attacking insect. The mechanisms of STID in some crop plants are well understood (e.g., Green and Ryan, 1972; Tallamy, 1985; Broadway et al., 1986) relative to the mechanisms of STID in woody plant leaves, which are poorly understood (Hartley and Lawton 1987; Jones and Coleman, 1989). Indeed, the existence of STID in woody plant leaves has been questioned (Fowler and Lawton, 1985; Myers, 1988).

In this paper, we report that simulated large aspen tortrix (*Choristoneura conflictana*) damage of quaking aspen (*Populus tremuloides*) leaves induces within 24 hr a sequence of changes in leaf phenolic glycoside chemistry that is potentially detrimental to the large aspen tortrix. We propose that these changes provide the first clearly defined chemical mechanism for STID in a woody plant.

Natural History of Quaking Aspen–Large Aspen Tortrix Interaction In Alaska. The natural history of the quaking aspen–large aspen tortrix interaction in Alaska has been described in detail elsewhere (Beckwith, 1968, and references therein). For the purposes of this study, suffice it to say that large aspen tortrix populations break out in interior Alaska at approximately 10- to 15-year intervals. During these outbreaks quaking aspen is severely (80–100%) defoliated early in the growing season (within three to four weeks of bud break) for two to four years in sequence by second to fifth instar larvae. When feeding upon aspen, larvae first spend several hours webbing themselves within two or more adjacent leaves (often all leaves on a single short shoot). Over the next two to four days the larvae eat these leaves. Thus, they feed upon damaged leaves for a sufficient period of time to experience the effects of the damage-induced changes we describe.

METHODS AND MATERIALS

Experimental Aspens. We studied 3-m-tall quaking aspen saplings growing on deep loess soils (Van Cleve and Oliver, 1982) near Fairbanks, Alaska. At the time of our experiments, these aspens had not been severely attacked by insects for 12 years, were experiencing minimal insect attack, and were located at least 5 km away from aspens experiencing significant insect attack. Thus, it is unlikely that either insect damage or communication between trees had altered their leaf chemistry (e.g., Rhoades, 1983) at the time we initiated experimental leaf damage.

In each experiment, several leaves on an aspen short shoot were damaged by tearing their edges to simulate damage caused by third to fifth instar tortrix larvae. Leaves from a similar short shoot on a different branch from the same

tree served as controls for this experiment. After 24 hr, damaged and control leaves were collected, immediately freeze-dried, and stored at -20°C until chemically analyzed (see below). Each individual aspen provided one replicate pair of leaves (control, damaged) for chemical analysis. This experimental design precluded pseudoreplication (Hurlbert, 1984), a problem in other studies of STID in woody species (Fowler and Lawton 1985). Because measurements of phenol glycoside levels were not normally distributed, a nonparametric test, the Wilcoxon paired-sample test (Zar, 1974) was used to test for significance.

We assayed leaves for phenol glycosides. To minimize the possibility of artifacts, fresh leaves were vacuum-dried immediately upon reaching the laboratory. Prior freezing or crushing of the leaves was not done because earlier observations (Lindroth and Pajutee, 1987; Clausen, unpublished) indicated that these procedures result in some conversion of salicortin and tremulacin into salicin and tremuloiden, respectively. Our methodology, however, did not result in these conversions because analyses of leaves collected late in the growing season indicated no salicin or tremuloiden unless leaves were frozen or crushed prior to drying (Clausen, unpublished). After drying, three leaves were soaked in 10.0 ml of absolute methanol containing 0.54 mg of pinosylvin as an internal standard. After soaking for 14 days at 10°C , the extracts were analyzed for phenol glycosides by HPLC using conditions reported earlier (Lindroth and Pajutee, 1987; Bryant et al., 1987).

Secondary Metabolite Bioassays. We incorporated aspen leaf phenol glycosides (3 and 6% dry wt) and their degradation products (1.6% dry wt; see below) into artificial diets (Bioserve; spruce budworm) supplemented with 1% freeze-dried aspen leaf powder as a feeding stimulant. In the cases of 6-hydroxycyclohexenone (6-HCH) and catechol, concentrations were used based on the salicortin/tremulacin diet (6% each) and calculations that assumed complete conversions (Figure 1). An unadulterated diet served as a control. Fifty larvae per diet were used in this experiment. Salicortin and tremulacin were isolated by the procedure of Lindroth et al. (1987). 6-HCH was prepared according to the procedure of Rubottom and Gruber (1978), and catechol was obtained from Sigma Chemical Co. Larvae were reared individually in 5-cm Petri dishes, and fresh food was added daily to ensure larvae never ran out of food. All larvae were reared at temperatures (24°C) and light conditions similar to that found in the crowns of quaking aspen early in the growing season when trees are attacked by second to fifth instar tortrix larvae.

Electrophilicity of 6-hydroxycyclohexenone (6-HCH). 2-Cyclohexen-1-one (40.7 mg, 0.42 mmol), 6-HCH (41.5 mg, 0.37 mmol), thiophenol (41.0 μl , 0.40 mmol), and camphor (38.7 mg, internal standard) were mixed in 1.0 ml of methanol and stirred at room temperature for 5 hr. GC analysis of the mixture was performed (RSL-200 column, 30 m \times 0.53 mm; flow rate of 6.0

FIG. 1. Structures of aspen's major secondary compounds and their products following simulated herbivory.

ml/min He); temperature program of 80°C, 1 min; 80–150°C at 10°/min; 150°C, 2 min). The retention times for cyclohexenone, thiophenol, 6-HCH, and camphor were about 4.0, 4.4, 5.2, and 7.0 min, respectively.

The above experiment was repeated using similar amounts of reagents except that a hydrophobic solvent (benzene) was used and the reaction progressed for 48 hr prior to GC analyses.

Base-Catalyzed Oxidation of 6-HCH. A buffered (pH 10) aqueous solution (3 ml) of 6-HCH (ca. 50 mg) was stirred vigorously in an open flask. After 2 hr, the mixture was analyzed by TLC (silica gel; CH₂Cl₂/acetone, 95 : 5) using phenol, catechol, and 6-HCH as standards.

Enzyme Preparation. A crude enzyme preparation was obtained from aspen leaves by the procedure of Spencer and Seigler (1984). It was tested by adding salicortin (10 mg/ml) and, after incubation (pH 6.8, phosphate buffer; 24 hr; room temperature), analyzed by TLC (silica gel; CHCl₃/MeOH, 85 : 15) for the presence of salicortin/salicin and by GC-MS of an ether extract for the presence of 6-HCH. The above procedure was repeated using tremulacin as a substrate and analyzing for tremuloiden/6-HCH products as described above.

In Vivo Conversion of Tremulacin and Salicortin into Tremuloiden and Salicin, Respectively, and 6-HCH. Fresh leaves (containing salicortin and tremulacin but little salicin and tremuloiden) were cut along the main vein and divided into two samples. One sample was immediately extracted with methanol and served as a control. The other sample was ground in a mortar and pestle containing a water-sand mixture. After 30 min, the crushed sample was also extracted with methanol. After 24 hr of extraction, both samples were analyzed

by HPLC (for glycosides) and by GC (for 6-HCH). The experiment was repeated except, prior to crushing, leaves were heated to 70°C for 20 min to denature any leaf enzymes.

RESULTS

Quaking Aspen Leaf Secondary Chemistry. In agreement with the reports of Lindroth et al. (1987) and Pearl and Darling (1971b), we found four related phenol glycosides—salicin, tremuloiden, salicortin, and tremulacin (Figure 1)—in aspen leaves. Additionally, a volatile component, 6-hydroxy-2-cyclohexenone (6-HCH), was found in damaged leaf tissue. This substance has only been reported once before as a natural product (Mattes et al., 1987). Arguments will be presented in this paper that this substance is not an artifact of extraction (e.g., Lindroth and Pajutee, 1987) and, furthermore, that it is a component of STID in quaking aspen leaves.

Effects of Simulated Herbivory. Leaf damage, as occurs when second to fifth instar large aspen tortrix larvae feed on quaking aspen leaves, resulted in a significant ($P < 0.0025$, Wilcoxon paired-sample test) increase in leaf salicortin within 24 hr (Table 1). In addition, tremulacin ($P < 0.05$, Wilcoxon paired-sample test) levels increased following leaf damage only to a lesser extent

(Table 1). No such change was observed in the concentrations of either salicin or tremuloiden. Thus quaking aspen is capable of selectively altering the concentrations of phenol glycosides in its leaves upon leaf damage.

Additional crushing of leaf tissue, as must occur when it is chewed by insects, resulted in complete conversion of salicortin and tremulacin into salicin and tremuloiden, respectively, with a significant (ca. fivefold; $P < 0.05$, paired t test) increase in leaf 6-HCH (Figure 2). This second change did not occur in previously heated leaves, indicating that it is enzymatically mediated. Further evidence for the enzymatic nature of these conversions was gathered by treating salicortin with an enzyme preparation obtained from quaking aspen leaves using the procedure of Spencer and Seigler (1984) and observing the formation of both salicin and 6-HCH at the expense of salicortin. Tremulacin, on the other hand, did not convert to tremuloiden and 6-HCH when treated with the same enzyme preparation. In this latter case, the lack of an observable reaction may have been due to tremulacin's insolubility in the reaction medium. In neither case did a boiled enzyme preparation result in any conversions.

Bioassays. Incorporation of salicortin, tremulacin, and their mixture in artificial diets at a 3% (dry wt) concentration leaves had no significant effect upon pupal weights. However, incorporation of salicortin, tremulacin, and their mixture at 6% (dry wt) levels reduced pupal weights in comparison to the control diet (Figure 3; $P < 0.01$, all comparisons). In addition, both 6-HCH and catechol, at concentrations potentially formed in the insect gut from salicortin and tremulacin, reduced pupal weights relative to control ($P < 0.01$, both comparisons). The possibility that the activity of 6-HCH in artificial diets was due only to the decomposition products (catechol or phenol) was tested by analyzing

FIG. 2. Effect of leaf crushing on secondary metabolite levels. All changes are significant at $P < 0.001$.

FIG. 3. Bioassay results on artificial diets. All comparisons with control diet are significant at $P < 0.01$. Concentrations of glycosides and their decomposition products were 6.0% and 1.6%, respectively.

unused 6-HCH diet for 6-HCH, catechol, and phenol by GC. Only about 30% of the original 6-HCH placed on the diet could be accounted for at the end of the feeding trial, but no phenol or catechol was detected.

Reactions of 6-HCH. When treated with base under aerobic conditions, 6-HCH was completely converted to catechol within 2 hr. In methanol, 6-HCH reacts with thiophenol slightly faster (about 10%) than 2-cyclohexen-1-one to give an addition product (Figure 4) whose structure was determined based on GC-MS and $[^1\text{H}]$ - and $[^{13}\text{C}]$ NMR spectra. Under hydrophobic conditions (benzene), however, 6-HCH reacted over twice as fast as 2-cyclohexen-1-one. Thus, especially in a hydrophobic environment, 6-HCH appears to be a potent electrophile, capable of reacting with biological nucleophiles (e.g., proteins, nucleic acids).

FIG. 4. Reaction mechanism of 6-HCH (an electrophile) with thiophenol (a typical nucleophile).

DISCUSSION

Herbivore-Related Consequences of Attacking Quaking Aspen Leaves. Mattson and Palmer (1987) found that simulated insect attack of quaking aspen leaves resulted in a significant increase in leaf phenols in damaged leaves. Our results indicate that this increase is a result of a rise in the concentrations of two of quaking aspen's four leaf phenol glycosides, salicortin and tremulacin. Although we have not systematically investigated the variables that could affect the magnitude of this response (e.g., nature and degree of leaf damage, induction time, seasonal effects, leaf age), our experimental procedure resulted in increases of ca. 13 and 3 mg phenol glycoside/g leaf tissue for salicortin and tremulacin, respectively. These increases potentially provide significantly enhanced defenses of leaves that originally had low levels of phenol glycosides but only marginal increases in the defense of previously well-defended leaves.

Furthermore, we found that ingestion of these two phenol glycosides has deleterious effects on the growth of large aspen tortrix larvae. This result is in agreement with our previous studies of effects of quaking aspen leaf secondary metabolites upon large aspen tortrix larvae (Bryant et al., 1987) and results of studies of quaking aspen leaf phenol glycosides on swallowtail butterfly larvae (Lindroth et al., 1988).

The increases in phenol glycoside content in aspen foliage following simulated herbivory can have significant effects on insect herbivores such as the large aspen tortrix and the swallowtail in the field. A large aspen tortrix larva confines itself within a group of leaves prior to feeding (Beckwith, 1968) and subsequently feeds for two to four days before emerging. Hence, the tortrix cannot avoid any induced changes that it has caused. A swallowtail larva, on the other hand, feeds on a single leaf for only a few hours before it leaves the leaf in search for a new one (MacLean, personal communication). This observation suggests that during feeding by the swallowtail, the food quality of the aspen leaf has declined sufficiently to eventually be rejected.

Crushing, as occurs when aspen leaves are eaten by chewing insects such as the large aspen tortrix or swallowtail butterfly, resulted in enzymatic conversion of salicortin to 6-HCH, a potentially very toxic natural product, with salicin as a by-product. Although we have not been able to obtain an enzyme preparation that converts tremulacin into 6-HCH and tremuloiden (presumably due, at least in part, to solubility restrictions), circumstantial experimental evidence (leaf crushing causes rises in 6-HCH and tremuloiden concentrations and a decrease in tremulacin levels) indicates that such an enzymatic conversion is likely. In addition, it is difficult to envision a nonenzymatic route that would allow these transformations under mild (room temperature, pH \approx 7) conditions. These results can also explain Lindroth and Pajutee's (1987) observation that certain extraction procedures cause aspen's leaf chemistry to change.

Irrespective of the relative contributions of salicortin and tremulacin to 6-HCH production, we observed a fivefold increase in 6-HCH concentration in crushed leaf tissue. This increase is a conservative estimate of the actual rise in 6-HCH in crushed leaf tissue because of the reactivity of this substance with leaf tissue (if 6-HCH is painted on leaves, they turn black immediately; Bryant, personal observation). However, our results (Figures 2 and 3) indicate that 6-HCH, at concentrations that can be formed from moderate levels of salicortin and tremulacin is sufficient to reduce the food quality of aspen leaves as food for second to fifth instar large aspen tortrix larvae.

Such a reduction in quality can be expected for several reasons. Under basic conditions, as occur in the gut of many forest defoliators, 6-HCH will rapidly convert to catechol (this paper; Pearl and Darling, 1971a), a substance that reduces the growth of tortrix larvae (e.g., Figure 3) and is toxic to other herbivores (Reese and Beck, 1976; Todd et al., 1971). Although less likely [because of the basic/oxidative conditions in most Lepidoptera guts (Isman, personal communication)], conversion of 6-HCH to phenol (a toxic substance; Sax, 1979) upon exposure to mildly acidic conditions (Mattes et al., 1987) provides another potentially detrimental effect of ingestion of 6-HCH. Additionally, 6-HCH, somewhat similar in structure to 4-hydroxy-2-cyclopenten-1-one (a substance toxic to herbivores because of its electrophilic properties; Spencer, 1987; Hall et al., 1977), can act as an electrophile.

Source of Salicortin and Tremulacin. There are two mechanisms that could cause the damage-induced rise in salicortin and tremulacin we observed in aspen leaves: (1) de novo synthesis from recent photosynthate and/or (2) translocation of salicortin and tremulacin from internodes or nearby leaves upon insect attack. While we cannot completely rule out the first possibility, circumstantial evidence supports the translocation mechanism. Current growth internodes of the quaking aspen population we studied contain salicortin and tremulacin in high concentrations (about 10 and 6%, respectively) and no salicin or tremuloiden (Clausen et al., 1989). Thus, translocation of phenolic glycosides from internodes to leaves could account for the rapid increase in salicortin and tremulacin and absence of an increase in the concentrations of salicin and tremuloiden that we observed in damaged aspen leaves. Experiments of MacLeod and Pridham (1966) provide further evidence for such a mechanism, and Tallamy (1985) has demonstrated that translocation of cucurbitacins is a likely mechanism of short-term induced defense (STID) in squash.

Proposed Mechanism for Short-Term Induced Defense in Quaking Aspen Leaves. We conclude by proposing a clearly defined, easily testable chemical model for STID in quaking aspen leaves (Figure 5). Upon initial attack (biting), the levels of salicortin and tremulacin rise in the damaged leaf within 24 hr. This rise is largely a result of upon-demand translocation of salicortin and tremulacin from internode stores to leaves, although some de novo synthesis by

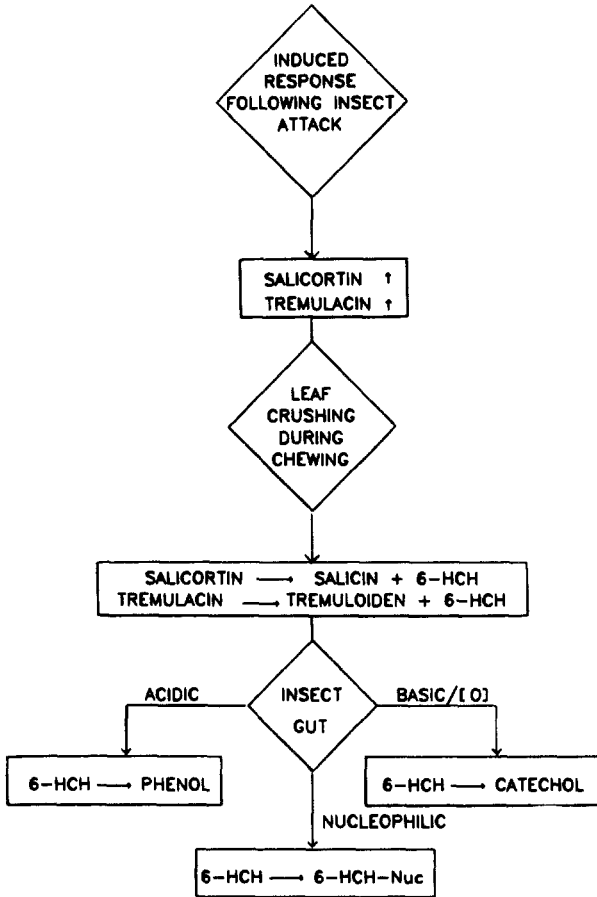

FIG. 5. Chemical model for short-term induction in quaking aspen.

the damaged leaves or leaves “plumbed” to the damaged leaves cannot be precluded as a contributing factor. Upon ingestion, salicortin and tremulacin are converted to 6-HCH by aspen leaf esterases. Within the herbivore’s gut, 6-HCH is converted to one of several toxins, such as catechol or phenol, depending upon gut conditions, or is trapped by nucleophiles. These chemical changes reduce the food value of aspen leaves for defoliators (such as the tortrix) that feed upon the damaged leaves for 24–72 hr. Validation of this mechanism for STID in quaking aspen would provide strong support for the Haukioja-Rhoades short-term induced defense hypothesis (Rhoades, 1979; Haukioja, 1980).

(Received November 1, 1988; accepted December 19, 1988)

Abstract—Xanthotoxin is a phototoxic allomone found in many of the host plants of the black swallowtail, *Papilio polyxenes* (Lepidoptera: Papilionidae). When added to the diet of final instar larvae, xanthotoxin can induce the cytochrome P450 monooxygenase (P450) activity in midgut microsomes by which it is detoxified. Induction is dose-dependent, increasing sevenfold when larvae feed on parsley treated topically with xanthotoxin at 0.5 or 1.0% fresh weight. Although xanthotoxin exerts much of its toxic effects when photoactivated by ultraviolet light, induction of P450 activity did not differ in the presence or absence of ultraviolet light. Despite a 4.7-fold induction of xanthotoxin-metabolizing P450 activity, total P450 content measured in the same microsomal samples did not increase significantly. These data indicate that multiple forms of P450 exist in the black swallowtail midgut and that they are differentially induced by xanthotoxin.

Key Words—Black swallowtail, *Papilio polyxenes*, Lepidoptera, Papilionidae, microsomal cytochrome P450, induction, xanthotoxin, furanocoumarins, plant defensive compounds.

INTRODUCTION

Cytochrome P450 monooxygenases (P450s) are heme proteins that function in the oxidation of a wide range of endogenous and xenobiotic substrates. Because plants produce a diversity of secondary metabolites that act as defensive compounds, many potentially toxic xenobiotics are encountered by organisms that

feed on plants. Studies on selected insects, notably lepidopterous larvae, have shown that many plant secondary metabolites act as inducers of P450 (e.g., Brattsten et al., 1977; Brattsten, 1987; Yu, 1987). However, as discussed by Dowd et al. (1983), Gould (1984), and Nitao (1989), P450 activity following treatment with plant allomones has, in almost all cases, been assayed against model substrates such as insecticides rather than against the inducing substrates themselves. Thus, the nature of the interaction between P450s and plant allomones has been examined for only a few natural systems. In this study, we examined ecological and physiological factors affecting P450 metabolism of a natural substrate, xanthotoxin, a furanocoumarin, by the black swallowtail, *Papilio polyxenes* (Lepidoptera: Papilionidae), which commonly encounters furanocoumarins in its host plants.

Furanocoumarins are secondary metabolites characteristic of the plant families Umbelliferae (=Apiaceae) and Rutaceae. The black swallowtail feeds exclusively on plants in these two families, and several of its hosts contain an abundance of xanthotoxin (Berenbaum and Feeny, 1981). Ivie et al. (1983) determined that tolerance of black swallowtail larvae to xanthotoxin is conveyed by rapid detoxification in midgut tissue and identified two oxidized metabolites of xanthotoxin in the excreta of larvae. It was subsequently determined that detoxification occurs principally in the microsomal fraction of the midgut, is NADPH-dependent, and is inhibited by piperonyl butoxide (Bull et al., 1986), suggesting that xanthotoxin metabolism in the black swallowtail is mediated by P450. Nitao (1989) found that the parsnip webworm, *Depressaria pastinacella* (Lepidoptera: Oecophoridae), a specialist on two umbellifers high in xanthotoxin content, also detoxifies xanthotoxin by P450 activity. Moreover, he demonstrated that xanthotoxin induces the P450 activity by which it is detoxified.

We investigated whether midgut P450 detoxification of xanthotoxin can be similarly induced in the black swallowtail, and we examined several additional aspects of xanthotoxin detoxification in this species, namely pH optimum, dose dependence, effect of ultraviolet (UV) light, and increase in total P450 content. Dose-dependent induction of P450 detoxification of xanthotoxin in the black swallowtail is of potential ecological significance in that the content of this allomone varies among host species (Berenbaum, 1981), within host populations (Berenbaum et al., 1986), and temporally and anatomically within a single host (Nitao and Zangerl, 1987; Zangerl and Bazzaz, 1989). Xanthotoxin and many other furanocoumarins exert at least part of their toxic activity, i.e., cross-linking of DNA strands and generation of oxygen radicals, upon photoactivation by UV light (Murray et al., 1982). However, it is not known whether photoactivation of xanthotoxin has an effect on its induction of cytochrome P450. Finally, there is strong evidence that insects, like mammals (Nebert and Gonzalez, 1987), have multiple forms of P450 (Hodgson, 1985). We compared the increase of P450-mediated xanthotoxin metabolism with the increase in

overall P450 content to determine whether a subset of P450 isozymes is induced, thus providing insight into the degree of specialization of P450 in oligophagous insect herbivores.

METHODS AND MATERIALS

Chemicals. Xanthotoxin was purchased from Sigma Chemical Co., St. Louis, Missouri, and from Aldrich Chemical Co., Milwaukee, Wisconsin. All other reagents, unless otherwise noted, were purchased from Sigma.

Insects. A laboratory colony of the black swallowtail was established with females collected in east central Illinois in June 1988. Larvae were maintained at 21°C and 70% relative humidity, on parsley, *Petroselinum sativum* (Italian flat leaf), grown in a plot on the University of Illinois at Urbana-Champaign campus. Parsley was chosen as host plant because of its low xanthotoxin content. The xanthotoxin content of leaves sampled from our plot in June and August ranged from 0.003 to 0.009% of fresh weight (fw), as determined by a method slightly modified from Berenbaum et al. (1984).

For all experiments, newly molted final instar larvae were transferred from untreated parsley to fresh parsley sprigs treated topically with either acetone or an acetone solution of xanthotoxin. Xanthotoxin solutions of different concentration were prepared, such that equal volumes (0.25 ml/g fw parsley) could be applied to obtain diets containing topically added xanthotoxin at 0.1, 0.5, and 1.0% fw. Larvae were reared on the treated parsley for three days before microsomes were isolated.

For experiments testing the effect of UV light on P450 induction by xanthotoxin, larvae were reared under 40-W BLB bulbs (General Electric Co., Cleveland, Ohio). Cages containing control larvae were shielded with Plexiglas UV screens opaque to wavelengths of less than 400 nm. Using a model UVX Digital Radiometer (Ultra-Violet Products, San Gabriel, California), the intensity of UVA light (approximately 320–420 nm) was measured as 270 $\mu\text{W}/\text{cm}^2$ in treatment cages, and as 5 $\mu\text{W}/\text{cm}^2$ in control cages.

Assays of P450 Activity and Content. Midguts were dissected from larvae and placed in sucrose medium [0.25 M sucrose, 1% polyvinylpyrrolidone, 1.1 mM EDTA (pH 7.5), and 2 mM phenylmethyl sulfonyl fluoride (PMSF)], then slit open, cleared of food, and rinsed in fresh medium (Crankshaw et al., 1979; Nitao, 1989); these and all further manipulations were carried out on ice. The midguts were ground in 3–10 volumes of sucrose medium (as described, except containing 0.5 mM PMSF and 5 $\mu\text{g}/\text{ml}$ leupeptin, a broad-spectrum protease inhibitor) by hand with 10 strokes of a ground glass tissue homogenizer. The homogenate was filtered through four layers of cheesecloth and centrifuged at 10,000g for 10 min at 4°C. The 10,000-g supernatant was centrifuged at

100,000g for 1 hr at 4°C, and the resulting microsomal pellet was resuspended in cold 0.1 M sodium phosphate (pH 7.8) containing 0.5 mM PMSF and 5 µg/ml leupeptin.

Assays measuring xanthotoxin-metabolic activities were run for 30 min at 30°C in a shaking water bath. One-milliliter reactions contained 0.1 M sodium phosphate (pH 7.8), 0.3 mM NADP, 3.0 mM glucose-6-phosphate, 0.5 units glucose-6-phosphate dehydrogenase, 10 µg xanthotoxin, and 0.05–0.2 mg protein. Reactions were started with the addition of microsomes and stopped with 250 µl 2 N HCl. After acidification, 10 µg of bergapten, an isomer of xanthotoxin, were added to each assay for use as an internal standard. Reaction mixtures were extracted twice with one volume of ethyl acetate, and the organic phases were evaporated to dryness. The samples were resuspended in 100 µl ethyl acetate and the amounts of xanthotoxin and bergapten were measured by high-pressure liquid chromatography, slightly modified from Berenbaum et al. (1984).

For all experiments, time zero control assays (equal in number to the number of duplicates run per treatment) were prepared, acidified before the addition of microsomal protein but otherwise treated identically to reaction flasks. To compensate for any substrate loss not attributable to enzymatic activity, the mean amount of substrate quantified in time zero controls was assumed to be the amount of substrate present in each reaction at the start of the enzyme assay. The amount of xanthotoxin metabolized in each reaction was calculated by subtracting the amount of xanthotoxin remaining in each flask at the end of the reaction from the mean amount of substrate at time zero.

Since the activity of P450 is affected by the pH of the assay conditions (Hodgson, 1985), we conducted a series of assays in reaction mixtures ranging from pH 7.0 to 9.0. The microsomes used were from final instar larvae reared on parsley treated with xanthotoxin at 0.1% fw. We observed a broad optimum for xanthotoxin metabolism ranging from pH 7.5 to 8.0 (Table 1) and conducted all subsequent experiments at pH 7.8. We also verified that the metabolism of xanthotoxin in our system was linear with respect to protein concentration and the 30-min incubation period.

Bull et al. (1986) demonstrated that xanthotoxin metabolism by black swallowtail midgut microsomes is carried out by mixed function oxidases, the activity of which is dependent on the presence of NADPH. To determine if increased metabolism due to prior exposure to xanthotoxin is also mediated by NADPH-dependent enzymes, we conducted preliminary xanthotoxin metabolism assays in the presence and absence of NADPH-generating systems. In two experiments with microsomes from induced larvae, xanthotoxin metabolism in assays lacking NADPH averaged only 6% of that in assays containing the NADPH-generating system.

Total P450 content was determined by carbon monoxide difference spectra

8.0	5.61 ± 0.51b
8.5	4.51 ± 0.09a
9.0	4.20 ± 0.39a

^aMeans ± SD of one experiment assayed in quadruplicate. One-way ANOVA showed a significant effect of pH on xanthotoxin metabolized ($F_{4,15} = 10.76$, $P = 0.003$). Means followed by the same letter are not significantly different at $P = 0.05$, pairwise comparisons using LSD.

(Omura and Sato, 1964). For each experiment, one or two samples from each microsomal protein preparation were analyzed, and two scans were run on each sample. Determinations of protein concentration in samples were made with protein dye from Bio-Rad Chemical Division, Richmond, California, using bovine serum albumin as a standard. Data were analyzed by one-way or two-way ANOVA with the following main effects included in the analyses: pH (Table 1), presence of UV light (Table 2), and xanthotoxin added to diet (Tables 2, 3, and 4).

RESULTS AND DISCUSSION

Xanthotoxin metabolism in the midgut of the black swallowtail is inducible, increasing approximately threefold and sevenfold when larvae are fed parsley treated with xanthotoxin at 0.1% and 0.5% or 1.0% fw, respectively (Table 2). The induction process appears to be dose-dependent, but maximum induction is reached at or before a diet with a xanthotoxin content of 0.5% fw. This result may reflect physiological adaptation to the levels of xanthotoxin encountered by the black swallowtail in its diet in nature. Of its three most common hosts in eastern North America, wild parsnip, *Pastinaca sativa*, wild carrot, *Daucus carota*, and poison hemlock, *Conium maculatum* (Feeny et al., 1985), xanthotoxin content is highest in wild parsnip, ranging up to 1% dry weight (dw) in foliage and ripe fruits (Zangerl and Berenbaum, personal observations). Since the parsley foliage used in our study was 83% water by fw, our xanthotoxin levels of 0.1, 0.5, and 1.0% fw correspond to approximately 0.59, 2.9, and 5.9% dw, respectively.

TABLE 2. EFFECT OF DIETARY XANTHOTOXIN CONTENT ON INDUCTION OF P450-MEDIATED METABOLISM OF XANTHOTOXIN IN MIDGUT MICROSOMES OF BLACK SWALLOWTAIL LARVAE

Diet (% fw xanthotoxin)	Xanthotoxin metabolized (nmol/min/mg protein) ^a
0	1.10 ± 0.30a
0.1	3.01 ± 0.39b
0.5	8.33 ± 0.76c
1.0	7.92 ± 1.73c

^aMean ± SD of two experiments, assayed in triplicate. One-way ANOVA showed a significant effect of diet on xanthotoxin metabolized ($F_{3,20} = 81.11$, $P = 0.0001$). Means followed by the same letter are not significantly different at $P = 0.05$, pairwise comparisons using LSD.

There are at least two ways in which a black swallowtail larva is likely to encounter differing xanthotoxin content in its diet within a single instar and, therefore, benefit from an inducible xanthotoxin-metabolic P450 activity. First, these caterpillars feed on the flowers, seeds, and foliage of umbelliferous plants (Scott, 1986), and all of these parts are often available to a larva during a single instar. The content of xanthotoxin and other furanocoumarins in the reproductive parts of the wild parsnip increases as a reproductive unit matures through bud, male flower, female flower, and ripe fruit stages (Nitao and Zangerl, 1987). Second, furanocoumarin content in parsnip leaves can be induced by UV light (Zangerl and Berenbaum, 1987), mechanical damage, and insect feeding (Zangerl and Bazzaz, 1989).

The amount of induction of P450 metabolism of xanthotoxin did not differ between larvae reared in the presence or absence of UVA light (Table 3); this result, however, may be due to the use of UV light of an intensity insufficient to photoactivate xanthotoxin to the degree necessary to effect the induction process. The intensity of UVA light measured on a sunny day in east central Illinois, 1500–1900 $\mu\text{W}/\text{cm}^2$, appreciably exceeds the value of 270 $\mu\text{W}/\text{cm}^2$ used in this study. However, in experiments using UV lighting comparable to ours, the southern armyworm, *Spodoptera eridania* (Lepidoptera: Noctuidae) (Berenbaum, 1978), and the corn earworm, *Heliothis zea* (Lepidoptera: Noctuidae) (Berenbaum, 1985), both polyphagous herbivores, suffered higher mortality when fed xanthotoxin in the presence of UV light, compared to control larvae shielded from UV light. Thus, xanthotoxin is apparently photoactivated under these lighting conditions. We conclude, therefore, that photoactivation of xanthotoxin is not necessary to initiate the induction process in the black swallowtail.

TABLE 3. EFFECT OF ULTRAVIOLET LIGHT ON INDUCTION OF P450-MEDIATED METABOLISM OF XANTHOTOXIN BY MIDGUT MICROSOMES OF BLACK SWALLOWTAIL LARVAE

UV light	Diet (% fw xanthotoxin)	Xanthotoxin metabolized (nmol/min/mg protein) ^a
No	0	1.51 ± 0.67a
No	0.1	4.35 ± 0.52b
Yes	0	1.52 ± 0.44a
Yes	0.1	4.05 ± 0.34b

^aMean ± SD of two experiments, assayed in triplicate. Two-way ANOVA showed no significant effect of UV light on xanthotoxin metabolized ($F_{1,19} = 1.75$, $P = 0.20$), and no significant UV light*diet interaction ($F_{1,19} = 0.00$, $P = 1.00$). Effect of diet on xanthotoxin was significant ($F_{1,19} = 164.85$, $P = 0.0001$). Means followed by the same letter are not significantly different at $P = 0.05$, pairwise comparisons using LSD.

Finally, despite a 4.7-fold induction in specific activity against xanthotoxin, total P450 content did not increase significantly (Table 4). These data indicate that multiple forms of P450 exist in the black swallowtail midgut and that a select subset of these is induced by xanthotoxin. If there were only a single form of P450 in the insect, then, assuming induction proceeding by de novo synthesis of enzymes (Hodgson, 1985) and a constant rate of substrate turnover, a fivefold induction of activity against xanthotoxin would require an equivalent increase in total P450 content.

Prior exposure to plant secondary compounds may not only induce P450-mediated metabolism of some substrates but may, at the same time, decrease activity against others (Yu, 1984; Brattsten, 1987). Yu (1984) found a 2.6-fold

TABLE 4. INDUCTION BY XANTHOTOXIN OF TOTAL P450 CONTENT AND OF P450-MEDIATED METABOLISM OF XANTHOTOXIN BY MIDGUT MICROSOMES OF BLACK SWALLOWTAIL LARVAE

Diet (% fw xanthotoxin)	Total P450 content (nmol/mg protein) ^a	Xanthotoxin metabolized (nmol/min/mg protein) ^a
0	0.159 ± 0.036a	2.02 ± 0.81a
0.5	0.180 ± 0.035a	9.44 ± 2.84b

^aMean ± SD of 2 experiments. P450 content assayed with one or two duplicates per treatment and two scans per duplicate. Enzyme activity assayed in triplicate. Means within a column sharing the same letter are not significantly different at $P = 0.05$, pairwise comparisons using LSD.

induction of total P450 content when fall armyworm larvae were reared on artificial diet containing 0.025% fw xanthotoxin. However, P450 activity against three of four model substrates decreased, while heptachlor epoxidase activity was induced 1.9-fold. It may be that, at a dietary content of 0.5% fw, xanthotoxin also decreases the level of some P450s in the black swallowtail, explaining in part why we observed no significant increase in total P450 content.

The presence of multiple forms of P450, with different and often overlapping substrate specificities, makes the suite of these enzymes a general and flexible detoxification system. However, it is clear that this system can be altered by selection and that it differs in composition among herbivores with different diets. For example, as discussed by Nitao (1989), the parsnip webworm, restricted in North America to two host species high in xanthotoxin content, has an uninduced *in vitro* capacity of xanthotoxin metabolism 30 times greater than that of the black swallowtail (Bull et al., 1986; this study), which feeds on several genera in two plant families, and 200 times greater than that of the fall armyworm (Bull et al., 1986; Yu, 1987) and cabbage looper, *Trichoplusia ni* (Lee and Berenbaum, unpublished), generalists reported from over 15 plant families (Tietz, 1972). In addition, xanthotoxin can induce the P450 activity by which it is detoxified in the parsnip webworm (Nitao, 1989) and black swallowtail (this study), but not in the cabbage looper (Lee and Berenbaum, 1989). The nature of this specialization of P450 monooxygenase systems probably lies in the evolution of particular isozymes and of pathways involved in the induction process for greater activity against defensive compounds characteristic of the diets of different herbivores.

PATTERN OF PHEROMONE-ORIENTED FLIGHT IN MALE POTATO TUBERWORM MOTHS

TOMOHIRO ONO and MOEKO ITO

*Laboratory of Biology
Kinjo Gakuin University
Moriyama, Nagoya, 463 Japan*

(Received May 9, 1988; accepted December 20, 1988)

Abstract—The pheromone-oriented flight of male *P. operculella* was observed under field conditions. Eighty percent or more of the flights were shorter than 1 m. Thus the approach of males of this species to a distant pheromone source is composed of a chain of short flights. The pattern of the flights changed when the males came within about 1 m of the lure, with a decrease of flight speed and an increased tortuosity. This probably facilitates eventual location of the female by a male. Only a few males succeeded in arriving at the high-dose lures. Males did not succeed in arriving at the lure when it was 70 cm above the ground: this was confirmed by a trap test; however, the flight pattern consisted of a chain of short flights even in these cases. The adaptive significance of this flight pattern is discussed.

Key Words—Lepidoptera, Gelechiidae, *Phthorimaea operculella*, oriented flight, sex pheromone, flight pattern, field behavior.

INTRODUCTION

There are many studies on the behavior serving mate location by male moths. In some examples the behavior is divided into two stages; flight from a relatively distant site and a change of behavior close to the female, often involving landing and walking (e.g., Cardé, 1979). There are few records of the flying approach in the field, mainly because of difficulty in following the flying moths. David et al. (1983) have analyzed flight patterns of male *Lymantria dispar* approaching a distant odor source in the field. Kawasaki (1981) has observed flight behavior of male *Spodoptera litura* in a field cage. Both studies showed that the approach to a distant odor source in these two species was achieved by continuous flight.

On the other hand, a number of studies have dealt with close-range behavior. Some of them showed hovering searching (zigzag flight) near the female (or lure) after a flying approach (Cardé, 1981; Hidaka, 1972), or landing and searching by walking, sometimes while wing-fanning (Baker et al., 1976; Cardé et al., 1975).

In contrast, the oriented movement towards a distant odor source in male potato tuberworm moths, *Phthorimaea operculella*, appears to be composed of a chain of short flights (Ono, 1985).

The present observations were, therefore, designed to analyze this behavior quantitatively and to compare the effects of different lures and of increased pheromone concentration on the upwind oriented flight of this species.

METHODS AND MATERIALS

The observations were conducted with males (2–3 days old) reared in a laboratory culture on potatoes (25°C, 14-hr light–10-hr dark regime) and then released in the field. This culture had been kept since 1983 when the larvae and pupae were collected from a potato field in Nagoya. A large cloth sheet (5 × 17 m) with a numbered grid of 10-cm squares (8500 squares total) was placed on the ground without crops, and males' behavior during approach to a lure (a rubber septum containing pheromone) on the sheet was observed. The rubber septum, on a stick 10 or 70 cm high, was set at an upwind position, and males were released from downwind. Males responding to the lure were followed until they arrived at the source, in the case of successful orientation, or until they flew away from the sheet or spent more than 5 min without successful arrival. The behavior and landing site (grid square number) were recorded on cassette tapes which were later transcribed. Marks were put on the transcribed track at 5-sec intervals.

Ideally, the behavior of the nocturnal moths should be observed under natural darkness. Such observations of *P. operculella* are impossible because the moths are very small and their movements are rapid. The observations were, therefore, conducted around sunset (about 1800 hr) between July and September 1986. Lights-off in the rearing room was set at 1600 hr, and males were kept separately from females in the room under the dark conditions (25°C) until just before testing. This procedure did not seem to alter their behavior.

To randomize the influence of daily conditions, all lures should ideally be examined on the same day. On the other hand, this procedure could cause contamination of the sheet with the previously tested lures. In these experiments, we examined one sample a day and attempted to minimize the differences of daily weather conditions by avoiding rainy or windy days.

All the analyses were done from the trials in which it was possible to trace

flight tracks longer than 4 m on the sheet. Flight length was measured from the transcribed tracks (Figure 1). Flight length was defined as the beeline length between the center points of grid squares where males landed subsequently. Also, "flight speed," "advance speed," and "tortuosity" were defined as shown in Figure 2. Flight length (Df) was defined as the summed length of the transcribed track, and flight speed (ground speed) was calculated as Df/time (sec) elapsed. Stop durations longer than 5 sec in each were excluded from the "time" used in this calculation. Advance speed was calculated from beeline length as Db/time (sec) elapsed. Tortuosity was defined as the $Df1/Db1$ ratio from the start to the point of the first crossing of the 2-m line, and $Df2/Db2$ ratio from that point of first crossing to the lure or the end point of observation. This analysis is similar to that of Nakamuta (1985).

Trapping tests were conducted in the same field. Two water-pan pheromone traps (30 cm in diameter and 15 cm in depth) containing water with detergent were placed 5 m apart. One of the traps was placed on a stand and the other directly on the ground. The lures were set at 70 cm and 10 cm above the ground, respectively. One hundred twenty males were released 10 m downwind from the traps, and the number of males caught in each trap was counted on the following day. The observations were repeated eight times.

FIG. 1. Schematic method for measuring flight length. Flight length was defined as the beeline length between the center points of grid squares where males landed subsequently. ■: landing point and ○: center point.

FIG. 2. Parameters for calculation of flight speed, advance speed, and tortuosity. Df1 and Df2: flight length of start to 2-m line and that of 2-m line to lure (end). Db1, Db2, and Dbt: beeline length of start to 2-m line, 2-m line to lure (end), and start to lure (end), respectively.

Female crude extract (FE: 100 female equivalents) and synthesized pheromone components, (*E,Z,Z*)-4,7,10-tridecatrienyyl acetate (T) and (*E,Z*)-4,7-tridecadienyyl acetate (D), were used as lures. Six treatments were tested: female extract 10 cm and 70 cm high (FE 10 and FE 70), T 30 μg + D 20 μg at 10 cm and 70 cm (TD 10 and TD 70), T 50 μg at 10 cm (T 10), and T 1200 μg + D 300 μg at 10 cm (HIGH 10). The data for FE 70 are excluded from this report because only two trials produced results.

TABLE 1. PERCENTAGES OF MALES ARRIVING AT LURE AND STOPPING ON THE WAY

Treatment		No. of males observed	Males arriving at lure (%)	Males stopping (> 5 sec) during their approach (%)	No. stops/trial
FE	10	10	90	60	1.6
TD	10	11	100	30	0.3
T	10	17	100	18	0.3
HIGH	10	13	38	31	0.4
TD	70	9	0	67	2.1

RESULTS

Table 1 shows the percentages of males arriving at the lure and showing a brief "stop" on the way. Arrival percentages at lures set at 10 cm were very high except for HIGH 10 (significantly different from other 10-cm data, 5% in Fisher's exact probability test). Although males approached close to the HIGH 10 lure (range: 30–200 cm), many of them (8/13) suddenly flew away. No males arrived at the source with TD 70.

FE 10 induced significantly more stops (> 5 sec) than TD 10 and T 10, and TD 70 significantly more than TD 10, T 10, and HIGH 10, at the 5% level in the Mann-Whitney U tests, respectively.

The frequency distribution of flight length and the percentages of flights longer than 1 m are shown in Figure 3 and Table 2. The longest flight recorded was 3.8 m. Table 2 shows that a majority of flights observed were shorter than 1 m with all the lures tested, although the percentages of flight longer than 1 m increased slightly as the distance from the lure increased. These facts support the conclusion that the approach flight of *P. operculella* males is not a continuous flight but a chain of short flights.

The lures in these tests were 10 cm above the ground (except TD 70). A possible factor inducing the short flight pattern noted in this experiment might be the low position of the lures (Figure 4). To check this point, observations were made with the lures at 70 cm above the ground. Males failed to arrive at these sources. In these experiments, males flew into the vicinity of the lures (five of nine approached within 200 cm of the source) but could not find the lure itself (Table 1). Their approach pattern differed from that in TD 10 (Figure 5), and they made frequent stops during the course of oriented flight. The distribution of flight lengths in the experiment was, however, similar to that when the lures were 10 cm high (Figure 3 and Table 2).

FIG. 3. Frequency distribution of flight length in each range of distance (A-E).

This fact was confirmed by a trap test. Many more males were caught at 10 cm than at 70 cm (Table 3). The short flight approach is, therefore, thought to be normal in *P. operculella*.

Table 4 shows the summarized data on the flight length in each range of distance. Flight lengths in the 1- to 0-m range were shorter than those in the >2-m range, except in the case of TD 70. In TD 10, flights in the 2- to 1- and 0- to -2-m range were also shorter than those >2 m.

TABLE 2. PERCENTAGES OF FLIGHTS LONGER THAN 1 m DURING ORIENTED FLIGHT OF POTATO TUBERWORM MOTH

Treatment	Percent of flights longer than 1 m (N)			
	-2 to 0 m	0 to 1 m	1 to 2 m	>2 m
FE 10	5 (20)	2 (144)	8 (80)	10 (182)
TD 10	2 (97)	1 (179)	5 (55)	16 (147)
T 10	13 (16)	1 (154)	10 (72)	13 (116)
HIGH 10	4 (28)	4 (97)	12 (43)	18 (203)
TD 70	0 (8)	3 (38)	7 (119)	4 (318)

FIG. 4. A hypothetical flight track to the lure set at 70 and 10 cm high. It shows the possibility that the same flight path is convertible continuous flight and chain of short flights depend on lure height.

Flight speed and tortuosity of the track are shown in Table 5. The data were separated into two portions for each lure, as in Figure 2. No differences were observed among lures set at 10 cm, although the flight speed in TD 70 differs from others (Duncan's multiple-range test). Differences between start to

FIG. 5. Position showing stop (>5 sec) on the way to the TD 10 (●) and TD 70 lures (○). Number of males tested and number of stops observed were 11 and 5 in TD 10, and 9 and 19 in TD 70, respectively.

TABLE 5. FLIGHT SPEED, ADVANCE SPEED, AND TORTUOSITY OF FLIGHT TRACK DURING ORIENTATION OF POTATO TUBERWORM MOTH^a

Treatment	Start to 2-m line			2-m line to lure (end)		
	Flt spd (cm/sec)	Adv spd (cm/sec)	Tort	Flt spd (cm/sec)	Adv spd (cm/sec)	Tort
FE 10	32.6ab	19.1ab	2.6a	21.0ab	7.1ab	4.0a
TD 10	35.5a	24.3a	1.9a	20.8ab	9.4ab	3.4a
T 10	40.5a	30.4a	1.4a	25.8a	14.1a	2.8a
HIGH 10	37.4a	20.7a	2.2a	21.1a	11.4ab	2.8a
TD 70	18.0b	9.4b	2.3a	11.1b	4.3b	5.7a

^aMeans followed by the same letter in the same column are not significantly different at 5% (Duncan's multiple-range test). Flt spd and Adv spd, and Tort refer flight speed, advance speed, and tortuosity, respectively.

TABLE 6. DIFFERENCES IN FLIGHT SPEED, ADVANCE SPEED, AND TORTUOSITY BETWEEN START TO 2-m AND 2-m TO LURE (END) RANGES WITH LURES SET AT 10 cm HIGH

	Start to 2 m	2 m to lure (end)	Difference ^a
Flight speed (cm/sec)	36.9	22.7	1%
Advance speed (cm/sec)	24.1	11.0	1%
Tortuosity	2.0	3.2	1%

^aMann-Whitney U tests.

2 m and 2 m to lure (end) in each treatment were not significant statistically because of large variations and small sample sizes. The data for the 10-cm-high lures were, therefore, combined before comparing the value for the two distance ranges (Table 6). All the parameters compared showed a significant difference (Mann-Whitney U test). The flight speed was reduced, and the tortuosity was increased as the males came closer to the source.

DISCUSSION

The behavior of male moths approaching a female in Lepidoptera is divided into two stages: flight from a distance and close-range behavior. The function of the distance flight is thought to be a fast approach to the vicinity of a female, and that of the close-range behavior is thought to enable the male to pinpoint the female. Continuous flight would seem to be the most effective procedure in the first stage.

In fact, many species do engage in continuous flight from a distance. This strategy may be especially adaptive in species whose habitat lies within the wide range in height of a tree. Elkinton and Cardé (1983) have shown that the catch of male *L. dispar* at the traps in the forest was evenly distributed at all heights (0–6 m). Also, height of flight in *Hyphantria cunea* is distributed over a wide range (1–6 m) (Hidaka, 1972), but it was considered questionable whether the same is true of species whose habitat is near the ground.

The approach behavior of *P. operculella*, composed of a chain of short flights as suggested by Ono (1985), differs from that of other species. This type of approach was observed with all the lures tested and even with lures set at the high position. The beeline measurement in this experiment (Figure 1) may underestimate the flight length, but flights between landings seemed to be fairly straight. The estimated length of flights shown here is, therefore, thought to be approximate, a supposition supported by the fairly high flight speed shown in

Table 5. We never saw long sustained flights during the whole series of observations.

In the present observations, the longest track observed was from the 12-m line. At least within this range, there were no changes in the flight pattern from the starting point to the 2-m line, except with the lure set at 70 cm. This suggests that the short flight type of approach observed in the range from start to about 2 m corresponds to the longer flight orientation of other moths (David et al., 1983; Kawasaki, 1981).

Ono (1985) has pointed out the adaptive significance of the close-range behavior of *P. operculella*, in which landing and walking were essential for mate finding. The approach behavior shown here is also thought to be adaptive because the habitat of *P. operculella* is on potato plants, which have dense foliage near the ground. Short flights would be more effective for finding females that are on or in this foliage than a continuous long flight, because well-defined plumes typical of unobstructed habitats may be replaced by broad active spaces enveloping the area of the plant near the female.

Males changed their behavior on arriving near a lure. The behavior in this area sometimes included jumping, walking, or walking while wing-fanning. The flight length was shortened, flight speed reduced, and the tortuosity of the track increased (Table 4 and 6). These behavioral changes represent a switch to close-range behavior. The distance at which switching occurs was similar to that observed in earlier tests (Ono, 1985).

There were clear differences among the lure treatments in the percentage of males arriving. The low percentages locating the female extracts may have been due to the low pheromone content. The pheromone content must have been very different from that of the other lures (100 female equivalents correspond to ca. 1/100 of a TD lure).

The arrival percentages at the HIGH 10 lure and lures set at 70 cm above the ground were quite low. In both cases, males would arrive near the lure but could not find the lure itself. There are a number of possible reasons for these results. With the lures set at 70 cm high, the flight length was not shortened in the 0- to 1-m range distance and the males frequently stopped further away from the source during oriented flight (Figure 5). This suggests that they missed a pheromone plume to follow, and they failed to switch to close-range behavior. With the HIGH 10 lure, there may have been an inhibitory or disrupting effect. Many males suddenly flew away on arriving within 2 m from the lure. Voerman and Rothschild (1978) have shown that there was an optimal dose of pheromone compound on a septum for trapping under field conditions. Although a decrease of trapping efficiency in their data appeared at doses 10 times higher than ours, these trends suggest that an extremely high dose of pheromone has an inhibitory or disrupting effect on male behavior.

The behavioral change occurred further away from the TD 10 lure (Table

4). This may have been due to the influence of D (diene component). The same pattern was not observed at the FE 10 lure. These two lures were not comparable, however, because of the difference in pheromone content referred to above.

Walking is an essential attribute of the final approach to the female in this species (Ono, 1985). In the present tests, males showed insufficient close-range behavior when the lure was set at 70 cm high (Table 4 and Figure 5). Males were also not caught by a trap set at that height (Table 3). Perhaps the height of 70 cm above the substrate may exceed the height limit for *P. operculella* flight in their normal life.

In these observations, behavioral responses to T (triene component) alone were similar to those with the blend lure. The role of D (diene component) is not clear from these results. Tóth et al. (1984) showed that addition of D prolonged the time spent at a lure source. Ono (1985) obtained similar results in the field, but field trapping in Nagoya failed to support these findings (Ono and Orita, 1986), suggesting that D does not have any role in flight from a distance.

Acknowledgments—The authors thank R. Yamaoka for supplying pheromone components, and R.T. Cardé and M.A. Willis for critical readings of an early draft. Thanks are also due to anonymous reviewers for their comments and improvement of English phraseology.

(Received October 11, 1988; accepted December 21, 1988)

Abstract—The three major components of setal exudate from nymphs of the Hawthorn lace bug, *Corythucha cydoniae*, were identified as 3,6-dihydroxy-2-[1-oxo-6(*E*),8(*E*)-tetradecadienyl]cyclohex-2-en-1-one; 3,6-dihydroxy-2-[1-oxo-dodecanyl]-cyclohex-2-en-1-one; 3,6-dihydroxy-2-[1-oxo-8-dodeceny]cyclohex-2-en-1-one. An additional 10 minor components were partially characterized.

Key Words—Hawthorn lace bug, *Corythucha cydoniae*, Hemiptera, Tingidae, 3,6-dihydroxy-2-[1-oxo-6(*E*),8(*E*)-tetradecadienyl]cyclohex-2-en-1-one, 3,6-dihydroxy-2-[1-oxo-dodecanyl]-cyclohex-2-en-1-one, 3,6-dihydroxy-2-[1-oxo-8-dodeceny]cyclohex-2-en-1-one, 3,6-dihydroxy-2-acyl-cyclohex-2-en-1-ones, setal exudate.

INTRODUCTION

The nymphs of many species of lace bugs destructively feed in contiguous aggregations on the abaxial leaf surface of many trees and ornamental shrubs. In several genera of lace bugs, the nymph has numerous external secretory hairlike structures (setae) over the surface of the body and antenna that support viscous microdroplets (Livingstone, 1978). We have noted the unusually low number of reports of parasites and predators that attack lace bug nymphs, an

obvious food resource (Oliver et al., 1985), and have been examining the chemical composition of the exocrine secretions to determine their function in a suspected defense system. Species were selected from two genera with presocial behavior; one of asiatic origin and one native to North America. To date, we have reported (Oliver et al., 1985) the occurrence of 1-(2,6-dihydroxyphenyl)-1,3-diketones, along with the corresponding 2-alkyl-5-hydroxychromones and chromanones, as well as normal chain aldehydes and ketones in the setal exudate from the azalea bug (*Stephanitis pyrioides*). From the rhododendron lace bug (*S. rhododendri*) a more elaborate series of 1-(2,6-dihydroxyphenyl)-1,3-diketones and related chromones, and chromones possessing an additional oxygen, have been identified (Oliver et al., 1987). From the sycamore lace bug (*Corythucha ciliata*), the novel compound 3,6-dihydroxy-2-[1-oxo-10(*E*)-tetradecenyl]cyclohex-2-en-1-one has been isolated and identified (Lusby et al., 1987).

In this continuing examination of the major components of lace bug setal exudates, we now report the isolation and identification of three major components from the hawthorn lace bug (*C. cydoniae*) and the partial characterization of an additional 10 minor components.

METHODS AND MATERIALS

Insects were maintained in a greenhouse on either pyracantha *Pyracantha coccinea* var. *Lelandei* or Washington Hawthorn *Crataegus phaenopyrum* (1–2 m tall) grown in 35.2-liter baskets. As the insects grew to maturity, their cast molt skins, which accumulated on the leaves, were collected by aspiration into Pasteur pipets, transferred to a fritted-disk funnel, and rinsed with methanol.

Isolation of Components

By means of methanol rinses (4 × 50 ml), microdroplets of setal exudate were washed from 7.2 g of cast skins and nymphs. After removing methanol under vacuum, the residue was extracted with several portions of warm hexane (total of 35 ml), which were combined and filtered. Removal of the hexane yielded 110 mg of dark brown residue. Flash chromatography of the residue was performed on a 20% silver nitrate-loaded silica gel column (8 × 2.5 cm) using hexane saturated with formic acid (100 ml) and 10%, then 25%, ethyl acetate in hexane saturated with formic acid (250 and 400 ml, respectively); 25-ml fractions were collected. Fractions 7 and 8 provided 42 mg of a dark brown residue that contained the compounds of interest as determined by gas chromatography (GC) and gas chromatographic-mass spectrometry (GC-MS) analyses.

HPLC separation (20% silver nitrate on 20- μ m silica gel) of the above

residue yielded six fractions. Fractions 4 and 5 were combined and separated further by flash chromatography on 25 g of 20% silver nitrate on Unisil using 100, 250, and 500 ml, respectively, of 2.5%, 5.0%, and 7.5% ethyl acetate in (1:1) hexane-hexane saturated with formic acid. After collecting two initial 50-ml fractions, a series of 5.5-ml fractions was collected and their content monitored by GC. Fractions 70 and 71 contained the major component and were combined and analyzed by GC-MS, [^1H]NMR, FT-IR, and UV. An aliquot was subjected to ozonolysis. A portion of the ozonolysis products was analyzed directly by GC-MS, while the remaining portion was reacted with *O*-benzylhydroxylamine and the resultant *O*-benzyloximes analyzed by GC-MS.

Instrumentation

Mass spectra were obtained from a Finnigan model 4500 quadrupole instrument fitted with an on-column injector (J & W Scientific) and a 30-m \times 0.32-mm-ID fused silica column with a 0.25- μm DB-1 film (J & W Scientific) with the temperature held at 170°C for 2 min and then programmed to 260°C at 2°C/min. Ammonia and deuterioammonia chemical ionization (CI) spectra were obtained at an indicated source pressure of 0.6 torr and a source temperature of 80°C. A source temperature of 150°C and an ionizing voltage of 70 eV were used to produce electron ionization (EI) spectra. High-resolution mass spectral analyses were performed by the Midwest Center for Mass Spectrometry (Lincoln, Nebraska). Gas-liquid chromatographic trapping was performed on a Varian model 3700 equipped with a thermal conductivity detector and a 15-m \times 0.58-mm-ID Megabore column with a 1.5- μm film of DB-1 (J & W Scientific) and operated at 210°C. HPLC separations were achieved using a Spectra Physics model SP 8700 fitted with a 1-cm \times 22-cm 20% AgNO_3 on 20- μm silica gel column which was eluted with 95:3:2 (hexane saturated with formic acid-tetrahydrofuran-9:1 hexane-isopropanol) at 4 ml/min and observing at either 220 or 270 nm. [^1H]NMR spectra were obtained from a Nicolet NT-300 (300 MHz) Fourier transform spectrometer using either CDCl_3 and C_6D_6 as solvents and TMS as an internal standard. ^1H chemical shifts are reported in δ from TMS and coupling constants are in Hz. UV spectra, 190–400 nm, were obtained with a Perkin-Elmer model 559 using 95% EtOH as solvent. Infrared spectra were obtained from a Nicolet model 205XC GC-FTIR instrument and processed with a Nicos V3.6 operating system.

Ozonolysis and Preparation of O-Benzylloximes

Into a 1-ml conical vial was placed 10 μg (30 nmol in 10 μl CH_2Cl_2) of compound 6. After cooling to -70°C (Dry Ice- CH_2Cl_2 bath), 600 nmol O_3 (24 μl CH_2Cl_2 at -70°C saturated with O_3) was added and the vial allowed to stand at -70°C for 0.5 hr. While still at -70°C , 41 μg (600 nmol) dimethyl

sulfide (41 μl 0.1% in CH_2Cl_2) was added, and the vial allowed to come to room temperature. An aliquot of the ozonolysis reaction mixture was analyzed by EI and CI GC-MS. To one half of the ozonolysis reaction mixture (equivalent to 5 μg , 15 nmol starting material) was added 19 μg (150 nmol) *O*-benzylhydroxylamine (25 μl aq. solution at pH 4.5). After standing, with occasional shaking, at room temperature for 1 hr, 10 μl 2 M HCl was added and the vial shaken. The CH_2Cl_2 layer was analyzed by EI and CI GC-MS. Compound 1 was examined in a similar manner.

Hydrogenation

An aliquot of a fraction from flash chromatography was dissolved in 0.2 ml *N,N*-dimethylformamide (DMF) saturated with $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$. While stirring vigorously at ambient temperature, 0.05 ml of 0.5 M NaBH_4 in DMF was added and approximately 10 sec later a black precipitate formed. A second 0.05-ml portion of the NaBH_4 was added, and after 1 min the reaction was quenched with aqueous NH_4Cl , and filtered through a pad of Celite. The filtrate was passed through a C_{18} extraction cartridge that was subsequently rinsed with water. The products were eluted from the cartridge with tetrahydrofuran, concentrated, and analyzed by GC-MS.

Physical Data

Compound 1 (3,6-Dihydroxy-2-[1-oxo-8-dodeceny]cyclohex-2-en-1-one). EI-MS *m/z*: 308(100) M^+ , 290(2)[$\text{M}-\text{H}_2\text{O}$] $^+$, 264(7)[$\text{M}-\text{C}_2\text{H}_4\text{O}$] $^+$, 219(13), 208(33), 183(86), 170(40), 168(52), 155(30), 142(24), 137(30), 126(44), 69(35), 55(72); CI(NH_3)-MS *m/z*: 326(100)[$\text{M} + \text{NH}_4$] $^+$, 309(19)[$\text{M} + \text{H}$] $^+$; CI(ND_3)-MS *m/z*: 332(100)[$\text{M} + \text{ND}_4$] $^+$, 312(21)[$\text{M} + \text{D}$] $^+$.

Ozonolysis Product from Compound 1 [3,6-Dihydroxy-2-(1,8-dioxooctyl)-2-cyclohexen-1-one]. EI-MS *m/z*: 268(3) M^+ , 240(63), 196(32), 183(100), 170(23), 153(54), 139(59), 95(68), 69(72), 55(83); CI(NH_3)-MS *m/z*: 303(4)[$\text{M} + (\text{NH}_3)_2\text{H}$] $^+$, 286(100)[$\text{M} + \text{NH}_4$] $^+$, 269(3)[$\text{M} + \text{H}$] $^+$.

O-Benzylloximes from Ozonolysis of Compound 1: O-Benzyloxime 1 (*n*-Butyraldehyde-*O*-Benzyloxime). EI-MS *m/z*: 177(2) M^+ , 160(5), 147(9), 105(21), 91(100), 77(10), 65(10); CI(NH_3)-MS: 212(79)[$\text{M} + (\text{NH}_3)_2\text{H}$] $^+$, 195(100)[$\text{M} + \text{NH}_4$] $^+$, 178(12)[$\text{M} + \text{H}$] $^+$.

O-Benzyloxime 2 [3,6-dihydroxy-2-(1,8-dioxooctyl)-2-cyclohexene-1-one-*O*-benzyloxime]. EI-MS *m/z*: 225(3), 183(4), 108(10), 91(100), 79(12), 77(11), 55(10); CI(NH_3)-MS: 391(100)[$\text{M} + \text{NH}_4$] $^+$, 374(9)[$\text{M} + \text{H}$] $^+$.

Compound 2 (3,6-Dihydroxy-2-[1-oxo-dodecanyl]cyclohex-2-en-1-one). EI-MS *m/z*: 310(42) M^+ , 292(3)[$\text{M} - \text{H}_2\text{O}$] $^+$, 266(22)[$\text{M} - \text{C}_2\text{H}_4\text{O}$] $^+$, 183(100), 170(27), 168(20), 153(21), 140(28), 126(16), 55(23); CI(NH_3)-MS:

328(100)[M + NH₄]⁺, 311(52)[M + H]⁺; CI(ND₃)-MS: 334(100)[M + ND₄]⁺, 314(54)[M + D]⁺.

Compound 6 (3,6-Dihydroxy-2-[1-oxo-6(E),8(E)-tetradecadienyl]-cyclohex-2-en-1-one). UV (nm, 95% EtOH); λ_{max} 229(ε ca. 45,000), 270(ε ca. 15,000). IR (cm⁻¹, gas phase); 3017(w), 2968(m), 2934(s), 2885(m), 1679(s), 1562(s), 1481(s), 1421(m), 1392(m), 1919(m), 984(m); EI-MS *m/z*: 334(5)M⁺, 316(100)[M - H₂O]⁺, 290(31)[M - C₂H₄O]⁺, 245(26), 219(29), 205(98), 183(34), 170(69), 155(36), 142(29), 137(32), 126(55), 79(67), 67(75), 55(53); HRMS *m/z*: 334.2144, M⁺ (C₂₀H₃₀O₄, Calc. 334.2144); 316.2035, [M - H₂O]⁺ (C₂₀H₂₈O₃, Calc. 316.2038); 290.1885, [M - C₂H₄O]⁺ (C₁₈H₂₆O₃, Calc. 290.1882); CI(NH₃)-MS *m/z*: 352(100)[M + NH₄]⁺, 335(32)[M + H]⁺; CI(ND₃)-MS *m/z*: 358(100)[M + ND₄]⁺, 338(28)[M + D]⁺; [¹H]NMR(CDCl₃); 0.84 (3H, t, *J* = 7, CH₃), 1.26–1.32 (6H, m, alkane CH₂), 1.44 (2H, m, CH₂), 1.56–1.69 (2H, m), 1.70–1.85 (H, m), 2.02 (4H, m), 2.33 (H, m), 2.33 (OH), 2.78 (2H, m), 3.01 (2H, m), 4.08 (H, dd, *J* = 13 and 4Hz), 5.57 (2H, m), 5.98 (2H, m), 18.20 (OH).

Ozonolysis Product from Compound 6 [3,6-Dihydroxy-2-(1,6-dioxohexyl)-2-cyclohexen-1-one]. EI-MS *m/z*: 212(39), 194(31), 183(62), 168(57), 153(55), 140(56), 126(28), 85(55), 67(100), 55(95); CI(NH₃)-MS *m/z*: 258(100)[M + NH₄]⁺, 241(4)[M + H]⁺.

O-Benzylloximes from Ozonolysis of Compound 6: O-Benzylloxime 3 (Hexanal-O-benzylloxime). EI-MS *m/z*: 205(1.2)M⁺, 188(0.7), 175(0.8), 149(8), 91(100), 77(5), 65(5); CI(NH₃)-MS: 240(54)[M + (NH₃)₂H]⁺, 223(100)[M + NH₄]⁺, 206(19)[M + H]⁺.

O-Benzylloxime 4 (Glyoxal-O-benzylloxime). EI-MS *m/z* 268(3)M⁺, 181(4), 161(2), 145(1), 105(2), 91(100), 77(8), 65(7); CI(NH₃)-MS: 303(2)[M + (NH₃)₂H]⁺, 286(100)[M + NH₄]⁺.

O-Benzylloxime 5 [3,6-dihydroxy-2-(1,6-dioxohexyl)-2-cyclohexen-2-one-O-benzylloxime]. EI-MS *m/z*: 345(0.5)M⁺, 221(1), 193(1), 183(2), 137(2), 108(6), 91(100), 77(8), 69(7), 55(7); CI(NH₃)-MS: 363(100)[M + NH₄]⁺, 346(3)[M + H]⁺.

RESULTS AND DISCUSSION

Initially, samples of setal exudate material were obtained by wicking the microdroplets onto small triangular pieces of absorbent filter paper. Samples obtained in this manner will be referred to as “wicked” samples. Examination by GC-MS of a dichloromethane extract of the filter paper revealed a remarkably clean sample consisting of a band of peaks (Figure 1) containing 13 components of retention times from 14 to 33 min and ranging in molecular weight

FIG. 1. Reconstructed total ion chromatogram of setal exudate compounds from *C. cydoniae*.

from 308 to 378 (Table 1). By comparing the value for the ammonium adduct ion using first ammonia then deuterioammonia CI-MS, it was determined that all of the components possessed two exchangeable hydrogens except compound 7, which had one. Electron ionization mass spectra, while being distinct from one another, were sufficiently similar to suggest the components of the mixture were structurally related.

Examination of cast skins revealed retention of setal microdroplets; therefore, in order to secure sufficient material for additional spectroscopic characterization, lace bugs were mass reared and cast skins collected. Extracts of cast skins yielded material that contained fewer spurious compounds than material obtained from extraction of intact nymphs, but the cast skin extract was not as clean as wicked samples. Gas chromatographic and mass spectral analyses of exudate wicked from insects reared on either hawthorn or pyracantha were indistinguishable, and therefore cast skins from both sources were pooled.

The isolation procedure yielded a sufficient amount of compound 6 to permit both [^1H]NMR analysis and ozonolysis followed by preparation of *O*-benzylloxime derivatives. However, only enough compound 1 was obtained to permit ozonolysis and subsequent formation of *O*-benzylloximes. No other components were individually isolated.

FIG. 2. Structures of setal exudate compounds from *C. cydoniae* (R defined in Table 1).

Compound 6

Examination of compound 6, the most abundant component, by [¹H]NMR yielded a spectrum nearly identical to that reported for 3,6-dihydroxy-2-[1-oxo-10(*E*)-tetradecenyl]-cyclohex-2-en-1-one that had been isolated from *Corythuca cilata* (Lusby et al., 1987). The near identity of the [¹H]NMR spectra together with both HRMS and CI-MS established that compound 6 contains the ring moiety shown in Figure 1 and possessed a side chain of 14 carbons containing two olefinic bonds. In order to locate the position of the olefinic bonds within the side chain, a portion of compound 6 was subjected to ozonolysis.

Ozonolysis of Compound 6. Mass spectral analyses of the ozonolysis products from component 6 indicated the formation of 3,6-dihydroxy-2-(1,6-dioxohexyl)-2-cyclohexen-1-one, thereby locating one of the olefinic bonds of 6 between carbons 6' and 7' of the side chain. Further examination of the mass spectral data of the ozonolysis reaction did not provide the identity of other products, which would locate the position of the second olefinic bond.

Reaction of the ozonolysis products with *O*-benzylhydroxylamine yielded three oximes, one of which corresponded to the above-identified aldehyde. A second oxime compound was derived from hexanal, indicating cleavage of a six-carbon fragment from the end of the side chain. The third oxime, a dioxime, yielded a multiplicity of gas chromatographic peaks due to combination of *syn* and *anti* configurations. Their mass spectra and a gas chromatographic comparison to an authentic sample established that they were derived from glyoxal. These data indicate the presence of a conjugated diene system with olefinic bonds located at carbons 6' and 8' of the side chain. Among the [¹H]NMR signals were two in the olefinic region: a multiplet at 5.98 δ and a multiplet at 5.57 δ. Irradiation at 5.57 δ collapsed the signal at 5.98 to a singlet, and irradiation at 5.98 δ yielded a triplet at 5.57 δ. These data confirm the presence of a conjugated diene system.

In order to establish isomeric configuration of the side-chain olefinic bonds, GC-FTIR analyses were performed on compound 6 and, as models, the four isomers of hexadeca-5,7-dienyl acetate. A band at 984 cm⁻¹, corresponding to C—H out-of-plane stretching, was present in both compound 6 and the *E,E* isomer of hexadeca-5,7-dienyl acetate but was absent in the remaining three isomers. A like band has been previously reported in the spectrum of the *E,E* isomer during the comparison of the four isomers of hexadeca-10,12-dien-1-ol (Butenandt et al., 1962).

The UV spectrum exhibited maxima at 229 nm (ε ca. 45,000) and 270 nm (ε ca. 15,000), with slight inflections at 216 and 235 nm (determined by inspection of the first derivative), and a shoulder at 226 nm. By comparison to a similar compound (Lusby et al., 1987) possessing a single olefinic bond in the side chain, it is seen that the conjugated diolefinic system in compound 6 produces both a greater extinction coefficient at the 229 nm maximum and a shift

of that maximum to slightly shorter wavelength. The above data establish compound 6 as 3,6-dihydroxy-2-[1-oxo-6(*E*),8(*E*)-tetradecadienyl]cyclohex-2-en-1-one. The configuration of the chiral center at C-6 was not determined.

Compound 2

Compound 2, which has a molecular weight of 310 and two exchangeable hydrogens, was identical in both GC retention time and mass spectrum to 3,6-dihydroxy-2-(1-oxododecanyl)-cyclohex-2-en-1-one, whose structure was recently confirmed by synthesis (Oliver and Lusby, 1988).

Compound 1

Compound 1 possesses a molecular weight of 308, thereby indicating a side-chain length of 12 carbons with a single olefinic bond. Hydrogenation of compound 1 yielded compound 2, thereby establishing the structure of the ring moiety. In order to determine the location of the olefinic bond in the side chain, compound 1 was subjected to ozonolysis and, under the gas chromatographic conditions used, a single reaction product was observed. Ammonia CI mass spectral analysis yielded a molecular weight of 238. EI analysis indicated the product to be 3,6-dihydroxy-2-(1,8-dioxooctyl)-2-cyclohexen-1-one. This indicated the presence of an olefinic bond between carbons 8' and 9' of compound 1. The ozonolysis products were converted to *O*-benzylloximes by reaction with *O*-benzylhydroxylamine. CI and EI mass spectral analysis of the *O*-benzylloxime reaction mixture revealed the presence of the *O*-benzylloxime of *n*-butyraldehyde, thus demonstrating the presence of *n*-butyraldehyde in the original ozonolysis product, and thereby confirmed the location of the olefinic bond. Insufficient material was available to determine the geometry of the double bond.

Compounds 3-5, 7-12

A fraction containing all components of the wicked sample except compounds 8 and 13 was hydrogenated using NaBH₄/NiCl₂/DMF. Catalytic hydrogenation with Pd or Pt catalysts provided results that were difficult to reproduce as well as to interpret. In contrast, the presumed *in situ* generation of both hydrogen and catalyst achieved by adding NaBH₄ to DMF containing NiCl₂ afforded clean reduction of olefinic side chains without affecting the enolic C=C or other functional groups. Interestingly, this same medium had been used recently to selectively reduce an isoxazole N—O bond in the presence of a side chain C=C (Oliver and Lusby, 1988). Slight modification of the reaction conditions (Methods and Materials) allowed, in this case, clean reduction of the side-chain double bonds while preserving the ring functionalities. Compounds 3, 4, 5, and 6, with molecular weights of 334, 336, 336, and 334 respectively, were hydrogenated to a single product with a molecular weight of 338 and

having a mass spectrum virtually identical to that of compound 2 except for the molecular ion and ions derived by simple losses from the molecular ion. In a like manner, compounds 9, 10, 11, and 12 yielded a single product with a molecular weight of 366 and a saturated side chain. These data indicate that compounds 1–6 and 9–12 all possess the same ring moiety but differ by length of the side chain (12, 14, or 16 carbons) and/or degree and position of unsaturation in the side chain.

These results demonstrate the presence of exudate compounds in *C. cydoniae* that are very similar to those isolated from *C. ciliata* (Lusby et al., 1987) and quite distinct from those isolated from *S. pyrioides* (Oliver et al., 1985) and *S. rhododendri* (Oliver et al., 1987).

Compounds from the two genera are distinct in that those from *Corythucha* are nonaromatic vs. the aromatics from *Stephanitis*; however, the gross structures and oxygenation patterns suggest related biosynthetic pathways.

ACIDIC FOG-INDUCED CHANGES IN HOST-PLANT SUITABILITY

Interactions of *Trichoplusia ni* and *Phaseolus lunatus*

JOHN T. TRUMBLE and J. DANIEL HARE

Department of Entomology
University of California
Riverside, California 92521

(Received August 1, 1988; accepted December 21, 1988)

Abstract—*Phaseolus lunatus* L. (Henderson Bush lima beans) were exposed to 2 hr acidic fogs with 2.5:1.0 (v/v) nitrogen-sulfur ratio typical of the west coast of the United States. Fogs with pH values of 2.0 ($P < 0.01$, t tests), 2.5 ($P < 0.05$), or 3.0 ($P < 0.01$) increased percent total nitrogen (dry weight) of foliage as compared to plants subjected to control fogs with a pH of 6.3–6.5. Fresh weight concentrations of soluble protein and certain free amino acid concentrations were increased by plant exposure to acidic fogs with a pH of 2.5 (t tests, $P < 0.05$). Concentrations of free amino acids considered essential for insect growth, as well as nonessential and total free amino acids were not significantly affected by any treatment ($P > 0.05$, t test). Water content (%) of foliage was not changed significantly ($P > 0.05$, t test) by exposure to any of the fogs. *Trichoplusia ni* (Hübner) (Lepidoptera: Noctuidae) larvae ate significantly more foliage and gained significantly more weight on plants treated with 3.0 pH fogs ($P < 0.01$, t test). Several potential explanations are offered for the lack of significant weight gain by larvae on plants in which soluble protein levels, free amino acid concentrations, or percent total nitrogen contents were enhanced by acidic fogs with a pH of 2.5 and 2.0. No larval feeding preference was detected for foliage exposed to acidic versus control fogs, and no significant differences were detected in percent survival of *T. ni* eggs exposed to acidic or control fogs. Some implications of acidic fogs for population dynamics of *T. ni* are discussed.

Key Words—Acidic fog, *Phaseolus lunatus*, *Trichoplusia ni*, cabbage looper, Lepidoptera, Noctuidae, nitrogen, free amino acid, soluble protein, plant-insect interactions, air pollution.

INTRODUCTION

Like the gaseous photochemical oxidants, acidic fogs can have beneficial as well as detrimental consequences for plants. Wet deposition of pollutants (rain, fog, dew) on foliar surfaces either can act as fertilizers or cause a sequence of cellular collapse resulting in necrotic lesions (Shriner, 1986). Previous reports noted deleterious effects such as lesion development, weathering of cuticular wax, foliar leaching, and modification of physiological responses (Cowling, 1982; Lintherst et al., 1982). These effects have been duplicated with short-term exposure to acidic fogs of pH 2.3 or lower under laboratory conditions (Granett and Taylor, 1981; Granett and Musselman, 1984). Because ambient fogs in the Los Angeles Basin exhibit an acidity of pH 1.69–3.0, significant foliar necrosis leading to yield losses in crop plants is not unusual (Hoffman, 1984).

Physiological changes in plants affected by air pollutants significantly alter the nutritional suitability of such plants for insect herbivores (Jones and Coleman, 1988). Substantial modifications in the form and content of nitrogen (e.g., both increases and decreases) have been reported following plant exposure to ozone and other pollutants (Chang, 1971; Mudd and Freeman, 1977). In tomatoes, ozone effects include an increase in free amino acids and soluble proteins (Trumble et al., 1987), which may be more readily assimilated by insects than the nitrogen bound in the structural components of cells. One objective of the study reported here was to determine if plants subjected to acidic deposition and damaged by acidic fogs develop different total nitrogen, soluble protein, and free amino acid profiles than plants exposed to nonacidic fogs.

The implications of increased concentrations of assimilable forms of nitrogen for insect herbivore development are considerable (Strong et al., 1984; White, 1984). Nitrogen availability dramatically affects key life processes such as growth rates, survival, and reproductive capacity (Onuf, 1978; Prestidge, 1982; Prestidge and McNeill, 1983). Because air pollutants in general, and acidic fogs in particular, often occur over broad geographic areas (Lee, 1982; Hoffman et al., 1985), the cumulative effects on herbivores at the population level may be of substantial importance (White, 1984). Thus, potential changes in plant physiology due to stress or direct injury from air pollutants may well have more serious consequences than are indicated when the plant system is examined in the absence of herbivores.

At present, little research has focused on the effects of acidic fogs on the nutritional suitability of plants for insect herbivores. Although several studies have, in some cases, documented an increase in food consumption or preference for foliage exposed to ozone or SO₂ (Hughes et al., 1981; Jeffords and Endress, 1984; Endress and Post, 1985; Trumble et al., 1987; Coleman and Jones, 1988; Jones and Coleman, 1988), these are by no means the only responses noted

(Jones and Coleman 1988). The impact on herbivores of foliar deposition of nitrates associated with high-nitrogen acidic fogs and potential damage or stresses associated with acidic fogs have not been reported. Therefore, a second objective of our research was to document the potential influence of acidic fogs on some key factors influencing herbivore population dynamics.

METHODS AND MATERIALS

The Plant-Insect System. Henderson bush lima beans, *Phaseolus lunatus* L., used in the experiments were germinated in the greenhouse in UC Soil Mixture (Matkin and Chandler, 1957) and fertilized twice weekly with one-half strength Hoagland's nutrient solution (Downs and Hellmers, 1975). Thus, all plants were provided with adequate nitrogen, similar to what would occur in an agricultural setting. Although populations of nitrogen-fixing symbiotes were not surveyed, the provision of adequate nitrogen and the use of washed seed and sterilized soil probably minimized the potential for differential impact due to symbionts between treatments. All plants within a test were from the same seedlot, the same age (4-5 weeks old), and had the primary and first trifoliolate leaves fully expanded.

For the nitrogen studies, 10 pairs of plants within each pH level of fog were further standardized by CO₂ assimilation rates using a Li-Cor 6000 photosynthesis measurement system (Li-Cor Inc., Lincoln, Nebraska). Nondestructive measurements were recorded 20 hr pretreatment in the laboratory under a metal halide lamp providing a minimum of 1000 $\mu\text{E}/\text{sec}\cdot\text{m}^2$. After sampling the primary leaves of ca. 40 plants, 10 pairs of plants were identified that differed in CO₂ assimilation by less than 0.003 mg CO₂/sec $\cdot\text{m}^{-2}$. One of each pair of plants with comparable CO₂ assimilation rates was exposed to a control fog, and the other to an acidic fog. Standardizing test plants by CO₂ assimilation rates is important, because even plants from the same seedlot grown concurrently can differ significantly in photosynthetic and physiological activity (Trumble et al., 1985), and CO₂ assimilation rates are proportionally related to percent nitrogen and soluble protein levels in plants (Hesketh et al., 1983; and references therein).

Cabbage looper, *Trichoplusia ni* (Hübner), eggs and larvae were obtained from a laboratory colony reared on artificial diet (Shorey and Hale, 1965). The colony was maintained at a photoperiod of 12:12 hr light-dark and a temperature of $21 \pm 1^\circ\text{C}$. Although larvae fed on an artificial diet may not respond to stimuli exactly the same in all situations as foliage-fed larvae, this approach did provide standardized experimental organisms with regard to age, stress, and nutritional backgrounds.

Simulated Acidic Fogs. Simulated acidic fogs were prepared by adjusting

distilled water to pH 2.0, 2.5, and 3.0 with reagent-grade nitric and sulfuric acid mixed at a 2.5:1 (v/v) ratio. This mixture is typical of the high-nitrate, low-sulfate fogs in California, but lacks other ionic components of ambient moisture (Waldman et al., 1982). Control fogs consisted of distilled water with a pH of 6.3–6.5. The simulated fogs were created within a 1-m² chamber using a fogging apparatus designed by Musselman et al. (1985), which produces a droplet size averaging 20 μm in diameter. Test plants were fogged for 2 hr and then placed outdoors to dry for at least 1–2 hr.

Total Nitrogen, Soluble Protein, and Free Amino Acid Analyses. Ten pairs of plants were analyzed for each pH level of the acidic fog. After air drying, the primary leaves and an upper trifoliate leaf were excised, combined, and then divided into aliquots for analyses of total nitrogen, soluble proteins, and free amino acids. Samples were weighed immediately after collection, frozen in liquid nitrogen, and stored in an ultracold freezer (-65°C). Enough leaf material was available on each plant to allow two samples of each of the variables to be analyzed. Potential long-term changes in plant chemistry were not addressed by this study.

Total nitrogen was analyzed using the micro-Kjeldahl technique (McKenzie and Wallace, 1954). The technique was modified by replacing the mercuric oxide catalyst with copper sulfate, and by utilizing bromocresol green in place of methylene blue as an indicator. Percent water content of the foliage was determined by subtracting the dry weight (oven-dried at 70°C for 72 hr) from the fresh weight, dividing by the fresh weight, and multiplying by 100.

The technique of Jones et al. (1988) was used to quantify soluble protein. Frozen samples (0.4–0.6 g fresh weight) were ground and extracted with 10 ml 0.1 M NaOH for 30 min at room temperature. Leaf tissue was removed by centrifugation (11,500g for 10 min) and the decanted supernatant was brought to 10 ml with 0.1 M NaOH. Protein concentration in the NaOH solution was measured with the Bradford (1976) reagent using ribulose 1,5-biphosphate carboxylase (RuBPase) (Sigma Chemical Co., St. Louis, Missouri) as the standard. Samples were diluted when necessary to avoid deviations from linearity due to NaOH at high protein concentrations. Duplicate readings were made on each extraction. Values are reported as milligrams RuBPase equivalent protein per gram fresh weight of foliage.

Free amino acids were extracted using procedures modified from Hare (1983). Twenty amino acids, including a nonprotein amino acid (gamma aminobutyric acid) and two secondary amino acids (hydroxyproline and proline) were quantified by reverse-phase HPLC on a Beckman model 332 liquid chromatograph with a fluorescence detector after precolumn *o*-phthalaldehyde (OPA) derivatization using methods described by Cooper et al. (1984). A Beckman 3- μm Ultrasphere-XL ODS column 4.6 mm ID \times 70 mm in length was used to improve resolution. Prior to injection, 200 μl of 1.3 M sodium phosphate (pH

3.5) was added to reduce the pH of the sample in order to improve column life (Sista, 1986). Quantities of each amino acid were calculated from their peak areas in relation to the peak area and known quantity of the appropriate internal standard (Cooper et al., 1984).

Data on nitrogen and water contents of treated and control plants were analyzed with paired and unpaired *t* tests. Paired *t* tests were included because CO₂ assimilation rates are proportionally related to percent nitrogen and soluble protein levels in plants (Hesketh et al., 1983). Unpaired *t* tests were presented for comparative purposes because no clear relationships between either free amino acid or water content and CO₂ assimilation rates have been established. Free amino acid analyses were performed on each amino acid individually, all combined, and grouped by the "essential" vs. "nonessential" criterion of Taylor and Medici (1966).

Influence of Acidic Fogs on Insect Developmental Parameters. In order to document the direct effects of acidic fogs on survival of eggs, caged moths were allowed to oviposit for 8 hr on 4- to 5-week-old *P. lunatus*. Plants with 20 eggs developing to the point of head capsule visibility were assigned randomly to control fogs or acidic fogs with a pH of 2.0 or 3.0. A control accompanied each pH level of fog because these tests were not concurrent. Six replicates of 20 eggs were tested at each pH level. Plants with eggs were exposed to control and acidic fogs for 2 hr and then held at $26.7 \pm 1^\circ \text{C}$, $65 \pm 5\%$ relative humidity and a photoperiod of 16:8 hr light-dark until eclosion. Eggs were monitored at 24-hr intervals for at least five days. Comparisons between treatment and control groups were made with unpaired *t* tests.

Food consumption by *T. ni* larvae on plants exposed to fogs with pH values of 2.0, 2.5, and 3.0 was quantified by individually caging a neonate larva on foliage of 30 treated and 30 control plants (one larva per plant) ca. 2 hr after fogging. All larvae were treated concurrently on plant material prior to transfer to cages on the test plants. Plants and larvae were randomly selected for each treatment. A control fog was conducted simultaneously for fogs with pH values of 2.0 and 2.5 + 3.0 because logistics precluded running all acidic fogs concurrently. Plants and larvae were maintained at room temperature, which ranged from 20 to 26°C. Larvae were held until any leaf in the test began to senesce (12–13 days, at which time larvae were in the third instar). All larvae then were removed and the test was concluded. The test was terminated at this time because attempts to relocate the larvae to undamaged leaves were unsuccessful, and substantial mortality resulted. Immediately after larvae were removed, test and control leaves were photocopied and the leaf area with and without excision of feeding damage was measured on a Li-Cor 3000 leaf area meter. Differences between the measurements provided the leaf area consumed per larva. To account for potential differences in specific leaf weight at 7 and 14 days post-treatment, 20 plants were treated with 2.0 pH acidic fog as described earlier

and compared for specific leaf weight (fresh weight) with 20 control plants treated with a pH 6.3–6.5 fog (10 per sample date). Six to eight 22-mm-diameter cores (No. 14 cork borer) were taken from each expanded primary leaf (at least 70% of the total leaf available) and the fresh weight measured. This information was necessary to calculate differences in consumption rate based on leaf area if specific leaf weight varied between treatments.

Larval weight gain on foliage treated with acidic (pH 2.0 or 3.0) or control fogs was measured by individually caging 15 neonate larvae per treatment on plants in the same fashion as the food consumption test. Plants and larvae were randomly selected for each treatment. When any leaf was ca. 90% eaten or began to senesce (as evidenced by onset of yellowing), the surviving larvae (third instars) were removed and weighed. Data were analyzed by unpaired *t* test.

Preference of *T. ni* larvae for foliage exposed to acidic fogs or control fogs was evaluated using a leaf disk bioassay technique. After random selection for treatment, plants were exposed to acidic fogs with a pH of 2.0 or 3.0 (nonconcurrently), or control fogs, and allowed to dry for 3 hr before 22-mm-diameter leaf disks (No. 14 cork borer) were cut from expanded primary leaves. Two control and two test disks from individual plants (total 20 plants per treatment) were placed on moistened filter paper at alternating cardinal points in 8 × 2-cm Petri dishes. Two larvae reared to third instar on artificial diet then were placed centrally in the Petri dish and allowed to feed for 23–24 hr. This test was replicated 20 times for each acidic fog and control fog tested. The remaining leaf area of the disks was measured with a Li-Cor 3000 leaf area meter. All Petri dish experimental units contained feeding damage. Differences in leaf area consumed were analyzed with a paired *t* test (treated versus control disks within a Petri dish) to remove variability in feeding rates between larvae.

RESULTS AND DISCUSSION

Total Nitrogen, Soluble Protein, and Free Amino Acid Analyses. The total nitrogen content of *P. lunatus* exposed to acidic fogs was substantially altered as compared to control plants (Table 1). Plants exposed to fogs with increasing acidity had significantly higher nitrogen content as compared to their respective controls ($P \leq 0.1, 0.05, 0.01$, for fogs of pH 3.0, 2.5, 2.0, respectively). This increase was not linear, suggesting a nonuniform uptake. Presumably at least some of the additional nitrogen was deposited by the acidic fog in the form of nitrate and was not converted on the leaf surface to a form usable by the plant. However, considerable evidence is available, which suggests that growth of plants exposed to acidic fogs may be enhanced by the increased availability of nitrogen and sulfur (Ferenbaugh, 1976; Irving, 1979; Shriner, 1986). The sig-

^a Analysis by unpaired and paired *t* tests, results were similar with both tests, so only the unpaired values were reported. Values presented in percent were subjected to arcsine square root transformation prior to analysis. Samples from paired comparisons based on 9-10 pairs of plants exhibiting similar photosynthetic rates (± 0.003 mg CO₂/sec/m²). Plant material was collected approximately 4 hr after fogging. **significance at $P < 0.01$ level, * $P < 0.05$.

^b Control plants fogged with distilled water with a pH of 6.3-6.5.

^c Significant at $P < 0.073$ level.

nificant ($P < 0.01$) increase in soluble protein concentrations for plants exposed to fogs with a pH of 2.5 suggests that some of the nitrate nitrogen responsible for the increase in total nitrogen was assimilated even within the 2-3 hr following fogging. If the increase in soluble protein was simply a response to stress, as has been demonstrated for other environmental factors (Beckerson and Hofstra, 1979; White, 1984), then foliage exposed to the 2.0 fogs also should have developed elevated concentrations. Fogs with pH values of 3.0 or below (i.e., more acidic) are well within the range shown to cause both visible and physiological damage to legumes (Shriner, 1986).

Although significant differences in concentrations of specific amino acids were observed in *P. lunatus* subjected to acidic fogs with a pH of 2.5 as compared to plant material from control fogs, no significant differences in total free amino acids, insect-essential or nonessential amino acid concentrations were evident (Table 2). Interestingly, all of the specific amino acids that showed significant changes in concentration actually increased in concentration. This is in contrast to the impact of another air pollutant, ozone, on the tomato system, where concentrations of certain amino acids were reduced (Mudd and Freeman, 1977; Trumble et al., 1987). No significant differences were observed for specific or total amino acid concentrations between plants exposed to control fogs

or acidic fogs with a pH of 2.0 or 3.0 and are not reported. Thus, the extensive quantitative changes in amino acid levels associated with physiological effects of other air pollutants (e.g., ozone) (Menzel, 1971; Craker and Starbuck, 1972) did not occur consistently (i.e., at all pH levels) in our study.

Influence of Acidic Fogs on Insect Developmental Parameters. There were no significant differences in specific leaf weight between treatments at either 7 (means \pm SD = $6.7 \pm 0.5 \text{ mg}/\text{cm}^2$ for controls and $7.0 \pm 0.6 \text{ mg}/\text{cm}^2$ for pH 2.0; *P* > 0.05, *t* test) or 14 days posttreatment (means \pm SD = $7.2 \pm 0.5 \text{ mg}/\text{cm}^2$ for controls and $7.1 \pm 0.5 \text{ mg}/\text{cm}^2$ for pH 2.0; *P* > 0.05, *t* test), so consumption has been reported as leaf area consumed.

Exposure of host foliage to the low and moderately acidic fogs chosen (pH 3.0 and 2.5) had a significant impact on larval feeding and weight gain (Table 3). *T. ni* larvae ate significantly more leaf area (*P* < 0.05, *t* test) and gained significantly more weight (*P* < 0.01, *t* test) on plants subjected to fogs of pH 3.0 than on plants exposed to control fogs.

Although a trend for greater average leaf area eaten per larvae was observed for larvae on plants exposed to fogs of pH 2.0 and 2.5, the magnitudes of the differences were less than those at pH 3.0 and were not significant at the *P* < 0.05 level (Table 3). Variation in foliar water content is often an important factor in insect growth and development (Scriber, 1984) but was not significant

and did not provide an explanation for the results in our study (Table 1). Because nitrogen is often a limiting factor for insects (Mattson, 1980), the lack of improvement in weight gain by *T. ni* larvae was surprising, given the elevated percent total nitrogen in plants exposed to 2.0 pH fogs and the increases in soluble proteins and specific free amino acids in plants subjected to 2.5 pH fogs (Tables 1 and 2). However, because nitrogen was added to the system in the form of fertilizer, the nitrogen availability may not have been as limiting in these plants as compared to other systems. Insects feeding on foliage from plants in either acidic fog treatment, therefore, would not have been limited by percent total nitrogen, but the ratios of amino acids conceivably could affect the acceptance or osmotic balance of treated foliage (House and Barlow, 1964; Broadbeck and Strong, 1987).

Several alternative explanations exist for the lack of increased weight gain of *T. ni* larvae on plants with higher percent total nitrogen, soluble protein, or specific free amino acids. One explanation amenable to further testing is that the nitrate form of nitrogen is unsuitable for *T. ni*. A second explanation is based on the observation that test plants from the pH 2.0 and 2.5 fogs had (by subjective evaluation) more necrotic areas, which reasonably could be expected to interfere with palatability or phagostimulation. Large necrotic regions on

Phaseolus species caused by acidic fogs typically have no intact cells and the cellular material coagulates into an undifferentiated mass less than one third the volume of undamaged tissue (Evans et al., 1977; Trumble and Walker, unpublished). Thus, larvae on these plants would spend more time in transit between acceptable or palatable regions and less time feeding than larvae on foliage with minimal damage. A third explanation is that the changes in nitrogen content and quality were at least partially offset by increases in other compounds (phenolics, phytoalexins, etc.) produced in response to damage that deterred feeding and/or assimilation by the larvae. Finally, because *T. ni* is a generalist feeder, the variation in nitrogen form and content between stressed and unstressed plants within the species observed in this study may be small relative to variation among species within the insect's broad host range.

Long-term effects of acidic fogs on the larval population dynamics of insects would be dependent, among other things, on the time following acidic fog exposure, the duration and acidity of the fog, and the rate at which nitrate nitrogen was converted to insect usable or acceptable forms. In our study, no significant ($P < 0.1$) effects of fogs were seen on the survivorship of the egg stage (Table 3) or on survivorship of larvae in any treatment-control comparison from the larval weight gain study or the leaf area consumption study (t test, P was always greater than 0.2). However, the survivorship of larvae was not followed through to pupation, nor were any direct effects of acidic fogs on adult oviposition or larval behavior monitored. Thus, additional research must be conducted before the impact of acidic fogs on the life history or population dynamics of *T. ni* can be estimated with confidence.

Acknowledgments—We thank H. Nakakihara, W. Carson, J. Rettig, and M. Reeve for their technical assistance. The critical reviews of T. Paine, W. Weisenborn, M. Brewer, W. Moar, and C. Jones are greatly appreciated. This study was supported in part by a grant from the Academic Senate of the University of California, Riverside.

Book Review

CRC Handbook of Natural Pesticides: Methods, Vol. I, Theory, Practice, and Detection.

N. Bushan Mandava (ed.).

Boca Raton, Florida, CRC Press, 1985, Second Printing 1988. 534 pp.

This book is a treasure that should be added to the library of every policy maker, administrator, instructor, and researcher concerned with the use of natural and synthetic chemicals for the protection of crops and regulation of their growth and development.

The book begins with a masterful chapter by the distinguished professor, synthesizer, and policy analyst, David Pimentel. Pimentel summarizes the losses caused by insects, diseases, and weeds, and explains factors and trends in losses and approaches to mitigating them from an ecological perspective. He also includes a tabulation of the environmental and social costs of pesticide use in the United States. A defect in this chapter is Pimentel's failure to use current information on pesticide usage. Thus, Pimentel implies that the volume of insecticide usage continues to increase and that the percent of pesticides used is 60% for herbicides; 25% for insecticides, and 15% for fungicides. Actually, the volume of insecticide usage peaked in 1978, whereas use of herbicides has continued to progressively increase at more than 6% per year and has more than doubled between 1975 and 1985 (see Carlson, 1989; Ayers, 1985; Gianessi, 1987). Thus, currently the percent of total usage of pesticides in the United States is roughly 70% for herbicides, 25% for insecticides and nematocides, and 5% for fungicides.

Chapter 2 on integrated crop management systems by El-Zik and Frisbie is crammed with wonderful facts and concepts from the entire historical record of agriculture. The chapter provides a very comprehensive discussion of cotton physiology in relation to all of the organisms and environmental factors that affect the crop in a negative or positive manner. This chapter should be required reading, not only for students of the cotton plant and its production and protection, but also for all students in agronomy and plant protection. They present the ancient wisdom of Epictetus that "one must not tie his ship to a single anchor, nor life to a single hope."

Chapter 3, by the late Warren C. Shaw, addresses technology for integrated weed management systems. Shaw describes the program classification for integrated pest management that was devised by the now defunct Science

and Education Administration of the U.S. Department of Agriculture. He explains our problems with weeds in relation to the natural successions of plants that occur in disturbed habitats. Agriculture often attempts to reverse these natural successions, and this can be achieved only by applying mechanical or chemical energy to the agroecosystem. Shaw enunciates a clear vision of reducing losses caused by weeds and the cost of their control, and leaves the reader with a sense of mission.

Chapter 4, by Tummala and Gage, is an excellent introduction to the use of computers and models in pest management. The chapter is based on seminal experience of the Michigan State University program.

Chapter 5, by Einhellig, discusses the fascinating phenomenon of allelopathy and supports the general discussion with useful case studies and a discourse on the chemistry of natural products exuded by plants to ward off competitors. The chapter amply demonstrates that the inhibitory as well as stimulating allelopathic capabilities provide a significant but complex channel for improving agricultural production. The chapter should be read by those concerned with groundwater contamination by synthetic organic herbicides.

Chapter 6, by Dickens and Payne, is a clearly written exposition on the fundamental aspects of insect chemoreception and of insect behavior in relation to chemical messengers. The authors have succeeded in distilling the essence of this vast topic into a few pages of considerable pedagogical and heuristic value.

Chapter 7, by Hodosh, Keough, and Luthra, provides a very clear and thorough exposition of the Environmental Protection Agency's requirements for registering biochemical and microbial pesticides. These requirements have continued to evolve, and the reader is advised to contact the agency for current and prospective requirements.

In chapter 8, Upholt compares and contrasts approaches to the regulation of pesticides used by various countries. The chapter is helpful in gaining an understanding of history and principles of pesticide regulation.

In chapter 9, Perkins attempts to apply to applied entomology Kuhr's concept that scientific revolutions occur when one fundamental paradigm is replaced by another. Perkins attempts to apply this concept not to the science of entomology but, rather, to the application of technologies to meet the problems created for man by insects. Thus, Perkins attempts to divide applied entomologists into one school that adheres to the integrated pest management paradigm and another that adheres to the total population management paradigm.

Chapter 10, by Yopp, addresses bioassays for plant hormones and other naturally occurring plant growth regulators. This 148-page compendium of bioassays should be on the desk of every scientist engaged in research on plant hormones growth regulators.

Chapter 11, by Redfern, is a very brief introduction to bioassays of insect

hormones, attractants, repellents, and antifeedants. It provides specific information on the methods used successfully by the author for several decades. Chapter 12, by Reichelderfer, is a very practical guide to assaying the toxic effects on various insects of bacteria, viruses, fungi, and protozoa. These two chapters could be most useful in instructing students and technicians.

This volume is highly recommended to those who set policies and design programs in plant protection, and to scientists and technicians who may benefit from inspiration and practical methods for contributing to this essential endeavor.

Book Review

CRC Handbook of Natural Pesticides: Methods, Vol. II, Isolation and Identification.

N. Bushan Mandava (ed.).

Boca Raton, Florida, CRC Press, 1985, £776, 545 pp.

The application of natural products plays an increasingly important role in integrated pest management. High selectivity and easy biodegradation render many of them superior to the "classical" synthetic pesticides. N. Bhushan Mandava, as editor-in-chief of the series, has undertaken to integrate the extensive themes in this area. The second volume of the first part, "Methods" (of a series of seven books) deals with general aspects of analytical organic chemistry with some special emphasis on selected compounds. The term "natural pesticides" is generously treated. It is debatable whether biologically active natural products or their derivatives "once . . . applied by external means . . . come under the label 'pesticides' because they contaminate the environment" (Introduction), or whether "pheromones, insect hormones and plant growth regulators are considered together because of their mode of action as pesticides" (p. 452). The term "natural" is also not taken too seriously, since GC-FTIR data of Mirex and its derivatives as well as GC-MS data of Arochlor are included.

The book is divided into two main topics: "Methods for Isolation" (four chapters) and "Methods for Identification" (14 chapters). Basic principles used in the analysis of natural products are compiled, and the nonspecialist who wants a rapid overview is carefully informed about the theoretical background of separation techniques and spectroscopic methods; the expert will also benefit from collected data. Subdirectories for each chapter would have been helpful.

The first part, isolation (30% of the book), starts with a nice and highly condensed review by E.D. Morgan and I.D. Wilson of a broad spectrum of isolation techniques of volatile and nonvolatile organic compounds from complex mixtures. Unfortunately, there are many misdrawings in the chemical formulas which may confuse the non-insider. The next chapter, by G.I. Kingston and M.M. Rao, deals with chromatography and is more oriented to theoretical and technical background than towards practical application. Modern injection techniques in GC, micromethods in derivatization and preparative isolation, as well as multidimensional separation in GC and HPLC are not discussed. Separation of enantiomers on optically active stationary phases, which could easily fill a chapter of its own, is not mentioned. Supercritical fluid chromatography (SFC) may be too new to be included. The next two chapters, written by W.D.

Conway, on countercurrent chromatography and distribution are highly instructive both from the theoretical and practical point of view. Several tables show solvent systems for the separation of various classes of compounds.

After a general introduction, the second part (identification) starts with extensive chapters on UV and IR spectroscopy to which the editor himself contributed. Many tables of absorption bands of functional groups are given. This part might have profited from condensation but nevertheless contains much useful information. Spectra of compounds, which are targets of this book, are presented in three short chapters. A very important contribution on NMR spectroscopy by D. Weisleder perfectly treated the theoretical background and provides extensive information on cephalotaxus alkaloids, rotenoids, phytoecdysones, and gibberellins. It is a pity that modern two-dimensional techniques are omitted. J.M. Ruth wrote an impressive chapter on mass spectrometry, giving a comprehensive overview of theory and application. More spectra of "natural pesticides" would have been highly desirable. Spectra of chlorinated dimethanonaphthalenes and methanoindene derivatives, such as aldrin or heptachlor, respectively, as well as the complete high-resolution MS of the bark beetle pheromone, lineatin (which covers 1% of the book), are certainly for specialists only. Two informative chapters on optical rotatory dispersion/circular dichroism (J.D. Weber) and X-ray diffraction analysis (J.L. Flippen-Anderson, R. Gilardi) deal with the determination of the absolute configuration of compounds. Application to structural assignment of some naturally occurring pesticides are discussed.

The book finishes with three chapters on methods and techniques that enable workers to investigate the effects of certain compounds on target organisms: electron spin resonance (ESR, by E.C. Toolson); fluorescence, including a valuable list of fluorescent derivatives (R.J. Argauer); and an exciting laboratory manual on the methodology for gene expression (G.R. Chandra, G.P. Albaugh, S.M. Krishnan). An additional chapter on radiolabeling techniques would have been nice to have in this context.

Despite these criticisms, the book is a useful collection of topics in the analytical chemistry of natural products, presented by a team of distinguished scientists. Interdisciplinary groups who are interested in a better understanding of analytical chemistry (and the people who are working in this area) should buy it. Many cross references to monographs, reviews, and original papers will help the reader to become an expert.

Book Review

CRC Handbook of Natural Pesticides, Vol. III, Insect Growth Regulators, Part A and Part B.

E. David Morgan and N. Bushan Mandava (eds.).
Boca Raton, Florida, CRC Press, 1987. 378 pp.

The first chapter is a short introduction to the insect neuroendocrine system by G. Richards and J.A. Hoffman. It is a useful, simple overview of hormones influencing growth and development in insects and the points at which research has, or may in the future, provide means of controlling pest species. I.D. Wilson gives a comprehensive account of known ecdysteroids and their chemical properties (up to 1984), although there are some unclear or slightly erroneous biological points (e.g., supermolts for supernumerary molts). N. Wakabayashi and R.M. Waters deal with juvenile hormones and related compounds. This chapter is a remarkable collation of the literature (875 references), much of it in table form, but it does suffer from being cryptic or confused. There is no attempt to resolve contradictions in the literature and no value judgments to help the reader with inconsistencies listed. There are a number of apparent errors (for example, precocenes are held to act on the brain, although Pratt and others have clearly shown direct effects on the corpora allata). In addition, the many tables telling us that there is an effect without any idea of what the effect is, are of limited value. Furthermore, two references that were checked referred to papers without the supposed data. Part A is completed by a chapter on chemistry and biology of selected insect peptides by W. Mordue and P.J. Morgan. Unfortunately this deals with the topic, as the title suggests, in a manner that is very selective. For example, there has been more work on insulin and glucagon-like hormones by Moreau and others. Overall, however, it is a useful review of chemistry and biology of peptide hormones up to 1985.

Part B deals with ways of influencing growth and development by using naturally occurring chemicals that in some way interfere with insect physiology. The effects described include effects on hormone production or target tissues, as well as more directly by toxic effects, while in some cases modes of action are quite unknown. The first chapter, by A.B. Bořkovec, deals with chemosterilants. These are divided broadly into mutagens and nonmutagens, although unequivocal designation is often not possible. Listed among mutagens are various alkaloids. Among nonmutagens, nutritional deficiencies are mentioned as well as phytecdysteroids and juvenile hormone analogs. A listing of plant-derived chemicals is given, but the chapter is too brief to be particularly useful.

J.C. Reese and C.W. Holyoke review plant secondary compounds (allelochemicals) affecting insect growth and development. After an introduction, the chapter is in the form of tables and chemical structures. For example, work on nonprotein amino acids (called amino acid analogs) and their effects are listed as well as the chemical data for the compounds, and their structures are shown. Similar data are given for phenylpropane derivatives, terpenoids, alkaloids, flavanoids, etc. Although such a compilation cannot be comprehensive and includes results that might have been due to antifeedant activity, it is a useful reference guide. The same authors have a similarly compiled chapter on acute insect toxicants (i.e., causing mortality) from plants. A number of small errors were noted (e.g., spelling of insect names) as well as some major ones (e.g., calling lignans lignins gives cause for concern about chemical expertise).

Finally, there is a chapter entirely devoted to chemicals from neem and chinaberry trees by H. Schmutterer. Genuine growth-disrupting effects are quite fully reviewed, and the current and future uses of the chemicals are discussed.

In summary, the two books provide 378 pages of useful reviews, although the chapters are of very mixed style and quality. Part A mostly does not fit under the overall title of "natural pesticides," and it is a pity that there were not some more detailed articles on actual modes of action. There would have been more to say on antihormones, for example. Libraries will need to have this book even if individuals do not find it worth the money.

Book Review

CRC Handbook of Natural Pesticides, Vol. IV, Pheromones.

E. David Morgan and N. Bhushan Mandava (eds.).

Boca Raton, Florida: CRC Press, 1988. 494 pp.

A CRC Handbook on the topic of pheromones does not conjure up images of an exciting treatise about new uses of pheromones or new insights into pheromone chemistry, or even a refreshing synthesis of existing ideas. Instead, the prospective reader envisions a rather dry book brimming with facts, figures, and endless tables. This two-book series (Parts A and B) harbors no surprises. In general, the appeal and utility of handbooks strongly depend on the type, the thoroughness, the arrangement, and the presentation of their important data. Thus, the interest in these books will not depend on whether they are interesting, stimulating, or controversial because, as is well known, handbooks rarely are; rather, interest will depend on whether these books are useful, well organized, and complete.

E. David Morgan and N. Bhushan Mandava are the editors of a multivolume series entitled *Handbook of Natural Pesticides*. Volume IV of this series is simply entitled *Pheromones* and consists of two books, Part A and Part B. Even though a handbook about pheromones is timely and potentially useful, the very title of these books strikes a terrible blow to the "cause" of pheromones because it places them within a larger series concerned with "natural pesticides." This designation as a pesticide is clearly misleading (to people outside the field) and, furthermore, it will probably be used to fuel arguments in support of EPA's classification of pheromones as "pesticides." Arguably, no other factor looms larger to people or organizations who want to commercialize the use of (a) pheromone(s) than the ruling by the EPA that a pheromone will be treated the same way as "hard" pesticides. The subject of pheromones would probably have been better served if the CRC organization had treated pheromones as a distinct entity separate from so-called natural pesticides.

However, the above complaints are minor and reflect personal biases; let us now consider the contents of these books. There are six distinct and almost disjointed chapters; five of the six chapters were written by different authors. Curiously, none of the chapters were written by the editors. The mere fact that there are so many different authors tremendously detracts from the book. For example, five of the six chapters are concerned in some way with cataloging actual pheromone substances and therefore each contains structural, analytical,

and biological activity data. The user should beware, however, because each author presents data in widely differing formats.

The first chapter, "Insect Olfaction and Molecular Structure," written by Richard P. Evershed, is a general review of insect olfaction, and in it are sections on the mechanisms of olfaction, the stereochemistry of olfaction, and the termination of the olfaction process by pheromone-degrading enzymes. This chapter is clearly intended to serve as an introduction to the remaining chapters; the reader, however, is left with the feeling that this chapter is somehow out of place in a handbook about pheromones. Although the chapter is well written and reviews a wealth of literature (178 references), it just does not contain the lasting factual information that makes handbooks useful.

Chapters 2–6 contain information about pheromones of the Lepidoptera; Coleoptera; Diptera; Hymenoptera and Isoptera; and Hemiptera, Blattoidea, and Orthoptera, respectively. Each of these chapters contains some type of background information, usually about the discovery and importance of pheromones in each of the orders covered. The individual chapters also contain, more or less, a review of the isolation, identification, and use of pheromones (and other attractants) for control purposes. None of these written reviews represent worthwhile additions to the already large review literature about pheromones.

Conversely, the abundance of factual data found in Chapters 2–6 represents the true merit and lasting value of these books. For instance, Chapter 2, by Yoshio Tamaki, contains information about and is entitled "Pheromones of the Lepidoptera." Table 1 of this chapter lists information on 160 species of Lepidoptera and lists 99 different compounds associated with these species. Table 2 follows with structural characteristics of the different lepidopteran families. In Table 3, the reader finds a list of synthetic sex attractants for male Lepidoptera as determined by field tests. The data in this table represent useful information for field work and pest control; the data do not, however, have any direct connection with pheromones. The chapter is closed with sections on biosynthesis, secretion of pheromones, and utilization of lepidopteran pheromones (and attractants) for pest management. A discussion of pheromone utilization for pest management is a common theme that is found in all remaining chapters with the notable exception of Chapter 5.

The remaining chapters (3–6) follow a similar pattern, although the specifics vary considerably. Chapter 3, "Pheromones of the Coleoptera," by Hans Jurgen Bestmann and Otto Vostrowsky, is probably the most complete chapter. The authors review not only the isolation and identification of coleopteran pheromones, but also their synthesis. The various tables and sections catalog chemical names, structural formulae, synthesis, occurrence of compounds, physical

and analytical properties, spectral data, function, and biological activity information.

The prose sections include discussions of specificity of beetle pheromones (stereobiology), biosynthesis, plant protection by pheromones, monitoring with pheromones, mass trapping, population suppression, disruption of mating, control of forest and shade-tree pests, control of field-crop insect pests, control of stored-product insect pests, control of grassland and pasture insect pests, and formulations of pheromones. Although the chapter is quite thorough and well written, there is unfortunately no quick or simple method of finding a particular pheromone compound or insect species. However, the compounds are numbered so that when one is found, it is easily cross-referenced to other tables in the chapter.

Chapter 4, "Pheromones of Diptera," and Chapter 6, "Pheromones of Hemiptera, Blattoidea, and Orthoptera," were both written by B.S. Fletcher and T.E. Bellas. The information found in the tables of these chapters is arranged similarly to that in the chapter on Coleoptera. The type of information is also quite similar; the significant addition found in this section is CAS Registry Numbers for each compound. Again, there is an apparent lack of design to the arrangement of compounds in the tables. Both chapters stress the importance of practical and useful aspects of these pheromones.

The remaining section is the chapter by James W. Wheeler and Richard M. Duffield entitled "Pheromones of Hymenoptera and Isoptera." These authors clearly had a different outlook when they wrote this chapter. At first glance, the reader is immediately impressed with the vast compilation of data and how well it is organized. The organization in this chapter deserves special mention: The compounds are arranged in groups by functional groups, and, within each group, by molecular formula. The process of locating specific compounds is quick and simple. Closer inspection reveals, however, that the title of this section should have been "Natural Products of Hymenoptera and Isoptera" instead of "Pheromones of . . ." The vast majority of the compounds compiled in their extensive tables are *not* associated with any particular insect behavior or form of communication. What is nearly always provided instead is the source of the material, e.g., from a certain gland or organ. The problem with this chapter is its lack of useful information on biological activity as well as an almost complete lack of potential uses of these compounds for pest control.

As far as handbooks go, this one is middle of the road. On the plus side, there is no other book or series of books that brings together so much factual information about pheromones with corresponding references to the primary literature. In fact, these books represent a good first-choice reference source for

inquiries ranging from simple factual questions on the one hand, to full literature searches on the other. Presumably, the authors' intentions have been fulfilled. The reader, however, suffers from the disjointed nature of the chapters and from the sometimes disorganized presentation of data. Finally, the potential buyer must question how long the information in these handbooks will remain useful in light of the dynamic and unpredictable nature of the entire field of pheromones.

STATISTICAL ANALYSIS OF THE JOINT INHIBITORY ACTION OF SIMILAR COMPOUNDS¹

THOMAS M. GERIG,² UDO BLUM,³ and KRISTEN MEIER²

²*Department of Statistics*

³*Department of Botany
North Carolina State University
Raleigh, North Carolina 27695*

(Received October 24, 1988; accepted December 21, 1988)

Abstract—A statistical model is presented that characterizes the joint action of similar compounds when the response variable is continuous. The model allows for antagonistic and synergistic as well as similar joint (additive) action of compounds. It also allows for differential potencies in the compounds. A method of statistical analysis using nonlinear regression analysis is presented along with sample SAS code for carrying it out. An efficient experimental design is given in the form of a set of mixture combinations. Two generalizations of the model are discussed. An example is presented relating the joint action of ferulic and vanillic acids to the growth of cucumber seedlings.

Key Words—Synergy, antagonism, similar joint action, mixture.

INTRODUCTION

The purpose of this article is to present an experimental design, a statistical model, and a method of analysis that can be used for mixture experiments when the response variable is continuous. In particular, the methodology is applicable to experiments in which the action of mixtures of two chemically similar compounds is being evaluated.

The potency of a compound, C_1 , relative to another compound, C_2 , is

¹Paper No. 11878 of the Journal Series of the North Carolina Agricultural Research Service, Raleigh, North Carolina 27695-7601. The use of trade names in this publication does not imply endorsement by the North Carolina Agricultural Research Service of the product named, nor criticism of similar ones not mentioned. This research was partially supported by US-Spain Joint Committee for Scientific and Technological Cooperation project CCA-8309/166.

defined as the concentration (or dose) of C_1 that must be applied to experimental material to achieve the same effect as that obtained by the application of a unit concentration (or dose) of C_2 . For the compounds under study, we shall assume that relative potency is constant over the range of concentrations under consideration.

The proposed model presumes that the potency of a mixture of two compounds relative to one of the constituent compounds (with respect to a particular response) is proportional to the effective concentration of the mixture, Z . That is, the magnitude of the response, Y , to such a mixture is predictable from the effective concentration alone. If the effective concentration of the mixture, Z , is a linear (additive) function of the concentrations, X_1 and X_2 , of the constituent compounds, we describe their joint effect on the response as being similar joint action. Alternatively, if the effective concentration of the mixture is a nonadditive function of the concentrations of the constituents, the joint effect of the two acids may be antagonistic or synergistic. Antagonistic action occurs when the effective concentration, Z , increases more slowly with increases in X_1 and X_2 than would be expected under similar joint action; whereas synergistic action occurs when Z increases more rapidly. The concept of similar action was first presented by Bliss (1939) and elaborated by Finney (1952). Mixture models for quantal response data are given in Finney where he discussed the concept. Morse (1978) reviews attempts to define the terms antagonism and synergism. She also examines existing models for describing the joint action of two compounds when no antagonism or synergism exists including the additive dose model (ADM) and the multiplicative survival model (MSM). The models proposed in this paper are generalizations of the additive dose model.

METHODS AND MATERIALS

Models

Effective Concentration Model. Suppose that a mixture of two compounds, C_1 and C_2 , is applied to experimental material. Let (X_1, X_2) denote the application of such a mixture with C_1 at concentration X_1 and C_2 at concentration X_2 . If the action of a mixture (X_1, X_2) on the experimental material is determined solely by the value of the function

$$Z = X_1 + \beta_4 X_2 \quad (1)$$

where β_4 is a constant, then we say that the compounds exhibit similar joint action. The value of Z may be thought of as the effective dose or concentration that results from the application (X_1, X_2) . Thus, if compound C_1 is present alone resulting in $(X_1, 0)$, then $Z = X_1$; if compound C_2 is present alone resulting in $(0, X_2)$ then $Z = \beta_4 X_2$. The value of the parameter β_4 is the potency of

compound C_2 relative to that of C_1 as defined above. When, for example, $\beta_4 > 1$, compound C_2 is more potent than C_1 since the effective dose for $(X, 0)$ is $Z = X$ while that for $(0, X)$ is $Z = \beta_4 X$. Equivalent compounds would have $\beta_4 = 1$.

It would be advantageous to have a more general nonlinear model which relates (X_1, X_2) to effective concentration that includes the model for similar joint action as a special case. One such generalization, given below, is obtained by adding to the similar joint action model a multiple of the geometric mean of its two additive components:

$$Z = X_1 + \beta_4 X_2 + 2\beta_5(\beta_4 X_1 X_2)^{1/2} \quad (2)$$

where β_4 and β_5 are constants. This model has the pleasing property that the effective concentration, Z , is expressed in the same units as that shared by X_1 and X_2 . The β_5 parameter, sometimes referred to as the coefficient of synergy, determines the degree of departure of this model from the similar joint action model. Positive values of this parameter result in the effective concentration being greater than would be predicted by similar joint action and therefore correspond to synergistic action. In the same way, negative values of β_5 correspond to antagonistic action. The permissible range for β_5 is $-1 < \beta_5 < +\infty$ and, as such, the degree of antagonism can be judged on a scale ranging from 0 (no antagonism) to -1 (complete antagonism). A comparable range for synergism is obtained through the expression $\beta_5/(1 + \beta_5)$ which ranges from 0 (no synergism) to 1 (complete synergism) as β_5 ranges from 0 to $+\infty$.

Response Model. The response, Y , of the experimental material to the joint action of the compounds as a function of the effective concentration, Z , is frequently sigmoidal in shape. This is particularly true in cases where the nature of the action of the mixture is inhibitory, as with growth. A versatile model that is adequate for many applications is the three-parameter logistic function.

$$Y = \beta_1 / (1 + \exp\{\beta_3[\ln(Z) - \beta_2]\}), \quad \text{for } Z > 0 \quad (3a)$$

$$= \beta_1, \quad \text{for } Z = 0 \quad (3b)$$

The parameters in the model have the following interpretation:

β_1 is the response under control condition (i.e., $X_1 = X_2 = 0$ implies $Y = \beta_1$); β_2 is the value of $\ln(Z)$ required to achieve 50% inhibition, i.e., values of X_1 and X_2 for which $Z = \exp(\beta_2)$ will yield response $Y = \beta_1/2$; and β_3 is the parameter controlling rate at which the curve descends.

Statistical Analysis

Assume that data are available in the form (X_{i1}, X_{i2}, Y_i) , where X_{ij} is the concentration of the j th compound for the i th observation and Y_i is the value of

the response for the i th observation, $i = 1, 2, \dots, n$ and $j = 1, 2$. Consider the five-parameter nonlinear regression model:

$$Y_i = f(X_{i1}, X_{i2}; \beta) + \epsilon_i \quad (4)$$

i is $1, 2, \dots, n$, where $\beta = (\beta_1, \beta_2, \beta_3, \beta_4, \beta_5)$ denote the parameters; $f(X_1, X_2; \beta)$ is $\beta_1 / (1 + \exp\{\beta_3[\ln(Z) - \beta_2]\})$; Z is $X_1 + \beta_4 X_2 + 2\beta_5 \beta_4 X_1 X_2$ ^{1/2}; and ϵ_i , $i = 1, 2, \dots, n$ are independent random errors each with mean zero and variance σ^2 .

The methods of nonlinear regression analysis (see Gallant, 1975) may be used to find the least-squares estimator of the parameter vector β , i.e., that which minimizes the sum of squares:

$$SS(\beta) = \sum_{i=1}^n [Y_i - f(X_{i1}, X_{i2}; \beta)]^2 \quad (5)$$

and find its variance-covariances matrix. Several statistical software packages are available for doing this. Given the model specification (sometimes to include expressions for the partial derivatives of the model with respect to each parameter), the data and starting values for the parameters, these programs will provide least-squares estimates, $\hat{\beta}_j$, for the parameters, β_j , along with estimates, $\hat{\sigma}_j^2$, of their standard errors, σ_j^2 , and confidence intervals for the true parameters. SAS computer code is given in the Appendix as an illustration of the use of PROC NLIN (see SAS Institute Inc., 1985) for analyzing data using this model.

Starting Values. Suitably chosen starting values for the parameters to be used by the nonlinear regression algorithm can ensure convergence and cut down on the time required to achieve it. For β_1 , pick as a starting value, b_1 , the value of the average response, Y , which corresponds to mixture (0, 0) in the data. For β_2 , first take a guess, a_2 , at the value of X_1 which would yield a response equal to $Y = b_1/2$, then take $b_2 = \ln(a_2)$. Or, more simply, set $b_2 = 0$, which works in most cases. For β_3 , for experiments in which the effect of the compounds on the response is thought to be inhibitory, set $b_3 = 1$. For β_4 and β_5 set $b_4 = 1$ and $b_5 = 0$, respectively.

Testing Hypotheses. From this output we may test relevant hypotheses about the values of the true parameters in the model. For testing the two-sided hypotheses, $H_0: \beta_j = \beta_j^0$ versus $H_1: \beta_j \neq \beta_j^0$, where β_j^0 is given, calculate the value of the statistic:

$$t = (\beta_j - \beta_j^0) / \hat{\sigma}_j \quad (6)$$

and reject the null hypothesis, H_0 , in favor of the alternative, H_1 , whenever $|t| > z_{1-\alpha/2}$, where if Z is a standard normal random variable, z_α satisfies $P(Z \leq z_\alpha) = \alpha$ (e.g., $z_{0.975} = 1.96$). For one sided hypotheses, $H_0: \beta_j \geq \beta_j^0$ versus $H_1: \beta_j < \beta_j^0$, reject H_0 whenever $t < -z_{1-\alpha}$ and for $H_0: \beta_j \leq \beta_j^0$ versus $H_1: \beta_j > \beta_j^0$, reject H_0 whenever $t > z_{1-\alpha}$.

Hypotheses of Interest. To determine whether the experimental material exhibits a significant dose-response to the mixtures, we can test the null hypothesis $H_0: \beta_3 = 0$ versus the alternative hypothesis $H_1: \beta_3 \neq 0$, that is set $\beta_3^0 = 0$. This can be tested by the two-sided test described above or by referring to the confidence interval for β_3 and rejecting H_0 whenever the interval fails to cover zero. If this hypothesis cannot be rejected, then the analysis should not be continued since the estimates obtained for the other parameters would be meaningless.

The hypothesis of similar joint action (lack of synergism or antagonism) corresponds to $H_0: \beta_5 = 0$ versus $H_1: \beta_5 \neq 0$ and can be tested using the one-sided test or by noting whether or not the value zero is included in the confidence interval. Alternatively, if the purpose of the experiment is to prove synergism, then we wish to test $H_0: \beta_5 \leq 0$ versus $H_1: \beta_5 > 0$ which can be tested using the one-sided test. A test for antagonism may be similarly defined.

The hypothesis of equally potent compounds is expressed as $H_0: \beta_4 = 1$ versus $H_1: \beta_4 \neq 1$ and can be tested using the two-sided test or by noting whether the value one is or is not included in the confidence interval for β_4 .

Blocked or Replicated Experiments: The model can be generalized to allow experiments to be run in r replicates or blocks. For this purpose, the parameter β_1 is permitted to assume a different value in each replicate: $\beta_{11}, \beta_{12}, \dots, \beta_{1r}$. The data become $(X_{i1}, X_{i2}, L_{i1}, L_{i2}, \dots, L_{ir}, Y_i)$, where $L_{ik} = 1$ when the i th observation is from the k th replicate and zero otherwise, where $i = 1, 2, \dots, n$ and $k = 1, 2, \dots, r$. Then the response model becomes:

$$Y = \beta_{1.} / (1 + \exp\{\beta_3[\ln(Z) - \beta_2]\}), \quad \text{for } Z > 0 \quad (7a)$$

$$= \beta_{1.}, \quad \text{for } Z = 0 \quad (7b)$$

where $\beta_{1.} = L_1\beta_{11} + L_2\beta_{12} + \dots + L_r\beta_{1r}$. Starting value, b_{1k} , for β_{1k} may be taken as the value of the response to the (0, 0) mixture in the k th replicate, $k = 1, 2, \dots, r$. The tests of hypothesis are carried out as before.

RESULTS AND DISCUSSION

Experimental Design

The proposed experimental design was devised to be efficient (in the sense of D-optimality) for situations where β_1 is arbitrary, β_3 is in the range 1 to 3, and β_5 ranges from extremely antagonistic ($\beta_5 = -0.75$) to extremely synergistic ($\beta_5 = 3$). This covers a large percentage of cases likely to be encountered in practice. Since the design may vary greatly with changes in the parameters $\exp(\beta_2) = \alpha_2$ (= concentration required to achieve 50% inhibition) and β_4 ,

estimates or guesses at their values must be supplied. Lacking all knowledge of β_4 , set it equal to 1.

The following seven-point treatment design should be run in three or more replicates. Assume that by prior experimentation or other means preliminary estimates, a_2 and b_4 , are available for the parameters $\alpha_2 = \exp(\beta_2)$ and β_4 . In each replicate, runs should be made at mixtures ($\mu\text{mol/g}$):

$$(0, 0), (0.5*a_2, 0), (0, 0.5*a_2/b_4), (1.3*a_2, 0), (0, 1.3*a_2/b_4), \\ (0.5*a_2, 0.5*a_2/b_4), (1.4*a_2, 1.4*a_2/b_4)$$

Thus, for example, if $a_2 = 0.2$ and $b_4 = 0.6$, the design becomes $(0, 0)$, $(0.1, 0)$, $(0, 0.17)$, $(0.26, 0)$, $(0, 0.43)$, $(0.1, 0.17)$, $(0.28, 0.47)$. If the compounds are known to be antagonistic, the last mixture may be omitted. If they are known to be synergistic, the next to last may be omitted.

Testing Model Assumptions

The model described depends on the assumption that the relative potency of the two compounds is constant. To test this assumption, we can define a generalization of the effective concentration model

$$Z = X_1 + [\beta_4(1 + X_2)^{\beta_6}X_2] + 2\beta_5[\beta_4(1 + X_2)^{\beta_6}X_1X_2]^{1/2} \quad (8)$$

where β_6 is a new parameter which, by taking values different from zero, can allow for changes in relative potency as a function of concentration. In the same way that equations 1 and 2 were combined to define the nonlinear model (equation 4), equation 8 can be combined with equation 2 to define an extended six-parameter nonlinear model. It can be fit using nonlinear least squares. SAS code is provided in the Appendix for fitting this model using PROC NLIN. In the context of this model, the hypothesis of constant relative potency is $H_0: \beta_6 = 0$ versus $H_1: \beta_6 \neq 0$ and can be tested using the one-sided test described earlier or by noting whether or not the confidence interval includes zero. If the null hypothesis is rejected, then the proposed analysis may be misleading.

Generalizations for Three or More Compounds

The model described can be generalized to three or more compounds. For this purpose, only the model for effective concentration need be extended. While a number of generalizations of the effectiveness model are possible, one obvious choice for allowing three compounds, C_1 , C_2 , and C_3 with concentrations (X_1, X_2, X_3) would be:

$$Z = X_1 + \beta_4X_2 + \beta_5X_3 + \beta_6(\beta_4X_1X_2)^{1/2} + \beta_7(\beta_5X_1X_3)^{1/2} \\ + \beta_8(\beta_4\beta_5X_2X_3)^{1/2} + \beta_9(\beta_4\beta_5X_1X_2X_3)^{1/3}$$

Similar joint action results when $\beta_6 = \beta_7 = \beta_8 = \beta_9 = 0$. The parameters β_4 and β_5 are, respectively, the potencies of compounds C_2 and C_3 relative to C_1 .

Example

Consider data from an experiment to study the joint action of two compounds, ferulic (C_1) and vanillic (C_2) acid, on the growth of cucumber seedlings. The response of interest was the increase in total leaf area over a fixed interval of time (i.e., mean absolute rate of leaf expansion). The experiment was run in $r = 3$ replicates at concentrations (0, 0), (0, 0.25), (0.0.5), (0.25, 0), (0.5, 0), and (0.25, 0.25), where concentrations are expressed in micromoles per gram. The experimental design used in this example was devised before the efficient design presented above was developed and, as such, differs from it. The SAS code and data listed in the appendix were used to obtain the analysis in Table 1.

From Table 1 we note that for the extended (six-parameter) model $H_0: \beta_6 = 0$ versus $H_0: \beta_6 \neq 0$ we get $t = (0.300 - 0)/2.9 = 0.10 < z_{0.995} = 2.58$ and therefore cannot reject $\beta_6 = 0$. We conclude that relative potency is constant.

For the five-parameter model, we first note that β_3 is significantly greater than zero, indicating that inhibition of leaf growth had a dose-response with the compound concentration. We note further that coefficient of synergy, β_5 , is significantly less than zero at the 1% level since

$$t = (-0.413 - 0)/0.092 = -4.49 < -z_{0.99} = -2.33.$$

From this we conclude that $\beta_5 < 0$ so that the action of the two acids is antagonistic. Finally we see that the confidence interval for the relative potency, β_4 , includes only values less than one, leading to the conclusion that with respect to the growth of cucumber plants, vanillic acid is less potent than equal con-

TABLE 1. PARAMETER ESTIMATES, STANDARD ERRORS (SE), AND CONFIDENCE INTERVALS (CI)

Parameter	5-Parameter model				6-Parameter model	
	Estimate	SE	95% CI		Estimates	SE
β_2	-1.64	0.16	-1.98	-1.30	-1.66	0.26
β_3	2.72	0.74	1.10	4.34	2.56	1.7
β_4	0.626	0.107	0.391	0.861	0.564	0.59
β_5	-0.413	0.092	-0.615	-0.212	-0.410	0.11
β_6	0.000				0.300	2.9

centrations of ferulic acid. To confirm this we can test $H_0: \beta_4 \geq 1$ versus $H_1: \beta_4 < 1$. Using the 1% level we compute

$$t = (0.626 - 1)/0.107 = -3.50 < -z_{0.99} = -2.33$$

and conclude that $\beta_4 < 1$.

We can compute estimates of the concentration required to achieve 50% inhibition for ferulic acid as

$$\exp(\beta_2) = \exp(-1.64) = 0.194 \mu\text{mol/g}$$

and for vanillic acid as

$$\exp(\beta_2)/\beta_4 = \exp(-1.64)/0.626 = 0.310 \mu\text{mol/g}.$$

(Received October 24, 1988; accepted December 21, 1988)

Abstract—Cucumber seedlings growing in A₁-horizon Portsmouth soil material adjusted to pH 5.2, 6.0, or 6.9 were treated with 0, 0.25 or 0.5, $\mu\text{mol/g}$ soil ferulic acid, *p*-coumaric acid, vanillic acid, or an equal mixture (0.5 $\mu\text{mol/g}$ total) of two acids every other day. A total of five treatments was given starting with day 7 from seeding. Absolute rates of leaf expansion were determined for seedlings. The experiment was terminated when seedlings were 17 days old. All three phenolic acids inhibited leaf expansion. The dose required for 50% inhibition of absolute rates of leaf expansion increased as pH of the soil systems increased. The order of toxicity based on 50% dose and relative potency were as follows: ferulic acid > vanillic acid = *p*-coumaric acid. Effects of mixtures of phenolic acids on absolute rates of leaf expansion, when compared to the effects of individual phenolic acids, were found to be antagonistic for the ferulic-vanillic acid mixture and the ferulic-*p*-coumaric acid mixture in the pH 5.2 soil systems. Several phenolic acid treatments were required before antagonistic effects of mixtures were evident. In all other instances, when treatment effects were significant, the effects of individual phenolic acids were additive.

Key Words—Allelopathy, cucumber, *Cucumis sativus*, phenolic acid mixtures, similar joint action analysis, leaf area expansion, pH.

INTRODUCTION

Mixtures of simple, water-soluble, phytotoxic phenolic acids have been isolated from various soils. The cinnamic acid derivatives, *p*-coumaric acid and ferulic acid, and the benzoic acid derivatives, *p*-hydroxybenzoic acid and vanillic acid, are the most frequently observed in soil extracts, although various other phenolic acids have also been identified (Whitehead 1964; Guenzi and McCalla, 1966; Whitehead et al., 1981, 1983; Kuiters and Denneman, 1987; Kuiters et al., 1987). Estimates of the concentrations of individual phenolic acids that are directly available in soil solution to interact with seeds or roots are frequently below those required for growth inhibition. A number of researchers, however, have suggested that mixtures composed of noninhibitory concentrations of individual phenolic acids could inhibit seed germination or plant growth (see Einhellig, 1987). Predicting how mixtures of varying compositions (i.e., numbers of phenolic acids and their concentrations) may affect seed germination or plant growth in soils is not simple, since effects of individual phenolic acids in mixtures may be synergistic, additive, or antagonistic (Rasmussen and Einhellig, 1977; Blum et al., 1984, 1985a; Einhellig, 1987). Furthermore, it appears that the action of the individual phenolic acids in a mixture, and therefore the action of the mixture, will be directly or indirectly modified by soil pH and microbial activity (Blum et al., 1985a,b; 1987; Shann and Blum, 1987; Blum and Shafer, 1988).

The objective of this study was twofold: (1) to study the impact of mixtures of phenolic acids on seedling growth and (2) to describe how the effects of phenolic acid mixtures on growth may be modified by soil pH.

METHODS AND MATERIALS

General Aspects. Cucumber seeds (*Cucumis sativus* cv Early Green Cluster; Wyatt Quarles Seed Company, Raleigh, North Carolina) were germinated in the dark at 28–30°C in trays containing sterile vermiculite and Hoagland's solution (Hoagland and Arnon, 1950). After 48 hr, the trays containing the seedlings were transferred to a light bank and given a 12-hr light period (189 μ Einsteins/m²/sec for 12 hr) and a 12-hr dark period. Seedlings were planted into 155-ml cups (one per cup) containing 150 g of a Portsmouth A₁ soil-sand mixture (see below). Cups did not have drainage holes. The cups were inserted through holes in a plywood sheet so that everything below the soil surface was protected from direct irradiance of the light banks (Blum and Dalton, 1985). Seedlings were grown at room temperature (21–30°C) with a 12-hr light period. Seedlings were supplied with 7 ml double-strength Hoagland's solution every other day. Sufficient distilled water was added daily to bring the weight of any given cup (160 g for cup and soil) and its seedling to approximately 190 g.

Cups containing the seedlings were not allowed to go below 170 g. For further details about the cup system, see Blum et al. (1987). Length and width measurements were taken for each leaf (excluding cotyledons) every other day.

Substrate and pH Treatments. A₁-horizon Portsmouth (fine loamy, mixed, thermic Typic Umbraqualts) soil material was obtained from the Coastal Plain of North Carolina. General soil characteristics were described by Blum et al. (1987). Aluminum sulfate or calcium hydroxide (to adjust the pH of the soil material) and Ottawa quartz sand (2 sand-1 soil by weight) were added, and the resulting soil preparation was then mixed for 12-15 hr in a twin-shelled mixer. Soil pH values (based on a 1:1 soil-water mixture) were adjusted to 5.2, 6.0, and 6.9.

Phenolic Acid Treatments. Seedlings were treated every other day (maximum of five times) with ferulic, vanillic, or *p*-coumaric acid (0, 0.25, or 0.5 $\mu\text{mol/g}$ soil material) or equal molar mixtures (0.25 $\mu\text{mol/g}$ each) of two phenolic acids starting with day 7. Phenolic acid treatments were alternated with nutrient solution applications. Solution pH values were adjusted to soil pH values with NaOH.

Experimental Design. The experimental design for the seedling bioassay was as follows: three pH levels, 10 phenolic acid combinations (including control) and three replicates. Replication was in complete blocks, a complete set of treatments being randomly arranged under each of three lightbanks.

Data Analyses. Leaf area was determined from length and width measurements of leaves and the following equation: Leaf area = $-1.457 + 0.00769(L \times W)$, $P = 0.0001$, $r^2 = 0.98$, $N = 121$ where leaf area is in cm^2 and length (L) and width (W) values are in mm (Blum and Dalton, 1985). Mean absolute rates of leaf expansion (AGR) were calculated for each seedling by the equation: $\text{AGR} = \text{leaf area of seedling at time}_{x+1} - \text{leaf area of seedling at time}_x$ (Radford, 1967). Since seedling measurements were taken at two-day intervals, values are based on two-day periods. Data were analyzed by analysis of variance or nonlinear regressions and joint action analysis (Gerig et al., 1989).

RESULTS

Means for absolute rates of leaf expansion (AGR) used in the similar joint action analysis are presented in Table 1. No significant phenolic acid treatment effects [i.e., the slopes, (β_3) were not significantly different from zero] were noted for the pH 6.9 soil system, thus model parameters are presented only for the pH 5.2 and 6.0 soil systems (Tables 2-7).

As pH of the soil systems increased, AGR increased (see Table 1 and β_1 values in Tables 2-7). The number of phenolic acid treatments required before β_3 (rate parameter, slope) was significantly different from zero increased with increasing pH of the soil systems.

The dose [$\mu\text{mol/g}$; $\alpha_2 = \exp(\beta_2)$] required for 50% inhibition of AGR increased as pH of the soil systems increased. The dose for 50% inhibition was $48 \pm 8\%$ ($\bar{X} \pm \text{SE}$) greater for the pH 6.0 than for the pH 5.2 systems. The dose required for 50% inhibition decreased with additional phenolic acid treatments. The dose of phenolic acid required for 50% inhibition of AGR for the 15 to 17-day growth period was $39 \pm 6\%$ lower than for the 9 to 11-day growth period. The order of toxicity of the phenolic acids based on the 50% dose and relative potency (β_4) was as follows: ferulic acid > vanillic acid = *p*-coumaric acid.

Effects of mixtures of phenolic acids on AGR when compared to the effects of individual phenolic acids were found to be antagonistic [i.e., the coefficients of synergy (β_5) were significantly different from zero and negative] for the ferulic-vanillic acid mixture and the ferulic-*p*-coumaric acid mixture in the pH 5.2 soil systems. The joint action of two compounds is antagonistic if, when applied together, they decrease each other's effectiveness. Several phenolic acid treatments were required before antagonistic effects of mixtures on AGR were evident. In all other instances where β_3 values were significantly different from zero (i.e., significant phenolic acid effects), the effects of the mixtures, compared to the effects of the individual phenolic acids, were additive (similar joint action; β_5 was not significantly different from zero).

DISCUSSION

A pH range of 6–6.5 is recommended for best growth of cucumber plants (Hughes et al., 1983). The pH treatments in this study were 5.2, 6.0, and 6.9. No phenolic acid effects were observed at pH 6.9. Maximum effects of phenolic acids were observed at pH 5.2, a pH below the optimum pH range for cucumber seedling growth, but a pH that is often found in field soils. The greater inhibition associated with the pH 5.2 soil systems could have been a result of greater sensitivity of cucumber seedlings to phenolic acids under the suboptimal growth conditions of the pH 5.2 soils. It is more likely, however, that the main reason for these differences in response is related to the solubility and ionization of the phenolic acids. The pK_a values for ferulic, vanillic, and *p*-coumaric acid fall within the 4.5–5.0 range. Solubility and ionization (phenolic acids become negatively charged) of these phenolic acids increase as the pH of the soil solution increases. Harper and Balke (1981) concluded from their studies with salicylic acid ($\text{pK}_a = 3$) and oat root tissue that membranes were more permeable to the undissociated form of salicylic acid found under acidic conditions. This also appeared to be the case for the uptake of ferulic and *p*-hydroxybenzoic acid by cucumber seedlings in nutrient culture (Shann and Blum, 1987). In addition,

the recovery of exogenously applied phenolic acids from sterile acidic Portsmouth soil has been found to be greater than from sterile neutral Portsmouth soil, suggesting that more phenolic acid molecules may be available for root uptake at the lower pH (Dalton et al., 1983). Under acidic conditions, a residual carry-over of phenolic acid from one treatment period to another is also more likely to occur than under more neutral conditions (Blum et al., 1987).

These observations may explain why, under acidic conditions, fewer phenolic acid treatments were required for initial inhibition of AGR and lower concentrations were required for 50% inhibition of AGR. Residual carry-over could also explain why, under acidic conditions, the 50% inhibition concentration declined with increasing number of phenolic acid treatments. Data from nutrient culture studies and soil studies (unpublished data) suggested that cucumber seedlings were not more susceptible or tolerant to ferulic acid exposures after preconditioning with ferulic acids (Blum and Dalton, 1985). Growth, in fact, recovered very rapidly once phenolic acid was removed from the root environment (Blum and Rebbeck, 1988). We suspect, however, that the role of residual carry-over was minimal for these experiments, since recovery of ferulic acid from nonsterile Portsmouth A₁ horizon soil was essentially zero 24 hr after ferulic acid treatment (Blum et al., 1987; unpublished data).

Another potential reason for the decline of the 50% inhibition concentration with time may have been the salinization of the soil systems (no drainage holes) by the additions of double-strength Hoagland's solution. The fact that the number of milliliters of double-strength Hoagland's solution required for best growth increased with age of the seedlings and that growth inhibition required applications of 9 ml or more suggested that this was not the case (Blum et al., 1987). The major reason for the decline of the 50% inhibition concentration with time we suspect was the continued suppression of AGR by the multiple ferulic acid treatments while AGR continued unchecked for the control seedlings.

Antagonistic effects of individual phenolic acids in a mixture may not be directly related to the total concentration of a mixture, but more likely to the magnitude of effects for each phenolic acid in the mixture (Blum et al., 1985a). The data here support this observation, since antagonistic effects were observed only under acidic conditions, conditions of maximum growth inhibition. Furthermore, antagonistic effects were only noted when ferulic acid was present in the mixture. Shann and Blum (1987) noted that ferulic acid inhibited the uptake of *p*-hydroxybenzoic acid by cucumber roots, but that *p*-hydroxybenzoic acid did not affect the uptake of ferulic acid. It is not clear why this occurs, but a similar inhibition of ferulic acid of uptake of other phenolic acids is possible, particularly under acidic conditions where maximum uptake rates occur.

The persistent question in the area of allelopathic interactions has been

whether available concentrations of inhibitors in soil environments are adequate to inhibit plant growth. Estimates of concentrations of individual phenolic acids in soils that are directly available to interact with roots are frequently below those required for inhibition of growth. The data here indicate that mixtures of phenolic acids in soil can inhibit growth of cucumber seedlings in an additive or antagonistic manner. We suspect that in nature it is a combination of phenolic acids that brings about an inhibitory effect and not individual phenolic acids. The fact that individual components in a mixture may be antagonistic in their action does not detract from the fact that mixtures have a greater impact on growth, unless, of course, the compounds are completely antagonistic (i.e., $\beta_5 = -1$). Finally, the data clearly indicate that soil characteristics such as acidity may influence the effects of phenolic acids and mixtures of phenolic acids on plant growth.

Acknowledgments—The authors wish to thank Drs. W.H. Swallow, T.R. Wentworth, and A.D. Worsham for their careful reviews of this manuscript.

SHORT-TERM INDUCTION OF ALKALOID PRODUCTION IN LUPINES

Differences Between N₂-Fixing and Nitrogen-Limited Plants

NELSON D. JOHNSON, LISA P. RIGNEY, and

(Received September 21, 1988; accepted December 22, 1988)

Abstract—We used N₂-fixing and nonfixing lupines to examine the effects of plant nutrition on short-term alkaloid production in damaged leaves. Three different treatments were used: damaged leaves from N₂-fixing plants; undamaged leaves from these damaged, N₂-fixing plants; and damaged leaves on nitrogen-limited, nonfixing plants. Relative to controls, alkaloids increased in concentration more quickly in the N₂-fixing than in the nitrogen-limited plants. The magnitude of this increase in alkaloids was correlated with the initial alkaloid concentration. These results suggest that nitrogen-rich plants may benefit from faster and higher alkaloid induction than nitrogen-limited plants. In addition, the detailed dynamics of individual alkaloids are consistent with earlier proposals for the mechanism of lupine alkaloid induction.

Key Words—Plant defense, induced defense, leaf damage, quinolizidine alkaloids, nitrogen fixation, *Lupinus succulentus*.

INTRODUCTION

Just as animals increase their immunity when infected by disease, plants beset by herbivores often quickly become less palatable or less nutritious (Tallamy, 1985; Broadway et al., 1986). One reason for this decline in palatability is that many plants produce defenses, called *induced* defenses, following herbivore attack (Rhoades, 1983; Schultz, 1988). The defenses of both animals and plants are also profoundly affected by nutrition (Gershenson, 1984; Larsson et al., 1986). But in plants, this interaction between nutrients and defenses is only

partly understood. Previous studies of the interactions between environmental nutrients and defenses have all focused on *constitutive* defenses, those present prior to herbivore attack. In this report, we describe interactions between induced defenses and plant nutrition.

Plant nutrition influences so many aspects of plant growth and development that it would be surprising if induced defenses were not also affected (Chapin, 1980). Indeed, several studies have reported significant interactions between the effects of nutrients and defoliation on plant defenses (Bryant, 1987; Johnson et al., 1987), but these previous studies investigated chemical changes that developed weeks after defoliation, not those that occurred within the first few hours.

We have focused on a nutritional factor that could readily alter the short-term induction of plant defenses: nitrogen availability. As an example, consider how nitrogen availability might regulate alkaloid induction. In low-nitrogen soils, plants are likely to have low levels of most nitrogenous molecules including the enzymes of alkaloid biosynthesis and the amino acids that are the precursors of many plant alkaloids (Waller and Nowacki, 1978). Nitrogen-limited plants therefore should mount a lower and slower alkaloid response to damage than plants with an adequate nitrogen supply. Of course, other factors such as enzyme inhibitors could also regulate toxic chemical synthesis, but environmental nutrient levels may affect these factors as well.

To examine whether nutrient availability does regulate induced responses in plants, we studied alkaloid levels in plants with and without symbiotic N_2 fixation. For our model N_2 -fixing plant we chose the annual *Lupinus succulentus* Dougl. ex Koch. (Fabaceae). Lupines are an appropriate study plant because their major defenses against leaf-eating herbivores, the quinolizidine alkaloids, are very sensitive to N_2 fixation and because the quinolizidine alkaloids are inducible (Wink, 1983; Johnson et al., 1987). In addition, by studying *L. succulentus*, we can contrast our results for short-term alkaloid induction with a previous study of long-term induction in the same species (Johnson et al., 1987). This earlier study found that, for plants relying on N_2 fixation, a three-week regime of partial defoliation ultimately led to a decline in leaf alkaloid concentrations. Thus, N_2 -fixing lupines may have a biphasic alkaloid response to defoliation, with rapid initial induction followed by a long-term decline in alkaloid concentrations.

METHODS AND MATERIALS

Plants and Rhizobia. Two treatment groups of *Lupinus succulentus* plants were grown in a greenhouse in sand culture during February and March 1987. One group of plants was inoculated with *Bradyrhizobium* sp. N_2 -fixing bacteria

isolated from lupines (Nitragin Co., Milwaukee, Wisconsin) and fertilized with a nitrogen-free nutrient solution. These plants were quite vigorous and had none of the red pigmentation characteristic of nitrogen-stressed *L. succulentus*. A second group, the low-NO₃-plants, were fertilized with a similar nutrient solution supplemented with 0.2 mM KNO₃. The plants in this group were clearly stunted, and both their petioles and adaxial leaf surfaces were red. Other general characteristics of plants grown under these nutrient treatments and the nutrient solution compositions are given in Johnson et al. (1987).

Experimental Design. The low-NO₃-plants were allocated to two groups: plants with damaged leaves and undamaged controls. Leaves from two to three of these stunted, small-leaved plants had to be pooled for each alkaloid analysis, yielding eight samples for the controls and nine samples of damaged leaves. The N₂-fixing plants were also allocated to damaged ($N = 22$ plants) and control groups ($N = 17$), but because these plants were much larger than the low-NO₃-plants, a third treatment was added. This last treatment involved harvesting undamaged leaves from previously damaged plants ($N = 22$).

To control for the large within-plant and among-plant variability in *L. succulentus* alkaloids, we tracked the alkaloid dynamics of the individual palmately compound leaves. Several fully expanded leaves were chosen from each plant, and these leaves were sampled at 1200 hr and then 4 and 24 hr later. At each sampling, two to three leaflets were removed from each leaf by snipping the narrow leaflet base, a procedure that causes no detectable alkaloid induction (personal observation). The harvested leaves were immediately placed on dry ice and stored frozen at -15°C until analysis. For the N₂-fixing plants, leaflets were pooled and analyzed separately for each plant and harvest time; for the smaller low-NO₃-plants, leaflets were analyzed as pools of several plants, as described above.

Leaves were damaged by pressing a screw-gripper on all of the leaflets of each designated leaf, generating a grid of wounds over the entire leaf spaced at 36/cm². This method was chosen because it left all of the leaflet behind for subsequent alkaloid analysis. The alkaloid induction caused by this method is similar to the induction caused by the more conventional method of leaflet-clipping (unpublished results).

Chemical Analyses. Alkaloids were extracted from weighed, dried leaf material into 0.5 M HCl, with cinchonidine HCl added as an internal standard to 0.1% dry leaf weight. The resulting extract was made alkaline with conc. NH₄OH, separated with CH₂Cl₂, and then concentrated under nitrogen. These concentrates were injected into a Shimadzu Mini-2 gas chromatograph equipped with a flame ionization detector and DB-1 megabore capillary column (J&W Scientific). Alkaloids were eluted by temperature programming from 150 to 300°C followed with 13 min at 300°C, and GC-mass spectrometry and co-GC with known samples were used for identification (Johnson et al., 1987).

Statistical Analysis. Most of the statistical analyses were done using variates that represented the changes in alkaloids over time. To examine the relative induction of alkaloids, the levels of each alkaloid after damage were expressed as a fraction of their initial concentrations, i.e., the ratio between final and initial alkaloids. These ratios were then log-transformed, and individual plants were represented as vectors of these ratios for the alkaloids tetrahydro-rhombifoline, lupanine, and the pooled *cis*- and *trans*-cinnamic acid esters of 13-hydroxylupanine. These particular alkaloids were chosen because they were present in all plants and accounted for 75–100% of the total plant alkaloids.

The overall effects of damage were examined for the three treatments (N_2 -fixing, low NO_3^- , and undamaged N_2 -fixing) with multivariate analysis of variance (MANOVA) of damage treatment vs. controls. To test for differences in the alkaloid dynamics of plants with different nitrogen sources, the changes in alkaloids over each subinterval (0–4 hr and 4–24 hr) were compared by two-way MANOVA of damage (damage/control) and nitrogen source (low NO_3^- and N_2 -fixing). Since the changes in alkaloids in both subintervals are calculated using the alkaloid concentrations at 4 hr, the variates for the two subintervals are not independent of each other. We therefore adjusted the significance levels of these MANOVAs for two nonindependent comparisons using the Dunn-Sidak method (Ury, 1976). The dynamics of individual alkaloids were examined using the same variates as in the MANOVAs, i.e., variates expressing the change in alkaloids over each time interval. Instead of analyzing these variates by MANOVAs, however, two-way ANOVAs were used to test the effects of damage and alkaloid type for each different treatment (low NO_3^- , N_2 -fixing, and undamaged N_2 -fixing). We also tested for alkaloid differences among treatments at the beginning of the experiment using one-way (damage) or two-way (damage \times nitrogen source) MANOVAs of the absolute alkaloid concentrations.

All statistical operations used either the GLM (general linear models) or the CORR procedure (product-moment correlations) of SAS (SAS Institute, Cary, North Carolina). Significance values for MANOVAs are derived from the *F* approximation of Pillai's trace.

RESULTS

Induced Responses in N_2 -fixing and low- NO_3^- Plants Relative to Controls.

Changes over All Alkaloids. Leaf damage caused a 55% increase in alkaloids relative to controls for both the N_2 -fixing and low NO_3^- plants, and a 33% increase in undamaged leaves on damaged N_2 -fixing plants (Figure 1). This increase in alkaloids was highly significant for the N_2 -fixing treatment (MAN-

FIG. 1. Alkaloid induction in *Lupinus succulentus*. Bars represent the treatment means of the values of $(A_i/C_i - A_0/C_0) \times 100$ for each plant, where A and C are the total alkaloid concentrations of experimental and control plants, respectively, and the subscript indicates the time since leaves were damaged. Error lines represent one standard error.

OVA, $P = 0.009$), marginally significant for low- NO_3^- plants ($P = 0.058$), and nonsignificant for the undamaged leaves on damaged, N_2 -fixing plants ($P = 0.66$).

Overall, the 24-hr alkaloid induction in damaged leaves did not differ significantly between the low- NO_3^- and N_2 -fixing treatments, as shown by the nitrogen source \times damage interaction in a two-way MANOVA of 24-hr changes in alkaloids (Table 1). The significant alkaloid induction noted above is also shown in this two-way MANOVA, and a further significant effect is revealed, that of nitrogen source (Table 1). Nitrogen source was a significant factor because the low- NO_3^- plants, both damaged and control, tended to increase in alkaloid levels relative to the N_2 -fixing plants (discussed below).

Although the N_2 -fixing and low- NO_3^- plants had similar induced responses overall, the timing of their responses differed. More than half the alkaloid increase in the N_2 -fixing plants occurred within 4 hr, whereas most of the response in the low- NO_3^- plants occurred later, between 4 and 24 hr (Figure 1). These treatment differences in the timing of induction were statistically significant in the period between 4 and 24 hr, as shown by a two-way MANOVA of

TABLE 1. TWENTY-FOUR-HOUR CHANGES IN ALKALOIDS ANALYZED BY TWO-WAY MANOVA OF LEAF DAMAGE AND NITROGEN SOURCE^a

Effect	df	F	P
Damage	3,48	5.25	0.007
N source	3,48	11.34	<0.0002
N source × damage	3,48	0.84	0.73

^aF statistics are from Pillai's trace.

nitrogen source and damage treatment (nitrogen source × damage interaction, $P = 0.045$).

A second way of analyzing induction is to determine if induction is proportional to initial alkaloid content. We did this by examining the correlations between the initial alkaloid levels and the arithmetic change in alkaloids following damage, with all data divided by the appropriate controls. That is, we determined the correlations between $(E_{24}/C_{24} - E_0/C_0)$ and E_0/C_0 , where E_i and C_i are the concentrations of alkaloids after i hours in experimental and control plants, respectively.

For both of the N_2 -fixing treatments, induction was correlated with initial alkaloid content ($r = 0.69$, $P = 0.0003$, damaged leaves; $r = 0.41$, $P = 0.057$, undamaged leaves on damaged plants). This indicates that the leaves with the highest alkaloid levels also had the highest increases in alkaloids relative to controls. But no significant correlation was found for the low- NO_3^- plants ($r = 0.12$, $P = 0.8$), perhaps because the low- NO_3^- plants spanned a smaller range of initial alkaloid concentrations. In the N_2 -fixing plants, alkaloid levels were distributed fairly uniformly across two orders of magnitude; but in the low- NO_3^- plants, the highest levels were only three times the lowest.

Induction of Individual Alkaloids. The dynamics of individual alkaloids tended to parallel those of total alkaloids with the exception of 17-oxosparteine and the hydroxylupanine esters (Figure 2). These two alkaloids are, respectively, the first and perhaps the last alkaloids in the quinolizidine biosynthetic pathway in *L. succulentus* (Wink et al., 1981). The variation in the levels of individual alkaloids is quite high, however, so that significant differences among alkaloids are only found in the N_2 -fixing plants at 0–4 hr (Figure 2A, $P = 0.01$ for alkaloid type × damage interaction in a two-way ANOVA of alkaloid type and damage).

Dynamics of Alkaloid Production.

At the beginning of the experiment, alkaloids differed significantly between the N_2 -fixing and low- NO_3^- groups ($P < 0.0001$, MANOVA), but not among the

FIG. 2. The dynamics of individual alkaloids following leaf damage treatments: (A) damaged N₂-fixing; (B) undamaged N₂-fixing; (C) low NO₃⁻. The means for each treatment and time were calculated using the formula from Figure 1 applied to individual alkaloids. Errors are one standard error. S = sparteine, T = tetrahydrohombifoline, O = 17-oxosparteine, L = lupanine, and E = *cis*- and *trans*-cinnamic acid esters of 13-hydroxylupanine.

damage treatments within each group (N₂-fixing, *P* = 0.3; low-NO₃⁻, *P* = 0.7; both MANOVA; Table 2). This significant effect of nitrogen source was due to differences in alkaloid composition rather than to differences in absolute alkaloid concentrations. The N₂-fixing plants had a relative alkaloid composition of 32:26:17:24 tetrahydrohombifoline–lupanine–sparteine–lupanine esters, whereas low-NO₃⁻ plants were 72:3:1:24 (both normalized to add to 100). These relative alkaloid compositions are those expected for N₂-fixing and low-NO₃⁻ plants, respectively (Johnson et al., 1987).

Damaged	0.068 (0.025)	0.072 (0.021)	0.101 (0.041)
Control	0.084 (0.046)	0.086 (0.058)	0.088 (0.041)

^a Alkaloids are percent of leaf dry weight.

The changes in the actual leaf alkaloid concentrations following damage contrast somewhat with the results described in the previous section. We previously showed that alkaloids were induced relative to undamaged controls, but, for the N_2 -fixing plants, the absolute effect of damage was to halt the decline in alkaloids seen in the control plants (Table 2). In contrast, the low- NO_3^- plants showed similar alkaloid dynamics both relative to controls and for absolute alkaloid concentrations.

DISCUSSION

Nitrogen Availability, Induced Responses, and Plant-Herbivore Interactions. Nitrogen availability affects virtually all aspects of plant physiology and chemistry, and it would be surprising if induced responses were not affected as well. Indeed, our results suggest that N_2 -fixation, by providing plentiful nitrogen, can regulate both the pace and magnitude of induced chemical changes in lupines. This interpretation does not readily explain all of our experimental observations, however. In particular, it does not explain why the alkaloids of N_2 -fixing plants tended to decline after the first harvest (Table 2). Other reasons that low- NO_3^- and N_2 -fixing lupines may have different alkaloid dynamics include differences in leaf age, plant developmental stage, and leaf and plant photosynthetic rates (Wink and Hartmann, 1982; Wink and Witte, 1985; Johnson and Bentley, 1989). These other mechanisms are testable alternatives to our hypothesis that the differences between low- NO_3^- and N_2 -fixing plants were directly due to differences in nitrogen availability.

In theory, the effects of N_2 -fixation on alkaloid induction should have straightforward consequences for lupine plant-herbivore interactions. N_2 -fixing plants will have rapid alkaloid induction in damaged leaves and perhaps in undamaged tissue as well, although the changes in undamaged leaves were not significant in this study. The quinolizidine alkaloids are potent toxins and feeding deterrents, serving as the principal lupine defenses against leaf-eating herbivores (e.g., Wink, 1984). Therefore, the faster the induction, the more effective the deterrence to further feeding by herbivores; however, as Fowler and Lawton (1985) have cautioned, the simple existence of induction does not prove its ecological and evolutionary importance.

The positive correlation between initial leaf alkaloids and the magnitude of alkaloid induction suggests a second consequence of N_2 fixation. Plants with abundant available nitrogen, either from N_2 fixation or from the soil, generally have higher alkaloids as well as higher protein than nitrogen-starved plants (Johnson et al., 1987). Young leaves also have high protein and alkaloid levels. Hence, the absolute induction of alkaloid production should be greater in pro-

tein-rich plants and foliage. This may be particularly important for lupines, since a given concentration of lupine alkaloids is less toxic at higher protein concentrations (for *Spodoptera eridania*, Lepidoptera; Johnson and Bentley, 1988).

The short-term alkaloid induction in N_2 -fixing plants stands in marked contrast to the long-term effects of damage. In a previous study, we showed that defoliation eventually depressed alkaloid levels in *L. succulentus* plants relying on N_2 -fixation (Johnson et al., 1987). Thus, the short-term burst of alkaloid production reported here cannot be maintained in the face of repeated defoliation.

Regulation of Alkaloid Induction by Nitrogen Availability. Because of the manifold effects of nitrogen availability on plant growth and physiology, many different mechanisms could account for the effects of nitrogen availability on induced responses. For example, nitrogen availability may affect average leaf age, plant developmental stage, or, as we suggested in the Introduction, the levels of alkaloid precursors or biosynthetic enzymes.

Of these latter two mechanisms, it is more likely that induction is regulated by the biosynthetic machinery than by the size of precursor pools. For example, if new enzymes must be synthesized before induction can occur, then protein translation inhibitors should halt induction. A study by Wink (1983) showed exactly this for leaves of *Lupinus polyphyllus*. The alternative, regulation by precursor availability, is disputed by circumstantial evidence from the data presented here. If induction were limited because precursors became depleted, then nitrogen-starved plants should have especially low levels of 17-oxosparteine, the precursor for all other *L. succulentus* alkaloids (Wink et al., 1981). In fact, our experiments gave exactly the opposite result. The low- NO_3^- lupines, with the slowest induction, had the highest concentrations of 17-oxosparteine, whereas the N_2 -fixing plants had the fastest induction and the lowest 17-oxosparteine levels (Figure 2). Thus, precursor depletion more likely regulated the induction of the N_2 -fixing than the low- NO_3^- plants.

SUMMARY

We showed that plant nitrogen source could affect both the timing and the magnitude of induced alkaloid production, perhaps because nitrogen stress reduced the levels of the enzymes of alkaloid biosynthesis.

Acknowledgments—We thank Nikhil Mallampoli for his excellent technical assistance, Paul Neal and Chester Wilson for their aid in damaging leaves, and two reviewers for helpful comments on the manuscript. This research was supported by NSF grant BSR84-19438, and it is contribution #731 from the Program in Ecology and Evolution at SUNY, Stony Brook, New York 11794.

(Received November 9, 1987; accepted December 27, 1988)

Abstract—The analyses of virgin female sex pheromone gland extracts by gas chromatography (GC), GC-electroantennographic detection (GC-EAD) and GC-mass spectrometry (GC-MS) followed by field-trapping experiments, have identified (*E*)-9-tetradecenyl acetate (*E*9-14:Ac) as the primary sex pheromone component of the spruce budmoth, *Zeiraphera canadensis*. Dosages of 1.0–100.0 µg of *E*9-14:Ac impregnated in rubber septa provide effective trap baits.

Key Words—*Zeiraphera canadensis*, spruce budmoth, (*E*)-9-tetradecenyl acetate, sex pheromone, Lepidoptera, Tortricidae, Eucosminae, trapping.

INTRODUCTION

Two species in the budmoth group, the spruce budmoth, *Zeiraphera canadensis* Mutuura and Freeman, and the purplestriped shootworm, *Zeiraphera unfortunana* Powell [= *Z. destitutana* (Walker)], are sympatric in New Brunswick and feed on white spruce [*Picea glauca* (Moench) Voss]. These species feed on

¹Lepidoptera: Tortricidae: Eucosminae.

developing apical shoots (Martineau, 1984), which results in reduced tree height and bole deformation.

The primary sex pheromone component of *Z. unfortunana* has recently been identified as (*E*)-9-dodecenyl acetate (*E*9-12:Ac) (Silk et al., 1988). The pheromone for *Z. canadensis* has not been identified; however, (*E*)-9-tetradecenyl acetate (*E*9-14:Ac) has been found to be electrophysiologically active and effective in trapping experiments (Turgeon and Grant, 1988).

We report here the identification of *E*9-14:Ac as the primary sex pheromone component of *Z. canadensis*. This was achieved by analyses of sex pheromone gland extracts using GC, GC-EAD, and GC-MS and field-trapping experiments.

METHODS AND MATERIALS

Insects. During 1986, white spruce foliage (50-cm branches), infested with *Z. canadensis* and *Z. unfortunana* larvae, was collected. The branches were suspended over trays of moist vermiculite in rooms at constant temperature (25°C) and relative humidity (70–80%). Mature larvae subsequently dropped into the trays where pupation occurred.

The two species were then initially separated on the basis of pupal size (*Z. unfortunana* is larger than *Z. canadensis*), sexed (Turgeon, 1985), and emerged adults were separated by differences in thoracic and wing maculations. Adults were maintained in small cages under the same environmental conditions as were pupae (Silk et al., 1988).

Collection of Pheromone. Virgin female *Z. canadensis* and *Z. unfortunana* were held one to two days postemergence, and their sex pheromone glands were manually everted and excised during the first 3–4 hr of scotophase. Four hundred twenty *Z. canadensis* glands were placed in Spectrograde hexane, and 40 glands were placed in chloroform–methanol (2:1 v/v) for subsequent methanolysis (Bjostad and Roelofs, 1984). In addition, 21 *Z. unfortunana* glands were also placed in chloroform–methanol for methanolysis. *Z. canadensis* glands, in hexane, were sonicated for 30 min, filtered through clean glass wool, and the extract was then used for subsequent GC, GC-EAD, and GC-MS analyses. All gland extracts were stored in solvent at –10°C prior to analyses.

GC-EAD Analysis. Portions of the pheromone gland extract in hexane were analyzed on a GC-EAD system (Struble and Arn, 1984; Silk et al., 1988) using detector antennae of 2- to 3-day-old male *Z. canadensis* and *Z. unfortunana* moths; EAD responses and GC retention times were also recorded from synthetic standards.

Fatty Acid Analyses. Forty virgin female glands of *Z. canadensis* in chloroform–methanol (2:1) were sonicated for 20 min, extracted as above, and the

extracts were subjected to alkaline methanolysis (Bjostad and Roelofs, 1984) followed by reaction with dimethyl disulfide (DMDS) (Dunkelblum et al., 1985). These DMDS adducts, in hexane, were analyzed by GC-MS as detailed below. Methanolized gland extracts of *Z. unfortunana* were derivatized and analyzed similarly.

GC and GC-MS Analysis. GC analyses were performed as previously described (Silk et al., 1988). The following columns were used: Column A, 30 m \times 0.32 mm DB-5 (Chromatographic Specialties Ltd.); Column B, 30 m \times 0.32 mm SPB-5 (Supelco); Column C, 50 m \times 0.30 mm Superox FA (Mandel Scientific Ltd.).

GC-MS analyses on extracts, adducts, and synthetics were performed as previously described (Silk et al., 1988) using column A.

Chemicals. Chemicals used in the above procedure were obtained from Chem. Samp. Co., Columbus, Ohio; Koken Fine and Aromatic Chemicals, Tokyo, Japan; or were synthesized in our laboratory using standard techniques; all chemicals were 98% pure (<0.1% opposite isomers) as determined by capillary GC and used without further purification.

Field Testing. Field-trapping studies were carried out in 1986 in the same plantations where larvae were collected. Plots ca. 50 m apart were chosen in homogeneous white spruce stands that were planted in 1976.

Two trapping experiments were conducted; the first was conducted for 11 nights (July 19–30) in a 6 (treatments) \times 10 (replicates) randomized block. The second experiment was conducted for 10 nights (July 20–30) in a 5 (treatments) \times 5 (replicates) randomized block. In both trapping experiments, Pherocon-1C traps were baited with red rubber septa lures (Arthur H. Thomas Co.) and suspended from white spruce foliage ca. 1.5 m from the ground (mid-crown) with 25-m spacings between traps.

All moths caught in the traps were identified (*Z. canadensis* and *Z. unfortunana* males) by examining their genitalia (Mutuura and Freeman, 1966).

Log-transformed data were analyzed by two-way ANOVA and means compared using Tukey's HSD multiple-comparison test.

RESULTS

Chemical and GC-EAD Analyses. From the 420 *Z. canadensis* glands obtained for analysis, aliquots containing ca. 50 female-gland equivalents in hexane (2 μ l) were injected on columns A, B, and C for GC-EAD analysis using male *Z. canadensis* as detector antennae. Several gland components produced small EAD responses, but only one discernible GC peak produced a large EAD response (on all columns). The GC retention time (columns A and B) of this EAD-active component closely matched that of synthetic 9-tetradecenyl

acetate (9-14:Ac). The retention time of the component suggested the *E* configuration of the double bond when GC-EAD analysis was carried out on column C (*E* and *Z* isomers well resolved).

GC-EAD responses of the gland component (largest EAD response) and synthetic compounds are shown in Table 1. For comparison purposes, GC-EAD responses of male *Z. unfortunana* antennae to several synthetics are also presented (Silk et al., 1988) (Table 1). The 9-14:Ac clearly gave medium to large EAD responses, while the saturated analogs, at 1-ng dosages, elicited no response in *Z. canadensis* antennae but a range of responses in *Z. unfortunana* antennae (Silk et al., 1988) (Table 1).

GC-MS analysis was carried out on the same DB-5 capillary column with the remaining *Z. canadensis* gland extract (ca. 120 gland equivalents). One weakly EAD-active region corresponded in retention time and MS characteristics to *E*9-12:Ac [*m/e* 61 ($\text{CH}_3\text{COOH}_2^+$) 68, 82, 166 ($\text{M}^+ - 60$)]. The MS scan corresponding to the region of highest EAD response corresponded to *E*9-14:Ac

[*m/e* 61 (CH₃COOH₂⁺) 67, 82 (base) 96, 110, 124, and 194 (M⁺-60)]. Insufficient material was available for double-bond confirmation by microchemical means.

Additional supportive evidence for double-bond assignment resulted from the fatty acid analyses that are shown in Table 2 (note the presence of 11-14:Me in *Z. unfortunana*). As expected, 9-14:Me (methyl 9-tetradecenoate) was detected, and this fatty acid is the presumed precursor to the 9-14:Ac (Roelofs and Bjostad, 1984), the primary EAD-active gland component. In addition, 9-12:Me (methyl 9-dodecenoate) was detected as expected from EAD and MS data. These data support the double-bond assignment in the gland-derived 9-dodecenyl and 9-tetradecenyl acetates.

extract (4.6 female equivalents) was also carried out using male *Z. unfortunana* antennae (*Z. unfortunana* strongly responds to *E9-12:Ac* and moderately to *E9-14:Ac*; Silk et al., 1988). EAD responses were recorded to two GC peaks coincident with the retention times of synthetic *E9-12:Ac* and *E9-14:Ac* under identical GC conditions indicating that these two compounds were indeed present in *Z. canadensis* sex pheromone gland extracts.

In summary, the evidence from GC, GC-EAD, and GC-MS analyses supports the assignment of *E9-14:Ac* as the major EAD-active component in *Z. canadensis* sex pheromone glands. In addition, MS and EAD data support the assignment of a smaller amount (<5% of *E9-14:Ac*) of *E9-12:Ac* in sex pheromone gland extracts. Other weakly EAD-active components were not identified.

Field Testing. The results of the first dosage and blend test (1986) indicated that all treatments were significantly different from controls (Table 3) ($P < 0.05$) but were not significantly different from each other. Clearly, in this test, *E9-14:Ac* effectively trapped *Z. canadensis* males, although a dose-response effect was not observed in these trapping experiments. Also, the addition of 10% *Z9-14:Ac* or 10% *E9-14:OH* to 1 μg of *E9-14:Ac* did not significantly affect trap captures ($P > 0.05$).

Our study with pure components and blends of *E9-14:Ac* and *E9-12:Ac* indicate that both *E9-14:Ac* and *E9-12:Ac* at the 10- μg dosage, were effective in capturing *Z. canadensis* and *Z. unfortunana*, respectively (Table 4). In the three blends of the two acetates tested, higher concentrations of a specific chemical constituent resulted in higher trap captures of the species specific to the given acetate (e.g., the higher the proportion of *E9-12:Ac*, the higher the proportion of *Z. unfortunana* captured). Addition of *E9-12:Ac*, identified as a

gland component, to E9-14: Ac, therefore, did not increase male *Z. canadensis* trap capture at the tested dosages.

DISCUSSION

Field-trapping data in this work indicate that E9-14: Ac, impregnated in rubber septa, in the 1- to 100- μ g range, effectively traps *Z. canadensis* males. A dose-response, however, could not be demonstrated, and this could be explained by mid-crown placement of traps. Turgeon and Grant (1988), for example, clearly showed a dose-response with E9-14: Ac when traps were placed at the tops of trees.

Addition of either Z9-14: Ac or E9-14: OH (Table 3) to E9-14: Ac does not affect trap capture. Traps with blends of E9-12: Ac (a sex pheromone component of *Z. unfortunana*; Silk et al., 1988) and E9-14: Ac capture both species (Table 4), but the pure components appear to be reasonably specific in capturing one species only. The role of E9-12: Ac in the sex pheromone glands of *Z. canadensis* is, therefore, unknown at this time.

Several lepidopteran sex pheromone components have been shown to be biosynthesized by reaction of fatty acids with two key enzyme systems that are found only in sex pheromone glands (Roelofs and Bjostad, 1984). These are a microsomal β -oxidation system, which yields limited chain shortening by two carbons, and a Δ 11-desaturase system. The characterized pheromones in the coniferophagous *Choristoneura* budworms, for example, can all be generated by these two enzyme systems starting from hexadecanoic acid (Wolf and Roelofs, 1987; Silk and Kuenen, 1988). The comparison of monounsaturated fatty acids in these two *Zeiraphera* species is interesting in this regard (Table 2): methyl 9-dodecenoate and methyl 9-tetradecenoate were identified in both spe-

cies, and corresponding acids are the presumed biosynthetic precursors to the identified unsaturated acetate pheromones. Other identified fatty acids may represent precursors to minor pheromone components. A plausible biosynthetic route to these acetate pheromones in both species is shown in Fig. 1. Both would be generated from hexadecanoate. For *Z. canadensis*, the $\Delta 11$ -desaturase (*E*-specific) inserts the double bond followed by limited β -oxidation to a (*E*)-9-tetradecenoyl moiety. Reduction and acetylation would produce the required *E*9-14:Ac. With *Z. unfortunana*, β -oxidation would occur first followed by $\Delta 11$ -desaturation (*E*-specific); a second β -oxidation step, then reduction and acetylation would yield *E*9-12:Ac. The fatty acid analyses reported in Table 2 support this scheme. Second, recent trapping studies in white spruce stands in Nova Scotia have found *E*11-14:Ac to be potentially active in capturing *Zeiraphera fortunana* (Butterworth and Silk, unpublished data). *Z. fortunana* is a relatively rare species found on white spruce in New Brunswick and Nova Scotia (Martineau, 1984). The male genitalis of *Z. fortunana* are morphologically

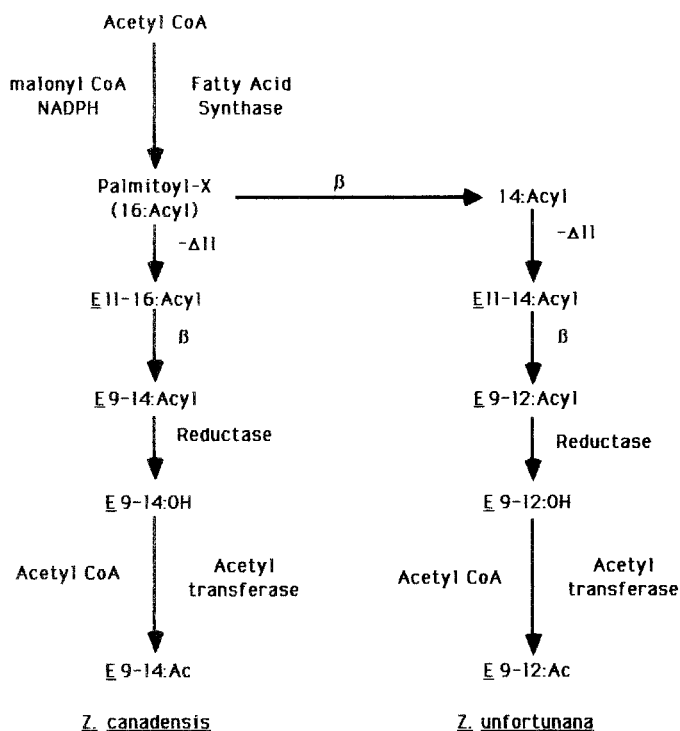

FIG. 1. Postulated divergent biosynthetic routes to the sex pheromones of *Z. canadensis* and *Z. unfortunana*. After Roelofs and Brown (1982) and Roelofs and Bjostad (1984). $-\Delta 11$ = $\Delta 11$ -desaturase; β = limited β -oxidation by two carbons.

very difficult to distinguish from *Z. unfortunana* and the two species are considered to be closely related (P. Dang, Biosystematics Institute, Agriculture Canada, personal communication). The fact that *E11-14:Ac* captures *Z. fortunana* is consistent with the postulated biosynthetic scheme outlined above and supports a close taxonomic relationship between *Z. unfortunana* and *Z. fortunana*.

Roelofs and Brown (1982) suggest a similar relationship between the two forms of *Z. diniana*, which occur on different host species in Europe. *Z. diniana* (larch form) produces *E11-14:Ac* (Roelofs et al., 1971; Guerin et al., 1984) while *Z. diniana* (cembran pine form) produces *E9-12:Ac* (Baltensweiler et al., 1978, Guerin et al., 1984).

REPELLENT OF ROOT-KNOT NEMATODES FROM EXUDATE OF HOST ROOTS

JAMES A. DIEZ and DAVID B. DUSENBERY

*School of Applied Biology
Georgia Institute of Technology
Atlanta, Georgia 30332*

(Received September 27, 1988; accepted December 27, 1988)

Abstract—A chemotaxis assay was developed to measure attraction or repulsion of infective juveniles of the root-knot nematode *Meloidogyne incognita* to exudates of host roots. The assay was sufficiently sensitive to measure the repellent activity of a 25- μ l sample of 7 mM NaCl. In tests of root exudate collected in a variety of ways from a variety of plants, avoidance responses were usually found but attraction was not. Extraction of the exudate from tomato with various organic solvents revealed that the repellent activity was highly polar. On Sephadex G-15 chromatography this exudate separated into two clearly defined peaks with apparent molecular weights of about 500 and 1000 daltons. The faster running peak (larger apparent size) contained much more activity than the other peak. Subsequent analysis of material from the larger peak via HPLC on a C18 column revealed a single peak of repellent activity. None of the chemical fractionations uncovered reproducible attractant activity.

Key Words—Root-knot nematode, *Meloidogyne incognita*, root exudate, bioassay, chromatography, repellent, chemotaxis, tomato.

INTRODUCTION

Nematodes are economically important pests in agriculture, but relatively little information is available on the mechanisms by which they locate host plants. In fact, there is little information on the cues used by any soil organism. The common assumption is that chemotaxis to chemicals released by the roots plays an important role (Steiner, 1925; Prot, 1980; Dusenbery, 1987b). One of the most widespread nematode pests is the root-knot nematode *Meloidogyne incognita*. As part of a series of investigations on the sensory behavior of infective

juveniles of this species (Diez and Dusenbery, 1989; Dusenbery, 1987a, 1988a-c; Goode and Dusenbery, 1985; Pline and Dusenbery, 1987; Pline et al., 1988), we have undertaken an investigation of its responses to root exudates from host plants. In addition, chemical characterization of the activity was initiated. A preliminary report on this work has been published previously (Diez and Dusenbery, 1986). A study of soybean cyst nematode responses to exudates of host roots has been reported (Papademetriou and Bone, 1982).

METHODS AND MATERIALS

Nematodes. The nematodes were grown on tomato plants (Rutgers cultivar) as previously described (Goode and Dusenbery, 1985). Eggs were collected from roots of infected plants using NaOCl (Hussey and Barker, 1973). Well-rinsed eggs were held on a nylon screen in a covered Petri dish with solution sufficient to just cover them. The solution consisted of sterile distilled water with 0.1% kanamycin sulfate and 0.05% gentamicin sulfate to control the growth of bacteria. Experiments indicated these antibiotics did not weaken the nematodes' responses to chemical stimuli as did hibitane. Each day the eggs were transferred to a fresh solution in another dish. Infective juveniles that had crawled through the screen were collected, rinsed, and concentrated in distilled water for use in the assay. The nematodes were generally used within two or three days of hatching when they are most infective (VanGundy et al., 1967).

Assay. Chemotaxis assays were conducted in small polystyrene boxes (2.0 × 2.0 × 6.0 cm) containing 4.0 ml of agar made up in deionized distilled water. Initially, 2% Bacto agar (Difco) was used (NaCl experiments); later 1.125% Bacto agar plus 0.375% Nobel agar was used to improve the way sample drops spread on the surface. After the agar was poured, the boxes were covered with paper towels to reduce air currents and the boxes were arranged to minimize temperature gradients while the agar cooled. This procedure promoted even hardening of the agar. After several hours, a sample (25 μ l with pure Bacto agar, 60 μ l with mixed agars) was spotted on the agar near one end and an equal volume of water or appropriate control solution was spotted on the other end. The boxes were again covered and allowed to sit for several more hours to allow the sample to diffuse into the agar. (This period generally varied from 5 to 10 hr between sets of experiments, but varied less than an hour within a given set of experiments. It had only a small effect on sensitivity as seen in Figures 1 and 2.) Several hundred nematodes were then applied to the agar surface in a minimal volume (10–20 μ l) of water. The plastic boxes were then placed side by side in a single row on a metal (copper or aluminum) plate (0.47 × 7.5 × 46 cm) that rested inside an insulated box, with internal dimensions

FIG. 1. Response to NaCl. Samples of 25 μ l of the indicated concentration were applied to the agar and scored after the indicated time interval had elapsed after the nematodes were added.

FIG. 2. Dose-response relationships for root exudate. Data for concentrated root exudate (CRE), and the major Sephadex peak (R3) are presented for nematode distributions 4 and 13 hr after nematode placement on the agar.

3.8 × 7.5 × 46 cm, made (on all six sides) from 2.5-cm-thick plastic foam. Three of these insulated boxes were then placed inside a larger insulated box, made from the same material but with internal dimensions of 15 × 28 × 53 cm. These elaborate procedures were taken to minimize thermal gradients to which these nematodes are extremely sensitive (Dusenbery, 1988c; Pline et al., 1988).

The distribution of nematodes on the agar within each box was observed under a stereomicroscope two or three times during the next 25 hr. The distribution was scored on the basis of a scale on which 0 corresponded to a symmetrical distribution around the center starting position, +5 corresponded to complete movement toward the sample, and -5 corresponded to complete movement away from the sample. Responses greater than four were rarely observed. This procedure was adopted after initial tests in which nematodes were counted in different sections of each box (Pline et al., 1988; Diez and Dusenbery, 1988) demonstrated that it was more useful to spend the additional time required to count nematodes on doing more replicates. In general, three replicates were performed for each sample tested, and the scores averaged together. The geometry of this test was chosen in order to make the assay equally sensitive to repellents and attractants.

Root Exudate. For a typical preparation of root exudate, eight tomato plants (Rutgers variety) that had grown about 30 days in a greenhouse after transplanting to 15-cm pots were washed free of soil. The roots were soaked in 2.0 liters of distilled water for 24 hr, while the tops were exposed to an artificial daylight regime. Approximately 1.5 liters of solution was recovered, and it was filter sterilized and refrigerated. In most cases, this raw root exudate was concentrated about 40-fold by rotary evaporation under reduced pressure at about 39°C. The resulting solution (concentrated root exudate) was frozen in small samples, if not used immediately. A variety of other methods of preparation were explored and most yielded similar results.

Solid-Phase Extraction. Residue extraction was performed by drying down 1-ml samples in glass test tubes, adding 2 ml of solvent, and vortexing. The solution was then transferred to a clean tube and the solvent evaporated. The residue from the second tube was redissolved in 0.5 ml water and tested for nematode responses.

Extraction from polar adsorbents was performed by drying down samples that were subsequently dissolved in 4 ml *n*-propanol. An equal volume of hexane was then added. The extraction was carried out in Baker 10SPE disposable columns containing silica gel or amino adsorbents, which were conditioned with propanol-hexane, 1:1. A sample of 0.2 ml was applied to each column. The columns were eluted with two 0.5-ml aliquots of each of several solvents of increasing eluting solvent strength (ϵ°) on silica (Baker-10SPE Application

Guide, vol. II, p. 112), and the effluent collected. Residual solvent was blown out between aliquots. Samples were dried down and resuspended in water for testing nematode responses.

Control samples were carried through each procedure in parallel with the samples being studied. This tested for artifacts caused by contaminants in the solvents or solid adsorbents.

Gel-Exclusion Chromatography. In a variety of experiments, concentrated root exudate was fractionated on Sephadex G-15 and G-50 and Biogel P2 and P4. Sephadex G-15 gave the best separations. The column used in the data presented here was 2.5 cm in diameter with a void volume of 85 ml and bed volume of 183 ml. The flow rate was 0.65 ml/min and fractions were collected at 6-min intervals. Ultraviolet light absorbance was measured at 280 nm with a flow-through detector. Fractions 92–96 from the run presented were pooled to make a sample called R3. The column was calibrated with molecular weight standards NaN_3 , reduced glutathione, glutathione disulfide, Evans blue, bacitracin, and blue dextran.

HPLC. A 25- μl sample of R3 was injected onto a C18 column (HP Hyperell ODS 5 μm , 100×2.1 mm, void volume 0.2 ml), which was eluted with 0.3 ml/min water (HP 1090 chromatograph). The effluent passed through a diode array detector (200–600 nm), and as drops emerged from the outlet, they were collected directly on the agar used to assay nematode responses. A similar procedure was also used with C8 and cyano columns.

RESULTS

In order to establish the sensitivity of our assay system, it was tested with NaCl, which is known to repel root-knot nematodes (Prot, 1980). Figure 1 shows the results of a test in which a 25- μl sample of various concentrations of NaCl were used in the assay. The results of observations at 4, 11, and 25 hr after the nematodes were placed on the agar are shown. An avoidance response is clearly apparent even at the earliest time with sufficiently high concentrations. Longer times clearly produced a more sensitive test with both significant responses at lower concentrations and stronger responses to high concentrations. However, there was little difference in sensitivity between 11 and 25 hr.

When the assay was applied to root exudates, the only strong or reproducible responses were avoidance (Table 1). This result was observed for exudates collected from a variety of plants (tomato, pepper, squash, watermelon, and soybean). Tomato was used as the source for subsequent studies. Rotary evaporation could be used to concentrate the activity and produce stronger responses that were easier to work with (Table 1). The volatile fraction contained no

TABLE 1. TYPICAL RESPONSES^a

Raw	-1.4	0.6	15	-1.7 to -1.1
Concentrated	-3.6	0.4	5	-4.1 to -3.1
Volatile	-0.3	0.4	2	

^a "Raw" is the starting root exudate that was subjected to rotary evaporation to yield the "concentrated" and "volatile" fractions. *N* is the number of preparations of root exudate that were tested. "Control" is for parallel experiments using water.

activity (Table 1). The activity of the nonvolatile fraction was stable and could be boiled or dried down without appreciable loss. All the activity appeared to be polar based on extraction between aqueous and organic phases.

In a series of preliminary experiments, activity appeared to be retained by cation exchangers and not by anion exchangers. However, interpretation was complicated by the apparent production of stimulus activity by the ion-exchange resins. Further exploration indicated that varying the pH of samples between 4.5 and 9.5 did not affect the response to them.

These observations led us to try fractionating concentrated root exudate via gel exclusion chromatography. Testing a variety of gels indicated that Sephadex G-15 worked best. A typical result is shown in Figure 3. The basic pattern is a strongly repellent peak (running with an apparent molecular weight of about 1000 daltons on a calibrated column), followed by a well-separated weaker peak (running at about 500 daltons). Frequently, there was an indication of a third peak running between these two. This pattern was very reproducible. Of seven such chromatographic runs with different root exudate preparations, the one with the greatest departure from this pattern had one strong peak followed by hints of one or two slower peaks, and five runs had very much the same pattern. Fractions from the stronger, faster peak were pooled to form a sample (R3) for further study.

The polarity of R3 was explored by extracting from a solid phase with solvents of differing polarity (Figure 4). If samples of R3 are simply dried and extracted with a variety of solvents, methylene chloride and ethyl ether extracted little activity, while propanol, methanol, and water extracted nearly all. Acetone appeared to extract some, but not all, of the activity. If silica gel was used as an adsorbent, approximately the same polarity was necessary to solubilize the activity. If an amine adsorbent was used, somewhat more polar solvents

FIG. 3. Response to concentrated root exudate fractionated on Sephadex G-15. UV absorbance was measured at 280 nm. The large peak at fraction 95 is near the position expected for a typical molecule of 1000 daltons. The smaller peak near fraction 75 is near the position expected for a molecule of 500 daltons.

FIG. 4. Extraction of R3 samples with solvents of various polarities. The solid line is extraction of the dried residue with different solvents applied to different samples. The broken lines are successive extractions of solid-phase adsorbents with solvents of increasing eluting strength (ϵ°) on silica. Thus, in the case of silica gel, activity presumably declines with water because the active material has already been eluted from the adsorbent.

FIG. 5. Response to R3 fractionated on an HPLC C18 column. Eluted with water. Absorbance is reported for 210 nm.

were necessary. Activity in R3 did not bind appreciably to C18 or cyano non-polar adsorbents.

In order to fractionate R3 further, experiments were begun to exploit HPLC techniques. A standard C18 column with water elution was used initially and drops of effluent collected directly on the agar surface of an assay box. The results (Figure 5) demonstrate that this approach is practical; a clearly defined peak of activity is observed. The peak appears quite broad, but this appearance may be an artifact of nonlinearity of the assay. As seen in Figures 1 and 2, the response is nearly proportional to the log of the concentration. If this relation is used to estimate the concentration of stimulus in Figure 5, the activity peak is substantially narrower. There is no clear correspondence between activity and UV absorbance. Similar behavior was observed with C8 and cyano columns.

DISCUSSION

The results reported here demonstrate that one can reliably measure a chemotactic response and use it as a bioassay to follow repellent activity through a variety of chemical fractionation procedures. The assay used is sufficiently sensitive to detect the response to $10 \mu\text{g NaCl}$, which produces an average concentration of $44 \mu\text{M}$ in the agar of the assay.

The fractionation experiments demonstrate clearly that the repellent is a polar molecule. Chromatography on Sephadex indicates it is of medium size

and that there are at least two different-sized molecules involved. The experiments initiated with HPLC demonstrate that the assay technique can be used successfully with HPLC and this approach probably holds the most promise for purification of the active chemicals.

An important question to address is whether the repellent characterized here actually came from the roots. One possibility (although far-fetched) is that the repellent was a contaminant of the deionized distilled water in which the roots were soaked. This possibility is eliminated by several contrary observations: (1) testing water without a control amount at the other end of the assay box led to attractive responses, which we attribute to a response to water activity (Prot, 1980); (2) incubation with roots changed this attraction to repulsion; (3) concentration of water samples fivefold and testing in the standard way produced responses not significantly different from water controls. Another possibility is that the repellent is produced by microorganisms associated with the roots rather than the roots themselves. We have not attempted to distinguish between these two possibilities. When we speak of root exudate, we mean a product of the rhizosphere, not necessarily a direct product of the plant.

Considering that we are looking at the product of millions of years of evolution in which nematodes have been selected for more efficient ways of locating hosts and the plants have been selected to avoid nematodes, it might be anticipated that a complex of repellent and attractant chemicals would be found to influence the interaction between host and parasite. Although it was suggested over 30 years ago that host roots have repellents as well as attractants (Wieser, 1956), this has remained a controversial point (Croll, 1970; Prot, 1980). Probably the most surprising finding of this study is that root exudate appeared to contain only repellent activity. Extensive efforts to uncover attractant activity by fractionation and other manipulations of the exudate were not successful in revealing attractant activity that was strong or reproducible. The repellent is obviously of potential benefit to the host; it could also benefit the nematode by directing it to appropriate sites for entry. This could occur, for instance, if mature roots, as opposed to growing root tips, are the source of the repellent. Resolution of these possibilities must await detailed studies of the site of release and the distribution of the chemicals around the rhizosphere.

It must be remembered that the assay used here is not expected to work with highly volatile stimuli and that there are several previous observations demonstrating that these and other plant-parasitic nematodes are attracted to carbon dioxide (Klingler, 1963; Pline and Dusenbery, 1987; Prot, 1980). These results suggest that carbon dioxide is the principle means by which nematodes locate host roots. As a cue, CO₂ has the advantage that it would be difficult if not impossible for a plant to stop releasing it under the selection pressure of nematode parasites. On the other hand, it has the disadvantage that it is not specific. There are many sources of CO₂ in soil, although most are at least

associated with roots. The lack of more specific attractants in the case of root-knot nematodes may be related to the fact that they are generalists with a very broad host range. It would be interesting to determine if nematodes with a narrower host range, such as cyst nematodes, utilize more specific cues. In summary, our current conclusions are that CO₂ is probably the primary stimulus by which root-knot nematodes locate hosts and that the repellent is either too weak to be effective or is released at a different site in the rhizosphere.

Abstract—(Z,Z)-7,9-dodecadienyl acetate, a reported male attractant for several New World spp. of *Epinotia*, was identified as the primary pheromone of female *E. tedella* (European spruce budmoth) through chemical analysis of pheromone gland washes, the electrophysiological study of male antennal receptor types, and field-trapping tests. The washes contained this compound at a level of approximately 0.4 ng per FE, along with a similar amount of the corresponding alcohol, (Z,Z)-7,9-dodecadien-1-ol. Each compound activated its own specialized type of male receptor cell. No traces of stereoisomers or monoenes were found in the washes. In field-trapping tests conducted in stands of Norway spruce in southern Germany, (Z,Z)-7,9-dodecadienyl acetate as a single chemical proved highly attractive to male *E. tedella* over a range of lure doses. The corresponding alcohol or aldehyde did not show attractivity; rather, in binary combinations with the primary pheromone, these compounds, and also the (E,Z)-7,9 stereoisomeric acetate, reduced captures. A 10:1 blend of (E)-9- and (Z)-9-dodecenyl acetates, reported as an *E. tedella* male attractant, did not reveal significant captures. No other *Epinotia* spp. besides *E. tedella* responded to the various 7,9-dodecadienyl test baits during this study.

Key Words—(Z,Z)-7,9-Dodecadienyl acetate, pheromone, sex attractant, attraction inhibitors, olfactory receptors, *Epinotia tedella*, *Epinotia* spp., Tortricidae, Lepidoptera.

INTRODUCTION

The spruce budmoth *Epinotia tedella* Clerck (Tortricidae: Eucosmini) is the most common microlepidopteran infesting Norway spruce, *Picea abies* (L.) Karst, in Europe and its impact on growing rates of trees is well documented (Führer, 1978). Usually the losses caused by this moth have not prompted control measures, even at high infestation levels. This view is changing as a result of the severe dieback of central European spruce forests due to airborne emissions, which appears to have increased their vulnerability to attack by secondary insect pests (Führer, 1985; Sierpinski, 1985; Baltensweiler, 1987). The monitoring of population fluctuations of forest insect species hitherto considered neglectable, such as *E. tedella*, is thus now timely.

The present study was initiated in order to identify the chemical composition of the *E. tedella* female pheromone and to develop a standard male attractant appropriate for routine population monitoring. While this study was being carried out, Booij and Voerman (1984) reported male *E. tedella* captures by a mixture of (*E*)-9- and (*Z*)-9-dodecenyl acetates, whereas Reed and Chisholm (1985) demonstrated specific attractiveness of certain 7,9-dodecadienyl compounds for North American species of the genus *Epinotia*.

METHODS AND MATERIALS

Insects. The *E. tedella* moths used in the chemical and electrophysiological analyses were collected as mature larvae, from spruce trees near Seewiesen, southern Germany, in late autumn. The larvae were provided sand for pupation and the pupae kept in outdoor conditions until early spring. Sexed pupae and adults were held in a 16:8 hr light-dark photoperiod at room temperature.

Test Chemicals. The dodecadienyl alcohols, acetates, and aldehydes were synthesized according to the methods described by Reed and Chisholm (1985) and had a purity of >98% and a steric purity of >99% by GC analysis. The monoenic analogs included in the field tests were purchased from the Institute for Pesticide Research, Wageningen, the Netherlands, in a steric purity of >99%. The series of olefinic compounds used in the electrophysiological tests were from our laboratory collections.

Electrophysiology. Electroantennograms (EAGs) were recorded from excised male antennae, whereas nerve impulse responses of single receptor cells were monitored from the cut ends of sensilla trichodea. Recording, stimulation, and data evaluation were as in studies on other tortricid moths (Priesner, 1983).

Pheromone Gland Washes. These were made from 1- to 3-day-old females at 2-3 hr after the beginning of scotophase. The extruded abdominal tips of 102

unmated females were dipped singly into *n*-hexane (Merck, for residue analysis; 3 μ l per female) for 5–10 sec and the wash stored at -18°C until use.

Chemical Pheromone Analysis. The analysis of pheromone present in the gland washes was similar to the method used by Priesner et al. (1984). Capillary gas chromatography (GC) and coupled GC–mass spectrometry (GC-MS) were carried out on samples of 20 FE per analysis, concentrated to 2 μ l. Further methodological details will be presented where relevant in the results section.

Field-Trapping Procedures and Study Sites. Synthetic baits were tested for attractancy to male *E. tedella* using tetratraps (Arn et al., 1979; sticky surface, 145 cm²) and rubber cap lure dispensers (red serum bottle caps, diameter 18 mm). The caps were impregnated with chemicals from dilutions in *n*-hexane and approx. 10 mg of antioxidant (2,6-di-*tert*-butyl-4-methylphenol) was added routinely. Lure sources of different chemical composition were compared as replicated series each comprising up to 14 traps. These were suspended, in a randomized order, from spruce branches 1.5–2 m off the ground, at distances of 2–5 m within series and 50 m or more between replicates. The traps were inspected once or twice weekly, collecting specimens and replacing the sticky liners where necessary. Trapping data from the replicated series were transformed to $\log(x + 1)$ and submitted to an analysis of variance.

Additional tests were aimed at assessing the effects of lure dose and trap placement on capture rates. A varying amount (0.1–1000 μ g) and a standard amount (100 μ g) of (*Z,Z*)-7,9-dodecadienyl acetate, respectively, were used in these tests.

Spruce forests of different age classes, representing varying levels of *E. tedella* infestation, were included in the study. The edges of older stands, showing a more homogeneous infestation by the moth, were generally used for placing the specificity and dosage series. The main sites were located near Freiburg and Mengen, Black Forest, and near Seewiesen, Upper Bavaria.

RESULTS

Electroantennography. Analysis of the *E. tedella* pheromone system began by recording male EAG responses to identified tortricid pheromone components and various structural analogs. First, an overall screening of test compounds (acetates, alcohols, and aldehydes, differing in chain length and double-bond position) was carried out at the standard amount of 1 μ g. These tests revealed (*Z,Z*)-7,9-dodecadienyl acetate (*Z7,Z9*-12:Ac) as the compound evoking the strongest EAG response. Relatively large responses were also recorded for the corresponding alcohol and aldehyde analogs, *Z7,Z9*-12:OH and *Z7,Z9*-12:Ald, and the stereoisomeric and 9-monoenic acetates, *Z7,E9*-12:Ac,

E7,Z9-12:Ac, *Z9-12:Ac*, and *E9-12:Ac*. Subsequent comparison of EAG dose-response curves showed that these six compounds were between 3- and 30-fold less stimulatory than *Z7,Z9-12:Ac*. Other acetates, alcohols, and aldehydes tested were at least 100-fold less stimulatory.

Single Receptor Study. By recording nerve impulse patterns from the cut tips of male antennal sensilla trichodea, two prevailing cell types were defined. The one was an acetate receptor maximally responsive to *Z7,Z9-12:Ac*, and the other, an alcohol receptor specific to *Z7,Z9-12:OH*. Most recordings showed action potentials originating from both types of cell, partially separable by spike amplitude and selective cross-adaptation. No efforts were made to define further potential cell types.

Chemical Pheromone Identification. Components with similar retention times to authentic *Z7,Z9-12:OH* and *Z7,Z9-12:Ac* were detected, in the gland washes, by flame ionization GC using a Hewlett Packard model 5890 gas chromatograph equipped with a DB-1 fused silica capillary column (30 m \times 0.3 mm ID; J&W Scientific Inc., Rancho Cordova, California) temperature programmed from 100°C to 250°C at 4°/min.

Identities of these components were verified by chemical ionization GC-MS using methane as the reagent gas and hydrogen as the carrier gas on a Finnigan model 3300 mass spectrometer coupled to an Incos model 2300 data acquisition system. Analyses were made using undecane and tetradecane as internal standards. The samples were chromatographed on a DB-5 capillary column (60 m \times 0.35 mm ID; J&W Scientific) under similar temperature program conditions. Standard 7,9-dodecadienyl aldehyde, alcohol, and acetate isomers eluted in the order: *ZE*, *EZ*, *ZZ*, *EE*. In the tip washes, two compounds were found whose retention times and mass spectra coincided with authentic standards of *Z7,Z9-12:OH* and *Z7,Z9-12:Ac*. Evidence included the diagnostic ions $[M - 1]^+$, $[M]^+$, and $[M + 1]^+$ for both compounds; $[(M + 1) - 18]^+$ for *Z7,Z9-12:OH*, and $[(M + 1) - 60]^+$ for *Z7,Z9-12:Ac*. No aldehydes or other alcohol and acetate isomers could be detected.

The compounds were quantitated by comparing their total ion counts in the extract to an external calibration curve. The alcohol and acetate were thus estimated at levels of 0.4 ng/FE each.

Field Trapping. *Z7,Z9-12:Ac* as a single compound proved strongly attractive to male *E. tedella*. On testing different lure doses (data not specified), *Z7,Z9-12:Ac* sources ranging from 0.1 to 1000 μ g revealed captures, which generally increased with increasing lure dose. The alcohol, *Z7,Z9-12:OH*, did not produce significant captures.

Potential modifying effects of second components were studied by means of binary combinations made with 100 μ g of *Z7,Z9-12:Ac*. As a 10- μ g addition (Table 1, series 1), the *EZ* stereoisomer strongly reduced captures; the *ZE* stereoisomer and the *ZZ* alcohol and aldehyde appeared to cause some reduc-

^aMengen, June 10/13 to July 14/18, 1986 (series 1) and Seewiesen, June 19 to July 29, 1987 (series 2). Each series four replicates. Numbers within the same column followed by the same letter are not significantly different ($P = 0.05$, Tukey's test).

tion, whereas the *EE* stereoisomeric and the Z9 and E9 monoenic acetates had no apparent effect. These same seven compounds were subsequently tested as 100- μg additions. The results (Table 1, series 2) confirm the strong inhibitory properties for the E7,Z9-12: Ac, and show that the Z7,Z9-12: OH and Z7,Z9-12: Ald are also inhibitors, whereas the four others appear to have virtually no effect on captures.

Traps baited with the 10:1 mixture of E9-12: Ac/Z9-12: Ac, the *E. ted-*

ella attractant reported by Booij and Voerman (1984), were included in both series. This mixture revealed only poor captures, not significantly differing from blank traps (Table 1). The Z7,Z9-12:OH and Z7,Z9-12:Ald as single compounds did not catch even a single male *E. tedella*.

No other species of *Epinotia* besides *E. tedella* were captured during this study.

DISCUSSION

The results of the electrophysiological, chemical, and field studies identify Z7,Z9-12:Ac as the primary female pheromone of *E. tedella* and as a highly potent male attractant.

No evidence for pheromone synergism was found. In the field tests, the alcohol, Z7,Z9-12:OH, although present in the pheromone gland washes at almost the same amount as the acetate, did not show attractivity as a single chemical and reduced responses to the acetate when added to it in amounts of 10% or more. Whether this alcohol is actually released by calling *E. tedella* females, and whether it has potential pheromonal effects in amounts lower than 10%, remains unknown. The three stereoisomeric acetates, and also the 7- and 9-monoenes, were not found in the washes at levels of >1% of the two major components (detection limit) and probably are not part of the pheromone.

Three different compounds, E7,Z9-12:Ac, Z7,Z9-12:OH, and Z7,Z9-12:Ald, acted inhibitorily on trap captures. These data suggest that the *E. tedella* male receptor system includes, besides the Z7,Z9-12:Ac and Z7,Z9-12:OH receptors found in the electrophysiological recordings, specialist cells also for the EZ pheromone stereoisomer and for the ZZ aldehyde analog.

The results of the present study indicate a close pheromonal relationship of *E. tedella* to three New World *Epinotia* spp. studied by Reed and Chisholm (1985): *E. silvertoniensis* (Kft.), *zandana* (Kft.), and *removana* McDunnough (the last two referred to by the authors as species A and B, respectively). The pheromone of these three species have not yet been chemically identified, but in the field the males of these species were strongly attracted by Z7,Z9-12:Ac, as with *E. tedella*. The alcohol, Z7,Z9-12:OH, was another potent attractant for *E. removana* but inhibitory on *E. silvertoniensis*. The E7,Z9-12:Ac and the monoene Z9-12:Ac both inhibited attraction of male *E. zandana* but had little effect on the two other species. Together with the *E. tedella* data reported here, these differential response patterns suggest a role of secondary pheromone components for maintaining reproductive isolation among species of *Epinotia* which share Z7,Z9-12:Ac as their primary female pheromone.

Booij and Voerman (1984) described a 10:1 blend of E9-12:Ac/Z9-12:Ac as an *E. tedella* male attractant, based on captures of 409 males of this species

recorded in a single trap containing this mixture. In our replicated series, this mixture failed to produce significant *E. tedella* captures. The reason for our failure to reproduce the above result is unknown.

It is noteworthy that, during this study, no other species of *Epinotia* besides *E. tedella* were captured with Z7,Z9-12:Ac (alone or in mixtures). The genus is represented in central Europe by some 35 species (Hannemann, 1961), some of which co-occur on Norway spruce together with *E. tedella*. For one of these, *E. nanana* (Treits.), a 1:1 blend of (*E*)-8- and (*E*)-10-dodecenyl acetates has been reported as the specific male attractant (Booij and Voerman, 1984).

Our results show that 100 μ g of Z7,Z9-12:Ac can be used as a standard trap bait for monitoring *E. tedella* populations, without need for improving, by secondary bait components, capture efficiency or selectivity. Isomerization of the Z7,Z9-12:Ac during field exposure has not yet been determined, but it is assumed to be similar to (Z, Z)-8,10-dodecadienyl acetate (Chisholm et al., 1985). This isomerization may be critical to the lure's relative attractancy over time if significant amounts of the E7,Z9-12:Ac are produced.

In 1986, a program using this standard attractant was started with the aim to evaluate trap position effects and to correlate moth captures with local population densities based on larval counts. Results of this aspect of the study will be reported elsewhere.

Acknowledgments—We would like to thank Dr. Richard L. Brown of the Mississippi Entomological Museum, Mississippi State, Mississippi, for his identification of *Epinotia silvertoniensis*, *E. zandana*, and *E. removana* (voucher specimens deposited in the Mississippi Entomological Museum). We also thank Doug Olson, Saskatoon, for his expert technical assistance in GC-MS analysis, and Peter Witzgall, Wädenswil, for his help with statistical analysis of trapping data.

VOLATILES RELEASED FROM INDIVIDUAL SPRUCE BARK BEETLE¹ ENTRANCE HOLES Quantitative Variations During the First Week of Attack

GÖRAN BIRGERSSON² and GUNNAR BERGSTRÖM

Department of Chemical Ecology
Göteborg University

(Received June 15, 1988; accepted December 27, 1988)

Abstract—Volatiles released from individual entrance holes of eight spruce bark beetles (*Ips typographus*) were collected during the first week of attack on a resistant host tree. In order to quantify the release of the highly volatile 2-methyl-3-buten-2-ol (MB) from attacking males, a new method was developed with deuterated quantification standard released at the time of collection. The amounts of collected volatiles, as analyzed by GC and GC-MS, showed a large variation between individual holes and also between subsequent entrainments from the same hole. Most of the quantified compounds on the average have two maxima, with a pronounced intervening depression. The amounts of released *cis*-verbenol (cV) increased five times during the first two days, while the amounts of MB were consistently high. The attacked spruce tree was not taken by the beetles, and the average amounts of the two aggregation pheromone components, MB and cV, increased again after the first maxima. The first peak of oxygenated monoterpene, released in the beginning of the attack containing α -terpineol, terpinen-4-ol, bornyl acetate, *trans*-pinocarveol, and verbenone, was possibly due to spontaneous oxidation of monoterpene hydrocarbons from the tree. Microorganisms established in the gallery wall phloem probably participated in the production of oxygenated monoterpenes during the second increase.

Key Words—*Ips typographus*, Coleoptera, Scolytidae, *Picea abies*, aggregation pheromones, host tree resistance, tree-switching, GC-MS, monoterpenes, 2-methyl-3-buten-2-ol, *cis*-verbenol, verbenone.

¹*Ips typographus* (Coleoptera: Scolytidae).

INTRODUCTION

Several species of bark beetles are known to produce aggregation pheromones when attacking their host trees (Vité and Francke, 1976; Borden, 1982; Wood, 1982). The pheromone of each species is usually a mixture of compounds. The behavioral activity of the individual compounds varies and may also elicit different steps in the behavior chain (Borden, 1974; Dickens, 1981; Schlyter et al., 1987a,b). In *Ips*, the production of pheromone components, reflected as their content in bark beetle hindguts, has been shown to start as soon as the males bore into the host tree phloem (Birgersson et al., 1984). It reaches a maximum during excavation of the nuptial chamber, and decreases when the males admit females, mate, and the females excavate galleries and lay eggs (Byers, 1981a; Birgersson et al., 1984).

The defensive monoterpene hydrocarbons produced by the host tree also show a quantitative variation as the attack of the spruce bark beetle (SBB, *Ips typographus* L.) proceeds (Leufvén and Birgersson, 1987). However, there is a marked difference in the quantitative patterns between the host-tree-produced compounds and the bark-beetle-produced ones. The amount of monoterpene hydrocarbons from the tree, after an intervening decrease, increases again during the end of the first week of attack, while the amount of volatiles found in bark beetle hindguts decreases continuously after a first rapid increase, when the males attack the spruce tree (Leufvén and Birgersson, 1987; Birgersson and Leufvén, 1988). Oxygenated monoterpenes present in the gallery wall phloem also show a quantitative variation during an attack (Leufvén and Birgersson, 1987). The amount of α -terpineol, borneol, terpinen-4-ol, and verbenone increased while the females elongated their galleries, especially when the gallery walls were brown-stained. This coloring is probably a sign of established microorganism.

In a theoretical model, Schlyter and Anderbrant (1989) have compared the quantitative variation of hindgut volatiles in male SBB attacking standing spruce trees (Birgersson *et al.*, 1984) with the dynamics of naturally attacking SBBs. This numerical model attempted to describe the process leading to a mass attack with regard to the fast initial production of the aggregation pheromone components 2-methyl-3-buten-2-ol (MB) and *cis*-verbenol (cV). However, the model failed to describe the chemical events accompanying the shifting from attacked and taken host tree, known as "tree-switching" (Gara and Coster, 1968); their predicted decrease of attractive semiochemicals comes too late. In addition, the production of ipsenol (Ie), with known antiaggregative properties (Bakke, 1981; Schlyter et al., 1989), is too low and also appears too late, if at all. Probably, there are missing components in the tree-switching phenomenon; some of these compounds may not be produced by the bark beetles themselves but are released

from the phloem surrounding the galleries where microorganisms have been established.

The behaviorally active compounds are not accurately represented by the quantities in bark beetle hindguts or the quantities in gallery wall phloem, but only by the amounts actually released from the bark beetle entrance holes. Most of the odor/volatile entrainments made from bark beetles have been done on batches of beetles excavating in cut logs (Young et al., 1973; Browne et al., 1979; Schlyter et al., 1987a). For nonaggressive species, which naturally attack dead material, such as windthrown trees and forest debris, laboratory studies can and/or may indeed show which compounds these beetles produce during their attacks. However, for some aggressive species, which are able to attack living trees and utilize host precursors in pheromone production, such as *I. typographus*, log experiments are not appropriate. A log is not able to mobilize a resin defense, neither by the primary nor by the secondary increase of toxic monoterpene hydrocarbons, as is a living tree (cf., Leufvén and Birgersson, 1987). In this regard, males of SBB excavating in spruce logs in the laboratory produce very small amounts of pinene alcohols (i.e., cV, *trans*-verbenol (tV), myrtenol (Mt), and *trans*-myrtenol (tM)) (Birgersson, unpublished).

Males of *I. typographus* are known to show a rapid increase in their production of aggregation pheromone components when they bore into a standing host tree (Birgersson et al., 1984). But exactly how soon after their attack do they release their semiochemicals to attract conspecific males and females to overcome the resistance of the selected host tree? We know that the variation in hindgut content of volatiles is very large, even between males in the same attack phase and attacking the same host tree (Birgersson et al., 1988).

In the present study we have quantified the amounts of different volatiles released from individual SBB entrance holes during the first week of an attack. We describe the method that was used and the quantity of the airborne aggregation pheromone components from attacking males as well as monoterpene hydrocarbons and oxygenated monoterpenes from the injured phloem. Since the entrainments were done from individual entrance holes, the results can be related to the attack success of each male.

METHODS AND MATERIALS

Biological Material and Sample Collection. The field work was carried out in Gribskov, 10 km north of Hillerød, Sjaelland, Denmark, during the main swarming period of *I. typographus* in late May 1985. The number of swarming SBB was low, and to ensure attack and colonization the selected Norway spruce tree [*Picea abies* (L.) Karst.] was baited with a commercial pheromone attrac-

tant for *I. typographus* (Ipslure, Borregaard a/s, Norway). Compounds volatilizing from each of eight entrance holes of SBB males, attacking the same spruce tree, were collected in 3-hr periods for one week. The selected spruce tree, with a diameter at breast height of 22.5 cm, was standing on the forest edge, which opened to the southwest. The tree was characterized as being in good physiological condition, indicated by many fresh spring shoots and a rich resin flow from hand-made holes in the bark. After attack by SBB, the tree was not judged as taken by the beetles, mainly due to the low number of swarming beetles and very few attacks on the tree (≤ 1 male/dm²). All the sampled entrances were located between 1 and 2 m above ground. The males attacked the tree during the early afternoon, and the first set of entrainments was started at 1630 hr. During the first 27 hr of the attack, the entrainment was continuous, and thereafter entrainments were done each afternoon (from 1400 to 1700 hr), when the production in pilot studies during the previous years was found to be largest.

During the entrainments, a silanized glass T (Figure 1) was attached outside each entrance hole, and stapled to the tree using a piece of rubber tubing. The volatiles were trapped on synthetic polymer adsorbent plugs; PTFE tubings

FIG. 1. Glass T used in entrainments from individual entrance holes. Internal standards (deuterated 2-methyl-3-buten-2-ol and pentanol dissolved in undecane, 1:1:8) are released from fused silica capillaries, one end sealed with beeswax.

(ID 3 mm × 55 mm) filled with Porapak Q (70 mg; 80–100 mesh). Pilot studies had shown that these plugs quantitatively adsorbed ($\geq 99\%$) all compounds released from bark beetle entrance holes, except the highly volatile 2-methyl-3-buten-2-ol (MB). In order to quantify the release of MB, internal standards were used at the time of collection. Deuterated-MB (D-MB) $[(D_3C)_2C(OH)CH=CH_2]$ and pentanol dissolved in undecane were released from a fused silica capillary (ID 0.2 mm × 25 mm), one end of which was sealed with beeswax (Figure 1). Pilot studies of the release of D-MB and pentanol showed these two compounds to have almost equal release rates, both when released separately from different capillaries and as a mixture dissolved in undecane (1 : 1 : 8). The latter was analyzed as the remains in the capillaries. In addition, pentanol is quantitatively adsorbed on the Porapak Q plugs used in this study. A small suction air-pump was used to achieve an air flow through each adsorbent plug of about 20 ml/min. Air entered between the glass T and the bark surface, just over and surrounding the entrance hole. Thus all volatiles released from the hole were drawn through the glass T and trapped on the adsorbent plugs. The glass T's were removed between each afternoon entrainment so that females could be admitted. All glass T's were washed in ethanol between the afternoon entrainments. The first set of entrainments was started only a few hours after the male beetles first attacked the spruce tree; i.e., as soon as it was possible to put the glass T's over the entrance holes without disturbing the excavating beetles. Some of the males were not yet completely into the phloem. The attack phase status of the beetles in each single attack after the entrainment period is shown in Table 1. The Porapak Q plugs were stored in liquid nitrogen until chemical analysis.

Chemical Analysis. The collected volatiles were extracted from the entrainment plugs with 400 μ l of *n*-pentane (doubly distilled). This volume of pentane proved enough to quantitatively elute the volatiles from the adsorbent plugs, since a second rinse with 400 μ l pentane gave less than 0.1% of monoterpene hydrocarbons and undetectable amounts of oxygenated compounds in pilot analyses. To enable GC and GC-MS quantifications of monoterpene hydrocarbons and oxygenated monoterpenes, respectively, 40 μ g tetradecane and 500 ng heptyl acetate (C_7Ac), dissolved in 100 μ l *n*-pentane (doubly distilled), were added to each entrainment extract.

Without prior concentration, the volatile extracts were analyzed on a Hewlett-Packard 5830A GC, using a fused silica capillary column (46 m × ID 0.35 mm) coated at our department with OV-351 (Ohio Valley) (Lanne et al., 1987). Nitrogen was used as carrier gas ($Q = 15$ cm/sec) and the temperature programming was 60°C for 4 min, 5°C/min to 210°C. The amounts of monoterpene hydrocarbons were quantified using the added standard, 40 μ g tetradecane, as described by Leufvén and Birgersson (1987).

^bNo male at end of entrainment period.

After the GC analysis, the extracts were concentrated in tapered glass tubes on a lab bench at room temperature, according to Klimetzek et al. (1989) to about 10 μ l. Three microliters of the concentrated extract was analyzed by a Finnigan 4021 GC-MS (quadrupole) system, continuous scanning over the region m/z 29–300, with exception of m/z 32, with one scan per second. The GC was equipped with a fused silica capillary column (25 m \times ID 0.15 mm) coated at our department with Superox FA (Alltech) (Lanne et al., 1987). The temperature programming was 50°C for 4 min, followed by an increase of 8°C/min to 200°C, and isothermal at this temperature for 15 min. Helium was used as carrier gas ($Q = 25$ cm/sec).

Several compounds, mainly oxygenated monoterpenes identified in SBB hindguts (Birgersson et al., 1984, 1988) and in gallery wall phloem (Leufvén and Birgersson, 1987), were searched for and quantified, using "extracted ion current profiles" (EICP) (Chen, 1979; Garland and Powell, 1981). For each compound, three to four prominent and/or typical MS fragments were used and the calculated amounts were compared with the added standard, 500 ng heptyl acetate, as described by Birgersson et al. (1984) and Leufvén and Birgersson (1987). According to pilot studies, the limit of quantification (LOQ) was estimated to be 10 ng, and the accuracy of the quantification to be $\pm 5\%$. To quantify the highly volatile MB, the ratio between m/z 71 for MB and m/z 74 for D-MB was compared with the amount of pentanol, which was released together with D-MB at the time of collection. For MB, LOQ was estimated to be 100 ng, and the accuracy $\pm 5\%$.

Since the number of sampled individuals was low, no thorough statistical analysis was done. We employed various programs in the Statgraphics program package, produced by Statistical Graphics Corp., Princeton, New Jersey, to examine trends in the data.

RESULTS

The amounts of different volatiles released from the entrance holes were found to show a very large variation among SBB males attacking the same host tree. A large variation was also found between subsequent entrainments from the same entrance hole. The results are presented both as general trends and as variations among different entrance holes.

Host-Tree-Produced Compounds. From most of the entrance holes, very large amounts of monoterpene hydrocarbons were passively emitted, even during the first 3-hr entrainment (Figure 2). During the first evening and night, the amounts of monoterpene hydrocarbons, such as α -pinene, β -pinene, 3-carene, myrcene, limonene, and β -phellandrene, emitted from the host tree, decreased, probably due to lower temperature during the night (3°C at 0530 hr. = sunrise; Figure 3), the release increased during the morning and reached a maximum in the afternoon. There was a decrease in emitted amounts of monoterpene hydrocarbons between days 3 and 5, but the emitted amounts increased clearly again during the last days of the first week, days 5 to 7 (Figure 2A).

Release of monoterpene hydrocarbons from most of the individual attacks followed the general pattern shown in Figure 2B. Large amounts of monoterpene hydrocarbons were emitted from entrance hole 8 during the first days of the attack. The resin flow from this entrance was relatively high, since a pitch tube was formed around the entrance hole. After the general decrease during days 3–5 (Figure 2B), the emitted amounts of monoterpene hydrocarbons from this individual did not increase during the last days. From entrance hole 6, only

FIG. 3. Temperature in Gribskov during the entrainment period. Solid line during the entrainments.

small amounts of monoterpene hydrocarbons were emitted, probably due to the low excavating activity of the attacking male. At the end of the entrainment period, only a short tunnel was found in the phloem, and the male was gone.

Bark-Beetle-Produced Compounds. Eight compounds that have been identified in bark beetle hindguts (Birgersson et al. 1984), 2-methyl-3-buten-2-ol (MB), *cis*-verbenol (cV), *trans*-verbenol, myrtenol, *trans*-myrtenol, ipsdienol, ipsenol, and 2-phenylethanol, were searched for and quantified. The two essential aggregation pheromone components, MB and cV (Schlyter et al., 1987b), showed different general patterns of appearance. The general trend for MB was continuously increasing amounts during the entrainment period (Figure 4A). On the other hand, the general pattern for cV was a fast increase during the first and second day of the attack, followed by decreasing amounts (Figure 5A). The maximum amounts of MB released during a 3-hr entrainment was 65 μg (Figure 4B), which corresponds to 0.4% of the body weight (dry weight) and was produced by a male with two females in ≥ 2 -cm-long galleries (No. 4). The corresponding maximum of cV was almost 700 ng (Figure 5B). In general, the released amounts of *trans*-verbenol, myrtenol, *trans*-myrtenol, and 2-phenylethanol follow the pattern for *cis*-verbenol. Ipsdienol and ipsenol were never detected in any entrainment (< 2 ng/entrainment, EICP), and cannot play any big role in attack termination or tree-switching.

Oxygenated Compounds from Phloem. Most of the quantified oxygenated compounds have been identified previously in gallery wall phloem (Leufvén and Birgersson, 1987). Among the most prominent compounds are α -terpineol, α -terpinyl acetate, bornyl acetate, terpinen-4-ol, *trans*-thujanol, and one uni-

FIG. 4. Amounts ($\mu\text{g}/3 \text{ hr}$) of 2-methyl-3-buten-2-ol collected during the entrainment period. (A) Mean \pm SE. (B) Entrainments from individual entrance holes. -- unmated males, — mated males, respectively, at the end of entrainment period.

identified oxygenated monoterpene (characteristic MS fragments: m/z 53, 81, and 108).³ Other quantified compounds were myrtenal, *trans*-pinocarveol, borneol, verbenone, cryptone, pinocamphone, isopinocamphone, anethole, and camphor. The general patterns for most of these compounds were similar to those for monoterpene hydrocarbons (Figure 6A and C). However, there are discernible differences. For α -terpineol, bornyl acetate, verbenone, and terpinen-4-ol, most of the individuals had a large second increase during days 5–7 (Figure 6B and D). The continuous increase of these compounds seems espe-

cially pronounced if their amounts are compared with the emitted amounts of supposed and/or probable monoterpene hydrocarbon precursors (Figure 7).

The release of all oxygenated compounds, except pinocamphone, was much larger from entrance 8 during the first average increase. From this entrance hole, very large amounts of oxygenated compounds were released as early as in the first entrainment only a few hours after the attack was initiated (Figures 6B and D). Only small amounts of these compounds were released from most other entrances during the first few days. However, during the second period of increase at the end of the entrainment period, the released amounts of oxygenated compounds from the gallery wall phloem increased from all entrance holes.

The frass production, visually measured as frass amount in the glass T at

the end of the 3-hr entrainment, was lower from the unmated males (Nos. 3 and 7) than from the mated ones during the last days of the entrainment period. When the galleries were cut open after the last entrainment, no attack showed brown-stained gallery wall phloem.

DISCUSSION

When males of *Ips typographus* start to bore into the bark and phloem, they meet the primary resin of the tree. This resin is a part of the tree's defense system (Berryman, 1972), due to both its sticky properties and the content of compounds, such as monoterpene hydrocarbons, which are toxic to the invading bark beetles (cf., Cates and Alexander, 1982). When exposed to monoterpene hydrocarbons, such as α -pinene, by both inhaling and feeding, the males start to produce one of their aggregation pheromone components, (*S*)-*cis*-verbenol (cV), which accumulates in the hindguts (Klimetzek and Francke, 1980). But how soon after the first attack can the beetles release these semiochemicals to attract conspecifics in order to overcome the resistance of their host tree? In addition, males walking on the bark of the tree have been found to release their own essential aggregation pheromone component, 2-methyl-3-buten-2-ol (MB) (J.P. Vité, personal communication).

To quantify the release of semiochemicals, especially the highly volatile MB, from individuals of attacking SBBs, a new method was developed. Vité analyzed the amounts of released MB from walking SBB males in the laboratory, by using a closed-loop stripping apparatus (CLSA) (Lorbeer et al., 1984)

together with active charcoal filters (Bender & Hobein AG, Zürich, Switzerland). This method works very well for trapping MB, but is not so practical for studying naturally attacking bark beetles in the field.

The reason for entraining volatiles from individual entrance holes is to come as close as possible to the source of semiochemicals under natural conditions. We know that there are both quantitative and qualitative variations in volatiles produced by individual bark beetles (Birgersson et al., 1984) as well as in the phloem of gallery walls (Leufvén and Birgersson, 1987). Following the same individuals during the first week of their attack by chemical analysis, we were able to determine such variation within and between individuals.

Average Amounts of Released Components. On average, all the quantified compounds, perhaps with the exception of MB, show similar patterns of variation (Figures 2A, 4A, 5A, 6A and C): two more-or-less pronounced maxima, with an intervening decrease. This general trend closely resembles the findings by Leufvén and Birgersson (1987) for compounds analyzed in phloem tissue around the galleries (cf., Byers, 1981b). There is a decrease in amounts of most volatiles in the phloem surrounding beetles in attack phases 4-5 (for the definition of attack phases, see Birgersson et al., 1984), when males had accepted females.

The amounts of emitted monoterpene hydrocarbons were relatively large in the first entrainment, only a few hours after the males started to bore into the spruce tree. This indicated that the primary resin is mobilized very fast. The amount of monoterpene hydrocarbons is very low in unattacked phloem and rises at least 10-fold when the males bore into it (Leufvén and Birgersson, 1987). For some of the entrances, the first entrainment contained the largest amounts of monoterpene hydrocarbons during the entire entrainment period (Figure 2B). The second increase, which appears during the last two days, likely resulted from the production of new, so-called secondary resin (Christiansen and Horntvedt, 1983). In addition to this newly produced resin, primary resin from the progressive ends of the mother galleries may, to some extent, have contributed to the total amounts of emitted monoterpene hydrocarbons.

The production and release of MB was shown to start very early in the attack (Birgersson et al., 1984) and may even start before the males begin to bore into the phloem (J.P. Vité, personal communication). This is also shown in the first entrainment here, where the released amounts averaged 4300 ng/3 hr. MB has been shown to promote landing (Schlyter et al. 1978b), and this early release can be interpreted as the males are adapted for a fast attack on a selected tree. In general, the release of MB was much larger than expected, according to what has been quantified in SBB male hindguts (Birgersson et al., 1984, 1988). The average of collected amounts during the first entrainment, 4300 ng, can be compared with the amounts found in hindguts by Birgersson et al. (1984) of 100 ng for males boring into the phloem, which rises to 500 ng

when they are excavating their nuptial chambers. The amounts released during 3 hr are at least 10 times larger than the average hindgut content. This implies a very high turnover for the production of MB.

The decrease in released amounts of MB on the third day is significant. One reason for this lower release can be the temperature, which was lower this day than the days before and after (Figure 3). However, this drop in afternoon temperature is considered too small to be the main reason for the lower production and release during the third day after the attack. During the first night, when the temperature fell from 18°C to only a few degrees above freezing, the average amounts of released MB decreased to half of the earlier amounts, which can be directly related to the drop in temperature, as both biological activity and vapor pressure are reduced at lower temperature. The lower production of MB on the third day coincides with the decrease of all quantified compounds, both hydrocarbon and oxygenated monoterpenes, although MB is not assumed to be a metabolite from host tree monoterpenes (Figures 2A, 5A, 6A and C). The most likely reason is that the tree is running out of primary resin, which is the first line of defense. This decrease also coincides with the decrease in male hindgut content, when the males have admitted females (Birgersson et al., 1984).

The significant increase in MB production on the fourth day and the continued large release may be due to the fact that this spruce tree was not taken by the beetles. The production of MB may also be an induced response to the host-tree production of defensive compounds. This interpretation is in agreement with the findings by Birgersson et al. (1988), who found high-MB-producing mated males in resinous spruce trees. Our hypothesis, that male SBBs attacking resistant spruce trees continue to produce aggregation pheromone components, is further supported by the results of Birgersson and Leufvén (1988), who showed that late-attack-phase males surrounded by unstained phloem on the average produce more MB than males surrounded by stained phloem. The brown staining is a sign of fungal establishment in the phloem, indicating that the defense of the tree has been overcome by the bark beetle-fungal attack. This relationship between pheromone production and host tree resistance was also discussed by Raffa and Berryman (1980).

cis-Verbenol is known to be produced from (-)- α -pinene by SBB males (Klimetzek and Francke, 1980). This compound is unique among bark beetles, as it has only been quantitatively determined (Byers, 1989) and shown to elicit attractive response in *Ips* species (Borden, 1982). In addition, cV is possibly an inhibitor of *Dendroctonus brevicomis* (Byers and Wood, 1980). Since Leufvén and Birgersson (1987) did not find cV to be produced in the gallery wall phloem in later attack phases, we assume that all the cV released from the beetle galleries is produced by the beetles themselves, predominantly by the males (Birgersson et al., 1984). Compared with the pattern of its precursor, α -

pinene, the amounts of released cV are low during the first afternoon of the attack (= day 0). It takes one to two days for the beetles to reach their maximum in cV production and release. The efficiency in producing cV from α -pinene, from the first entrainment until the maximum, increases more than five times (Figure 8A). The decrease in the efficiency during the first night and the third day can probably be explained as an effect of the lower temperature (cf., Figure 3). However, the decreasing release at the end of the entrainment period cannot be temperature dependent, as the temperature was increasing during these days. This decreased release of cV in relation to the amount of α -pinene is probably due to microbial activity in the gallery wall phloem, where the beetle-produced cV is converted to Vn (Leufvén et al., 1984). In addition, the microbial activity in the gallery wall phloem, giving increasing amounts of oxygenated compounds, mainly monoterpenes (Birgersson and Leufvén, 1988), influence the attacking bark beetle males to reduce their production of aggregation pheromone components in relation to events in the surrounding phloem.

Several oxygenated monoterpenes in the gallery wall phloem show pronounced quantitative increases during the later attack phases (Leufvén and Birgersson, 1987). Since many of these compounds can be produced by yeasts, isolated from SBB (Leufvén et al., 1988), and the number of these microorganisms increases during the attack (Leufvén and Nehls, 1986), the oxygenated compounds in the phloem were interpreted to be of microbial origin (Leufvén and Birgersson, 1987). In the present study, many of the non-beetle-produced oxygenated compounds were collected in large amounts during the first days of attack. These compounds are unlikely to be produced by microorganisms this early in the attack. Instead, in the beginning of the attack, the only source has

FIG. 8. (A) Bark beetle efficiency in production of *cis*-verbenol from α -pinene during the entrainment period: ratio between *cis*-verbenol (ng/3 hr) and α -pinene (μ g/3 hours), mean \pm SE. (B) Ratio between verbenone and *cis*-verbenol during the entrainment period, mean \pm SE.

to be spontaneous, abiotic oxidation (Leufvén and Birgersson, 1987). A second mechanism for this early production of oxygenated monoterpenes can be through enzymes released from host tree cells, that were injured by the excavating beetles. After the intervening decrease of emitted oxygenated monoterpenes and during the larger second quantitative increase (Figures 6A and C), established microorganisms may have contributed to the production. This is probably also the case, because the oxygenated monoterpenes, compared with the likely precursors, show an increase at the end of the entrainment period (Figure 7).

In the quantitative study by Leufvén and Birgersson (1987), borneol was a prominent oxygenated compound in the gallery wall phloem. In the present study, only trace amounts of borneol have been quantified. However, bornyl acetate, which was only found in trace amounts in the gallery walls, is a prominent compound in the entrainments. From this we infer that borneol in microorganism-inoculated phloem is given off as bornyl acetate.

Variation among Entrance Holes. All the males attacked the same spruce tree at about the same time, but they did not meet the same degree of defense. Most of the beetles met a "medium" defense, as judged by the emission of around 500 μg monoterpene hydrocarbons during the first entrainment (Figure 2B). Two males were faced with very low amounts of monoterpene hydrocarbons, while one male (No. 8) was fighting for three days in a heavy resin flow. After the intervening decrease in emitted monoterpene hydrocarbons, the amounts increased from almost all attacks during the last days, probably due to the production of secondary resin.

The individual patterns for the two aggregation pheromone components, cV and MB (Figures 4B and 5B), differ from each other and from other oxygenated compounds. All males released large amounts of MB (several micrograms per 3 hr) during the first entrainments and did not increase their release the next day (day 1). At the same time, almost all males released low amounts of cV during the first day (day 0) and increased their production and release 10-fold the next day, possibly in order to detoxify the α -pinene they were exposed to in the phloem. If cV is produced as a detoxification product by mixed-function oxidases (Hunt and Smirle, 1988), it could take some time to induce the enzyme system. The male fighting in resin (No. 8) might have been poisoned by the very large amounts of resin, since he did not produce either MB or cV in excessive amounts.

The general decrease of released cV, during days 3–5, cannot be simply temperature dependent, as not all the males decrease their production during these days. However, all males, except No. 8, clearly decrease their MB production on the third day, only to increase it again the next day. It is notable to see that entrances 3 and 7, where the males were still unmated (i.e., attack phase 3) at the end of the entrainment period, are both among the high producers during the last days (Figure 4B).

The very large amounts of monoterpene hydrocarbons present in entrance 8 were probably the main reason for the high release of oxygenated monoterpenes from this entrance (Figure 2B, 6B and D). Terpinen-4-ol predominated from this entrance during the first days; the release from other entrance holes was low (Figure 6B). However, during the second increase, at the end of the entrainment period, all galleries release terpinen-4-ol. Notable is the large amounts of terpinen-4-ol from entrance 8 during the last days (Figure 6B), which can be interpreted as microbial oxidation. The increased production of terpinen-4-ol from its possible precursor, limonene, during the end of the entrainment period, is shown in Figure 7A.

The average release of verbenone (Vn) probably has two maxima; even though No. 8 is predominantly responsible for the first one, Vn is released from most of the entrances. After the intervening decrease, Vn is released from all the galleries during the last days. This increased production of Vn compared with the beetle production of cV yields an increasing ratio between Vn and cV towards the end of the entrainment period (Figure 8B). The reason for this changed ratio is likely the conversion of cV to Vn (Leufvén et al., 1984) by microorganisms established in the gallery wall phloem (Leufvén and Birgersson, 1987).

Released Compounds and Attack Success. Bark beetles attacking a host tree that has not been taken seem to continue their production of aggregation pheromones as long as the tree defends itself by producing secondary resin. It is difficult to determine the attack phase of a male from only the patterns of released compounds from the entrance hole. In Figure 9, the amounts of α -pinene, MB, cV, and Vn trapped outside the galleries of one unmated male (Figure 9A) and three mated ones (Figure 9B-D) are shown. The only difference between the mated and the unmated males is the continually increasing amount of MB released from the unmated males (Figure 9A; cf., Nos. 3 and 7 in Figure 4B). General for all the attacks is the increasing amounts of Vn during the end of the entrainment period. However, the large variations between the studied males might be a result of the fact that the host tree was not taken by the attacking beetles.

Oxygenated compounds are released from the attacks on the first day. For the majority of these compounds, the increase was more pronounced towards the end of the seven-day entrainment period, when they are presumably produced by microorganisms established in the gallery wall phloem. However, this second, and larger, increase appears too late to play a role in the mechanism of tree-switching. It is known from field bioassays that SBB males avoid high concentrations of their own aggregation pheromone components, especially cV (Schlyter et al., 1987b). Probably the large amounts of aggregation pheromones, produced by the male bark beetles, and oxygenated monoterpenes, such as verbenone (Bakke, 1981; Schlyter et al., 1989), as well as possibly α -ter-

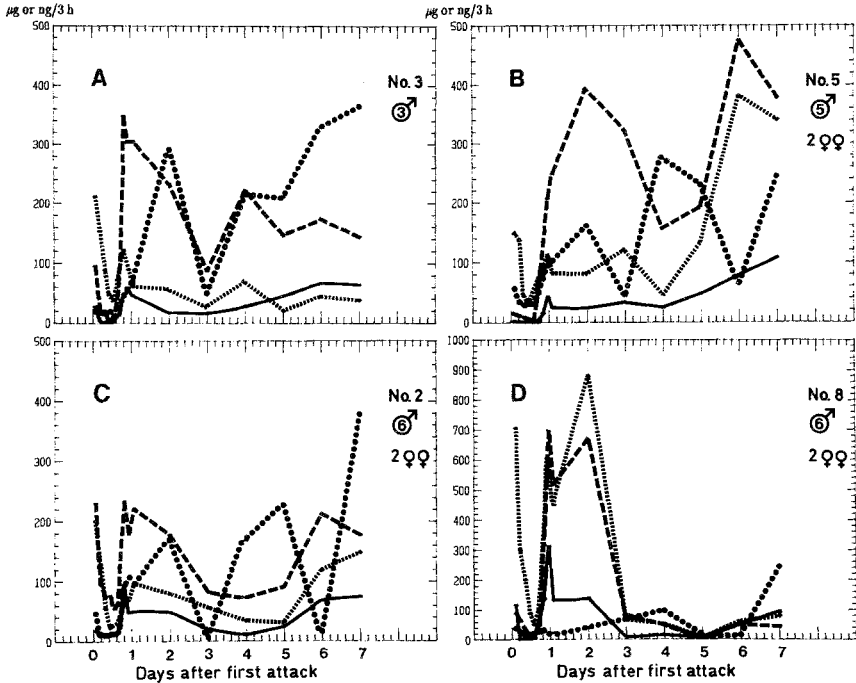

FIG. 9. Amounts of α -pinene (μg) ■■■■■■■■■■, *cis*-verbenol (ng) — — — — —, verbenone (ng) —————, and 2-methyl-3-buten-2-ol (ng/100) ● ● ● ● ● collected from individual entrance holes. pineol, terpinen-4-ol, *trans*-pinocarveol, and bornyl acetate, released during the first days of an attack will cause the males to both space out on the bole of the attacked spruce tree and participate in the tree-switching mechanism.

Acknowledgments—Thanks are due to Statskovvesendet in Gribskov, Esrum forest district and the University of Copenhagen, for access to the experimental area and use of the Strodan Ecological Station, Hillerød. We acknowledge Dr. Fredrik Björkling for the synthesis of deuterated methylbutenol. Ann-Britt Wassgren skillfully made all the capillary GC columns used in this study. We are indebted to Dr. Anders Leufvén, for his laborious preparation of Figure 1. We thank our colleagues, who made valuable comments on the manuscript, and in particular Dr. John A. Byers for also correcting the language. This study was performed with financial support from Swedish Research Councils (NFR, FRN, SJFR, and STU), within the project "Odour Signals for Control of Pest Insects."

Abstract—Catches of male *Panolis flammea* in traps baited with lures containing 25 μg of sex attractant are enhanced when in the proximity of traps baited with 125- μg lures. The degree of enhancement is increased as the intertrap distance is decreased, and when the low-dose trap is upwind of the high-dose one. The patterns of alteration in trap catch suggest that moths initially attracted by one lure may divert into other traps, which may be either upwind of the original trap (“overshooting”), or downwind (“undershooting”). “Overshooting” can result in up to fivefold increases in catch and may provide a useful method for estimating the attractant zone of particular lure/trap combinations.

Key Words—Pine beauty moth, *Panolis flammea*, Lepidoptera, Noctuidae, sex attractant, monitoring trap, chemoorientation, odor plume, trap interference.

INTRODUCTION

Traps, baited with synthetic pheromone lures, are increasingly being used as a survey method for many species of pest Lepidoptera. The relationships among trap catch, population parameters that refer directly to unit area, and subsequent

¹Current address: Department of Biology, Medical & Biological Sciences Building, Bassett Crescent East, University of Southampton, Southampton SO9 3TU, U.K.

insect damage are complex and can usually only be derived empirically, species by species and crop by crop. One of the factors that determines catch is the characteristic of the trap as a sampling device; i.e., the relationship between the local insect population and the probability of an individual insect being caught. This relationship can be split into a number of parts, including the attraction zone of the lure, the attraction and capture efficiencies, the ways in which lure release rates and micrometeorology affect these parameters, and the changing responsiveness of the insects themselves. Remarkably little is known about any of these factors, mainly because it is difficult to account for all of them simultaneously under field conditions.

Several attempts have been made to estimate the dimensions of the attraction zone. Direct observations of caged gypsy moths, *Lymantria dispar*, downwind of an artificial lure have yielded important information on both the distance and time course of effective stimulation of flight (Elkinton et al., 1984). Mark-recapture techniques have also been used (e.g., Elkinton and Cardé, 1980, 1981; Hartstack and Witz, 1981; Schwalbe, 1981; Ramaswamy et al., 1983). However, such experiments are expensive in biological material and cannot reliably estimate the effects of other parameters that affect recapture rates, such as dispersal independent of stimulation by pheromones, and any idiosyncrasies of released insects compared to the undisturbed wild population; the responsiveness of male moths to the female pheromone is notoriously susceptible to handling.

Traps laid out in regular rows or grids have been used to estimate attraction distances, based upon the degree of interference. Estimates for the attraction of codling moth *Cydia pomonella*, obtained in this way, have not tallied with one another (Reidl and Croft, 1974; McNally and Barnes, 1981), which indicates that some unidentified factor must have contributed to relative trap catches. Wall and Perry (1978, 1980) reported that, in lines of two or three traps parallel to the wind direction, baited with (*E, E*)-8,10-dodecadien-1-yl acetate, the upwind trap caught more pea moths *Cydia nigricana* than the average for the line, but the degree of difference was insensitive to intertrap spacings ranging from 25 to 200 m. The bias in favor of the upwind trap disappeared when the lure dose was reduced 100-fold (Wall and Perry, 1981). However, both these lure strengths were equally effective at catching males when deployed simultaneously (Greenway and Wall, 1981), which suggests that the higher dose may have been partially inhibitory at close range, enhancing the probability that moths would move from one trap to another in the multitraps experiments.

In these, and the more complex experiment of van der Kraan and van Deventer (1982), all of the traps were baited with identical doses. In this article we report our attempt to measure perturbations in catch in traps that are in the proximity of other traps baited with lures five times stronger. This arrangement should have two advantages over uniform doses. First, the degree of interfer-

ence should be assymmetric, i.e., the effect of high dose on low dose should be greater than vice versa. Therefore, it should be easier to assign interactions to a particular trap. Second, the lower dose can be chosen to have little attractant power of its own, and hence any increase in catch due to interference by the high dose trap should be easily measured.

The insect chosen was the pine beauty moth *Panolis flammea* (Denis & Schiffermuller) (Lepidoptera: Noctuidae), a pest of lodgepole pine (*Pinus contorta*) plantations. Monitoring traps for this species in Scotland and the north of England are placed in forest rides, which are long, narrow, straight clearings between densely planted areas of pine trees. The male moths normally approach the traps along the axis of the ride (Ellis and Bradshaw, unpublished), probably because the wind tends to be funneled in this direction. Thus traps can be set out in lines that are parallel to the predominant flight directions for most of the time, which simplifies the situation compared to that obtained in an open field and eliminates the need for traps to be realigned with every change of wind direction.

METHODS AND MATERIALS

Two experiments were carried out in consecutive years, in the Elchies block of Craigellachie Forest in Scotland. Large plastic delta traps with removable sticky inserts, 380 cm² in area (Wolfson Unit of Chemical Entomology, Southampton, U.K.), were baited with either 25 μ g or 125 μ g of (*Z*)-9-tetradecenyl acetate, with 10% (*Z*)-11-tetradecenyl acetate added, loaded on to red rubber sleeve stoppers (West Pharmarubber, St. Austell, U.K.). This lure, although not identical to the natural pheromone (Baker et al., 1982), is within the range of blends that are as effective at catching moths in traps (Bradshaw et al., 1983a; Priesner and Schroth, 1983). The doses chosen are well within a regular and positive dose-response relationship for this species, and the 25- μ g lure catches less than 10 moths per night even from economically damaging populations (Bradshaw et al., 1983b). Traps were deployed on posts approximately 1.5 m from soil level, equidistant from the sides of the rides, and with their open ends facing along the ride axis. Each ride selected contained a line of three traps, a single central high-dose (125 μ g) trap flanked by two low-dose (25 μ g) traps (see Figure 1).

In experiment 1, forty such lines of traps were deployed at intertrap spacings of 1, 5, 20, 50, and 100 m. Treatments were allocated to particular rides so as to balance out different compass orientations and the population densities as estimated by pupal surveys in the previous autumn (Holden and Bevan, 1979). The first trap in each line was placed 10 m from the ride end (usually a junction with other rides). Traps were set out between March 15 and 19, before the main

flight period, and sticky inserts were removed for counting and replacement on April 3–4 and April 13–14, and final removal on May 19–20. Catches in the first period exceeded 50 in many traps; since the efficiency of the traps declines above 50 (Bradshaw et al., 1983b; Bradshaw and Ellis, unpublished), the results for this period were excluded. No single trap catch exceeded 50 in the second and third periods.

In experiment 2, three pairs of adjacent east–west rides were selected. Two lines, one of 5 m spacing, and one of 50 m spacing, were assigned at random to each pair of sites. All traps were at least 100 m from any junction between rides. The traps were set out on March 27, and catches were recorded daily until April 19. Most of the catches occurred on six nights when the wind in a seventh parallel ride was recorded as predominantly from the west, during the flight period (1700–1900 hr GMT); on the other nights the wind was predominantly easterly, and temperatures were below the flight threshold. Analysis was performed on the total catches for each trap for these six nights only.

RESULTS

Experiment 1. The total catches from each of the treatments exhibited quite a large range (Table 1), suggesting that the assignment of population densities to sites was imperfect. However, analysis of variance (ANOVA) indicates the overwhelming influence of trap spacing on catch in the low dose traps ($F = 8.98$, $df = 4$, $P < 0.0001$). No significant ($P < 0.10$) effect was found for low-dose trap position (i.e., first or third from the start of the ride). To correct for site-to-site differences in total trap catch, high/(mean low) ratios were calculated for each site (Table 1). These ratios were log-transformed to minimize dependence of the treatment variances on the means. Nested ANOVA on these ratios indicates that the most powerful effect is from spacing ($F = 9.13$, $df = 4$, $P < 0.0001$). The value of the ratio increases with distance up to 50 m, while at 100 m it declines slightly (Table 1). This can be interpreted in terms of an increasing proportion of the moths that are initially attracted by the high-dose trap being caught by the flanking low-dose traps as the distance between traps is decreased from 50 m.

Experiment 2. The first experiment gave no indication as to the mechanism whereby the low-dose trap catch was enhanced by proximity to a high-dose trap. Catches for nights with westerly winds in the second experiment indicate that upwind low-dose traps caught considerably more moths than downwind low-dose traps (Table 2). This effect was more pronounced for the 5-m spacing (as expected from the results of the previous experiment), and ANOVA on the low-dose catches indicates significant effects for both spacing and orientation to the

TABLE 1. MEAN CATCHES OF MALE *Panolis flammea* IN LINES OF THREE TRAPS (EXPERIMENT 1)^a

Spacing (m)	N	Mean trap catch				Mean log (high catch/mean low catch)
		Low 1	High	Low 2	Total	
1	8	7.3	15.1	6.4	28.7	0.322a
5	8	3.4	11.9	2.8	18.1	0.569ab
20	8	3.2	23.8	3.9	30.8	0.861c

100	8	2.3	16.0	2.4	20.6	0.857bc

^aHigh/mean low ratios were calculated for individual sites and catching periods, and converted to \log_{10} before calculating means. Ratios followed by the same letter are not significantly different by Duncan's new multiple-range test at $P = 0.05$.

TABLE 2. MEAN CATCHES OF MALE *P. flammea* IN GROUPS OF THREE TRAPS AT 5 m AND 50 m SPACINGS (3 REPLICATES EACH, SIX NIGHTS WITH WESTERLY WINDS)^a

Spacing (m)	Mean trap catch				Mean log (high catch/mean low catch)
	Low (upwind)	High	Low (downwind)	Total	
5	14.7a	24.3	4.7b	43.7	0.401
50	3.0bc	29.7	1.3c	34.0	1.238

^aLow-dose trap catches followed by the same letters are not significantly different by Duncan's new multiple-range test at $P = 0.05$.

wind (Table 2). Catches in both upwind and downwind low-dose traps at 5 m were enhanced compared with those at 50 m. The mean high/(mean low) ratios were numerically similar to those obtained for the same spacings in Experiment 1, suggesting that the same mechanism for enhancement of the low-dose traps was in operation for the two years.

DISCUSSION

Interpretation of these complex interaction effects is simplified if it is assumed that, in experiment 2, the low-dose traps that are 50 m upwind of a high-dose trap are the least affected by the proximity of other traps. That this

FIG. 1. Diagram showing the relative positions of traps at 50-m spacing in experiment 2 and their inferred attraction zones, with wind blowing from left to right. The trap containing the high-dose lure ($125 \mu\text{g}$) is shown as a solid square, those containing low doses ($25 \mu\text{g}$) by open squares. The borders of the ride are shown shaded.

is likely is illustrated in Figure 1. The catch in the other low dose traps can be interpreted as follows:

Upwind Trap at 5 m. The catch is considerably enhanced by its proximity to the high-dose trap, probably because many moths, originally attracted towards the high-dose trap, overshoot and proceed the short distance upwind to be caught by the low-dose trap.

Downwind Trap at 50 m. The small (just nonsignificant) depletion of catch compared to the upwind trap at 50 m can be explained by the same mechanism; some moths attracted towards the downwind low-dose trap overshoot and proceed upwind towards the high dose one.

Downwind Trap at 5 m. There is apparently a balance between overshooting (depleting catch) and additional recruitment of moths due to the proximity of the high-dose lure (i.e., undershooting).

This interpretation is at least qualitatively supported by observations of the behavior of *P. flammea* (Bradshaw and Ellis, unpublished), which is similar to that of many other noctuids (e.g., *Spodoptera littoralis*; Murlis and Bettany, 1977). Males accidentally flying past a pheromone source during their upwind approach frequently cast back downwind to relocate the pheromone plume. In the experiments described here, however, after overshooting, the male may find itself within the interference zone of another trap upwind, provided that trap is sufficiently close, and will then tend to proceed upwind, increasing the catch in the upwind trap and decreasing the catch in the trap that the moth originally approached. There may also be a contribution from "plume-switching" away from the vicinity of the traps.

The data from experiment 1 (Table 1) are consistent with this interpretation. The high/mean low ratio is a composite function of effects on all three traps, but is predominantly due to the probability of moths that overshoot the high-dose trap being attracted on to the upwind low-dose trap. At some intertrap

distance greater than 5 m, but almost certainly less than 50 m, the probability of this occurring becomes negligible. At this distance there is still a significant probability that moths overshooting the downwind trap will still be attracted to the high-dose trap, but at some greater distance all three traps should become independent. This will cause the high/(mean low) ratio to fall again, and this is possibly observed at the 100-m spacings.

This mechanism is similar to that proposed by Lundberg and Lofstedt (1987) to model competition between "calling" females; they also demonstrated, in wind-tunnel experiments, that a low-dose lure 1 m upwind of a high-dose lure could successfully attract males of *Yponomeuta cagnagellus*. Wall and Perry (1978, 1987) and Perry and Wall (1984a,b) proposed similar mechanisms to account for enhanced catches of *C. nigricana* in upwind traps containing identical high doses to downwind traps. We have here demonstrated the same effect for lure doses that fall within an increasing dose-response relationship and may therefore more naturally mimic the calling female. The asymmetric arrangement of lure doses has made the effect more obvious and provides a useful method for determining the interference distance of a particular lure. For *P. flammea*, this method gives an estimate of between 5 and 50 m, and probably in the lower part of this range, for the effective interference distance of a 25- μ g lure under the conditions of the experiments described. Since this distance is likely to be affected both by wind strength and local topography (Perry and Wall, 1984a), it may vary with location, but should be useful in interpreting catches in standard (25 or 5 μ g baited) monitoring traps for this species.

The relationship between the interference distance (i.e. attraction from just upwind of a higher-dose lure) and the attraction distance (i.e. attraction in the absence of other synthetic lures) remains to be established. They need not be identical; the behavior of a moth when it overshoots a high-dose lure may differ from its appetitive flight behavior (Elkinton and Cardé, 1983; Sabelis and Schippers, 1984) or flight which has not been stimulated so recently by high concentrations of pheromone.

These experiments also indicate that trap spacing will have a profound effect on the dose-trap-catch relationships obtained for this (Bradshaw et al., 1983b) and presumably many other species, when traps containing different doses have been sufficiently close for interference to occur (e.g., Chisholm et al., 1979; Flint et al., 1978; Heath and Landolt, 1987; Kraemer et al., 1979, 1983; McNally and Barnes, 1980; Olaifa et al., 1984; Roelofs et al., 1977, 1982; Turgeon et al., 1983; Vick et al., 1979; Yonce et al., 1976). In particular, the slopes of the lines obtained may need reevaluating, in view of the fivefold difference in catch ratio for the same pair of doses, as reported here. There may also be effects on trials designed to evaluate optimum blends of pheromone components where the traps are placed within their mutual interference distances.

(Received March 4, 1988; accepted January 9, 1989)

Abstract—The GC-MS and GC-EAD analyses of sex-gland components and sex-gland-released volatiles have identified (*E*)- and (*Z*)-11-tetradecenal (90:10) and (*E*)- and (*Z*)-11-tetradecenyl acetate (85:15) as components of the sex pheromone chemical communication system of *Croesia curvalana* (Kearfott). The aldehyde-to-acetate ratio of 9:1 was found in the gland-released components. This blend at a 0.1–1 µg/day release rate from PVC lures was shown to be as effective as virgin females in the trapping of male *C. curvalana*.

Key Words—Lepidoptera, Tortricidae, *Croesia curvalana*, blueberry leaftier moth, sex pheromone components, (*E*)-11-tetradecenal, (*Z*)-11-tetradecenal, (*E*)-11-tetradecenyl acetate, (*Z*)-11-tetradecenyl acetate.

INTRODUCTION

Croesia curvalana is a destructive pest of low-bush blueberry crops in north-eastern North America (Morris, 1981). Eggs hatch in early spring (Ponder and Seabrook, 1988), and newly emerged larvae burrow into the protective flower buds making insecticide control difficult. Identification of the pheromone system of the adult moth may have potential for management of this species.

Aldehydes and acetates have been found to be attractants and primary pheromone components in the sex pheromone systems of the subfamily Tortricinae,

which includes *Croesia* and *Choristoneura* (Booij and Voerman, 1985; Ando et al., 1981; Grant et al., 1981; Inscoe, 1982). However, the chemical identification of sex pheromone components in the *Croesia* sp. has not been reported to date.

In the course of conducting trapping studies with *Choristoneura fumiferana* (spruce budworm), it was observed that *C. curvalana* males were attracted to traps baited with virgin *C. fumiferana* females, which release a blend of (*E*)-11-tetradecenal, (*Z*)-11-tetradecenal, tetradecanal, and (*E*)- and-(*Z*)-11-tetradecenyl acetate (95:5) in a ratio of 95:5:2:0.2, respectively (Silk et al., 1980). This indicated the possibility that the pheromone systems of these two species contained similar pheromone components.

Identification of the major and some minor pheromone components has been accomplished by GC-EAD and GC-MS analysis of the female sex gland constituents as well as gland-released volatiles. The structural assignments are supported by field-trapping studies.

METHODS AND MATERIALS

Insects. *C. curvalana* pupae were collected from the field, separated by sex, and incubated under a 17:7 light-dark cycle at $21 \pm 2^\circ\text{C}$, and 70% relative humidity until emergence. Adult moths were maintained under similar environmental conditions.

C. fumiferana were obtained as second-instar larvae from Great Lakes Forestry Research Laboratory, Saulte Ste. Marie, Ontario, and were maintained on the above environmental regime throughout the larval, pupal, and adult stages.

Choristoneura pinus pinus (Jack pine budworm) adults were field collected in central New Brunswick in late July.

Chemicals. Compounds employed as analogs and reference standards were synthesized using established procedures (Loneragan, 1986) and include the following: (*E*)-12-tetradecenyl acetate (*E*12-14:Ac), (*E*)-11-tetradecenyl acetate (*E*11-14:Ac), (*Z*)-11-tetradecenyl acetate (*Z*11-14:Ac), (*E*)-9-tetradecenyl acetate (*E*14:Ac), (*Z*)-9-tetradecenyl acetate (*Z*9-14:Ac), (*E*)-5-tetradecenyl acetate (*E*5-14:Ac), (*Z*)-5-tetradecenyl acetate (*Z*5-14:Ac), tetradecanyl acetate (14:Ac), 13-tetradecenal (Δ 13-14:Ald), (*E*)-12-tetradecenal (*E*12-14:Ald), (*E*)-11-tetradecenal (*E*11-14:Ald), (*Z*)-11-tetradecenal (*Z*11-14:Ald), (*E*)-9-tetradecenal (*E*9-14:Ald), (*Z*)-9-tetradecenal (*Z*9-14:Ald), (*E*)-7-tetradecenal (*E*7-14:Alc), (*Z*)-7-tetradecenal (*Z*7-14:Ald), tetradecanal (14:Ald), and (*E*)-11-tetradecenol (*E*11-14:OH). Sample purity was greater than 95% with geometrical isomer purity greater than 99% (Houx et al., 1974), as determined by gas chromatography (GC) and gas chromatography-mass spectrometry (GC-MS) techniques.

Compounds used for the field studies were formulated in polyvinyl chloride (PVC) lures at 0.03% active ingredient (Fitzgerald, 1973; Sanders, 1981). The 1 × 0.4-cm PVC lures were aged under field conditions for two weeks, placed in Pherocon 1C traps (Zoecon Corp., Palo Alto., California) and set out in the field experiments.

Effluvia Collection. A slightly modified version of Baker's single-insect-effluvia collection technique was employed for the collection of sex-gland-released volatiles (Baker et al., 1981). The abdominal-gland portion of the female moth was ligated at the second segment, severed, and placed in a constricted, open-ended tube (Eppendorf disposable pipet tube). The gland was extruded by applying gentle pressure with a small glass rod. Four of these gland preparations were placed in the glass collection device, and nitrogen gas (HP grade passed through 4 Å molecular sieve and activated charcoal) was passed over the extruded glands at a flow of approximately 1 ml/min for a 2-hr period during the first 2 hr of the scotophase (period of peak female attractiveness to males; Ponder and Seabrook, 1988). The released volatiles were adsorbed onto two small, precleaned, glass wool filters connected in series. At the end of the collection period, the walls of the collector and the glass wool filters were washed with 2 ml of purified hexane. The collected material was stored in hexane at -20°C until analysis.

Gland Extraction. Fresh glands were severed, homogenized, stored in hexane at 4°C for 48 hr, filtered, and the hexane-soluble material stored at -20°C until analysis.

Instrumentation. GC analyses were performed on a Varian 6000 instrument equipped with a flame ionization detector (FID) and a split/splitless injector. Helium was used as the carrier gas. SPB-5 (30 m, 0.32 mm ID, 0.2 µm film), SP-2340 (60 m, 0.24 mm ID, 0.2 µm film), and SP-2330 (30 m, 0.32 mm ID, 0.2 µm film) capillary columns were employed.

GC-MS analysis was performed on a Finnigan 4021 EI-CI-INCOS system. Helium was used as the carrier gas. An SP-2330 column was utilized; temperature program was 50°C to 200°C at 15°C/min and 0.85 kg/cm pressure. Injections were made in the splitless mode. The EI mass spectra were generated at 70 eV.

GC-EAD Analysis. The sex pheromone gland extracts and volatiles were analyzed by the gas chromatography-electroantennogram detector (GC-EAD) technique (Struble and Arn, 1984), a procedure combining gas chromatography with FID detection and electroantennogram detection (EAD). A modified method (Kuenen, unpublished) was employed in which the effluent from the GC capillary column was split equally and delivered simultaneously to the FID and antennal detectors. The antenna was positioned between the tips of two glass capillaries containing saline solution (Roelofs, 1984) and chloridized silver wire electrodes that were connected to a 10× DC amplifier. The GC effluent

exited into an air stream (flow approx. 50 ml/min, approx. 100% relative humidity) passing over the antennal preparation. The antennal and FID responses were recorded in synchrony on a Honeywell dual-channel chart recorder.

Responses to gland extracts and gland volatiles were recorded from *C. curvalana* antennae to determine electrophysiologically active components. In addition, *C. fumiferana* and *C. pinus pinus* antennal detectors were used to estimate isomer ratios and to corroborate structural assignments of the two major EAD active components.

Field Studies. Tests were conducted at Blackville, New Brunswick, using Pherocon 1C traps baited with lures releasing test compounds. These compounds singly or in combinations were incorporated into PVC lures at concentrations designed to produce release rates of approximately 0.1 to 1 $\mu\text{g}/\text{day}$ (Sanders, 1981).

Traps baited with virgins had two 0- to 24-hr-old females placed in a 5 \times 3-cm screened cage made from clear plastic pill vials. All lures were placed on bottoms of traps. The light-dark rearing cycle of females used as baits was synchronous with field conditions. Female baits were replaced every 48 hr, and PVC lures were renewed after two weeks in all tests. Traps were spaced 30 m apart at a height of approximately 40 cm such that trap bottoms were at the blueberry canopy level. Initial positioning of traps was randomized. Trap captures were counted every 24 or 48 hr, depending on the experiment, and the traps were moved forward by one position at this time. The trap bottoms were changed every five days or when more than 20 moths were present.

Test 1. In 1981, E11-14:Ald, Z11-14:Ald, E- and Z11-14:Ac (95:5) and 14:Ald were tested singly and in combinations in arrays that included traps baited with two virgin *C. curvalana* and two virgin *C. fumiferana* females. This experiment was replicated in four fields separated by at least 100 m and monitored throughout a 26-day flight period. The data were analyzed using the Tukey multiple comparison test (Zar, 1984).

Test 2. In 1982, attractancy studies were carried out to determine the optimum E:Z ratio of the Δ 11-14:Alds and to ascertain the effect of the addition of varying amounts of 11-14:Ac on these blend ratios. Four blends of E and Z11-14:Ald (95:5, 90:10, 85:15, and 80:20) were tested alone and with the addition of 0.2 and 2% E- and Z11-14:Ac (95:5). The trapping test was run, at one site only, for 22 days.

Test 3. In 1984, field studies were conducted in which the two most attractive E:Z aldehyde ratio blends of the 1982 study were repeated but with the addition of a wider concentration range of the 11-14:Ac components. This test was run for 14 days during the height of the flight season. The data from tests 2 and 3 were subjected to analysis using nonparametric two-way ANOVA (Zar, 1984).

RESULTS AND DISCUSSION

GC-EAD Analysis. GC-EAD analysis of a portion of the hexane gland extract as well as the hexane-soluble gland-released volatiles showed the presence of a number of electrophysiologically active components. The two most active compounds displayed retention times identical to those of *E*11-14:Ald and *E*11-14:Ac (Table 1). Since the SP-2340 column provides separation of *E* and *Z* isomers by at least 0.3 min under the conditions employed, the major components are assigned the *E* configuration. However, additional antennal responses were elicited by components with retention times corresponding to *Z*11-14:Ald and *Z*11-14:Ac. Employing *C. curvalana* antennal detectors, the comparison of the EAD response produced by 11-14:Ald in the gland extract with the responses to synthetic standards of known ratios suggested that the *E*:*Z* ratio of the active aldehyde components was approximately 85:15. The ratio of Δ 11-14:Alds to Δ 11-14:Ac in the gland was estimated to be 1:1 based on the comparison of gland-extract-induced antennal responses with GC-EAD responses to standards of known concentrations and ratios. Extrapolation of the EAD dose-response data leads to the estimate of 60-90 pg of *E*- and *Z*11-14:Ald (85:15) and 60-120 pg of Δ 11-14:Ac present in each female sex gland (3-4 days of age) (Table 2).

In addition to the detection of the above unsaturated aldehydes and acetates, the GC-EAD study indicated the presence of an electrophysiologically active gland component at a retention time corresponding to the saturated aldehyde, tetradecanal (Table 1). The amplitude of the antennal response generated by this compound, when compared with that of synthetic 14:Ald, indicated its concentration in the gland to be roughly equivalent to that of the unsaturated aldehyde, *E*11-14:Ald (60-90 pg; Table 2).

Similarly, GC-EAD analysis of the effluvia also detected the presence of Δ 11-14:Alds and Δ 11-14:Ac. However, an aldehydes-to-acetates ratio of 9:1 was found in the effluvia as opposed to the 1:1 ratio in the gland. Also the *E*:*Z* ratio of the Δ 11-14:Alds was estimated to be 90:10, contrasting with the 85:15 ratio in the gland. The release rate of the major effluvial compound *E*11-14:Ald was estimated to be approximately 30 pg/hr/female (Table 2). GC-EAD confirmation of the presence of 14:Ald in the effluvia was inconclusive. A response was generated at the correct retention time in one effluvial sample but not in two others.

Investigation of gland effluvial components employing *C. fumiferana* and *C. pinus pinus* antennal detectors supported the structural assignments. The primary pheromone components of *C. fumiferana* are *E*- and *Z*11-14:Ald (95:5) (Silk et al., 1980; Sanders and Weatherston, 1976), while those of *C. pinus pinus* are *E*- and *Z*11-14:Ac (85:15) (Silk et al., 1985). The presence of Δ 11-14:Ac in the gland extract and effluvia was detected by *C. pinus pinus* antennae

TABLE 1. GC RETENTION TIMES OF SEX-GLAND-DERIVED MATERIAL MEASURED WITH FID AND EAD

GC column/ standards	Standards Retention (min) ^a	Gland extract retention (isomer ratio) ^b [Ald to Ac ratio] ^c	Effluvia retention (isomer ratio) [Ald to Ac ratio]	Antennal detector (sensitivity for)

Z11-14:Ac	18.65			

^a Retention times of standards were first determined by flame ionization detection.

^b Ratio of double bond geometrical isomers (*E*:*Z*) was estimated by comparison of EAD responses of biological samples with synthetic samples of known *E*:*Z* ratios.

^c Component ratios were estimated by comparison of EAD responses of biological samples with synthetic samples of known blends of aldehydes and acetates and by GC-MS analysis.

^d Temperature program: 50°C (0.5 min) to 200°C at 10°/min; head pressure 1.5 kg/cm².

^e Temperature program: 50°C (0.5 min) to 170°C at 25°/min; head pressure 1 kg/cm².

^f Temperature program: 50°C (0.5 min) to 200°C at 10/min; head pressure 1.5 kg/cm².

(Table 1). The determination of the 85:15 *E*:*Z* ratio of the Δ 11-14:Ac found both in the gland and the effluvia was primarily based on the responses of the *C. pinus pinus* antennae. The *C. curvalana* antennae were not sufficiently responsive to the acetate component to provide quantitative discrimination of the *E* and *Z* acetate isomers.

were obtained (Table 3). In the case of the gland extract, a full mass spectrum of 14: Ald was produced (*M*⁺212). Although lacking definitive molecular ions, characteristic mass ion fragments were found for *E*11-14: Ald and *E*11-14: Ac at 192 (*M* - 18) and 194 (*M* - 60), respectively. Analysis of the effluvia sample provided a partial spectrum, displaying a low mass fragmentation pattern similar to that of *E*11-14: Ald, at the correct retention time.

Test 1. Mean daily trap capture of male *C. curvalana* in traps baited with two virgin *C. curvalana* females, two virgin *C. fumiferana* females, and PVC lures releasing *E*11-14: Ald, *Z*11-14: Ald, 14: Ald, and *E* and *Z*11-14: Ac (95:5) are given in Table 4. The results of this study indicate that the four-component blend of *E*11-14: Ald, *Z*11-14: Ald, and *E*- and *Z*11-14: Ac (95:5)

^aPVC release rate = 0.1-1.0 μ g/day of 11-14:Ald.

^b Δ 11-14:Acs (*E*:Z, 95:5).

was equivalent in trapping activity to two virgin *C. curvalana* females. Caution should be exercised when making direct comparisons between trap capture by live virgin females and PVC lures because of the effect of environmental factors (Sanders and Lucuik, 1972; Sanders, 1981). Later studies have indicated that female *C. curvalana* virgins mate in the laboratory at 1-3 days of age (Ponder and Seabrook, 1988). Virgin *C. curvalana* females of more advanced age might have resulted in increased trap captures. It is interesting to note the apparent ability of 14:Ald to trap male *C. curvalana* when presented alone, although it contributed nothing to trap capture when present in other component combinations, with the possible exception of its addition to 11-14:Ac.

Test 2. The 1982 study (Table 5) demonstrated that the blend *E*11-14:Ald, Z11-14:Ald, Δ 11-14:Acs (90:10:2) was the most effective trapping combination at the 0.1- to 1- μ g/day release rate. As the concentration of the Δ 11-14:Acs in the blend was increased, the activity differential between the *E* and Z11-14:Ald ratios decreased. This indicated the upper limit of the activity threshold for Δ 11-14:Ac may not have been reached.

Test 3. In the 1984 study (Table 6) the two most effective *E*:Z blends of Δ 11-14:Ald from 1982 were again tested alone and with quantities of Δ 11-14:Ac ranging from 0% to 40%. The highest moth catches were obtained with the 2% acetate blend. The results of the 1982 and 1984 tests clearly show that,

within any given acetate level, the *E*:*Z* aldehyde ratio of 90:10 was the more attractive blend and that the optimum loading quantity of Δ 11-14:Ac is between 2% and 10% of the total blend (nonparametric two-way ANOVA; *P* (0.001).

CONCLUSION

The sex pheromone components (*E*)- and (*Z*)-11-tetradecenal (90:10) and (*E*)- and (*Z*)-11-tetradecenyl acetate (85:15), have been identified for *Croesia curvalana*. These compounds have been found in the sex-gland-released volatiles and were shown to be electrophysiologically active. In addition, they were formulated in PVC lures and were observed to be as effective as virgin *C. curvalana* females in trapping studies.

The aldehyde-to-acetate ratio in the sex gland was found to be approximately 1:1, while that of the effluvia was 9:1. This is not unprecedented. In *C. fumiferana* for example, there are large quantities of *E*- and Z11-14:Ac

(95:5) present in the female sex gland and only small quantities of *E*- and Z11-14:Ald (95:5). The reverse is true for the effluvia in which the aldehyde is the major component and the acetate (not designated as a pheromone component) is found in only minor amounts (Silk et al., 1980).

Although tetradecanal was shown to be an EAD-active gland component, its presence in the effluvia was not established. The attractancy of the PVC lures was not affected by its presence or absence. The possibility that tetradecanal is a pheromone component cannot be ruled out at this time.

This work represents the first isolation and identification of pheromone components of a *Croesia* sp. It is unknown whether the components identified here represent the complete pheromone blend of this species. The sex gland extract produced a number of very weak EAD responses in addition to those produced by the components identified in this study. A means for obtaining large numbers of females is required before a search for additional pheromone components can begin; approximately 40 female moths were available for the present study.

Acknowledgments—We wish to thank the research group of Dr. Peter Silk, Research and Productivity Council of New Brunswick, for constructive suggestions on several aspects of this work. Financial support from Agriculture Canada and the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged.

Book Review

Invertebrate-Microbial Interactions: Ingested Fungal Enzymes in Arthropod Biology

M.M. Martin. (1987). Series: Explorations in Chemical Ecology. T. Eisner and J. Meinwald (eds.).

Ithaca and London: Comstock Publishing Associates, 1987. Cloth \$32.50, Paper \$14.95.

In this series, the editors state two objectives, first to bring "the molecular dimension to our understanding of biological relationships, the relationships between animal and plant, the multicellular and unicellular, social and nonsocial, and kin and non-kin." Second, their "purpose is not only to summarize what they have learned but to convey a feeling for what it is like to venture into an unknown area of promise." In Professor Michael Martin, they have found just the author to accomplish their aims.

Invertebrate-Microbial Interactions is too broad a title for this book; its real subject is encapsulated in the subtitle *Ingested Fungal Enzymes in Arthropod Biology*, and the author's summary of his thesis is "I propose that the augmentation of digestive capacity through the ingestion of active fungal or bacterial enzymes may be widespread among invertebrates."

The author demonstrated this thesis in 1978 when he and his wife showed that the fungus-growing termite *Macrotermes natalensis* acquires fungal enzymes from *Termitomyces*, the mutualistic fungus it cultivates, by eating nodules. These cellulolytic enzymes are utilized in the midgut to digest cellulose in the wood the termites eat. In the same year, Abo-Khatuo published an account of a similar process in the related termite *M. subhyalinus*, indicating that the time was ripe for this concept. Subsequently, Martin and his coworkers have gone on to demonstrate sequestered enzymes in the siricid woodwasp *Sirex cyaneus*, and in several cerambycid beetles. They have so far failed to establish their importance in detritivores such as tipulid larvae and woodlice where one might have expected a suite of microbial enzymes to be particularly valuable in the digestion of the more recalcitrant compounds that remain in dead leaves and wood once they are cast off by the plant.

Perhaps the most curious case is the symbiotic relationship between the fungus-growing attine ants, and their symbiotic basidiomycete. Here it appears

that enzymes ingested by the ants (but from exactly what part of the fungus has not been rigorously established) pass right through the gut, where they seem to be unimportant in the ants' digestive process, and emerge in the feces. This was the work in the late sixties and early seventies that stimulated the author's interest in the use of microbial enzymes by arthropods, and yet the explanation seems intuitively to be the least satisfactory. Martin claims that "the feeding and defecation behavior of the workers can be viewed as a mechanism that has replaced the process of enzyme secretion by the fungus." In short, the ants feed on mature fungus garden portions, but defecate in areas where the fungus is just being established, so enhancing the competitive ability and fitness of the fungus. Other workers (Powell, R. J., 1984 *The influence of substrate quality on fungus cultivation by some attine ants*. Ph.D. Thesis, University of Exeter, U.K.) have, however, shown that the fungus is capable of secreting enzymes into its substrate, and it is not clear why other competitive fungi should not find a predigested substrate just as good for rapid growth as the ant fungus itself. It is mysteries like these that make this subject so fascinating and this book such a challenging read.

However, the book is not only an excellent technical account of a specialized area of modern biology, it is a record of a scientist's professional career, what motivated him to take up certain research themes, and how he set about the task. This in its own way is as interesting as the findings and is very frank. It is written in a highly personal way: "I undertook the research . . . with an undisguised preconception about how it would turn out . . . I had convinced myself that the termites were using their fungal symbiont as a source of digestive enzymes . . .," and is a clear demonstration of the quiet revolution that has occurred in the way science is reported (if not necessarily in the way it is conducted). Gone is the use of the passive, impersonal grammar we were instructed to use as students; gone the tenets of the inductivist interpretation of scientific method, where a dispassionate objective scientist observes large numbers of singular examples of biological phenomena, before inducing cautious generalizations that he tests and discards or gradually enlarges to encompass more phenomena. Here we have Popper's falsificationism unashamedly triumphant. "I have been upbraided repeatedly by co-workers, colleagues, students and reviewers for making statements about the general importance of ingested enzymes to arthropod nutrition that are not justified by the comparatively small number of species in which the phenomenon has been rigorously established. I must acknowledge the validity of these criticisms, but am still unable to restrain myself."

Here we catch a glimpse of the genuine scientist with a "bee in his bonnet." I shall use this book with undergraduate students, not only for its technical information and its honest account of the way a research program actually develops, but as a stimulus for seminars on how we should present science and

the extent to which the personalization of issues now so much a feature of political discussion should be allowed to spread to science. At times, my editorial pen twitched convulsively.

OPTIMAL SEARCH DIRECTION FOR AN ANIMAL FLYING OR SWIMMING IN A WIND OR CURRENT

DAVID B. DUSENBERY

*School of Applied Biology
Georgia Institute of Technology
Atlanta, Georgia 30332*

(Received July 14, 1988; accepted January 3, 1989)

Abstract—The problem of the optimal direction in which a flying or swimming animal should search for a chemical plume was addressed. Active spaces were approximated by sphere, prolate ellipsoids, or rectangular parallelepipeds of various length-to-width ratios. The optimum course direction for the sphere was in the direction of flow (downwind). For active spaces that were highly elongated along the direction of the wind or current, the optimal course heading (with respect to the moving medium) was nearly across the flow. For intermediate shapes, the optimal course was intermediate. Because of the effect of the moving medium, these course headings resulted in actual ground tracks that were more in the direction of the flow, depending on the relative speeds of flying (swimming) and the wind (current). When the two speeds were equal, the magnitude of the advantage of choosing the optimum direction over a random direction was close to 50% with a small dependence on the shape of the active space. If the active space was spherical or highly elongated or locomotor speed was much greater than the speed of the current, the advantage approached a factor of $\pi/2$ (≈ 1.57).

Key Words—Search, crosswind, crosscurrent, odor, plume, active space, apparenacy, pheromone.

INTRODUCTION

It has often been asserted that the optimum strategy for an animal searching for a chemical plume is to move across the wind (or current) carrying the plume (e.g., Janzen, 1984). This seems plausible, since a plume has a larger cross section to movement across the wind than parallel to it; undoubtedly this strategy is optimal for animals walking on a substrate in certain circumstances.

However, Sabelis and Schippers (1984) have shown that fluctuations in wind direction can make crosswind searching the least effective direction. Another situation in which crosswind searching is a questionable strategy is for animals flying or swimming in the medium that carries the plume, because they can move faster downwind than crosswind. More specifically one might ask if it is the course heading with respect to the medium that is aimed across the wind or the actual track resulting from the combined effects of wind and locomotion. Another question of interest is how much this matters. How much difference is there on the average between the optimal direction and a randomly chosen direction? This article addresses these questions using simple geometrical shapes for the active space of the plume. Terms will be used that are appropriate for an animal flying in wind to an airborne plume, but the ideas and results apply equally to an animal swimming in a current of water to a waterborne plume.

METHODS AND MATERIALS

The basic assumptions were that the target of the search is stationary with respect to a substrate and the wind is measured with respect to the same substrate, with speed v_w . The animal making the search was assumed to fly at a constant speed with respect to the air, v_a (airspeed), in a straight line with a course heading in any chosen direction, θ , measured from the downwind direction. As a consequence of the wind, in general, the actual track of movement with respect to the substrate has a different direction and speed, v_g (ground speed). In order to detect the target, the searcher must move within a certain volume surrounding the target. This volume is called the active space (Wilson, 1970).

A detailed theory has been worked out for searching for ships at sea (Koopman, 1980). This theory was modified to apply to three dimensions for the problems at hand. Assume identical targets are distributed at random with density, ρ . Each target has a cross-sectional area, σ , perpendicular to the movement of the searcher. The searcher moves with velocity, v_g , in a straight line for a time, t . The advantage of searching in a straight line is discussed elsewhere (Pline and Dusenbery, 1987; Dusenbery, 1989). The probability of finding at least one target is

$$p = 1 - \exp(-\rho\sigma v_g t)$$

The cross section, σ , can represent the cross-sectional area of the active space of a chemical plume around the target or the space defined by the range of detection around the searcher for other types of stimuli. In either case, $S = \sigma v_g t$ is the volume searched. It can be thought of as the volume around the search track in which a target must be located for detection to occur. Search efficiency

is maximized by maximizing the search volume per unit time, $S/t = \sigma v_g$. Thus, the effective search rate is simply the product of the velocity of the searcher with respect to the target times the appropriate cross section. This formulation is consistent with that of Nicholson and Bailey (1935), who treated the effects of searching efficiency of populations on competition. Here we are considering the searching efficiency of individuals—a problem they did not address.

There exists little solid information on the actual shape of chemical plumes under natural conditions because of the ubiquitous occurrence of turbulence in both air and water for size scales relevant to all but microorganisms (Elkinton and Cardé, 1984; Tolmazin, 1985; Murlis, 1986). Consequently, the analysis concentrated on active space shapes that are amenable to mathematical analysis—rectangular parallelepipeds and prolate ellipsoids. Comparison of different shapes was made for active spaces of equal volume.

Spheres. The sphere has the same cross section in all directions, and the volume searched per unit time (search rate) is simply this cross-sectional area times the ground speed. Consequently, the effect of course direction is only to alter the ground speed. For a sphere of radius r , the search rate is

$$S/t = \pi r^2(v_w^2 + v_a^2 + 2v_w v_a \cos \theta)^{1/2}$$

If the searcher flies downwind ($\theta = 0$), the ground speed is simply the sum of the wind and flying speeds, and $S/t = \pi r^2(v_w + v_a)$. This is the maximum search rate because ground speed is maximized. Searching crosswind ($\theta = 90^\circ$) gives $S/t = \pi r^2(v_w^2 + v_a^2)^{1/2}$. For upwind searching, $S/t = \pi r^2(v_w - v_a)$ and, if the speeds are equal, no search is made because there is no net movement. If the two velocities differ greatly from one another, the search rate is simply proportional to the larger velocity, $S/t \approx \pi r^2 v$. This is plausible since, with greatly differing velocities, the direction and speed of the lesser have little influence. The effect of the direction of search is maximum when the two velocities are equal, $v_w = v_a = v$, in which case $S/t = \pi r^2 v(2 + 2 \cos \theta)^{1/2}$. By integrating over all directions, it can be determined that the average search rate for randomly chosen directions is $\langle S/t \rangle = 4r^2 v$. The ratio of optimum to random search rates is thus $\pi/2 \approx 1.5708$, under the assumption of equal speeds.

Chemical plumes in nature are elongated downwind, but their shape is poorly defined. They were represented by two types of shapes: rectangular parallelepipeds permit relatively simple calculations, while prolate ellipsoids probably provide a more realistic representation of actual active spaces. The height (H) and width (W) were assumed equal and perpendicular to the wind. The search was confined to the plane containing the width and length (L), and perpendicular to the height.

Rectangular Parallelepipeds. For these the cross section for crosswind movement is height times length, $\sigma = HL$, while that for up- or downwind movement is height times width, $\sigma = HW$. The maximum cross section is the

height times the length/width diagonal, $\sigma = H(L^2 + W^2)^{1/2}$. With the rectangular geometry parallel to the wind, the volume searched is simply the sum of two parts. One is the cross section perpendicular to the wind times the component of ground velocity parallel to the wind. The other part is the cross section parallel to the wind times the component of ground velocity perpendicular to the wind. Thus,

$$S/t = v_w HW + v_a H(W \cos \theta + L \sin \theta)$$

If flying speed is much greater than windspeed, the first term drops out. Conversely, if windspeed is much greater than flying speed, $S/t \approx v_w HW$. For flight in the downwind direction, the two velocities sum and $S/t = HW(v_w + v_a)$. For upwind flight, it is the difference rather than the sum that is proportional to search rate. Flying crosswind results in $S/t = v_w HW + v_a HL$. The average search rate for randomly chosen directions can be determined by integrating over all directions to obtain $\langle S/t \rangle = v_w HW + (2/\pi) v_a HL$. The optimum search direction is $\theta = \arctan(L/W)$. A search in this direction has a rate of $S/t = v_w HW + v_a H(W^2 + L^2)^{1/2}$. If $L \gg W$ and $v_a \approx v_w$, the ratio of optimal to random search rates simplifies to $\pi/2$.

Prolate Ellipsoid. For an ellipsoid with semiaxes a , b , and c , a prolate ellipsoid is defined by $a > b = c$. (A sphere has $a = b = c$.) It will be assumed that the major semiaxis, a , is parallel to the wind direction. The length is twice the major semiaxis, $L = 2a$, and the height and width are twice either of the minor semiaxes, $H = W = 2b = 2c$. The axial ratio is $a/b = L/W$. It can be shown that the projected area in any direction, θ , measured from the major axis, a , and perpendicular to c gives a cross section, $\sigma(\theta) = \pi c(a^2 \sin^2 \theta + b^2 \cos^2 \theta)^{1/2}$. The search rate for any track direction is the product of the appropriate cross section and ground speed. Integration of the search rate over all directions to determine the average search rate for random directions and determination of the direction of maximum search rate were performed using numerical approximations on a computer.

RESULTS

In order to make quantitative comparisons, flying speed was assumed equal to windspeed, which maximizes the importance of search direction. These speeds were assumed to have a numerical value of 1 in the units used (e.g., m/s). An additional assumption was that the different-shaped plumes all had the same volume equal to 1 (e.g., 1 m^3). Since search rate is simply related to speed of movement and size of plume, the data presented can easily be scaled to fit other values for speed or volume.

Basic data for rectangular active spaces of various axial ratios are presented in Table 1. Similar data for ellipsoids are presented in Table 2.

TABLE 1. DATA FOR RECTANGULAR SHAPES

Active space				
Axial Ratio	1	10	100	1000
Width	1.000	0.464	0.215	0.100
Height	1.000	0.464	0.215	0.100
Length	1.000	4.642	21.544	100.000
Volume	1.000	1.000	1.000	1.000
Optimum angle to wind (°)				
Heading	45	84.3	89.43	89.943

Random	1.637	1.587	3.001	6.376
Ratio	1.475	1.500	1.562	1.570

The optimum course angle to the wind is 0 for the sphere and increases toward 90° as the active space becomes more elongated. Figure 1 shows the relationship between search rate and the full range of course headings for five ellipsoids or varying axial ratio. In each case, the search rate goes to 0 for an upwind course ($\theta = 180^\circ$) because of the assumption of equal wind and flying speeds. The figure shows that the efficiency of a downwind search ($\theta = 0^\circ$) depends strongly on the shape of the active space; for a sphere it is the optimal direction but, as the active space elongates, the efficiency diminishes sharply.

The tables also show the angles the resulting tracks make under the influ-

^aThe ellipsoid with axial ratio of 1 is a sphere.

FIG. 1. Search rate as a function of course heading. Search rate is the volume searched per unit time. Active spaces are prolate ellipsoids of equal volume with axial ratios of 1, 2, 5, 10, and 100 as indicated.

ence of the wind. With the assumptions of equal wind and flying speeds, the tracks were directed just half as far from the downwind direction as is the course heading.

The search rates for optimum and random course headings are also presented in the tables. For each type of heading, the search rate varies little from isometric shapes out to axial ratios of about 10 but increases as the active space is elongated further. This pattern can be understood from the more detailed data on rectangular active shapes (Figure 2). The search rate actually goes through a minimum for L/W ratios of about 3, and then increases steadily, approaching a relation of $S/t \propto (L/W)^{1/3}$.

The relative advantage of choosing the optimum course heading can be determined from the ratio of optimum to random search rates. The data of the table show this ratio to vary in a narrow range around 1.5. The sphere has the highest value of $\pi/2 \approx 1.5708$. The pattern for rectangular spaces is shown in more detail in Figure 3. It is clear that the ratio goes through a minimum at $L/W \approx 2$ and then increases toward a plateau value of $\pi/2$, the same as the value for the sphere. Table 2 shows that ellipsoidal shapes give a similar pattern.

FIG. 2. Search rate as a function of length-to-width ratio of rectangular active spaces.

DISCUSSION

The question of the optimum direction for searching in wind for a chemical plume can now be answered, at least for certain situations. For a spherical active space, the optimum direction is downwind. As the active space elongates downwind, the optimal course heading swings toward a crosswind direction. Although there always remains a slight downwind bias, this would probably not be observable for plumes with axial ratios of 10 or more. There is at least some evidence that some animals search downwind (Gillies and Wilkes, 1974).

The data also clearly demonstrate that a longer plume of a given volume has greater apparency. However, it should be pointed out that a simple increase in wind velocity does not generally produce a more elongated plume. In the model of Bossert and Wilson (1963), an increase in wind velocity increases turbulent mixing, which actually decreases the volume of the active space without much change in proportions. If diffusion is assumed constant, the length of a plume is independent of wind speed (Roberts, 1923).

The question of the magnitude of the advantage of choosing the optimum course direction can be answered fairly precisely. From the data of the tables and Figure 3, it is clear that the advantage depends on the shape of the active space. However, the variation is confined to a small range, with ratios between 1.3 and 1.58. Thus, it can be said that the optimal search direction is about

FIG. 3. Ratio (of the search rate for the optimal direction of search to the average search rate for random directions) as a function of length-to-width ratio of rectangular active spaces.

50% more efficient than a randomly chosen direction. In many situations of interest, flying speed is greater than wind speed and the plume is elongated. This leads to an optimum/random ratio of $\pi/2$, corresponding to an increase in efficiency of 57%.

QUINOLIZIDINE ALKALOIDS OBTAINED BY *Pedicularis semibarbata* (SCROPHULARIACEAE) FROM *Lupinus fulcratus* (LEGUMINOSAE) FAIL TO INFLUENCE THE SPECIALIST HERBIVORE *Euphydryas editha* (LEPIDOPTERA)

Abstract—*Pedicularis semibarbata* is apparently an obligate hemiparasite of coniferous trees. It is also a facultative parasite of *Lupinus fulcratus* from which we find that it obtains quinolizidine alkaloids, principally α -isolupanine. As a result, a single population of *P. semibarbata* contains both alkaloid-rich and alkaloid-free plants. The butterfly *Euphydryas editha* naturally oviposits on both plant types. This butterfly population, which is the principal herbivore attacking *P. semibarbata* at this site, is known to contain two morphs. Individuals of a specialist morph discriminate when ovipositing among individual *P. semibarbata* plants and produce offspring that survive better on accepted than on rejected plants. Those of a generalist morph accept all *P. semibarbata* plants and produce offspring that survive equally well on plants accepted or rejected by the discriminating morph. Because of the existence of this complex variation among the butterflies, the presence of naturally laid eggs on alkaloid-containing plants still leaves the possibility that the alkaloids may defend the plants against the specialist morph. In experiments on both oviposition preference and larval performance in early instars, we failed to detect any correlation between alkaloid content of a plant and either its acceptability to or suitability for the discriminating morph of the insect. Alkaloid presence in the host-plant population, achieved through root parasitism, is currently neither subject to strong insect-mediated selection nor a major cause of selection on the insects.

Key Words—*Pedicularis semibarbata*, Scrophulariaceae, *Lupinus fulcratus*, Fabaceae, *Euphydryas editha*, Lepidoptera, Nymphalidae, herbivory, quinolizidine alkaloids, isolupanine, oviposition, parasitic plants.

INTRODUCTION

Harris and Stermitz (1987) showed that root parasitic *Castilleja* species acquire quinolizidine alkaloids from their hosts. This class of alkaloid has been implicated several times in the allelochemical defense of plants (Dolinger et al., 1973; Bentley et al., 1984; Wink, 1985; for example). A single population of parasitic *Castilleja* was found to contain both plants with alkaloids and plants without them. Here, we report a similar finding for a population of the hemiparasite *Pedicularis semibarbata* Gray (Scrophulariaceae) that also contains both alkaloid-rich and alkaloid-free individuals. Such plant populations provide natural systems in which correlations between alkaloid concentration and herbivore preference can be studied, with implications for the importance of secondary utilization by hemiparasites of host defensive compounds (Atsatt, 1977). For these purposes we explored the interaction between *P. semibarbata* and *Euphydryas editha* Bdv (Lepidoptera: Nymphalidae).

METHODS AND MATERIALS

Study Site. Our study site was at Rabbit Meadow along the Generals' Highway above Fresno in Sequoia National Forest, California. At this site the distribution of *E. editha* eggs among four host-plant species has been described by Singer (1983), who found that *P. semibarbata* received about 70% of the eggs deposited by the insect population. Search behavior of the insects for *P. semibarbata* has been studied by Rausher et al. (1981) and by Mackay (1985).

Plant Chemistry. *Lupinus fulcratus* Greene was identified by D. Wilken, Department of Biology, Colorado State University and a voucher (FRS 326) deposited in the Colorado State University Herbarium. The alkaloid content of *L. fulcratus* and its parasitic *P. semibarbata* was determined as follows.

For a typical alkaloid isolation, 1.3 g of *L. fulcratus* was crushed, wetted with 5% NaHCO₃ and stirred in 55 ml of 1:1 butanol-toluene for 48 hr. The mixture was filtered and extracted three times with 10 ml of 1 M H₂SO₄. The combined acid layers were extracted with CHCl₃ and made basic to pH 9 with NaOH pellets. The basic solution was extracted three times with equal volumes of CHCl₃, the CHCl₃ layers combined, and evaporated to yield 34 mg of alkaloid mixture.

Essentially the same procedure was used for semiquantitative alkaloid analysis of individual *P. semibarbata* plants. Samples of either 100 or 50 mg

of dry *P. semibarbata* plants from a 1986 collection were extracted and the final CHCl_3 solutions evaporated in test tubes. To each tube was added 1.0 ml of CHCl_3 . Then, 0.10 ml for the 100-mg samples or 0.20 ml for the 50-mg samples was applied to Si gel (0.25 mm, Merck 60) TLC plates. The plates were developed in 9:1 CHCl_3 -MeOH and spots visualized with iodoplatinic acid spray. Spot sizes and intensities were visually compared. Five 100-mg samples of individual *L. fulcratus* plants were treated and analyzed similarly. Alkaloid presence was readily detected qualitatively using 5–10 mg of dry small individual *P. semibarbata* leaf samples with a modified procedure. Here, the leaf was macerated in a drop or two of 1 M Na_2CO_3 solution in the bottom of a small test tube and about 0.5 ml of 2:1 CHCl_3 -MeOH added. The mixture was agitated with a small stirring rod for a few minutes, allowed to stand briefly, and the CHCl_3 was drawn off with a disposable pipet into a depression in a spot plate. The CHCl_3 was allowed to evaporate to a small volume and one tenth to one half spotted on a TLC plate, then developed and visualized as above. This procedure is easily adapted to use in the field.

Alkaloid residues from the 1986 1.3 g *L. fulcratus* extraction and the combined *P. semibarbata* extractions were analyzed by NH_3 chemical ionization mass spectrometry, ^{13}C NMR spectroscopy, and TLC.

Insect Preferences. Insect preference was tested by placing field-caught insects on undisturbed plants still growing in their natural positions, using the technique of Singer (1986). If deprived of the opportunity to oviposit, discriminating insects will consistently accept some individual plants and reject others.

We performed two experiments in separate years, 1986 and 1988. In 1986 we tested randomly selected morphologically similar plants with no initial knowledge of their alkaloid content. By this means we obtained pairs of accepted and rejected plants. We then analyzed the plants for alkaloids. Only in those cases where alkaloid concentrations were different in accepted and rejected members of a pair could we obtain information about the correlation between alkaloid content and acceptability. In order to increase our efficiency in the second experiment in 1988, we assessed alkaloid content first, then paired each plant that contained alkaloids with a morphologically similar plant that was alkaloid-free. Persons who performed preference trials to determine which (if any) member of the plant pair was more acceptable were ignorant of the identities of the plants that actually contained alkaloids.

Insect Performance. Eggs of *E. editha* are laid in clusters and larvae are gregarious, occurring naturally in groups of 5–100. As each egg cluster hatched, two groups of 20 newly hatched larvae were isolated. One group of 20 was placed on each member of a plant pair (still growing *in situ*) and allowed to feed for 10 days, after which the remaining larvae were gathered and counted. Again, two experiments were performed in separate years, but with some differences between the years. In 1986, we used eggs gathered at random and

performed alkaloid analyses after larval feeding, while in 1988 we used offspring of discriminating butterflies and performed the analyses before the experiment.

RESULTS

Alkaloid Content. TLC on *L. fulcratus* and 16 of 40 individual *P. semi-barbata* plants from the 1986 experiment showed the presence of one major alkaloid at R_f 0.40 along with a small amount of a second at R_f 0.05. NH_3 chemical ionization mass spectra of the alkaloid fractions from both plants were nearly identical and showed a very large $M+1$ ion at m/z 249 and a very small one at 263, indicating the presence of one major and one very minor alkaloid of mol wt 248 and 262, respectively. The mass and [^{13}C]NMR spectra and TLC of the *L. fulcratus* extract corresponded to data for α -isolupanine (Scheme 1), which we had previously isolated (Harris and Stermitz, 1987; Harris, 1987) and identified from *Castilleja miniata* (GH 167, Emerald Lake; Harris, 1987) and its host, *L. argenteus* subsp. *spathulatus*. The molecular weight 262 corresponds to that of 17-oxoisolupanine (or an isomer; Kinghorn and Balandrin, 1984), but no attempt was made to further identify this minor component.

Alkaloid Content and Butterfly Oviposition Behavior. In the 1986 experiment, alkaloid analyses were performed on 20 previously identified pairs of accepted and rejected plants. Table 1 shows that eight pairs contained no alkaloids in either plant and three contained alkaloids in both members. This left nine pairs in which one member contained alkaloids while the other did not. Of these, six pairs had alkaloids in the rejected plant and three in the accepted plant. Among the three pairs that both contained alkaloids, the concentrations were about equal in both plants of one pair and greater in the rejected members of the other two pairs. So, in total, we found eight pairs with more alkaloids in the rejected than in the accepted plant and three with more in the accepted than in the rejected. If alkaloid content is independent of acceptability, the probability of observing pairs in which the accepted plant contained more alkaloids than the rejected plant should be equal to the probability of observing pairs in

α -isolupanine

^bBold face: alkaloid-containing.

which the accepted plant contained less alkaloids than the rejected plant (0.50 each). With the finding of eight pairs of plants with more alkaloids in the rejected member and three pairs of plants with more alkaloids in the accepted member, we cannot reject this null hypothesis (Sign test, $Z = 1.21$, $P > 0.10$). In the 1988 experiment, where the alkaloid content of the plants was identified first, the acceptabilities of 15 pairs of plants with and without alkaloids were compared. No difference in acceptability was found between alkaloid-containing and alkaloid-free members in two of the 15 pairs. The alkaloid-containing member was preferred in eight pairs, while the alkaloid-free member was preferred in five pairs (Sign test, $Z = 0.55$, $P > 0.10$).

Alkaloid Content and Early Larval Survival. The number of larvae, out of each grouping of 20, that survived to 10 days is also given in Table 1. Overall, there is no significant difference in larval survival on alkaloid-containing versus alkaloid-free plants ($t = 0.554$, $df = 38$, $P > 0.25$). In this and other studies at Generals' Highway, a number of cases are always observed where there is no survival. Small larval webs are set up initially, but the larvae disappear after only one or two days. From observations, such young larvae are not able to survive away from web or the plant, so their disappearance is considered as mortality. We cannot, however, attribute this mortality specifically to a plant effect since the actual cause is not known. If the cases with zero larval survival are eliminated, the average number of larvae surviving (out of 20 placed) is 11.8 (SD = 4.53, $N = 11$) on alkaloid-containing plants, and 10.1 (SD = 4.97, $N = 21$) on alkaloid-free plants (not significantly different; $t = 0.61$, $df = 30$, $P > 0.25$). There is also no significant difference in larval survival between alkaloid-containing and alkaloid-free members of paired plants (average paired difference -2.09 , SD = 6.66, $t = 1.04$, $df = 1$, $P > 0.25$).

In 1988 we observed higher larval survival on the alkaloid-containing plant in five pairs, higher survival on the alkaloid-free member in five pairs, and equal survival on both plants in a single pair. Because there is no trend at all in these data, statistical analysis is not necessary.

DISCUSSION

Plant Parasitism and Alkaloid Transfer. With this work, the transfer of alkaloids from a host plant to a normally alkaloid-free root parasite has now been established for *Pedicularis*, extending the results we found for *Castilleja* (Harris and Stermitz, 1987). As in the *Castilleja* case, root parasitism on a *Lupinus* species has resulted in quinolizidine alkaloid transfer. The quinolizidine alkaloid *N*-methycytisine was previously reported (Ubaev et al., 1963) to be present in *P. olgae*. Our finding of isolupanine as a transferred alkaloid in *P. semibarbata* adds weight to the suggestion (Harris and Stermitz, 1987) that

the *N*-methycytisine in *P. olgae* was probably also the result of root parasitism on a quinolizidine-containing host plant.

P. semibarbata appears from its distribution to be an obligate associate of conifers. This hypothesis is supported by the observation that, whenever trees are removed by clear-cutting, the *Pedicularis* invariably die in one to two years, even though many of them must also be parasitizing *L. fulcratus*, which is not killed by logging. The deaths of *P. semibarbata* after logging do not result from increased insolation, since this plant often grows in open habitats, provided that conifers are close by. In contrast to the obligate association with conifers, many *P. semibarbata* are much too distant from *L. fulcratus* for the possibility of root contact, so the association of the parasite with this plant must be facultative. It appears, then, that *P. semibarbata* requires conifers for survival, but cannot survive solely as a parasite of *L. fulcratus*, from which it nonetheless acquires alkaloids.

Oviposition Behavior. Ng (1988) showed that, with respect to *P. semibarbata*, all discriminating female *E. editha* accept and reject the same plants. Individual plants retain their accepted or rejected status from year to year. Plants that are accepted in preference trials receive more naturally laid eggs than rejected plants (Ng, 1987). We were interested in learning whether or not the acquisition of alkaloids was relevant to the correlated variation of insect adult preference and larval performance shown by Ng (1988). With respect to preference, nine pairs of accepted/rejected plants in our 1986 experiment showed no difference within the pair in alkaloid concentration. For pairs in which there was such a difference, the nonsignificant correlation between alkaloids and host acceptability found in 1986 was in the opposite direction to the even less significant trend in 1988. We conclude that any correlation between alkaloid content and acceptability that may exist could at best explain only a small proportion of the variation in plant acceptability. It could not be the basis of the discrimination phenomena demonstrated by Ng, the chemical basis of which remains unsolved. Ng (1987) showed that variation of water content and nitrogen content were likewise not correlated with acceptability of *P. semibarbata* in the field.

Early Larval Survival. In 1986 we found a nonsignificant trend for better survival on the alkaloid-containing plants and in 1988 found no trend at all in the data. Our conclusion is that the quinolizidine alkaloid content (principally α -isolupanine) of *P. semibarbata* does not render it toxic to young *E. editha* larvae at General's Highway even if they are the offspring of discriminating mothers. We do not think it likely that toxic effects would have been found if we had used later development stages, since early instar lepidopteran larvae are usually more sensitive than later instars to host-plant quality (e.g. White, 1978; Harrison and Karban, 1986; Johnson and Bentley, 1988).

Our sample sizes (20 plant pairs in 1986 and 11 in 1988) are not large,

and a larger data set with more power to detect small correlations between alkaloid content and host-plant acceptability or suitability would be advantageous. Such a data set would, however, be difficult to obtain because the season is short (four weeks) and the work of establishing accepted and rejected plant pairs is labor-intensive.

Context. Previous assessments of insect herbivore interactions with quinolizidine alkaloids or quinolizidine-containing plants have encompassed a variety of situations. Most recently, the lupine alkaloids lupanine and sparteine were shown to reduce growth and survival of first instars of the generalist *Spodoptera eridamia*, but not the growth of later instars (Johnson and Bentley, 1988). Extensive work on quinolizidine alkaloids and "sweet" (alkaloid-free) or "bitter" *Lupinus* species (Wink and Römer, 1986; Wink, 1985, 1987 and references therein) has shown deterrence of leaf miner and aphid generalist feeding and the use of sequestered alkaloids as toxic defenses by specialist aphids. Others have also shown quinolizidine alkaloid deterrence to aphids (Dreyer et al., 1985) and to spruce budworm (Bentley et al., 1984) feeding. In some of these cases, it was clearly evident that there was both herbivore taxon and quinolizidine structure dependence on bioactivity, but even here consistency has not always been observed. For example, 13-acyllupanines were highly deterrent to spruce budworm (*Choristoneura fumifera*) larval feeding, but several other quinolizidines, including α -isolupanine, were not (Bentley et al., 1984), at least at the concentrations used. In contrast, *Lupinus floribundus*, the most heavily attacked of three lupine species studied at several sites (Dolinger et al., 1973) had relatively high concentrations of 13-acyllupanines, which were lacking in the less attacked species. The herbivores, *Glaucopsyche lygdamus* lycaenid butterfly larvae, were also reported to have higher survival in feeding studies on the 13-acyllupanine containing *L. floribundus* than on those species containing nonester quinolizidines.

The much-cited work of Dolinger et al. (1973) was perhaps the closest to our own work in aim. These authors were the first to suggest that interindividual variability of host-plant quinolizidine alkaloid content may have evolved in response to frequency-dependent selection exerted by insects. Working at several high elevation sites in Gunnison County, Colorado, both Dolinger et al. (1973) and Breedlove and Ehrlich (1972) searched for correlations between traits of different lupine species and oviposition by *G. lygdamus*. The plant traits investigated were different in the two studies; Breedlove and Ehrlich used pubescence and Dolinger et al. used alkaloid content. Breedlove and Ehrlich concluded that differences among attack rates on three lupine species were related to differences in pubescence among these species. Dolinger et al. (without discussing the prior results of Breedlove and Ehrlich) concluded that the same differences were related to "alkaloid configuration." Neither conclusion appears to be justified, because both the correlation shown by Breedlove and

Ehrlich between insect attack and pubescence and the correlation shown by Dolinger et al. between insect attack (or host availability) and alkaloid content fall far short of statistical significance. However, the work of Dolinger et al. does show indisputably that accumulation of high quantities of a complex mixture of quinolizidine alkaloids, some of which were subsequently shown to be highly toxic to a generalist (Bentley et al., 1984), is not sufficient to deter extensive attack by a specialist.

Some of the difficulties encountered by Dolinger et al. stemmed from attempts to make comparisons simultaneously across species and populations. In our work, we have attempted to reduce problems of data interpretation by estimating traits within, rather than among, plant and insect populations. In our *P. semibarbata* and *E. editha* system, the conclusion is that alkaloid concentration, although highly variable, is currently neither subject to strong insect-mediated selection nor a major cause of selection on the insects. We earlier identified *Castilleja* species and have now found additional *Pedicularis* species that accumulate other, perhaps more deterrent or toxic, quinolizidine or pyrrolizidine alkaloids. These populations also contain alkaloid-free plants, are attacked by insects, and should provide additional systems for study.

CONSPECIFIC SCENT TRAILING BY GARTER SNAKES
(*Thamnophis sirtalis*) DURING AUTUMN
Further Evidence for Use of Pheromones in Den Location

JON P. COSTANZO

(Received August 15, 1988; accepted January 11, 1989)

Abstract—Adult garter snakes (*Thamnophis sirtalis*), collected in October near a traditional, communal hibernaculum in central Wisconsin, were acclimated to autumnal conditions and subjected to laboratory tests to determine whether they could follow scent trails of a conspecific. Graded responses were obtained, but 75% of the sample showed at least some inclination to follow scent trails. The results suggest that pheromone cues may be used by male and female garter snakes to locate traditional dens during autumnal migrations. Evidence from this and other studies suggests that pheromones are probably used in conjunction with other homing mechanisms and that the role of pheromones in den location may be more important in younger snakes and in populations inhabiting northern latitudes.

Key Words—Pheromone, scent trail, chemical cue, hibernation, denning, homing, garter snake, *Thamnophis sirtalis*, Colubridae.

INTRODUCTION

An increasing literature concerning the role of chemical signals in the socio-biology of snakes (see Ford, 1986, for a recent review) has shown that the vomeronasal sense of these organisms is important and highly developed. Most studies of snake pheromones have addressed reproductive behaviors; however, scent trailing of conspecifics has been implicated in the formation of nonsexual aggregations for the purpose of avoiding unfavorable environmental conditions and reducing predation (e.g., Dundee and Miller, 1968; Duvall et al., 1985; Graves et al., 1986; Noble and Clausen, 1936). Additionally, chemical cues

have long been suspected to play a part in the relocation of communal snake dens during autumn (Hirth, 1966; Klauber, 1956; Noble and Clausen, 1936), but few investigators have attempted rigorous tests of this hypothesis.

In northern climates, strong selection pressures have likely played a major role in the evolutionary development of mechanisms by which snakes relocate traditional dens during autumnal migrations from (often distant) summer habitats. Hibernacula with features that effectively protect snakes from severe winter conditions may be limited on a local basis; in fact, this may be a reason why snakes den communally (Gregory, 1984). Snakes unable to relocate "proven" dens are likely subject to greater risks of mortality during winter. Also, mating opportunities in northern snake populations are often restricted to the den site (Gregory, 1982, 1984); thus, any individual not in attendance may forfeit its chance to contribute to the genome. Not unexpectedly, long autumnal migrations (up to 17.7 km in *T. sirtalis*; Gregory, 1984) to communal dens are made by many species and, in numerous cases, individuals show remarkably high fidelity to particular hibernacula (Gregory, 1982, 1984).

Evidence that snakes are able to follow scent trails of conspecifics has been documented for 24 species representing five families (Ford, 1986). Few studies, however, have addressed this behavior in the context of den relocation (Brown and MacLean, 1983; Graves et al., 1986; Lawson, 1985). Accordingly, this study was undertaken to assess the ability of adult garter snakes, from a communally denning population in Wisconsin, to follow conspecific scent trails under simulated autumnal conditions.

METHODS AND MATERIALS

Eastern garter snakes (*Thamnophis sirtalis*) were collected during October 1986 as they gathered near a traditional, communal den in central Wisconsin (described by Costanzo, 1986). Twenty-eight snakes were housed, irrespective of body size or sex, in small groups. One additional snake, a large (94 g) female designated for use in forming scent trails, was maintained separately. Snakes were kept in plastic boxes and were exposed to autumnal circadian thermal and light regimes (20°C, 13 hr photophase; 5°C, 11 hr scotophase) for 14 days prior to testing. Snakes were provided with water, but food was withheld.

Trailing ability was tested (procedure modified after Ford, 1981) during the last week in October, under photophase conditions (overhead fluorescent lighting; 387 lux), in a rectangular, plywood arena (Figure 1). Seventeen nails spaced at 5.5-cm intervals protruded from the floor and formed a continuous series of gates through which a snake could pass. The nails were arranged in a slight arc so that all gates were located 200 cm from an entrance port in the front wall of the arena. The arena surface was covered with corrugated paper

FIG. 1. Diagram of the testing arena used to measure the trail following ability of garter snakes during autumn. Scent trails were produced by guiding the movement of a stimulus snake, which was confined inside a bottomless, removable tunnel (shown), down the length of the arena and through a randomly chosen gate.

upon which 1200 ml of unscented cat litter (clay particles) was dispersed to provide traction. Nails were covered with cocktail straws to protect them from scent contamination. All coverings were replaced after each trailing and control test to ensure that residual odors were removed.

To promote stimulus uniformity, only one animal was used to create scent trails; fresh trails were produced within 30 min of testing each subject for trailing ability. This was done by guiding the movements of the large female snake, which was enclosed inside a 4.5-cm wide, bottomless tunnel, down the length of the arena and through a gate (Figure 1). The tunnel and snake were removed prior to introducing the experimental subject. Gates containing scent were chosen randomly, except that the three nearest each side wall were never used; this restriction was necessary since pilot studies and Ford (1986) indicated that non-trailing and control snakes had a strong affinity for arena walls.

Prior to testing, each subject was habituated for 20 min inside a holding box at the front of the arena. A pulley system was used to remove a partition between the holding box and the entrance port, thus allowing the snake to enter

the arena. Trials involving snakes not entering the arena within 15 min were terminated. Movements and gate choices of snakes were observed from behind a blind 2.5 m away. After a subject passed completely through a gate and reached the distal wall of the arena, it was replaced in its holding cage. Snakes were tested in control situations (no scent trail present) four to six days later and then sexed.

RESULTS

Twenty-four of 28 snakes completed the control trials. All but one individual (96%) passed through end gates (the two adjacent gates nearest each side wall), thus, "wall-seeking" was a prominent behavioral characteristic of non-trailing snakes. This necessitated statistical evaluation of the results using a binomial test (choice of four end gates vs. choice of 14 middle gates; Sokal and Rohlf, 1969). Frequencies recorded for control snakes were significantly different from probabilities based upon random gate choice (Table 1). Binomial probabilities calculated for experimental and control groups showed that the presence of conspecific scent in the arena significantly influenced snake behavior (Table 1).

Of the 28 snakes completing experimental (trials present) trails, 75% showed at least some inclination to follow scent trails. Trailing snakes demonstrated a behavior similar to the trail contact response (TCR) (Brown and MacLean, 1983), which involved slow and methodical sampling of the substrate, over which the trail-forming snake had passed, with its tongue tips. This behavior, which did not occur in control tests, allowed the observer to estimate (to within 10 cm) the length of the trail followed.

Garter snakes showed differential responses to the presence of conspecific

TABLE 1. EXPECTED AND OBSERVED BINOMIAL PROBABILITIES FOR GATE CHOICES OF GARTER SNAKES TESTED IN LABORATORY ARENA FOR ABILITY TO FOLLOW CONSPECIFIC SCENT TRAILS DURING AUTUMN

Test condition	Probability of end gate choice	Probability of middle gate choice	N	Significance (P)
Expected	0.222	0.778		
Control	0.958	0.042	24	<0.005 ^a
Experimental	0.607	0.393	28	<0.005 ^b

^aProbability that responses of snakes tested in the absence of scent trails do not differ from random gate selection.

^bProbability that responses of snakes tested in the presence of scent trails do not differ from those obtained in control tests.

scent in the test arena. Strong trailing inclination was demonstrated by seven snakes (25%) that correctly chose the scented gate and four snakes (14%) that chose a gate immediately adjacent to the scented one. Ten snakes (36%) trailed initially (mean distance \pm SEM = 74 ± 15 cm), but eventually passed through end gates. Seven individuals (25%) showed no inclination to trail and also chose end gates. Snakes were classified, based on their inclination to trail, as exact trailers, near-exact trailers, partial trailers, or nontrailers (Table 2). Relative to males, a greater proportion of females (75%) showed partial and nontraining responses, but contingency analysis (Sokal and Rohlf, 1969) indicated that this difference was nonsignificant (chi square = 1.79, $df = 1$, $P > 0.20$).

DISCUSSION

The present study showed that garter snakes of both sexes, acclimated and tested under autumnal conditions, can follow the scent trails of a conspecific. This result concurs with the field observation that *T. sirtalis* followed common and well-defined "travel lanes" in their approach to the den (Costanzo, 1986, 1988) and further supports the hypothesis that pheromones are used for den location by snakes in nature.

The present study is the first to provide direct experimental evidence for trail following, in the context of den location, for any colubrid snake. However, Brown and MacLean (1983) convincingly demonstrated that neonate timber rattlesnakes (*Crotalus horridus*) from New York followed the trails of litter mates and adults of both sexes during autumn. This behavior apparently was not demonstrated by congeneric (*C. viridis*) adults from Wyoming, although details of testing protocol and specific results were not reported (King et al., 1983). Graves et al. (1986) later showed that *C. viridis* neonates were attracted to scents depos-

ited by adults and concluded that neonates follow knowledgeable conspecifics short distances to the den site.

Among snakes, pheromones facilitate aggregation for both sexual and non-sexual purposes. Nonsexual aggregations probably form when snakes follow conspecifics of both sexes (Burghardt, 1980; Dundee and Miller, 1968; Graves et al., 1986; Heller and Halpern, 1981); however, during the mating period, the trailing response is clearly sex-limited (i.e., males trail females but not other males, and females do not trail either sex; Ford, 1986). Thus, it is unclear whether separate chemical cues are involved. Although further study is needed to fully characterize these substances, the pheromone permitting *C. viridis* neonates to locate dens is likely a skin lipid (Graves et al., 1986).

Snake locomotion is well suited to the deposition of a continuous scent trail (Ford, 1986), yet the hypothesis of pheromone use for den location is not without conceptual problems. One criticism is that snakes would have an even chance of following a scent trail in the wrong direction. Ford and Lowe (1984), however, cleverly demonstrated that snakes gain directionality information from the differential placement of scent on objects contacted by the trail-forming individual. Nevertheless, the first snake to arrive at a den would not have the benefit of these cues. It is probable that older, experienced snakes may relocate traditional dens using other means, e.g., solar and celestial orientational cues (Landreth, 1973; Newcomer et al., 1974), topographic landmarks (Parker and Brown, 1980), and polarized light (Lawson, 1985). Naive snakes, such as neonates and juveniles (in the case where snakes hibernate apart from adults their first winter; Gregory, 1982, 1984), may rely more heavily on pheromones for den location than do adults. This contention is consonant with the finding in the present study that nontrailing *T. sirtalis* were significantly (Kruskal-Wallis, $P = 0.02$) larger (older?) than trailing snakes; it is also supported by the relatively late arrival of smaller snakes at some communal dens (Costanzo, 1986; Gregory, 1982, 1984; Parker and Brown, 1980), and by Lawson's (1985) suggestion that solar orientational abilities are less well developed in younger *T. radix*. Since many hibernacula are inconspicuous landscape features, orientational cues alone seem insufficient to precisely locate den sites. A more parsimonious explanation is that a combination of orientational, landmark, and pheromonal cues are involved (Brown and MacLean, 1983; Gregory et al., 1987; Hirth, 1966; Lawson, 1985; Parker and Brown, 1980).

It is not surprising that snakes inhabiting high latitudes show remarkable abilities to relocate traditional dens during lengthy autumnal migrations. The original northward expansion of species' ranges doubtless depended upon the evolution of ecophysiological adaptations to colder environments and the use of winter refuges that enhanced survival. Although den fidelity typically is high, it is also imperfect (Gregory, 1984). Accordingly, individuals that located (perhaps during summer forays) and used suitable hibernacula likely prospered and

established new communal dens. The progressive northward expansion of snake populations probably was associated with increasing selection pressures for the evolution of effective mechanisms (including pheromones) for den relocation and possibly relied on traditional, communal dens as "stepping stones." This may partly explain why communal denning behavior is more prominent in snake populations near the northern extent of the species' range (Gregory, 1982, 1984). Garter snakes inhabiting milder climates (with presumably less stringent requirements for overwintering sites and consequently a greater abundance of suitable dens) show reduced inclination to trail conspecifics outside of the courtship period (Ford, 1986). The role of pheromones in den location may therefore be of greatest importance in populations inhabiting the harsh environment characteristic of northern latitudes.

Most trail-following studies are performed under idealized conditions, thus their results are only suggestive of what may occur in nature. Precipitation decreases the arrival frequency of snakes at communal dens (Costanzo, 1986; Parker and Brown, 1980), perhaps by interfering with pheromone detection. Tongue flicking, a critical element in the pheromone detection process, is slowed dramatically in *T. elegans* at low body temperatures (Stevenson et al., 1985). Preliminary work in the present investigation showed that, at body temperatures of 5 and 12°C, *T. sirtalis* were largely unresponsive to the scent trails of conspecifics. Future studies should address the influence of environmental factors (e.g., temperature, precipitation, humidity, substrate texture, wind velocity, etc.) on the trail-following ability of snakes, as well as the taxonomic and geographical limits of pheromone use for den location.

EMPIRICAL CORRELATIONS BETWEEN ELECTROANTENNOGRAMS AND BIOASSAYS FOR *Periplaneta americana*

M. L. CONTRERAS, D. PEREZ, and R. ROZAS

Department of Chemistry and Biochemistry
University of Santiago
Casilla 5659, Santiago-2, Chile

(Received August 1, 1988; accepted January 12, 1989)

Abstract—Determination of electroantennograms (EAGs) with an electroantennometer having a positive and a negative peak detection option, and with a stimulus delivery device providing local stimulation of the antenna of *P. americana*, allowed for the detection of three typical EAG patterns for a wide range of compounds tested. Some of the compounds presented at least one positive EAG peak (0.1–0.3 mV), others showed a single negative EAG peak (–1.0 to –1.1 mV), and a third group had more than one negative EAG peak (–0.2 to –0.8 mV). These EAG results correlate with behavioral assays of *P. americana*. Thus compounds having a positive EAG response act as repellents, while those having negative EAG responses act as attractants, depending on concentration. EAG patterns thus can permit prediction of behavioral responses of *P. americana*.

Key Words—Electroantennography, EAG, bioassays, *Periplaneta americana*, Orthoptera, Blattidae, electroantennogram, attractants, repellents, pheromones, mimics, chemical stimulation, American cockroach.

INTRODUCTION

The electroantennography of insects has normally been done with pheromones, mimic compounds, plant volatiles and, sometimes, repellents (Andersen et al., 1987; Gothilf and Bar-Zeev, 1972; O'Connell et al., 1986; Roelofs, 1984). For *P. americana*, these studies have been done mostly with pheromones, mimics, and general odors (Manabe and Nishino, 1986; Nishino and Takayanagi, 1979). The electroantennometers used in most of these experiments have been con-

structed to detect just a single depolarization response, i.e., a negative peak if the grounded electrode is connected to the distal part of the antenna. The devices used for obtaining the EAGs normally have considered stimulation of a very wide zone of the antenna as a whole. In these conditions the reported EAG results always have shown a single depolarization, negative in sign, for the active compounds (Gothilf and Bar-Zeev, 1972; O'Connell et al., 1986). On the other hand, bioassays for determining the activity of the compounds as attractant pheromones or mimics have been carried out with compounds presenting a negative peak under the EAG recording conditions. To the best of our knowledge, no clear results have been reported about any positive EAGs.

In this work, we present the results obtained in the electroantennography of *P. americana* with a specially constructed electroantennometer that has a simultaneous positive and negative peak detection option (Perez and Rozas, 1984) and a stimulus delivery system that has been designed to work with local stimulation of the antenna (Rozas and Perez, 1987). We also present the results of the bioassays of *P. americana* with the same compounds tested in the EAGs. It will be shown that compounds with a repellent effect on the insects in the bioassay have a positive EAG; those that behave as attractants in the bioassay have a negative EAG.

METHODS AND MATERIALS

Stimulation Chemicals. A wide structural array of available compounds was tested in this study, taking in consideration the structure of some repellents (Hagenbuch et al., 1987), some chemicals present in ventral glands of *P. americana* (Fukushima et al., 1987), common solvents, and known pheromones. All of the chemicals tested were *pro analysi* reagents; before the experiments they were further purified up to 99.0–99.5% purity as determined by GC. Periplanone B was prepared according to Schreiber and Santini (1984).

Insects. The male and female *P. americana* were maintained at 23–27°C, 45 ± 10% relative humidity, and a photoperiod of 6:18 light–dark. During the day, darkness was provided by a dark crypt inside a box, which allowed restricted light access to the crypt. Adult males of similar size and weight chosen for the EAG and bioassay experiments were separated into another box five days before the experiments and kept as before in the same environment. After use in the EAG and bioassay, they were discarded.

Electroantennography. The electroantennography of *P. americana* was done with an electroantennometer previously described (Perez and Rozas, 1984) and with a specially designed stimulus delivery device (Rozas and Perez, 1987), which basically consists of a glass tube of 3.8 mm internal diameter where the antenna is held perpendicular to it. The antenna at each extreme is attached to

a conductor that consists of a silver electrode in Ringer solution. One of the conductors is coated with a copper conductive paint for electrostatic shielding. A controlled flux of air (60 ml/min) is introduced through the tube, and the chemical stimulus is injected in the airstream through a lateral capillary injector. There is no apparent fluctuation of the chemical concentration during the stimulation. This was shown by injecting a iodine vapor puff in the airstream during a control of the setup. In this way, the angle between the injector capillary and the direction of the flux was determined to be smaller than 60°. Bigger values for that angle caused variations in the flow. This device is then placed in an electrostatically shielded box.

A filter paper strip ($2 \times 0.5 \text{ cm}^2$) was impregnated with a chemical (1–50 μg). For that, a 5- μl amount of a hexane or ether solution of the chemical was applied to the filter paper strip, and then the solvent was allowed to evaporate. More volatile chemicals as carbon disulfide, chloroform, 1,2-dichloroethane, diethyl- and triethylamine, were applied neat. The impregnated filter paper was placed in a 10-ml glass syringe. After 10 ml of air had been drawn into the syringe, the odor was mixed into the filtered airstream (60 ml/min) that was continuously blown over the antennal setup by pushing the plunger quickly (ca. 30 msec), so that air including odor (ca. 1 ml) was puffed onto the antennal preparation through the 3.8-mm-diameter glass tubing. This general procedure for presenting the stimulus has been of general use for EAG determinations (Manabe and Nishino, 1986; Nishino and Takayanagi, 1979; Roelofs, 1984). As established earlier (Roelofs, 1984), we found that slight variations in the speed at which the syringe plunger was depressed and in the amount of puffed air do not seem to be critical for the resulting response intensity. Small changes in concentration or differences in compound volatility at the dosage level used also have little effect on the relative responses to a standard compound like camphor. No changes in polarity were observed.

The antenna was removed from the insect and located in the supporting tube of 3.8 mm internal diameter. There was no variation in the response if the EAG was done either with the first or the second antenna of the insect. Reliable results were obtained during the first 20 min after removing each of the antennae. Chemical stimulation was done on the central part of the antenna where most of the chemoreceptors are located (Nishino and Takayanagi, 1979). Each antenna was stimulated a couple of times with the same chemical. An interval of 30 sec between tests was used routinely. As a control, the same procedure was performed without a test chemical. This type of control was done at the beginning and at the end of each EAG determination. Ten animals or 20 preparations were used for testing a single chemical. EAG shape pattern remained unchanged. Maximum peak values had a variation lower than 8–10%.

Bioassays. The bioassays were done in a polystyrene box (Figure 1), which

FIG. 1. (A). Box used for the bioassays of *P. americana* with different attractants and repellents; (B) amplification of the inverted grided funnel where the chemical is placed; $R = 25$ cm; vol = 157 liters; $d = 4.5$ cm; $f =$ air flow.

was kept closed during the experiments in order to simulate a habitat similar to the natural one for *P. americana*. The box was provided with four independent dark glass tubes (crypts) located on opposite faces. One adult male was located in each crypt of the box, so four adults were used in any one experiment. Each experiment was repeated twice with the same insects and then, after changing the insects, the whole cycle was repeated five times. Thus, 20 different insects were used twice for every chemical.

Between bioassays, the box was ventilated in order to start with a similar atmosphere. The chemicals to be tested, 40–55 μg , were absorbed in the usual way on a piece of filter paper. Then, the paper was located in the center of the bottom area of the box. A perforated glass funnel was inverted over the sample (see Figure 1B), through which air was swept; this air (10–20 ml/min/crypt) carried the volatiles out through a stopcock at the end of each crypt. The cover of the box was provided with a window for watching the insects every 3 min after exposing them to the chemicals. A control experiment, done without any test chemical absorbed on the piece of filter paper, revealed a random distribution of the insects in the box after a few minutes. Based on this observation, if after 20 min no insects approached to the chemical, it was considered to be a repellent (R). This behavior was checked visually through another window located at the back of each crypt. On the other hand, if the insects were all moving around the chemical during the time of observation, it was considered to be an attractant (A). These two extreme categories were used for the classification of the compounds given in Table 1.

RESULTS

Typical EAGs are given in Figure 2. Table 1 gives the maximum positive or negative values of the EAG peaks for the different chemical stimuli tested. As can be seen from Table 1, the EAGs obtained by a narrow local stimulation (3.8 mm) on the central part of the antenna of *P. americana* showed three typical patterns: (1) those with a double positive response (Figure 2A) or with a positive response followed by a normal negative one, (2) those with a single negative peak as is normally observed in EAG, and (3) those with a double negative response (Figure 2B).

The bioassay results showed a very interesting tendency (Table 1): compounds with repellent effects, designated as R, presented under EAG experi-

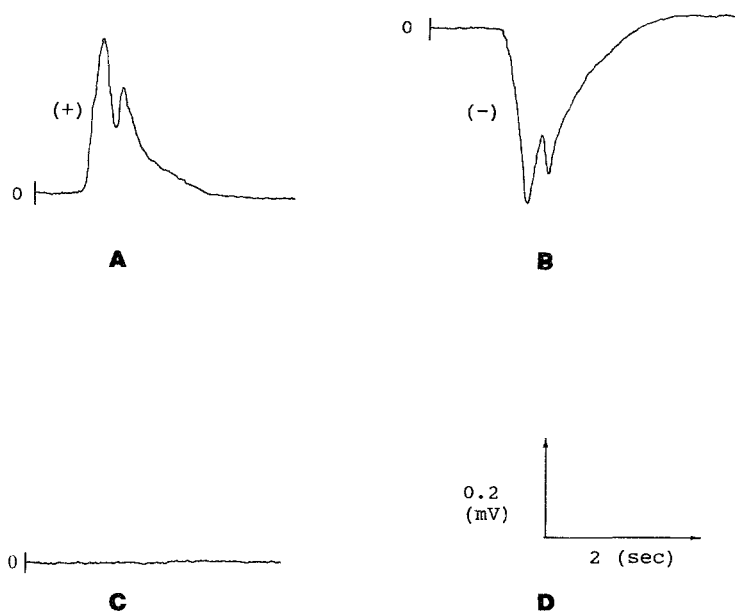

FIG. 2. Typical electroantennograms of *P. americana* to different stimuli: (A) EAG with CS₂; (B) EAG with *n*-octanol; (C) control stimulation EAG with no test chemical; (D) voltage-time scale used in the EAGs.

ments the characteristic pattern described in (1) with at least one positive peak. This was not observed for the rest of the compounds studied. On the other hand, compounds that were attractive on bioassay, designated as A in Table 1, had pattern (2) in EAG with a single negative peak. Compounds that belong to the pattern described as (3) under EAG conditions (double negative response) had a bioassay behavior that depended on concentration; these compounds were attractive at low concentrations (40–50 μg absorbed on the filter paper), but when their concentration was increased stepwise over 50 μg and in some cases up to 500 μg , they became repellent to insects; that is why they were designated as A/R compounds in Table 1. Bioassays with R or with A type chemicals showed no dependence with the concentration of chemical stimuli. However, all the EAGs and bioassays represented in Table 1 are compared in the range of 1–50 μg of chemical stimulus.

Mixtures of attractants (A) with repellents (R) that had a positive peak on the EAGs always showed a repellent effect during the bioassays. That general fact was first detected by working with 1:1 molar mixtures of A and R compounds. Other molar proportions showed a repellent effect during the bioassay as long as the EAG detected a positive peak. For mixtures between A and A/R compounds, the EAG had a double negative peak, and the final bioassay

result was attraction if the stimulus was less than 50 μg or repellency at higher concentrations of the mixture. The last compounds in Table 1 did not show bioactivity either on EAG or bioassay.

DISCUSSION

The use of an electroantennometer with positive and negative peak detection options (Perez and Rozas, 1984) and the use of a selective stimulus delivery device (Rozas and Perez, 1987) allows one to do EAG determinations by selective stimulation of particular zones of the antenna of *P. americana*. Under these conditions, very characteristic patterns for the EAGs were found. These patterns are quite reproducible, and for attractant stimuli, we have found the usual reported EAGs (Nishino and Takayanagi, 1979; Roelofs, 1984) with maximum values of -1.0 to -1.1 ± 0.08 mV for 40 determinations. Meanwhile EAG results for compounds acting as repellents are less common, and the reported ones (Gothilf and Bar-Zeev, 1972) have not revealed the existence of any positive peak, probably because of the EAG set-up used. In our hands, positive peaks obtained in the EAG of repellent compounds showed intensities varying between 0.1 and 0.3 ± 0.01 mV for 40 determinations. Polarity was kept constant for all of the repetitions.

Bioassays carried out with the same chemicals tried on EAG correlate fairly well with the EAG patterns, as can be seen in Table 1. All of the repellent compounds, as determined by bioassay, show at least one positive peak when analyzed by EAG. This fact seems to be very significant for the prediction of a general repellent behavior of a particular compound by the insect. At the moment, we do not have any reasonable explanation for these experimental EAG findings. However in terms of the affinity of a compound for the sex pheromone receptors, intrinsic activity EAG responses ranging from negative to positive signs have been theoretically expected for *P. americana* (Manabe and Nishino, 1986). On the other hand, attractant compounds behave as usual and show a single negative peak on EAG. Both of these kinds of compounds, R and A, showed a concentration-independent behavior. A/R chemicals in Table 1 presented at least two negative peaks on EAG, and their behavior on bioassay was dependent on their concentration: they are attractive at low concentrations (under 50 $\mu\text{g}/\text{filter paper}$) and become repellents at higher concentrations.

These correlations seem to us to provide striking experimental evidence of the existence of a relationship between the results that can be obtained by stimulating the insect as a whole on bioassay and parts of a removed antenna on EAG. In spite of the difficulty in understanding of these facts, the coupling of

EAG and bioassay experiments should be studied further in order to gain new insights into the correlation of the results from these two simple techniques and the structure of bioactive compounds. This type of study also can allow one to know more about the types of sensillae distributed along the antenna and individual responses.

Until now, researchers have done EAGs with nonselective stimulus delivery systems and with electroantennometers having a single peak detection capability. From these, the chemical has been considered to be or not to be a pheromone or a mimic (Manabe and Nishino, 1986). A careful EAG and bioassay could change such a deduction, as we have found for *P. americana*.

In this way, after the EAG has been carried out, it would be possible to predict if the analyzed chemical should be a repellent or an attractant to the insect according to the pattern displayed and to the empirical relationship found between EAG and bioassay experiments for *P. americana*, which could be confirmed by doing some bioassays at different concentrations.

Therefore, a detailed EAG together with bioassay experiments for insects seem highly advisable in the search for active compounds, for a better understanding of chemical communication of insects, and for their possible control.

(Received June 14, 1988; accepted January 13, 1989)

Abstract—Seven analogs of aristolochic acids (I, II, III, B, C, D, and E) were isolated from the leaves of *Aristolochia debilis* and characterized as the larval feeding stimulants of an Aristolochiaceae-feeding swallowtail butterfly, *Atrophaneura alcinous*. Aristolochic acids showed synergistic activity in combination with the water-soluble components in the leaf extract. Aristolochic acids were detected in the body tissues and specialized organs throughout all life stages of *A. alcinous*. Larval osmeterial fluid contained aristolochic acids as high as 2% of the secretions, the compositions of which were similar to that found in the leaf extracts. In contrast, the eggs selectively contained aristolochic acids I and II. These two acids were present both in the egg yolk and egg coating material as well as in the collateral glands (glandulae sebaceae) of the adult females. The cannibalistic activity of the larvae against the eggs and pupae seemed to be triggered by aristolochic acids present on the egg surface and pupal cuticle, suggesting a possible adaptive mechanism in this species. Aristolochic acid I deterred feeding of tree sparrows, which suggested a defensive role against vertebrate predators.

Key Words—*Atrophaneura alcinous*, Lepidoptera, Papilionidae, *Aristolochia debilis*, Aristolochiaceae, aristolochic acid, sequestration, feeding stimulant, defense, cannibalism, osmeterium, sparrow, *Passer montanus*.

INTRODUCTION

A large number of swallowtail butterfly species (Papilionidae) feed on the plant family Aristolochiaceae. The host adaptation in some of these species is associated with the host-originated toxic substances, aristolochic acid (AAs) (Rothschild et al., 1972). A Japanese pipevine swallowtail, *Atrophaneura alcinous*, feeds exclusively on *Aristolochia* plants. The adult butterfly exhibits aposematic red coloration on its body and hindwings and is supposed to be an unpalatable model for several mimicry species. *A. alcinous* appeared to sequester AAs in body tissue as in other troidine species (Euw et al., 1968; Urzúa et al., 1983; Urzúa and Priestap, 1985). Not only adults but also eggs, larvae, and pupae of *A. alcinous* have been found to store AAs in high concentration. It is here demonstrated that AAs act as deterrent allomones against birds. Chemical sequestration and consequent protection require appropriate host recognition. Adult females of *A. alcinous* have been shown to be stimulated to oviposit by AAs, in addition to other components in their host plant, *A. debilis* (Nishida and Fukami, 1989). Furthermore, AAs were found to initiate feeding activity by *A. alcinous* larvae. We describe here the chemical basis of the ecological adaptation of *A. alcinous* mediated by its host plant chemicals, the AAs.

METHODS AND MATERIALS

Instruments. Mass spectra (MS) were obtained with a Hitachi M-80 mass spectrometer at 70 eV (in-beam). Ultraviolet (UV) spectra were obtained with a Shimadzu UV-360 recording spectrophotometer, and infrared (IR) spectra were measured with a Shimadzu IR-400 spectrometer. Proton and carbon-13 nuclear magnetic resonance ($[^1\text{H}]$ NMR, $[^{13}\text{C}]$ NMR) spectra were obtained with a JEOL JNM FX-90Q spectrometer (90 MHz) in d_6 -dimethylsulfoxide using TMS as an internal standard, unless otherwise mentioned. A JEOL JNM FX-200 was also employed for the measurements of $[^1\text{H}]$ NMR spectra at 200 MHz. The letters s, d, t, q, and m represent singlet, doublet, triplet, quartet, and multiplet, respectively. Melting points (mp) are uncorrected.

Larval Feeding Stimulant Bioassay. Newly hatched first instar larvae were used for feeding tests within 24 hr after emergence. (The eggs had been removed from the host-plant leaves before hatching to prevent the larvae from direct contact with the host chemicals.) Solutions of test samples of given concentrations were applied as bands (5×10 mm), at least 15 mm apart, to a thin tissue strip (5 mm width, Kimwipe S-200, Kimberly-Clark Corporation) as shown in Figure 1. Doses were expressed either as gram-leaf equivalent (GLE) per 50-mm^2 area of the tissue strip or as the absolute amount applied to the test area. The test strip, after misting with distilled water, was placed in a Petri dish (30

FIG. 1. Feeding responses of *Atrophaneura alcinous* larvae to the water layer of *Aristolochia debilis* (W), aristolochic acid I (I), and a mixture of both (W + I). The first-instar larvae actively bit the area where I + W was applied.

mm inner diameter), and several larvae (about two individuals per 50-mm² area) were released. After 18 hr (8:10 dark–light photoperiod, 22–24°C), the feeding activity of the insects was measured. Each 5 × 10 mm square was divided into 50 sections (each 1 × 1 mm), and the sections where the bites were observed were counted. The activity was expressed as a percentage of the bitten sections per 50 sections. Usually larvae selectively bit into the area where diluted methanolic extracts of *A. debilis* were applied (1 mGLE/50 mm²), and consumed 10–25 sections within a test period. The mean number of counts was obtained from at least eight duplicate tests.

Extraction and Fractionation of Aristolochia Leaves. The aerial parts (leaves and shoots) of *A. debilis* were collected in Kyoto prefecture in September 1984 and extracted with methanol (7 liters/kg of plant). The methanolic extract (50 g/kGLE) was dissolved in water (1 liter) and washed with ether (400 ml × 3), followed by ethyl acetate (300 ml × 3), and butanol (400 ml × 3). The combined ethereal layer (12.5 g) was extracted successively with saturated sodium bicarbonate (200 ml × 3), 1 N HCl (200 ml × 2), and saturated sodium chloride (150 ml × 4), and dried over anhydrous sodium sulfate to obtain the neutral fraction (12 g). The sodium bicarbonate layer was extracted with 20%

methyl ethyl ketone in ether (100 ml \times 3) after acidification to pH 2 with hydrochloric acid. The upper phase was washed with saturated sodium chloride and dried over anhydrous sodium sulfate. Removal of the solvent yielded a yellow solid mass of acidic components (0.30 g). The basic components (6 mg) were obtained from the hydrochloric acid layer after adjusting to pH 12 with sodium hydroxide and extracting with ether.

Isolation of AAs. The ethereal acidic fraction was composed mainly of several analogs of AAs, which were monitored by high-performance liquid chromatography (HPLC) using Radial Pak, μ Bondapak C₁₈, 100 mm \times 8 mm ID (Waters Associates), eluted with a mixture of methanol, water, and formic acid (66:33:1) at 3 ml/min (detector: Jasco UVIDEC-100-II, 254 nm). The retention times (R_t) of AAs C, B, D, II, III, E, and I were 2.7, 3.4, 3.8, 4.8, 5.3, 5.9, and 7.0 min, respectively. AA-I (80 mg) was crystallized from an acetone solution of the acidic fraction. The residual acidic mixture (0.25 g) was chromatographed on a reverse-phase column (8 g of ODS-W, microbead silica gel 5D, 100–200 mesh, Fuji-Devison Chemical Ltd.) eluted with a mixture of methanol–*N,N*-dimethylformamide–water–acetic acid (60:10:30:1). The first 40-ml portion of the eluate was rich in the phenolic AAs(B, C, and D), and the next 40-ml portion was mainly composed of AA-I, II, III, and E. Aliquots of these fractions were finely separated under the HPLC conditions mentioned above, and each isolated component was further purified by recrystallization from mixtures of benzene and acetone. The approximate yields of AAs from 1 kGLE were as follows: I = 120 mg, II = 20 mg, III = 3 mg, B = 80 mg, C = 10 mg, D = 3 mg.

AA-E Methyl Ester. The MS and IR spectra were identical to those of AA-B 7-O-methyl ether methyl ester.

HPLC Analysis of AAs in A. alcinous Tissues at Various Stages. The con-

tents of AA analogs in the larval osmeterial fluid, pupae, adults, and eggs were quantified by means of HPLC using a reverse-phase column (Capcell Pak C₁₈ S-5 μm , 250 mm \times 4.6 mm ID eluting with 60% methanol plus 1% acetic acid in water (1 ml/min) as shown in Figure 3. The chromatograms were monitored by UV detection at 254 nm (R_t : AA-C = 4.9, B = 6.0, D = 6.3, II = 10.1, III = 10.9, E = 11.1, I = 13.5 min). All the insects used here were reared in outdoor screen cages, and fed with fresh leaves of *A. debilis* during their larval stage. As a general procedure for preparation of AA fractions, the insect bodies or the organs were homogenized and extracted with various solvent mixtures. Acetone was used preferably for extraction because of the high solubility of AAs in the solvent, but it was usually mixed with other solvents (ethanol, methyl ethyl ketone, and benzene). The crude extracts were subjected to acid-base extraction using ether, saturated sodium bicarbonate, and 1 N hydrochloric acid in the same manner as described above for fractionation of *A. debilis* leaves. The ether-soluble acidic fractions were passed individually through a Sep-pak C₁₈ cartridge (Waters Associates), and the aliquots were subjected to HPLC analysis.

Larval osmeterial fluid was collected from the fifth-instar larvae by using glass capillary tubes while the eversible glands were extruded (Figure 2A). The glandulae sebaceae were dissected out from the female abdomen (100 females 7–12 days old, extracted with an ethanol-acetone mixture (1:1, 20 ml \times 2), Figure 2C). In order to obtain the egg yolk, full grown eggs were taken out from the female's body (5–10 days old, Figure 2B and C), crushed in an ethanol-acetone mixture (100 μl /egg), and then extracted. Egg coating was obtained by wiping the resin-like material on the egg shell (Figure 2B) immediately after the eggs were deposited on a piece of filter paper (Nishida and Fukami, 1989). Pupal rinse was obtained by washing the pupae (at least 10 days after pupal ecdysis) in a mixture of acetone and hexane (1:1, 2 ml/pupa) for 15 sec.

Deterrence Bioassay of AAs against Sparrows. Two square plates (16 \times 16 cm) were placed next to each other in an outdoor bird-feeding arena (Kyoto, May 1987). Thirty rice grains treated with an acetone solution of AA-I were placed in one plate, and 30 untreated grains (solvent blank) were placed in the other plate. The number of grains from the initial 30 grains were counted after exposure to sparrow feeding (Nishida et al., 1988).

RESULTS

Larval Feeding Stimulants. Methanolic extracts of *A. debilis* stimulated feeding by *A. alcinous* larvae when the solution was applied to a piece of thin tissue. In particular, the first-instar larvae, which had no experience of direct contact with the host plant leaves, were strongly arrested and bit into the tissue

FIG. 2. (A) An *Atrophaneura alcinous* larva everting its osmeterium when the posterior end of the larva was squeezed. The osmeterial fluid can be introduced in a glass capillary tube. (B) Eggs of *A. alcinous* normally oviposited (left), and dissected from oviduct. (C) Ovarian view of a mature adult of *A. alcinous*. The larva consumed one whole egg within an hour and doubled in weight.

fiber where the extracts had been applied. In order to examine the feeding-stimulant activity of the host plant extract, thin tissue strips (Kimwipe, 5 mm in width) were used as a biting substrate (see Figure 1). A methanolic extract of *A. debilis* (aboveground parts) was fractionated into ether, ethyl acetate, butanol, and water layers by solvent extraction. Table 1 test series 1 shows the mean biting counts of each fraction at a dose of 1 mGLE/50 mm². The water layer was found to be the only fraction that exhibited the activity, but it appeared to be weak compared with that of the methanolic extract. However, the activity of the water layer was significantly increased up to the level of the original methanolic extracts by adding the inactive ether layer. The synergistic ether layer was then separated into acidic, basic, and neutral fractions, in which only the acidic fraction was found to be responsible for inducing the significant feeding activity in combination with the diluted water layer (Table 1 test series 2).

The acidic layer consisted mainly of several analogs of AAs (I, II, III, B, C, D, and E). Each AA analog was isolated by combination of preparative HPLC and crystallization. Figure 3 (top) shows a typical HPLC profile of AAs

^aDose: 1 mGLE/50 mm² in test series 1; 0.3 mGLE (W) and 1 mGLE (each fraction)/50 mm² in series 2; and 0.3 mGLE (W) and 0.3 μg (AAs)/50 mm² in series 3.

in the young leaf extract. Each AA analog was individually tested at a 0.3-μg dose in combination with the water layer (Table 1 test series 3). AA-I exhibited distinct synergistic activity. The activities of AA-II, B, and C seemed to be relatively weak. Preliminary experiments also indicated that AA-III, D, and E also act as synergists to some extent on the water layer.

Identification of AAs. Several AA analogs have been previously isolated from *A. debilis* (Scheme 1). Tomita and Kura (1957, 1959) isolated AA-I(A), B, and C from the root. The authentic specimens of AA-B and C, kindly provided by Professor Tomita, coincided in all respects with our samples of B and C. Although AA-C was determined as 3,4-methylenedioxy-6-hydroxy-10-nitrophenanthrene-1-carboxylic acid (Sasagawa, 1962; Kupchan et al., 1965), the structure of AA-B has been uncertain (Tomita and Sasagawa, 1959). As shown in the physical data section, spectrometric data of AA-B assigned its structure to be 3,4-methylenedioxy-7-hydroxy-8-methoxy-10-nitrophenanthrene-1-carboxylic acid. The position of the 8-methoxy group was unequivocally determined by measurements of a nuclear Overhauser effect between the neighboring protons (12% increase of H-9 (δ 8.44) by an irradiation of the methoxy proton

SCHEME 1.

FIG. 3. Liquid chromatograms of aristolochic acids in the fresh leaves of *Aristolochia debilis*, larval osmeterial secretion, pupal whole body, adult male body, and whole eggs. The chromatogram was done on a Capcell Pak C₁₈ (S-5 μm, 250 × 4.6 mm ID), eluting with 60% methanol + 1% acetic acid in water at a flow of 1 ml/min, monitored by UV detector (254 nm).

at δ 3.99). Because AA-E (molecular weight = 371) gave the same methylated product as that of AA-B when reacted with diazomethane, AA-E was verified as a 7,8-dimethoxy analog of AA. Chen et al. (1981), however, already reported these two AA analogs from *A. debilis* roots by the names of 7-hydroxyaristolochic acid-A and 7-methoxyaristolochic acid-A. The former compound is a synonym of aristolochic acid B. To adopt the traditional nomenclature, we here propose the name aristolochic acid E for the latter compound. AA-I, II, III, and AA-D were identified by spectrometric analysis and comparison of the physical data with those reported in the literature (Pailer et al., 1956, 1965; Pailer and Schlepplik, 1957; Pailer and Bergthaller, 1966; Kupchan and Merianos, 1968).

Sequestration of AAs at Various Stages of A. alcinous Larvae. When the larvae of *A. alcinous* are irritated, they secrete orange-colored fluid from their osmeteria, which are situated between the head and prothorax, and quickly smear the fluid onto the object (Figure 2A). The fluid possesses a characteristic odor and bitter taste. The last-instar larvae usually secrete 1–2 μ l of the fluid, which can be readily introduced into a glass capillary tube. Although the fluid is usually a clear solution, a yellow crystalline mass precipitated when the fluid was dissolved in a small quantity of 1% acetic acid in ethanol. The crystals were found to be pure AA-I (mp 280°C, decomp.). A liquid chromatogram of AAs in the intact osmeterial fluid is shown in Figure 3, in which all AA-analogs were found, exhibiting a similar profile to that of the host plant extracts. The content of the major analog, AA-I, in the osmeterial fluid of the last-instar larva was found in a range of 5–10 μ g/ μ l (Table 2). The concentration of total AAs was as high as 2% of the secretion, although the composition appeared to be variable, probably due to fluctuation of the AA composition in the host plant. Besides AAs, the osmeterial fluid contained glycerol (80 μ g/ μ l), myoinositol (10 μ g/ μ l), inosine (25 μ g/ μ l), adenosine (5 μ g/ μ l), and guanosine (2 μ g/ μ l).

Pupae. The composition of AAs in a whole body extract of *A. alcinous* pupae is shown in Figure 3. All seven AA analogs were present in the extract. The analysis of a hexane–acetone rinse of pupae revealed that a portion of the AAs was deposited on the cuticular surface. The cuticular rinse seemed to contain relatively higher quantities of minor AA analogs (III and E) than were found in the body tissue (Table 2).

Adults. Male and female butterflies were analyzed separately. The HPLC profiles were not much different between the sexes, in which AA-I and II were found in almost equal quantities (Figure 3). The content of total AAs in one female was found in a range of 100–180 μ g, and that in one male was 50–120 μ g (Table 2). The quantities of AAs in the adults seemed to be proportional to their body weight.

Eggs. Eggs of *A. alcinous* are onion shaped with a rough coating of resin-like material (Figure 2B, left). However, the eggs found in the oviducts are round and lack coating material (Figure 2B, right, and 2C). A bright orange-colored material contained in the reservoir organ (glandulae sebaceae) seems to

<i>Aristolochia debilis</i> (1 g)	320	180	25	160	15	5	170

be squeezed out during egg deposition to coat the egg surface, gluing it to the leaf. The egg coating can be readily scraped off while fresh, but it gradually becomes hard within a few hours. Thin-layer chromatography revealed that the chemical composition of the egg coating was identical to that of the viscous material contained in the reservoir organ, both being composed mainly of unidentified polar lipids. As shown in Table 2, acidic fractions of both egg coating and the glands contain AA-I and II almost in equal quantities but the other analogs were much less abundant or absent. Similarly, egg yolk also contained high concentrations of AA-I and II. A liquid chromatogram of the whole egg is shown in Figure 3.

Deterrent Effect of AAs to Sparrows. Deterrent effects of AAs were examined by the rice-grain feeding test. The rice grains treated with AA-I strongly deterred feeding of the tree sparrow, *Passer montanus*. The average number of grains remaining from an initial sample of 30 grains was 16.6 ± 10.9 at a dose of $3 \mu\text{g}/\text{grain}$, while the control grains were all consumed. AA-B also exhibited moderate deterrence to sparrows.

DISCUSSION

Aristolochic acids are secondary metabolites contained characteristically in the plant genus *Aristolochia*. Nine AA analogs, namely I(A), Ia, II, III, IV, B, C(IIIa), D(IVa) and E, have heretofore been known from plants. All contain

a 3,4-methylenedioxy-10-nitrophenanthrene-1-carboxylic acid structure with different functional groups at positions C-6, C-7, and C-8 (Mix et al., 1983). Among these, seven AA analogs have been verified here from the leaves of *A. debilis* as the larval feeding stimulants for a Japanese pipevine swallowtail butterfly, *A. alcinous*. AAs did not induce the phagostimulant activity by themselves, but acted synergistically in combination with unidentified component(s) in the aqueous layer. AAs have also been characterized as synergistic factors for oviposition stimulants of *A. alcinous* (Nishida and Fukami, 1989). Considering the rare distribution of AAs in the plant kingdom, it would be an efficient cue, although both stimulants are composed of multiple components. The coincidence of oviposition and larval feeding stimulants has been found in the case of pierid butterflies in which glucosinolates act as the specific stimulants (Verschaffelt, 1911; David and Gardiner, 1962).

AAs have been recognized as factors responsible for toxicity and other biological activities shown by *Aristolochia* plants (Kupchan and Wormser, 1965; Kupchan and Merianos, 1968; Moretti et al., 1979). These plants seem to have developed the rare nitrophenanthrene skeleton as chemical barriers against herbivores (Miller and Feeny, 1983). *A. alcinous* not only uses them as a host-finding cue, but also utilizes the analogs as defense substances throughout all stages of its life.

Sequestration of AAs in the adult bodies has been demonstrated among several troidine species, namely *Pachliopta aristolochiae* (Euw et al., 1968), *Battus archidamas* (Urzúa et al., 1983), and *B. polydamas* (Urzúa and Priestap, 1985), and also in an *Aristolochia*-feeding Parnassiinae, *Zerynthia polyxena* (Rothschild et al., 1972). The composition of AA analogs in each insect species varied, probably depending on the variation of AA contents in their host plants, and differences of the physiological properties in the process of sequestration. Although six AA analogs were detected from both male and female adults of *A. alcinous*, the total AA content was much higher in the female specimens, in which concentration seemed to be more or less dependent on body weight. These *Aristolochia*-feeders exhibit aposematic coloration, which suggests unpalatability against predators (Brower, 1984). In addition, the occurrence of mimic species strongly implies chemical protection afforded by AAs. Feeding deterrence of AAs to sparrows clearly suggests its defensive role against vertebrate predators. AAs seemed to play a role as a gustatory cue, but further effects of AAs as noxious emetic or toxic agents against natural enemies remain to be clarified. A preliminary feeding bioassay, however, indicated that crude extracts of butterflies and osmeterial secretion induced much stronger deterrence against sparrows, suggesting the presence of an additional chemical factor(s) incorporated besides AAs. Male adults of *A. alcinous* emit a distinguishable floral odor which is composed of a mixture of phenylacetaldehyde, linalool, and other minor

volatile components (Honda, 1980a). The characteristic odor may function as an olfactory aposematic cue in addition to its visual aposematism.

Larvae of *A. alcinous* sequester extraordinarily high concentrations of AAs in the osmeteria, exhibiting HPLC profiles similar to those of fresh leaf extracts of *A. debilis*. The concentration of total AAs in the fluid was approximately 2%. In addition, the osmeterial fluid contained 8% glycerol, 3% nucleosides (inosine, adenosine and guanosine), and 1% myoinositol as the aqueous components. In contrast to irritant fatty acid components commonly found in the last-instar larvae of *Papilio*, the osmeterial secretion of *A. alcinous* larvae contains sesquiterpene volatiles (Honda, 1980b). The extremely bitter taste of the secretion in this species seems to play an initial defensive role against predators. Although the osmeterial fluid contains such a variety of ingredients, the biological functions of each individual component remain to be determined.

The pupae of *A. alcinous* exhibit seasonal color dimorphism. The diapausing pupae are mostly grayish brown, matching the background color, and nondiapausing summer pupae are aposematic bright yellow with some red spots on the back. Deposition of AAs on the cuticular surface may be effective only by contact toward certain predatory and/or parasitic attacks. Obnoxious smell and noise production of the pupae may also account for the warning signs.

Eggs of *A. alcinous* are an aposematic reddish orange color with a rough coating of resin-like material. The chloroform-soluble fraction of the coating contained unidentified viscous lipids as the major components. A mixture of AA-I and II was found both in the egg coating and yolk. No other AAs were found in significant quantity. This may be due to the difference in the stability of AAs in the body tissue during storage. The egg coating is stored in an extraordinarily large quantity in the mother's reservoir organ, which seems to be characteristically well developed among many troidine species. A large portion of AAs in the female butterflies is thus concentrated in the reservoir and transferred efficiently to the next generation. Similarly, mustard glucosides are known to occur in the eggs of pierid butterflies, and cardiac glycosides in danaid eggs (Brower, 1984). The eggs of *A. alcinous* are often laid as a cluster. This may create a more effective warning signal to certain enemies than that of solitary eggs.

The larvae of *A. alcinous* often display cannibalistic behaviors toward eggs and pupae. Deposits of AAs on egg and pupal surfaces seem to trigger cannibalistic activity. A newly hatched first-instar larva quickly gains weight by feeding on neighboring eggs (Figure 2D). Similar behavior also occurs in other *Aristolochia*-feeding swallowtails (Young, 1977; Brown et al., 1980), danuids (Brower, 1961), and a *Heliconius* butterfly (Williams and Gilbert, 1981). Population control by cannibalism at high density might be of ecological significance since low predation due to their unpalatability sometimes results in

catastrophic outbreaks of these "poisonous" species. Although the specific kairomonal and allomonal activities discussed above may not be determined solely by AAs at each step, the presence of AAs seems to have opened up an ecological niche for *A. alcinous*.

Acknowledgments—We thank Professor emeritus M. Tomita of Kyoto University for authentic samples of AA-B and C. We are also grateful to Dr. Z.H. Chen for sending us spectral data of 7-hydroxyaristolochic acid A (AA-B) and 7-methoxyaristolochic acid A (AA-E). Measurements of 200 MHz [¹H]NMR spectra were done by Dr. T. Harayama of Kyoto University. We wish to thank Dr. Z. Kumazawa and Dr. Z. Yamashita of Mie University for their advice and support at the initial stage of this study. We wish to thank Dr. P.P. Feeny, Cornell University, for useful comments on the manuscript.

OVIPOSITION STIMULANTS OF AN
ARISTOLOCHIACEAE-FEEDING SWALLOWTAIL
BUTTERFLY, *Atrophaneura alcinous*

RITSUO NISHIDA and HIROSHI FUKAMI

(Received June 14, 1988; accepted January 13, 1989)

Abstract—Oviposition stimulants of an Aristolochiaceae-feeding swallowtail butterfly, *Atrophaneura alcinous*, were isolated from the leaves of *Aristolochia debilis* and characterized as a mixture of aristolochic acids and sequoyitol. An artificial blend of these components applied to filter paper induced a significant oviposition response by the female butterflies, identical to that elicited by intact leaves of the *Aristolochia* host plant.

Key Words—Oviposition stimulant, host selection, butterfly, Lepidoptera, Papilionidae, *Atrophaneura alcinous*, *Aristolochia debilis*, aristolochic acid, sequoyitol, synergist.

INTRODUCTION

A Japanese pipevine swallowtail butterfly, *Atrophaneura alcinous* Klug (Papilionidae) feeds exclusively on the plant family Aristolochiaceae. The females lay eggs very accurately on the *Aristolochia* vines. Nishida (1977) demonstrated that methanolic extracts of the host plant, *Aristolochia debilis* Sieb. et Zucc., strongly induce oviposition by *A. alcinous* females (Figure 1). The oviposition stimulant activity of the extract appeared to be highly specific in the genus *Aristolochia*, and the female butterflies detect the essential component(s) by contact receptors located on the fifth segments of the foretarsi (Nishida, 1977). Although visual and olfactory cues are also involved at the initial phase of oviposition behavior of papilionid butterflies (Vaidya, 1969; Saxena and Goyal, 1978; Rausher, 1978), nonvolatile contact chemical stimuli play a decisive role

FIG. 1. Oviposition response of an *Atrophaneura alcinous* female to a piece of filter paper treated with the methanolic extract of *Aristolochia debilis*. The female curled her abdomen and laid eggs immediately after touching the filter paper with the tarsal chemoreceptors located on her forelegs.

after landing on the host-plant leaves (Nishida, 1977; Ichinosé and Honda, 1978; Feeny et al., 1983), and the essential components responsible for the oviposition have been characterized for two Rutaceae-feeding swallowtail species, *Papilio xuthus* (Ohsugi et al., 1985, Nishida et al., 1987) and *P. protenor* (Honda, 1986). A large number of papilionids are associated with Aristolochiaceae as well as Rutaceae. Thus, it is of great interest to compare the profiles of oviposition stimulants among these two major oligophagous groups, namely Aristolochiaceae feeders and Rutaceae feeders. Here we describe the isolation and characterization of the oviposition stimulants of *A. alcinous* contained in the leaves of *A. debilis*.

METHODS AND MATERIALS

Insects. *A. alcinous* at various stages were collected in Kyoto and Mie prefectures and reared for several generations on *A. debilis* vines mostly under a short photoperiod (10:14 light-dark, 22–26°C). The diapausing pupae were stored in a refrigerator (0–7°C) until use. The butterflies after adult eclosion at around 24°C were hand-paired within two days. The mated females were indi-

vidually confined in small screen cages (16:8 light-dark photoperiod) and fed a sucrose solution (5–10%) daily.

Oviposition Bioassay. The bioassay chamber (50 × 50 × 50 cm) was open in front and its interior was illuminated by a fluorescent lamp (15 W) placed behind a screen at the rear. Test samples were applied to a piece of filter paper (approximately 10 cm²) by cutting a round filter paper (9 cm diameter) into six equal fan-shaped pieces. Aliquots of 100 μl of each concentration of the sample were applied to the filter paper and allowed to dry. Doses were expressed either as gram leaf equivalents per 10 cm² of filter paper (GLE/FP) or as the absolute amount applied to the filter paper (μg/FP). Test filter papers were misted with distilled water immediately before the bioassay. Each female butterfly (3–10 days old) was placed in turn on the filter paper and kept in contact with it as much as possible during 30 sec (Figure 1). Females usually responded immediately to the standard methanolic extract of *A. debilis* (0.03 GLE/FP), curling their abdomens, and eventually laying eggs. Any females either giving a positive response to a moistened blank filter paper or giving no response to the standard methanolic extract were rejected from the test. The activity was evaluated by the percentage of females that gave a positive response at given doses. The bioassay was conducted during daylight hours.

Extraction and Fractionation. Leaves and stems of *A. debilis* (1.8 kg) were collected in Kyoto Prefecture during July 1983 and extracted with methanol (12 liters). Evaporation of the extract gave a viscous oil (83 g). An aliquot of the methanolic extract (23 g, 500 GLE) was dissolved in water (500 ml) and washed with ether (300 ml × 3), followed by ethyl acetate (150 ml × 3), and butanol (200 ml × 3) as shown in Figure 2. The yields of the ether, ethyl acetate, butanol, and water layers were 6.20, 0.20, 1.51, and 19.47 g, respectively. The ether layer was fractionated into acidic (0.20 g), basic (0.02 g), and neutral (5.79 g) fractions by using saturated sodium bicarbonate and 2 N hydrochloric acid. The water layer (2 g, 50 GLE) was dissolved in 2% acetic acid in water (5 ml) and chromatographed on a reverse-phase column (20 g of ODS-W, microbead silica gel 5D, 100–200 mesh, Fuji-Davison Chemical Ltd., packed in water, 120 mm × 20 mm ID) eluted in sequence with 100 ml of 1% acetic acid in water (W-1), 1% acetic acid + 10% methanol in water (W-2), 1% acetic acid + 40% methanol in water (W-3), and 1% acetic acid in methanol (W-4). The yield of W-1 was 1.64 g.

Instruments. Mass spectra were obtained with a Hitachi M-80 mass spectrometer. The infrared (IR) spectrum was recorded with a Shimadzu IR-400 spectrometer. [¹H]- and [¹³C]NMR spectra were obtained with a JEOL JNM FX-90Q spectrometer (90 MHz) using either DSS (for D₂O solution) or TMS (for CDCl₃ solution) as the internal standards.

Isolation of Aristolochic Acids (AAs). Four analogs of AAs (I, II, B, and C) were isolated from the ether soluble acidic fraction by means of high-per-

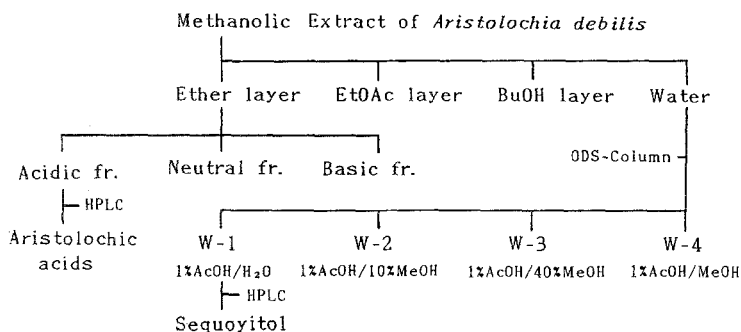

FIG. 2. Procedure for separation of the methanolic extract of *Aristolochia debilis*.

formance liquid chromatography (HPLC) using a reverse-phase column (μ Bondapak, 10 μ m, Waters Associates, 100 mm \times 8 mm ID, eluting with a mixture of methanol–formic acid–water = 66:1:33, at 3 ml/min). The retention times (R_t), melting points (mp; decomposed points) and yields (per 1 GLE) of AAs are as follows. AA-I: R_t = 7.0, mp = 280°C, yield = 120 μ g. AA-II: R_t = 4.8 min, mp = 268°C, yield = 40 μ g. AA-B: R_t = 3.4 min, mp = 274°C, yield = 80 μ g. AA-C: R_t = 2.7 min, mp = 272°C, yield = 10 μ g (Nishida and Fukami, 1989).

Isolation of Sequoyitol. Fraction W-1 was separated into 11 fractions on an HPLC column (YMC-Pack PA-24, 300 mm \times 8 mm ID, 67% acetonitrile in water, 3 ml/min) as shown in Figure 3. Fraction 5 was found to contain an active principle, sequoyitol, in high purity. In order to obtain a larger quantity of sequoyitol, the water layer (100 GLE) was passed successively through a column of cation-exchange resin (Amberlite CG-50, type 1, 160 mm \times 20 mm ID) and anion-exchange resin (Dowex-1 \times 8, 200–800 mesh, conditioned with formic acid, 150 mm \times 30 mm ID), both eluted with 500 ml of distilled water. The nonretained (neutral) fraction (1.77 g) was then chromatographed on a column of active charcoal (30 g, 160 mm \times 32 mm ID, Wako Pure Chemical Industries Ltd.) eluted with water. After elution of 300 ml of water, the remaining 100 ml eluate (42 mg) was crystallized from 70% methanol in water to yield colorless prisms of sequoyitol (yield 23 mg, mp 239–240°C).

Analysis. Found: C, 43.03%; H, 7.43%; O, 50.00%. Calcd. for $C_7H_{14}O_6$: C, 43.30%; H, 7.27%; O, 49.44%. IR: ν (nujol) 1263, 1185, 1130, 1105, 1070, 1055, 1025, 940, 930, 885. 1H NMR: δ (D_2O) 3.99(1H, triplet, J = 2.5 Hz), 3.66(2H, triplet, J = 9 Hz), 3.54(3H, singlet), 3.26(2H, double doublet, J = 2.2 and 9 Hz), 3.30(1H, triplet, J = 9 Hz). ^{13}C NMR: δ (D_2O) 86.54(C-5), 74.41(C-2), 74.11(2 \times C), 73.60(2 \times C), 61.89(OCH₃).

Sequoyitol Pentaacetate. Sequoyitol (13 mg) isolated from *A. debilis* was acetylated in a mixture of acetic anhydride (1.5 ml) and pyridine (1.5 ml) to

[^{13}C]NMR: δ ($CDCl_3$) 169.81, 169.59, 169.38, 80.12, 70.70, 68.88, 68.45, 59.94, 20.64, 20.37.

RESULTS

The components responsible for stimulating oviposition of *A. alcinous* were efficiently extracted with methanol from its host plant, *A. debilis*. As shown in Figure 4, the oviposition stimulant activity of the methanolic extract was dosage

FIG. 4. Dose oviposition responses of the methanolic extract of *Aristolochia debilis*, aristolochic acid I(AA-I), sequoyitol, and a mixture of the two.

dependent, and 100% positive responses were obtained at doses of 0.01 GLE/FP and higher. The methanolic extract was separated into ether, ethyl acetate, butanol, and water layers by solvent extraction (Figure 2). The water layer was found to be the only fraction that showed significant oviposition activity by itself, but the activity appeared to be considerably lower than that of the original methanolic extract (Table 1). The original activity of the extract, however, was almost fully recovered when the ether layer was added in an equivalent dosage (0.01 GLE/FP) to the water layer. The synergistic factors contained in the ether layer were acidic in nature (Figure 2 and Table 1). The acidic fraction was found to consist mainly of several analogs of aristolochic acids (AAs). Seven AA analogs, namely I, II, III, B, C, D, and E, have been identified from *A. debilis* (Tomita and Sasagawa, 1959; Chen et al., 1981; Nishida and Fukami, 1989). All of the AA analogs bear a nitro, a carboxylic acid, and a methylenedioxy group on the phenanthrene ring, but the functional groups on the upper ring differ from one structure to another. The two major analogs, AA-I and AA-B, were found to act as synergists of oviposition activity, when combined with the water layer. As shown in Table 2, both AAs were inactive alone, but a remarkable enhancement of the activity was observed when either AA-I or AA-B was added to the water layer at a threshold dose (0.003 GLE/FP) (Scheme 1).

The oviposition stimulant(s) in the aqueous layer was examined in combination with AA-I. The water layer was chromatographed on a reverse-phase column into four fractions, eluted with mixtures of acetic acid, methanol, and

water (Figure 2). Fraction W-1 exhibited weak but significant activity by itself at a 0.03 GLE dose, and its activity was markedly enhanced by adding AA-I (3 $\mu\text{g}/\text{FP}$) (Table 2). The active substance in W-1 was efficiently separated by a partition mode HPLC, as shown in Figure 3. Among the 11 fractions, only fraction 5 exhibited distinct activity in the presence of AA-I. The activity of fraction 6 appeared to be due to a tailing effect of the active peak in fraction 5. The pure active substance in the HPLC fraction was obtained in larger quantities by a combination of ion-exchange and charcoal columns, followed by recrystallization (mp 239–240°C). The content of the active compound was approximately 800 $\mu\text{g}/\text{GLE}$. The molecular formula of the compound was determined to be $\text{C}_7\text{H}_{14}\text{O}_6$ by an elemental analysis. It gave a pentaacetyl deriv-

ative (mp 197–198°C, m/z 404, in-beam MS). The [^1H]NMR [^{13}C]NMR spectra of both original and pentaacetyl compounds indicated the presence of an equatorial methoxy group attached to a cyclitol ring. The coupling constants in the [^1H]NMR spectra clearly provided the stereochemical relationship between adjacent methines. Thus the active compound was unequivocally assigned as sequoyitol (5-*O*-methyl-myoinositol) (Ohmoto et al., 1979; Binder and Had-don, 1984).

Figure 4 shows the dose responses of AA-I, sequoyitol, and a mixture of both in a leaf equivalent base, where the actual contents of AA-I and sequoyitol in the *A. debilis* extract were tentatively estimated to be 100 μg and 800 μg per gram of leaf, respectively. In contrast to AA-I alone, sequoyitol showed some stimulatory activity by itself at relatively high doses. When both were mixed together, it gave distinct activity and exhibited a typical dose–response curve. A 100% positive oviposition response was obtained at a dose of 0.1 GLE/FP or higher. However, the dose–response of the mixture still appeared to be lower than that of the original methanolic extract of *A. debilis*. The difference between the mixture (AA-I + sequoyitol) and the methanolic extract is considered to be

^aResponse significantly greater than that of the water layer alone.

^bResponse significantly greater than that of W-1 alone.

^cResponse significantly different both from aristolochic acid I (3 μg) alone and sequoyitol alone (chi-square 2 \times 2 test of independence with Yates' correction, $P < 0.01$).

partly due to the absence of other AA analogs besides AA-I in this bioassay series, but there are also some other additional factors present in the aqueous fraction (Nishida and Fukami, unpublished). The activity of AA-I, II, B, and C in combination with sequoyitol are summarized in Table 2. All of the AAs were shown to act significantly as synergists. Myoinositol did not induce the oviposition response in combination with AA-I, although it is one of the cyclitol constituents of *A. debilis* (approximately 800 $\mu\text{g}/\text{GLE}$).

DISCUSSION

Four analogs of aristolochic acids (AA-I, II, B, and C) and sequoyitol have been characterized here as oviposition stimulants for *A. alcinous*. Each individual component was inactive or only weakly active alone, but distinct oviposition activity was generated when either one of the AA analogs was mixed with sequoyitol. AAs are secondary metabolites contained characteristically in the genus *Aristolochia* (Mix et al., 1983). Considering the rare distribution of AAs in the plant kingdom, it would be an efficient chemical cue for the butterflies to recognize the host plant. In contrast to AAs, sequoyitol seems to be more commonly distributed in the plant kingdom, although it has been reported mostly from the Gymnospermae (Sato et al., 1966; Anderson et al., 1968, Cranswick and Zabkiwicz, 1979; Ohmoto et al., 1979; Binder and Haddon, 1984; Murakami et al., 1985). Sequoyitol is an *O*-methyl derivative of myoinositol, but myoinositol itself was found to be entirely inactive when admixed with AA-I, suggesting a fairly specific structural requirement. The simultaneous occurrence of AAs and sequoyitol in the plant seems to ensure an extremely high specificity for *A. alcinous* oviposition.

A. alcinous sequesters AAs in the body tissues or specialized organs throughout all stages from the egg to the adult (e.g., egg coating and larval osmeteria), and utilizes AAs as a defense against certain predators (Nishida and Fukami, 1989). AAs also synergize larval feeding activity (Nishida and Fukami, 1989). An assessment of the host-plant quality at both oviposition and larval feeding stages could guarantee consequent protection. Ecological adaptation of *A. alcinous* seems to be strongly associated with a sensory mechanism specifically developed for perception of AAs.

The chemical basis of oviposition behavior of papilionid butterflies has been extensively studied, particularly among the genus *Papilio*. A variety of flavonoid glycosides together with other polar components has been clarified as oviposition stimulant components of two Rutaceae-feeding swallowtail species, *Papilio xuthus* (Ohsugi et al., 1985; Nishida et al., 1987) and *P. protenor* (Honda, 1986). The importance of the multiple-component system has been emphasized in both cases. Feeny (1987) also reported a flavonoid as a key

substance of the oviposition stimulants for an Umbelliferae-feeding swallowtail, *P. polyxenes*. The contribution of the flavonoid components for *A. alcinous* oviposition, however, has not been clarified, although the butanol layer of *A. debilis* extracts contains a large quantity of rutin (600 $\mu\text{g}/\text{GLE}$), which is known as an oviposition stimulant for *P. xuthus* (Nishida et al., 1987).

More than 80 species in the family Papilionidae are associated with the family Aristolochiaceae. They are considered to represent remnants of the stock from which the rest of the Papilionidae evolved (Ehrlich and Raven, 1964). Seventy species of the tribe Troidini feed on Aristolochiaceae, but some (eight species) have been recorded from Rutaceae (Feeny et al., 1983). The oviposition stimulant, sequoyitol, is a cyclitol closely related to chiro-inositol that has been characterized as an oviposition stimulant component for *P. xuthus* (Ohsugi et al., unpublished). During the food-assessment phase of oviposition behavior, such underlying chemical similarity might have opened a new adaptive zone for the papilionid butterflies. A systematic survey of swallowtail oviposition stimulants may provide an evolutionary view of host specificity in the phylogenetic tree of the Papilionidae.

Acknowledgments—We thank Professor Z. Kumazawa of Mie University and Professor Z. Yamashita for their advice and support, particularly at the initial stage of this study. We are also grateful to Professor P.P. Feeny, Cornell University, for useful comments on the manuscript.

(*S*)-2-PENTADECYL ACETATE AND 2-PENTADECANONE
Components of Aggregation Pheromone of
Drosophila busckii

Abstract—(*S*)-2-Pentadecyl acetate and 2-pentadecanone were identified as the major aggregation pheromone components in *Drosophila busckii*. Both sexes of flies were attracted equally in a wind-tunnel olfactometer. The flies also responded to racemic 2-pentadecyl acetate but not to the pure *R* enantiomer. In bioassay, (*S*)-2-pentadecyl acetate and 2-pentadecanone were each active alone, and a mixture of both increased the number of flies responding ca. twofold. The aggregation pheromone components are found in the ejaculatory bulb of sexually mature males and are transferred primarily to the female cuticle during mating. One third of the pheromone transferred is released by the female to the surrounding environment in a few hours after mating. None of the aggregation pheromone components remained on the mated female's cuticle, leaving two thirds unaccounted for. The same results were obtained when racemic 2-pentadecyl acetate was topically applied to immature and mature virgin males and females. Both *D. mulleri* and *D. busckii* were attracted to (*S*)-2-acetates of 13, 14 and 15 carbons, but *D. mulleri* preferred (*S*)-2-tridecyl acetate and *D. busckii* preferred (*S*)-2-pentadecyl acetate.

Key Words—*Drosophila busckii*, *D. mulleri*, Diptera, Drosophilidae, aggregation, pheromone, (*S*)-2-pentadecyl acetate, 2-pentadecanone, chiral.

INTRODUCTION

Male-produced aggregation pheromones have been identified in a number of *Drosophila* species (Bartelt and Jackson, 1984; Bartelt et al., 1985a,b, 1986, 1988, 1989; Moats et al., 1987; Schaner et al., 1987, 1989a, b,c). Active compounds have included hydrocarbons, esters, and ketones. Mixtures of two or more compounds have often been required for optimum aggregation activity.

Drosophila busckii was chosen to continue *Drosophila* pheromone research since it is the only member of the subgenus *Dorsilopha* and we hoped to encounter new compounds that had not previously been identified as aggregation pheromones in other species studied. Here we report the identification, transfer, and bioassay characteristics of the aggregation pheromone of *D. busckii*.

METHODS AND MATERIALS

Flies. *D. busckii* (strain 13000-0081.0) was obtained from the National *Drosophila* Species Resource Center at Bowling Green, Ohio. They were originally collected at Heredia, Costa Rica. Flies were reared on Formula 4-24 Instant *Drosophila* Medium (Carolina Biological Supply House, Burlington, North Carolina) in 1-liter jars, 60-ml vials, or 10-ml test tubes under a 16 : 8 light-dark cycle and 23°–25°C.

Age of Maturity. Methods used to determine age of maturity of males and females have been described previously (Moats et al., 1987). Age of maturity of males is important because in other *Drosophila* species studied, pheromone production begins as the males approach sexual maturity. Male *D. busckii* become sexually mature at 2–3 days of age and females at 1–2 days of age. Therefore, 0 to 2-day-old flies were used for bioassays because the immature males would be less likely to produce pheromone that could compete with bioassay treatments. Six- to 7-day-old flies were used for extracts to ensure optimum levels of pheromone production.

Extracts and Chromatography. Flies were separated by sex when 0–16 hr old, maintained in 60-ml food vials to 6 to 7 days old, and extracted by soaking the flies in hexane at room temperature for 24 hr. The crude extracts were fractionated on open columns of silica gel (100–200 mesh; Bio-Rad) (Bartelt and Jackson, 1984) eluted with: hexane; 10% ether in hexane; 50% ether in hexane; and 10% methanol in methylene chloride.

Gas chromatography (GC) was conducted on a Varian 3700. For preparative GC, a 1.3-m × 4-mm 5% SE-52 column was used, and the effluent monitored with a thermal conductivity detector. A 15-m × 0.53-mm-ID Megabore DB-1 (J & W Scientific), and a 50-m × 0.2-mm-ID HP-1 narrow-bore capillary column (Hewlett-Packard) were utilized for analytical GC.

Electron impact mass spectra were obtained on a VG-MM16 mass spectrometer using a 30-m \times 0.25-mm-ID DB-5 capillary GC column for introduction of the sample.

Bioassay. Bioassays were conducted in a wind-tunnel olfactometer (23°–25°C) containing ca. 1000 flies (0–2 days old) that had been without food or water for approximately 2 hr (Bartelt and Jackson, 1984). An extract, fraction of an extract, synthetic compound, or control solvent was applied to a filter paper strip inserted around the lip of a glass vial. Each bioassay test consisted of placing two differently treated vials, to be compared, into the upwind end of the olfactometer for 3 min. When an experiment included more than two treatments, they were tested in pairs, in all possible combinations (a balanced incomplete block design). After 3 min, the vials were capped, removed, and the captured flies were sexed and counted. Tests were separated by 7–10 min, and as many as 50 tests could be run in a day after stocking the olfactometer once.

The bioassay data were transformed to the log ($X + 1$) scale before analysis to stabilize variance; analysis was done by the method of Yates (1940).

Production, Transfer, and Dispersal of Pheromone. Methods for the analysis of production of pheromone have previously been described (Schaner et al., 1989a). Briefly, ejaculatory bulbs were removed from male flies at various ages, extracted with hexane and analyzed by GC relative to an internal standard.

The transfer of (*S*)-2-pentadecyl acetate and 2-pentadecanone from males to females during mating and the subsequent release of the pheromone components from the females were investigated. Flies were separated by sex at 0–6 hr of age. Virgin male flies were raised individually in 10-ml test tubes that contained food medium. Virgin females were raised ca. 50 per 60-ml vial that contained food medium. At 6–7 days of age, when pheromone production for the male is optimum, a virgin female was aspirated without anesthesia into the test tube occupied by the virgin male where she remained until mating took place. After completion of mating, the male and female were separated, and in sets of three flies, either extracted or placed into empty 8-ml glass vials fitted with wire mesh caps for 6 hr and then extracted. Extraction consisted of removing the female reproductive tract or the male ejaculatory bulb and ducts, followed by a 5-min cuticular soak of the fly in 30 μ l of hexane. The glass vials used to evaluate recovery of any pheromone that had been released were rinsed with 500 μ l of hexane. Comparable sets of extracts were obtained from males and females that had not been allowed to mate. Each extract was replicated three times. The amount of pheromone components was quantified by GC relative to an internal standard of nonadecane.

Application of Racemic 2-Pentadecyl Acetate to Immature and Mature Virgin Males and Females. Immature virgin flies (2–3 hr) or mature virgin flies (6–8 days) were refrigerated for ca. 10 min to facilitate handling and placed in a Petri dish that was in direct contact with crushed ice. Using a 1.0- μ l syringe,

0.2 μ l of acetone containing 750 ng racemic 2-pentadecyl acetate for the immature flies or 550 ng racemic 2-pentadecyl acetate for the mature flies was applied to the posterior end of the fly's abdomen. Treated flies were put into empty 8-ml glass vials fitted with wire mesh caps (three flies per vial). At specific time intervals over a 6-hr period, three sets of flies were extracted. Extraction consisted of soaking the flies in 30 μ l of hexane for 5 min and rinsing the vials with 500 μ l of hexane. Each was analyzed using GC relative to an internal standard of nonadecane. Mature males possess (*S*)-2-pentadecyl acetate, therefore as a control, comparable extracts of mature males without racemic 2-pentadecyl acetate topically applied were obtained. The amount of (*S*)-2-pentadecyl acetate in each control extract was subtracted from the amount of racemic 2-pentadecyl acetate in the corresponding extract of males that had racemic 2-pentadecyl acetate applied to their cuticle.

Synthetic Ketone and Esters. Synthesis of the methyl ketone (2-pentadecanone) and esters [racemic 2-pentadecyl acetate, (*S*)-2-pentadecyl acetate, (*R*)-2-pentadecyl acetate and (*S*)-2-tetradecyl acetate] have been described in detail previously (Moats et al., 1987; Bartelt et al., 1989, and references therein). Methods were the same except tetradecanal was substituted for dodecanal when synthesizing racemic 2-pentadecyl acetate and 1-bromododecane or 1-bromoundecane was substituted for 1-bromodecane when reacted with the appropriate stereoisomer of lactate to synthesize (*S*)- and (*R*)-2-pentadecyl acetate or (*S*)-2-tetradecyl acetate. (*S*)-2-Tetradecyl acetate and (*S*)-2-tridecyl acetate (on hand from previous work with *D. mulleri*) were used in bioassay to test the flies' response to esters of various chain lengths with asymmetric centers. After silicic acid chromatography and preparative GC, the methyl ketone and synthetic esters were >98% pure.

Absolute Configuration. Diastereomeric esters from synthetic racemic, (*S*)-, (*R*)-, and male-derived 2-pentadecyl acetate were prepared as described previously (Bartelt et al., 1989, and references therein). Briefly, the acetates were reduced with LiAlH_4 to form the alcohol and derivatized with (*S*)-(2-acetyloxy)propanoyl chloride (Slessor et al., 1985). GC analysis was on a 50-m \times 0.2-mm-ID HP-1 narrow-bore capillary column (Hewlett-Packard) programmed from 150 $^\circ$ to 280 $^\circ$ C at 2 $^\circ$ /min.

RESULTS

Bioassay Characteristics. When the flies were first introduced into the olfactometer, they formed tight clusters in the upper corners with little movement and only a few in flight. Within 2 hr, the flies dispersed on the sides and back screen of the olfactometer, with ca. 20–30 flies in flight at any given time. Response to an attractive treatment included an increase in the number of flies

in flight, an upwind zigzag flight to the vial, hovering within a few inches of the vial, alighting on or near the vial, and walking to the lip of the vial where the majority proceeded down the inside of the vial.

Identification of Pheromone Components. The crude extract of male *D. busckii* was clearly active in bioassay, while the crude extract of females was inactive (Table 1). Both sexes responded similarly to all preparations discussed in this report.

After chromatography of the crude extract of males on silicic acid, only the 10% ether-hexane fraction was substantially more active than controls (Table 1). The 10% ether-hexane fraction from males contained only two detectable compounds as analyzed by capillary GC. From retention times of aggregation pheromone components of *D. mulleri* and *D. hydei* (Bartelt et al., 1989; Moats et al., 1987), the first of the two compounds (287 ng/fly) was tentatively identified as 2-pentadecanone. Gas chromatography-mass spectra (GC-MS) confirmed this identification. Mass spectra of the second compound (1067 ng/fly) appeared similar to mass spectra of (*S*)-2-tridecyl acetate, an aggregation pheromone component of *D. mulleri* (Bartelt et al., 1989), except it was two carbons greater in chain length. Synthetic racemic 2-pentadecyl acetate had identical GC retention times (DB-1) and mass spectra. Racemic 2-pentadecyl acetate was active in bioassay (Table 2, A).

The fly-derived 2-pentadecyl acetate, with one asymmetric center, was analyzed for absolute configuration. The two diastereomers derived from racemic 2-pentadecanol were easily separated on the HP-1 narrow-bore capil-

TABLE 1. ACTIVITY OF SILICA GEL FRACTIONS AND EXTRACTS RELATIVE TO CRUDE EXTRACT OF MALE *D. busckii*

Extract or fraction ^a	Relative response (<i>N</i> ≥ 8) ^b
Crude extract of males	100*** ^c
Hexane fraction	5 (3.0, 4.0, 23.5) ^d
10% Ether-hexane fraction ^e	92***(0.9, 38.3, 41.5)
50% Ether-hexane fraction	2 (0.7, 1.1, 17.5)
10% Methanol-methylene chloride	19* (6.5, 16.0, 56.5)
Crude extract of females	2 (0.4, 0.7, 16.0)

^a All extracts and fractions were used at one fly equivalent per test.

^b Relative response = (fraction - control)/(crude extract of males - control) × 100.

^c 100 by definition. * and *** denote significance of *t* tests vs. controls at the 0.05 and 0.001 levels, respectively.

^d Mean bioassay catches for control, treatment, and crude extract of males, respectively, shown in parentheses.

^e Because 10% and 50% ether-hexane solvents were attractive, these fractions were taken to dryness under nitrogen and back up in hexane.

TABLE 2. BIOASSAY RESULTS LEADING TO IDENTIFICATION OF ACTIVE COMPOUNDS IN 10% ETHER-HEXANE FRACTION FROM MALE *D. busckii*

Treatment	Mean bioassay catch
A. Preliminary identification of ester component ($N = 12$)	
Control	4.5a ^a
Racemic 2-pentadecyl acetate (1000 ng)	34.9b
B. Determination of active enantiomer ($N = 12$).	
Control	0.7a
(<i>R</i>)-2-Pentadecyl acetate (1000 ng)	0.9a
(<i>S</i>)-2-Pentadecyl acetate (1000 ng)	11.1b
C. Synergism of synthetic ester and ketone ($N = 12$) (ketone and ester were used at 287 and 1067 ng, respectively, per test)	
Control	0.4a
2-Pentadecanone	2.6b
(<i>S</i>)-2-Pentadecyl acetate	9.5c
(<i>S</i>)-2-Pentadecyl acetate + 2-pentadecanone	24.1d
D. Comparison of the male 10% ether-hexane fraction and synthetic ester and ketone ($N = 12$) [both treatments had 1068 ng (<i>S</i>)-2-pentadecyl acetate and 287 ng 2-pentadecanone, ca. 1 fly eq.]	
Control	0.2a
(<i>S</i>)-2-Pentadecyl acetate + 2-pentadecanone	22.1b
Male 10% ether-hexane fraction	17.1b

^aWithin each subheading, means followed by the same letter were not significant at the 0.05 level (LSD). Comparison of means between subheadings are not meaningful because the experiments were done on different days, with different groups of flies.

lary column. Based on the retention times of synthetic standards, the first of these peaks corresponded to the *R* configuration while the second peak corresponded to the *S* configuration. The derivative prepared from the *D. busckii* pheromone component corresponded only to the *S* configuration. *D. busckii* responded in bioassay only to the (*S*)-2-pentadecyl acetate; whereas (*R*)-2-pentadecyl acetate was inactive (Table 2, B).

Dose Study of S-2-Pentadecyl Acetate. Doses of 100 and 1000 ng of (*S*)-2-pentadecyl, along with a control, were compared in bioassay. The mean catches for control, 100 ng (*S*)-2-pentadecyl acetate, and 1000 ng (*S*)-2-pentadecyl acetate were 1.8, 4.7, and 26.0, respectively ($N = 16$). The 100-ng dose of (*S*)-2-pentadecyl acetate was significantly more attractive to the flies than the control, but the response was subtle.

Synergistic Activity of S-2-Pentadecyl Acetate and 2-Pentadecanone. (*S*)-2-Pentadecyl acetate and 2-pentadecanone were active alone in bioassay; however, a two fold increase in the mean number of flies caught was observed when

the ester and ketone were combined (Table 2, C). The combination of (*S*)-2-pentadecyl acetate and 2-pentadecanone accounted for all the activity of the 10% ether-hexane fraction from males (Table 2, D).

Aggregation Activity Specificity to S-2-Acetates of 13, 14, and 15 Carbons. When synthetic (*S*)-2-tridecyl acetate, (*S*)-2-tetradecyl acetate, and (*S*)-2-pentadecyl acetate, along with a control, were compared in bioassay (Table 3), both *D. busckii* and *D. mulleri* responded best to the (*S*)-2-acetate ester they produce. Both species responded to all of the (*S*)-2-acetate esters significantly over controls. The attraction towards the (*S*)-2-acetate esters decreased as the number of carbons increased away from the conspecific acetate ester.

Location and Production of 2-Pentadecanone and S-2-Pentadecyl Acetate. As observed in other *Drosophila* species (Brieger and Butterworth, 1970; Schaner et al., 1987, 1989a, b, c), the ejaculatory bulb of *D. busckii* mature males was the site of storage of the aggregation pheromone components. (*S*)-2-Pentadecyl acetate and 2-pentadecanone increased in concentration from 0 ng/fly at 0-4 hr to a plateau of 1100 and 250 ng/fly, respectively, at day 4 (Figure 1).

Transfer and Dispersal of Aggregation Pheromone Components. Virgin females of any age did not possess (*S*)-2-pentadecyl acetate or 2-pentadecanone (Table 4, A). In mature mated or virgin males, 90% of the aggregation pheromone components are found in the ejaculatory bulb, while 10% are found on the surface of the fly. During mating, males transferred approximately one third of their quantity of aggregation pheromone components to the female. Ninety percent of the (*S*)-2-pentadecyl acetate and 2-pentadecanone was transferred to the female cuticle and only 10% was transferred to the reproductive tract.

TABLE 3. SPECIFICITY FOR ACETATE ESTER STRUCTURE IN AGGREGATION BIOASSAY FOR *D. busckii* AND *D. mulleri*.

Treatment ^a	Mean bioassay catch (N = 12)	
	<i>D. busckii</i>	<i>D. mulleri</i>
Control	0.2a ^b	3.8a
(<i>S</i>)-2-Tridecyl acetate	2.3b	27.3c ^c

(<i>S</i>)-2-Pentadecyl acetate	15.4d ^c	15.4b

^aThe acetate ester treatments were 1000 ng for *D. busckii* and 300 ng for *D. mulleri*.

^bMeans followed by the same letter were not significantly different at the 0.05 level (LSD). Comparisons of means between columns are not meaningful because the experiments were done on different days, with different species of flies.

^cDenotes male-specific acetate ester.

FIG. 1. Pheromone content in the ejaculatory bulb of male flies as they age.

Within 6 hr after completion of mating, approximately one third of the quantity of aggregation pheromone components transferred to the female could be found in the holding vial with none remaining on the female, leaving two thirds unaccounted for (Table 4, B). When a known amount of racemic 2-pentadecyl acetate was deposited in a vial fitted with a wire mesh cap for 6 hr, 91% was recovered. The amount of (*S*)-2-pentadecyl acetate and 2-pentadecanone the female emitted to the holding vial, however, was three times more than a mated or virgin male emitted to the holding vial in a 6-hr period. Six hours after mating, males still had the same quantity of (*S*)-2-pentadecyl acetate (ca. 100 ng/fly) and 2-pentadecanone (ca. 25 ng/fly) on their body surface as virgin males or males that had just finished mating. Also, males that had mated recently or 6 hr previously had the same quantity of the aggregation pheromone components in their ejaculatory bulbs.

Application of Synthetic Racemic 2-Pentadecyl Acetate to Immature and Mature Virgin Males and Females. To acquire some more information on the disappearance of (*S*)-2-pentadecyl acetate, synthetic racemic 2-pentadecyl acetate in acetone was applied to the cuticle of immature and mature virgin males and females. Surface extracts of the flies and a rinse of their holding vials were obtained and analyzed. Racemic 2-pentadecyl acetate rapidly disappeared from the surface of all the flies at virtually the same rate. Within the first hour, racemic 2-pentadecyl acetate rapidly disappeared and the decrease was more gradual for the next 3 hr (Figure 2). After 4 hr, the applied racemic 2-pentadecyl acetate was nearly gone from the cuticle of all the flies. The holding vials contained 20–30% of the applied racemic 2-pentadecyl acetate, and the amount deposited was independent of time.

DISCUSSION

Drosophila busckii have a male-produced aggregation pheromone comprised of two major components identified as (*S*)-2-pentadecyl acetate and 2-pentadecanone. (*S*)-2-Pentadecyl acetate was the most abundant component and the most active in bioassay. (*S*)-2-Pentadecyl acetate is homologous to (*S*)-2-tridecyl acetate, an aggregation pheromone component in *D. mulleri* (Bartelt et al., 1989). This is not the first observation of compounds of a homologous

FIG. 2. Application of synthetic racemic 2-pentadecyl acetate to immature and mature virgin males and females.

series functioning as aggregation pheromone components in different species of *Drosophila*. In the *melanogaster* group, members of the *melanogaster* subgroup use (*Z*)-11-octadecenyl acetate as their aggregation pheromone (Bartelt et al., 1986; Schaner et al., 1987; Schaner et al., 1989c) and members of the *bipunctinata* complex of the *ananassae* subgroup use (*Z*)-11-eicosenyl acetate, which differs in length by two carbons, as their aggregation pheromone (Schaner et al., 1989a, b). 2-Pentadecanone had previously been identified as a minor component of the aggregation pheromone in *D. hydei* (Moats et al., 1987). This is, however, the first observation of (*S*)-2-pentadecyl acetate and 2-pentadecanone produced by a single species and acting as coattractants.

In most of the *Drosophila* species studied to date, the aggregation pheromone components were transferred predominantly to the reproductive tract of the female. In *D. busckii*, however, a major portion of the (*S*)-2-pentadecyl acetate and 2-pentadecanone was transferred onto the surface of the female while only a small portion was found in the reproductive tract. The timing and mechanism of transfer of the aggregation pheromone components from male to female is unknown in *D. busckii*. It does not appear that the transfer is from cuticle to cuticle since the content on the cuticle of males remained nearly constant while there was a dramatic increase on the cuticle of the female.

In just a few hours after copulation, the mated female *D. busckii* no longer has pheromone components on her cuticle. The mated female appears to have transferred a small portion of pheromone components from her cuticle to her surroundings. This is most likely a major process in the release of the pheromone to cause aggregation at or near sites where mating has taken place (Bartelt et al., 1984). The majority of the transferred (*S*)-2-pentadecyl acetate and 2-

pentadecanone disappeared and was not available to stimulate aggregation. Synthetic racemic 2-pentadecyl acetate disappears at the same rate when topically applied to immature and mature virgin males and females. The vapor pressure for the pheromone compounds is too low to account for the loss due to evaporation. It would appear that the cuticle of both female and male *D. busckii* have enzymes that catabolize the pheromone components so that only recently mated females are appreciable emitters of the pheromone.

Catabolism of acetate esters by enzyme(s) on the cuticle has been observed in other species of *Drosophila*. In *D. funebris*, (*Z*)-11-octadecenyl acetate was transferred from the ejaculatory bulb of the male primarily to the female cuticle during mating, where it was rapidly catabolized by the cuticle of the female (Skiba et al., submitted). *D. melanogaster*, *D. virilis*, *D. americana*, *D. buzzatii*, *D. limpiensis*, and *D. macrospina* (Skiba, et al., submitted) virgin females all catabolize (*Z*)-11-octadecenyl acetate (1000 ng in acetone) applied to the posterior end of the abdomen with at least 90% catabolism in 8 hr. This would suggest that mated females only emit the pheromone to the surroundings for a few hours after mating and acetate ester components of the pheromone that are on the cuticle of the abdomen are catabolized to limit the time that a female can emit the pheromone.

The types of compounds (i.e., ketone and acetate ester of a secondary alcohol) that comprise the pheromone of *D. busckii* are like the compounds previously identified as aggregation pheromones in species of the *repleta* group. *D. busckii* employs a two-component blend more like the aggregation pheromone from *D. mulleri*, which employs (*Z*)-10-heptadecen-2-one and (*S*)-2-tridecyl acetate (Bartelt et al., 1989), than *D. hydei*, which employs 2-tridecanone, 2-pentadecanone, and tiglate esters (Moats et al., 1987). The transfer of aggregation pheromone components from male to female *D. busckii* is more like the transfer in *D. funebris* where the pheromone components appear on the cuticle of the female. *D. busckii*, while phylogenetically separated in the *Dorsilopha* subgenus, utilizes biochemical and biological strategies to promote aggregation that are similar to species in the *Drosophila* subgenus, utilizes biochemical and biological strategies to promote aggregation that are similar to species in the *Drosophila* subgenus.

(Received October 12, 1988; accepted January 25, 1989)

Abstract—Males of several species of *Myrmecocystus* produce mandibular gland secretions that contain 2,4-dimethyl-2-hexenoic acid and a variety of monoterpenes that include neral, geranial, citronellol, limonene, and 2,6-dimethyl-5-hepten-1-ol. Other components identified include methyl anthranilate, octanal, octanol, octyl octanoate, and 2-hexyl-2-decenal. Methyl salicylate has been identified as a mandibular gland constituent of workers of several species in addition to mellein and monoterpenes such as cymene, limonene, and the isomers of citral. The Dufour's gland secretions of workers and females of 14 species contain typical formicine alkanes (e.g., undecane), 2-alkanols (e.g., 2-tridecanol), and 2-alkanones (e.g., 2-tridecanone). Two species in the subgenus *Eremnocystus* produce secretions that are distinguished by the presence of significant quantities of tridecyl esters. The functions of these compounds as well as their possible chemosystematic significance in the genus *Myrmecocystus* are discussed.

Key Words—*Myrmecocystus* species, Hymenoptera, Formicidae, mandibular glands, Dufour's gland, chemosystematics, sex pheromones, defensive allomones, methyl anthranilate, citral, methyl salicylate, tridecyl esters.

INTRODUCTION

Honey ants in the small genus *Myrmecocystus* are characteristic of the arid and semiarid habitats of western North America. In terms of number of species, this is the only successful formicine genus in the North American deserts, 28 species having been described from these xeric communities (Snelling, 1976, 1982). *Myrmecocystus* species are generally omnivorous, exploiting carbohydrate-rich sources from plants and insects as food, in addition to being predators and scavengers. Workers of many species function as a honeypot caste, storing large amounts of concentrated carbohydrate solutions in their filled crops that are accommodated by their greatly expanded gasters. In addition to this distinctive behavior, some species maintain territories by engaging in elaborate display tournaments with nearby conspecific colonies that often result in nest raiding (Hölldobler, 1976).

In view of the recent revision of the genus *Myrmecocystus* (Snelling, 1976, 1982), it is an especially appropriate time to undertake a comparative investigation of the exocrine chemistry of the species in this taxon. In the present report we describe the mandibular gland chemistry of members of different castes of several species of *Myrmecocystus*. In addition, the Dufour's gland chemistry of females and/or workers are described for 14 species in this genus.

METHODS AND MATERIALS

Ants

Collections were made at the sites listed below.

Subgenus Myrmecocystus. *M. christinae*: 9.5 mi NNE Cima, San Bernardino County, California; *M. mexicanus*: 9.5 mi NNE Cima, San Bernardino County, California and 2 mi S Pearblossom, Los Angeles County, California; *M. navajo*: 15 mi W Albuquerque, Bernalillo County, New Mexico and 23 mi SW Silver City, Grant County, New Mexico; *M. testaceus*: Jackass Springs, Inyo City, California.

Subgenus Endiodioctes. *M. mendax*: 9.5 mi NNE Cima, San Bernardino County, California, 8.1 mi SE Sunnyside, Cochise County, Arizona, and 6 mi W Adrian, Oldham County, Texas; *M. depilis*: 11.4 mi W Las Cruces, Dona Ana Co., New Mexico, and Jornada Experimental Range, Dona Ana County, New Mexico; *M. mimicus*: 2 mi S Pearblossom, Los Angeles County, California; *M. romainei*: 9.5 mi NNE Cima, San Bernardino County, California, Jackass Springs, Inyo City, California, Jornada Experimental Range, Dona Ana County, NM, 15 mi W Albuquerque, Bernalillo County, New Mexico, and 10 mi SE El Paso County, Texas; *M. semirufus*: 2 mi S Pearblossom, Los Angeles

County, California; *M. wheeleri*: 6 mi SE Pearblossom, Los Angeles County, California; *M. kennedyi*: 5 mi N Wadsworth, Washoe County, Nevada; *M. kathjuli*: 2 mi S Pearblossom, Los Angeles County, California; *M. intonsus*: 17 mi E Todos Santos, Baja California Sur, Mexico; *M. flaviceps*: 3 mi E Thousand Palms, Riverside County, California.

Subgenus Eremnocystus. *M. colei*: 7 mi NW Cajon, San Bernardino County, CA; *M. creightoni*: 2 mi S Pearblossom, Los Angeles, County, California.

Specimens of all species have been deposited in the Natural History Museum of Los Angeles County.

Fragments of colonies of *M. mexicanus* were maintained in laboratory nests for testing of glandular secretions or identified compounds. Nests contained 200–300 workers and were fed honey water and insects. Mandibular and Dufour's glands (plus reservoirs) were dissected from frozen workers and crushed on sharpened match sticks, which were presented within 2 cm of the nest entrance. The reactions of workers were observed for 60 sec. In addition, the effects of synthetic compounds (2 μg) were evaluated after applications to 1-cm filter paper disks as 1- μl pentane solutions. Controls consisted of pentane applied to disks.

Chemistry

Extracts of Dufour's and mandibular glands were prepared by dissecting these organs from frozen workers under water and crushing the glands in a small volume of pentane. In addition, concentrated extracts of these glands were prepared from extracts of heads and gasters in pentane.

The extracts were concentrated and examined by GC-MS on an LKB-9000 or an LKB-2091 instrument utilizing the following stationary phases: 1.86 m 1% OV-17 programmed from 60° to 300°C at 10°/min; 3.7 m 10% SP-1000 programmed from 50° to 220°C at 10°/min; 25 m SE-30 capillary column programmed from 50° to 320°C at 10°/min.

Structural assignments were based on comparisons of mass spectra and GC retention times of authentic standards with glandular constituents. Standards were obtained from commercial sources or were synthesized. Octyl octanoate was synthesized from octyl alcohol and octanoyl chloride. The tridecyl esters were prepared from tridecanol and the appropriate acid chlorides.

RESULTS

Chemistry of Mandibular Gland Secretions of Males. The volatile constituents in the mandibular glands of males of six species of *Myrmecocystus* were analyzed (Table 1). Four of these species, *M. depilis*, *M. romainei*, *M. semi-*

^a Minor and major compounds indicated by one and two pluses, respectively.

^b Produces an unidentified monoterpene alcohol as a major constituent.

^c One population lacks methyl anthranilate but produces 2-hexyl-2-decenal.

^d Only octanol and 2,4-dimethyl-2-hexenoic acid detected in one population; 2,4-dimethyl-2-hexenoic acid not detected in two populations.

rufus, and *M. wheeleri* are members of the subgenus *Endiodioctes*, the largest and most widely distributed of the three subgenera of *Myrmecocystus* (Snelling, 1976). *M. christinae*, on the other hand, is a member of the subgenus *Myrmecocystus*, whereas *M. colei* is a taxon in the subgenus *Eremnocystus*.

The only compound that is common to the secretions of all six species is 2,4-dimethyl-2-hexenoic acid (Table 1). Several monoterpenoids are concomitants of this acid, and in the cases of *M. christinae* and *M. wheeleri* they constitute the only other volatile compounds detected. The secretion of *M. christinae* is distinguished by the presence of citronellol, whereas that of *M. wheeleri* contains 2,6-dimethyl-5-hepten-1-ol and an unidentified monoterpene alcohol that possesses a mass spectrum similar to that of citronellol. *M. colei* also produces this monoterpene alcohol as well as limonene and the dimethylheptenol. The exudates of *M. semirufus* are distinctive in containing two other monoterpenes, the geometric isomers of citral: neral and geranial.

Males of *M. depilis* and *M. romainei* produce secretions that are dominated by octanol, octanal, and octyl octanoate; 2-hexyl-2-decenal is a minor component in the secretions of both species. Males of one population of *M. romainei* are also distinctive in synthesizing methyl anthranilate, the only aromatic constituent detected in these male exudates. This ester is also produced by males of *M. semirufus* (Table 1).

Chemistry of Mandibular Gland Secretions of Workers and Females. Volatile compounds were identified in the mandibular gland secretions of females of one species and workers of five other species of *Myrmecocystus*. As was the case with the male secretions, monoterpenes were characteristic components in the secretions of most of the species.

Females of *M. creightoni* produced a distinctive secretion that contains two monoterpene hydrocarbons, cymene and limonene (Table 2). On the other hand, the glandular exudate of workers of *M. mendax* contains neral and geranial, as does the secretion of males of this species (Table 1).

By contrast, the secretions of workers of *M. kathjuli* and *M. mexicanus* contain a single detectable volatile, the aromatic ester methyl salicylate. This compound also dominates the citral-rich secretions of workers of *M. semirufus* and *M. testaceus* (Table 2). One population of *M. testaceus* was particularly distinctive in producing the lactone mellein. Volatiles could not be detected as mandibular gland products of workers of eight other species of *Myrmecocystus*. Only structural lipids were evident in analyses of extracts of either mandibular glands or heads of *M. christinae*, *M. depilis*, *M. flaviceps*, *M. intonsus*, *M. kennedyi*, *M. mimicus*, *M. navajo*, and *M. wheeleri*.

Chemistry of the Dufour's Gland Secretions of Workers and Females. Dufour's gland constituents were identified from workers of 14 species of *Myrmecocystus* as well as females of three of these species (Table 3). Dufour's

^c Only detected in one population of workers.

gland chemistry of females was comparable to that of their corresponding workers.

The alkanes undecane and tridecane are characteristic of the secretions of all species, the former compound invariably being a major constituent. Although C₁₀, C₁₂, and C₁₅ alkanes are produced by some species (Table 3), these compounds constitute minor glandular products at best.

2-Tridecanol is a glandular product detectable in only four species; higher 2-alkanols have only been identified in the secretion of *M. mexicanus*. On the other hand, the methyl ketones 2-tridecanone and 2-pentadecanone are synthesized by most of the species; 2-heptadecanone and 2-nonadecanone are present in the exudates of only a few species (Table 3).

Tridecyl esters distinguish the Dufour's gland secretions of *M. colei* and *M. creightoni* from those of the other *Myrmecocystus* species. A single ester, tridecyl decanoate dominates the exudate of *M. colei*, and this compound is also the major volatile compound in the secretion of *M. creightoni*. However, in addition, the latter species produces tridecyl octanoate, nonanoate, undecanoate, and dodecanoate.

Phenol, a minor constituent, in the secretions of *M. mendax*, *M. navajo*, *M. romainei*, and *M. semirufus*, (Table 3), is the only aromatic compound identified as a Dufour's gland product of *Myrmecocystus* species.

Behavioral Effects of Exocrine Compounds. Crushed mandibular glands of *M. mexicanus* (10 tests) cause excited movements in the nearby ants, which frequently are attracted to the pheromonal source. Workers exhibit jerky movements and sometimes elevate their legs. Additional alerted workers from the

nest are attracted to the emission source, and they frequently challenge nest-mates momentarily. Methyl salicylate produces very similar reactions in the workers.

Crushed Dufour's glands generally produce repellency ($N = 10$), the workers moving frenetically from the glandular source, often into the nest. Excited workers sometimes bolt from the nest. Mixtures of 2-tridecanol and 2-tridecanone ($N = 10$) produce reactions similar to those obtained with crushed Dufour's glands, but the addition of the other 2-alkanols and 2-alkanones in the secretion (Table 3) does not appear to appreciably augment the activity of the binary mixture.

DISCUSSION

The exocrine chemistry of species in the genus *Myrmecocystus* is clearly consistent with that of species in several taxa in the subfamily Formicinae. Analyses of the formicine genera *Lasius* (Bergström and Löfquist, 1970), *Acanthomyops* (Chadha et al., 1962; Regnier and Wilson, 1968), *Formica* (Bergström and Löfquist, 1973), and *Camponotus* (Brand et al., 1973a,b; Duffield, 1976) have demonstrated that characteristic classes of compounds are biosynthesized in common in their mandibular and Dufour's glands. In particular, the suggestion that *Myrmecocystus* is allied with the genera in tribe Lasiini (Snelling, 1976) is consistent with the natural product emphases observed for these taxa.

For example, males in the lasiine genera *Acanthomyops* and *Lasius* synthesize 2,6-dimethyl-5-hepten-1-ol in their mandibular glands (Law et al., 1965), as do *Myrmecocystus colei* and *M. wheeleri*. The identification of seven terpenes as mandibular products of *Myrmecocystus* species (Tables 1 and 2) is paralleled by the demonstration that *Lasius* species produce a variety of terpenes in these organs (Bergström and Löfquist, 1970; Blum et al., 1968). Monoterpenes such as neral, geranial, and citronellol are commonly produced by *Lasius* species (Bernardi et al., 1967; Law et al., 1965) as they are by *Myrmecocystus* species. Even the nonterpenoid octanol, a product of males of *M. depilis* and *M. romainei*, has been identified as a mandibular gland constituent of *L. niger* (Bergström and Löfquist, 1970).

On the other hand, the monoterpene hydrocarbons cymene, a product of females of *M. creightoni*, and limonene, a glandular constituent of females of *M. creightoni* and males of *M. colei*, have not been previously identified as a formicid mandibular gland products. It may be significant that these terpenoids have only been identified as exocrine products of two species in the subgenus *Eremnocystus*.

While terpenes appear to be widely distributed in the mandibular gland

secretions of males of *Myrmecocystus* species, a nonterpenoid, 2,4-dimethyl-2-hexenoic acid, is the most widespread compound identified in these male exudates. This acid has been previously identified as a mandibular gland product of males of several *Camponotus* species, particularly those in the subgenus *Myrmentoma* (Brand et al., 1973a; Duffield, 1976). Indeed, *Camponotus* males in this subgenus also produce methyl anthranilate (Brand et al., 1973a; Duffield, 1976), a glandular constituent synthesized by males of both *M. romainei* and *M. semirufus*, two species in the subgenus *Endiodioctes*. The blend of compounds synthesized by males of some populations of *M. romainei* is further distinguished by the presence of octyl octanoate, octanal, and octanol, an aliphatic trio which they share with males of *M. depilis*.

Methyl anthranilate may be chemotaxonomically significant for *M. romainei*. This compound is a glandular constituent of males of one California population of this species. On the other hand, the secretions of males from west Texas populations do not contain detectable amounts of this ester but rather, in its place, 2-hexyl-2-decenal, which represents the aldol condensation-dehydration product of octanal. This difference in chemical characters parallels morphological differences between major workers in the two populations, and one of us (R.R.S.) is analyzing the possible significance of these incongruities.

Although *Camponotus* males are not distinguished as producers of terpenes, one species, *C. clarithorax*, excels in the biosynthesis of these compounds. One of the major terpenes produced by this species is 2,6-dimethyl-5-hepten-1-ol, which is accompanied by several other monoterpenes (Lloyd et al., 1975). This compound is also a major product of males of two *Colobopsis* species, which produce other monoterpenes (e.g., citronellol) as well (Duffield, 1976). If males of *Colobopsis* species generally synthesize terpenes, they will join *Myrmecocystus* and lasiine species as characteristic producers of terpenoid pheromones.

Hölldobler and Maschwitz (1985) demonstrated that the sex-specific secretions of *Camponotus* males function as sex pheromones. Suffice it to say that the compounds produced by *Myrmecocystus* males, several of which are shared with *Camponotus* males, seem eminently suited to be utilized as sex pheromones for honey ant species.

Methyl salicylate, a mandibular gland product of workers of *M. kathjuli*, *M. mexicanus*, and *M. semirufus*, has not previously been identified as a natural product of ants. Indeed, this ester is only known as an exocrine product of one other arthropod, the carabid beetle *Idiochroma dorsalis* (Schildknecht et al., 1968). Our laboratory investigations indicate that this compound functions as an alarm pheromone for workers of *M. mexicanus*, the odor of this ester being readily evident when the ants are disturbed.

Although it is not unlikely that sex-specific mandibular gland products (=sex pheromones) are characteristic of males of *Myrmecocystus* species, the

same cannot be said for the workers or females. Notwithstanding the fact that we have identified six compounds as glandular products of workers or females of six species, no volatiles were detected in cephalic extracts of workers of eight other species. As in most *Camponotus* species, males of some *Myrmecocystus* species produce volatile sex pheromones in their mandibular glands, but none are detectable as worker products (e.g., *M. christinae*, *M. wheeleri*). On the other hand, in the case of at least one species (*M. semirufus*) males and workers share two compounds (neral, geranial) but not another, methyl salicylate. Workers of one population of *M. testaceus* are noteworthy in producing, in addition to neral and geranial, the lactone mellein, a compound that is characteristic of males of many *Camponotus* species (Brand et al., 1973b). Analyses of the mandibular gland products of males of additional species will be required in order to determine how widespread the occurrence of sex-specific compounds is in the genus *Myrmecocystus*.

For the most part, the Dufour's gland constituents of workers and females are characteristic of those previously identified in species in other formicine genera, especially those of *Lasius* and *Acanthomyops* species. The alkanes, 2-alkanols, and 2-alkanones are typical products of a variety of *Lasius* (Bergström and Löfquist, 1970) and *Acanthomyops* (Regnier and Wilson, 1968) species. Hölldobler (1981) reported that the Dufour's gland secretion of *M. mimicus* contains three alkanes and two methyl ketones, compounds that we have identified in this and other *Myrmecocystus* species. Furthermore, Hölldobler demonstrated that while crushed Dufour's glands generally caused escape behavior, some workers exhibited aggressive behavior in response to the volatiles. Our results with *M. mexicanus* workers were very similar with either a crushed gland or a mixture of 2-tridecanol and 2-tridecanone.

The tridecyl esters produced by workers of *M. creightoni* and *M. colei* are the most distinctive compounds identified as Dufour's gland constituents of *Myrmecocystus* workers. Tridecyl decanoate is the only ester present in the secretion of *M. colei*, whereas five tridecyl esters fortify the exudate of *M. creightoni*. As is the case for *M. colei*, tridecyl decanoate is the major Dufour's volatile, tridecyl dodecanoate being the only other ester that is quantitatively significant. It may be chemosystematically significant that both *M. colei* and *M. creightoni* are in the small subgenus *Eremnocystus*, and it will be worthwhile to examine the Dufour's gland chemistry of other species in this taxon.

Phenol, a minor product of four species of *Myrmecocystus* is the only aromatic compound identified in the Dufour's gland secretions. This compound, which has recently been identified in a myrmicine species, *Monomorium destructor* (Blum et al., 1985), is an atypical compound in secretions that characteristically contain aliphatic constituents.

Book Review

Introduction to Ecological Biochemistry, Third Edition. J.B. Harborne. London, Academic Press, 1988, 356 pp.

Breadth and brevity are the hallmarks of this wonderful little book. Each chapter is an engaging, skillfully crafted, self-contained discussion of a major area of contemporary research in chemical ecology. The titles of the 10 chapters are "The Plant and Its Biochemical Adaptation to the Environment," "Biochemistry of Plant Pollination," "Plant Toxins and Their Effects on Animals," "Hormonal Interactions Between Plants and Animals," "Insect Feeding Preferences," "Feeding Preferences of Vertebrates, Including Man," "The Co-evolutionary Arms Race: Plant Defense and Animal Response," "Animal Pheromones and Defense Substances," "Biochemical Interactions Between Higher Plants," and "Higher Plant-Lower Plant Interactions: Phytoalexins and Phytotoxins."

In working through this volume the reader will be treated to interesting and authoritative discussions of topics as diverse as the ecological significance of Crassulacean acid metabolism (CAM), the evolution of flower color, the chemistry and ecology of cyanogenesis, food selection by wild gorillas, the chemistry of sweetness, mammalian pheromones, allelopathy, and phytoalexins. In presenting this tremendous diversity of material, the author shifts easily between fairly detailed accounts of individual case histories, passing references to isolated but interesting facts, and lucid informative summaries of topics that have extensive bodies of literature associated with them. The chapters on pollination, pheromones, and phytoalexins are outstanding reviews of very complex subjects.

Every reader of this book will be able to think of a few topics that he or she feels ought to have been included or discussed in greater depth. For example, my list would have included a discussion of foraging energetics of bumblebees as a final section of the chapter on pollination. An account of various approaches to assess the costs of producing or detoxifying defensive chemicals would have been useful in the chapter on plant toxins. A discussion of recent work on the induction of detoxifying enzymes in insects by naturally occurring plant chemicals would have rounded out the section on the fate of plant toxins in animals. A discussion of the importance of the composition of foliage volatiles in the attraction of the Colorado potato beetle to host plants would have

added to the discussion of the role of alkaloids as feeding deterrents for this insect. A chapter on the role of microorganisms in plant-herbivore interactions would have been a good companion to the one on higher plant-lower plant interactions. I would have preferred that more space be allocated to discussions of recent work on the chemical ecology of beetle-willow interactions, pharmacophagy in Danaine and Ithomiine butterflies, iridoid glycosides and insect herbivores, and the mode of growth inhibition in insects by tannins, even if the coverage of these topics had been at the expense of space dedicated to some of the studies that so influenced this field during the 1970s.

These, however, are minor quibbles about content. The author has, in fact, exercised masterful judgment in his selection of topics. By his choice of subject matter, Prof. Harborne illustrates the broad range of questions addressed by the field of chemical ecology, introduces studies that have influenced the development of ideas in a significant way, and communicates the current excitement that pervades the field.

I am able to point to only a single topic in which the discussion has been weakened by the omission of pertinent material. In discussing possible explanations for the distribution, abundance, and diversity of plant secondary chemicals, the apparency hypothesis is presented, but there is no mention of the resource-availability hypothesis. There is also no discussion of the nutrient-balance hypothesis, of the responses of plant secondary metabolism to nutrient and light stress, or of genetically based within-species variation in secondary chemicals. As a consequence, the chapter on coevolution of plants and their herbivores is weak. It is essentially a restatement of the Ehrlich and Raven model of pairwise coevolution interpreted within the framework of the apparency hypothesis.

The value of the book as a reference work would be greatly enhanced by a better subject index, which is largely an alphabetical list of chemical names. Latin binomials for plant and animal species are separately indexed. The subject index includes very few common names of organisms and very few entries that identify processes or phenomena. For example, none of the following words or phrases are indexed: apparency, birch, deterrent, generalist, host-parasite, host selection, induced defense, induction, inhibition, inhibitor, mimicry, monarch, mutualism, parasitism, pharmacophagy, predictability, sequestration, slug, snowshoe hare, specialist, swallowtail, symbiosis, three-trophic-level interaction, trichome, variability, variation. The reader has no way of determining whether sequestration is discussed in the chapters on plant toxins, animal defenses, coevolution, or all of the above. There are no entries in the index that would direct a reader interested in the role of trichomes in plant defense to the chapters on feeding preferences and coevolution where this topic is discussed.

This deficiency in the subject index is amplified by somewhat arbitrary

placement of some topics in chapters where they do not quite seem to belong. For example, the excellent account of pheromonal interactions in pine bark beetle biology has been placed in the chapter on hormonal interactions between plants and animals rather than the one on pheromones. Since this discussion is not referenced under "pheromone" in the index, and there are no entries for "aggregation," "attraction," or "bark beetle," the only way a reader can find it is by looking up "myrcene," "pinene," or "verbenone," or by reading the entire book and remembering where it is. Other examples of questionable organization include reference to the toxic effects of many plant chemicals in the chapter on feeding attractants and deterrents, the placement of the discussion of induced plant defense in the chapter on coevolution, and a discussion of the synthesis of cardenolides by some insects in a section on pyrrolizidine alkaloids, which immediately follows a section on cardiac glycosides.

The first edition of this book was published in 1977. It had nine chapters and 243 pages. In the preface to the first edition, the author noted that the book was "based on a course taught over a number of years" and that it was "intended as an introduction to...new developments in biochemistry that have...expanded our knowledge of plant and animal ecology." A second edition appeared in 1982. The third edition has expanded to 10 chapters and 356 pages. Despite the publication of many excellent books in the area of chemical ecology during the past decade, *Introduction to Ecological Biochemistry* remains a one of a kind. It is still the only comprehensive single-author book that attempts to summarize the whole field of chemical ecology. Because of its uniqueness in this regard, it has become much more than the "simple introduction to new subject matter," it was originally designed to be. Some of us are beginning to look upon it as the book that defines what chemical ecology is. Perhaps this third edition is not yet quite chemical ecology's equivalent to Wigglesworth's *The Principles of Insect Physiology*, but at least it is close enough to suggest the analogy. Let us hope that Prof. Harborne will continue to accept the challenge of providing us with an up-to-date, expanded, and improved edition of this singularly important book every five years. In the meantime, I would encourage anybody with an interest in chemical ecology or ecological chemistry, both students who are new to the field and researchers who have been active in it for years, to buy a copy of the third edition of *Introduction to Ecological Biochemistry* and to read it from cover to cover.

Announcements

**SEVENTH ANNUAL MEETING OF THE INTERNATIONAL SOCIETY OF
CHEMICAL ECOLOGY (ISCE)**

The 7th meeting of the ISCE will be held jointly with the Phytochemical Society of North America (PSNA) on August 12-15, 1990 at Laval University, Ste. Foy, Province of Quebec, Canada. Among the planned symposia will be one on modern phytochemical methodology and two on chemical and ecological aspects of reproduction and defense in plants and animals. A call for submitted papers and posters will appear in January 1990.

Inquiries relative to the meeting and housing details should be addressed to:

Professor Jeremy N. McNeil
Department of Biology
Laval University
Ste. Foy, P.Q.
G1K 7P4 Canada

**5TH INTERNATIONAL WORKING CONFERENCE ON STORED-
PRODUCT PROTECTION**

- DATE AND PLACE:** September 9-14, 1990
Bordeaux, France
- ORGANIZED BY:** French National Institute of Agricultural Research
(INRA)
- PROGRAM:** Biology and physiology of insects and mites, chemical control, fumigation, pesticide resistance, control methods, sampling, rodent, birds, warm-climate protection, storage facilities, economics, modeling.
- INFORMATION:** 5th IWCSPP Conference
Secretariat, Bordeaux Congrès
33300 Bordeaux-Lac, France

REIMER-TIEMANN ADDUCTS AS POTENTIAL INSECT ANTIFEEDANT AGENTS

Reviewing the Structure–Activity Relationship Theory of the Antifeedant, Warburganal¹

(Received July 7, 1988; accepted January 19, 1989)

Abstract—Structure–activity relationships of naturally occurring enedials with antifeedant activity against *Spodoptera* species have been extended via the synthesis and bioassay of a series of Reimer-Tiemann adducts. The activities attributed to the different chemical structures of these and other analogs interacting with the chemoreceptor site have been observed; a three-pronged mode of substrate binding via aromatic pyrrole formation, Michael addition of free sulfhydryl moieties, and van der Waals interactions of the A ring has been postulated to account for these observations.

Key Words—Enedial, *Spodoptera*, Lepidoptera; Noctuidae, feeding deterrent, pyrrole, sulfhydryl, van der Waals interaction, Reimer-Tiemann adducts.

INTRODUCTION

Interest in the protection mechanism that plants use against pest insects prompted the isolation and identification of the insect antifeedant *Warburgia* sesquiterpene dialdehydes (Barnes and Loder, 1962; Brooks and Draffen, 1969). Some of these enedial compounds are polygodial (**1**), warburganal (**2**), and muzigadial (**3**) (Scheme 1), all of which also exhibit other biological activity including: fish

toxicity (Asakawa et al., 1985), hot taste to humans (Govindarajan, 1979), inhibition of alcoholic fermentation (Kubo et al., 1983), and antimicrobial activity (Kubo et al., 1984). The ability of these compounds to inhibit feeding of *Spodoptera* spp. at ≥ 0.1 ppm (Kubo et al., 1977; Sodano et al., 1987) initiated interest in the syntheses of warburganal (2) (Kende and Blacklock, 1980) and cinnamodial (4) (White and Burton, 1985), as well as numerous analogs (5–12) and intermediates (Table 1).

The observed biological activity led to four proposals that relate chemical structure to activity: The first suggests that when the C-8 enal moiety is allowed to react with the free sulfhydryl groups of the insect's chemoreceptor membranes, there is inhibition of stimuli transduction (Ma, 1977; Rozental et al., 1975). In support of this proposal, it was observed that α,β -unsaturated aldehydes inhibited papain (an enzyme containing 1 mol of active $-\text{SH}$) while benzaldehyde had virtually no effect. This type of reactivity is indicative of the addition of a free $-\text{SH}$ moiety to the $\beta\text{-sp}^2$ hybridized carbon atom as in a Michael addition (Scheme 2) (Kubo and Ganjian, 1981) and can be easily monitored by measuring the disappearance of the UV absorption band (λ_{max} 229 nm) of the α,β -unsaturated aldehyde. Kubo et al. (1976) found that addition of L-cysteine to a solution of polygodial at pH 7 or 9 (phosphate buffer) produced an absorbance change, as well as a decrease in the insect antifeedant activity.⁴ Several other SH-containing compounds produced similar results under these

⁴When the dialdehyde was oxidized to the diacid, the corresponding methyl diester [8] with the correct C-9 configuration showed no feeding deterrent activity at 100 ppm, indicating that the aldehydic functionalities at C-8 and C-9 are important to the biological activity (Warthen et al., 1983).

conditions, while no absorbance change was observed when the polygodial solution was treated with a variety of amino acids that contained no $-SH$ moiety. However, because both the active polygodial (**1**) and the inactive epipolygodial (**7**) showed a similar absorbance decrease upon reaction with L-cysteine; there was speculation that the stereochemistry of polygodial was an important factor influencing biological activity since polygodial differs from epipolygodial only in the configuration of the C-9 aldehyde (Scheme 3a). The absorbance decrease produced by the reaction of polygodial and L-cysteine occurs three times faster than that produced when epipolygodial is allowed to react with L-cysteine. Clearly, the configuration of the C-9 substituent plays a critical role by interacting with approaching nucleophiles and, consequently, may be important for binding of the substrate to the receptor site.

Kubo et al. (1984) tested this hypothesis by examining the interactions of the C-9 methanol analogs of polygodial and epipolygodial with L-cysteine. The 9- β alcohol (**13**) showed no UV absorbance even before the addition of L-cysteine, since an intramolecular addition of the CH_2OH hydroxyl moiety to the C-8 carbonyl had produced a hemiacetal furan (**14**). The UV absorbance (α,β -unsaturated aldehyde) of the epipolygodial analog (**15**) was virtually unchanged after the addition of L-cysteine, supporting the hypothesis that the C-9 aldehydic substituents in the α -configuration inhibit addition of the free $-SH$ moiety to the double bond of epipolygodial (Scheme 3b). However, Kubo et al. (1984) did not explain why the 9- β alcohol (**13**) formed a furan ring via intramolecular hemiacetal formation while the 9- α alcohol (**15**) did not react in this fashion.

Sodano et al. (1982) provided the second proposal to explain the biological activity of these enedials and the differences in activity between polygodial and epipolygodial. They postulated that pyrrole formation by reaction of the C-8, C-9 dialdehyde moieties with a primary amine of the receptor site was responsible for the antifeedant activity. Under biomimetic conditions, polygodial was allowed to react with a variety of primary amines, including: L-cysteine, L-lysine, L-alanine, and methylamine. In each case the amine caused a decrease

SCHEME 3.

in UV absorbance associated with the α,β -unsaturated aldehyde. Sodano et al. (1982) used Driending models to calculate the intramolecular distances between the aldehyde carbonyls of polygodial and epipolygodial, respectively (Scheme 4); they concluded that the 9- β isomer's carbonyl groups were close enough to allow for intramolecular ring closure while the 9- α isomer's carbonyls were too far apart for this to occur, thereby showing that the configuration of the C-9 aldehyde plays a critical role in the binding of the substrate to the chemoreceptor site. Additional evidence was obtained to support this hypothesis when two new

SCHEME 4.

intermediates (**16** and **17**) were identified from the various reactions of primary amines on the α,β -unsaturated aldehydic carbonyl moiety of polygodial (Scheme 5) (Sodano et al., 1984). The pyrrole formation was only observed for molecules that had the appropriate stereochemical configuration (i.e., the 9- β of the *trans*-fused decalins) to allow intramolecular cyclization. Sodano et al. (1984) suggested that this information confirmed that pyrrole formation was responsible for the observed biological activity.

The third proposal relating the chemical structure of the enedials to biological activity was also made by Sodano et al. (1987), when it was observed that the steroidal analogs (**18** and **19**) of polygodial, having the identical C-9 polygodial stereochemical configuration (Scheme 6), were inactive. These authors claimed that the large steroid ring system inhibited the molecule from reaching the active site, thereby preventing any reaction with the $-\text{NH}_2$. Thus, there was a molecular size limitation even though the polygodial functionality and stereochemical backbone were present. The fourth proposal by these same authors originated because the addition of a prenyl substituent to the α -C-4 methyl group of polygodial (saccalutal, **6**) and epipolygodial (isosaccalutal, **12**) had no effect on the activity of either molecule. Thus, it seems as though a change of the alkyl substituent on C-4 of polygodial has no effect on insect antifeedant activity.

This paper reports new information relating the chemical structure of enedial analogs to insect antifeedant activity.

SCHEME 6.

METHODS AND MATERIALS

Gas-liquid chromatography (GLC) analyses were performed on a Hewlett Packard 5830A instrument equipped with a split injector (flame ionization detector, He carrier gas). A DURAWAX-DX1 (J&W Scientific, Inc.) capillary column (0.25 mm \times 15 m) was operated at the temperature ranges indicated. Infrared (IR) spectra were obtained with a Nicolet 60SX Fourier Transform IR spectrometer using neat sample smears between KCl plates. ^1H nuclear magnetic resonance (NMR) spectra, unless otherwise stated, were obtained with a Nicolet (General Electric) QE 300 MHz instrument. All spectra were obtained using deuteriochloroform (CDCl_3) solutions with tetramethylsilane (TMS) as an internal standard. Flash chromatography by the procedure of Still (1984) was performed using Bio-Rad silicic acid-HA (-325 mesh). Analytical thin-layer chromatography (TLC) was performed on prescored silica gel GF (250- μm) plates (Analtech, Inc). Hydrogenations were performed using a Pressure Reaction Apparatus (Parr Instrument Company, Inc.). All commercially obtained chemicals were used without further purification.

Chemicals

6-Dichloromethyl-6-methyl-3-(2-propyl)-2,4-cyclohexadienone (20). The dienone (Scheme 7) was prepared in 8% yield and had physical constants identical to those first reported by Wenkert (1970), who had prepared this compound in a similar yield by refluxing a two-phase mixture containing a chloroform solution of the appropriate phenol, carvacrol, and $\sim 10\%$ aq. NaOH solution. The pure sample (flash chromatography, hexane) was subjected to GLC analysis with an oven temperature at 70°C for 1 min and then programmed at $5^\circ\text{C}/\text{min}$; 98% purity, $R_t = 17.36$ min. IR (neat) 1662 ($\text{C}=\text{O}$), 1642 cm^{-1} ($\text{C}=\text{C}$).

6-Dichloromethyl-2,6-dimethyl-2,4-cyclohexadienone (21). The dienone was prepared in 17% yield as described for compound **20** and was purified by flash chromatography (hexane). The pure sample was subjected to GLC analysis with an oven temperature at 90°C for 1 min and then programmed at $5^\circ\text{C}/$

SCHEME 7.

min; 99% purity, $R_f = 7.16$ min. IR (neat) 1662 (C=O), 1650 cm^{-1} (C=C); ^1H NMR (CDCl_3) δ 1.30 (s, 3H, 6- CH_3), 1.92 (bs, 3H, $\text{CH}_3\text{C}=\text{C}$), 6.09 (s, 1H, $-\text{CCl}_2\text{H}$), 6.40 (dd, 1H, $J = 7.5, 11$ Hz, C-4 H), 6.58 (d, 1H, $J = 11$ Hz, C-5 H), 6.90 (bd, 1H, $J = 7.5$ Hz, C-3 H).

cis- and *trans*-2-Dichloromethyl-2-methyl-5-(2-propyl)cyclohexanone (**22**). An ethanol solution (50 ml) of dienone **20** (2.00 g, 8.58 mmol) was hydrogenated over 10% Pd/C at 50 psi for 24 hr and filtered over Celite. The solvent was removed in vacuo; the residue was purified by flash chromatography (petroleum ether, 35–60°C) to give a 57% yield of product (1.16 g, Scheme 8). GLC

SCHEME 8.

analysis with an oven temperature at 70°C for 1 min and then programmed at 5°C/min revealed the presence of a 3:1 mixture of two diastereomers; R_f = 17.34 and 17.67 min, respectively. No attempt was made to isolate the individual isomers. Wenkert (1970) obtained a 4:1 ratio of these isomers; the isomer in the greater quantity (Scheme 8) had the isopropyl and methyl groups *trans* to each other. In our mixture the isomer in the greater quantity was identical to the *trans* isomer isolated by Wenkert (1970). IR (neat) 1716 (C=O), 762 cm^{-1} (C-Cl); [^1H]NMR (CDCl_3) δ 0.92 [m, 6H, $(\text{CH}_3)_2\text{CH}-$], 1.27 and 1.32 (s, 3H, *trans* isomer $-\text{C}-\text{CH}_3$ and *cis* isomer $-\text{C}-\text{CH}_3$, respectively), 1.32-2.49 (m, 8H), 6.19 and 6.29 (s, 1H, *cis* isomer $-\text{CCl}_2\text{H}$ and *trans* isomer $-\text{CCl}_2\text{H}$, respectively).

cis- and trans-2-dichloromethyl-2,6-dimethylcyclohexanone (23). Dienone **21** (4.83 g, 19 mmol) was hydrogenated as described for compound **22** to give a 91% yield of **23**. GLC analysis with an oven temperature of 90°C for 1 min and then programmed at 5°C/min revealed a 1:15 ratio⁵ of isomers; R_f = 7.69 and 7.73 min, respectively. IR (neat) 1702 cm^{-1} (C=O); [^1H]NMR (CDCl_3) δ 1.05 (d, 3H, $J = 6.0$ Hz, $\text{CH}_3\text{CH}-$), 1.37 (s, 3H, $-\text{C}-\text{CH}_3$), 1.30-2.20 (m, 6H, $-\text{C}-(\text{CH}_2)_3-\text{CH}-$), 2.56 (m, 1H, $\text{CH}_3\text{CHCH}_2-$), 6.20 ppm (s, 1H, $-\text{CCl}_2\text{H}$).

Bioassay

Fall armyworm larvae, *Spodoptera frugiperda* (J.E. Smith), from our stock culture, reared on an artificial diet (Redfern and Raulston, 1970), were used for antifeedant tests. The samples were dissolved at an appropriate concentration in a 50:50 acetone-dimethyl sulfoxide solvent mixture; the resultant solution was added to a hot diet and mixed by using a 1/2-pint (720 ml) jelly jar fitted with an Osterizer blender cutter head. After the treated diet was blended for approximately 1 min, it was poured into 1-oz clear plastic cups (~8 g/cup) and allowed to cool to room temperature. Control diets were only treated with the neat solvent. One first-instar larva (newly emerged) was placed in each cup (10 cups for each sample concentration). The cups were then capped with pre-punched lids and placed in a holding room at $27^\circ \pm 1^\circ\text{C}$ with $50 \pm 5\%$ relative humidity. The larvae were observed for mortality, and the live larvae weighed on the sixth or seventh day after introduction into the cups. The sum of weights for the 10 repetitions per sample, as well as the control, were then divided by

⁵The isomerization of the 15:1 mixture was accomplished by the addition of lithium diisopropylamide to a THF solution (-78°C) of **23**, stirring for 2 hr as the temperature rose to 26°C , and then acidifying with 10% (v/v) aq. HCl. GLC revealed the presence of a 50:50 mixture. Repetitive flash chromatography (petroleum ether, $35-60^\circ\text{C}$) gave a fraction in which the new isomer predominated in a 60:40 ratio. IR (neat) 1702 cm^{-1} (C=O); [^1H]NMR (CDCl_3) δ 1.05 (d, 3H, $J = 6.0$ Hz, CH_3CH), 1.27 (s, 3H, $2-\text{CH}_3$), 1.32-2.19 (m, 5H), 2.30 (ddd, 1H, $J = 3.9, 6.6, 14$ Hz; C-4 H_{ax}), 2.59 (m, 1H, $\text{CH}_3\text{CHCH}_2-$), 6.40 (s, 1H, $-\text{CCl}_2\text{H}$).

the number of live larvae weighed in order to obtain an average larval weight for each sample. The ratio of these average larval weights (treated/control) was then used to assess the antifeedant activity of the various samples (Table 2).

RESULTS AND DISCUSSION

The work of Kubo and Sodano has been very thorough. However, there are still several questions to be addressed that relate the structures of the enedials to their antifeedant activity, namely: (1) are both the C-8 and C-9 aldehydic oxidation states necessary for antifeedant activity at low sample concentrations (≤ 10 ppm); (2) if pyrrole formation is the most important reaction for activity, does the $-SH$ moiety react in conjunction with the NH_2 to enhance the activity; (3) why does the addition of the $\alpha-OH$ at C-9 of warburganal enhance the antifeedant activity compared to polygodial (no $\alpha-OH$, Scheme 1); (4) if steric bulk inhibits the approach of the substrate to the receptor site, what effect will a truncated natural product analog have; and (5) what effect do the alkyl substituents have on the antifeedant activity?

The first conclusion that can be drawn from the data in Table 1 is that the C-8 and C-9 carbon atoms must have their substituents in the aldehydic oxidation state in order to demonstrate potent antifeedant activity. This is especially apparent when comparing the structural differences of polygodial (**1**) and the diester analog (**8**) (Scheme 9). Both molecules would be expected to form a cyclic intermediate, since both corresponding β -C-9 carbonyl moieties should be in close enough proximity to the C-8 carbonyl to allow the intramolecular cyclization (see above). Once cyclization has occurred in both systems, only the intermediate arising from the dialdehyde can proceed to form the aromatic pyrrole (**24**). At this point it becomes necessary to interject our viewpoint that the sulfhydryl attack on the β -carbon of the enal, as proposed by Kubo and

SCHEME 9.

Ganjian (1981), and the pyrrole formation by NH_2 attack on the aldehyde carbonyls, as proposed by Sodano et al. (1982), are not necessarily independent reactions. One can hypothesize that both the L-lysine $-\text{NH}_2$ and the L-cysteine $-\text{SH}$ moieties of the chemoreceptor site complex with the substrate in accordance with both the Sodano and Kubo mechanisms in order to produce the biological activity (Scheme 10a). Initial imine formation at the C-8 carbonyl followed by β -addition of the SH and subsequent ring closure and pyrrole aromatization would produce a product similar to compound **24**. This mechanism could explain why warburganal is a more potent antifeedant than the simple polygodial. For example, if the α -C-9 hydroxide were displaced by an $\text{S}_{\text{N}}2'$ attack of the SH moiety on the β -carbon of the enal, the resultant alkene would force the C-8 and C-9 substituents into an even closer proximity; thereby enhancing the pyrrole formation (Scheme 10b).

SCHEME 10.

There are other mechanisms by which SH moieties are known to react in vivo. One of the more common reactions is the oxidative decarboxylation reaction of the acid dehydrogenase (Scheme 11a) (Lehninger, 1975). This type of reaction could occur with compounds like warburganal (Scheme 11b) to generate an intermediate (**25**), which would then induce the antifeedant activity; our synthetic compounds, **20** and **21**, would be expected to react in a similar fashion with the sulfhydryl moiety via Michael addition to the alkene. The synthetic compounds **20–23** would also be expected to form an imine via coupling of the substrate's dichloromethyl moiety (carbon in the aldehydic oxidation state) and amine groups of the active site in a manner identical to that expected of the aldehyde moiety of the warburganal metabolite, **25**. Compounds **20–23** would

SCHEME 11.

therefore be expected to be as active as warburganal since the chemical reactivity is similar to that proposed for the intermediate (**25**) and other quinones that are known to elicit antifeedant activity (Rozental et al., 1975). Unfortunately, all the synthetic compounds were inactive at 100 ppm, and this mechanistic pathway was therefore discarded in favor of the one shown in Schemes 10a and 10b. Obviously, these cyclohexane molecules are not inactive at the 100-ppm level because their steric bulk prevents binding with the chemoreceptor site, as in the case of the steroidal analogs of polygodial. Since the synthetic samples are not sterically prohibited from reaching the receptor site, it must be the inability of compounds **20–23** to form the pyrrole ring that accounts for their inactivity at low sample concentration. This observation supports the idea that the C-8 and C-9 aldehydes are necessary for antifeedant activity at lower concentrations. However, the 1000-ppm test results indicate that some dramatic differences exist between the inactive compounds, **20** and **22**, and the active compounds, **21** and **23**.

SCHEME 12.

Compounds **20** and **21** differ only in the alkyl substitution pattern (Scheme 12). Our reasoning used to explain the difference in activity was that the two methyl groups of the C-3 isopropyl substituent on compound **20** were sterically blocking the SH from adding to the β -carbon of the α,β -unsaturated ketone in the same manner that the 9- α CH_2OH prevented sulfhydryl coupling in alcohol **15** (Scheme 3b). This could not explain why the saturated analog **23** was nearly as active as compound **21** at 1000 ppm (72% and 79% weight reduction, respectively) since **23** had no alkene with which the SH could react. In hindsight, it was no surprise that compounds **20** and **22** were inactive, since it had previously been demonstrated that the alkyl substitution changes that produced saccalutal (**6**) from polygodial (**1**) and isosaccalutal (**12**) from epipolygodial (**7**) had had virtually no effect on the activity of the compounds. Apparently then, it is the C-2 methyl group of compound **21** and the corresponding C-6 methyl of compound **23** that was responsible for the difference in activity between these two active compounds and their inactive counterparts, **20** and **22**. We noted that the bridge-head methyl group had been reported to exist exclusively in the axial position in all of the naturally occurring antifeedant compounds **1-4**, and **6** (Table 1), while the C-2 methyl group of compound **21** and the C-6 methyl group of compound **23** were both equatorial (the C-2 methyl of compound **21** lies in the plane of the cyclohexadiene ring and can therefore be formally considered equatorial, Schemes 7 and 8). Epimerization of compound **23** produced only equatorial methyl groups, as determined by proton NMR analysis (Scheme 13). Alkyl groups have been known to effectively bind to chemoreceptor sites via dispersion and van der Waals forces that require tight fits to the active site since the magnitude of these attractive forces decreases rapidly with distance (Liljefors and Thelin, 1985). There is, therefore, precedence to expect that an

TRANS 23

CIS 23

SCHEME 13.

appropriately positioned alkyl substituent would enhance the binding ability of the substrate to the active site once pyrrole formation had occurred. The alkyl substitution patterns of our active molecules correspond to the C-1 methylene in the A ring of the naturally occurring enedial antifeedants. Our findings suggest that a three-pronged binding between the substrate and the receptor site, which involves pyrrole formation, Michael addition of the sulfhydryl moiety, and van der Waals interactions of the A ring, occurs to produce the antifeedant activity.

CONCLUSION

Data are provided to show that only compounds having a 1,4-dialdehyde moiety will allow the formation of an aromatic pyrrole, which is necessary in order to observe insect antifeedant activity at low sample concentrations. The reaction of the —SH moiety in conjunction with this pyrrole formation was postulated when it had been observed that the C-8 and C-9 diester analog of polygodial had no antifeedant activity at 100 ppm. Although this compound could form a pyrrole-like product in vivo (the mode of action proposed for polygodial), further reaction with the free sulfhydryl of the chemoreceptor site would be impossible. Differences in the antifeedant activities of compounds **20–23** support the idea that the activities of the naturally occurring enedial antifeedants, produced by pyrrole formation and sulfhydryl attack, may be enhanced by the van der Waals interactions of the A ring with the receptor site, although these weak interactions are obviously not a prerequisite for activity.

Abstract—For some species, chemical analogs have been identified that can substitute for the major pheromone component and reduce pheromone-trap captures in atmospheric permeation experiments. The ability to substitute these analogs for the major pheromone component in field tests raises the question: Do the same set of olfactory receptor neurons on the insects' antennae respond to both the major component and the effective structural analogs? To investigate this question, extracellular responses were recorded from single sensilla on the antennae of male *Heliothis zea* (Boddie) (Lepidoptera: Noctuidae) to stimulation with increasing doses of (Z)-11-hexadecenal, the major pheromone component, (Z)-9-tetradecen-1-ol formate, and (Z)-1,12-heptadecadiene. Both (Z)-9-tetradecen-1-ol formate and (Z)-1,12-heptadecadiene can substitute for (Z)-11-hexadecenal in trap disruption experiments and affect the sexual behavior of males, although neither has been identified in the volatiles released by calling females. All three compounds elicited responses from the same class of pheromone-sensitive receptor neurons over a range of stimulus concentrations. At equivalent stimulus concentrations, however, (Z)-11-hexadecenal elicited about a 10-fold greater response than (Z)-1,12-heptadecadiene. (Z)-9-Tetradecen-1-ol formate elicited a response slightly higher than, but not significantly different from, the response to (Z)-1,12-heptadecadiene.

INTRODUCTION

Recently, much effort has been devoted to investigating the potential use of pheromones and other semiochemicals in the control of insect pest species (Mitchell, 1981). One control strategy involves the disruption of normal chemical communication between males and females by releasing large quantities of the major pheromone component into the atmosphere surrounding an agricultural crop or commodity (Shorey et al., 1974; Mitchell, 1975; Sanders, 1981). Ideally, this atmospheric permeation with pheromone prevents many males from being able to locate females, thereby drastically reducing insect mating and subsequent egg production. The efficiency of this approach is severely comprised in those species whose major pheromone component is unstable in storage or in the field. This has prompted evaluation of closely related analogs of major pheromone components with the view toward finding more stable mimics (Beevor and Campion, 1979; Carlson and McLaughlin, 1982a,b; Silk et al., 1985; Silk and Kuenen, 1986; Curtis et al., 1987).

Heliothis zea (Boddie) (Lepidoptera: Noctuidae), the corn earworm moth, is one insect where communication disruption using both pheromone components and analogs has been demonstrated (Mitchell, 1975; Mitchell et al., 1976; McLaughlin et al., 1981; Tingle and Mitchell, 1982; Mitchell and McLaughlin, 1982). Female *H. zea* produce a complex blend of pheromones that attract conspecific males for mating. The major component of their blend, (*Z*)-11-hexadecenal (AL), constitutes approximately 92% of the volatiles released by calling females (Klun et al., 1979). Mitchell et al. (1975) have demonstrated that in addition to disruption using AL, a structural analog, (*Z*)-9-tetradecen-1-ol formate (FO), can also disrupt this insect's communication. Carlson and McLaughlin (1982a,b) have shown a similar disruption ability with *H. zea* using another structural analog, (*Z*)-1,12-heptadecadiene (OL). Neither FO nor OL have been identified in gland extracts or volatiles released from this species.

The apparent ability of these analogs to substitute for the major pheromone component in disruption experiments raises an interesting question concerning the detection of these semiochemicals by the insect's peripheral sensory system. In most lepidopteran systems studied to date, receptor neurons sensitive to pheromone components show a high degree of selectivity for their target compounds. Consequently, one might question whether the effective mimics would stimulate the same or a different population of olfactory receptor neurons. Several researchers (Mitchell et al., 1975; Priesner, 1979) have suggested that such

chemical mimics compete for activation sites on the same set of olfactory receptor neurons, which are responsive to the major component of the pheromone. To investigate the specificity of pheromone-sensitive neurons, we recorded responses using standard extracellular recording techniques from olfactory receptor neurons contained within sensilla on the antenna of male *H. zea* in response to increasing doses of AL, FO, and OL. We investigated those sexually dimorphic sensilla that are oriented in rows along the proximal 40 flagellar subsegments on the male antenna.

METHODS AND MATERIALS

Insects and Chemicals. Male *H. zea* were taken as pupae from colonies maintained at this laboratory. Insects were held at 75–85% relative humidity and 24–26°C under a 14:10 hr light–dark regimen. Neurophysiological recordings were conducted 24–72 hr following adult emergence. Chemical samples used in this study were provided by Dr. J. H. Tumlinson (AL and FO) and Dr. D. A. Carlson (OL). (Z)-11-Hexadecenal was analyzed by GLC on a OV-1, 36-m capillary column and found to be 99.3% pure. (Z)-1,12-Heptadecadiene was analyzed on a DB-1, 15-m capillary column, and no impurities, such as AL, were detected. (Z)-9-Tetradecen-1-ol formate was analyzed on 3% OV-1 on 100–120 mesh Gas Chrom-Q (1.8 m × 2 mm ID glass column) and found to >99% pure.

Recordings. Insects were secured for single sensillum recordings with low-melting-point wax and their antennae positioned to allow access with microelectrodes. The microelectrodes, electrolytically sharpened tungsten wire (tip diameters approx. 1 μm), were held and positioned under a compound microscope (E. Leitz, Inc., Rockleigh, New Jersey; 600×) with micromanipulators (E. Leitz). The indifferent electrode was inserted into the lumen of a flagellar subsegment on the distal one third of the antenna, and the recording electrode was positioned at the base of an individual sensillum trichodeum on a more proximal subsegment. Penetration of the sensillum cuticle with the recording electrode was accomplished by gently tapping the manipulator along the long axis of the electrode. The signals from the microelectrodes were amplified by a Grass P-18 preamplifier and sent concurrently to a Tektronix 5113 storage oscilloscope for observation and to a Digital PDP-11/23 minicomputer for data acquisition and analysis (Mankin et al., 1987).

Following penetration of the sensillum by the recording electrode, the preparation was allowed to stabilize for 10–15 min prior to the first stimulus presentation. During this period and throughout the recording session, purified carrier air (1000 ml/min) passed over the preparation to isolate the sensillum

from potentially contaminated room air. The spontaneous activity of each neuron in the sensillum was measured before stimulation and was monitored at intervals during the recording session to assess the stability of the preparation.

Stimulation. The methods of dispenser preparation and stimulus delivery are described elsewhere (Mayer, 1973; Grant et al., 1989). Briefly, desired quantities of the chemical component, diluted in 0.5 ml of hexane, were distributed over the inner surfaces of the cylindrical glass dispensers. Following the evaporation of the hexane solvent, the ends of the assembly were attached by ground-glass joints to the stimulus delivery system. Control dispensers contained only 0.5 ml of hexane solvent. Delivery of the stimulus was accomplished by combining a stimulus airstream (200 ml/min), which passed through the pheromone-dosed dispenser, with a purified carrier airstream (1000 ml/min). The mixture of these two streams subsequently passed over the preparation. Initiation and termination of the stimulus period was accomplished by computer-controlled activation and deactivation of a solenoid valve attached to the stimulus airstream (Mankin et al., 1987; Grant et al., 1989). In all cases, 10 sec of neural activity were recorded. This 10 sec was composed of three periods: prestimulus (0–3.0 sec), stimulus (3.0–6.0 sec), and poststimulus (6.0–10.0 s). Responses are expressed as the mean frequency of impulses generated during the stimulus period minus the mean frequency of impulses generated during the prestimulus period.

Dose-Response Relationships. To establish mean dose-response relationships, increasing doses of AL were presented to at least 21 preparations. To establish the mean dose response relationships for FO and OL, each of 10 preparations was stimulated a single time at each dose. Each preparation was exposed to graded doses of only one stimulus compound. In all cases, the lowest dose stimulus was presented first, followed by stimuli of increasing dosages. Interstimulus intervals ranged from 4 to 10 min depending on the magnitude of the previous response. Control stimuli were presented approximately every five stimulations. The actual concentrations that stimulated the antenna were estimated from emission rate calibrations (Mayer et al., 1987).

Scanning Electron Microscopy. To determine the distribution of the sexually dimorphic sensilla on the male antenna, three antennae were examined using scanning electron microscopy. Micrographs were taken of every tenth subsegment beginning at the tenth flagellar subsegment from the pedicel. Prior to sputter coating with 60:40 gold-palladium, portions of the antenna were washed in spectrophotometric grade hexane, allowed to air dry, and grounded to the grid supports with silver paint. Coated specimens were immediately examined with a Hitachi 500 STEM microscope at 30 kV accelerating voltage and magnifications to 25,000 \times . Micrographs were recorded with Polaroid Type 55 P/N film.

RESULTS

Distribution of Sensilla. In agreement with a previous description of the antennal morphology of *H. zea* (Callahan, 1969), we found sexually dimorphic sensilla trichodea oriented in rows along the lateral surfaces of the proximal 40–50 flagellar subsegment (Figure 1A,B). These sensilla were absent from the distal 20–30 subsegments (Figure 1C) and appeared to be typical lepidopterous sensilla trichodea (e.g. Zacharuk, 1986), with their surfaces annulated and sparsely pitted by pores (Figure 1D). From our micrographs, we estimate that there are approximately 2200 of this type of sensillum on each male antenna.

Response Characteristics. Extracellular recordings from *H. zea* indicate that each sensilla trichodeum is innervated by at least two spontaneously active receptor neurons. The action potentials range in amplitude from 50 to 400 μV and have typical durations of approximately 2.5 msec. These impulses can be reliably discriminated from each other by their amplitudes and waveforms. The receptor neuron producing the larger impulse is designated as A and the neuron producing the smaller as B. In several of the preparations, very small impulses ($< 30 \mu\text{V}$) were observed that could not be reliably discriminated from the noise.

FIG. 1. Scanning electron micrographs of the antenna of a male *H. zea*. (A) A flagellar subsegment showing the rows of long, sexually dimorphic sensilla trichodea. (B) A single s. trichodeum from the distal row located on one of the proximal subsegments. (C) A histogram of the mean ($\pm\text{SD}$) number of sensilla in rows on every tenth subsegment ($N = 3$) from the antennal base. (D) A higher magnification of the area enclosed by the square in Figure 1B illustrates the sensillar surface and pores.

For this reason, their responses were excluded from further analysis in this report.

Dose-Response Relationships. Responses from the A neuron were consistently observed to stimulation with each of the three compounds tested; AL, FO, and OL. No responses were observed from the B neuron to stimulation by any of these compounds at any of the doses tested. The observation that one class of receptor neuron responds to each of these three stimuli does not preclude the possible existence of other classes of receptor neurons in other morphological types of sensilla that may well have more pronounced differences in response selectivity with respect to these three compounds.

In all cases, responses from the A neuron were such that an increase in stimulus dosages led to an increase in the frequency of impulse production during the stimulus period. Mean responses of the A neurons to stimulations with different doses of AL, FO, and OL are shown in Figure 2A. In addition to similarities in the mean discharge frequencies, similarities also were observed in the averaged temporal discharge pattern in response to stimulation with equal doses of each compound (Figure 2B). With all these compounds, the initial part of the response was enhanced as stimulus intensity was increased. Since the OL was synthesized via a Wittig reaction with AL as the starting material (Carlson and McLaughlin, 1982b), the possibility exists that trace amounts of AL could be in the sample, yet go undetected by conventional GC analysis. However, since samples of the olefin produced via the synthetic route described above were shown to be >99%, the responses seen in Figure 2A cannot be attributed solely to the presence of trace AL contaminants in the OL sample.

DISCUSSION

The neurophysiological data presented here indicate that there is a class of receptor neurons on the antenna of male *H. zea* that responds to stimulation with the major pheromone component and to stimulation with two other analogs. The mean dose-response curves for the three compounds are quite similar (Figure 2A). However, the similarity in dose-response curves may be misleading, since these chemicals differ by over half an order of magnitude in vapor pressure (Carlson and McLaughlin, 1982b) and consequently may differ in the rate at which they are released from the surface of the dispenser. Therefore, comparisons among the responses from equivalently dosed stimuli should be evaluated in terms of the concentration differences among the compounds and not solely on the amount of material loaded into a stimulus cartridge.

To make comparisons on the basis of concentration, emission rates were calibrated from the stimulus dispensers for a series of long-chain hydrocarbons (Mayer et al., 1987), including the three compounds evaluated in this study.

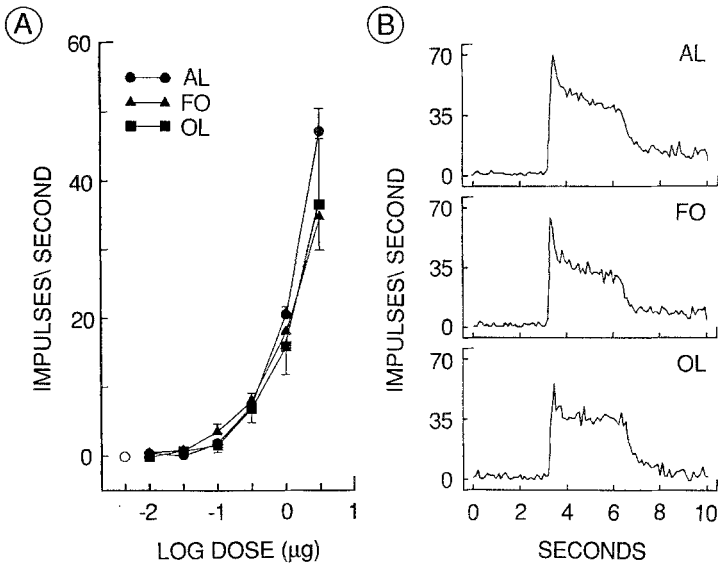

FIG. 2. (A) Mean (\pm SEM) dose-response relationships from the A neuron of *s. trichodea* on the antenna of male *H. zea* to stimulation with increasing doses of (Z)-11-hexadecenal (closed circles), (Z)-9-tetradecen-1-ol formate (closed triangles), and (Z)-1,12-heptadecadiene (closed squares). Standard error bars have been omitted from some mean values to enhance clarity of the figure. Doses on the *x* axis equal the amount of material loaded into the dispensers and not the amount reaching the preparation. The mean response to the hexane control stimulation is indicated by the open circle. (B) Averaged event-time histograms illustrating responses from the A neuron to stimulation with equal doses (3.16 μ g) of (Z)-11-hexadecenal ($N = 29$); (Z)-9-tetradecen-1-ol formate ($N = 11$); and (Z)-1,12-heptadecadiene ($N = 10$). Responses are averaged in 100-msec intervals. The stimulus period began at 3.0 sec and ended at 6.0 sec.

From the measured concentration emitted from the dispenser at known doses, we calculated regression equations for each material, relating the amount of material loaded into the dispenser (dose in micrograms) to the amount of pheromone emitted from the dispenser outlet. Concentration in micromoles/per cubic centimeter can be calculated from emission rate, given the total rate of flow of stimulus-laden air over the antenna (concentration = emission rate/1200 cm^3/min). Due to the extreme sensitivity of olfactory receptor neurons to stimulations with semiochemicals, the lowest stimulus dose for which we could reliably quantify the emission rate was equal to the highest dose tested in these electrophysiological studies. It was necessary to estimate concentrations for lower doses (those effective in the electrophysiological studies) by extrapolating from the dose emission functions in Mayer et al. (1987). The resulting concentration

estimates were then used to replot (Figure 3) the data shown in Figure 2. When replotted, there is a larger quantitative difference among the mean stimulus-response curves elicited by the three compounds. (*Z*)-11-Hexadecenal is a more effective stimulant than either (*Z*)-9-tetradecen-1-ol formate or (*Z*)-1,12-heptadecadiene. It should be noted, however, that these differences in sensitivity are relatively small when compared to the very large differences expected when pheromone-sensitive receptor neurons are stimulated with other nonpheromone compounds.

These neurophysiological responses are difficult to interpret unambiguously because the processes involved in disruption of insect chemical communication by atmospheric permeation with the major pheromone component are not well understood. For example, modification of the insect's sensory system by either adaptation of the peripheral receptor neurons or habituation of the central nervous system has been proposed to explain elements of the disruption process (Bartell, 1982). Alternatively, persistent activity in these pheromone-

FIG. 3. Mean concentration vs. response relationships from the A neuron to stimulation with increasing concentrations of (*Z*)-11-hexadecenal (closed circles); (*Z*)-9-tetradecen-1-ol formate (closed triangles), and (*Z*)-1,12-heptadecadiene (closed squares).

sensitive receptor neurons may act to confuse or modify the normal behavioral response of the male and render him unable to orient to a calling female. A widely accepted theory proposes that individual trails of pheromone emanating from calling females are camouflaged by the large synthetic release of pheromone in disruption experiments (Cardé, 1981). Whatever the mechanism, we assume that in order for disruption to occur, the major pheromone component must interact in some fashion with the highly sensitive pheromone receptor neurons in the trichoid sensilla. Additionally, the present data suggest that the olefin and the formate analogs may achieve their disruptive effects via interaction with the same population of olfactory receptor neurons that are sensitive to the major pheromone component.

Acknowledgments—We thank Drs. J. H. Tumlinson and D. A. Carlson for graciously providing pheromone and analog samples used in these neurophysiological studies. We also thank Ms. Jane E. Sharp for excellent technical assistance and Drs. R. J. O'Connell, D. A. Carlson, J. R. McLaughlin, J. A. Coffelt, and J. C. Webb for helpful comments on the manuscript. We acknowledge support for A. J. G. during preparation of this manuscript from grants NS 14453 from NINCDS and from the Alden Trust awarded to R. J. O'Connell.

(Received December 1, 1987; accepted January 30, 1989)

Abstract—A still-air, wing fanning bioassay measured male pheromone response in the pink bollworm moth, *Pectinophora gossypiella* (Saunders). As pheromone concentration was increased, the duration of wing fanning increased while its latency decreased. Response duration was longest for the natural pheromone blend [44:56 (*Z,E*)- and (*Z,Z*)-7,11-hexadecadienyl acetates], although responses to 38% and 50% *Z,E* blends were not significantly briefer. Preexposure to pheromone had no effect on wing fanning in males retested after 24 hr. Wing fanning was highly correlated with upwind flight and other responses observed in a wind tunnel. Wing fanning duration provides a continuous measure of pheromone response and allows a large number of males to be tested in a short time; these two characteristics of the wing-fanning assay are helpful for genetic analyses of male response.

Key Words—Pink bollworm, *Pectinophora gossypiella*, Lepidoptera, Gelechiidae, sex pheromone, (*Z,E*)-7,11-hexadecadienyl acetate, (*Z,Z*)-7,11-hexadecadienyl acetate, bioassay.

INTRODUCTION

The evolution of pheromone communication systems depends on their genetic architecture and the selective forces acting upon them. We have examined the genetic basis of pheromone communication in the pink bollworm moth, *Pectinophora gossypiella* (Saunders) (Collins and Cardé, 1985, 1989a,b, 1990; Col-

¹Current address: Department of Entomology, Waters Hall, Kansas State University, Manhattan, Kansas 66506.

lins et al., 1990). The pheromone of this moth is a female-produced, two-component blend of (*Z,E*)- and (*Z,Z*)-7,11-hexadecadienyl acetates (*ZE* and *ZZ*, respectively) (Hummel et al., 1973; Bierl et al., 1974). The mean blend found in pheromone gland extracts is 44% *ZE* (Collins and Cardé, 1985). This pheromone is used by males to locate females and also induces courtship (Colwell et al., 1978; Guerra, 1968).

In this study, we describe a still-air, wing-fanning bioassay and the effect of various pheromone dose-blend combinations on male pheromone response. Wing fanning in the pink bollworm is a component of courtship behavior (Colwell et al., 1978; Guerra, 1968). This bioassay was developed for studies of the genetic bases of male response.

Criteria for a diagnostic bioassay are that the behavior(s) included are well correlated with the success of mate finding and that they provide a continuous (graded) measure of response. We examined the relationship of wing fanning to other pheromone-induced behaviors that are expressed in a wind tunnel. To gauge the relative responses of individual males to two ratios of pheromone components, males must be tested twice. However, male response is inhibited by preexposure to pheromone 1 hr before testing (Collins, 1988). The effect of initial pheromone exposure on wing fanning responses in bioassays conducted 24 hr after preexposure is documented in this paper.

METHODS AND MATERIALS

Insects and Test Conditions. Moths were obtained as pupae from the USDA APHIS Pink Bollworm Rearing Facility in Phoenix, Arizona, where they have been reared in the laboratory for more than 50 generations. Male pupae were placed in 100- × 15-mm glass screw-cap test tubes upon receipt. Moths used in the wind-tunnel study were from a laboratory colony that was started from pupae obtained from the USDA rearing facility (Collins and Cardé, 1985). The wheat germ-soybean flour diet and rearing methods were modified from those of F.D. Stuart (personal communication). Three larvae were reared with ca. 5 g of diet medium in 21-ml clear plastic cups covered with opaque plastic lids. Pupae were removed from the diet after 17 days, sexed, and held singly in 85- × 15-mm glass test tubes with cork stoppers. All pupae were checked daily for adult emergence.

All life stages were held at $26 \pm 1^\circ\text{C}$ and 15:9 hr light-dark. Inadvertent exposure to pheromone prior to testing was avoided by holding the males in a controlled environment chamber isolated from female moths.

Males were tested during the second and third scotophases postemergence. All tests were conducted between 3.5 and 0.5 hr before the end of the scotophase, corresponding to the flight activity period in the field when males are

most responsive to pheromone (Graham et al., 1964; Van Steenwyk et al., 1978). All tests were conducted at $26 \pm 1^\circ\text{C}$ with a light intensity of 1.8 lux, which is within the optimal response range (Farkas et al., 1974). Males were acclimated to these conditions for at least 15 min prior to testing.

Pheromone Stimulus Preparation. For all pheromone blends tested, $10 \mu\text{g}/\mu\text{l}$ concentrations in *n*-hexane were prepared gravimetrically from synthetic pheromone (Farchan Chemical Co.). Lower concentrations were made by serial dilutions in decade steps to $10^{-4} \text{ ng}/\mu\text{l}$. Stimuli were applied in $10 \mu\text{l}$ of solvent to 0.5-cm-wide strips of Whatman No. 1 filter paper, and the solvent was allowed to evaporate. Stimuli were kept in separate 30-ml plastic cups with plastic lids until used. Control stimuli in all experiments consisted of $10 \mu\text{l}$ of *n*-hexane on filter paper.

Bioassay Tubes. The effects of preexposure and of various dose-blend combinations were tested using 10-cm-long \times 2.5-cm-diam glass bioassay tubes with 1-cm-long central transverse slits. Relatively small tubes were used to reduce variation in pheromone concentration that could result from movement of the moth during the bioassay, to facilitate observations under low light intensity, and to permit the storage and handling of a large number of males without having to remove residual pheromone from the bioassay chambers between tests.

On the day after emergence, males were transferred to individual bioassay tubes and the open ends and transverse opening sealed with parafilm. During testing, the transverse opening was uncovered to allow insertion of the pheromone stimulus. Inadvertent exposure to extraneous pheromone during the bioassay was obviated by directing air filtered with activated charcoal and glass wool over the bioassay tube and exhausting this air from the bioassay room.

Effect of Dose-Blend Combination. Treatments consisted of all combinations of five stimulus dosages (10^{-3} to 10 ng of pheromone in decade steps) and seven component blends (10, 25, 38, 44, 50, 65, and 90% ZE). A modified randomized complete block design was used. Blocks consisted of three to five observations for each of the 36 treatments (35 dose-blend combinations and the control). Blocks were completed in two to three consecutive days of testing.

Each male was observed for ca. 2 min prior to testing. Males that wing fanned spontaneously were discarded. The parafilm covering the transverse slit in the bioassay tube was then removed and the male was observed for an additional 10–15 sec and discarded if wing fanning was observed. Fewer than 1% of males were discarded before testing. The filter paper strip impregnated with the appropriate blend and concentration of synthetic pheromone was then inserted. Each male was observed for 2 min. Latency of reponse (time elapsed from the introduction of the stimulus to the initiation of wing fanning) and total duration of wing fanning were recorded. For males that did not wing fan, latency was defined as 120 sec. Males were bioassayed once.

Effect of Preexposure. To examine the effect of preexposure to pheromone

on subsequent response, individual males were bioassayed twice. Males were first exposed during the second scotophase following adult emergence. The stimuli used consisted of 10 ng of pheromone in blends of 10, 44, or 90% ZE. After testing, the bioassay tubes were resealed with parafilm and returned to the controlled environment chamber. Twenty-four hours later these males were exposed to stimuli containing 1 ng of pheromone in blends of 10, 25, 44, 65, or 90% ZE. The combination of blends used for each male was selected randomly.

The effect on wing fanning of bioassay-tube contamination during preexposure was checked. Stimuli with 10 ng of 44% ZE were placed in 10 empty tubes for 2 min. No wing fanning was observed when males were placed in these tubes 1 hr later.

Wind-Tunnel Bioassays. The relationships between wing fanning and other pheromone-mediated responses were examined by observing the response of males to different pheromone blends in a small wind tunnel patterned after that of Cardé and Hagaman (1979), but lacking a visual pattern on the tunnel floor. The Plexiglas wind tunnel was 81 cm long with crosswind dimensions of 28 × 28 cm. Wind velocity was 0.30 ± 0.05 m/sec. Light was provided by a DC-main fluorescent light shielded with a red filter eliminating wavelengths below 680 nm. Light intensity at the middle of the tunnel was 1.8 lux.

Stimuli used in the wind-tunnel bioassays consisted of 10 ng of pheromone containing 25, 44, or 65% ZE. This concentration elicited response levels that allowed differentiation among the 44% ZE and the off-blends (25 and 65% ZE). The filter-paper stimuli were attached to the end of 12-cm-long wires inserted into cork stoppers. After solvent evaporation, these stimuli were placed in 2.5- × 20-cm test tubes until used. New stimuli were prepared immediately before the start of each day's bioassays. For each test, a stimulus was placed in the center of the wind tunnel 10 cm from the upwind end. A male was then released 50 cm downwind from the pheromone source. A test tube containing a male was opened and placed on a 10-cm-high metal platform 50 cm downwind with the open end facing upwind. The occurrences of five behaviors were recorded: (1) wing fanning before taking flight; (2) zigzag, upwind flight in which the male approached within 10 cm of the source; (3) landing on the pheromone source; (4) wing fanning after landing at the source; and (5) wing fanning latency. Wing fanning that lasts but a few seconds either may not be evoked by pheromone or may be caused by very low levels of pheromone contamination (see Results). Therefore, only wing-fanning bouts lasting more than 5 sec were tabulated. Each male was observed until it wing fanned after landing at the source or until 7 min had elapsed.

Statistical Analysis. The significance of differences in the duration of wing fanning in still-air bioassays for various dose-blend combinations and for multiple pheromone exposures were evaluated with the STP method of nonpara-

metric multiple comparisons (Sokal and Rohlf, 1981, p. 438). The significance of differences in the percent of males that wing fanned to various pheromone blends was determined using Friedman's method (Sokal and Rohlf, 1981, p. 446), treating observations made at different concentrations as randomized blocks. A chi-square test was used to compare response incidences among dose-blend combinations. The effect of dose-blend combinations on latency of wing fanning among all males tested was assessed with the STP method; the latency for males that did not wing fan was assumed to be 120 sec (the length of the observation period). Specific distributions were compared using the Mann-Whitney U test (Sokal and Rohlf, 1981, p. 433).

Percentages of response for the three blends tested in the wind tunnel were compared using a chi-square test. The significance of wing-fanning latency was evaluated by the Kruskal-Wallis test (Sokal and Rohlf, 1981, p. 430).

RESULTS AND DISCUSSION

Dose-Blend Combinations. The cumulative durations of wing fanning in response to various dose-blend combinations ranged from 0.1 ± 0.3 to 77.1 ± 37.4 sec (mean \pm SD) (Figure 1). Response was longest at the highest concentration (10 ng) for all blends and generally higher for blends closer to the natural (44% ZE) blend. No significant differences were found among the responses to any blend for the lowest pheromone concentration tested (10^{-3} ng), but these were not different from the control (0.7 ± 2.1 sec) (STP; $P > 0.05$).

FIG. 1. Mean duration of wing fanning as affected by pheromone blend and concentration; $N = 40$ per dose-blend combination. Means not followed by a common letter are significantly different, STP multiple comparison test; $P < 0.01$.

The durations of male wing fanning in response to blends containing 38, 44, and 50% ZE were not significantly different at any concentration tested (STP; $P > 0.05$). These percentages are, respectively, the mean blend emitted by calling females (Haynes et al., 1984), the mean blend found in pheromone gland extracts (Collins and Cardé, 1985), and the blend used commercially to disrupt mating in field populations (Doane and Brooks, 1981). This demonstrates a relatively broad response spectrum for wing-fanning duration and is consistent with patterns of trap catch (Flint et al., 1979) and wind-tunnel response (Linn and Roelofs, 1985).

The percentage of males that wing fanned in response to various dose-blend combinations ranged from 5.0% to 95.0% (Figure 2). Pheromone blend had a significant effect on the incidence of response (Friedman's test, $\chi^2 = 73.5$; $P < 0.01$). The overall patterns observed for the incidence and duration of wing fanning were similar. However, the effects of blend and concentration on wing fanning duration were more pronounced. Although 17.5% of males wing fanned to filter paper treated with solvent, the mean duration of their wing fanning was only 0.7 sec. This suggests that duration is more discriminating than response incidence in separating responses to different blends and concentrations.

Response latencies were longer for lower doses and for extreme blends, and thus, inversely related to wing-fanning duration (Figure 3). No significant differences were found among the latencies for the lowest pheromone concentration tested (10^{-3} ng) and the control (107.9 ± 31.2 sec) (STP; $P > 0.05$). Latencies for blends containing 38, 44, and 50% of the ZE isomer were not

FIG. 2. Percentage of males wing fanning as affected by pheromone blend and concentration; $N = 40$ per dose-blend combination. Means not followed by a common letter are significantly different, χ^2 test; $P < 0.01$.

FIG. 3. Mean latency of wing fanning as affected by pheromone blend and concentration; $N = 40$ per dose-blend combination. Means not followed by a common letter are significantly different, STP multiple comparison test; $P < 0.01$.

significantly different at any of the concentrations tested (STP; $P > 0.05$), reflecting the same broad response spectrum as wing-fanning duration.

Although qualitatively similar, the relationships between latency and stimulus parameters were not as pronounced as for wing fanning duration (Figure 1), and latency was more variable than duration (coefficients of variability among males that wing fanned = 70.0% and 140.3%, respectively). These results suggest that the duration of wing fanning is a more reliable measure of male response than latency.

The relationship between concentration and response in the pink bollworm appears to be direct: increased pheromone doses evoke increased duration of wing fanning. The relationship between pheromone ratio and the intensity of wing fanning also appears to be straightforward: the incidence of response is higher and response duration is elevated for ratios approaching the natural blend.

Effect of Preexposure. Preexposure did not affect the duration of wing fanning in bioassays conducted 24 hr later, as the same response patterns were observed in both tests (Table 1). For each blend used in the second exposure, the duration of wing fanning was not significantly affected by the stimulus to which the male was preexposed (STP multiple comparison test; $P > 0.05$). No pattern is evident in these data to suggest that initial exposure alters subsequent response in a predictable manner.

Wind-Tunnel Bioassays. One or more overt response behaviors were observed for 20.0, 72.5, and 27.5% of the males tested in the wind tunnel using blends with 25, 44, and 65% ZE, respectively ($N = 40$ per blend) (Table 2).

TABLE 2. FREQUENCY OF RESPONSE SEQUENCES TO THREE PHEROMONE BLENDS IN A WIND TUNNEL^a

PW	Behavioral sequence ^b			25% ZE	44% ZE	65% ZE	Total
	UF	LS	WF				
*				1	2		3
	*			1		1	2
	*	*		1		1	2
	*	*	*	3	16	9	28
*	*	*	*	2	11	1	14
	No response			32	11	28	71

^a Stimuli contained 10 ng of pheromone.

^b Behaviors: PW, preflight wing fanning; UF, upwind flight; LS, landing on the pheromone source; and WF, wing fanning after landing.

The percentage of males that wing fanned after landing at the 44% *ZE* source was 67.5% and was significantly different from the 12.5 and 25.0% for the 25 and 65% *ZE* blends ($\chi^2 = 22.97$ and 12.87 , respectively, $P < 0.01$). The percentages of males that wing fanned after landing on the 25 and 65% *ZE* stimuli were not significantly different ($\chi^2 = 1.31$, $P > 0.05$). The relationship between pheromone blend and response incidence in the wind tunnel is consistent with relationships observed in the still-air bioassays (Figures 1 and 2).

Among males that flew upwind, 91% (42/46) landed at the source and wing fanned after landing. All males that landed at the source wing fanned. Wing fanning was always accompanied by clasper extension (as described by Colwell et al., 1978). Among 49 responding males, the sequence of flight, landing, and wing fanning was observed for all but seven individuals.

In the wind tunnel, male pink bollworms usually take flight abruptly and without discernible preflight behavior. Wing-fanning behavior in our wind tunnel was qualitatively indistinguishable from wing fanning observed in the glass bioassay tubes. Preflight wing-fanning bouts appeared identical to bouts that took place after landing on the pheromone source and are assumed to be courtship related. Preflight wing fanning was observed for 17 males; 14 of these flew upwind, landed, and wing fanned after landing. No males exposed to the control responded.

Among males that wing fanned after landing on the source, the mean (\pm SD) wing-fanning latencies were 1.95 ± 2.17 , 2.19 ± 1.91 , and 2.86 ± 2.87 min for the 25, 44, and 65% *ZE* blends, respectively. These latencies were not significantly different (Kruskal-Wallis test, $H = 2.20$; $P > 0.05$).

Our wind-tunnel bioassays suggest that the incidence and duration of wing fanning of confined males are well correlated with upwind flight and landing near the pheromone source. A similar correlation has been demonstrated for the Oriental fruit moth, *Grapholita molesta* (Busck) (Baker and Cardé, 1979): once a male wing fans, he is very likely to complete the entire response sequence. However, this relationship is not universal. For example, in *Ostrinia nubilalis* (Hübner) the characteristics of wing fanning of males confined in a 2.5-cm-diam \times 90-cm-long glass tube with a 1.2 m/sec air flow (Webster and Cardé, 1984) did not reflect the discrimination found in a wind-tunnel assay (Glover et al., 1987). Similarly, the duration of preflight wing fanning and dosage are unrelated for the gypsy moth, *Lymantria dispar* (L.) (Cardé and Hagaman, 1979; Hagaman and Cardé, 1984). However, in this species wing fanning prior to flight is evidently involved in thoracic temperature regulation (Cardé and Hagaman, 1983).

Conclusions. The wing-fanning bioassay used in this study appears to provide a reliable indicator of the effects of blend and concentration on pheromone-mediated attraction and courtship behavior in *P. gossypiella*. It also provides a continuous measure of response intensity useful in genetic analyses. Traits with discrete phenotypes (e.g., upwind flight) must be based on assumed (but not

directly observable) underlying continuous variables (Falconer, 1981). The wing-fanning bioassay is simple and allows many moths to be processed in a short interval. To evaluate the response of males to a spectrum of pheromone stimuli, individual males must be tested repeatedly. The preexposure experiment indicated that males may be retested on consecutive days without discernible alterations in the pattern of response on the second day. Examples of the application of this assay in measurements of the heritability of male response are given by Collins and Cardé (1989a) and in artificial selection by Collins and Cardé (1990).

(Received December 3, 1987; accepted January 30, 1989)

Abstract—Heritability of variation in male pheromone response by pink bollworm moths, *Pectinophora gossypiella* (Saunders), was examined using a still-air, wing-fanning bioassay. Heritability (\pm SE) of overall responsiveness, as measured by the mean duration of wing fanning to the blend of pheromone components produced by females [44:56 ratio of (*Z*, *E*)- to (*Z*, *Z*)-7,11-hexadecadienyl acetate], was 0.385 ± 0.095 . Heritabilities of wing-fanning duration to blends with 25 and 65% *Z*, *E* isomer were 0.377 ± 0.113 and -0.145 ± 0.103 , respectively. These findings indicate an asymmetry in the genetic component of variation in response to pheromone blends with high and low proportions of the *Z*, *E* isomer. An index of response specificity for individual males was developed based on the response to an off-blend (either 25 or 65% *Z*, *E* isomer) relative to the response to the 44% *Z*, *E* blend. Heritabilities of response specificity were 0.117 ± 0.059 and -0.043 ± 0.067 for the 25 and 65% *Z*, *E* blends, respectively.

Key Words—Pink bollworm, *Pectinophora gossypiella*, Lepidoptera, Gelechiidae, sex pheromone, genetics, heritability, pheromone response, (*Z*, *E*)-hexadecadienyl acetate, (*Z*, *Z*)-7,11-hexadecadienyl acetate.

INTRODUCTION

The genetic bases of pheromonal communication in the pink bollworm moth, *Pectinophora gossypiella* (Saunders), are of particular interest because synthetic pheromone is used commercially to disrupt mating (Doane and Brooks, 1981;

¹Current address: Department of Entomology, Waters Hall, Kansas State University, Manhattan, Kansas 66506.

Baker et al., 1989), and this application creates the potential for the evolution of new pheromone strains that are resistant to such disruption. The sex pheromone of the female pink bollworm is a blend of the (*Z*, *E*)- and (*Z*, *Z*)-isomers of 7,11-hexadecadienyl acetate (*ZE* and *ZZ*, respectively) (Hummel et al., 1973; Bierl et al., 1974). Females produce a blend containing a mean (\pm SD) of $44.2 \pm 2.3\%$ *ZE* (Collins and Cardé, 1985). In contrast to the narrow variance signal produced by females (Collins and Cardé, 1985; Haynes et al., 1984), pink bollworm males are attracted to a relatively broad range of pheromone blends (Flint et al., 1979; Haynes et al., 1984).

Since efficient communication depends on the coordination of signaling and reception, evolutionary change in pheromone-mediated systems depends upon the nature and extent of heritable variation in pheromone production and response. Heritable variation in the blend and amount of pheromone produced by female *P. gossypiella* has been documented (Collins and Cardé, 1985, 1989a; Collins et al., 1990). The current study is an analogous investigation of heritability in male pheromone response using a wing-fanning bioassay. Wing-fanning duration increases with concentration and is greater for blends more closely approximating the blend normally produced by females. Wing fanning is well correlated with other pheromone response behaviors, including upwind flight (Collins and Cardé, 1989b).

This paper examines variation in wing fanning and estimates heritabilities for overall responsiveness to various blends, the specificity of response to particular blends, response latency, and response thresholds in a laboratory population. Heritability measures the fraction of phenotypic variance that is available to selection and is a function of the genes influencing the character, environmental conditions, and genotypic frequencies in the population (Falconer, 1981). Heritability also measures the degree of resemblance between relatives and can be used to predict the rate of change in average phenotype in response to selection pressure in the field or in the laboratory.

METHODS AND MATERIALS

Moths. Pupae were obtained from USDA, APHIS in Phoenix, Arizona. These pupae were sexed and the females discarded. Inadvertent exposure to pheromone prior to testing was avoided by placing male pupae individually in 85- × 15-mm test tubes with screw-caps or cork stoppers and keeping them in a controlled environment chamber at 27°C and 15:9 hr light-dark, isolated from sources of natural and synthetic pheromone. Pupae were checked daily for adult emergence. On the day after emergence, each male was transferred to a 10-cm-long × 2.5-cm-diam glass bioassay tube with a 1-cm-long centrally

located transverse opening (Collins and Cardé, 1989b). The ends and transverse opening were sealed with parafilm.

Stimulus Preparation. Pheromone stimuli used in the bioassays consisted of various combinations of concentrations and blends of the *ZE* and *ZZ* isomers. For all blends, 10 $\mu\text{g}/\mu\text{l}$ concentrations in *n*-hexane were prepared gravimetrically from synthetic compounds (Farchan Chemical Co.). Lower concentrations were made by serial dilutions in decade steps to 10^{-4} $\text{ng}/\mu\text{l}$. Each stimulus was applied in 10 μl of solvent to a strip of filter paper. Solvent was allowed to evaporate, and the stimuli were kept in separate 30-ml clear plastic pill cups with plastic lids. New stimuli were prepared immediately before the start of each day's bioassays.

Bioassay. A still-air, wing-fanning bioassay (Collins and Cardé, 1989b) was used to measure male response. Males were first tested during the second or third scotophase. Each male was observed for ca. 2 min prior to bioassay. If spontaneous wing fanning was observed, the male was discarded. The parafilm covering the transverse opening in the bioassay tube was then removed and the male observed for an additional 10–15 sec and discarded if wing fanning was observed. Each male was then bioassayed by inserting the filter paper stimulus with the appropriate blend and concentration of pheromone into the bioassay tube through the transverse opening. Males were observed for 2 min using 10^{-1} ng of pheromone. In a previous study, only 1.8% of males wing fanned for more than 110 sec, and none wing fanned for more than 117.8 sec using this dose for any blend tested in this study (Collins and Cardé, 1989b). Latency (the time elapsed from the introduction of the stimulus to the start of wing fanning) and total duration of wing fanning were recorded using two stop watches. Bioassays were conducted during the last 4 hr of the scotophase when males are most responsive (Graham et al., 1964; Van Steenwyk et al., 1978) at 27°C and 1.8 lux.

Males were bioassayed twice, first with a 44% *ZE* blend (the blend normally produced by females), and then with an off-blend containing either 25 or 65% *ZE*. The two tests for each male were conducted on consecutive days. When pheromone exposures are separated by 24 hr, the initial exposure does not alter the subsequent response in a consistent or systematic manner (Collins and Cardé, 1989b).

Responsiveness. Two aspects of male response were examined: overall responsiveness and response specificity. The general level of responsiveness was measured in two ways: (1) the latency and duration of wing fanning to the 44% *ZE* blend, and (2) the sum of the responses to both stimuli (the 44% *ZE* blend and the off-blend).

Response Specificity. A specificity index (*S*) was calculated by comparing relative responses to the normal (44% *ZE*) and off-blends (25 or 65% *ZE*) using

a modification of the Shannon-Weaver index. This index equals 0.0 for males that respond only to the off-blend, 1.0 for males that respond only to the normal blend, and 0.5 for males that do not differentiate between the blends (Figure 1). Its construction is described in Appendix A.

Heritability Estimation. Heritabilities of characters associated with pheromone response behaviors were estimated by parent-offspring regressions. Males in the parental generation were bioassayed and then mated with virgin females selected randomly from our laboratory colony. Male-female pairs were placed in 7.5- × 7.5- × 2.8-cm clear plastic oviposition cages. Sucrose solution was available to the adults in 1.9-ml vials with cotton wicks on the bottom of each cage. Paper oviposition substrates were changed daily. To segregate the progeny of each male-female pair, oviposition substrates were sealed in 15- × 15- × 2-cm plastic bags until the larvae hatched.

Newly hatched larvae were placed individually in 21-ml clear plastic cups covered with plastic lids. Each cup contained ca. 5 g of wheat germ-soybean flour diet (Collins and Cardé, 1985). Pupae were removed after 17 days, sexed, and placed singly in 85- × 15-ml glass test tubes with cork stoppers. All life stages were kept at 27°C and 16:8 hr light-dark photoperiod.

Male offspring from these matings were bioassayed as before. Approximately five male offspring per family were tested with the same stimuli and order of presentation used to test their fathers. Heritabilities of response param-

FIG. 1. Response specificity (S) as a function of the relative response to the normal (44% ZE) blend, $R_n [= D_n / (D_n + D_o)]$, where D_n and D_o are the wing-fanning durations for the normal and off-blends, respectively].

eters were estimated by the regression of parent (father) on mean offspring values. The number of male offspring available for testing varied among families. Thus, regression coefficients were estimated by weighting families according to the number of offspring measured (Falconer, 1981, p. 167).

The duration of wing fanning was not normally distributed because many males did not wing fan. Thus, nonparametric tests were used in intergenerational comparisons. The Mann-Whitney U statistic was calculated for each comparison, and a value, t_s , was computed based on this statistic (Sokal and Rohlf, 1981, p. 435) and used to test the significance of observed differences. The percentages of males that wing fanned to different pheromone stimuli within generations were compared using a χ^2 test.

Threshold. Response threshold was measured by the latency of wing fanning of males exposed to a series of increasing pheromone concentrations. Males were obtained as pupae and reared as before. Each male was tested on two consecutive days. During each test, the male was exposed to a series of stimulus concentrations. Test series consisted of six pheromone stimuli in 10 μ l of *n*-hexane, increasing by decade steps from 10^{-3} ng to 10^2 ng of total pheromone (*ZE* plus *ZZ* components). All stimuli in series A contained 25% *ZE* isomer, and series B contained stimuli with 65% *ZE*. Males that were exposed to series A on the second day postemergence were tested against series B on the third day, and vice versa.

Males were exposed for 30 sec to each stimulus, from the lowest to the highest concentrations. Each stimulus was kept in the bioassay tube until the next stimulus was introduced. Tests were terminated upon initiation of wing fanning. Prior to each stimulus series, the parafilm was removed from the transverse slit in the bioassay tube and the male observed for 30 sec. Males that spontaneously wing fanned during this period were discarded. Latency was the time elapsed from the introduction of the first stimulus until wing fanning. The primary advantage of this approach to estimating response latency is that nearly all males respond.

After testing, males were paired with virgin females selected randomly from a laboratory colony, and the offspring of these pairings were reared as before. Male offspring were tested using the same stimuli series used to test their male parents.

Latency of response to all blends was estimated by the sum of the latencies observed during exposure to each of the two stimulus series. The degree of symmetry associated with responses to blends with high and low percentages of the *ZE* isomer was measured by the difference between the latencies observed for the two stimulus series. Heritabilities of these latency measures were estimated by a weighted regression of mean offspring on paternal values.

RESULTS

Overall Responsiveness. The duration of wing fanning in a 2-min observation period to 10^{-1} ng of pheromone containing 44% ZE isomer was 46.10 ± 30.97 sec (mean \pm SD). In subsequent exposures to 25 and 65% ZE stimuli, mean responses were 19.45 ± 27.47 and 10.18 ± 25.38 sec, respectively. These findings are consistent with those of a previous study (Collins and Cardé, 1989b).

These males were used to produce a second generation for the estimation of heritabilities. Mean response durations for blends with 25, 44 and 65% ZE isomer among F_1 males were 16.18 ± 24.53 , 41.79 ± 34.07 , and 8.46 ± 21.10 sec, respectively. The mean responses in the parental and F_1 generations were not significantly different for each blend tested (Mann Whitney U test; $t_s = 0.84, 1.60, \text{ and } 0.94$ for the 25, 44, and 65% ZE blends, respectively; $P > 0.05$). Therefore, random drift or unidentified selective forces did not appear to affect gene frequencies at loci influencing wing fanning.

A higher percentage of males wing fanned to the 25% ZE blend than to the 65% ZE blend in both generations. Of the males tested in the parental generation, 61.70 and 36.71% responded to the 25 and 65% ZE blends, respectively (significantly different, $\chi^2 = 9.75, N = 173; P < 0.01$). Similarly, 55.17 and 30.75% responded to the 25 and 65% ZE blends, respectively, in the F_1 generation (significantly different, $\chi^2 = 44.407, N = 754; P < 0.01$).

Males that were more responsive to the 44% ZE blend also tended to be more responsive to blends with 25 or 65% ZE. The durations of wing fanning in the two tests were significantly correlated in both the parental and F_1 generations (Table 1). These data suggest that some males were more responsive than others over a relatively wide range of component blends. Thus, differences

TABLE 1. CORRELATIONS BETWEEN DURATION OF WING FANNING TO INITIAL STIMULUS WITH 44% ZE ISOMER AND WING-FANNING DURATION IN SECOND BIOASSAY WITH 25 OR 65% ZE BLEND

Generation	Second stimulus	Correlation coefficient	N	F
Parents	25% ZE	0.422	94	20.25 ^a
	65% ZE	0.394	79	14.44 ^a
Offspring	25% ZE	0.198	406	16.81 ^a
	65% ZE	0.298	348	33.64 ^a

^aSignificantly different; $p < 0.01$.

among males did not appear to be the result of different response thresholds for specific blends.

Significant correlations were found between the wing-fanning duration observed in the first and second bioassays for each male within both the parental and F_1 generations. (Table 1; coefficients transformed by the inverse hyperbolic tangent; $z = 2.15$, $P < 0.05$; Sokal and Rohlf, 1981, p. 583). The reason for the difference between generations is not known, and there were no other significant differences among correlation coefficients.

Heritability of Responsiveness. Estimated heritability (\pm SE) of responsiveness, measured by wing-fanning duration to a 44% ZE blend, was 0.385 ± 0.095 (statistically significant, $t = 4.052$, $N = 173$; $P < 0.01$) (Figure 2b). Thus, 38.5% of variance in the observed response to the 44% ZE blend was attributable to the additive effects of genes.

Heritability of responsiveness measured as the sum of the responses to the 44% ZE blend and to an off-blend (either 25 or 65% ZE) was 0.326 ± 0.085 (significantly different from zero, $t = 3.83$, $N = 173$). The estimated heritability for the combined response is similar to the estimate obtained using the natural blend alone. However, when males exposed to the 25 and 65% ZE blends are considered separately, a pronounced asymmetry is apparent. The heritability of combined responses to the 44 and 25% ZE blends was 0.542 ± 0.103 ($t = 5.273$, $N = 173$; $P < 0.01$). The heritability of response duration to the 25% ZE blend alone was also significant ($h^2 = 0.377 \pm 0.113$, $t = 3.341$, $N = 94$; $P < 0.01$) (Figure 2a). However, the comparable estimate for the summed responses of males exposed to 44 and 65% ZE blends was 0.064 ± 0.137 ($t = 0.465$, $N = 173$; $P > 0.05$). This is a result of the nonsignificant heritability of response to the 65% ZE blend ($h^2 = -0.145 \pm 0.103$, $t = 1.404$, $N = 79$; $P > 0.05$) (Figure 2c).

Heritability of Response Specificity. Heritability of response specificity was 0.146 ± 0.045 ($t = 3.273$, $N = 177$; $P < 0.01$). However, due to the asymmetry in response to the 25 and 65% ZE blends, the heritability of response specificity for males exposed to these blends differed substantially. The heritability for males exposed to the 25% ZE blend was 0.117 ± 0.059 ($t = 1.99$, $N = 98$; $P < 0.05$), while the heritability for males exposed to the 65% ZE blend was -0.043 ± 0.067 ($t < 1$, $N = 78$; $P > 0.05$).

Latency. The estimated heritability of the latency associated with wing fanning to the 44% ZE blend was 0.027 ± 0.109 and was not significantly different from zero ($t = 0.245$, $N = 166$; $P > 0.05$). The low heritability of latency is partly due to a high degree of variability associated with this response measure. The mean (\pm SD) latencies of males responding to the 44% ZE blend in the parental and F_1 generations were 7.97 ± 13.34 and 10.33 ± 16.63 sec, respectively. The coefficients of variation (CV) for these estimates are 167.38

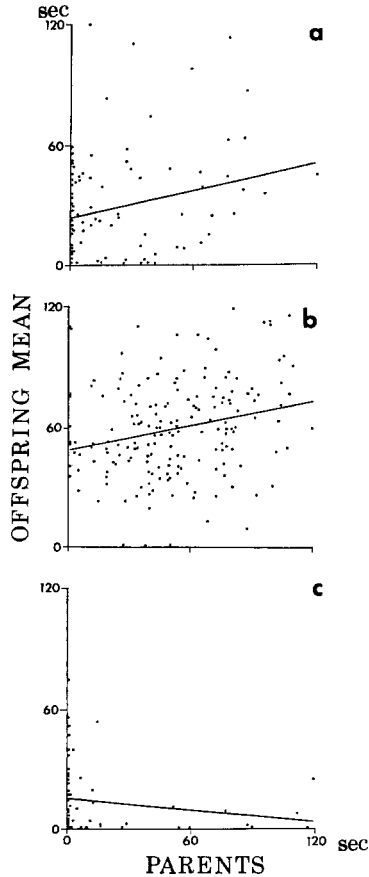

FIG. 2. Regression of wing-fanning duration to pheromone blends containing (a) 25%, (b) 44%, or (c) 65% (*Z, E*)-7,11-hexadecadienyl acetate by male parents on the mean wing-fanning durations of their sons.

and 160.99. Corresponding CV estimates for the duration of response to the 44% *ZE* blend were 51.4 and 49.3% for the parental and F_1 generations, respectively.

Threshold. Pheromone response threshold was measured by the latency of wing fanning by males exposed to increasing pheromone concentration series. Mean latencies (\pm SD) for the 25 and 65% *ZE* blends were 79.38 ± 53.24 and 102.98 ± 62.37 sec, respectively, for males in the parental generation. Comparable means for the offspring of these males were 96.14 ± 41.03 and 113.58 ± 45.27 for the low and high *ZE* blends, respectively. The latencies in the

parental and F_1 generations were not significantly different for the stimulus series involving the 25% ZE blend (Mann-Whitney U test; $t_s = 1.56$; $P > 0.05$) but were different for the 65% ZE series (Mann-Whitney U test; $t_s = 2.11$; $P < 0.05$).

Heritabilities (\pm SE) of threshold were 0.113 ± 0.175 and 0.217 ± 0.164 for the 25 and 65% ZE stimuli, respectively, and were not significant ($t = 0.644$ and $t = 1.325$, $N = 58$, $P > 0.05$). Heritability of the summed latencies for both stimuli was 0.110 ± 0.131 (not significant, $t = 0.844$, $N = 58$; $P > 0.05$).

Heritability of threshold asymmetry (measured by the difference between latencies for the two stimuli series) was 0.314 ± 0.23 (not significant, $t = 1.33$, $N = 58$, $P > 0.05$). Thus, variance in threshold (measured by response latency) upon which either natural or artificial selection may act was not found in our laboratory colony.

DISCUSSION

Selection may reduce additive genetic variance in characters closely related to fitness, because alleles that increase fitness will become fixed as a population approaches equilibrium (Fisher, 1958). Thus, heritabilities for characters closely associated with reproductive success are typically low (Falconer, 1981). For example, Gustaffsson (1986) found an inverse relationship between heritability and the influence on fitness for a number of morphological and life history characters in the collared flycatcher (*Ficedula albicollis*). Particular components of fitness may be heritable, but negative genetic correlations between them tend to reduce the heritability of lifetime reproductive success (Jones, 1987), although positive correlations have also been documented (Palmer and Dingle, 1986).

Male mating behavior is generally considered to be an important component of fitness (Ehrman and Parsons, 1981). Nonetheless, significant heritable variation in both overall responsiveness and in response specificity has been demonstrated for a laboratory population of the pink bollworm. A number of mechanisms have been suggested to account for the persistence of additive genetic variance, including mutation (Lande, 1976), linkage disequilibrium (Taylor and Williams, 1982), variable environments (Cade, 1984), genetic drift, and immigration (Jones, 1987). However, heritability estimates must be interpreted carefully because they are strictly applicable only for the population used in making the estimates and for the particular set of behavioral and ecological circumstances in which the measurements were made. Further, heritability estimates assume negligible genetic-environmental interactions, dominance and epistatic effects, genetic drift, and natural selection.

Evolutionary change in male response could occur through an altered pro-

pensity to respond to all blends or through a change in the pattern of relative responses to particular blends. The heritability of overall responsiveness by males observed in this study (0.385) is similar to the estimated heritability for the amount of total pheromone produced by females (0.410) (Collins and Cardé, 1985). These estimates demonstrate that there is heritable variance associated with quantitative aspects of both signal production and response. It has been suggested that females emitting little pheromone may tend to attract males that have low response thresholds (Greenfield, 1981). On the other hand, resistance to synthetic pheromone used as a mating disruptant could evolve by increased emission rates (Cardé, 1976, 1981; Haynes et al., 1984). Male response to inappropriate stimuli (such as a low background concentration of formulated pheromone) could be minimized by an elevated response threshold, although the same end might be achieved by behavioral habituation *sensu lato*.

A shift in the ratio of pheromone components emitted also has been proposed as a qualitative mechanism for the evolution of resistance to synthetic pheromone (Cardé, 1976, 1981). The ratio produced by pink bollworm females has a significant heritability (0.342) (Collins and Cardé, 1985). However, interpretation of the degree of genetically based variation in male response specificity is complicated by an asymmetry in the heritabilities of responses to ratios on either side of the natural mean.

Males were more responsive to the 25% *ZE* blend than to the 65% blend, and heritable variation was found for the 25% *ZE* blend, but not for the 65% *ZE* blend. A similar asymmetry in the heritability of response specificity was observed. Thus, the ratio evoking maximum response could be shifted in males toward a blend with less *ZE* isomer, but selection in the other direction should be more difficult. Genetic influence on variation may be greater for dose–blend combinations that elicit a greater response, but the relationship between response level and heritability is not known.

Heritability estimates in this study were derived using blends of a single concentration at a constant temperature. However, blend preference patterns may shift with concentration (Linn and Roelofs, 1985), and response specificity can be modulated by temperature (Linn et al., 1988). Therefore, a full understanding of the response asymmetry would require heritability estimates for a range of pheromone doses at several temperatures.

Although the pink bollworm was originally described from specimens collected in India, it is believed to be indigenous to Australia (Flint et al., 1979). Attraction to different blends of (*Z*, *E*)- and (*Z*, *Z*)-7,11-hexadecadienyl acetate has been examined for three closely related *Pectinophora* species in Australia (Rothschild, 1975). Based on pheromone trap-catch data, *P. gossypiella*, *P. endema* Common, and *P. scutigera* (Holdaway) were maximally responsive to blends with 50, 33, and 10% *ZE*, respectively. Where these species are sym-

patric, a reduction in heritable variance in the responsiveness of pink bollworms to blends with a lower percentage of *ZE* might be expected.

Based on the relatively high degree of heritable variation in overall male responsiveness reported here, and the estimated heritability previously observed for pheromone titer in females (Collins and Cardé, 1985), rapid changes in quantitative features of the pheromone communication system of the pink bollworm appear feasible under appropriate selection pressures, such as the use of formulated synthetic pheromone to disrupt mating.

APPENDIX A

Response Specificity. The specificity of wing-fanning to different pheromone blends was measured by first computing the relative responses to the normal (44% *ZE*) and off-blends (25 or 65% *ZE*) for each male. Relative response to the normal blend, R_n , was defined as:

$$R_n = D_n / (D_n + D_o) \quad (1)$$

where D_n and D_o are the durations of wing-fanning to the normal and off-blend, respectively. Relative response to the off-blend, R_o , was thus:

$$R_o = 1 - R_n \quad (2)$$

Specificity (S) was then estimated by comparing relative responses using a modification of the Shannon-Weaver index (Shannon, 1949):

$$S = \begin{cases} [-(R_n \log_e R_n + R_o \log_e R_o)] / 1.386, & R_n \leq 0.5 \\ [1.386 + (R_n \log_e R_n + R_o \log_e R_o)] / 1.386, & R_n > 0.5 \end{cases} \quad (3)$$

Equation 3 is partitioned into two ranges to permit differentiation between males that respond predominantly to the normal blend and males that respond primarily to an off blend. Thus, if the duration of wing-fanning is longer for the normal than for the off-blend, S will be greater than 0.5, whereas S for males that are more responsive to the off-blend will be less than 0.5 (Figure 1). For example, if the duration of wing fanning to 25 and 44% *ZE* blends were 10 and 30 sec, respectively, then R_n would equal 0.75 [=30/(10 + 30)], $R_o = 0.25$ (=1 - 0.75), and $S = 0.594$ {=[1.386 + (0.75 log_e 0.75 + 0.25 log_e 0.25)/1.386]}. If the responses were reversed (30 and 10 sec for the 25 and 44% *ZE* blends), then R_n would equal 0.25, $R_o = 0.75$, and $S = 0.406$ {=[-(0.25 log_e 0.25 + 0.75 log_e 0.75)/1.386]}. Because specificity is undefined for males that did not respond to at least one of the stimuli, families were excluded from the analysis if the male parent or all male offspring failed to respond to either blend.

Acknowledgments—This research was supported in part by NSF grant PCM-8309398, and a University of Massachusetts Bio-Medical Research Grant. We thank Robert Staten, Fred Stuart, and Anna Lowe, USDA, APHIS, for generously supplying material used to establish and maintain the laboratory colonies, Sheri Rosenblum for culture maintenance and technical assistance, and an anonymous reviewer for comments on the measurement of response specificity.

(Received September 7, 1988; accepted January 31, 1989)

Abstract—A method based on ion-pairing reversed-phase liquid chromatography was developed to separate and quantify the total alkaloid content in *S. ptycanthum* (eastern black nightshade). The method is shown to separate satisfactorily the aglycones and some of the glycoalkaloids. The mobile phase used was aqueous sodium dodecyl sulfate-acetonitrile.

Key Words—*Solanum ptycanthum*, eastern black nightshade, glycoalkaloids, ion-pairing chromatography, solanidine, solasodine.

INTRODUCTION

Solanum ptycanthum (known as eastern black nightshade) is a problem weed in North America. Many crop fields, such as soybean, wheat, and sunflower, are infested with this weed. Black nightshade has a high content of steroidal alkaloids. Since alkaloids are known to be germination inhibitors (Evenari, 1949), it is of interest to study and evaluate them as potential means for weed control.

Early work relating to the identification, separation, and quantification of alkaloids was done using thin-layer chromatography (TLC) (Paquin and Lepage, 1963). The TLC method, however, was not always successful in separating the alkaloids. More recently, high-performance liquid chromatography (HPLC) has been used. Bushway et al. (1979) succeeded in separating the glycosides α -chaconine, β -chaconine, and α -solanine by using three different columns. Crabbe and Fryer (1980) analyzed and separated solasodine, solanine, solamargine, and solasodiene using reversed-phase partition chromatography. Hunter et al. (1980) used adsorption chromatography on a silica column for the

separation of *Solanum* and *Veratrum* alkaloids. Hunter and Heftmann (1983) fractionated *Solanum laciniatum* leaves using the chromatotron and analyzed the glycoalkaloid obtained by reversed-phase HPLC. Cham and Wilson (1987) used mass spectral analyses to analyze the glycoalkaloids extracted from *Solanum sodomaeum*. Eldridge and Hockridge (1983) identified the glycoalkaloids present in eastern black nightshade dried berries (*Solanum ptycanthum*). These studies showed that HPLC is a more reliable and easier method than TLC to identify and quantify the alkaloid content in various plant extracts. Most of the investigations, however, dealt with the glycoalkaloids.

In this study, a simpler and more rapid method for quantifying the total alkaloid content was developed. The method initially hydrolyzes the *Solanum ptycanthum* glycoalkaloids to their aglycones and then uses ion-pairing reversed-phase chromatography to separate and quantify the total alkaloid content. The advantages of this method are: (1) the aglycone is more stable, (2) the aglycone is more easily identifiable, and (3) the standards for aglycones are more readily available.

METHODS AND MATERIALS

Fresh green berries from *Solanum ptycanthum* picked locally were ground and extracted with boiling methanol, filtered, and concentrated to the desired volume. A portion of the sample was taken and diluted, if necessary, with methanol. For the detection of glycoalkaloids, this portion was injected in the HPLC along with the standards. Another portion of the original extract was hydrolyzed, according to Eldridge and Hockridge (1983), and the aglycone was extracted using chloroform. Then 10 μl of the chloroform extract was injected into the HPLC.

The HPLC used has an Isco V_4 absorbance detector, a Milton Roy mini-pump having a pulse dampener, a Valco injection valve, and Alltech C_{18} column (10 μm particle size, 25 cm long, and 4.6 mm ID). Tomatidine, solanidine, α -solanine, α -chaconine, and solasodine standards were purchased from Sigma Chemical Company, (St. Louis, Missouri). Solamargine was generously supplied by Dr. S.L. Sinden, U.S. Department of Agriculture, Beltsville, Maryland. All standards were dissolved in methanol except for solanidine, which was dissolved in chloroform. The concentration of all the standards was 0.2–0.3 mg/ml. All solvents and reagents were analytical grade or HPLC grade. The wavelength used was 205 nm, sensitivity 0.02 a.u.f.s, and the flow rate of the solvent was 1.4 ml/min. The solvent used for the ion-pairing reversed-phase chromatography method was 0.017 M (0.5% w/v) aqueous sodium dodecyl sulfate–acetonitrile (15:85). Going to a 1% concentration did not improve the resolution. The aqueous sodium dodecyl sulfate was adjusted to pH 2.3–2.5

with 85% phosphoric acid before mixing it with the acetonitrile. Severe peak broadening was observed at pH higher than 3. Sodium dodecyl sulfate was chosen because it is a commonly available counter ion and is transparent at the wavelengths used. Acetonitrile was used because it usually gives better column efficiency than methanol and is also transparent at short wavelengths. The C₁₈ column was used because it gave better separation of the alkaloids than the C₈ column.

RESULTS AND DISCUSSION

It is difficult to find standards for some glycoalkaloids. Furthermore, the use of crude extract in the separation and detection of alkaloids is easier and faster than if purified extract is required. It would be useful, therefore, to find a method that resolves these two difficulties. Ion-pairing reversed-phase chromatography is such a method. It uses hydrolyzed crude extract, which is more stable, and relies on the aglycone whose standard is more readily available. Moreover, the determination of the alkaloid aglycones avoids the coextractants commonly interfering with the glycoside separation and the variation in glycoside patterns resulting from decomposition of extracted material.

Figure 1 shows the combined standard for solanidine and solasodine co-chromatographed. The figure shows the solanidine standard to be eluted in about 18 min and the solasodine standard by about 24 min. Figure 1 shows that the two standards are clearly separated in approximately 5 min. Moreover, the two peaks are well defined with no interference.

Figure 2 is a chromatogram of the hydrolyzed crude extract of *Solanum ptycanthum* fresh green berries. This chromatogram was obtained using the same conditions as those for the standards in Figure 1. Figure 2 clearly shows the presence of the aglycone solasodine in the *Solanum ptycanthum* green berries extract. The sample does not appear to contain any solanidine.

Chromatograms were also run on tomatidine, the aglycone of tomatine, found mainly in tomatoes, using ion-pairing reversed-phase chromatography. It was found that a much larger quantity of the standard, 5 μ g or more should be injected into the HPLC to obtain an appreciable peak. The retention time was found to be intermediate between solanidine and solasodine—about 22.7 min.

To check whether the ion-pairing reversed-phase chromatography method also works for glycoalkaloid separation, some available glycoalkaloid standards were tested in the same way. Solamargine and α -solanine were cochromatographed. Figure 3 shows that they were successfully separated. The resolution of α -chaconine and α -solanine was poor when the two standards were cochromatographed. The same poor result was obtained with solamargine and α -chaconine.

FIG. 1. Chromatogram of mixture of solanidine and solasodine standards. Flow rate 1.4 ml/min; detector sensitivity, 0.02 a.u.f.s.; wavelength, 205 nm; chart speed, 6.6 mm/min; 2 μ g injection. Peak 1 = solanidine; peak 2 = solasodine.

FIG. 2. Chromatogram of hydrolyzed *Solanum ptycanthum* berries. Flow rate 1.4 ml/min; detector sensitivity, 0.02 a.u.f.s.; wavelength, 205 nm; chart speed, 6.6 mm/min; 10 μ l injection. Peak 1 = solasodine.

FIG. 3. Chromatogram of mixture of solamargine and α -solanine. Flow rate 1.4 ml/min; detector sensitivity, 0.02 a.u.f.s.; wavelength, 205 nm; chart speed, 6.6 mm/min; 10 μ l injection. Peak 1 = solamargine; peak 2 = α -solanine.

CONCLUSIONS

The aglycones solanidine and solasodine can be separated and identified by ion-pairing reversed-phase chromatography. Tomatidine, solasodine, and solanidine are resolved when all three are present in the same mixture. Some of the glycoalkaloids were separated. This method could also be used to separate aglycones from glycoalkaloids when they are present in the same mixture. It is suggested that the column used in ion-pairing experiments be used only for that purpose. Finally, it is easier and faster to quantify total alkaloid content as aglycones rather than as glycoalkaloids.

ACTIVATION OF PLANT FOLIAR OXIDASES BY INSECT FEEDING REDUCES NUTRITIVE QUALITY OF FOLIAGE FOR NOCTUID HERBIVORES

G.W. FELTON, K. DONATO, R.J. DEL VECCHIO, and S.S. DUFFEY

*Department of Entomology
University of California at Davis
Davis, California 95616*

(Received July 11, 1988; accepted February 3, 1989)

Abstract—The foliage and fruit of the tomato plant *Lycopersicon esculentum* contains polyphenol oxidases (PPO) and peroxidases (POD) that are compartmentally separated from orthodihydroxyphenolic substrates in situ. However, when leaf tissue is damaged by insect feeding, the enzyme and phenolic substrates come in contact, resulting in the rapid oxidation of phenolics to orthoquinones. When the tomato fruitworm *Heliothis zea* or the beet armyworm *Spodoptera exigua* feed on tomato foliage, a substantial amount of the ingested chlorogenic acid is oxidized to chlorogenoquinone by PPO in the insect gut. Additionally, the digestive enzymes of the fruitworm have the potential to further activate foliar oxidase activity in the gut. Chlorogenoquinone is a highly reactive electrophilic molecule that readily binds covalently to nucleophilic groups of amino acids and proteins. In particular, the —SH and —NH₂ groups of amino acids are susceptible to binding or alkylation. In experiments with tomato foliage, the relative growth rate of the fruitworm was negatively correlated with PPO activity. As the tomato plant matures, foliar PPO activity may increase nearly 10-fold while the growth rate of the fruitworm is severely depressed. In tomato fruit, the levels of PPO are highest in small immature fruit but are essentially negligible in mature fruit. The growth rate of larvae on fruit was also negatively correlated with PPO activity, with the fastest larval growth rate occurring when larvae fed on mature fruit. The reduction in larval growth is proposed to result from the alkylation of amino acids/protein by *o*-quinones, and the subsequent reduction in the nutritive quality of foliage. This alkylation reduces the digestibility of dietary protein and the bioavailability of amino acids. We believe that this mechanism of digestibility reduction may be extrapolatable to other plant-insect systems because of the ubiquitous cooccurrence of PPO and phenolic substrates among vascular plant species.

Key Words—Polyphenol oxidase, peroxidase, digestibility reduction, plant-insect interactions, phenolic-protein binding, chlorogenic acid, *Heliothis zea*, *Spodoptera exigua*, *Lepidoptera*, *Noctuidae*, *Lycopersicon esculentum*, host-plant resistance.

INTRODUCTION

Phenolic compounds, ranging from simple C₆-C₁ and C₆-C₃ forms to more complex polymers such as tannins and lignins, are widely distributed among vascular plants (Harborne, 1982). Many phenolics are thought to function as chemical defenses against herbivory, in part because of their ability to interact with proteins and inhibit enzyme functions (Singleton, 1981; Feeny, 1976; Rhoades, 1983; Coley et al., 1985). Current ecological theories ascribe the digestibility-reducing properties of quantitative defenses to many phenolic compounds such as lignans and tannins (Coley et al., 1985; Feeny, 1976; Rhoades and Cates, 1976; Rhoades, 1985). Abundant literature citations exist concerning the ability of phenolics to function as both inducible and constitutive defenses against herbivory (Schultz and Baldwin, 1982; Rhoades, 1983; Coley et al., 1985; Zucker, 1982; Lincoln, 1985; Lindroth and Peterson, 1988). However, a paucity of data exists that demonstrate phenolics such as tannins function as digestibility-reducing defenses against insect herbivores (J.S. Martin et al., 1987).

Much of the evidence for the defensive role of phenolics is derived from *ex planta* bioassays; that is, the candidate phenolic compound is isolated from foliage and incorporated into the artificial diet of the insect and its effects on herbivore feeding behavior, growth and/or survival are determined. This mechanistic approach has been applied to various agricultural crops such as cotton (e.g., Hedin et al., 1983; Chan et al., 1978), tomato (Isman and Duffey, 1982a,b; Elliger et al., 1981), and corn (Waiss et al., 1979). Alternatively, some investigators have relied upon a more holistic approach wherein the concentration of a given phenolic may be correlatable with insect populations and/or resistance under more natural, field conditions (Lincoln, 1985; Zucker, 1982; Widstrom et al., 1982). These approaches are invaluable in improving our understanding of the role of plant phenolics in insect-plant interactions. However, both approaches may be inadequate in determining cause-effect in situations where the effect of a given phytochemical is dependent upon other factors such as:

1. The dynamic state of the phenolic both within the plant and within the herbivore. For example, some authors have shown that insect feeding induces changes in the phenolic metabolism of the host plant, which may then alter the defensive quality of the plant (Chiang et al., 1987; Schultz and Baldwin, 1982;

Rhoades, 1983; Loper, 1968; Thielges, 1968; Haukioja and Niemela, 1977). Certain phenolic glycosides such as glucoside of DIMBOA (2,4-dihydroxy-7-methoxy-1,4-benzoxazine-3-one) are hydrolyzed by glucosidases following tissue damage by herbivores to release the aglycone, which is the primary active agent against insects (Klun et al., 1967).

2. The greater chemical context of the host-plant. For instance, when phenylalanine was nutritionally limiting to certain herbivores, dihydroxyphenols appeared not to function as plant defenses but instead functioned as nutrients by sparing phenylalanine in the production of cuticular tanning agents (Bernays et al., 1982). The toxicity of gossypol to the boll weevil was ameliorated by increased dietary protein (Moore, 1983). Conversely, Duffey and Bloem (1986) reported that the toxicity of the phenolic, rutin, was enhanced by increasing the concentration of dietary protein.

3. The physiological and/or chemical properties of the gut environment of the specific herbivore. The ultimate fate of tannins in the gut environment of the herbivore is crucial to understanding the potential defensive nature of these phenolics (Bernays, 1981; M.M. Martin and Martin, 1984; J.S. Martin et al., 1987). Binding of tannins to protein is determined by a number of plant- and herbivore-related factors such as the pH of the insect digestive fluid, the presence of surfactants in the digestive system, and the specific structures of both the protein and the tannin (Berenbaum, 1980; J.S. Martin et al., 1987; Zucker, 1983; Hagerman and Butler, 1981; Asquith and Butler, 1986). Because these factors may inhibit tannin-protein complexes, several authors have argued against digestibility reduction as a mode of action for tannins in insect herbivores and have, instead, claimed that tannins act as feeding deterrents or toxins (Bernays, 1981; J.S. Martin et al., 1987; Berenbaum, 1983).

The interaction of phenolics with protein may be a critical factor in understanding the ability of phenolics to act as plant defenses. Other plant phenolics, in addition to tannins, are known to interact chemically with protein. Phenolics may react with protein in four different ways: the formation of tannin-protein complexes via hydrogen bond interactions, valence forces such as hydrophobic interactions, formation of Schiff bases (e.g., gossypol), and alkylative reactions via the oxidation of orthodihydroxyphenolics to orthoquinones by polyphenol oxidases or peroxidases to form covalent bonds with the nucleophilic groups of amino acids (Pierpoint, 1983; Matheis and Whitaker, 1984; McManus et al., 1983; Singleton, 1981). Because phenolic compounds are known to interact chemically with proteins and to serve as substrates for a number of plant hydrolytic and oxidative enzymes (Butt, 1981; Butt and Lamb, 1981), it is imperative that the toxicity of these compounds be assessed under conditions more representative of their *in situ* occurrence within the host plant. Reliance solely on artificial diet experiments or solely on correlational field studies may yield mis-

leading conclusions regarding both the mode of action and potential function of these plant compounds as bases of host-plant defense.

The tomato plant *Lycopersicon esculentum* contains several *o*-dihydroxyphenols, including chlorogenic acid, rutin, and caffeoyl-aldaric acid, which have been shown to inhibit the growth of noctuid larvae when incorporated into artificial diets (Duffey and Isman, 1981; Isman and Duffey, 1982a; Elliger et al., 1981). However, when *Heliothis zea* larvae were grown on excised tomato leaflets, their growth was not correlatable with the foliar concentration of *o*-dihydroxyphenols (Isman and Duffey, 1982b). Implicit in this finding was that the toxicity of these phenols may be dependent upon the chemical context of the host plant, that is, the interaction of the phenolic with other phytochemicals in the foliage.

A component of foliage that has been unaccounted for in the tomato–noctuid system and may be crucial to understanding the toxicity of *o*-dihydroxyphenolics is the presence of foliar oxidative enzymes. The tomato plant contains polyphenol oxidases (PPO) and peroxidases (POD), which are compartmentalized apart from their phenolic substrates *in situ* but have the ability to rapidly oxidize *o*-dihydroxyphenolics to the corresponding *o*-quinone when leaf tissue is damaged (Duffey, 1986). In particular, chlorogenic acid is a substrate for these enzymes and is rapidly converted to chlorogenoquinone, a highly reactive molecule that is known to covalently bind to nucleophilic $-\text{NH}_2$ and $-\text{SH}$ groups of molecules such as amino acids and proteins (Pierpoint, 1966, 1969, 1983; Hurrell et al., 1982; Matheis and Whitaker, 1984). This alkylative binding of chlorogenoquinone to amino acids may reduce leaf protein digestibility *in vitro* (Free and Satterlee, 1975; Barbeau and Kinsella, 1985; Horigome and Kandatsu, 1968) and/or the bioavailability of essential amino acids to the herbivore (Hurrell et al., 1982; Igarashi and Yasui, 1985). If a significant amount of the ingested chlorogenic acid is oxidized when insect larvae feed on foliage containing polyphenol oxidases (PPO) or peroxidases (POD), the effect of the phenolic on the insect may be profoundly different from its effect in a reduced state. In an oxidized state, the ultimate effect and fate of chlorogenic acid in the herbivore depends upon foliar oxidative activity and the relative amounts of the reactants including chlorogenic acid and available $-\text{SH}$ and $-\text{NH}_2$ groups. For this reason, a better understanding of phenolic toxicity will emerge if assessed under conditions approximating those that occur *in situ*.

In this paper, we determined if chlorogenic acid is oxidized when the generalist larval noctuids *Heliothis zea* and *Spodoptera exigua* ingest tomato foliage, and what, if any, consequence this oxidation may have on the growth of these insects. Additionally, we examined the relationship of phenological changes in the concentrations of foliar oxidases and phenolic concentrations with the ability of foliage to support larval growth.

METHODS AND MATERIALS

Quantification of Phytochemicals. The concentrations of *o*-diphenols, rutin and chlorogenic acid, were determined colorimetrically at OD₃₉₀ and OD₄₄₀ using 0.5% diphenylborate-ethanolamine complex (Broadway et al., 1986). In the experiments with leaflet bioassays, phenolic concentrations were determined using two leaflets per leaf. The variation in the phenolic concentration between the two leaflets used for phenolic determination and the three leaflets used for the bioassay averaged less than 10% when leaflets from the same leaf were used ($N = 20$).

The concentration of leaf protein was determined using the Coomassie brilliant blue reagent (Bio-Rad Laboratories, Richmond, California) after Bradford (1976) and Snyder and Desborough (1978) with bovine serum albumin as a standard. The concentration of free amino groups in the foliage was determined colorimetrically with TNBS (2,4,6-trinitrobenzenesulfonic acid) following the method of Fields (1972). An 80% ethanolic extract of the foliage was partitioned against an equal volume of chloroform. The ethanolic fraction containing free amino acids was evaporated and reconstituted with 0.1 M NaBO₄ and analyzed with TNBS.

Measurement of Polyphenol Oxidase and Peroxidase Activity. To isolate enzyme from foliage, individually weighed leaflets (ca. 300 mg wet weight) were homogenized in 2.5 ml of 0.1 M potassium phosphate buffer, pH 6.8, containing 7% (w/v) polyvinylpyrrolidone (PVPP). Then 0.8 ml of 10% (v/v) Triton X-100 was added and the sample was vortexed for 10 sec. The sample was centrifuged at 11,000g for 10 min, and the supernatant was used immediately as the enzyme source. Polyphenol oxidase activity (as CHA oxidase) was measured spectrophotometrically (Ryan et al., 1982) by recording the increase in OD₄₇₀. Activity was expressed as the change in OD₄₇₀ $\times 10^{-2}$ /min/g wet weight unless otherwise indicated. Peroxidase activity was measured identically except with the addition of 0.1 ml 3% H₂O₂. Also, both PPO and POD activity were initially determined with chlorogenic acid, caffeic acid, hydroquinone, *p*-coumaric acid, *p*-hydroxybenzoic acid, tyrosine, and guaiacol as potential substrates in the presence and absence of exogenous hydrogen peroxide (Ryan et al., 1982).

The effect of different pHs on enzymatic activity was determined by homogenizing leaf material in 0.1 M sodium acetate or potassium phosphate buffer at pH ranging from 4.0 to 10.0. Subsequent treatment of samples was as described and PPO activity was determined at the respective pH.

The PPO/POD activity (without added H₂O₂) of fruit from field-grown tomato plants described below was determined. Enzyme from fruit was isolated as from leaflets except that a single plug of mesocarp and endocarp tissue (ca.

100 mg fresh weight) was removed from each fruit. Fruit ranged from immature green (ca. 2 g fresh weight) to mature red (> 100 g fresh weight).

Insects. Larval *S. exigua* and *H. zea* were reared on artificial diet (Chippendale, 1970) at 25°C with a photoperiod of 16:8 hr light-dark after Broadway and Duffey (1986a).

Bioassays with Foliage and Fruit. Foliage from greenhouse-grown or field-grown *L. esculentum* var. Castlemart was used in the bioassays. To determine if oxidation of phenolics in tomato foliage reduces the growth rate of *S. exigua*, leaflets were excised from greenhouse plants at the six- to eight-leaf stage and transported to the laboratory on ice.

Treatment I was the oxidized treatment where PPO inhibitors were not added to the foliage until substantial oxidation had occurred. For this treatment, 100 g fresh wt foliage was macerated in a blender for 2 min in 200 ml of ice-cold ddH₂O, transferred to a beaker, and mechanically stirred for 2 hr at room temperature. The 2-hr stirring period was chosen because it represents the minimal time that larvae retain tomato foliage in their digestive system (unpublished data), although >90% of tomato PPO activity occurs during the first 15 min following maceration. After stirring for 2 hr to allow oxidation, the PPO inhibitor phenylthiourea (50 mg) and reducing agent ascorbic acid (150 mg) were added, and the solution was stirred for an additional 10 min. The solution containing the foliage and PPO inhibitors was frozen and lyophilized. Dried foliage was reconstituted in H₂O and agar to the original weight of 100g and fed to *S. exigua* larvae.

Treatment II, the treatment without oxidation, was similar but with the following exceptions: The foliage was macerated for 2 min in a blender with ice-cold ddH₂O containing 50 mg of phenylthiourea and 150 mg of ascorbic acid. The solution was transferred to a beaker and stirred for 2 hr and 10 min. A diet was prepared from foliage as described above. The concentrations of protein, free amines, *o*-dihydroxyphenolics, and PPO activity in samples of leaf material were measured before treatment (maceration) and after treatment as described. Ten neonate *S. exigua* larvae were placed in each paper cup containing the appropriate diet with five cups (replicates) per treatment. Diet was supplied ad libitum, larvae were weighed daily to the nearest 0.1 mg for 13 days, and relative growth rates were determined following Waldbauer (1968). Differences between treatments were determined by Student's *t* test.

To determine the effect of plant age on the ability of foliage to support the growth of noctuid larvae, leaflets from greenhouse- and field-grown tomato plants were utilized. For the experiments with greenhouse plants, 20 tomato plants (var. Burpee VFN) were grown in 1-gallon containers. Leaflets were excised from five to six plants at three different growth stages: preflowering, flowering, and green fruit stage. Three weighed leaflets from each leaf were placed in a Petri dish containing a single third-instar *H. zea* (one day postec-

dysis). After 72 hr, insect and leaf weight were recorded and the relative growth rate (RGR) was computed after Waldbauer (1968). The remaining 4 leaflets from each leaf were used for quantification of PPO and phenolics according to methods described. Leaflets used for bioassay or phytochemical analysis were removed from the same position on a leaf throughout the experiment. Fifteen larvae were used per plant stage.

To determine the impact of seasonal variation of field-grown plants on larval growth rates, 400 tomato plants were grown in the field during the summer of 1987 (University of California at Davis research plots). Seeds of *L. esculentum* var. Castlemart were planted in 100-ml plastic pots in the greenhouse. When plants reached the 1–2 leaf stage, they were transplanted to the field and irrigated weekly. Two fully expanded terminal leaves per plant were excised for bioassays from plants at the flowering, immature green fruit, mature green fruit, and ripe fruit stages. Three leaflets per leaf were fed to larvae as described above and RGRs were computed following Waldbauer (1968). Quantification of PPO activity was made from one of the remaining four leaflets from each leaf as described above. Leaflets for PPO analysis or bioassay were removed from the same position on the leaf throughout the assays. A minimum of 50 larvae per plant stage was tested.

Bioassays were also conducted with tomato fruit from various stages of development, including ripe (> 100 g); mature green (> 100 g); large immature green (50–100 g); medium immature green (10–49.9 g), and small immature green (2–9.9 g). Samples from each of these categories were analyzed for PPO activity as described above ($N = 5$ /stage). Bioassays were conducted with third instar *H. zea* in 500-ml beakers covered with gauze. The RGRs of larvae were determined as previously described and a minimum of six larvae per fruit stage were tested.

Bioassays with Artificial Diet. To determine if the effect of oxidation of chlorogenic acid resulted from the formation of a polymer, the alkylation of dietary protein, or the reduction in availability of free amino acids, experiments with artificial diets (Chippendale, 1970) were conducted. In the first treatment, where oxidized chlorogenic acid was not allowed to interact with dietary protein so that only a polymer was formed, CHA at 3.5 $\mu\text{mol/g}$ diet and PPO (= tyrosinase, Sigma Chemical Co., St. Louis, Missouri) at 0.100 $\text{OD}_{470}/\text{min/g}$ diet of CHA oxidase activity were incubated for 2 hr in ddH_2O and added to the remaining diet ingredients, which contained 0.5% (w/w) casein. In the second treatment, CHA, PPO, and casein were incubated simultaneously so that the casein was alkylated by the quinone. In the third treatment, an enzymatic digest of casein containing only TCA-soluble amines and/or peptides (Sigma Chemical Co) was incubated at 0.5% (w/w) with CHA and PPO for 2 hr, and then added to diet. This treatment involved alkylation of small peptides and free amino acids instead of protein. Treatment diets were fed to neonate *S. exigua*

ad libitum for 12 days and consisted of at least three replicates of 10–15 larvae per treatment with total of $N = 336$ for the experiment. Larval weights were recorded to the nearest 0.1 mg on the 12th day and compared to the appropriate control containing no added phytochemicals (Broadway and Duffey, 1986b).

Amino Acid Analyses. To determine the effect of alkylation on the amino acid composition of leaf protein, protein was first isolated from foliage by macerating for 2 min in 0.1 M potassium phosphate buffer, pH 7.0, containing 10^{-4} M phenylthiourea (PTU) to inhibit PPO activity. The homogenate was filtered through cheesecloth and Whatman No. 1 filter paper, followed by acid precipitation at pH 3.5, and centrifugation at 10,000g for 15 min. The protein pellet was dialyzed for 48 hr against ddH₂O, frozen, and lyophilized.

The lyophilized protein was given one of four treatments. In treatment 1, 1.2 g of protein was incubated with 320 mg of chlorogenic acid and 3.2 mg of PPO (mushroom tyrosinase, Sigma Chemical Co.) in 100 ml 0.1 M potassium phosphate buffer, pH 7.0. After 2 hr, the reaction was stopped with 5 mg of PTU. In treatment 2, the PTU was preincubated with the tyrosinase to inactivate the enzyme prior to incubation with CHA and protein. In treatment 3, the effect of polyphenol oxidase from tomato foliage on tomato protein was determined as follows. An enzyme solution was obtained (described above) and incubated with 1.2 g tomato protein and 320 mg chlorogenic acid as described. The enzyme solution, in addition to containing polyphenol oxidase, was contaminated with significant amounts of free amino acids (ca. 0.7% w/w following Fields, 1972). In treatment 4, the PTU was preincubated with the tomato PPO prior to incubation with protein. Therefore, the effect of oxidation of CHA on proteinaceous and free amino acids was determined in treatments 3 and 4. Immediately following incubation, each treatment was then frozen and lyophilized. The amino acid composition of the four treated proteins was determined using a Beckman amino acid analyzer after protein had been hydrolyzed with 6 N HCl for 24 hr in sealed tubes in vacuo. Kjeldahl nitrogen was determined using a micro-Kjeldahl method.

Determination of Polyphenol Oxidase Activity in Feces and Regurgitate of Larvae. Third-instar *H. zea* larvae were placed on artificial diet containing 3.5 μ mol CHA/g or on tomato foliage (Castlemart) for 24 hr. Freshly produced feces from 100–125 larvae per treatment were collected (ca. 1.0 g total weight) during the last 4 hr of the experiment and were placed immediately on ice and homogenized with 1 ml 0.1 M potassium phosphate, pH 8.0, and 7% PVPP. At the end of the 24-hr feeding, the regurgitate of these same insects was obtained by gently holding the larvae behind the head with forceps and collecting regurgitated digestive fluid into microcentrifuge tubes. Fluid (ca. 500 μ l/treatment) was held on ice and mixed with 1 ml of 0.1 M potassium phosphate buffer, pH 8.0, containing 7% (w/v) PVPP. The enzyme solutions for both feces and regurgitate were centrifuged at 15,000 g for 15 min and assayed

immediately. The assay was otherwise identical to that described for foliar PPO. The POD activity was determined with POD-specific substrate guaiacol in the absence of exogenous H_2O_2 . PPO activity of the foliage fed to larvae was also determined using the potassium phosphate buffer at pH 8.0.

Determination of Effect and Midgut Enzymes on PPO Activity of Foliage. To determine if the midgut enzymes of *H. zea* affect foliar PPO activity, we incubated homogenized foliage with midgut tissue from larvae. Midguts were prepared as described by Broadway and Duffey (1986a) and added to ca. 1 g wet weight of tomato foliage (four small leaflets). Foliage was homogenized for PPO assay as described above. Three concentrations of midgut tissues were used: 18.75, 37.5, and 75.0 mg midgut wet weight per 250 mg foliage wet weight and including a control with no midgut tissue. Additionally, a midgut preparation containing 75 mg midgut was heated to 100°C prior to adding to the PPO preparation as a control. The midgut and PPO solution was incubated at 25°C for 15 min prior to PPO determination. A total of five replicates per treatment was completed.

Determination of Oxidation of Chlorogenic Acid During Insect Feeding. Chlorogenic acid ($[^3H]CHA$) was used to determine if it was oxidized when larvae fed upon tomato foliage. The isotope was prepared and purified as described by Isman and Duffey (1983). Sixth-instar *H. zea* or *S. exigua* were removed from artificial diet and starved for 3 hr. Leaflets of greenhouse-grown *L. esculentum* var. Ace 55 were excised from plants at the six to eight-leaf stage and transported on ice to the laboratory. Paired leaflets were collected so that one leaflet could be used for phenolic assay while the opposite leaflet could be used in the feeding experiment. The phenolic concentrations within each pair did not significantly differ when 25 pairs were examined ($P > 0.05$). This allowed us to estimate the chlorogenic acid concentration in each leaflet fed a larva so that the specific activity of the isotope could be determined for each leaflet.

Leaflets were removed from ice, one of the paired leaflets was placed in 5 ml of 50% aqueous methanol for 24 hr at 60°C, its phenolic concentration was determined as above. An 8- μ l sample of $[^3H]CHA$ in 75% aqueous methanol (specific activity of 0.7 mCi/mmol) was added to each leaflet and allowed to evaporate. Leaflets were weighed and fed to larvae. Only larvae that consumed the entire leaflet within 8 hr were used in the experiment. Four hours after ingestion of the leaflet, larvae were placed on ice, and 2.5 μ l of hemolymph was extracted from a proleg and used for estimation of chlorogenic acid after thin-layer chromatography (TLC) separation of chlorogenic acid (Isman and Duffey, 1983). Feces were pooled for each larva and immediately placed in 100% methanol at 60°C for 24 hr.

The feces were pelleted from the methanol by centrifugation at 11,000g for 10 min and were extracted 5X in 100% methanol until no radioactivity

remained in the supernatant. Methanolic extracts were pooled for each larva, evaporated in vacuo, and reconstituted in 0.1 ml methanol. The fecal pellet was extracted $3 \times$ in 2 ml 8 M urea. Urea extracts were pooled for each larva. An aliquot of the methanol and urea extracts was used for two-dimensional TLC with cellulose plates using 2% formic acid followed by *n*-butanol-ethanol-2% NH_4OH (6:1:3) as solvents. Unbound or free chlorogenic acid was extracted primarily in the methanol treatment (>90%) and had R_f values of 0.70 and 0.81 in 2% formic acid solvent (*cis* and *trans* isomers) and an R_f value of 0.95 in the butanol-ethanol- NH_4OH solvent. To determine if CHA was covalently bound to protein and/or amino acids, different replicates of the cellulose plates were sprayed with reagents for phenolics (0.5% diphenylborate for orthodihydroxyphenols, and Folin-Ciocalteu reagent for phenols; Harborne, 1982) and with ninhydrin for primary amines (Harborne, 1982). The bands were scraped from the TLC plates, eluted with the appropriate solvent, and mixed with aqueous scintillation fluid (ACS, Amersham Corporation, Arlington Heights, Illinois). Total radioactivity in each sample was determined by the channel ratios method in a Beckman LS 230 liquid scintillation counter.

Phenologic and Species Differences in Phenolics and PPO. In order to examine how much phenolic content and PPO activity vary over time and between varieties and species in the field, we grew 25 plants of the following during the summer of 1985: *L. esculentum* var. Castlemart; *L. esculentum* var. Walter; *L. hirsutum* f. glabratum LA 2100, and *L. hirsutum* f. glabratum PI 134417. The plants were transferred from the greenhouse to the field and grown there as described. Two fully expanded, terminal leaflets were carefully excised from each plant from three different plant stages: flowering, green fruit, and mature fruit. The measurement of *o*-dihydroxyphenols and PPO from individual leaflets were as described above.

RESULTS

Substrate Specificities of Foliar Oxidases. The majority of chlorogenic acid oxidation in tomato foliage is due to PPO and not due to POD or laccase activity (Figure 1). The oxidation of hydroquinone, a substrate for laccase, was not observed in our assays. CHA is a substrate for POD as shown by a 31% increase in the rate of CHA oxidation when H_2O_2 was added. The diphenol, caffeic acid, was also a substrate for PPO/POD. However, the POD substrate, guaiacol, was oxidized at a very slow rate in the absence of exogenous H_2O_2 . Thus, endogenous levels of H_2O_2 appear to be insufficient for POD to be a major factor in the oxidation of CHA or caffeic acid during tissue damage. Tomato PPO/POD showed little or no monophenolase activity when tyrosine, *p*-coumaric acid, and *p*-hydroxybenzoic acid were used as substrates. Henceforth, the oxidation of

FIG. 1. The oxidative activity of tomato foliage towards various phenolic substrates. The absence of horizontal bars indicates no detectable activity.

chlorogenic acid will be referred to as PPO activity because of comparatively low POD activity in the absence of exogenous H₂O₂ and the absence of laccase activity.

Bioassays with Foliage and Fruit. The larval growth rate of *S. exigua* was reduced by more than 45% when larvae fed on diet made from foliage containing active polyphenol oxidase (Table 1). The polyphenol oxidase activity was inhibited by greater than 95% when the PPO inhibitors were added during maceration of the foliage. Additionally, in the treatment with oxidation, the measurable concentration of *o*-diphenols was reduced by over 48% and the rel-

TABLE 1. EFFECT OF POLYPHENOL OXIDASE ACTIVITY IN TOMATO FOLIAGE ON GROWTH RATE OF *Spodoptera exigua*^a

Treatment	RGR	PPO	Free NH ₂	[<i>o</i> -Diphenols]
+ Oxidation	0.215a	38.6a	0.92a	.071a
- Oxidation	0.396b	1.6b	1.10b	.138b

^aRGR = relative larval growth rate as mg/day/mg larva; PPO = polyphenol oxidase activity expressed as ΔOD₄₇₀/min/g foliage; free NH₂ = foliar concentration of free amines after treatment, expressed as percent wet weight; *o*-diphenols = foliar orthodihydroxyphenol concentration following treatment, expressed as percent wet weight. Means not followed by same letter (in columns) are significantly different at P < 0.05 following Jones (1984).

ative levels of free NH_2 groups in the amino acid extract (80% ethanol) were reduced by 16% (Table 1). A 37% reduction in Biorad-detectable protein occurred in the treatment with oxidation (data not shown). These data indicated that nearly 50% of the dihydroxyphenolics had been oxidized and that statistically significant changes in protein and amino acids occurred. In contrast, the concentrations of protein and *o*-diphenols prior to oxidation were not significantly different ($P > 0.05$) between treatments. The levels of *o*-diphenols and protein in both treatments were 2.44–2.47 $\mu\text{mol/g}$ and 3.70–3.76% fresh wt, respectively, as determined from samples of leaves taken before maceration.

In the experiments with leaflets from greenhouse plants, the relative growth rates (RGR) of *H. zea* larvae declined by nearly 50% as the plant matured (Table 2). This reduction in larval growth rate was significantly correlated with both PPO activity and rutin concentration ($P < 0.01$) but not with chlorogenic acid concentration. The variability in chlorogenic acid concentration over the three plant stages examined was smaller than the variability in rutin. Bioassays with artificial diet indicate that these changes in chlorogenic acid concentration were too small to produce observable changes in RGR (unpublished data).

The experiments with field grown plants helped us to investigate the relationship between foliar PPO and larval RGR at different stages of plant maturity. A significant correlation between PPO and RGR was found within three of the stages examined: flowering ($r = -0.496$, $N = 99$, $P < 0.01$); immature green fruit ($r = -0.609$, $N = 100$, $P < 0.001$); and mature green fruit ($r = -0.323$, $N = 50$, $P < 0.05$). The relationship between PPO and RGR was not significant when plants with ripe fruit were examined ($r = -0.208$, $N = 70$, $P > 0.05$). In the case of the plants with mature green fruit, the PPO activity was over 3X higher than at any other stage, and consequently, most larvae were

TABLE 2. EFFECT OF PLANT STAGE OF GREENHOUSE-GROWN TOMATO PLANTS ON GROWTH RATE OF *Heliothis zea* LARVAE^a

Plant stage	RGR	N	PPO	[CHA]	[Rutin]
Preflowering	0.316	16	12.0	3.58	1.84
Flowering	0.202	15	14.8	4.87	3.89
Green fruit	0.159	15	19.8	4.42	6.83
Regression coefficient (r)			-0.55 ^b	-0.13	-0.43 ^b

^aRGR = relative larval growth rate (mg/day/mg larva); PPO = foliar polyphenol oxidase activity as $\Delta\text{OD}/\text{min}/\text{g}$; [CHA] or [rutin] = foliar concentration of chlorogenic acid or rutin expressed as $\mu\text{mol/g}$ foliage wet weight. Regression coefficient (r) = coefficient from the regression of RGR with PPO, CHA, or rutin.

^bSignificant coefficient at $P < 0.01$.

unable to grow. A logarithmic transformation of PPO activity provided the best fit of the data using the equation $y = a + b(\ln x)$. The overall regression coefficient for samples from all plant stages was -0.417 ($N = 319$, $P < 0.001$). To determine if the PPO activity reduced the rate of food consumption by larvae and hence RGR, we calculated the relative consumption rate (RCR) following Waldbauer (1968). There appeared to be no relationship between RCR and PPO and RGR: the correlation coefficient of RCR with PPO was $+0.201$ ($N = 50$, $P > 0.05$). This agrees with results obtained from bioassays using CHA + PPO in artificial diets (Kreisfeld, 1987).

The mean values of PPO and RGR for each stage of plant development examined are plotted in Figure 2, which includes the experiments with both greenhouse and field plants. A correlation between the mean PPO and RGR values was highly significant ($r = -0.953$, $P < 0.01$). The RGR of larvae was also correlated with polyphenol oxidase activity in fruit (Figure 3). The PPO activity of fruit is much lower than foliage and virtually ceases by the time the fruit matures. The RGR of larvae on maturing fruit (0.37–0.47) was faster than on foliage from any of the stages examined (0.316, the fastest). The correlation between PPO activity and RGR on fruit was significant ($r = -0.811$, $N = 30$, $P < 0.01$).

Bioassays with Artificial Diet. The bioassays with CHA + PPO added to artificial diet indicated that the polymer formed during oxidation of CHA in the absence of competing $-\text{NH}_2$ or $-\text{SH}$ groups was not toxic to *S. exigua* larvae at the levels tested (Table 3). However, when CHA + PPO were allowed to

FIG. 2. The relationship of foliar polyphenol oxidase activity to the relative growth rate of *Heliothis zea* at different plant stages. The regression equation was $y = \ln(0.968) - 0.134(\ln x)$; $r = -0.953$, $N = 6$. This regression was derived from the mean values obtained for each plant stage from greenhouse plants and field plants. PPO activity expressed as $\Delta\text{OD} \times 10^{-2}/\text{min/g}$ foliage.

FIG. 3. The relationship of fruit polyphenol oxidase activity to the relative growth rate of *Heliothis zea* at different stages of fruit maturity. The regression equation was $y = \ln(0.940) - 0.081(\ln x)$; $r = -0.811$, $N = 30$. The equation was obtained from the regression of the individual larval growth rates with the mean polyphenol oxidase activity of fruit for each stage.

react in the presence of casein protein or the casein digest, a substantial reduction in larval weight occurred. These data indicate that the reduction in larval growth by CHA + PPO occurred as a result of its interaction with protein or free amino acids and was not due to any direct toxic properties of the polymer. In contrast, CHA in its reduced state was not toxic to larvae at a low level of

casein (0.5% w/w) but was considerably more toxic in diets containing tryptically digested casein (0.5%). Unpublished data indicate that the toxicity of CHA is enhanced by increasing levels of free amines. The concentration of CHA used in the bioassays (3.5 $\mu\text{mol/g}$ wet weight) was the approximate mean concentration of CHA in Castlemart variety tomato plants during a preceding growing season (Felton et al., 1987).

Amino Acid Analyses. The amino acid analyses of isolated tomato protein incubated with active tomato PPO or with tomato PPO inactivated by PTU, indicate significant changes in amino acid composition between treatments (Table 4). When protein is incubated with an active preparation of tomato PPO (which also is contaminated with ca. 0.7% free amino acids), nearly all of the amino acids were reduced by over 11% except for glutamic acid. The overall reduction in identifiable free and proteinaceous amino acids was 14.4%. However, the experiments with tomato protein and purified mushroom tyrosinase as

^a Amino acid content expressed as mM/100 g sample. An asterisk denotes differences between oxidation treatments greater than 15%.

^b Treatment contained chlorogenic acid, tomato foliar protein, and tomato PPO containing soluble protein and free amino acids. PPO inhibitors added to - oxidation treatment prior to reaction.

^c Treatment contained chlorogenic acid, tomato protein, and purified mushroom tyrosinase for PPO activity. PPO inhibitors added to - oxidation treatment prior to reaction.

PPO showed little difference in amino acid compositions (Table 4). The most significant changes in the latter tests were a 14% reduction in phenylalanine and an 8% reduction in each of lysine and tyrosine.

In contrast to the changes in amino acid composition that occurred as a result of phenolic oxidation, the measurable percent of Kjeldahl nitrogen was not affected by oxidation. The treatment containing tomato protein and active tyrosinase had 78.3% Kjeldahl protein N (% protein = $N \times 6.25$), whereas the treatment with inactivated tyrosinase had 78.4%. In the treatments containing tomato PPO, the Kjeldahl protein N was 47.3% for treatments containing either active or inactivated PPO.

Determinations of Polyphenol Oxidase Activity in Regurgitate and Feces. Significant PPO activity exists in the larval mid- and hindgut when larvae are fed tomato foliage (Table 5). However, no PPO activity could be detected in the regurgitate or the feces of larvae fed artificial diet. The activity of PPO in the regurgitate of foliage-feeding larvae was 66.7% of that in the ingested foliage, whereas the feces produced by these larvae had PPO activity significantly higher than the foliage. No POD activity with guaiacol substrate could be detected in regurgitate or feces in the absence of exogenous H_2O_2 . These results indicate that the tomato PPO is not inhibited or neutralized by the insect gut, and do suggest that factors in the gut may increase PPO activity as the food bolus passes through the digestive system.

Effect of Larval Midgut on PPO Activity. When homogenates of tomato foliage were incubated with larval midgut tissue, a significant increase ($P < 0.01$ with $r = 0.91$) in foliar PPO activity of nearly 40% was observed (Figure 4). When midgut tissue was heated to inactivate digestive enzymes, no increase in PPO activity was observed. These results suggest that tomato PPO activity is not reduced as a consequence of midgut proteases but that PPO activity is

FIG. 4. The effect of *Heliothis zea* midgut tissue on tomato foliar polyphenol oxidase activity. One midgut = 75.0 mg with a tryptic activity of 35 nmol *p*-TSA/min/mg gut after Broadway and Duffey (1986a). Error bars represent 95% confidence limits with $N = 4$ determinations per midgut concentration. PPO activity expressed as $\Delta OD \times 10^{-2}/\text{min/g foliage}$.

activated by these enzymes. Additionally, no PPO activity (as chlorogenic acid oxidase) could be detected in the midgut homogenates used in the assay. POD activity was absent in all assays in absence of exogenous H_2O_2 .

Effect of pH on Tomato Foliar PPO. Tomato foliar PPO is active across a wide pH range (Figure 5). Optimal activity occurs at pH 6.8, but substantial

FIG. 5. The effect of pH on tomato foliar polyphenol oxidase activity. The horizontal bars indicate the pH range of the midguts of the species shown: *Trichoplusia ni*, *Manduca sexta*, *Heliothis zea*, *Spodoptera exigua*. Midgut pHs are from Broadway (1985), J.S. Martin et al. (1987) and unpublished data. PPO activity expressed as $\Delta OD \times 10^{-2}/\text{min/g foliage}$.

activity is present from 6.0 to 10.0. The midgut pH values of four lepidopterous pests of the tomato plant appear in Figure 5. All four pest species—*Manduca sexta*, *Trichoplusia ni*, *S. exigua* and *H. zea*—have gut pH values within the range of PPO activity. In fact, the gut pH of the first two species *M. sexta* and *T. ni*, is near 10.0, a pH concentration at which CHA will autoxidize to form the quinone (Barbeau and Kinsella, 1983).

Experiments with [³H]Chlorogenic Acid. The results we obtained with the isotope are summarized in Table 6. When both *S. exigua* and *H. zea* larvae fed on artificial diet containing chlorogenic acid, ca. 90% of the excreted chlorogenic acid was found to be in a free form rather than bound to amino acids or protein. However, when larvae were fed tomato foliage, much less of the ingested chlorogenic acid was free and significant amounts were bound to protein: nearly 50% of the excreted chlorogenic acid was bound to protein for *H. zea* larvae and nearly 40% for *S. exigua*. These results do not necessarily suggest that there are species differences, however, because the foliage ingested by *H. zea* larvae was substantially higher in PPO activity than that ingested by *S. exigua* (19.3 OD₄₇₀/min/g foliage vs. 12.0).

The amount of chlorogenic acid absorbed into the hemolymph was not significantly different for *H. zea* larvae ingesting either artificial diet or tomato foliage (Table 6). However, *S. exigua* larvae ingesting tomato foliage showed slightly higher levels of uptake than those fed artificial diet. More than 85% of the recoverable radioactivity in the hemolymph samples occurred as free chlorogenic acid. Less than 10% of the radioactive chlorogenic acid was bound to protein for either species.

Excreted chlorogenic acid in the free form was obtained primarily in the methanolic extracts of the feces. A brownish phenolic- and amino-positive material was detected in the urea extracts with an $R_f = 0.70-0.96$ in formic

acid and $R_f = 0.00-0.02$ in NH_4OH solvent. This material contained radioactivity from the labeled CHA and reacted with all reagents used for the detection of phenolics and amines. Additionally, it reacted strongly with Coomassie blue reagent for the detection of proteins (Bradford, 1976). Furthermore, a purification process consisting of elution from the cellulose, dialysis (6000 mol wt cutoff) against 8 M urea to dissociate hydrogen-bonded CHA, and dialysis against ddH_2O failed to alter the effect of the reagents on the material or to remove any significant amount of radioactivity. Several properties of the material indicated the presence of chlorogenic acid covalently bound to protein: it was insoluble in 10% TCA and 100% methanol, showed very little mobility in NH_4OH solvent, tested positive with phenolic and amine reagents, contained radioactivity, and was not dialyzable in 8 M urea at a 6000 mol wt. The phenolic-protein material was then saponified with 2 N NaOH for 24 hr at 2°C , a treatment known to hydrolyze the quinic acid ester of chlorogenic acid when bound to protein (Davies et al., 1978). Following saponification, quinic acid was detected on TLC and compared to a standard (Davies et al., 1978). The released quinic acid contained radioactivity associated with the $[^3\text{H}]\text{CHA}$. Moreover, a similar material was extracted from foliage that had been macerated and allowed to oxidize for 1 hr, but no comparable material was obtained from intact foliage that had been heated at 80°C for 2 hr prior to maceration and extraction. Finally, 5–10% of the radioactivity of extracts from foliage-derived feces was associated with a phenolic-positive material that remained near the origin in both TLC solvents. This material was not amine positive and may represent the polymer formed during the oxidation of CHA. A similar material is produced when PPO (mushroom tyrosinase) and CHA are incubated in the absence of any other additional protein. Experiments are under way to characterize the chemical properties of these materials. Approximately 80% of the total ingested radioactivity was recoverable in the methanol and urea feces extracts in all treatments.

Phenological and/or Varietal Changes in PPO and Phenolics. Foliar PPO activity significantly increased during plant maturation for all four plant species and varieties examined (Figure 6). The greatest PPO activity occurred within the two commercial varieties of *L. esculentum*, Castlemart and Walter, whereas consistently lower values occurred in *L. hirsutum* species. These results were obtained from 1985 and differed slightly from those obtained in 1987 with the Castlemart variety. PPO activity was highest at the mature green fruit stage during 1987 and lower at the ripe stage. In 1987, the last sampling date was approximately one month later than in 1985 (October vs. September). Reductions in PPO activity may be a consequence of the lower temperature and/or reduced solar radiation. Foliage also contains peroxidase activity (not reported here) that has chlorogenic acid oxidase activity but with only 20–25% of the activity of PPO.

In contrast to the above findings with PPO, levels of phenolics remained

FIG. 6. The effect of plant stage on foliar polyphenol oxidase activity in four varieties or species of *Lycopersicon*. PPO activity expressed as $\Delta OD \times 10^{-2}/\text{min/g}$ foliage.

fairly stable in most species or varieties with the exception of *L. hirsutum* f. *glabratum* LA2100, which showed a significant decline in phenolic concentration during plant maturation (Figure 7). The levels of phenolics were generally higher in *L. hirsutum* species than in commercial species *L. esculentum*.

FIG. 7. The effect of plant stage on foliar phenolic levels in four varieties or species of *Lycopersicon*.

DISCUSSION

A significant amount of ingested chlorogenic acid was oxidized by foliar PPO when noctuid larvae fed on tomato foliage. Apparently, the greatest majority of CHA is oxidized by PPO and not by laccase or POD, which are either absent from or at very low activity in foliage (Figure 1). Extracts of foliage failed to oxidize the laccase substrate, hydroquinone, and showed little activity against guaiacol, a peroxidase substrate, unless exogenous H_2O_2 was added. Also POD could not be detected in insect regurgitate, midgut, or feces in the absence of exogenous H_2O_2 . We have preliminary data that indicates that H_2O_2 is rapidly eliminated in ingested plant tissues by catalases of plant and insect gut origin.

Other studies have reported the presence of PPO activity in the digestive systems of insects (e.g., foregut of a grasshopper; Rhoades, 1977; and salivary glands of Hemiptera; Miles, 1978). Rhoades (1977, 1983) speculated that the PPO in these insects may be an adaptation to neutralize the defensive properties of plant phenolics. In marked contrast, our data indicated that PPO activity substantially reduced larval growth rates and that activity present in the gut was derived from ingested foliage.

The reduction in larval growth in bioassays with oxidized tomato foliage (Table 1) or artificial diets (Table 3) may be due to one or more of the following mechanisms: first, reduction in the bioavailability of amino acids via direct binding of the chlorogenoquinone to $-NH_2$ and/or $-SH$ groups of free amino acids and proteins (Hurrell et al., 1982; Igarashi and Yasui, 1985); second, loss of free amino acids via the enzymatic degradation of free amino acids to aldehydes in the presence of PPO and phenolic substrates (Motoda, 1979); third, reduced digestibility of dietary protein (Free and Satterlee, 1975; Barbeau and Kinsella, 1985); and fourth, potential inhibition of insect digestive enzymes (G.W. Felton, unpublished data). Substantial reductions in foliar free amino acids occurred when a preparation of tomato PPO (containing free amino acids) oxidized chlorogenic acid (Table 4), suggesting that the bioavailability of free amino acids may be severely reduced to herbivores feeding on foliage rich in PPO and diphenol substrates. Although minor changes occurred in the amino acid composition of tomato protein in the presence of PPO (purified mushroom tyrosinase) and CHA, it is known that alkylation of the *E*- NH_2 moiety of lysine reduces the digestibility of protein (Hurrell et al., 1982; Pierpoint et al., 1977). We observed an 8% reduction in the measurable lysine of tomato protein treated by CHA and PPO (Table 4), indicating a loss of available lysine, which may contribute to reduced protein digestibility. Other researchers have documented the reduced *in vitro* digestibility of leaf protein alkylated by oxidized chlorogenic acid (Barbeau and Kinsella, 1985). Our data from bioassays with artificial diet indicated that the adverse effects of chlorogenic acid oxidation occurred as

a result of the covalent interaction between the generated quinone and dietary protein (or free amines) and were not due to the polymerization of the phenolic in the absence of reactive SH or NH₂ groups (Table 3). The CHA-amine product isolated from the feces, although having a molecular weight greater than 6000, does not exclude the possibility that chlorogenoquinone binds to free amino acids in the insect gut because the product formed may be a result of secondary reactions involving intermolecular cross-linking of amino acids, peptides, and proteins (Pierpoint, 1983; Matheis and Whitaker, 1984).

Our results may be extrapolatable to other plant-insect systems and suggest that the oxidation of phenolics may contribute significantly to reducing the nutritive quality of foliage. Polyphenol oxidases are widespread among angiosperm and gymnosperm plant species and cooccur with *o*-diphenol substrates (Mayer and Harel, 1979; Mayer, 1987). The oxidation of phenolic compounds and their subsequent polymerization on the leaf surface via damaged trichomes has been identified as a defense mechanism against small sucking insects such as aphids or leafhoppers (Gregory and Tingey, 1981; Gregory et al., 1986; Duffey, 1986). Rhoades (1977) showed that the growth rate of the orthopteran *Astroma quadrilobatum* was negatively correlated with polyphenol oxidase activity in the creosote bush *Larrea cuneifolia*.

The antibiotic effect of oxidized phenolics may be enhanced by the normal gut conditions of these insects. For example, at pHs lower than 6.5, the alkylation of free amino acids by chlorogenoquinone apparently does not occur (Haider et al., 1965), but at alkaline pH (ca. pH 10), the oxidation of chlorogenic acid can occur both nonenzymatically and enzymatically via polyphenol oxidase or peroxidase (Barbeau and Kinsella, 1983; Pierpoint, 1983). The gut pH of most lepidopterous larvae exceeds 6.5 (Berenbaum, 1980) and sometimes even 10.0, as in the case of a specialist folivore of tomato, *Manduca sexta* (J.S. Martin et al., 1987), thus the potential for oxidation appears greater for these insects than other insects such as acridids whose gut pHs may often lie at or below 6.0 (Bernays, 1981). The gut pH of both *H. zea* and *S. exigua* is within the range for activity of tomato PPO (Figure 4). Characteristically, ranges of pH activity for plant polyphenol oxidases are quite broad (Mayer, 1987), suggesting that these enzymes are active in the gut of many insects and may present a formidable barrier against selection for resistance by herbivores via changes in midgut pH. Furthermore, our data indicate insect proteolytic enzymes may activate latent or insoluble membrane-bound PPO activity. Because of the ubiquitous cooccurrence of PPO and diphenols among plant species and the potential for PPO activity in insect guts, this potential mechanism of digestibility reduction may be more applicable to plant defense theories (e.g., Rhoades and Cates, 1976; Feeny, 1976; Coley et al., 1985) than are the digestibility-reducing properties previously ascribed to tannins but now strongly contested (Bernays, 1981; J.S. Martin et al., 1987).

Many herbivores have higher growth rates, fecundity, and survival on young leaves than on senescing leaves (White, 1984; Raupp and Denno, 1983). In many plants, including tomatoes, the level of PPO activity increases with leaf or plant age (Figure 7) (Mayer and Harel, 1979; Mayer, 1987) while the highest levels of foliar antioxidants occur in young leaves (e.g., ascorbic acid, glutathione, tocopherols, and carotenoids). Thus, the greater potential for phenolic oxidation in mature foliage may be one reason why insect growth sometimes correlates with the phenology of foliage. The larvae of both *S. exigua* and *H. zea* migrate to tomato fruit at an early instar (Lange and Bronson, 1981). This behavior allows the larvae to feed on a food source with higher water content and to escape mortality from parasites, predators, and pathogens on the exposed leaf surfaces. Another selective advantage for this feeding behavior could be the avoidance of toxic levels of PPO activity and of phenolics. Green or mature fruit contained significantly less PPO activity than foliage, as measured in our studies (Figure 3) and others (Rhodes and Wooltorton, 1977). In addition, the fruit levels of substrates (e.g., chlorogenic acid) for this enzyme significantly decline with fruit development (Wardel, 1973). Consequently, larvae migrating from foliage to the maturing fruit not only can feed in a protected microenvironment but may also avoid the antibiotic effects of these phytochemicals.

Many studies indicate that nitrogen is a limiting factor for herbivore survival (White, 1984; Mattson, 1980; Scriber and Slansky, 1981 and references therein), but most have relied solely upon the estimate of foliar nitrogen by the Kjeldahl procedure. Here, the oxidation of chlorogenic acid by PPO did not result in any significant change in total Kjeldahl nitrogen (measures all N liberated as NH_3) of tomato protein despite striking changes in amino acid composition induced by alkylation (Table 4). The alkylation of protein or free amino acids by chlorogenoquinone appears to reduce the quality of the foliage as a food source for larvae (Table 3). In instances where herbivores consume foliage rich in PPO and *o*-diphenols, or other plant chemicals that can covalently bind to protein such as lactones, allylisothiocyanate, gossypol, hydroperoxides (Kawakishi and Kaneko, 1987; Finley et al., 1973), the relationship of herbivore performance to dietary nitrogen (e.g. Scriber's physiological efficiency model (1984), may be obscured when the measurement of nitrogen is limited to the Kjeldahl procedure. Conversely, the detectability of protein by Coomassie blue reagent was reduced in tomato foliage that was allowed to oxidize after maceration. This reduction may be due to specific binding of chlorogenoquinone to lysine or histidine, which may cause changes in the aqueous solubility of foliar protein and/or interfere with the binding of the protein reagent to these amino acids (Mattoo et al., 1987). Coomassie blue reagent binds specifically to basic amino acids such as arginine, histidine, and lysine (Bradford, 1976; Compton and Jones, 1985). More rigorous procedures for estimating qualitative and quantitative changes in foliar nitrogen are needed if cause-and-

effect relationships between plant nitrogen and herbivore fitness are to be better assessed.

The oxidation of *o*-dihydroxyphenolics in the gut of insects may have other consequences in addition to the reduced capacity to utilize plant nitrogen. Because chlorogenoquinone is highly reactive and alkylates free primary amines, sulfhydryl groups, and possibly peptide bonds, other molecules containing these nucleophilic groups may be alkylated (Matheis and Whitaker, 1984; Pierpoint, 1983). We have experimental evidence that the proteinase inhibitors of the tomato plant are alkylated by oxidation of chlorogenic acid, resulting in reduced ability to inhibit trypsin and a subsequent loss of antibiotic activity to insects (Felton et al., 1989). Additionally, the protein coat of a nuclear polyhedrosis virus infecting noctuid larvae is readily alkylated by these quinones, causing substantial loss of viral infectivity in larval *H. zea* (Felton and Duffey, 1990).

It follows that the effects of oxidized phenolics on insect herbivores may be multifaceted and multitrophic: with adverse effects on nutrients through reduced utilizability of protein and free amino acid nitrogen but potentially salutary effects through reduced activity of toxins (e.g., proteinase inhibitors and nonprotein amino acids) and reduced infectivity of pathogens (e.g., nuclear polyhedrosis viruses). Further ecological and physiological investigations are needed to clarify the complex multitrophic interactions among the plant, the herbivore, and its natural enemies.

Acknowledgments—This research was supported by USDA competitive grants 84-CRCR-1-1439, 86-CRCR-1-1993, and 87-CRCR-1-2371 awarded to S.S.D. We thank Dr. B. Campbell for assistance with the amino acid analyses. The technical assistance of D. Buster and H. Eichenseer was much appreciated. Critical reviews of an earlier draft of this manuscript by Ms. C. T. Ludlum and Dr. D. Dahlman were greatly appreciated.

(Received November 14, 1988, accepted February 2, 1989)

Abstract—In the pentatomid bug, *Erthesina fullo* Thunberg, the odor of male metathoracic scent gland elicits an alarm response, making the male individuals of the same species alert and disperse; the alarm response of males is more obvious than that of females. Chemical composition of the glandular secretion was identified by gas chromatography and mass spectrometry data in comparison with authentic compounds. No sexual dimorphism exists in the glandular composition in this species. A total of 9 compounds [(*E*)-2-hexenal, (*E*)-4-keto-2-hexenal, (*E*)-2-hexenyl acetate, *n*-undecane, *n*-dodecane, (*E*)-2-decenal, *n*-tridecane, (*E*)-2-decenyl acetate, and *n*-pentadecane] are identified, among which *n*-tridecane and (*E*)-4-keto-2-hexenal comprised nearly 70% of the total secretion in both females and males.

Key Words—Alarm pheromone, metathoracic scent gland, Hemiptera, Pentatomidae, *Erthesina fullo*.

INTRODUCTION

In Hemiptera, the existence of an alarm pheromone was first reported by Calam and Youdeowei (1968); (*E*)-2-hexenal and some other aldehydic scent components of fifth instar larvae of *Dysdercus intermedius* Distant had an alarm effect to both larvae and adults. Ishiwatari (1974) also indicated that (*E*)-2-hexenal had an alarm effect on three species of pentatomid bugs, *Eurydema rugosa* Motschulsky, *E. pulchra* (Westwood), and *Nezara viridula* (L.). Lockwood and Story (1985) reported that the first instar *N. viridula* use *n*-tridecane as a bifunctional pheromone which caused dispersal at high concentrations (10^0 and 10^1 individual equivalent) and aggregation at low concentration (10^{-2} indi-

vidual equivalent). Recently, the metathoracic scent gland secretion of adult *N. viridula* was found to function as an alarm pheromone and two components, (*E*)-2-hexenal and (*E*)-2-hexenyl acetate, significantly increased movement during the first minute of exposure (Lockwood and Story, 1987).

The *Erthesina fullo* Thunberg (Hemiptera: Pentatomidae) is a major pest of pine trees and nato trees (hardwood) in Taiwan. Both males and females of this species also produce a secretion from the metathoracic scent gland that causes conspecific adults to drop from a plant or scurry and fly away from the emission site. This phenomenon indicates that the secretion may function as an alarm pheromone in *E. fullo*. In this study, we examined the biological activity and chemistry of the male and female metathoracic scent gland secretions in pentatomid bugs in Taiwan.

METHODS AND MATERIALS

Insects and Gland Extracts. Adults and late fifth instars of the *E. fullo* were collected during summer from luchu pine trees, *Pinus luchuensis* Mayer, and Formosan nato trees, *Palaquium formosanum* Hayata, in a suburb of north Taiwan. In the laboratory, nato tree twigs and 10% honey solution were supplied. The insectory was kept at 27–28°C, on a 12:12 hr light–dark cycle.

The adults were disturbed by using a forceps to strike their heads, then a clean filter paper (5 × 5 mm) was placed near the orifice of the metathoracic scent gland on the ventral metathoracic surface. The discharge sprayed on the filter paper was extracted with methylene chloride. Because different numbers of filter papers of male or female extract were immersed in different volumes of methylene chloride, a total of 136 males and 108 females were extracted in 3500 μ l and 2400 μ l methylene chloride, respectively. The extract was stored under 0°C for later bioassay and chemical analysis.

Bioassay of the Gland Extract. Two hours before the bioassay, one female or male was placed in each 17-cm × 9-cm glass jar with a piece of host twig. A total of 70 such glass jars of males or females were prepared for the six different concentrations and control. During bioassay, a small amount of female and male stock extract was taken out with a syringe and solvent was added to make the dilution equal to 1 individual equivalent (IE) per 30 μ l, and then serially diluted solutions of different IE (10^{-5} , 10^{-4} , 10^{-3} , 10^{-2} , 10^{-1} , and 1 IE) were obtained. Each solution was injected with a syringe onto the inside wall of a pipet tip, and the air was expelled with a rubber bulb toward each test individual on the host plant in the glass jar. The number of individuals that dropped from the host plant or began to move away was the criterion of the biological activity. The experiment had three replicates, so a total of 30 insects

were used at each concentration. The Kruskal-Wallis one-way analysis of variance by ranks (Siegel, 1956) was used to analyze the results.

Chemical Analysis. Gas chromatography (GC) of the extract was performed on three capillary columns. A Varian 3700 GC equipped with a flame ionization detector was used with a 4-m fused silica capillary column coated with a 0.25- μm film of DB-1 phase, a 25-m vitreous silica capillary column coated with 1.5- μm film of DB-5 phase, and a 35-m fused silica capillary column coated with 0.25- μm film of Carbowax 20 M phase. Helium, at a flow rate of 30 cm/min, was the carrier gas. In the DB-1 and DB-5 column, the extract was run at 50°C for 2 min to 250°C at 5°C/min. In Carbowax 20 M, the extract was run at 60°C for 2 min to 200°C at 5°C/min.

Gas chromatographic-mass spectrometric (GC-MS) analysis was conducted using a Finnigan 4600 mass spectrometer. The GC-MS data were obtained using a 30-m \times 0.25-mm (ID) column of DB-5 phase. The column temperature was held at 50°C for 2 min to 300°C at 30°C/min using helium as carrier gas. Electron impact (EI) mass spectra were collected at 70 eV with separator and source at 150°C.

Each compound was identified by comparison of its mass spectrum with the published mass spectrum or the mass spectrum of the authentic standards (Aldrich and Yonke, 1975; Cornu and Massot, 1979; Kitamura et al., 1984; Staddon et al., 1987). Subsequently, all the compounds identified by mass spectral data were cross-checked by comparison of the GC retention of the natural product to that of an authentic standard using the three capillary columns under the same GC conditions as described above. Standards of (*E*)-2-hexenal, (*E*)-2-hexenyl acetate, *n*-undecane, *n*-dodecane, *n*-tridecane, and *n*-pentadecane were purchased from Sigma Chemical Co., (St. Louis, Missouri). (*E*)-4-Keto-2-hexenal, (*E*)-2-decenal, and (*E*)-2-decenyl acetate were supplied by J.R. Aldrich (Insect Physiology Laboratory, USDA-ARS, Beltsville, Maryland). The relative proportions of these nine compounds in the scent secretion was ascertained from GC peak-area integration.

RESULTS

Bioassay of Gland Extract. The bioassay results showed that females are not as responsive as males to the metathoracic scent extraction (Figure 1). Although the male alarm response to 1 IE female scent extract was 85.0%, no significant difference was found at all tested female concentrations (Figure 1A), and the alarm response of females to female scent extract was not-significant at all tested female concentrations (Figure 1A). The alarm response of males to 1 IE male scent extract was 100.0%, significantly different from the alarm

FIG. 1. Percent response of adults to different concentrations of female (A) and male (B) metathoracic scent gland extract. (●: female response, ○: male response, IE: individual equivalent). Uppercase and lowercase letters above confidence bars represent the statistical difference of females and males, respectively. Bars topped by the same letter(s) do not differ significantly; $P = 0.05$, Kruskal-Wallis one-way analysis of variance by ranks.

response to 10^{-5} male concentration ($P < 0.05$, Figure 1B); the alarm response of females to male scent extract was almost nonsignificant at all tested male concentrations (Figure 1B).

Chemical Analysis. Gas chromatographs of the metathoracic scent gland secretions of male and female are qualitatively alike (Figure 2). The secretion was composed of straight-chain alkanes [*n*-undecane (4), *n*-dodecane (5), *n*-tridecane (7), and *n*-pentadecane (9)] and α , β -unsaturated carbonyl compounds [(*E*)-2-hexenal (1), (*E*)-4-keto-2-hexenal (2), (*E*)-2-hexenyl acetate (3), (*E*)-2-decenal (6), and (*E*)-2-decenyl acetate (8)]. The mass spectral data of these compounds are listed in Table 1. The relative proportion of compounds in the scent secretion was the same in both females and males (Table 2), in which *n*-tridecane and (*E*)-4-keto-2-hexenal comprised nearly 70% of the total secretion. The other two unsaturated aldehydes, (*E*)-2-hexenal and (*E*)-2-decenal, comprised nearly 20% of the total secretion; the unsaturated acetates, (*E*)-2-hexenyl acetate and (*E*)-2-decenyl acetate, comprised nearly 8% of the total secretion; the other straight-chain alkanes only comprised nearly 2% of the total secretion.

DISCUSSION

Our work indicates that the male metathoracic scent gland secretion of *E. fullo*, functions as an alarm pheromone, which is concentration dependent, and induced obvious dispersal response at 1 IE in males. The females do not show significant alarm response to their own and male's secretion. Chemical defense against predation had been reported as the most important function of the scent glands of the pentatomids Hemiptera-Heteroptera (Blum, 1981), but in the laboratory, the phenomenon that *E. fullo* was preyed on by mantids without any defensive effect from the metathoracic gland secretion was usually observed. The biological activity of female metathoracic scent gland secretion and the reason why females are not as responsive as males still needs further study.

The metathoracic scent gland secretions of male and female *E. fullo* are nearly identical. The composition of this glandular secretion is similar to that of other pentatomids (Gilby and Waterhouse, 1965, Staddon et al., 1987). Among all identified compounds, (*E*)-2-hexenal, *n*-tridecane, and (*E*)-2-hexenyl acetate had been reported as alarm pheromones as mentioned before. Calam and Youdeowei (1968) suggested that the saturated hydrocarbons such as *n*-undecane, *n*-dodecane, *n*-tridecane, and *n*-pentadecane may function as relatively nonvolatile solvents for the active alarm pheromone components and as spreading and wetting agents in the pyrrhocorid, *D. intermedius*. Kitamura et al. (1984) also indicated that in Pentatomidae and Plataspidae hydrocarbons act as the solvent for aldehydes such as the oxohexenal. Moreover, Remold (1963),

TABLE 1. MASS SPECTRA OF NINE COMPOUNDS IDENTIFIED IN METATHORACIC SCENT GLAND SECRETION OF *Erthesina fullo*

Compound	Mass spectral data, <i>M/Z</i> (intensity, %)
(<i>E</i>)-2-Hexenal	69(100), 55(88), 41(86), 83(80), 57(55), 42(53), 84(43), 70(42), 86(34), 43(27), 56(22), 53(16), 80(15)
(<i>E</i>)-4-Keto-2-Hexenal	83(100), 55(69), 84(24), 57(22), 43(18), 56(12), 54(8), 67(7)
(<i>E</i>)-2-Hexenyl acetate	67(100), 82(95), 84(93), 43(70), 55(58), 57(57), 86(54), 83(40), 49(34), 56(22), 100(18), 54(17), 51(16), 41(15)
<i>n</i> -Undecane	43(100), 57(90), 55(56), 41(39), 49(38), 84(33), 71(32), 83(29), 85(26), 56(25), 42(22)
<i>n</i> -Dodecane	57(100), 43(94), 71(42), 41(36), 85(33), 55(29), 56(26), 84(19), 49(18), 86(10)
(<i>E</i>)-2-Decenal	55(100), 43(70), 57(64), 41(62), 70(58), 83(48), 56(43), 69(35), 54(21), 97(20), 53(18), 67(17)
<i>n</i> -Tridecane	57(100), 43(98), 71(97), 85(73), 41(69), 56(50), 79(41), 55(34), 42(29), 84(22), 69(20)
(<i>E</i>)-2-Decenyl acetate	43(100), 54(43), 55(42), 67(35), 81(28), 68(25), 41(24), 57(23), 96(22), 82(21), 95(18), 69(17), 110(14)
<i>n</i> -Pentadecane	57(100), 43(80), 71(54), 85(42), 41(36), 55(32), 56(22), 42(15), 70(13), 99(10)

Filshie and Waterhouse (1969), and Kitamura et al. (1984) reported that many bugs possess an area of precisely elaborated cuticles surrounding the orifices of the metathoracic glands, and these structures are supposed to be the evaporative area. The present results show that *n*-tridecane and the unsaturated compounds

TABLE 2. PERCENTAGES OF COMPOUNDS IN METATHORACIC SCENT SECRETION OF FEMALE AND MALE *Erthesina fullo*

Compound	Female	Male
(<i>E</i>)-2-Hexenal	8.4	6.4

<i>n</i> -Tridecane	46.3	50.5
(<i>E</i>)-2-Decenyl acetate	5.6	5.9
<i>n</i> -Pentadecane	0.1	0.1

such as (*E*)-4-keto-2-hexenal are the major constituents of the scent secretion of *E. fullo*. The relative proportion of (*E*)-2-hexenal was 8.4% and 6.4% in female and male, respectively, and the relative proportion of (*E*)-2-hexenyl acetate was only 2.4% and 1.6% in female and male, respectively (Table 2). Although the composition of the glandular secretion has been identified, the precise quantity and biological function of each compound in the scent secretion still need further study.

Acknowledgments—We thank the National Science Council, Taiwan, R.O.C., for financial support; Dr. J.R. Aldrich for supplying the authentic compounds; and Ms. Y.H. Chen for help during the experiment.
