Journal of Chemical Ecology, Vol. 16, No. 1, 1990

INTRODUCTION

The fifth annual meeting of the International Society of Chemical Ecology was held on June 24–27, 1988, at the University of Georgia in Athens. Four symposia were featured, highlighting progress in diverse areas of chemical ecology. They were: Sensory Behavior of Microorganisms, Chemical Ecology of Reptiles, Arthropod Sequestration of Natural Resources, and Chemical Ecology in the Aquatic Environment. The *Journal of Chemical Ecology*, the official journal of the ISCE, is dedicating this issue to the proceedings from these symposia.

The first symposium, organized by Michael D. Manson (Texas A&M University), emphasized two important aspects of microbial physiology: microorganisms display an astonishing diversity of responses to environmental cues, and the molecular and cellular bases of these behaviors often are similar to those observed in multicellular organisms.

The first paper introduces bacterial motility and chemotaxis, emphasizing recent studies on signal transduction. Other papers address the physical constraints on motility and chemoreception in bacteria, chemical communication in gametes of the aquatic slime mold *Allomyces*, and the mechanism of aggregation in slime mold amebae. Also included are abstracts of talks about the evolution of bacterial signal transducers, chemical interactions between *Rhizobium* and legume roots, motility and chemotaxis in spirochetes, control of bioluminescence in marine bacteria, fruiting body formation in *Myxobacteria*, and ion channels in *Paramecium*, yeast, and bacteria.

The second symposium, organized by Paul J. Weldon (Texas A&M University), is concerned with both chemical production and chemical perception by reptiles. All extant reptiles produce skin or skin gland secretions for intraspecific communication, predator deterrence, or other functions. New information is presented on the components and possible functions of epidermal and skin gland secretions from lizards and crocodilians.

The studies of reptile chemical perception focus on the ability of squamate reptiles, specifically lizards and snakes, to identify chemicals from prey and predators. Several contributions are concerned with snakes' responses to prey chemicals, where progress is described in identifying the source and nature of chemical releasers of feeding behavior and in relating chemical perception to feeding ecology. A Letter to the Editor discusses terms to denote chemical perception by various vertebrate chemosensory organs.

0098-0331/90/0100-0001$06.00/0

The third symposium, organized by Murray S. Blum (University of Georgia), is concerned with the abilities of species of Lepidoptera, Coleoptera, Hemiptera, Diptera, Hymenoptera, and Orthoptera to selectively sequester plant compounds and the metabolic transformations accompanying the process of compound storage. Both specific and nonspecific sequestration were examined, especially for species that exhibit both types of biomagnification.

The varied roles of sequestrable compounds were analyzed in terms of the adaptive significance for herbivores specializing on plants fortified with "toxic" natural products. A number of contributions to this symposium indicate that, in addition to acting as feeding deterrents to predators, these secondary compounds and/or their metabolites possess other diverse functions. The adaptiveness of sequestration for specialist insect herbivores is manifest by the utilization of plant-derived chemicals as pheromones, growth regulators, and oviposition and feeding stimulants.

The fourth symposium, organized by Donald J. Gerhart (Duke University), features chemical defense, chemical communication, and allelopathic competition in freshwater and marine environments. These papers describe the influence of isothiocyanates on interactions between small crustacean grazers and some aquatic macrophytes, the roles played by peptides in chemical signaling and chemoreception by marine invertebrates, and long-term studies of the chemical ecology of benthic invertebrates on the Great Barrier Reef.

Each invited symposium paper has undergone peer review in accordance with the standard policy of the *Journal of Chemical Ecology*. We are grateful to the reviewers for their valuable services.

We acknowledge the cooperation of the Plenum Publishing Corporation in producing extra copies of this issue to accommodate registrants of the meeting and others interested in the symposia proceedings.

ANALYSIS OF GULAR AND PARACLOACAL GLAND SECRETIONS OF THE AMERICAN ALLIGATOR (*Alligator mississippiensis*) BY THIN-LAYER CHROMATOGRAPHY

Gland, Sex, and Individual Differences in Lipid Components

PAUL J. WELDON, TIMOTHY P. SCOTT, and MICHAEL J. TANNER

Department of Biology

College Station, Texas 77843

(Received February 1, 1989; accepted March 17, 1989)

Abstract—Secretions from the gular and the paracloacal glands of adult male and female American alligators (*Alligator mississippiensis*) were extracted with chloroform, weighed, and analyzed by thin-layer chromatography. In both sexes, more lipoidal secretions were recovered from the paracloacal glands than from the gular glands. Females produce more lipoidal secretions in both sets of glands than do males. The thin-layer chromatograms of extracts from both glands exhibit bands consistent with aliphatic alcohols, sterols, free fatty acids, and steryl esters. Triglycerides, hydrocarbons, phosphatidylethanolamine, and lysophosphatidylcholine also are indicated in some chromatograms. Gland, sex, and individual differences are suggested in the thin-layer profiles.

Key Words—*Alligator mississippiensis*, gular glands, paracloacal glands, lipids.

INTRODUCTION

The American alligator (*Alligator mississippiensis*), as with other extant crocodilians, possesses two prominent pairs of skin glands, the gular and the paracloacal glands. The gular glands are situated on the ventral aspect of the lower jaw in folds of the skin adjacent to each mandibular ramus (Weldon and Sampson, 1988). The paracloacal glands are embedded in the walls of the cloaca,

0098-0331/90/0100-0003$06.00/0

and they release secretions through duct openings near the vent (Weldon and Sampson, 1987).

Either or both pairs of skin glands may be everted when alligators are physically restrained immediately after capture (Weldon, personal observation), but the function(s) of the secretions, and even the conditions under which they are discharged, is uncertain. Immature alligators respond by increased gular pumping to airborne presentations of gular and paracloacal gland exudates from adult males (Johnsen and Wellington, 1982), lending support to the frequent suggestion that these materials contain pheromones. Neill (1971) dismissed accounts that secretions from *A. mississippiensis* skin glands could be detected by humans. Vliet (1989), however, states that this species' secretions linger in the air after the head-slapping display and that an oily sheen, presumably from the paracloacal glands, appears on the surface of the water.

Analyses by gas chromatography–mass spectrometry (GC-MS) of glandular secretions from *A. mississippiensis* indicated that the paracloacal glands contain cholesterol, free fatty acids, a variety of esters, and α-tocopherol (Weldon et al., 1988) and that the gular glands contain cholesterol, free fatty acids, α-tocopherol, and squalene (Weldon et al., 1987). Thin-layer chromatography (TLC) and carbon-13 nuclear magnetic resonance of the gular gland secretions indicated steryl esters, triglycerides, and other compound classes (Weldon and Sampson, 1988).

We report here the results of TLC analyses of the gular and paracloacal gland secretions from adult *A. mississippiensis*. This study documents differences in the chemicals produced in these glands, provides evidence for sex and individual variation, and details the amounts of chloroform ($CHCl_3$)-soluble materials present in these exudates.

METHODS AND MATERIALS

Gular and paracloacal gland secretions were obtained from 20 male (total lengths = 1.6–2.5 m; $\bar{X}$ = 2.0 m) and 14 female (1.4–2.2 m; $\bar{X}$ = 1.8 m) alligators from Cameron parish, Louisiana, during September 1988. All specimens had been sacrificed 3–4 hr before secretions were obtained.

Secretions were collected by manually everting and compressing the capsule of the glands. Secretions from the paracloacal glands generally flowed freely from the opening of the gland duct into a vial; caseous exudates from the gular glands were scraped onto the rim of a vial or, if present as a residue around the gland duct, collected on the end of a capillary tube, which was broken off into a vial. The exudates of each pair of glands from each individual were kept separate. Approximately 1.5 ml of $CHCl_3$ were added to each vial. They were transported on ice and stored at $-90°C$.

Secretions were extracted by adding 10 ml of $CHCl_3$ to each vial, shaking for 1 min, and inserting a pipet to draw off the solvent; this process was performed twice. The extract was filtered, and the solvent was removed by rotoevaporation. The dried residue was dissolved in $CHCl_3$ and transferred to a preweighed vial. The vial was placed under a stream of nitrogen, allowed to desiccate in vacuo for 12 hr, and weighed. One milliliter of $CHCl_3$ was added to each vial, and the vials were stored at $-90°C$.

Aliquots of the gular and paracloacal gland solutions (300 μg for both polar and nonpolar lipids) were applied to 1-cm lanes on a 0.25-mm layer of silica gel 60 G on 20 × 20-cm glass plates. Secretions from eight females were applied separately on the left side of each plate; those from eight males were applied on the right side. The same individuals, spotted in the same order, were used for the chromatograms of polar and nonpolar secretions from each set of glands; different individuals were used for the analyses of gular and paracloacal secretions. Mixed lipid standards (Nu-Chek-Prep, Elysian, Minnesota, for nonpolar lipids; Supelco, Bellefonte, Pennsylvania, for polar lipids) were developed in the center lane of each plate. Separate nonpolar plates (not shown) were developed using an aliphatic alcohol (nonanol) and a hydrocarbon (squalene) as standards.

The nonpolar lipids were resolved by successive development in hexane, then toluene, and finally hexane–diethyl ether–acetic acid (80:20:2, v/v/v). The polar lipids were resolved by development in $CHCl_3$–methanol–water (65:35:5, v/v/v). The plates were sprayed with 50% sulfuric acid and heated on a hot plate to char the lipids. At least three plates of nonpolar and polar secretions from both sets of glands were examined.

RESULTS

All chromatograms of the nonpolar gular gland secretions (Figure 1) indicate bands consistent with sterols ($R_f = 0.2$), free fatty acids ($R_f = 0.4$), and steryl esters ($R_f = 0.9$); several chromatograms display a band just below that of steryl esters. A prominent band in the region to which triglycerides migrate ($R_f = 0.7$) is evident in most of the females' secretions; in males, two distinct bands (R_fs = 0.6 and 0.8) are displayed. A band at the solvent front of all chromatograms indicates hydrocarbons.

Aliphatic alcohols migrate slightly above sterols in the solvent system used here, as confirmed by tests with nonanol. One or more bands consistent with aliphatic alcohols ($R_f = 0.2$) are observed in all gular gland chromatograms.

Chromatograms of the nonpolar paracloacal gland secretions (Figure 2) display bands corresponding to sterols, free fatty acids, triglycerides, and steryl esters; all chromatograms display a band just below that of steryl esters. Two

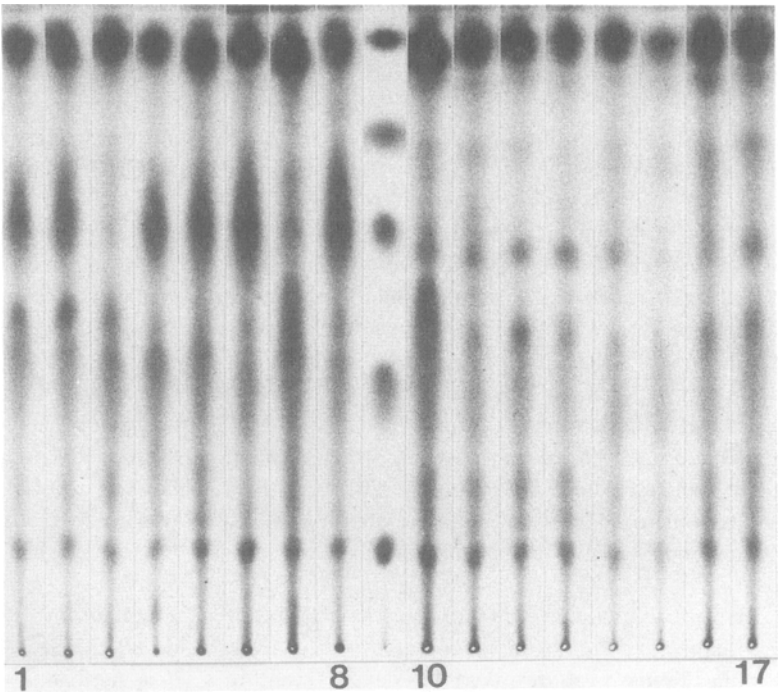

FIG. 1. Thin-layer chromatograms of nonpolar gular gland secretions from eight female (lanes 1–8) and eight male (lanes 10–17) *A. mississippiensis*. Lane 9 contains lipid standards (from bottom): sterol (cholesterol), free fatty acid (oleic acid), triglyceride (triolein), methyl ester (methyl oleate), and steryl ester (cholesteryl oleate).

prominent bands of unknown chemical classes possess R_f values of approximately 0.8 and 0.9. A faint band ($R_f = 0.1$), and others in this region, indicate the presence of compounds more polar than sterols. Another minor band ($R_f = 0.5$) also is evident. A faint band at the solvent front of several chromatograms (e.g., lane 6) is consistent with hydrocarbons.

A band in the paracloacal extracts consistent with aliphatic alcohols ($R_f = 0.2$) is evident in all chromatograms; it is more prominent in males. One male (lane 13) displays a band ($R_f = 0.3$) not apparent in the chromatograms of other individuals.

Chromatograms of the polar gular and paracloacal gland secretions (Figures 3 and 4, respectively) indicate a predominance of compounds less polar than lysophosphatidylcholine. The gular gland secretions of three females (lanes 5, 6, and 8) exhibit bands consistent with phosphatidylethanolamine ($R_f = 0.3$)

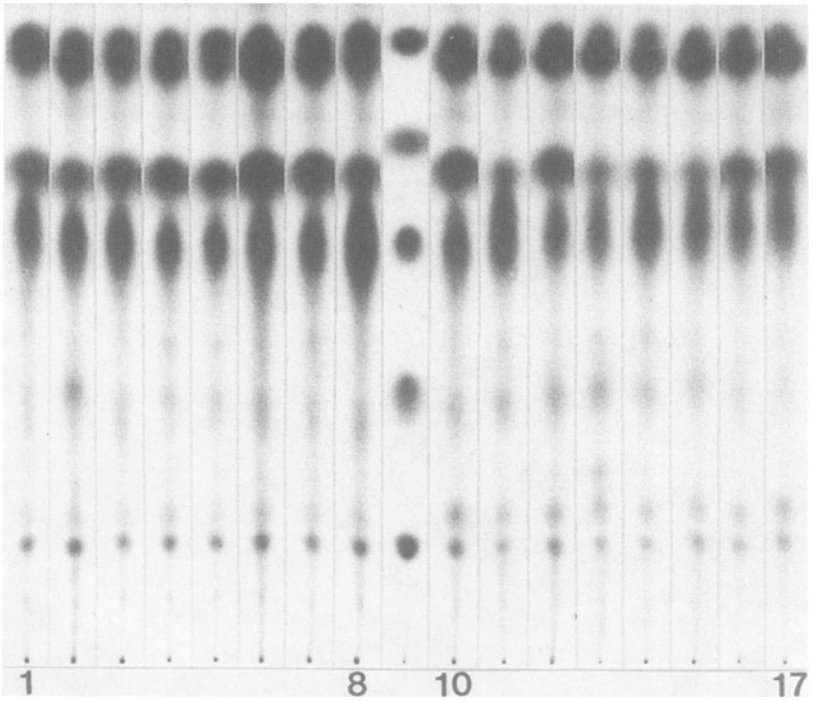

FIG. 2. Thin-layer chromatograms of nonpolar paracloacal gland secretions from eight female (lanes 1–8) and eight male (lanes 10–17) *A. mississippiensis*. Lane 9 contains the lipid standards indicated in Figure 1.

and lysophosphatidylcholine ($R_f = 0.6$); a faint band in the chromatogram of a male (lane 11) is intermediate ($R_f = 0.4$). The paracloacal gland secretions of one female (lane 7) exhibit bands consistent with phosphatidylethanolamine and lysophosphatidylcholine. One other female (lane 2) exhibits a band consistent with phosphatidylethanolamine. Other bands in this region are not apparent in the other paracloacal gland chromatograms.

The amounts of $CHCl_3$-soluble materials obtained from the gular and paracloacal gland secretions are shown (Table 1). A t test for independent samples of unequal variance (Ott, 1988) detected significantly more secretions from both the gular and the paracloacal glands of females than from those of males ($P < 0.05$ for both glands). A Wilcoxon matched-pairs signed-ranks test (Siegel, 1956) detected significantly more paracloacal than gular gland secretions in both sexes ($P < 0.05$).

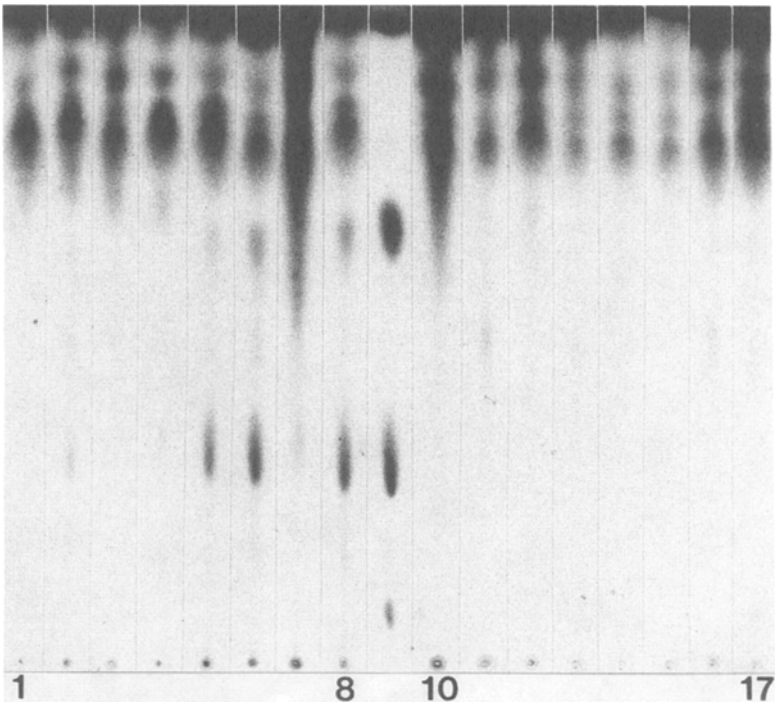

FIG. 3. Thin-layer chromatograms of polar gular gland secretions from eight females (lanes 1–8) and eight male (lanes 10–17) *A. mississippiensis*. Lane 9 contains lipid standards (from bottom): phosphatidylcholine, phosphatidylethanolamine, lysophosphatidylcholine, and sterol (cholesterol).

DISCUSSION

Differences in the gular and paracloacal gland chemicals of *A. mississippiensis* are indicated by our analysis. Nonetheless, all nonpolar TLC chromatograms of these secretions display bands consistent with sterols, free fatty acids, and steryl esters. Triglycerides are suggested in all paracloacal chromatograms and most of those of the gular gland secretions. These compound classes have been indicated in a number of TLC analyses of vertebrate epidermal or skin gland secretions (Burken et al., 1985; Stewart, 1986; Weldon and Bagnall, 1987). The structures of at least a few compounds within these classes—cholesterol and saturated and unsaturated fatty acids—have been elucidated by GC-MS analyses of the secretions of alligators (Weldon et al., 1987, 1988) and other crocodilians (Navajas Polo et al.; 1988a,b; Shafagati et al., 1989).

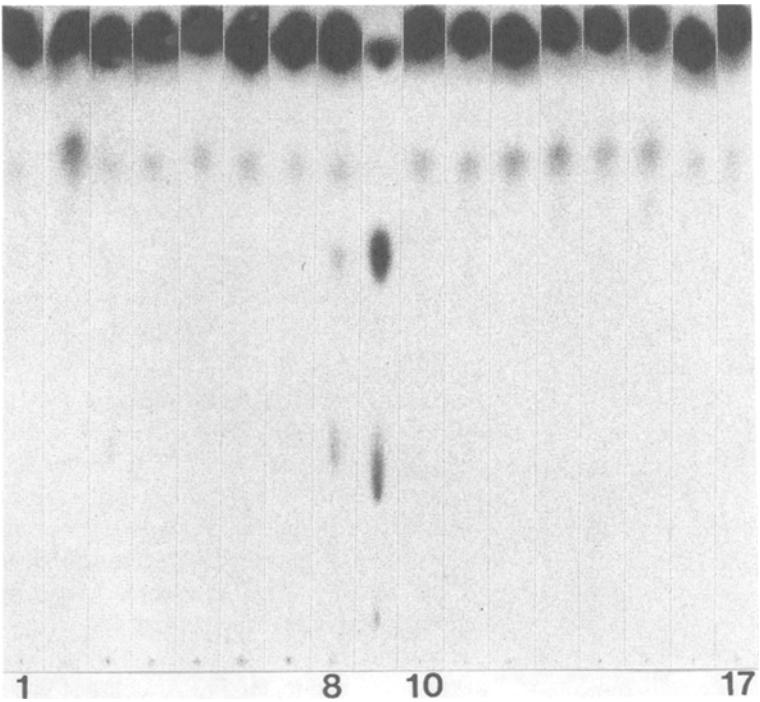

FIG. 4. Thin-layer chromatograms of polar paracloacal gland secretions from eight female (lanes 1–8) and eight male (lanes 10–17) *A. mississippiensis*. Lane 9 contains the lipid standards indicated in Figure 3.

TABLE 1. MEAN (±1 SD) WEIGHTS OF CHLOROFORM-SOLUBLE MATERIALS FROM GULAR AND PARACLOACAL GLAND SECRETIONS OF *A. mississippiensis*

	Secretion (mg)	
	Gular gland	Paracloacal gland
Male (N = 18)	$\bar{X}$ = 3.5 ± 2.6	$\bar{X}$ = 158.7 ± 158.4
Female (N = 14)	$\bar{X}$ = 27.1 ± 23.0	$\bar{X}$ = 240.5 ± 233.5

and Sampson (1988) indicated a band consistent with hydrocarbons, but this was suspected of being a contaminant. Squalene, however, has been demonstrated in a GC-MS analysis of these secretions (Weldon et al., 1987). Bands consistent with hydrocarbons occur in all gular gland and several paracloacal gland chromatograms.

A band in both the gular and paracloacal chromatograms is consistent with aliphatic alcohols. The appearance of this band in the latter exudate is noteworthy since a GC-MS analysis of paracloacal gland secretions from juvenile and adult *A. mississippiensis* failed to indicate these compounds (Weldon et al., 1988). Fester and Bertuzzi (1934) and Fester et al. (1937), on the other hand, found citronellol and other alcohols in the saponified paracloacal secretions of two caimans, *Caiman crocodilus* and *C. latirostris* (apparently pooled from both species), and Shafagati et al. (1989) found saturated and unsaturated alcohols in the secretions of dwarf (*Paleosuchus palpebrosus*) and smooth-fronted caimans (*P. trigonatus*).

In Weldon and Sampson's (1988) TLC analysis of alligator gular gland secretions, extracts were developed from three males (pooled) and one female. The chromatogram of the males displayed bands not evident in that of the female, but it was not clear whether these results reflected sex-related differences, given the small number of individuals compared. The separate development of gular gland secretions from males and females in our analysis provides evidence of sex differences in the TLC region to which triglycerides migrate. Sex differences in the paracloacal secretions are not as obvious, although the concentration of one band (possibly denoting alcohols) apparently is higher in males. Further analyses are required to determine whether sex differences exist in the polar lipids from either set of glands.

Our results indicate that the polar and nonpolar TLC profiles of gular and paracloacal glands vary among members of the same sex. The individuals we sampled ranged from approximately 5–15 years of age, judging from their lengths. Thus, all animals in our study were reproductively mature. Our results, therefore, likely reflect individual variation in the presence or concentration of gular and paracloacal gland lipids.

Measurements of the weights of $CHCl_3$-soluble substances in alligator skin glands indicate that both sexes produce more lipoidal secretions in the paracloacal glands than in the gular glands, and that females produce more lipoidal secretions in both gular and paracloacal glands than do males. Seasonal differences, however, may exist in the quantity (and quality) of glandular exudates. Bell (1827), in fact, stated that his two captive *A. mississippiensis* produced less gular gland secretions in winter than during warmer months.

Alligators in the population from which our specimens were obtained are active during September, when secretions were collected, but they mate during May and females nest during the summer. Comparisons of the amounts of secretions produced in alligator skin glands, and of the chemicals in them, at different seasons are needed.

Some authors have suggested that alligators spray secretions from the gular glands while bellowing (e.g., LeBuff, 1957). Unless, however, alligators produce substantially more gular gland materials when bellowing occurs than the

quantitites we found, the amounts of exudates in these organs probably are insufficient to be discharged in this way (even though we have weighed only the $CHCl_3$-soluble materials) (see also McIlhenny, 1935). Observations of free-ranging alligators are needed to determine the occasions upon which skin gland secretions are released.

Acknowledgments—R. Elsey, T. Joanen, L. McNease, and the staff of the Rockefeller Wildlife Refuge in Grand Chenier, Louisiana, graciously provided logistical support during this study. J. Dang, M. Kroeger, and M. McClure helped extract alligator secretions. C. Navajas Polo and K. Vliet shared with us unpublished manuscripts. Bedoukian Research Inc., Danbury, Connecticut, donated some standards used in this study. This research was supported by grants to P.J.W. from Sea Grant and The National Geographic Society.

CHEMICAL PROPERTIES OF FEMORAL GLAND SECRETIONS IN THE DESERT IGUANA, *Dipsosaurus dorsalis*

ALLISON C. ALBERTS

Research Department
Zoological Society of San Diego
P.O. Box 551,
San Diego, California 92112

(Received February 1, 1989; accepted March 17, 1989)

Abstract—This study investigates the chemistry of femoral gland secretions in the desert iguana, *Dipsosaurus dorsalis* (Lacertilia: Iguanidae), and discusses their possible functional significance. Electrophoretic and proton NMR studies indicated that the secretions are composed of approximately 80% protein and 20% lipid material. Individual differences in polyacrylamide gel banding patterns of femoral gland proteins were found. Reflectance spectroscopy revealed that the secretions strongly absorb longwave ultraviolet light, a feature that may be important in the localization of secretion deposits in the environment.

Key Words—Desert iguana, *Dipsosaurus dorsalis*, femoral glands, contact pheromones, ultraviolet light, signal localization.

INTRODUCTION

The femoral glands of lizards are follicular skin glands present in a row on the ventral surface of the hindlegs and open to the exterior through femoral pores. Femoral glands are present in many, although not all, families of lizards. Although the existence of femoral glands has been documented for over 200 years (Linnaeus, 1758), little is known of either the chemical nature of the secretion or its functional significance.

Each gland consists of several branching tubules leading to a separate pore through which a solid plug of exudate is secreted. The secretion is holocrine in nature, and, at least in some species, is composed of cells that undergo transformation and subsequently move down through the secretory duct of the glands

0098-0331/90/0100-0013$06.00/0

where they are expelled to the outside (Cole, 1966a; Maderson, 1972). It can vary in color from white to yellowish cream, gray, or black, a feature which may be dependent on differential concentrations of melanin in the secretions of different species (Cole, 1966b). The number of pores present in the femoral series varies across species, but within a species, the glands are usually present in equal numbers in both sexes.

The microscopic anatomy of femoral glands has been described for the collored lizard, *Crotaphytus collaris* (Cole, 1966a), and for sphaerodactyline and eublepharine gekkonid lizards (Maderson, 1972). In male lizards, the glands are usually larger, more deeply embedded in the muscles of the leg, and more complex in structure, consisting of a greater number of tubules than those of females. Although the glands are evident in the embryonic stages of development, they exhibit no sexual dimorphism at this stage and do not become active until sexual maturity is reached (Cole, 1966a). The activity of femoral glands in several species reaches its peak during the breeding season (Cole, 1966b), suggesting they play some role in reproduction. The anatomical positioning of femoral glands on the underside of the hindlegs indicates that these secretions are probably passively deposited in the environment as the animal moves through its home range (Maderson, 1972; Fergusson et al., 1985).

Numerous studies have noted that treatment with androgenic hormones can induce activity of femoral glands in lizards even outside their normal breeding season (Forbes, 1941; Chiu et al., 1975; Duvall, 1979). Fergusson et al. (1985) quantitatively documented the hormonal control of femoral gland secretion in an agamid lizard, *Amphilbolurus ornatus*. They found that secretory activity in castrated males was significantly reduced but could be restored to normal levels by exogenous testosterone propionate and raised to hypernormal levels by injection of 5α-dihydrotestosterone. In females, injection of both of these androgens resulted in stimulation of secretory activity in femoral glands that had previously exhibited little or no activity. Similar results have been reported by Chiu et al. (1970) for female geckos. Seasonal activity and androgenic control of glandular activity is commonly observed in mammalian scent glands known to have communicative function (see Johnson, 1973; Ebling, 1977, for reviews).

The complex histological structure of femoral glands (Cole, 1966b), combined with their sexual dimorphism, highly seasonal activity, and control by reproductive hormones, makes it improbable that the glands are vestigial. It should be noted, however, that the glands are present in diverse taxa and occur in families spanning a wide range of ecological conditions. This makes it unlikely that the current utility of femoral gland secretions is identical in every lizard species in which they are produced. Laboratory experiments have shown that femoral gland secretions stimulate chemosensory investigation in desert iguanas, *Dipsosaurus dorsalis* (Alberts, 1989). These lizards respond to the secretions with elevated levels of tongue-touching, a chemoreceptive behavior

in which the tongue is extruded and touched to the substrate (see Simon, 1983, for review). As part of a comprehensive study of chemical signalling in *Sceloporus occidentalis,* Duvall (1986) also reported a slight increase in tongue-touches to femoral gland secretions compared to controls.

This study was undertaken to characterize the chemical nature of femoral gland secretions in *Dipsosaurus dorsalis,* an exclusively diurnal species that inhabits hot, arid desert habitats from southern Nevada, through southern California and central Arizona, into Baja California and Sinaloa in Mexico (Stebbins, 1966). Such extreme environmental conditions are expected to impose strong limitations on pheromone transmission, since volatile pheromones exhibit rapid fade-out times due to increased diffusion rates at high temperatures (Bossert and Wilson, 1963). If femoral gland secretions are used as pheromones by *D. dorsalis* in nature, these physical constraints are expected to have influenced the evolution of their chemistry. In particular, low volatility and resistance to degradation at high temperatures are predicted properties of chemical signals utilized by diurnal animals inhabiting desert environments.

METHODS AND MATERIALS

Secretion Collection. Femoral gland secretions were collected from two female and three male *D. dorsalis* captured in the Coachella Valley, Riverside County, California, in April and May 1987. For comparative purposes, secretions were also obtained from one male western fence lizard (*Sceloporus occidentalis;* Iguanidae), one male granite spiny lizard (*S. orcutti*), and one male western whiptail (*Cnemidophorus tigris;* Teiidae) during the same time period. Samples were collected in the field by applying gentle manual pressure around the gland openings of the lizards and removing the secretion plugs with small forceps. Following collection, samples were transported on ice and stored at −15°C. A 5-mg sample of *D. dorsalis* femoral gland secretion was subjected to melting-point analysis.

Chemical Separation. To isolate the nonpolar chemical components, several secretion plugs from both male and female *D. dorsalis* were placed in methylene chloride (CH_2Cl_2), stirred for 1 hr, and stored at room temperature overnight. After filtration of the insoluble components and rotary evaporation of the solvent under reduced pressure, 4.24 mg of CH_2Cl_2-soluble material was recovered and dissolved in 2.5 ml deuterated chloroform ($CDCl_3$). The sample was then stored at −15°C. The insoluble part of the secretion, a white solid representing 79.52% of the total secretion weight, was recovered from the filter, air dried overnight, and stored at −15°C.

Chemical Analyses. A proton nuclear magnetic resonance (NMR) spectrum was obtained on the organic-soluble secretion in $CDCl_3$ on a 360-MHz

NMR spectrometer. Tetramethylsilane was added as a reference compound. Elemental analysis of the CH_2Cl_2-insoluble part of the secretion was carried out to determine the percent carbon, nitrogen, hydrogen, and sulfur present. To examine this part of the secretion in more detail, CH_2Cl_2-extracted secretion plugs from five *D. dorsalis,* one *S. occidentalis,* one *S. orcutti,* and one *C. tigris* were dissolved in 8 M urea to a final concentration of 1 $\mu g/\mu l$ by heating them in a 100°C water bath with intermittent stirring. Upon dissolving, 50 μl of each sample was loaded onto a 12% nonreducing SDS polyacrylamide gel to determine the apparent molecular weight and relative concentration of protein components present (Laemmli, 1970). Molecular weight standards (Biorad, Richmond, California) were also run on the gel. Bromphenol blue was used as the tracking dye. The gel was run at 13 mA for approximately 30 min until the samples had exited the stacker, and then run at a constant 80 V until the sample front had reached the end of the gel approximately 3.5 hr later. Following electrophoresis, the gel was stained with 0.1% Coomassie blue in 50% methanol–10% acetic acid for 20 min, then destained overnight in a 50% methanol–10% acetic acid solution.

Spectroscopic Analyses. Reflectance spectra for fresh whole *D. dorsalis* femoral gland secretion were measured with a LI-COR LI-1800 spectroradiometer and calibrated fiberoptic probe with an acceptance angle of less than 10%. The sample was illuminated with an Oriel model 68735 lamp and reflectance measurements were taken between 300 and 800 nm. To examine the fluorescence of the secretion, the light source was outfitted with a Kodak 18-A filter, which only passes light below 400 nm (transmittance spectrum given in Eastman Kodak Publication B-3, 1981). In order to standardize for the varying intensity of the light source and differential sensitivity of the spectroradiometer at different wavelengths, a measurement was also taken of a polished aluminum standard which reflects nearly 100% of incident light.

RESULTS

Chemical analyses demonstrated that femoral gland secretions of *D. dorsalis* are composed of roughly 80% protein and 20% lipid material by weight and indicated that the secretion begins to decompose when subjected to temperatures of 225°C. It does not melt, even at temperatures in excess of 250°C. Proton NMR spectroscopy of the CH_2CL_2-soluble components of the secretion (Figure 1) reveals peaks exhibiting chemical shifts consistent with the presence of lipids, possibly including triglycerides and sterols (Bhacca and Williams, 1964; Gunstone, 1967). The chemical shifts observed in the spectrum are probably due to tertiary methyl group protons (0–2 ppm region), methylene protons (1.2 ppm), glyceride methylene (4.2 ppm), and olefinic protons (5.2 ppm).

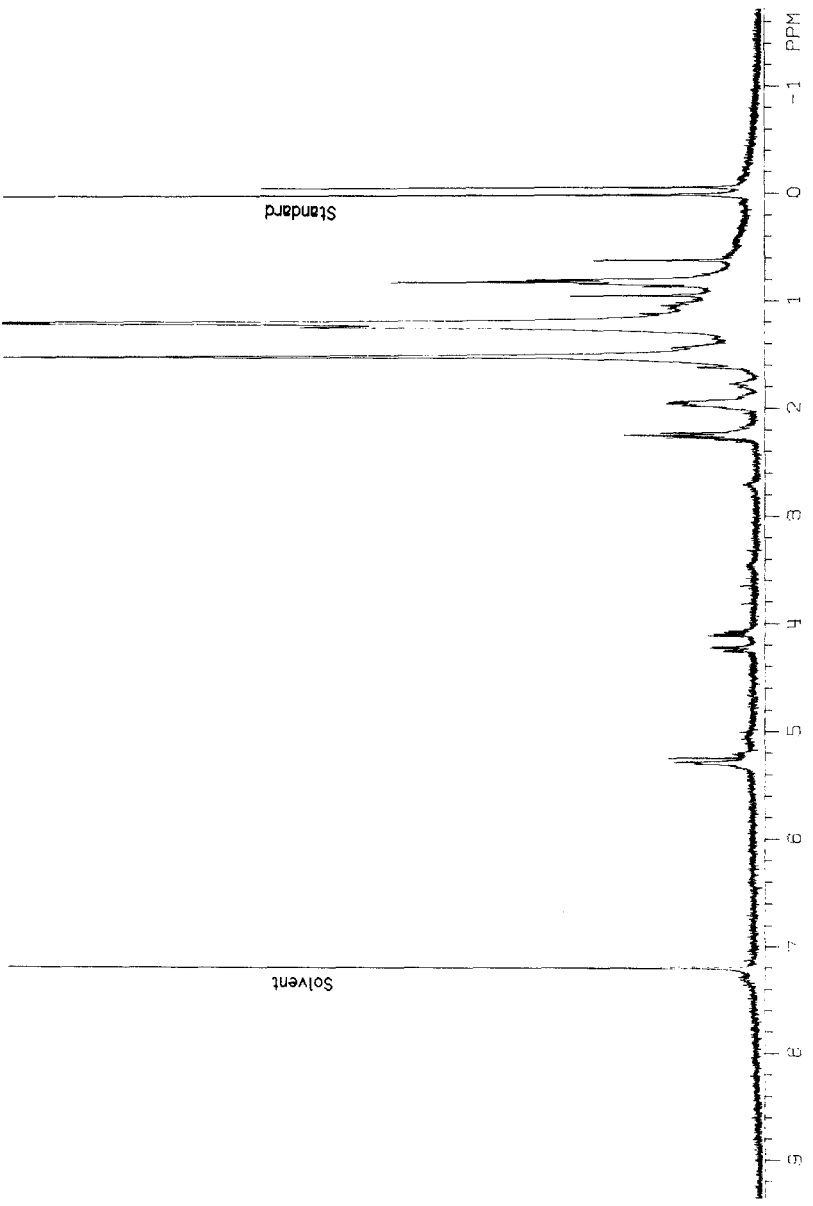

FIG. 1. Fourier transform proton NMR spectrum of femoral gland secretion from the desert iguana, *Dipsosaurus dorsalis*. Solvent is deuterochloroform. Tetramethylsilane (TMS) was added as a reference compound.

Without further supporting data, however, it is difficult to unequivocably identify which lipid classes are present. The peak at 1.5 ppm is probably due to water present in the sample. Elemental analyses of the nonorganic extractable part of the secretion reveals that it is composed of 47.20% carbon, 13.91% nitrogen, 7.09% hydrogen, and 2.82% sulfur. Together with its insolubility, these ratios indicated that this part of the secretion was likely to be proteinaceous in nature. This was supported by spectrophotometry showing a ratio of 220/230 nm absorption equal to 2.98, characteristic of peptide bond linkages.

Results of the 12% SDS polyacrylamide electrophoresis gel are shown in Figure 2. Each of the first five lanes on the gel represents secretions taken from five different individual *D. dorsalis*; the first two lanes are samples from females, the next three are from males. From the staining pattern (Figure 2), the secretion appears to be composed of two major protein components, represented by the darkest bands, at approximately 30,000 and 20,000 daltons, and several smaller components, the majority smaller than 14,000 daltons. While all five *D. dorsalis* possess the same general banding pattern, there are differences among individuals in the lower molecular weight components. Certain components are missing in some individuals, and differences in band intensity indicative of concentration differences are evident. Gels run on these samples which have been stained using the modified silver staining technique of Morrissey (1981) show similar patterns of band intensity (Alberts, unpublished data), indicating that

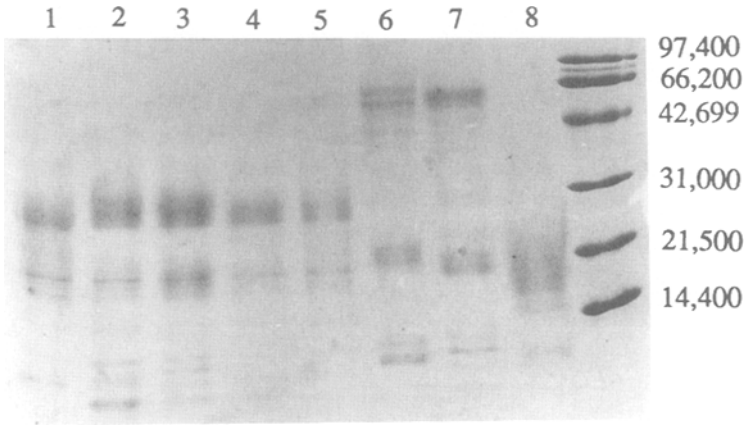

FIG. 2. Results of 12% nonreducing SDS polyacrylamide electrophoresis gel showing banding patterns of femoral gland secretion proteins. Lanes 1 and 2 represent secretions from female *Dipsosaurus dorsalis*, lanes 3–5 are from male *D. dorsalis*, lane 6 is from *Sceloporus occidentalis*, lane 7 is from *S. orcutti*, lane 8 is from *Cnemidophorus tigris*, and a series of molecular weight standards has been run in lane 9.

these concentration differences are not simply a staining artifact. There are no apparent sex differences, but secretions from a greater number of individuals need to be examined before a more definitive conclusion can be reached.

The electrophoretic banding patterns of the other lizards show interspecies difference in the proteins of femoral gland secretions. The two samples from lizard species in the genus *Scelporous* are very similar, and each shows major protein components ranging from 50,000 daltons to less than 14,000 daltons. Three major protein bands are evident in the profile of *S. orcutti.* In *S. occidentalis*, the largest and smallest components are apparent as double bands, indicating that the secretions of this species may contain as many as five different proteins. The banding pattern in *Cnemidophorus tigris* appears to be quite different from those of all three iguanid lizard species, with an indistinct band centered around 20,000 daltons and a faint smaller band below 14,000 daltons.

Figure 3 shows the reflectance spectrum of *D. dorsalis* femoral gland

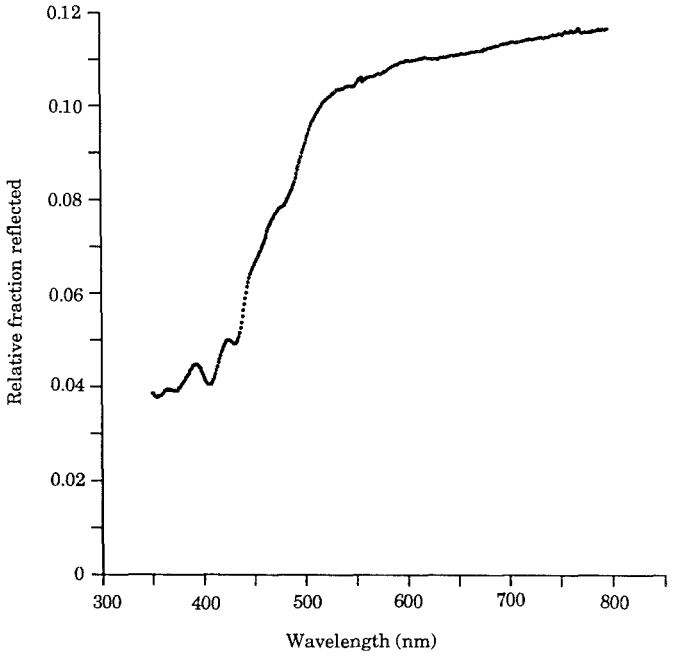

FIG. 3. Reflectance spectrum for *Dipsosaurus dorsalis* femoral gland secretion when illuminated with light between 300 and 800 nm. The curve has been subtracted from that for an aluminum standard, which reflects nearly 100% of incident light, in order to account for the differential output of the light source and sensitivity of the spectroradiometer at different wavelengths. The curve thus represents the fraction of light reflected relative to this standard over the range of wavelengths tested.

secretion when it is illuminated with light ranging from 350 to 800 nm. The curve is plotted relative to an aluminum standard that reflects nearly 100% of incident light. Longwave ultraviolet light between 350 and 400 nm appears to be absorbed rather than reflected by femoral gland secretions, but levels of reflectance rise sharply as the secretions are illuminated with visible light. This steady climb in reflectance above 400 nm is consistent with the whitish appearance of the secretions to the human eye under a visible light source.

The absorption of longwave ultraviolet light by femoral gland secretions results in molecular excitation, producing a visible fluorescence as the excited molecules relax back to their normal lower-energy state. The emission spectrum of fluorescing femoral gland secretion (Figure 4) spans visible light wavelengths from 400 to 600 nm, but its peak corresponds to 500 nm, the yellow-green part

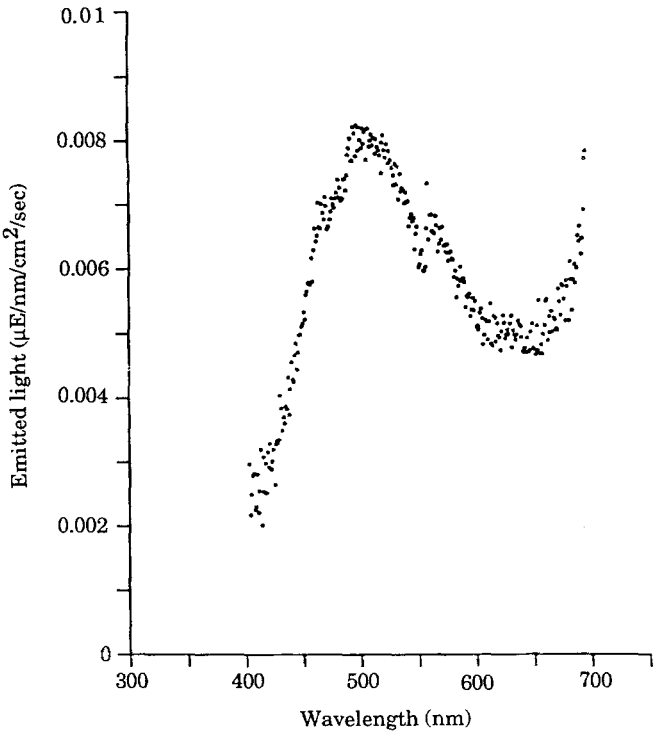

FIG. 4. Emission spectrum showing the production of green light in the 400- to 600-nm range by fluorescing femoral gland secretions of *Dipsosaurus dorsalis* when illuminated with longwave ultraviolet light. The light source has been outfitted with a cutoff filter that only passes light below 400 nm. The visible fluorescence is very weak and does not exceed 0.01 μE/nm/cm^2/sec.

of the visible light spectrum. This is the color perceived by the human eye when femoral gland secretions are viewed under a 365-nm black light in the absence of visible light. This fluorescence is so weak (less than 0.01 microEinstein/nm/cm^2/sec) that it appears to be obscured by ambient sources of visible light and cannot be seen by the human eye under natural light even though human cones have their peak of visual sensitivity at approximately 555 nm (Schenk, 1973).

DISCUSSION

This study has shown that femoral gland secretions of *D. dorsalis* are composed of both lipids and proteins, either or both of which could potentially function as pheromones. Skin lipids that potentially have pheromonal function are known to be widespread in both lizards (Weldon and Bagnall, 1987) and snakes (Burken et al., 1985; Schell and Weldon, 1985). Garstka and Crews (1981) have reported a lipoidal pheromone on the skin of female garter snakes that serves to attract mates. The urodaeal gland pheromones of female broad-headed skinks (*Eumeces laticeps*) have been shown to contain a biologically active neutral lipid fraction containing mono-, di-, and triglycerides, cholesterol, sterol esters, and complex waxy esters (Cooper and Garstka, 1987).

There is abundant evidence for the role of lipids in chemical signalling in a number of vertebrate pheromone systems (Albone, 1984; Hadley, 1985), and theoretically there is good reason to expect that lipids should be widely used as pheromones. The formation by lipids of structural and geometric isomers, and the interchangeability of functional groups on the same basic carbon skeleton of lipids, gives them a high degree of molecular diversity (Hadley, 1985; Cooper and Garstka, 1987). These properties could greatly increase the potential information content of a pheromone (Wilson and Bossert, 1963) without significantly increasing the energetic costs of its biosynthesis.

The protein components of femoral gland secretions, either alone or chemically bound to lipids, could potentially have communicative function as well. While it is possible that femoral gland proteins function only as a matrix to hold lipids, many lizards have specialized chemosensory structures and behavior that could facilitate detection of the proteins themselves. Most lizards possess a vomeronasal organ (Burghardt, 1970; Parsons, 1970) that mediates the perception of molecules brought in on the tongue. The majority of substances that have been shown to stimulate the vomeronasal system are pheromones of relatively high molecular weight including proteins (see Halpern, 1987, for review). The tongue-touching behavior of *D. dorsalis* has been well documented in both the field and the laboratory (Pedersen, 1988; Krekorian, 1989) and is potentially capable of delivering large nonvolatile molecules such as femoral gland proteins to the vomeronasal organ. It is also possible that femoral

gland proteins could be detected by taste receptors on the tongue. Numerous taste buds occur on the tongue tips of iguanid lizards, indicating that tongue-touching behavior could potentially stimulate both the gustatory and the vomeronasal system of lizards (Schwenk, 1985). Beidler (1977) reviews some of the evidence for the detection of proteins based on taste and proposes that although proteins probably require a high degree of stereospecificity in their reception, it is quite possible they could be utilized as contact pheromones in some species.

If *D. dorsalis* are capable of detecting femoral gland proteins via either taste or vomeronasal function, then the individual differences in protein secretion chemistry demonstrated here may be relevant in social communication. Fresh secretion samples collected from the same individual in different months of the year produce identical banding patterns on protein electrophoresis gels (Alberts, unpublished), indicating that these differences are consistent over time. Femoral gland proteins, therefore, could potentially function in individual recognition. Glinski and Krekorian (1985) showed that male *D. dorsalis* are capable of distinguishing familiar from unfamiliar conspecifics, and they hypothesized that chemical cues may play some role in this discriminatory ability. During the breeding season, proteins in the femoral gland secretions of adult lizards are potential candidates for this information.

Interspecific differences in femoral gland proteins appear to be quite striking in the few species studied here and may have ecological relevance in the recognition of heterospecifics for lizards that can detect them. The high degree of correspondence in the major proteins of the two closely related *Sceloporus* species, and the distinctiveness of the banding pattern of the single teiid lizard, *Cnemidophorus tigris*, compared to those of the iguanid lizards, indicates variation along phylogenetic lines. Oldak (1976) noted such strong phylogenetic associations for scent gland lipids in snakes that he proposed secretion chemistry be used as a tool to help evaluate evolutionary relationships between species. The relative roles of phylogeny and ecology in determining the chemistry of femoral gland proteins cannot be adequately evaluated until comparative studies of secretions have been done.

Large proteins have essentially zero vapor pressure, indicating that the bulk of *D. dorsalis* femoral gland secretion is of low volatility. Behavioral tests with *D. dorsalis* demonstrate that the secretions probably have to be contacted directly for information to be obtained from them (Alberts, 1989). This is consistent with results Cooper and Vitt (1986) have reported for the skin and cloacal pheromones of skinks of the genus *Eumeces*. The melting point analyses, which showed that femoral gland secretions retain their durability even at high temperatures, together with the low volatility of these secretions, indicates that these chemical signals will remain active in a desert environment for some time after their deposition. This may be very important for a species like *D. dorsalis*,

which is known to inhabit fairly large home ranges relative to its body size (Krekorian, 1976) and which may not be physically capable of investigating widely dispersed secretion deposits immediately after their release into the environment.

The strong absorption of longwave ultraviolet light by femoral gland secretions may function as a visual cue in the localization of these low volatility secretions in the environment. Behavioral tests with *D. dorsalis* suggest that they are visually sensitive to ultraviolet light in the 365- to 400-nm range, and provision of an ultraviolet light source signficantly increases their ability to locate femoral gland deposits (Alberts, 1989). To these lizards, ultraviolet-absorbing femoral gland secretions may contrast with the sandy substrate in their natural habitat, which is known to be highly reflective of ultraviolet radiation (Frohlich, 1976; Koller, 1985). Thus, absorption of ultraviolet light by femoral gland secretions could act as a long-range visual cue allowing initial localization of low-volatility femoral gland deposits, which are then approached and investigated at close range for more fine-tuned chemosensory information.

Acknowledgments—I thank J.W. Bradbury for his continued support of this project and for useful discussions about the evolution of animal signalling. W.H. Fenical provided advice on much of the chemical analysis, and I am indebted to him for his help in interpretating the NMR spectrum and to J.M. Wright for instruction on use of the NMR spectrometer. I am grateful to P.A. Price and M.K. Williamson for generously providing laboratory space, equipment, and supplies used in the protein analyses and thank them for their guidance throughout this aspect of the study. I thank J.A. Endler for his essential collaboration on the spectral analyses and his help with their interpretation. The melting point and elemental analyses were performed by Galbraith Laboratories, Knoxville, Tennessee. J.W. Bradbury, I.E. Akerblom, C.L. Booth, W.H. Fenical, M.A. Luther, P.A. Price, P.J. Weldon, and M.K. Williamson provided critical comments that have improved the manuscript. This research was partially supported by Chancellor's grants through the Regents of the University of California and by a training grant to the Department of Biology, University of California at San Diego, from the National Institutes of Health.

SEX RECOGNITION IN THE LEOPARD GECKO, *Eublepharis macularius* (SAURIA: GEKKONIDAE) Possible Mediation By Skin-Derived Semiochemicals

ROBERT T. MASON[1] and WILLIAM H.N. GUTZKE[2]

Department of Zoology
University of Texas at Austin
Austin, Texas 78712

(Received February 1, 1989; accepted March 17, 1989)

Abstract—Male leopard geckoes, *Eublepharis macularius*, rely on skin-derived semiochemicals to determine the sex of conspecifics. Males respond to other males with agonistic behavior while females elicit courtship behavior from males. While females were shedding, males responded to them with agonistic behavior. The same females were courted both before and after shedding. An initial survey of hexane-extracted skin lipids from male and female geckoes revealed fatty acids common to both sexes. Several steroid analogs of cholesterol were unique to males while long-chain methyl ketones were unique to females. Results are discussed in the context of skin lipids serving as pheromones in reptiles.

Key Words—Sex recognition, Gekkonidae, gecko, semiochemicals, sex behavior, agonistic behavior, skin lipids, fatty acids, steroids, methyl ketones.

INTRODUCTION

Sex recognition in lizards is thought to rely primarily on two sensory modalities: vision and chemoreception. Only one of these is of primary importance within a taxon, however (Camp, 1923). For example, gekkonids have long been recognized as utilizing chemical communication in many aspects of their social behaviors (Evans, 1961; Carpenter and Ferguson, 1977), but no experimental studies have been conducted on these lizards.

Greenberg (1943) observed and quantified social behavior of a gekkonid under laboratory conditions. He proposed two primary mechanisms of sex recognition in the banded gecko, *Coleonyx brevis*: visual displays of stereotyped behaviors and chemoreception of skin-derived chemicals. Greenberg observed that sex recognition in the gecko was not acquired at a distance and close contact was essential before sex recognition occurred. He noted that male *Coleonyx* readily distinguished other males from females and responded accordingly with agonistic or fighting behavior to the former and courtship to the latter. Greenberg hypothesized that females might be identified as mating partners through chemical stimuli. To test this hypothesis, he devised an ingenious experiment. In the majority of courtship displays observed, the male approached from the rear and took a grip on the female's tail. Females were courted further while males were ignored or attacked. Greenberg anesthetized four male and four female geckoes and surgically exchanged their tails. Courting males responded by courting the males with the female's tails. Conversely, when a courting male gripped the male tail of the female, these females were not courted but attacked. He concluded that male *Coleonyx* respond to a chemical stimulus emanating from the skin, reinforcing behavioral cues such as fighting and receptivity to courtship.

The present study continues these investigations of chemical communication in the leopard gecko, *Eublepharis macularius*, a gecko with courtship and agonistic behaviors similar to those of *Coleonyx* (see Gutzke and Crews, 1988). Unlike Greenberg's study, the present study investigates the role of chemical communication in geckoes by observing untreated, intact animals. Based on studies involving other reptiles (Andren, 1982; Radcliffe and Murphy, 1983), we hypothesized that during shedding, those chemical cues contained in or on the female's skin would be temporarily unavailable or in such low concentrations as to be undetectable by males. If skin-derived chemical cues are the primary means by which males distinguish gender, one might expect males to behave differently toward shedding males and females as opposed to the same individuals both before and after shedding. In order to test this hypothesis we observed pairs of geckoes (male–male and male–female) and recorded their behavioral interactions at three distinct periods: preshedding, shedding, and postshedding. Essential in this regard, unlike Greenberg's study, is the fact that in the present study, the male and female stimulus animals were not anesthetized and thus were free to display normal behaviors to the male with which they were paired.

Because Greenberg and others had hypothesized that sex recognition in geckoes is mediated by semiochemicals sequestered on the skin of both males and females, an initial investigation was undertaken to isolate and chemically characterize the skin surface lipids that may serve as semiochemicals in this

lizard. The skin lipids were analyzed by gas chromatography–mass spectrometry (GC-MS).

METHODS AND MATERIALS

Description of Behaviors Measured. Mating behavior in the leopard gecko begins with the male rapidly vibrating his tail and approaching the female slowly. The male then touches the female and begins to lick her tail. He then grips and shakes the female's tail. The biting involved is gentle and does not result in any discernible wounds. The male then shifts his grip to the female's back, neck or head, simultaneously moving his body parallel to hers. If the female is receptive she will raise her tail and allow the male to appose his cloaca to hers and intromission soon follows. A nonreceptive female will terminate courtship by fleeing from the male or biting him (Gutzke and Crews, 1988).

Agonistic or fighting behavior is readily discernible from courtship behavior in the leopard gecko. In the fight pattern, the male raises high off the ground, fully extending his limbs and arching his back. Intense aggression is characterized by the male swelling his throat, followed by short dashes at his opponent and quick, vigorous bites. These bites frequently lacerate the skin and sometimes seriously damage it. Thus, the body posture of the male and the intensity of his bites unequivocally characterize the difference between courtship behavior and agonistic behavior.

Behavior Experiments. Subjects used in this research were sexually mature. Their care and maintenance have been described elsewhere (Bull, 1987). Ten male geckoes were randomly assigned as pairs with 10 female geckoes. The females were then presented to the males in the latter's home cage at three distinct times as determined by the stage in the female's shedding cycle. The preshedding state was defined as at least five days prior to clouding of the skin. Shedding was indicated as the time when the skin was opaque but still intact over the new skin underneath. Finally, postshedding was defined as one day after the complete loss of the old skin. Females were presented to the males once during each of these periods. The order, in terms of shedding condition, in which the females were presented to the male was systematically varied.

The test periods consisted of the female being introduced into the male's cage for 10 min or until the male courted and mounted the female or attacked and drove off the female. As mating may alter subsequent breeding behavior, each trial was concluded before mating or damage was inflicted on the female. Five male geckoes were paired with another five males in a similar fashion.

Isolation and Identification of Skin Lipids. Analytical grade hexane was obtained from Fisher Scientific. Hexane was purified by stirring over H_2SO_4

overnight, decanting and stirring over K_2CO_3 for 4 hr. The solution was filtered, dried over $MgSO_4$ for 1 hr, and redistilled before use.

The five adult male and nine female geckoes were killed with an overdose of Brevital sodium and placed dorsal side down in a separate 500-ml glass beaker with 5–10 ml of hexane. Care was taken that the head and cloaca did not touch the solvent in order to prevent contamination of the wash with body fluids. Each beaker was covered with aluminum foil and sealed with parafilm and left overnight at room temperature. The bodies were removed and the solution filtered through a sintered glass funnel to remove particulate matter and inorganics present on the skin. The extracted lipids were pooled and the solvents removed on a rotavaporator at 50°C. The resulting viscous semisolid mixture was redissolved in fresh hexane, transferred into 7.0-ml amber glass vials with Teflon caps, and stored at −20°C.

Capillary gas chromatographic analyses were performed on a Finnigan-MAT 4920 with a combined quadropole mass spectrometer. This system is supported by the INCOS data system and includes a library of over 42,000 spectra. The capillary column was a fused silica 4-m BP1 (0.5 μm film) (Scientific Glass Engineering). Samples were analyzed under electron impact (EI) mode. Helium was used as a carrier gas in this instrument at 12 psi. The conditions of the GC-MS were as follows: injector temperature at 290°C, source at 150°C, detector at 250°C, EM voltage at −2200 volts. The temperature program was set at 60°C for 1 min. ramping to 290°C at 10°C/min. Samples (1 μl/10 mg/ml) were injected by means of a 5-sec splitless injection.

RESULTS

The results of the behavior tests were unambiguous. The test males all courted their respective stimulus females during the preshedding and postshedding phases of the test (Figure 1). However, during the time when the females were shedding, all the males responded to them with aggressive behavior. Indeed, one female was attacked and had to be removed from the experiment. Thus, each male responded to the same female with both courtship behavior and aggressive behavior depending on the shedding stage of the female. No differences in the behavior of the females were detected during the course of this study. Males always exhibited aggressive behavior towards other males irrespective of the shedding stage of the stimulus male.

Identities of components by GC-MS were made by comparison to published spectra and comparison of GC retention time and similarity to synthetic standards. The mass spectral data revealed at least 33 components of the skin lipids of male and female geckoes (Figure 2, Table 1). The majority of the components were shared in common by both males and females. For instance, fatty acids with carbon chain lengths of C_{16} and C_{18} were the major peaks in

terms of concentration in both males and females. The other major peak shared in common by both sexes is cholesterol, which is ubiquitous in vertebrate tetrapod epidermis. A minor component shared by both sexes is squalene. Finally, a series of straight-chain hydrocarbons was noted in both sexes at approximately equal levels.

Some differences appear in the skin lipids of higher mass. For example, both sexes have several steroids that are analogs of cholesterol including cam-

pesterol and sitosterol, as well as the methyl ether of cholesterol. However, males also possess cholestanol, stigmasterol, and stigmastanol, which do not appear in the females' skin lipids. Females, on the other hand, possess a series of long-chain saturated and mononunsaturated methyl ketones that are not found in the male chromatograms.

DISCUSSION

The results of this study demonstrate that the behavioral responses of male leopard geckoes toward females differ over the course of the female's shedding cycle. We propose that chemicals in the skin of females normally detected by males become unavailable while the female is shedding. Males responded to these shedding females in the same way that they responded to males. Males attacked other males whether those males were shedding or not. *Eublepharis macularius* does not exhibit obvious sexual dimorphism so perhaps visual cues alone would not be sufficient for males to determine gender. Unlike some geckoes, *Eublepharis* does not use vocalization to any great degree. It seems evident from these data that if a male cannot ascertain a conspecific's gender by means of chemical cues, he behaves toward that individual as if it were a male and attacks it.

These observations and hypotheses are supported by similar behaviors observed in other reptiles. For instance, skin-derived chemical cues sequestered in female garter snake skin elicit courtship behavior from males (Noble, 1937; Crews, 1976; Kubie et al., 1978; Garstka and Crews, 1981; Mason and Crews, 1985, 1986). Additionally, among zoo workers it is almost axiomatic, although not essential, that snakes breed best soon after the female has shed her skin (Radcliffe and Murphy, 1983). These authors state that the frequency with which courtship and copulation follow skin shedding in snakes strongly suggests that there is a sex pheromone associated with the newly shed snake and skin that acts as a releaser of courtship.

Perhaps the closest approximation to the behaviors observed in this study occur in the European adder, *Vipera berus* (Andren, 1982, 1986). The males in this species are aggressive and fight for access to unmated females. Vernal courtship behavior begins only when sexually active males shed their skin. In the adder, males actively tongue-flick chemical cues from shed females and initiate courtship behavior. When a male encounters another shed male, he begins combat behavior. Interestingly, in the adder, if a recently shed male encounters a nonshed male or female, he will ignore them. Andren (1982) concluded that male European adders must obtain chemical information from a conspecific's skin in order to initiate courtship or combat behavior.

Anecdotal observations suggest that diverse reptilian groups use sex pher-

omones, but few aspects of their chemistry are known. Only two studies have investigated the chemical constituents of skin lipids in any lizard, and these did not focus on intraspecific differences between the sexes. Roberts and Lillywhite (1980) isolated skin lipids from the green iguana (*Iguana iguana*) by thin-layer chromatography (TLC). They identified lipids in several classes, including fatty acids, sterol esters, cholesterol, wax esters, and others. The other study was an extensive survey of the shed skins of 23 species of lizards by TLC and demonstrated the great variability in the composition of skin lipids in lizards (Weldon and Bagnall, 1987). These authors conclude that more details are needed on the chemical structures of these lipids, many of which could not to be determined by TLC techniques.

The present study identifies several lipids suggested in previous studies of saurian skin lipids, thus verifying their presence in lizard skin. Cholesterol is a common constituent in all vertebrate skin and seems to be present in all of the reptiles examined thus far. Fatty acids are also commonly found in the skin lipid profiles of vertebrates including reptiles (Ahern and Downing, 1973; Weldon and Bagnall, 1987; Mason et al., 1987). For example, fatty acids have been demonstrated to serve as pheromones in four species of tortoise (*Gopherus*). Rose (1970) identified several fatty acids in the mental glands of male tortoises. He applied either a control solution of solvents or a mixture of fatty acids to the head of a plaster tortoise model. Females responded by approaching the models and head-bobbing, a display indicating courtship. Males responded by ramming the models—clearly an aggressive response.

The presence of straight-chain hydrocarbons in the skin lipids of both male and female geckoes is an interesting finding. Hydrocarbons were identified in the indigo snake, *Drymarchon corais*, but were thought to be contaminants (Ahern and Downing, 1973). However, evidence of hydrocarbons was found in a TLC survey of skin lipids in lizards by Weldon and Bagnall (1987). These authors concluded that the hydrocarbons indicated in their study were not contaminants and that hydrocarbons may occur commonly among squamates. We agree that the hydrocarbons identified in the present study are indeed components of the skin lipid profiles of these lizards. The possible function of these integumental hydrocarbons warrants further study.

Other possible sources of semiochemicals in these reptiles include the sex differences found in the steroids and methyl ketones. Although the steroids identified here are not sex steroids (androgens or estrogens and progestins), they may still impart information about the sex of the individual. Finally, the methyl ketones found in the females' skin lipids are known to occur in female snakes. Ahern and Downing (1973) and Schell and Weldon (1985) identified methyl ketones in the skin lipids of a female indigo snake, *Drymarchon corais*, while Mason (1987) has identified them in the skin lipids of female garter snakes, *Thamnophis sirtalis parietalis*, where they serve as sex attractiveness pheromones (Mason, 1987).

Both Maderson (1986) and Graves et al. (1986) have suggested that reptilian skin lipids have been protoadapted or exapted to serve as semiochemicals or pheromones. It is now widely acknowledged that skin lipids originally evolved in reptiles to serve as a water-retention mechanism. Over the course of evolutionary time, males and females of a given species have acquired the ability to recognize and respond differentially to integumental chemical cues of conspecifics. It has been demonstrated in this study and a previous study (Mason et al., 1987) that clear sex differences exist in skin lipids, which would be a necessary condition for this mechanism of sex recognition to occur.

The results of this work and the previously cited studies pose some questions on the evolution of skin-derived pheromones in reptiles. In the case of sex recognition pheromones, do males of various species of reptile cue in on a set of specific components of the female's skin lipids such as fatty acids, steroids, or methyl ketones? If this is generally the case, as has been demonstrated in a few species, how could such a mechanism evolve?

(Received February 1, 1989; accepted March 17, 1989)

Abstract—Young corn snakes, *Elaphe guttata*, were tested for responses to chemicals from heterospecific snakes. Corn snakes exhibited more tongue-flicks to swabs freshly rubbed against the skin of an ophiophagous kingsnake, *Lampropeltis getulus*, than to blank swabs. Responses to *L. getulus* and a nonophiophagous western plains garter snake, *Thamnophis radix haydeni*, did not differ significantly. Corn snakes exhibited more tongue-flicks to swabs treated with chloroform extracts of the shed skins of *L. getulus*; an ophiophagous eastern coachwhip, *Masticophis flagellum*; and a nonophiophagous gray ratsnake, *Elaphe obsoleta*, than to blank swabs, but they did not discriminate between ophiophagous and nonophiophagous species in every case. Corn snakes, when offered shelters containing bedding from the home cages of a nonophiophagous water snake, *Nerodia erythrogaster*; an occasionally ophiophagous water moccasin, *Agkistrodon piscivorus*; or *L. getulus* and untreated bedding, failed to reside under snake-scented shelters at a rate significantly different from that expected by chance. The responses of corn snakes are compared with those reported for other snakes presented with heterospecific snake chemicals.

Key Words—Corn snake, *Elaphe guttata*, skin chemicals, predator detection.

[3]Present address: Audubon Zoo, New Orleans, Louisiana 70178.

INTRODUCTION

Snakes enact a variety of defensive behaviors, including biting, tail display, and cloacal discharge, when confronted directly by predators (Greene, 1987). Avoidance of predators also should contribute to survivorship, but for this to occur mechanisms to recognize enemies at a distance must exist.

Many snakes exhibit responses to chemicals from ophiophagous snakes. Rattlesnakes, *Crotalus* spp. (Crotalinae), respond to the kingsnake, *Lampropeltis getulus*, by a posture known as "body bridging," where their trunk is raised off the substrate. Bogert (1941) showed that this behavior, which may obstruct attempts to grasp rattlesnakes, is elicited by chemicals from the dorsal skin of kingsnakes and other species. Since the publication of Bogert's report, other crotalines have been observed body bridging during encounters with snake predators (Carpenter and Gillingham, 1975) or during presentations of chemicals from them (Weldon and Burghardt, 1979; Marchisin, 1980).

The involvement of chemoreception in the detection of ophiophagous snakes by colubrid snakes (Colubridae), the most speciose snake family, has been examined in a few studies. Garter snakes, *Thamnophis* spp., presented with swabs rubbed against the skin of heterospecific snakes or with an airstream directed over them, exhibited more tongue-flicks to chemicals from ophiophagous snakes than to those from some generally nonophiophagous species (Weldon, 1982). Young pine snakes, *Pituophis melanoleucus*, orient toward trails deposited by conspecifics but not to those of kingsnakes, suggesting a mechanism by which pine snakes avoid these predators (Burger, 1989). The hognose snake, *Heterodon platyrhinos*, on the other hand, failed to exhibit defensive responses or changes in tongue-flicking rate to filter papers containing kingsnake odors (Durham, 1980).

No systematic tests have been conducted on the behavioral defenses of ratsnakes, *Elaphe* spp., but rapid flight from kingsnakes (Weldon, 1982) and the delivery of body blows toward these predators (Marchisin, 1980) have been observed. Field studies involving wholesale collections of snakes and analyses of their stomach contents provide information consistent with the hypothesis that *Elaphe* spp. possess mechanisms that reduce snake predation. The results of these investigations indicate that a variety of snake species are taken as prey, but that *Elaphe* spp. are absent (Uhler et al., 1939; Hamilton and Pollack, 1955, 1956; Brown, 1979) or rare (Clark, 1949) in the stomachs of ophiophagous snakes, even though they occurred in the areas surveyed.

We report here the results of tests of the corn snake, *Elaphe guttata* (Colubridae), with fresh and chloroform-extractable skin chemicals from heterospecific snakes, including those from ophiophagous species. The responses of

corn snakes to heterospecific snake skin chemicals are compared with those of other snakes.

METHODS AND MATERIALS

Swab Presentations. In experiment 1, nine corn snakes [$\bar{X}$ snout–vent length (SVL) = 32 cm], hatched from eggs laid by a female captured in Blount County, Tennessee, were tested for responses to swabs freshly rubbed against the skins of stimulus snakes. Snakes were individually housed in 31 × 16 × 8-cm clear plastic boxes with lids; subjects in this and all other experiments were maintained and tested at 25–27°C. Snakes were 5 weeks old at the time of testing. Each ate a small mouse five days before testing began.

Snakes were presented in their home cages with cotton swabs laden with skin chemicals from adults of a kingsnake and a western plains garter snake, *Thamnophis radix haydeni*; only the former is ophiophagous. Swabs were dipped into methylene chloride (CH_2Cl_2) and rubbed against the dorsal surface of a stimulus snake. Control swabs were dipped into CH_2Cl_2.

Swabs were allowed to air-dry for 15 min before being held in front of a subject's snout for 2 min while tongue-flicks were counted. Each snake was presented with a different condition over three consecutive days in a Latin-square design. Testing was done between 1500 and 1600 hr.

In experiment 2, eleven corn snakes ($\bar{X}$ SVL = 29 cm), hatched from eggs laid by a female captured in Aiken county, South Carolina, were tested for responses to swabs treated with chloroform ($CHCl_3$) extracts of shed snake skins. Snakes were individually housed and tested in 9.5 × 18-cm cylindrical glass containers, the bottom of which was lined with a paper towel. Subjects had access to water ad libitum. They were 7 weeks old at the time of testing. Each ate a small mouse five days before testing began.

A shed skin (1.8 g) of an adult kingsnake was placed into 400 ml of $CHCl_3$ and heated (40°C) for 2 hr. The $CHCl_3$ was poured off and the extraction procedure was repeated. The combined extracts were placed on a rotary evaporator to remove the solvent. The residue was redissolved in $CHCl_3$, transferred to a vial, and the solvent was removed under nitrogen. After drying in vacuo, the weight of the residue was 10 mg. A 5 mg/ml $CHCl_3$ solution of snake skin extract was prepared; swabs treated with shed snake skin solutions have elicited heightened tongue-flicking and predatory attack in kingsnakes (Weldon and Schell, 1984).

Swabs were dipped into $CHCl_3$ or a $CHCl_3$ skin extract and allowed to air-dry for 20 min. Swabs were then presented as described above while tongue-

flicks were counted. Each snake was presented in its home cage with a control or a snake-scented swab once a day. The alternate condition was presented on the next day. Swabs were stored at −70°C between tests. All tests were run between 1700 and 1900 hr.

In experiment 3, eleven corn snakes used in the previous experiment were tested for responses to swabs treated with shed skin extracts from several snake species. Snakes were maintained and tested in their home cages as described for experiment 2, except that water dishes were removed from their containers 12 hr before testing. Subjects were 11 weeks old at the time of testing. Each ate a small mouse four days before testing began.

Shed skins were obtained from adults of a gray ratsnake, a kingsnake, and an eastern coachwhip, *Masticophis flagellum*; the latter two species are routinely ophiophagous. The skins (7.3, 4.7, and 2.4 g, respectively) were extracted in $CHCl_3$. The solvent was removed by rotoevaporation. Residues of 10, 17, and 10 mg, respectively, were obtained. A 5 mg/ml $CHCl_3$ solution was prepared from each.

Swabs were dipped into each solution and allowed at least 20 min to air-dry before being presented to the subjects. Control swabs were dipped into $CHCl_3$. They were presented as described above in a Latin-square design over one day from 1000 to 1600 hr, with at least 1 hr between presentations.

Substrate Presentations. Fourteen corn snakes ($\bar{X}$ SVL = 40 cm), hatched from eggs laid by females from Aiken and Barnwell counties, South Carolina, were tested for responses to substrate-borne chemicals from heterospecific snakes. Snakes were individually housed in 40 × 27 × 17-cm plastic cages. Subjects were 1 year old at the time of testing. Each ate a mouse one week before testing began.

The stimulus snakes were adults of a yellow-bellied water snake, *Nerodia erythrogaster*; a water moccasin, *Agkistrodon piscivorus*; and a kingsnake. The latter species is routinely ophiophagous, *A. piscivorus* is occasionally so. Snakes were maintained in 40 × 27 × 17-cm plastic cages lined with corncob bedding, which was collected after three days from each snake's home cage.

Snakes were tested over 21 days in either of two 0.8-m-high circular tanks (diameter = 270 cm) lined with wrapping paper. Eight 30 × 30-cm ceramic tile refuges were elevated 5 cm above the substrate on blocks of wood evenly spaced around the perimeter of each arena. Approximately 250 ml of bedding from a stimulus snake was placed under two refuges situated opposite one another; untreated bedding was placed under the other refuges. The position of the refuges containing snake-scented bedding was randomized.

Each *E. guttata* was placed individually in the center of a tank at 1600 hr and allowed to move freely. The subject's location was noted at 0900 and 1600 hr the following day, and at 0900 hr on the third day. A snake was scored

present at a site if it was observed on two of three occasions under the same type of refuge. The arena was washed with ethanol, lined with fresh wrapping paper, and equipped with new tiles and wood blocks after each test.

RESULTS

The Kruskal-Wallis test applied to data from experiment 1 (Table 1) detected overall significant differences in tongue-flick scores ($H = 8.9$; $P \leq 0.05$). The STP aposteriori test (Sokal and Rohlf, 1981) detected significant differences between tongue-flick scores to kingsnake-treated and blank swabs ($P \leq 0.05$). No other significant differences among treatment groups were detected.

In experiment 2, snakes exhibited mean tongue-flick scores ($\pm$ 1 standard deviation) of 68.5 $\pm$ 27.1 and 44.5 $\pm$ 19.9 during 2 min to the kingsnake- and solvent-treated swabs, respectively. The Wilcoxon matched-pairs signed-ranks test (Siegel, 1956) detected a significant difference between these scores ($P \leq 0.05$).

The Kruskal-Wallis test applied to data from experiment 3 (Table 2) detected overall significant differences in tongue-flick scores ($H = 20.4$; $P \leq 0.05$). The STP a posteriori test detected significant differences between the tongue-flick scores to the blank swabs and each of the three snake scents, between scores to kingsnake and eastern coachwhip scents, and between scores to eastern coachwhip and corn snake scents ($P \leq 0.05$ in all cases). No significant difference was detected in the tongue-flick scores to kingsnake and corn snake scents.

Snakes in the substrate tests were scored four, three, and two times under the shelters containing the bedding from water snake, water moccasin, and kingsnake, respectively. The chi-square test failed to indicate that snakes resided under snake-scented shelters at rates significantly different from that expected by chance ($P > 0.05$).

DISCUSSION

Anecdotal accounts indicate that rattlesnakes and other crotalines exhibit less tongue-flicking during confrontations with kingsnakes or while body bridging (Carpenter and Gillingham, 1975; Marchisin, 1980). Chiszar et al. (1978) demonstrated that water moccasins exhibit fewer tongue-flicks in a tank previously occupied by a kingsnake than in a clean tank or in one that had contained a nonophiophagous hognose snake; a similar trend with rattlesnakes however, was not significant. Marchisin (1980) suggested that the infrequent and reduced tongue-flicking to ophiophagous snakes prevents a predator's attention from being drawn to a crotaline's head.

Tests of garter snakes with both swab-laden and airborne chemicals indicated that they detect heterospecific snakes and that they tongue-flick more to chemicals from ophiophagous species (Weldon, 1982). Weldon (unpublished) found that garter snakes also exhibit more tongue-flicks in glass tanks that previously had housed a kingsnake than in ones that either had contained a ratsnake or had been misted with distilled water. Several subjects, in the kingsnake-conditioned tanks only, emitted slow-motion tongue-flicks; this behavior also is exhibited by garter snakes in response to human molestation (Gove and Burghardt, 1983) and was hypothesized by Gove (1979), for snakes in general, to have a defensive (warning) function.

The results of our experiment 1 indicate that corn snakes tongue-flick more to swabs freshly rubbed against the integument of a kingsnake than to blank swabs, but significant differences in tongue-flick scores were detected for neither garter snake vs. blank nor garter snake vs. kingsnake conditions. In experiment 2, corn snakes responded more to chloroform-extracted chemicals from a kingsnake shed skin than to blank swabs. Similarly, the results of experiment 3 indicate that corn snakes detect chemicals extracted from the skins of a kingsnake, an eastern coachwhip, and a gray ratsnake. The apparent failure of our subjects to distinguish (as indicated by tongue-flick scores) between the kingsnake and the garter snake in experiment 1, and between the kingsnake and the ratsnake in experiment 3, however, is not consistent with the hypothesis that

corn snakes distinguish between chemicals from ophiophagous and non-ophiophagous snakes.

Corn snakes failed to reside under snake-scented shelters in our substrate experiment at a rate significantly different from that expected by chance. The concentrations of chemicals contained on the bedding material we used may have been insufficient for our subjects to detect; it is unclear whether naturally occurring deposits from snakes in the field could provide more potent stimuli. In an analogous test, Parker (1978) found that several crotaline snakes, including species of *Agkistrodon*, *Crotalus*, and *Sistrurus*, failed to avoid the side of an arena that had contained a kingsnake. Using a Y maze, Burger (1988) observed that pine snakes follow trails deposited by conspecifics but not those left by kingsnakes. Trail-following experiments need to be performed comparing the responses to ophiophagous and nonophiophagous stimulus snakes. Tests of this sort may indicate responses that can be related more directly to features likely to confer an advantage vis-à-vis predators in nature.

Acknowledgments—P. Freed and J. Holman supplied shed snake skins. J. Wright helped extract snake skins. W. Dennis and K. Thomes assisted with some of the experiments. This study was conducted while P.J.W. was supported by Sea Grant and the National Geographic Society, and while N.B.F. was supported by a University of Texas at Tyler Faulty Research Grant.

Abstract—In studies of squamate responses to prey chemicals presented on cotton-tipped applicators, investigators typically record several responses, each of which gives only part of the overall picture. The tongue-flick/attack score (TFAS) is a widely used composite measure of response strength that accounts for attack, its latency, and number of tongue-flicks. We present data and analyses on these variables and investigate the utility of several other possible response variables. It is concluded, for both practical and theoretical reasons, that TFAS and two modifications of it are the best measures of response strength. Uses and statistical analyses of TFAS and variables derived from it are discussed. It is recommended that information on tongue-flick rate, number of individuals attacking, and latency to attack be presented.

Key Words—Reptilia, tongue-flicks, broad-headed skink, *Eumeces laticeps*, garter snake, *Thamnophis sirtalis*.

INTRODUCTION

Many lizards and snakes respond to chemicals presented on cotton-tipped applicators (swabs) by tongue-flicking and, in some cases, by biting the swab, especially if it bears chemical stimuli from preferred prey. Measurements of tongue-flick rate and latency to bite have been combined by Burghardt (1967, 1970) to

0098-0331/90/0100-0045$06.00/0

provide a single index of overall response strength to a particular stimulus: the tongue-flick/attack score (TFAS). Some investigators have used different measures (e.g., Halpern and Frumin, 1979; Arnold, 1981), but the TFAS has become a standard and highly successful tool for studying the ability of snakes and lizards to discriminate prey chemicals from odorless controls and biologically irrelevant but odorous controls presented on swabs.

Various aspects of data obtained in such studies often are not presented or analyzed. Among these are tongue-flick rate, latency to bite, and number of individuals biting. In this study, results on raw tongue-flick rate and latency to bite are compared to each other and to the TFAS. The greatest advantage of TFAS as a measure of response strength is that it incorporates both tongue-flicks and latency in a single index. Although TFAS is a somewhat arbitrary measure of response strength, its possible strengths and weaknesses have not received much attention. Burghardt (1970) developed the TFAS based on the assumptions that an attack indicates a stronger predatory response than any number of tongue-flicks and that latency decreases with increasing stimulus strength. He selected maximum number of tongue-flicks by any individual as an arbitrary but reasonable base unit for TFAS for individuals that did attack. He scaled the relationship between number of tongue-flicks and latency by adding one TFAS unit per second for every second of a projected 60-sec testing interval remaining at the time biting occurred. Thus, if the subject did not attack, TFAS was given by total number of tongue-flicks in 60 sec. If an animal bit, its TFAS was the base unit + (60 − latency). Similar results were obtained using 30-sec trials and adjusting the contribution of latency accordingly (Burghardt, 1975).

A preliminary comparison of TFAS, biting, and latency by Burghardt (1970) showed that results based on TFAS were similar to those for number of individuals biting in *Thamnophis r. radix*, but the agreement was not complete. Results on latency differed somewhat from those for TFAS. However, because all snakes responded to worm extract, these comparisons may not be directly relevant to chemical discrimination experiments in which individuals respond to several different stimuli.

The goals of this study were (1) to examine data on tongue-flick rate (TFR), latency to bite, and number of bites to determine whether information might be lost by amalgamating tongue-flicking and latency data in the TFAS; (2) to determine relative merits of other potential variables; (3) to consider whether the TFAS is a conceptually optimal variable for analysis; and (4) to suggest possible improvements in response measures and their analysis. A possible alternative method of calculating response strength that accounts for both tongue-flicks emitted and latency to bite was investigated. In addition, a modified method of calculating TFAS for repeated-measures designs was considered.

METHODS AND MATERIALS

Data from a study of prey chemical discrimination in the broad-headed skink, *Eumeces laticeps* (Cooper and Vitt, 1989), were used to compare results based on various response measures. Each of 12 lizards was tested with deionized water, a pungency control (cologne), and chemicals from cricket integument. One stimulus per day was presented in a counterbalanced sequence on a cotton-tipped swab. Numbers of tongue-flicks directed toward swabs were counted for 60 sec beginning with the first tongue-flick or until the lizard bit the applicator (if this occurred within 60 sec). Latency to bite also was recorded.

The primary data analyzed were TFR, latency, and tongue-flick/attack scores (TFAS) calculated as in Burghardt (1970). If a lizard did not bite the swab, its TFAS for that condition was the number of tongue-flicks emitted in the 60-sec interval. If it did bite, the TFAS was (60 sec minus latency to bite in seconds) plus the maximum number of tongue flicks emitted by any lizard in any of the three conditions. The TFAS heavily weights biting, assuming that it indicates a stronger predatory response than any number of tongue-flicks.

An additional analysis was conducted involving a modification of the traditional TFAS for use with experimental designs in which a single individual responds to stimuli in multiple conditions. TFAS(R) was calculated by adding the greatest number of tongue-flicks for any stimulus for each individual (rather than for all individuals) to the latency component. That is, for each individual, i, tested for response to several stimuli,

$$TFAS(R)_i = TF_{\max_i} + (TL - \text{latency}_i)$$

In this notation the traditional calculation is

$$TFAS_i = TF_{\max} + (TL - \text{latency}_i)$$

where $TF_{\max}$ is the largest number of tongue-flicks emitted in any trial in the entire study, TL is trial length in seconds in the absence of attack, and $TF_{\max_i}$ is the maximum number of tongue-flicks emitted by individual i in any trial.

Another method of scaling responses was investigated. Instead of giving heavy weight to bites, the tongue-flick rate prior to biting was projected through the entire minute. In this projected tongue-flick rate (PTFR), the response measure was

$$PTFR = \text{tongue flicks}^* \frac{TL}{\text{latency}}$$

This measure was used by Arnold (1978) as a primary index of response to prey chemicals and by Halpern and Frumin (1979) as part of a response measure

including effects of biting and latency. PTFR may be interpreted in two ways. First, it may indicate the number of tongue-flicks that would have occurred had the subject not bitten. A potential problem with interpreting PTFR in terms of tongue-flick rates is the assumption that the rate is constant throughout the test. Because no adequate data on response to prey chemicals were available, this assumption was examined using data from pheromone studies for responses to deionized water, cologne (English Leather), aqueous swabs of male cloacal epithelia, and aqueous swabs of female cloacal epithelia (Cooper and Vitt, 1984, 1986b). Tongue-flicks emitted by adult male *E. laticeps* during the first 20 sec were compared to total tongue-flicks in the final 40 sec divided by two. These data were subjected to *t* tests for correlated samples. In the second interpretation, PTFR is considered an arbitrary index of response strength that combines effects of tongue-flicks and biting. In the latter case, PTFR heavily weights early biting if tongue-flick rates are highest early in the trials. Thus, possible effects of variation in response rate among stimuli are important for both interpretations of PTFR.

After data from the prey chemical discrimination experiment were tested for homogeneity of variance with Hartley's test, a single-factor ANOVA for a repeated-measures design was conducted (Winer, 1962) if variances were homogeneous. Individual comparisons among treatment means were made using Newman-Keuls tests (Winer, 1962). The alpha value was 0.05 and tests were two-tailed unless otherwise noted. One-tailed tests were used for the predictions of greater TFR, TFAS, and shorter latency for cricket stimuli than for control stimuli. They are justified because Burghardt (1973) and Von Achen and Rakestraw (1984) made similar findings for *E. fasciatus*, and because *E. laticeps* repeatedly tongue-flick while foraging and often eat cryptic prey (Cooper and Vitt, 1986a) that might best be located by chemical cues. Numbers of trials in which biting occurred and other variables for which variances were heterogeneous were compared among conditions by nonparametric methods (Siegel, 1956) using multiple comparison tests described in Hollander and Wolfe (1973).

Data from a study of garter snake (*Thamnophis sirtalis*) responses to components of earthworm extracts (Burghardt et al., 1988) also were used to compare measures of feeding responses. In that study, seven snakes were tested for responses to seven stimuli presented on swabs in a counterbalanced order. Each stimulus was presented for a maximum of 30 sec. Number of tongue-flicks directed toward the swab, total tongue-flicks, and latency to attack were recorded. The stimuli were water, raw lyophilized earthworm extract (EW), and five reconstituted chemical fractions of earthworm extracts (B7, C7, D7, E7, and F7); the chemical nature of these is not relevant here. Data were analyzed as above for TFR, latency, PTFR, number of attacks, and TFAS.

RESULTS

Skinks. Lizards tongue-flicked and/or bit swabs in all conditions (Table 1) but had higher TFR and TFAS and shorter latency when responding to cricket chemicals than to control stimuli. ANOVA was not used to test differences in TFR among conditions because (1) Hartley's test showed significant heterogeneity of variance ($F_{max} = 6.35$; $df = 3, 11$; $P < 0.05$); and (2) although a square-root transformation somewhat reduced F_{max}, it remained significant and increased in magnitude when third roots were taken. Logarithmic transformation might have worked, but it was not performed. A Friedman two-way analysis of variance showed a significant stimulus effect (chi square = 8.67; $df = 2$; $P < 0.02$). Multiple comparisons revealed that the lizards emitted significantly more tongue-flicks in response to cricket chemicals than to cologne ($P = 0.0027$, one-tailed) or deionized water ($P = 0.037$ one-tailed). TFRs in response to water and cologne were statistically indistinguishable ($P > 0.10$, one-tailed).

8	8	3	2	32	60	60
9	16	37	5	56	60	60
10	11	52	2	32	60	4
11	30	4	5	51	60	60
12	21	7	6	36	49	60
Mean	17.5	13.0	6.8	44.5	59.1	55.3
SE	2.1	4.1	1.9	4.8	0.9	4.7

Latency to bite was least for cricket chemicals (Table 1) but was not tested for significance parametrically because the variances were heterogeneous (F_{max} = 27.33; df = 3, 11; $P < 0.01$) and the heterogeneity increased after square-root transformation (F_{max} = 41.81; df = 3, 11; $P < 0.01$). A Friedman test revealed a significant stimulus effect (chi square = 11.60; df = 2; $P < 0.01$). After ties were eliminated, latency to bite swabs bearing cricket chemicals was shorter than for those bearing cologne in eight of eight trials and shorter than for deionized water in seven of eight trials. The difference was significant in multiple comparison tests for cologne (P = 0.028, one-tailed) but not water (P = 0.092). Latencies were similar in response to deionized water and cologne, there being 10 ties and one latency shorter for each stimulus ($P > 0.10$, one-tailed).

Eight skinks bit swabs in 10 trials. Eight bit in response to cricket chemicals. One skink bit in tests with each of the other stimuli; in these cases, the same lizard also bit during its trial with cricket chemicals. The attack on a swab bearing only water preceded a trial with cricket stimuli; that in a cologne trial followed a test with cricket stimuli. Effects of prior stimuli have been reported in snakes (Burghardt, 1969; Burghardt et al., 1988). No lizard bit in all three trials. An analysis of biting frequency was performed using binomial tests of the data cast in the manner of McNemar's tests for individual treatment comparisons (Siegel, 1956). Skinks bit in a significantly higher number of trials when the swabs bore cricket chemicals rather than either water alone or cologne (binomial P = 0.016, two-tailed). All four lizards that did not bite in any condition had higher tongue-flick rates when responding to crickets than to the other stimuli.

The TFAS showed the most pronounced responses by lizards to cricket stimuli for 11 individuals (Table 2). The remaining individual gave strong

TABLE 2. RESULTS OF THREE METHODS FOR ESTIMATING RELATIVE RESPONSE STRENGTHS FOR *Eumeces laticeps*[a]

	Response variables								
	TFAS			TFAS(R)			PTFR		
	CR	CO	DW	CR	CO	DW	CR	CO	DW

Range	15–98	2–63	1–108	15–80	2–52	1–108	15–45.7	2–52	1–30

[a] Stimuli are CR (cricket chemical stimuli), CO (cologne), and DW (deionized water).

responses to all conditions. Variances were homogeneous, with Hartley's $F_{max} = 1.89$ ($P > 0.10$). The main treatment effect was highly significant ($F = 12.68$; $df = 2, 22$; $P < 0.001$). Comparisons of pairs of treatment means revealed that TFAS was significantly greater for the cricket chemicals than for deionized water or cologne ($P < 0.01$ each) but did not differ significantly between the two control conditions ($P > 0.10$).

The patterns of results and statistical significances for TFAS(R) were identical to those for TFAS (Tables 2 and 3). Variances were homogeneous ($F_{max} = 3.03$; $df = 3, 11$; $P > 0.05$), and the main stimulus effect was significant at $P < 0.001$ ($F = 10.37$; $df = 2, 22$). Cricket chemicals elicited significantly greater response than cologne or water ($P < 0.01$ each); mean TFAS(R)s to cologne and water were nearly identical ($P > 0.10$).

Results for PTFR (Tables 2 and 3) were similar in pattern to those for TFAS. Variances were homogeneous ($F_{max} = 3.21$; $df = 3, 11$; $P > 0.05$). The main effect was significant ($F = 5.04$; $df = 2, 22$; $P < 0.05$). PTFR was significantly higher in response to cricket chemicals than to cologne or deionized water ($P < 0.05$ each). There was no detectable difference in PTFR between water and cologne ($P > 0.10$).

The assumption of uniform tongue-flicking rates throughout the test interval was rejected for water ($t = 4.40$, $df = 20$, $P < 0.001$), cologne ($t = 3.97$, $df = 17$, $P < 0.001$), and male cloacal stimuli ($t = 2.42$, $df = 20$, $P < 0.05$), but not for female cloacal stimuli ($t = 0.65$, $df = 20$, $P > 0.10$). Mean tongue-flick rate in the initial 20 sec in response to commonly used control stimuli, i.e., water and cologne, is consistently higher than during the final 40 sec (Table 4). A similar but less pronounced trend is present for male cloacal stimuli. The high tongue-flicking rate in response to female cloacal stimuli was sustained for the entire 60 sec.

[a] Data from Burghardt et al. (1988, Table 2) and related experiments.
[b] S-stimuli: water (WA), raw lyophilized earthworm extract (EW), and several chemical fractions of EW (B7, C7, D7, E7, and F7).
[c] s-tongue-flicks to swab; t-total tongue-flicks.
[d] Friedman two-way ANOVA was used due to several zero variances.
[e] *P* values are two-tailed; $df = 6, 36$ for *F* tests (used for tests of all variables except latency and number of bites).

EW and the three stimuli that elicited no attacks, water, C7, and D7 (one-tailed binomial $P = 0.016$) and between E7 and the stimuli eliciting no attacks ($P = 0.031$). No test of the main effect of biting was conducted because of the low expected cell frequencies. Latency could not be analyzed parametrically because of zero variance for the three extracts that failed to elicit biting. However, a Friedman two-way ANOVA revealed significant variation in mean latency among stimuli ($\chi^2 = 16.59$, $df = 6$, $P < 0.01$). For total tongue-flicks and tongue-flicks directed only to the swab, F values are largest and alpha values lowest for TFAS. If the same data are analyzed by Friedman two-way ANOVA, the rank order of relative magnitudes of alpha values among stimuli is preserved for both total tongue-flicks and tongue-flicks to swabs. P values are slightly larger in the nonparametric analysis. Higher F values were obtained for TFAS and PTFR, but not TFR when only tongue-flicks were directed toward the swab, rather than all tongue-flicks, including those directed away from the swab, were used.

DISCUSSION

Comparisons of Response Measures

Skinks. TFR, latency to bite, number of lizards biting, PTFR, TFAS and TFAS(R) were concordant in the skink study in detection of a significant difference among stimulus conditions and between responses to cricket chemicals and deionized water and of no significant difference between responses to water and cologne. However, using the same data set, the ability of these measures to resolve other differences in responses among conditions varied; similarly, suitability of the data for parametric analysis differed among the measures (Table 3). The variables allowing maximal detection of differences in responses among conditions were TFAS, TFAS(R), and PTFR, in descending order. Although patterns of results were similar for all variables, number of lizards biting could not be adequately analyzed without a larger sample size, and the multiple comparisons for latency and TFR were significant only at higher alpha levels than for TFAS, TFAS(R), and PTFR.

Response to cricket chemicals differed significantly from that to cologne for all variables except latency to bite, for which the difference was not significant, in part because of the failure of several individuals to bite. Latency alone should be relatively uninformative in revealing treatment effects for prey chemicals failing to elicit biting in a high proportion of trials. Its effectiveness is reduced whenever some individuals also bite control swabs. A further consideration is that variances will be zero in conditions not eliciting biting and will be low in conditions eliciting infrequent biting. The usefulness of number of lizards biting is similarly limited. Furthermore, it is a nominal variable, whereas

the others considered are at least ordinal. Relatively large sample sizes are required to meet the assumptions of the Cochran Q test if more than two conditions are tested. At best, important information available from tongue-flicking is discarded when latency is used; further quantitative information regarding latency is discarded in using number of lizards biting.

Biting is important in two ways, as an end point for trials and as a presumed feeding attempt. Once a lizard has bitten, the trial ends because tongue-flicking before and after biting may not be commensurate, because it is difficult to determine or interpret the duration and number of bites, and, most importantly, because biting is a natural termination of prey capture. Nevertheless, some individuals bite swabs not bearing prey chemicals. Fortunately, such behavior is relatively rare. In studies of several other snake and lizard species, either no bites were directed to control stimuli or they were rare and usually occurred in trials immediately following testing with attack-eliciting prey extracts (Burghardt, 1973; Burghardt et al., 1988; Cooper, unpublished). Prey-directed strikes usually are unambiguous and motivated by hunger (Burghardt, 1970), whereas tongue-flicking is affected by various contextual variables, including novelty (De Fazio et al., 1977; Gove and Burghardt, 1983; Burghardt et al., 1986; Wellborn et al., 1982).

Results for TFR and PTFR were similar. Minor differences in alpha levels may have been due in part to differences in the Friedman test and ANOVA as well as to inherent differences between variables. TFR and PTFR suffer from loss of all biting information. Raw numbers of tongue-flicks inadequately represent trials in which biting occurs, the inadequacy increasing as latency to bite decreases. The use of PTFR addresses this difficulty by projecting each animal's TFR to the time of biting through the entire 60-sec interval. This projection should improve as latency increases.

Equal TFRs for the intervals before and after biting are assumed in PTFR. This assumption of uniform tongue-flicking rate is invalid for the control stimuli water and cologne and for conspecific male cloacal stimuli, but it is valid for female cloacal stimuli. Thus, uniformity cannot be assumed and should be determined empirically for each stimulus used. Violation of the uniformity assumption for water and cologne would have minimal effects because these stimuli rarely induce biting in a variety of species (Cooper, 1989a,b; unpublished; Cooper and Vitt, 1989), but it would have a greater effect for prey chemicals. PTFR becomes increasingly unrealistic as the departure from uniformity increases and as the proportion of lizards biting increases. PTFR could be improved by recording the temporal distribution of tongue-flicks and applying correction factors for each stimulus found to have a significantly nonuniform rate.

Results for TFAS and TFAS(R) were nearly identical, both separating con-

ditions at lower alpha levels than did PTFR. As expected, the *F* value for TFAS was slightly greater than for TFAS(R) because a constant maximum number of tongue-flicks was added to the TFAS for every individual that bit, whereas a variable and usually lower number was added to arrive at TFAS(R). TFAS, although appropriate for independent group designs, somewhat inflates group differences for studies involving repeated measures of performance by the same individual. Because a major advantage of the randomized blocks design is matching of responses across stimuli within individuals, this advantage is lost by assigning a value for one individual to other individuals. Therefore, TFAS(R) may be preferable to TFAS for use with randomized-block designs. Some individuals that attack but tongue-flick little may have a lower TFAS(R) than others that never attack, but this cannot be so for TFAS. In practice, there may be little difference between the two. However, for the nonparametric Friedman two-way ANOVA, which compares ranks of each individual across conditions, TFAS(R) would be best.

Garter Snakes. Results differed from those in the skink study in that TFR did not differ among stimuli and PTFR produced only a marginally significant main stimulus effect. Thus, whereas similar results were obtained using TFR or PTFR for the skinks, results from these variables are discrepant for the garter snakes. This difference is attributable to the shorter latency among those individuals that attacked for the snakes, resulting in low TFR and a greater increment in PTFR.

TFAS gave a much better overall picture of differences in responsiveness to the various stimuli than the other measures. Because such a high percentage of garter snakes attacked prey stimuli at fairly short latencies, the number of individuals attacking swabs is a better response index than TFR alone. With sufficient sample size to allow assessment of main effects nonparametrically, number of attacks might be preferable to TFR and PTFR for this species. Latency appears to be the best single-component measure for these data because it differs markedly among stimuli, is amenable to analysis of the main effect, and is suitable for multiple comparisons. Latency is a priori a poorer measure than TFAS because it fails to account for variation in tongue-flicking rate. Practically, it is inferior because it is more likely to require nonparametric analysis and because it yields larger alpha values (as seen for both data sets).

Comparison of differences among conditions has been based on data for all individuals, including latencies for those that do not attack. We may also wish to ascertain whether the latency to attack varies among stimuli given that attack has occurred. For the garter snake data, this conditional latency does not appear to differ among stimuli. Mean latencies were 12.9 for earthworm extract, 11.4 for extract B7, 16.6 for extract E7, and 14.0 for extract F7. No analysis was conducted because the data were a mixture of independent and correlated

observations. Nevertheless, it is clear that (1) results differ greatly from those including all latencies and (2) all latencies should be included when assessing whether response strengths vary among stimuli.

That the *F* value for TFAS based on tongue-flicks directed to the swab was greater than that for total tongue-flicks suggests that the former better reflects response to chemicals. We have observed in many studies that snakes and lizards sometimes tongue-flick while moving about the cage, without apparent reference to stimuli on the swabs. Some individuals give the impression of searching for the prey object by tongue-flicking away from the swab; others may be escaping or merely moving away. Because it is difficult to distinguish the motivation for tongue-flicks away from the swab and because tongue-flicks away from the swab may also differ among stimuli, tongue-flicks directed to the swab give the best indication of response to prey stimuli.

Characteristics of Good Index of Response Strength

TFAS has the advantages of giving bites heavier weight than any number of tongue-flicks. PTFR, if modified to account for the temporal distribution of tongue-flicks, might give a somewhat less arbitrary weight in terms of tongue-flicks for the interval following biting. Because, however, it would not allow additional weight for biting, the adjusted PTFR would be inferior to TFAS and TFAS(R). When the tongue-flick rate is highest in the early part of the trial, PTFR effectively weights early biting heavily. In this case TFAS is preferable because the degree of weighting is unknown for PTFR. A measure of response strength combining the features of a modified PTFR with some nonarbitrary weight for biting in terms of tongue-flick units could be a further improvement.

If we ask how many tongue-flicks a bite is worth or what fraction of a bite a given tongue-flick and latency combination is worth, it becomes clear that the units must be arbitrary. Yet it is possible to specify properties of a good measure of response strength to prey chemicals combining the effects of tongue-flicking, latency to bite, and biting. They include: (1) monotonic increase with increases in number of tongue-flicks, (2) monotonic increase as latency decreases, and (3) greater magnitude for trials involving biting than for any number of tongue-flicks alone.

TFAS and TFAS(R) have these properties with the single exception noted above; PTFR has property 1, has property 2 unless biting occurs with zero latency, but does not have property 3. For a bite at zero latency, no tongue-flicking rate has been established for projection through 60 sec. However, bites at zero latency occur very rarely, and only in experiments in which the test interval is considered to begin with the first tongue-flick or bite rather than immediately upon introduction of the stimulus. A related problem with PTFR is that for short latencies, the projection is less likely to be realistic. Because

of these shortcomings and the additional data and computation required for a projection reflecting the true temporal distribution of tongue-flicking, PTFR is a less satisfactory measure than TFAS or TFAS(R). PTFR could be modified to handle zero latency by adding some base unit, but this would impose an additional arbitrary element. Furthermore, unless a base unit were to be added for biting as in TFAS, it would be possible for one individual to have a higher PTFR in a condition in which it did not bite than for one in which it did. Halpern and Frumin (1979) developed an index adding a latency component: response strength = PTFR + 2(60 − latency to attack).

This measure is similar to TFAS except that PTFR is substituted for the base unit and the latency component is multiplied by two. We prefer TFAS and its derivatives to this index because of the problems with PTFR discussed above.

Characteristics of TFAS and its Relationships to Tongue-Flicks, Biting, and Latency

For individuals that do not bite, TFAS is simply the number of tongue-flicks emitted; for individuals that do bite, it is the base unit (maximum number of tongue-flicks in the study) plus (60 − latency to bite). The portion of the TFAS function in the absence of biting coincides with the 60 sec latency in Figure 1. A wide TFAS range is possible when no biting occurs. When a bite does occur, there is a unique TFAS associated with each latency. A negligible difficulty with TFAS is that a squamate biting at exactly 60 sec could receive a score identical to that in the trial with the most tongue-flicks.

Relationships between TFAS, TFR, and latency are strongly affected by the frequency and timing of biting. If no individuals bite, TFAS and TFR are identical. As the proportion of individuals biting in response to prey chemicals increases and the mean latency decreases, TFR gives an increasingly poorer indication of responsiveness to prey chemicals and diverges from TFAS. If all individuals bite after a few tongue-flicks, it is possible to have lower TFR to prey chemicals than to control stimuli.

If all animals bite swabs bearing prey chemicals, latency and TFAS are perfectly correlated; with decreasing proportions of individuals biting in response to prey chemicals, the correlation decreases, reaching zero if no individuals bite.

In the foregoing, it is assumed that biting occurs solely in response to prey chemicals. In studies involving 11 species of lizards representing eight families and two species of colubrid snakes (Cooper, unpublished), biting of control swabs was rare. Two *Eumeces laticeps* bit a control swab (Cooper and Vitt, 1989); two other individuals were discarded from the study because they bit immediately without any preliminary chemical testing. A single *Tupinambis rufescens* could not be used because it attacked any small object introduced into

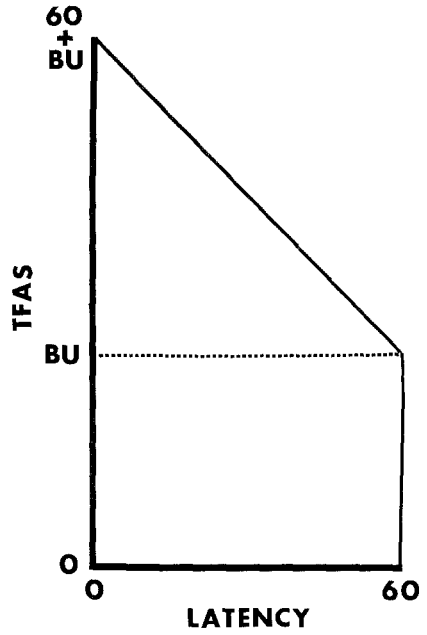

FIG. 1. The tongue flick/attack score (TFAS) consists of two components: the number of tongue-flicks for individuals that do not bite, and a base unit + (maximum trial length − latency) for those that bite. The base unit (BU), which is the maximum number of tongue-flicks emitted by any lizard in the entire sample in response to any stimulus condition, is constant for a given study but varies among studies. Trial length shown is 60 sec.

its cage without prior chemosensory investigation. Infrequent biting of swabs bearing control substances has not created any difficulty in detection of prey chemical discrimination to date but could do so in a species that bit control swabs frequently. This might occur in highly aggressive species that bite defensively (e.g., Herzog and Burghardt, 1986).

Published analyses of TFAS data have used both parametric and nonparametric statistical methods. Because TFAS and TFAS(R) are unlikely to be interval scales, nonparametric analyses are safest. In a stringent nonparametric approach, medians would be presented rather than means and variance-based parameters would be unavailable. One way to avoid this difficulty would be to construct an interval scale of response using psychological scaling techniques involving normalized TFAS, but this would demand much larger sample sizes and would involve considerable additional calculation. These disadvantages seem to outweigh the potential gains.

Parametric ANOVA is robust enough with the nearly interval data on TFAS

to warrant its use if variances are homogeneous or can be rendered homogeneous by transformation. In the numerous instances in which we have analyzed the same data by parametric and nonparametric methods, the results have been equivalent. When nonparametric tests are used for experiments involving three or more groups, a need for significance tests for individual pairs of treatment or condition means arises if the main effect is significant. However, most statistics books used by biologists do not describe appropriate multiple comparison tests. However, such tests are available (Hollander and Wolfe, 1973) and should be used with Kruskal-Wallis and Friedman ANOVAs.

Adjustment of Scores for Biters to Base Unit Differences

A different approach to improvement of TFAS is standardization of the relationship between the base unit and the latency component. When biting occurs, the contribution of latency to TFAS is constant between all studies having the same trial length, but the base unit may vary among studies. If the base unit is large relative to the latency contribution, biting will affect TFAS less than if the base unit is relatively small. However, because the base unit depends on the extreme response of one individual and on factors such as food deprivation and temperature, it may be expected to be quite variable.

TFAS may be adjusted to maintain a constant ratio between the maximum possible contribution of latency and the base unit. The new base unit-adjusted TFAS, BTFAS, is given by

$$BTFAS = \text{base unit} + c(TL - \text{latency})$$

where c is a latency constant and TL is trial length in seconds. To give equal weight to the base unit and immediate biting (so that maximum BTFAS = 2 × base unit),

$$c = \frac{\text{base unit}}{TL}$$

For TFAS, the proportion of the total variance attributable to biting and its latency increases with the ratio of the base unit to (TL − latency) because multiplication of data by a constant increases the variance by the square of the constant. In similar conditions the mean increases by the constant of multiplication. Results based on BTFAS are more comparable between studies than those based on TFAS because the proportion of total BTFAS due to biting at a given latency is identical in all studies. Because the latency coefficient c is applied only to scores involving biting, effects on mean and variance increase with the proportion of individuals biting and the deviation of the base unit to (TL − latency) ratio from unity.

BTFAS and TFAS were calculated (with TL = 60) and statistical tests

were conducted to obtain preliminary information regarding effects on outcomes of ANOVA for the *E. laticeps* data and three smaller hypothetical data sets. The data sets varied in values of the latency coefficient, proportion of individuals biting in response to prey chemicals, and latencies. Magnitudes of F values obtained for each data set were compared by computing the ratio of F(BTFAS) to F(TFAS). Results for each data set are reported for both randomized blocks and independent groups analyses (Table 6).

These examples show that F values may increase or decrease when c is not equal to 1.0. Relatively large changes occurred for samples in which c deviated substantially from 1.0. For comparisons based on the same data set, the relative values of F for BTFAS and TFAS differed only slightly for repeated measures and independent groups analyses when c was close to 1.0, but to a larger extent for the c values far above or below 1.0. This shows that F values are sensitive to the proportion of the total response measure assigned for effects of biting and latency and that the effect is complex, presumably varying with c, experimental design, and proportion of animals biting.

BTFAS for the *E. laticeps* data set gave results very close to those for TFAS because the base unit (52) was close to 60, giving a c value of 0.8667. BTFAS means $\pm$ SE and ranges were 55.5 $\pm$ 8.0 and 15–91.9 for cricket stimuli, 17.5 $\pm$ 6.2 and 2–61.5 for cologne, and 15.0 $\pm$ 8.0 and 1–100.5 for deionized water. Variances were homogeneous ($F_{max} = 1.69$; $df = 3, 11$; $P > 0.10$). The pattern and levels of statistical significance for BTFAS were identical to those reported for TFAS. However, the main effect was slightly larger for BTFAS ($F = 13.06$; $df = 2, 22$; $P < 0.001$, F ratio = F(BTFAS)/F(TFAS) = 1.03). The individual comparisons between cricket stimuli and control stimuli also exceeded critical values by larger margins than in similar comparisons for TFAS.

TABLE 6. RELATIVE MAGNITUDES OF F VALUES FOR TFAS AND BTFAS VARIED EVEN WITH IDENTICAL DATA SETS[a]

Sample size[b]	Proportion biters	c[c]	F(BTFAS)/F(TFAS) Randomized blocks	F(BTFAS)/F(TFAS) Independent groups
4	0.50	0.5000	1.31	1.36
12	0.75	0.8667	1.03	1.04
4	0.50	1.1667	1.05	1.04
4	0.50	2.0000	0.86	0.76

[a] Each data set was analyzed using independent groups and randomized blocks designs.
[b] Sample size is 12 for the *E. laticeps* data, 4 for hypothetical data sets.
[c] c is the latency coefficient.

Among studies done in a comparative survey of prey chemical discrimination (Cooper, unpublished) in which at least one individual bit, base units for lizards in 60-sec tests were 15, 23, 30, 31, 48, 52, and 59; for a single snake study it was 47. For several of these studies c would be considerably below 1.0 (as low as 0.25) because the base unit is considerably smaller than 60. The short trial period limits the size of the base unit, but a potential for base units considerably larger than 1.0 is indicated by the 116 tongue-flicks emitted in 60 sec by a male *E. laticeps* responding to conspecific female cloacal stimuli (Cooper and Vitt, 1986b).

Recommendations

Comparisons of response variables show that Burghardt's (1967, 1970) widely used TFAS or a slightly modified version of it is the best index of response by squamates to prey chemicals on swabs. Continued use of TFAS or TFAS(R) is acceptable, but for comparison of results between studies of multiple species or populations, BTFAS may be preferable. A drawback of BTFAS is that the decision to give an immediate bite twice the weight of the base unit is arbitrary.

It is also suggested that the base unit be changed so that a bite at exactly 60 sec latency would receive a greater TFAS than the greatest number of tongue-flicks in the absence of biting. All versions of TFAS could be slightly improved by adding a small constant to the current base unit. If no individuals bite at exactly 60 sec, which is the case for the data set analyzed here and for many others, the current base unit is adequate. Because intervals of less than 1 sec are not usually recorded, addition of 0.5 to the base unit for TFAS or of $0.5c$ for BTFAS would suffice. Alternatively, an arbitrary deduction of 0.1 sec from latency of a bite at 60 sec would accomplish the same thing. One of these minor changes is suggested only to satisfy property 3 in a rare case. It is highly unlikely that the suggested change in base unit will have any appreciable effect. We plan to use TFAS, TFAS(R), BTFAS, or BTFAS(R) without modification in future studies unless one or more bites have 60-sec latencies, in which case the base unit will be increased as stated.

Solely for detection of prey chemical discrimination, separate analysis of latency to bite and number of bites does not appear to provide information in addition to that obtained from TFAS. However, to reach a thorough understanding of the behavioral responses to chemical stimuli, attention must be paid to separate information on tongue-flicking rate, latency, and biting and their interrelationships (Cooper and Vitt, 1989). Information on all these variables should be included in papers on squamate prey chemical discrimination.

Experimental procedures used in recording tongue-flicks and initiating trials may affect the magnitudes of all response measures considered here. For exam-

ple, trials may be initiated immediately upon presentation of the stimulus (Burghardt, 1975) or upon emission of the first tongue-flick (Cooper and Vitt, 1989). The rationale for the latter procedure is that defensive immobility in the presence of the experimenter may initially prevent tongue-flicking. Use of a behavioral starting point eliminates this problem, but prevents zero scores and is not feasible for species that frequently fail to tongue-flick swabs (e.g., *Anolis carolinensis*, *Sceloporus malachiticus*, *Calotes mystaceus*, Cooper, 1989a).

A second procedural consideration is whether to touch the reptile's snout with the swab if it does not tongue-flick after some predetermined interval. Touching may induce tongue-flicking by individuals that would otherwise be unresponsive, but in some species it induces defensive bites (Cooper, unpublished observations on *E. laticeps* and *Masticophis flagellum*).

Another source of variation among studies is the categories of tongue-flicks recorded, i.e., all tongue-flicks or only those directed to the swab (e.g., Burghardt, 1975). Among lizards some species direct most tongue-flicks to the swab (e.g., *E. laticeps*, Cooper, unpublished); some may direct a few tongue-flicks to the swab and then move away while continuing to tongue-flick, sometimes at high rates (*Ophisaurus ventralis*, *Cnemidophorus sexlineatus*, *C. tigris*, Cooper, unpublished); others may tongue-flick swabs repeatedly, move away while tongue-flicking, and return (*Heloderma suspectum*, *Tupinambis rufescens*, Cooper, 1989b). Similar variation exists in snakes. In garter snakes (*Thamnophis sirtalis*) most tongue-flicks for effective stimuli are directed to swabs. In *Elaphe guttata* a higher proportion of tongue-flicks is directed elsewhere. Given such procedural differences and their potential effects on response variables, caution must be used in making comparisons between studies, populations, or species.

Other Measures not Analyzed Here

Other response measures may be constructed, including multiplicative relationships between tongue-flicks and latency. One such would be the number of tongue-flicks if no attack occurred or the maximum number of tongue-flicks for the group (or each individual) multiplied by [trial length/(trial length − latency)] if attack occurred. Such measures would be infinitely large for attack at zero latency. A potentially important factor in such indices might be the number of attacks divided by mean latency (Burghardt, 1975). Whether the relationship between latency and the base unit should be additive, as in TFAS, or multiplicative is uncertain. However, TFAS and its modifications are likely to yield smaller differences among stimuli. Means of additive or multiplicative measures could be further adjusted for the proportions of individuals biting prey and control stimuli. Such adjustment could be useful in comparative studies,

but effects of biting would be entered for both individual trials and entire conditions.

TFAS and its modifications are composite variables derived rationally from ethologically reasonable premises about the importance of tongue-flicking and attack as indicators of feeding response strength. Another approach would be to use multivariate methods to select weights for each response variable empirically to yield the maximum possible statistical discrimination among conditions or treatments, as in MANOVA. We prefer the rational approach because statistical compositing procedures may capitalize on features unique to each data set. Use of different relative weights in each study would make comparisons among studies unnecessarily difficult.

We have not considered cases in which each individual is tested more than once with each stimulus. For such data, Halpern and Frumin (1979) use a preference score, which is the difference in mean response strength for prey extracts and water expressed as a proportion of mean response strength to water. This method was used in an attempt to eliminate effects of differences in response rates among snakes and to control for indiscriminate responses, i.e., responses not attributable to prey extract. Such a complex approach is not necessary to detect prey chemical discrimination in experiments using randomized blocks designs because each individual serves as its own control. Use of preference score requires the assumption that equal ratios (difference in response scores/water response score) indicate equal response to prey chemicals regardless of the overall response rates. This is unlikely to be true in the general case because at high response scores for water, it would be impossible for subjects to tongue-flick and/or bite rapidly enough to attain as high a ratio as would be possible with lower response scores to water.

In addition to the measures of response strength used in experiments in which chemical stimuli are presented on swabs, a tongue-flick interest score (Reformato et al., 1983; Halpern et al., 1984) incorporating number of tongue-flicks and relative amounts of time spent at two sample trays has been used for simultaneous discrimination experiments. This method appears to be reasonably efficient, but its merits relative to the procedures used in successive discrimination procedures with chemical stimuli on swabs are unknown. Experimental results based on tongue-flick interest scores and tongue flick-attack scores are unlikely to be directly comparable. TFAS includes no component similar to time spent at a tray, which is reminiscent of the orientation time to a swab recorded as a measure of response strength in an early study by Loop and Scoville (1972). Because this measure does not account for either number of tongue-flicks or latency to attack, it has not been widely used. The tongue-flick interest score includes the influence of numbers of tongue-flicks, but does not account directly for attacks (which do occur in this procedure) or their latency. Although

a response measure including the effects of latency and attack might be developed for use in simultaneous discrimination tests, there is no guarantee that it would give results comparable to TFAS and no necessity that it should.

(Received September 20, 1988; accepted March 17, 1989)

Abstract—Materials previously shown to elicit increased tongue-flicking and prey attack in garter snakes (*Thamnophis sirtalis*) were isolated from both earthworms (*Lumbricus terrestris*) and fish (*Pimephales promelas*). Both high- and low-molecular-weight components from earthworms and fish stimulated attacks and increased tongue-flicking in previously unfed neonate garter snakes relative to distilled water controls. Earthworm collagen was also effective, but even concentrated fractions were less effective than raw extract. Conflicting reports on the effectiveness of collagen suggest that the salient chemical(s) is a smaller molecule tightly bound to collagen and resisting standard purification methods.

Key Words—Chemoreception, garter snakes, *Thamnophis sirtalis*, chemical cues, *Lumbricus terrestris*, earthworm, *Pimephales promelas*, fish, prey odors, glycopeptide.

INTRODUCTION

Snakes of the genus *Thamnophis*, as well as many others, use chemical cues to discriminate among prey items (Burghardt, 1970, 1980; Arnold, 1981). Surface chemicals can be removed from various prey and used to elicit feeding responses. The most common method involves presenting aqueous prey extracts

0098-0331/90/0100-0067$06.00/0

to snakes on cotton swabs and recording the number of tongue-flicks and the latency of any prey attack (Cooper and Burghardt, 1990). Extensive comparative studies show that newborn garter snakes respond to a wide range of prey chemicals highly correlated with the normal prey preferences of particular species in captivity and in the field (e.g., Burghardt, 1969). The tongue–vomeronasal organ system is responsible for these discriminations (Burghardt, 1970; Halpern and Kubie, 1984).

In an earlier paper (Burghardt et al., 1988), we reviewed the current status of the chemistry of the relevant prey cues and presented our results on a comparison of the chemicals extracted from two prey species, a fish (*Pimephales promelas*) and an earthworm (*Lumbricus terrestris*). Halpern et al. (1986) reviewed the chemistry of earthworm recognition in adult common garter snakes (*Thamnophis sirtalis*) based on their extensive work. They report that purified earthworm cuticle collagen is a potent source of chemoattractant for garter snakes and identify the main effective component as a collagen-like substance (Kirschenbaum et al., 1986). However, using highly purified collagen, this result could not be replicated in adult common garter snakes with our bioassay (Goss, 1986). Two factors may contribute to the discrepancy: the two methods of extraction now used [aqueous extract (Sheffield et al., 1968) and the recently reported chloroform–methanol method (Burghardt et al., 1988)] and the different bioassays employed by the two laboratories to define activity.

The bioassay issue has been discussed in Burghardt et al. (1988). In brief, our method involves a successive discrimination task with open-mouth prey attack being the definitive response in contrast to a simultaneous discrimination test based primarily on tongue-flick rate (Halpern et al., 1986). Any differences in chemical results between the two laboratories may be due to the bioassay employed and may account for our discovery of an active low-molecular-weight fraction in the aqueous extract that has not apparently been observed by the Halpern group.

The chloroform–methanol extraction method (Burghardt et al., 1988) provides especially high yields of active low-molecular-weight materials. These clearly differ in molecular weight from the principal component of the aqueous extract, but are equally or more effective than the low-molecular-weight component(s) of the aqueous extract in bioassay results. An amino acid and carbohydrate analysis showed only partial similarity of low- and high-molecular-weight components to the reported constitution of collagen. One explanation is that the three substances are different and that garter snakes respond to all three.

To date, no single investigation has demonstrated that garter snakes from the same population respond to low- and high-molecular-weight fractions and collagen derived from earthworms. We demonstrate this here and must now question the simple explanation noted above. An alternative explanation would suggest that each fraction contains a component(s) that has the requisite struc-

ture for recognition by garter snakes. Specific structural details have not yet been determined; however, occurrence of activity only in fractions reflecting a peptide and carbohydrate composition clearly suggests a glycopeptide nature.

The ability of garter snakes to discriminate among extracts from different prey implies that more than a single chemical cue is involved. Even within the same species, initial and experience-altered preferences show that individual snakes discriminate chemical cues from different prey (e.g., Burghardt, 1970). In the present study, we compare the effective chemicals from two phylogenetically diverse prey: a fish, the fathead minnow, and the well-studied *Lumbricus* earthworm. We have previously shown that adult snakes respond to both high- and low-molecular-weight fractions from both prey, but not to earthworm collagen (Goss, 1986; Burghardt et al., 1988). Ingestively naive newborn snakes have not previously been tested. All the results presented here are based on neonates.

METHODS AND MATERIALS

Animals. Surface extracts were prepared from freshly obtained adult earthworms (*Lumbricus terrestris*) and fathead minnows (*Pimephales promelas*).

Neonate eastern garter snakes (*Thamnophis s. sirtalis*), born in the laboratory to commercially obtained females from Michigan (Wayne County), were used in the bioassay. All animals were individually housed and tested in their home cages (styrene boxes measuring 18 × 13 × 5 cm). Each box contained a commercial cage liner, a water dish, and a shelter made from a small piece of folded cage liner. Snakes were tested at a temperature of 25 ± 2°C. The snakes had not previously been fed and were between 15 and 20 days old when tested.

Aqueous Prey Extractions Procedure. Preparation of aqueous prey extracts followed Burghardt (1969). We extracted intact prey animals for 2 min with a ratio of 3 g of prey to 10 ml of distilled H_2O at 60°C. The solution was decanted and centrifuged for 10 min at 2500 rpm. The aqueous extract was then lyophilized to preserve activity. The amount of material obtained from prey ranged from 2 to 3 g/liter. References to this aqueous extract obtained from the earthworm and fathead minnow will be referred to as AQ-EW and AQ-FM respectively.

Chloroform–Methanol Prey Extractions Procedure. In this procedure, 1000 g of prey was extracted for 4 min at 23°C with a solution containing 2000 ml of methanol and 1000 ml of chloroform. The solution was decanted and the prey extracted again with 1000 ml of chloroform for 4 min. The decanted chloroform solution was combined with the original organic solution, and the total organic extract was filtered with a coarse glass frit to remove particulate matter.

The filtered solution was poured into a 5-liter separatory funnel and vigorously shaken with 1000 ml of distilled H_2O. The resulting emulsion was allowed to stand at 4°C, during which time it separated into two layers. After two days, the biphasic solution was allowed to warm to room temperature. The water layer was removed and filtered with a medium glass frit. The water layer was lyophilized and the organic layer was evaporated to dryness at aspirator pressure using a rotary evaporator. About 3–5 g of material was obtained per kilogram of prey, and approximately 30% and 40% by mass of these materials were obtained from the earthworm and fathead minnow water layers, respectively. This extraction procedure is referred to as the CM extraction.

Chromatographic Separations. All chromatographic separations, unless otherwise stated, were conducted with low-pressure liquid chromatography. The system included an FMI pump (model RP-SV), Laboratory Data Control refractive index detector (model 1107H), and a Scientific Manufacturing Industries fraction collector (model 12050).

Separation of the high- and low-molecular-weight fractions of earthworms and fathead minnows was conducted using Bio-Rad P-10 gel, 50–100 mesh with 10% ethanol elutant according to Burghardt et al. (1988).

Preparations of Cuticle Collagen. Two procedures were used to obtain collagen samples from earthworms. In the first, based on Murray et al. (1982), 100 earthworms, 15–20 at a time, were frozen for 20 min using a Dry Ice–acetone bath. The frozen earthworms were placed in distilled H_2O and allowed to thaw overnight at 5°C. The cuticles were removed and washed several times with distilled water, minced, and ground in a mortar with 0.5 M sodium chloride solution. The resulting slurry was stirred in 100 ml 0.5 M sodium chloride solution for 48 hr at 5°C and then centrifuged to remove insoluble materials. The supernate was submitted to ammonium sulfate precipitation to isolate the collagen as a pellet after centrifugation. This was reprecipitated twice from 0.5 M sodium chloride solution and finally reconstituted in distilled water for testing. This was a method used by Kirschenbaum et al. (1986) in obtaining their positive results.

A second collagen preparation, based on the procedure of Muir and Lee (1970), also was used to obtain test material. In this procedure, the cuticles were lyophilized prior to extraction with sodium chloride solution. The remainder of the preparation followed the procedure outlined above. Goss (1986) obtained negative results with this method.

Bioassay Procedures. The number of snakes tested in each bioassay was four or ten. All had responded to fish or earthworm aqueous extracts in a survey carried out on a previous day using the same testing procedure. Each snake was tested only once with each stimulus in a given bioassay session, with order in sequence equalized as completely as possible.

All extracts were reconstituted in distilled H_2O to a concentration repre-

senting, as near as possible, that found in the original extracts, less estimated losses on columns, etc. Each bioassay session included four or five stimuli; it always included a distilled water control and an AQ extract of the prey being tested. All tests were conducted blind.

In the bioassay, a 15-cm wooden cotton-tipped swab was dipped in the extract and introduced into the snake's home cage about 2 cm from its snout. It remained in that position as closely as possible (by following snake movements) for 30 sec or until the snake gave an open-mouth attack. The number of tongue-flicks directed towards the swab, total tongue-flicks, and the latency of any attacks were recorded. If the snake did not tongue-flick in 10–15 sec after being presented with a swab, the end of the swab was brushed lightly on the snake's back to induce it to emit at least one tongue-flick. For any bioassay session the time between tests was kept to 10–12 min. This basic methodology has been used in many studies (see Cooper and Burghardt, 1990).

Statistical analysis was accomplished by comparing responses to test extracts with distilled water controls and to the AQ extract. The water control represented no activity, whereas the AQ extract represented strong activity. The measures used for the statistical analyses were the number of attacks, attack latencies, and the number of tongue-flicks each snake exhibited toward each stimulus. These were combined into a tongue-flick/attack score (TFAS) (Burghardt, 1969) in which any attack received a higher score than any number of tongue-flicks. In brief, TFAS = base unit + (30 − attack latency) where the base unit was the maximum number of tongue flicks given in any nonattack trial by any snake in a given experiment.

A repeated measures analysis of variance (stimulus × subject × position in sequence) was performed on the data for all the extracts tested each bioassay session. All variances in an experiment were homogeneous according to Cochran's C test. However, a nonparametric Friedman's two-way analysis of variance also was performed. If both overall ANOVAs were significant, planned comparisons of prey extracts with water were made. A nonparametric Wilcoxon signed rank matched pairs test confirmed all paired comparisons conclusions. One-tailed P values are presented for these comparisons since in all cases only an increase in responsivity compared to water was being evaluated. All statistical calculations were performed using the Statgraphics package (Version 2.6).

RESULTS

Earthworm Extracts. Extraction of prey with organic solvents followed by extraction of the organic layer with H_2O provided active material easier to chromatograph than material obtained by direct H_2O extraction. The organic layer from the chloroform–methanol prey extract was not active, whereas the water

layer was very active. Compounds obtained from the H_2O layer were separated on the Bio-Gel P-10 column into two fractions: a multicomponent high-molecular-weight fraction eluting at the void volume of the column and a low-molecular-weight fraction eluting approximately at the volume of the column.

Two low-molecular-weight fractions were obtained after we noticed a change in the detector response as a function of the reference cell solution composition. The tested fractions represent a maximization of this difference as the reference is changed from the elution mixture (10% ethanol) to pure H_2O.

Ten snakes were tested on five stimuli with position in test sequence equated. The five stimuli were the two low-molecular-weight fractions, the high-molecular-weight fraction, the aqueous earthworm extract, and distilled water. All stimuli except water elicited attacks and increased tongue-flick/attack scores (Figure 1). The ANOVA was highly significant for the stimulus effect ($F = 15.04$, $df = 4, 32$, $P < 0.0001$). Results for the high-molecular-weight fraction

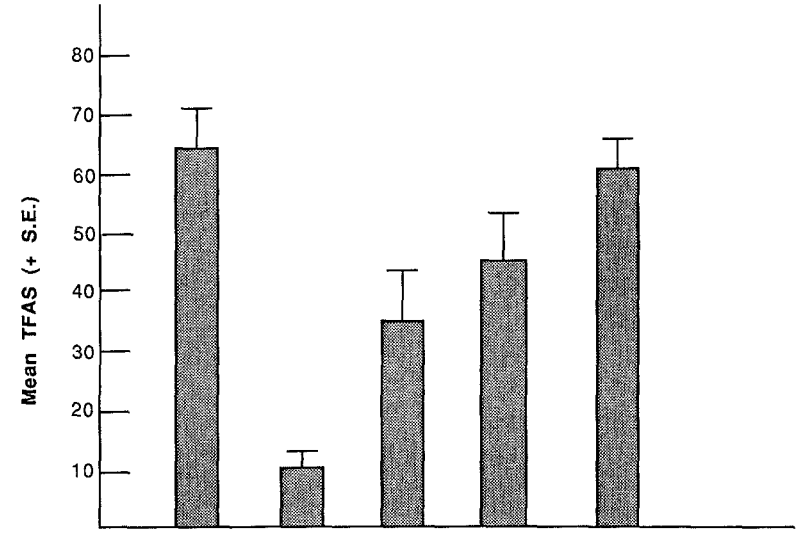

FIG. 1. Mean tongue-flick/attack scores (+1 SEM) and number and mean latency of prey attacks (in 30-sec trials) given by 10 ingestively naive garter snakes to distilled water, aqueous earthworm surface extract, two low-molecular-weight fractions, and a high-molecular-weight fraction prepared from chloroform–methanol earthworm extractions.

were virtually identical to those for the aqueous earthworm extract. Both low-molecular-weight fractions were somewhat less effective than the high-molecular-weight fraction but even the lowest was significantly more effective than water ($Z = 2.45$, $P < 0.01$).

Fathead Minnow Extracts. A Bio-Gel P-10 separation was conducted on the active water layer of the CM extraction. Two fractions were obtained from the preparative P-10 column. A high-molecular-weight fraction eluted at the void volume of the column, and a low-molecular-weight fraction eluted approximately at the volume of the column.

Four snakes were tested once each on four stimuli with test position equalized. The stimuli were the high- and low-molecular-weight fractions, the aqueous minnow fraction, and distilled water. All extracts were significantly more effective than water and statistically indistinguishable from the aqueous extract ($F = 42.18$, $df = 3, 6$, $P = 0.0002$) (Figure 2). The TFAS of the lowest-scoring extract was greater than that for water ($Z = 1.65$, $P = 0.05$).

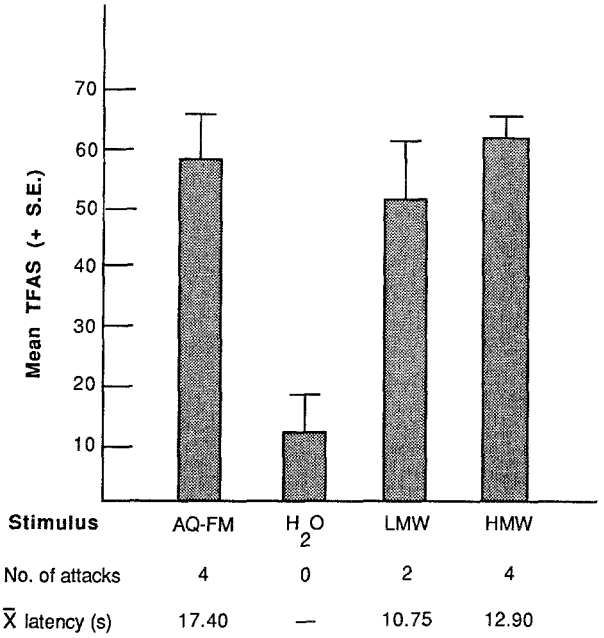

FIG. 2. Mean tongue-flick/attack scores (+1 SEM) and number and mean latency of prey attacks (in 30- sec trials) given by four ingestively naive garter snakes to distilled water, aqueous fathead minnow surface extract, and a low-molecular-weight fraction, and a high-molecular-weight fraction prepared from chloroform–methanol minnow extractions.

All extracts also elicited attacks. Although, as with the earthworm fractions, the low-molecular-weight substances led to a lower TFAS, the low-molecular-weight minnow fraction was, relative to the high-molecular-weight fraction, more effective than the-low molecular-weight earthworm fractions. This confirms the finding with experienced adult snakes reported earlier (Burghardt et al., 1988).

Earthworm Collagen. Ten snakes were tested on five stimuli, as in the earthworm separation experiment. Stimuli tested were collagen prepared according to Muir and Lee (1970), collagen prepared according to Murray et al. (1982) both in a normal and double-concentration reconstitution, aqueous earthworm, and distilled H_2O. TFAS scores varied significantly among stimuli ($F = 26.78$, $df = 4, 32$, $P < 0.0001$). However, while attacks were given to all collagen samples (Figure 3), the TFAS scores were in every case significantly less than scores obtained with the aqueous earthworm extract (Tukey

	AQ-EW	H_2O	Muir & Lee	Murray	Murray (conc.)
No. of attacks	10	0	5	2	4
$\bar{X}$ latency (s)	3.83	—	18.46	4.20	12.45

Fig. 3. Mean tongue-flick/attack scores (+1 SEM) and number and mean latency of prey attacks (in 30-sec trials) given by 10 ingestively naive garter snakes to distilled water, aqueous earthworm surface extract, and three earthworm collagen preparations based on Muir and Lee (1970) and Murray et al. (1982).

HSD test). Even the concentrated Murray fraction was only slightly more effective than the unconcentrated one. This latter extract was the least effective of the collagen fractions but was still more effective than water ($Z = 2.45$, $P < 0.01$).

DISCUSSION

Our previous investigation of earthworm and fathead minnow extracts demonstrated their similar glycopeptide nature and the presence of behaviorally important high- and low-molecular-weight fractions in both extracts (Burghardt et al., 1988). In preliminary investigations it was shown that the high- and low-molecular-weight fractions were significantly different in composition. It was not possible to estimate the absolute purity of the fractions in the earlier study or the relationship of the high- to the low-molecular-weight materials. However, during the separation procedure employed for the present study, a serendipitous problem with the refractive index monitor demonstrated the existence of at least two components in the low-molecular-weight fraction from earthworms.

During separations of several portions of earthworm extract over a two-day period, the response of the detector clearly changed with respect to the low-molecular-weight material. What had appeared as a slightly asymmetrical peak at the start of the separations changed to a partially inverted peak and finally to a completely inverted response that left no doubt that it represented at least two components. During this time the composition of the reference cell solution changed because of ethanol evaporation and thus alerted us to heretofore unrecognized differences in the refractive indices of the low-molecular-weight components. Indeed, when the solution in the reference cell was changed from the 10% ethanol solution normally used for elution of the column to pure water, the observed change in response was reproduced. Collection of fractions when the difference in response was at a maximum provided the two different low-molecular-weight fractions from earthworms employed in the recorded experiments. The overlapping nature of the peaks made complete separation of components impossible, but it was anticipated that a discernible difference in activity of the resulting fractions might be achieved. It was not; both were equally active. Attempts to duplicate this effect with the fish extract were unsuccessful.

The demonstration of responsiveness to the various fractions of earthworm and fish extracts by ingestively naive garter snakes, as well as limited responsiveness to earthworm cuticle collagen material, completes a preliminary study of prey-recognition substances. It is possible that these responses are mediated by similar chemical cues in each of the studied materials. Thus, the high-molecular-weight fractions may be chemically related to the surface collagens of the

prey and, likewise, the low-molecular-weight fractions may be related to the high-molecular-weight materials, presumably as hydrolytic fragments.

The fact that even concentrated earthworm cuticle collagen was less effective than the aqueous extract might either indicate that substances other than collagen are involved or simply reflect the relative insolubility of collagen. In view of the modest responses shown to collagen in this study and our failure to find activity in adult snakes using highly purified collagen (Goss, 1986), it seems likely that collagen activity is due to a substance that is not easily removed during the collagen extraction and purification process. Given the known necessity of a functioning vomeronasal system in the garter snake response to prey chemical cues, this interpretation seems most logical. A small chemically related molecule such as the glycopeptide materials in our readily soluble fractions might be very difficult to remove from the collagen. It could, however, easily be obtained by a tongue-flicking snake and transferred to the vomeronasal organ, a sequence that is less readily imagined for high-molecular-weight collagen molecules. Furthermore, the ability of this snake to discriminate among earthworm and fish species (Burghardt, 1970) argues against the evolution of a chemical prey detection system based solely on the core of a conservative structural macromolecule.

Our previous study demonstrated a dissimilarity of amino acid and carbohydrate composition of the low- and high-molecular-weight fractions from both extracts, and we have now demonstrated the presence of at least two components in one of these fractions. Thus, the composition differences may not reflect dramatically different stimuli. It seems reasonable to suspect that some portion of the glycoprotein is responsible for the activity.

That both of the low-molecular-weight earthworm fractions show activity is not inconsistent with this hypothesis. They could be two related glycopeptide fragments; there could easily be a third component that eluted with both fractions; or overlap of components could have provided activity in both fractions. The manner in which they were separated does not guarantee that separation of either component was complete. The observation of different refractive index responses does not change the obvious tailing of one component into the other; it provides only an arbitrary distinction on which our fractionation was based. Thus, while we failed to demonstrate a distinct difference in biological activity, the fact of chemical difference between the two fractions is certain. A more complete separation of these materials is needed so that their biological relationship can be more convincingly established and their chemical constitutions reliably compared.

Acknowledgments—This work was supported in part by NSF grants BNS-8217569 and BNS-8709629 awarded to G.M.B. and by the UTK Science Alliance. The collagen data on adult snakes was reported in a paper presented at the Snake Behavior and Ecology Symposium, American Soci-

ety of Ichthyologists and Herpetologists, Vancouver, B.C., June 1986. The data on neonate snakes was presented, in part, at the Reptile Chemical Ecology Symposium at the Fifth Annual International Society of Chemical Ecology Meeting, Athens, Georgia, June 1988. Paul Weldon and two reviewers made helpful suggestions on an earlier draft.

CHEMICAL CUES USED BY PRAIRIE RATTLESNAKES (*Crotalus viridis*) TO FOLLOW TRAILS OF RODENT PREY

(Received February 1, 1989; accepted March 17, 1989)

Abstract—Each of 10 prairie rattlesnakes (*Crotalus viridis*) was exposed to three types of trails after striking rodent prey (*Mus musculus*). One trail was made with mouse urine, another was made with tap water, and the third consisted of materials from mouse integument. The snakes exhibited trailing behavior only when integumentary trails were available. It was concluded that prairie rattlesnakes do not utilize urinary cues; instead they attend to materials associated with rodent skin and fur.

Key Words—Rattlesnake, *Crotalus viridis*, mouse, *Mus musculus*, trails, predation.

INTRODUCTION

Prairie rattlesnakes (*Crotalus viridis*) practice several feeding strategies, including active foraging around rodent burrows, sit-and-wait tactics along traditional rodent trails, and carrion eating (Klauber, 1956; Duvall et al., 1985; Diller, 1989; Hennessy and Owings, 1988; see also Gillingham and Baker, 1981; Reinert et al., 1984). When an adult rodent is envenomated, it typically is

0098-0331/90/0100-0079$06.00/0

released by the snake within 0.3 sec and allowed to wander while the venom takes effect (Kardong, 1986). A rodent can travel several meters from the site of attack before succumbing to the venom (Estep et al., 1981; Hayes and Galusha, 1984), and the snake then follows the prey's trail in order to recover the carcass (Brock, 1980; Golan et al., 1982; Chiszar et al., 1983, 1986). It has been established that chemical cues are used by the snake during trail-following, but the precise source of these cues remains to be determined (see Burghardt, 1970, for a review of chemical perception in reptiles; see also Kubie and Halpern, 1979; Halpern and Kubie, 1980).

It has long been our suspicion that rodent urine contains the cues used by rattlesnakes. This idea was based partly on the fact that mice usually urinate copiously upon being envenomated and partly on the fact that rodent urine contains a variety of chemicals known to be important for rodent communication, social behavior, reproduction, and development (Vandenberg et al., 1976; Drickamer, 1977; Bronson, 1979; Nyby, 1983). Consequently, we speculated that rattlesnakes detect some of these chemicals, especially urinary components that might be associated with alarm. Rodents also possess several glands that produce materials that are spread on their integuments through grooming. Such materials might adhere to rodent paws and therefore be deposited on the substrate as an envenomated individual wanders away from the site of attack.

The present experiment was designed to determine whether trail cues are of urinary or integumentary origin. Although we fully expected prairie rattlesnakes to follow urine trails, a pilot study (Duvall and Chiszar, 1989) showed that such trails were ignored and that snakes followed only trails made with integumentary materials. The present study was therefore conducted to replicate the surprising results of the pilot study.

We are mindful of the possibility that some alarm substances produced by mice might be nonurinary and might, therefore, be part of the integumentary materials that we manipulate in this study. Hence, we do not view the distinction between urinary and integumentary trails as being correlated with presence versus absence of alarm substances. See Thiessen and Cocke (1986) for a review and conceptualization of rodent alarm substances, and see Weldon (1983) for related evolutionary considerations.

METHODS AND MATERIALS

Subjects. Ten adult *C. viridis* were observed (five others had been observed by Duvall and Chiszar, 1989). These snakes had been in captivity for at least three years, living in individual glass cages (50 × 27.5 × 30 cm) and eating one mouse (*Mus musculus*) weekly. Although the snakes had been used in previous experiments involving presentation of chemical cues, no invasive manip-

ulations had been performed. Hence, these snakes were typical of long-term captives.

Procedure. Each snake was observed in four experimental conditions, and all of these observations were made in wooden pens (180 × 66 × 81 cm) divided into two compartments (150 and 30 cm long, respectively) by a partition containing a guillotine door. The smaller compartment contained a paper floor cover and a stainless-steel vessel filled with water. A snake was placed into this compartment for one week before the start of observations, which were then made at the rate of one per week for four weeks. See Golan et al. (1982) for a description of laboratory temperature, photoperiod, and other conditions. Three identical pens were used simultaneously in this study.

A paper covered the floor of the large compartment, and a solid meandering line (150 cm) was drawn on the paper, starting from the guillotine door and ending behind a rock on the opposite side. Two additional dashed lines paralleled the first one, each 2 cm from the solid line. Trails were deposited along the center line, and the space between the two dashed lines constituted the trail area. A snake was judged to be in the trail area if its head was between the dashed lines. The trail area comprised 11.3% of the floor area in the large compartment.

In three of the experimental conditions, snakes struck a mouse in the small compartment just prior to the opening of the guillotine door, permitting them to enter the large compartment. This mouse was suspended in the small compartment by forceps and was removed immediately after the strike. Hence, the mouse never touched the floor or walls of the small compartment, and deposition of odoriferous materials was therefore minimized. In the large compartment, one of three trails was available: urine, water, or integumentary material.

Mouse urine was collected in metabolism cages and stored at 13°C until needed but never for more than 48 hr. Urine was then warmed to 35°C and pipetted onto the trail line at the rate of one drop per 5 cm. This was done 2.5 min prior to permitting the snake to strike a mouse and beginning a trial. Urine drops usually expanded to form a circle of 1–2 cm diameter. So, for a control (i.e., blank) trail, we pipetted tap water along the center line at the rate of one drop per 5 cm. The integumentary trail was deposited by dragging a freshly killed mouse carcass along the center line. The inguinal region of this carcass was covered with cotton, and the carcass was dragged in dorsal recumbancy. No urine was visible on this trail, and we suspect that the only chemicals deposited were those that are normally present on the fur.

A freshly killed mouse carcass was positioned behind the rock at the end of the trail. This carcass was not used to make integumentary trails, nor was it a urine donor. Dependent variables were: (1) rate of tongue-flicking per minute (RTF) during 5 min prior to the predatory strike (i.e., baseline RTF), (2) RTF following the strike, (3) latency to make initial contact with the trail area, (4)

number of seconds that the snakes' heads were in the trail area, (5) number of tongue-flicks emitted while the head was in the trail area, and (6) latency to discover the carcass at the end of the trail (timed from the moment snake made initial contact with trail area until the snake touched the carcass). A maximum of 20 min was allowed per trial. If a snake did not reach the end of the trail during this time, a score of 1200 sec was assigned.

The fourth observation involved a no-strike presentation of a mouse at the start of the trial. A live mouse was suspended in the small compartment, but was held out of striking range for 5 sec and then removed. An integumentary trail had been deposited in the large compartment, and a freshly killed mouse was behind the rock. The guillotine door was raised immediately after the live mouse was withdrawn from the small compartment. Dependent variables were the same as those taken after strikes had been delivered.

Each snake was observed in all conditions, but a different random order of trials was used for each snake. Paper floor coverings were removed from the large compartment after each trial and replaced with clean ones.

Snakes were permitted to eat the carcass at the end of the trail upon discovering it. If this carcass was not discovered within 20 min, it was moved by forceps to the snake's mouth and ingestion was permitted. If a snake refused food, the data from that day were discarded, and food was again offered three days later. Trials were resumed seven days after the snake ate. This occurred only three times. No trials were run if a snake exhibited signs of ecdysis, but they were resumed seven days after the first postecdysis feeding. This occurred twice. Hence, each snake ate after each trial from which data are reported, and hunger was thereby maintained at a constant level across the four trials (i.e., snakes were always seven days hungry at the start of a trial).

RESULTS

Since all snakes were observed in all experimental conditions, data were analyzed by repeated-measures analyses of variance (ANOVAs) containing three factors: subjects, conditions, and subjects × conditions (i.e., the appropriate denominator for F ratios testing the main effect of conditions) (Winer, 1971). In most ANOVAs the respective degrees of freedom were 9, 3, and 27, with 3 and 27 being associated with F ratios (Table 1). When subsets of conditions were selected for analysis, the degrees of freedom associated with conditions and subjects × conditions were adjusted accordingly.

Average RTF during baseline observations was 2.7, and the four conditions did not differ ($F < 1$), indicating that snakes were quiescent prior to introducing live mice into the small compartment. Mean RTF during the three strike trials (i.e., from the strike until the trial terminated) was 39.5 and the

TABLE 1. MEANS OF FOUR DEPENDENT VARIABLES IN EACH EXPERIMENTAL CONDITION[a]

Dependent variable	Condition				Average SEM[b]	F 3/27
	No strike, integumentary trail	Strike, urine trail	Strike, water trail	Strike, integumentary trail		
Mean latency to contact trail area (sec)	736.0a	262.4b	288.5b	225.6b	101.1	3.79[c]
Mean % time on trail	1.9a (−1.50)	10.1a (−0.19)	7.7a (−0.57)	33.7b (3.58[c])	6.2	31.30[c]
Mean % tongue flicks on trail	3.8a (−1.37)	12.5a (0.21)	7.4a (−0.71)	35.0b (4.33[c])	5.4	33.50[c]
Mean latency to reach carcass (sec)	976.1a	642.5b	602.7b	485.5c	53.2	3.72[c]

[a] Means within a row bearing the same letter did not differ significantly by post hoc tests (Newman-Keuls). Values in parentheses are single-sample t tests ($df = 9$) comparing tabled mean with expected score of 11.3 (see text).

[b] The Greenhouse-Geisser (1959) test confirmed equality of variances and covariances across experimental conditions for each measure. Hence, average SEMs are representative of standard errors within each condition.

[c] $P < 0.05$.

three types of trials did not differ ($F < 1$). Mean RTF during the no-strike trial was 22.2. After presentation of the mouse, RTFs were higher than the baseline rate ($F = 134.57$, $df = \frac{1}{9}$, $P < 0.05$), and the mean poststrike RTF was significantly higher than the mean RTF after no-strike presentations of mice ($F = 5.39$, $df = \frac{3}{27}$, $P < 0.05$).

The remaining dependent variables are summarized in Table 1. After striking a mouse, snakes typically made contact with the trail area in less than 5 min, and this measure did not vary as a function of type of trail. After no-strike presentations, however, there was a much longer latency to contact the trail. In fact, only four of 10 snakes passed through the guillotine door and contacted the trail area after no-strike presentations, while there was only a single failure to contact the trail in all of the strike conditions combined. Three sign tests compared this aspect of performance after no-strike presentations to that after each of the three strike presentations ($Ps = 0.03$, 0.03, and 0.06). These data plus the RTF data suggest that striking activates searching behavior and that chemical cues in the environment make no additional contribution to this initial aspect of poststrike performance (Golan et al., 1982; Chiszar, 1986).

The remaining rows of Table 1, however, reveal that behavior following initial contact with the trail was strongly influenced by the chemical contents of the trail area. Since no-strike presentations did not inspire sustained searching behavior, the trailing scores were very low in this condition. This result confirms previous findings (Golan et al., 1982; Chiszar et al., 1983), and the no-strike performance will not be discussed further. The only strike condition that resulted in significant trail-following was the one containing an integumentary trail. This can be seen in two ways in the second row of Table 1. First, the mean percent time on trail was significantly higher in the strike-integumentary trail condition than in the other two strike conditions. Second, the *t* tests reported in Table 1 compare the mean percent time on trail with the chance expectation of 11.3%. Since the trail area occupied 11.3% of the floor area in the large compartment, a snake moving randomly in that compartment would be expected to have its head in the trail area about 11.3% of the time. Only in the strike-integumentary trail condition did the mean percent of time on trail exceed 11.3%. The same pattern of results also obtained for the percent tongue-flicks on trail. Indeed, all 10 snakes exhibited trailing behavior by both measures (i.e., scores greater than 11.3%) when an integumentary trail was available; none did so with a water trail, and only one did so with a urine trail.

Not surprisingly, snakes discovered the hidden carcasses more rapidly in the strike-integumentary trail condition than in all other conditions. Indeed, we suspect that the differences seen with this measure would be much larger if a larger apparatus was used for trail-following tests because the probability of a randomly moving snake discovering the carcass by chance would be lower than was the case in our relatively small pen. This would increase the difference between performance in the strike-integumentary trail condition and that seen in the other strike conditions. Nevertheless, a prairie rattlesnake that struck a mouse and found an integumentary trail discovered the hidden carcass in our apparatus in 25% less time than was needed when no trail or a urine trail was available.

DISCUSSION

These results and those of Duvall and Chiszar (1989) indicate that trails made with mouse urine are not used by prairie rattlesnakes in laboratory tests. The active materials seem to be chemicals associated with mouse integument. Since chemicals from many exocrine glands and other sources contribute to skin and fur chemicals, it is premature to speculate about the particular components that rattlesnakes use during trail-following (but see Blake et al., 1983). Furthermore, it is not necessarily the case that endogenously generated compounds are exclusively used, since Melcer and Chiszar (1989) have shown that exog-

enous materials applied to mouse integuments can be detected by rattlesnakes during predatory strikes and remembered for at least 60 min afterwards. Consequently, the most reasonable conclusion at present is that rattlesnakes obtain information from rodent integument. Some integumentary contents are probably deposited (by rodent paws) during locomotion, and rattlesnakes apparently have an ability to detect and follow such trails.

Desert and prairie rodents urinate much less than do laboratory strains of *Mus musculus*. Perhaps rattlesnake attention is focused on nonurinary chemicals because urinary ones are less available and, therefore, less dependable under natural conditions (but see Cushing, 1984).

Acknowledgments—We thank Brian Atkins, Thomas Byers, and Helen Yun for their help in gathering the data, and we thank Paul Weldon for inviting us to present an account of these results at the 1988 meeting of the International Society of Chemical Ecology, Athens, Georgia (June 24–27). The oral presentation was made by Joan Chiszar, and we thank her for stepping in on short notice to solve a problem created by schedule conflicts among the authors.

Abstract—Free-ranging prairie rattlesnakes (*Crotalus viridis viridis*) exhibit lengthy vernal migrations upon emergence from winter hibernation. A series of laboratory experiments was designed to test hypotheses regarding the function and causation of vernal movements. Rattlesnakes obtained from Wyoming and Colorado populations were used. First, we hypothesized that the function of vernal movements is to locate small mammal prey. Second, we predicted that active *C. v. viridis* use prey chemicals, as well as other cues, to decide whether or not rodents are present in an area. Third, we hypothesized that vernally active males would be more responsive to rodent prey and their odors than females, given observed differences in behavior in the field. Fourth, we predicted that rattlesnakes captured in Colorado would be more sensitive to prey odors than those obtained in Wyoming, because of disparate community structure and, hence, small mammal spatial distributions. As expected, snakes exhibited reduced activity, as well as certain other dependent measures reflecting predatory investigation, in arena zones containing either live rodents or their chemicals. However, responses to the latter were reduced in Wyoming rattlesnakes tested with chemicals from deer mice (*Peromyscus maniculatus*), relative to Colorado animals tested with chemicals obtained from house mice (*Mus musculus*). In contrast to patterns observed in nature, males and females exhibited almost no differences in overall responsiveness. Results are discussed in the context of simulation modeling and ongoing studies of prairie rattlesnake behavior.

Key Words—*Crotalus viridis viridis*, rattlesnake, foraging, predation, chemical signals.

INTRODUCTION

Prairie rattlesnakes (*Crotalus viridis viridis*) in southcentral Wyoming exhibit lengthy, straight-line (i.e., fixed angle) vernal migrations (Duvall et al., 1985; King, 1987). Males travel on straighter lines over longer distances than do females (King and Duvall, 1990). This minimizes the likelihood that males and, to a lesser extent, females will cover the same terrain over again, as they search for food and other resources. Prairie rattlesnakes probably are not unique among snakes in these respects (Gibbons and Semlitsch, 1987; Gregory et al., 1987; Macartney et al., 1988).

Field data indicate that the primary function of the vernal phase of the season-long migration among *C. v. viridis* is to find food (Duvall et al., 1985; King, 1987; King and Duvall, 1990). Field experiments corroborate this view (Duvall and Chiszar, 1989; Duvall et al., unpublished data). At our field site in the high desert communities along the Continental Divide of southern Wyoming, *C. v. viridis* eat primarily deer mice (*Peromyscus maniculatus*), the most common small mammal in the area. Deer mouse populations are widely and patchily distributed, and their occurrence is unpredictable from year to year (Duvall et al., 1985; King, 1987). This circumstance poses a significant foraging problem for the rattlesnakes, especially given their brief active or growing season (ca. 95 days/year; King and Duvall, 1990). Males must also search for receptive females as the summer progresses, compounding the importance of their finding food early in the season (King and Duvall, 1990).

We have hypothesized that the survival value of lengthy, straight-line vernal movements lies in the search for spatially unpredictable and widely distributed small mammal prey. In field research conducted from 1982 to 1984, we found that migrating snakes ceased movement upon initial encounters with patches of deer mice (Duvall et al., 1985; King, 1987; King and Duvall, 1990). Moreover, because males face the dual problems of finding food and mates (females concentrate only on the former; King and Duvall, 1990; Trivers, 1972), we have hypothesized that they would be especially responsive to deer mouse patches located in the spring, and relatively more responsive to these rodents and stimuli derived from them than are females. This is because females feed all summer long, while males feed primarily in the first half of the season (King and Duvall, 1990). Males are unresponsive to food and highly responsive to females during the latter half of the summer.

Given the demonstrated importance of the chemical senses to the behavior of snakes and lizards (e.g., Bellairs, 1984; Burghardt, 1970; Halpern and Kubie, 1984), we hypothesized that migrating (= active or locomoting in a lab setting; see below) male more so than female *C. v. viridis* would employ prey chemicals to determine if rodents occur in particular areas. Prairie rattlesnakes that have

located rodent patches in the field exhibit predatory actions ranging from active searching, characterized by reduced locomotory rates and elevated tongue-flicking, to carrion feeding, to sit-and-wait ambushing (Duvall et al., unpublished data; cf., Diller, 1989; Gillingham and Baker, 1981; Gillingham and Clark, 1981; Golan et al., 1982; Hennessy and Owings, 1988). Hence, dependent measures reflecting this variation in predatory response were employed here (see below).

We also compared responses of snakes from different populations. Work by Arnold (1981) and Drummond and Burghardt (1983) has shown that different populations of garter snakes (*Thamnophis* spp.), occupying disparate local selection regimes, exhibit qualitatively different patterns of behavior. Even though we know very little about the behavior of *C. v. viridis* in the spatially homogenous, Pawnee grassland vegetation communities of northeastern Colorado, we attempted to compare snakes from this population with those from the Wyoming site. Differences in key habitat parameters (e.g., summer seasons are about two months longer on the Pawnee grasslands; Martner, 1986) and community structure (e.g., uniform spatial distribution of dominant grasses could in turn lead to a uniform spatial distribution of rodents) between the two sites may have resulted in the evolution of differing patterns of foraging behavior, including functional reasons for vernal migrations and responses to prey chemicals.

The work discussed here was designed to test the following hypotheses: (1) one function of vernal movements of *C. v. viridis* is to find food, as evidenced by reduced activity in and preferences for regions of test arenas containing live prey or certain prey-derived stimuli; (2) prey chemicals alone can signal the presence of rodent prey in a test arena zone to a locomoting *C. v. viridis*; (3) males from the Wyoming site would be more responsive to prey and prey-derived stimuli than are females, when tested in spring and early summer; and (4) subjects drawn from two allopatric populations, occurring in regions with different habitats and communities, would respond differently to chemicals derived from rodents.

METHODS AND MATERIALS

Four experiments are described. The first three were conducted at the University of Wyoming, Laramie, and the fourth at the University of Colorado, Boulder. Although the objectives of the four experiments were similar, different designs were used in the two laboratories. Both general and specific methods sections are presented for experiments 1–3. One comprehensive methods section is given for experiment 4.

General Methods in Wyoming Experiments

Subjects and Maintenance. Twenty-eight *C. v. viridis* were captured as they emerged from hibernation in the spring and were transported immediately to Laramie. Half were males, half were nonpregnant females. [Females eat little or nothing in the seasons they are pregnant and, hence, are not discussed here (see Duvall et al., 1985; Graves et al., 1986).] The dens from which snakes emerged are in the Haystack Mountains of the northeastern Red Desert, along the Continental Divide of southcentral Wyoming. Snakes were housed and maintained between trials in glass aquaria fitted with clean paper flooring, a hide box, a water bowl, and a 100-W heat lamp. All subjects were maintained and tested on a 14:10 light–dark photoperiod. Ambient temperature averaged 23.6°C (range = 19.4–27.8°C) throughout maintenance and experimentation. All three experiments were conducted in late spring and summer.

Deer mice, the preferred prey of snakes at our Wyoming field site (King, 1987), were live-trapped and brought to Laramie both to maintain snakes and to use in experiments. Deer mice were provided commercial wild bird seed mix and water ad libitum. To determine if subjects would be responsive to prey in our protocol, snakes were offered at least one live deer mouse (*Peromyscus maniculatus*) prior to experiments. Snakes that did not readily attack and accept prey, and those shedding, were excluded from the study.

Experimental Design, Testing, and Analytic Procedures. Behavioral tests took place in wooden arenas (240, 76, and 90 cm in length, width, and height, respectively), the floor of which was covered with a fresh piece of Kraft food wrapping paper prior to each trial. The paper on the floor was demarcated with a pen into two equal sized halves (76 × 120 cm). Next, a smaller rectangular area (34.5 × 45 cm) was drawn in the center of the floor of each of the respective halves, in which one white plastic mouse cage (29.5 × 18.5 × 13 cm) was then centered. Depending on the experiment, mouse cages (i.e., prey conditions) contained either (1) clean sawdust shavings, (2) shavings soiled by deer mice for a period of two weeks, or (3) similarly soiled shavings plus two live deer mice. Arena sides containing respective conditions were randomly determined prior to each test trial. Mouse cages were covered with hardware cloth tops and fitted with water bottles. A water bowl for snakes during trials was placed along the midline of arenas.

Trials commenced as individual subjects were lowered by snake hook onto the center of the arena floor. Snakes were then observed during nine, 10-min intervals spread over a period of three days. Observations occurred between 0630 and 0830, 1230 and 1430, and 1800 and 2000 hr, on the first, second, and third days.

Dependent variables quantified during trials included (1) percent time spent on either side of the midline, (2) percent time spent in the rectangular area surrounding respective cages/conditions, divided by percent duration on a par-

ticular side, (3) percent time spent in ambush postures within respective rectangular areas (characterized by snakes lying coiled with the snout oriented towards the stimulus, the neck retracted slightly, and the head lying on the cage; see Reinert et al., 1984), divided by duration in respective rectangular arenas, (4) accumulated tongue-flicks on the respective sides, (5) accumulated mouth gapes on the respective sides (see Graves and Duvall, 1983), (6) accumulated peers (where snakes tilted their heads to inspect cage contents from above) on the respective sides, (7) accumulated nudges (where snakes pushed against the cage with their snout) on the respective sides, and (8) accumulated strikes (where snakes bit at the contents of a cage from above) on the respective sides. All proportional data were arcsin transformed prior to ANOVA.

Experiments 1, 2, and 3 corresponded to a $2 \times 2 \times 9$ (prey conditions by sex of snake by observation trials), mixed repeated measures analysis of variance (ANOVA) design. Therefore, prey conditions were presented to males and females as a simultaneous two-choice discrimination factor.

Experiment 1

We have observed free-ranging *C. v. viridis* investigating rodent burrows in the field with high levels of tongue-flicking, as well as establishing ambush sites in active deer mouse patches where thermal or visual cues derived from prey are not always immediately available (Duvall et al., 1985, unpublished data; King, 1987; cf., Klauber, 1972; Reinert et al., 1984). We hypothesized that snakes rely on the presence of deer mouse odors in an area to make decisions about when to cease migrating and where to search or ambush and that males more than females would prefer to occupy areas containing prey chemicals.

Specific Methods. The 11 males and 11 females used in this experiment were exposed to a 2-cm-deep layer of clean shavings in the bottom of one mouse cage and a layer of soiled deer mouse shavings of similar depth in the other. However, because of ecdysis, only eight males and seven females concluded the experiment and comprised the sample analyzed.

Results. Responses of snakes exposed to cages containing clean and deer mouse shavings are presented in Table 1. No significant main or interaction effects were detected.

Experiment 2

Specific Methods. This study was similar in design and purpose to experiment 1, except that the 2-cm-deep layers of clean or soiled shavings were elevated by a false bottom in mouse cages up to and flush with hardware cloth tops. This allowed snakes to make lingual contact with any prey chemicals in

[b] T_{side} = percent time spent on respective sides of the arena midline; $T_{rectangle}$ = percent time spent in rectangular areas surrounding respective cages/conditions, divided by the percent duration spent on a particular side; T_{ambush} = percent time spent in ambush postures (see text for explanation) within respective rectangular areas, divided by respective $T_{rectangle}$. See text for explanations of all additional dependent measures.

the shavings, presumably facilitating vomeronasal organ (VNO) chemosensory investigation (e.g., Bellairs, 1984). The design employed in experiment 1 could not guarantee this and may have partly resulted in the absence of significant effects. It seemed possible that key prey-derived exudates might be nonvolatile chemicals requiring direct physical contact with the tongue, in order to make their way into the VNO (e.g., Kubie and Halpern, 1978). Twelve males and nine females were used in the experiment.

Results. Descriptive statistics reflecting the responses of snakes to clean versus soiled shavings that were moved by a false bottom up near the tops of cages are presented in Table 2. In contrast to experiment 1, a main effect was detected; both males and females exhibited significantly more time in ambush postures (T_{ambush}) near cages containing soiled as opposed to clean shavings [$F(1, 19) = 4.321$, $P < 0.049$].

Experiment 3

Only one of several dependent measures was significant in experiment 2, and none were in experiment 1. Hence, we must interpret an apparent VNO-mediated T_{ambush} effect cautiously. Although most of the data argue against such a conclusion, it appears that snakes from Wyoming are guided to some extent by prey chemicals. However, since migrating snakes in nature probably detect prey stimuli other than just chemical ones in making decisions about when and where to cease moving and begin to forage (e.g., Hennessy and Owings, 1988), we hypothesized that snakes would be responsive to a more complete configuration of prey stimuli rather than to chemical cues alone. The paucity of major effects in experiments 1 and 2 seems consistent with this observation. Furthermore since *C. v. viridis* at the Wyoming site forage in a community where deer mice are widely distributed and spatially unpredictable, we hypothesized that active rattlesnakes studied in the laboratory would be more responsive to actual mice than any potentially indirect (e.g., chemical) evidence of their physical presence. Again, we also expected greater responsiveness by males.

Specific Methods. Snakes in this experiment also were exposed to two cages, one containing two live deer mice residing on a 2-cm-deep layer of soiled shavings and the other a 2-cm-deep layer of soiled shavings alone. Eleven males and nine females were used in this experiment.

Results. Responses of snakes to cages containing soiled shavings or live deer mice residing on soiled shavings are presented in Table 3. Unlike experiment 1 and 2, the conditions factor resulted in a number of significant main effects. Both males and females spent significantly more time on the side (T_{side}), time in the rectangle ($T_{rectangle}$), T_{ambush}, and exhibited more peering (peers), [$F(1, 18) = 10.033$, $P < 0.005$; $F(1, 18) = 15{,}869$, $P < 0.001$; $F(1, 18) = 13.141$, $P < 0.002$; and $F(1, 18) = 5.952$, $P < 0.024$, respectively] in arena

halves containing caged deer mice. These main effects were paralleled by significant two-way interactions for conditions by trials for T_{side}, $T_{rectangle}$, and T_{ambush} [$F(8, 144) = 2.439$, $P < 0.017$; $F(8, 144) = 2.339$, $P < 0.021$; and $F(8, 144) = 2.258$, $P < 0.026$, respectively], indicating that snakes came to prefer arena zones containing live deer mice as trials progressed. A significant two-way interaction for sex by trials for nudges [$F(8, 144) = 2.464$, $P < 0.016$] indicates that males but not females exhibited a decrease in this action across trials. No additional main or interaction effects were detected.

Experiment 4

Evidence suggests that snakes vary in the extent, duration, directionality, and timing of seasonal patterns of activity (e.g., Gibbons and Semlitsch, 1987; Gregory et al., 1987; Macartney et al., 1988). We have argued that the length, duration, timing, and so forth, of vernal and seasonal movements exhibited by *C. v. viridis* may vary between populations as a function of local community and habitat selection variables (Duvall et al., 1985; King and Duvall, 1990). Individuals residing in the grasslands of northeastern Colorado—where rodents might be expected to be more uniformly distributed than at our Wyoming site, because of a more uniform spatial distribution of locally dominant grasses—might be just as likely to exhibit a random walk while foraging than the lengthy straight-line movements of snakes living in the patchy and unpredictable prey communities characteristic of the Wyoming site. In models where prey resources are widely or patchily distributed, computer simulations of search paths for *C. v. viridis* foragers indicate that the most spatially efficient route is a straight line (Duvall et al., unpublished data). That is, straight line paths give the highest probability of patch location. However, when resource units are more uniformly distributed and closer together, there is no benefit to traveling along straight-line or fixed-angle paths, as opposed to random walks. Hence, it is in the latter type of community that *C. v. viridis* should be expected exclusively to sit and wait in ambush for prey.

What this means in the context of the work discussed here is that Colorado snakes may be more responsive to chemicals derived from potential rodent prey than are Wyoming animals, because waiting in ambush for prey, as opposed to actively searching for them, has a better chance of paying off in a community where prey resources are less widely distributed in space. Accordingly, we hypothesized that when tested in the laboratory, rattlesnakes from the grasslands of northeastern Colorado would be highly responsive to arena zones containing chemicals derived from rodent prey.

Maintenance and Source of Subjects. Five long-term resident *C. v. viridis*, captured in the Pawnee grasslands of northeastern Colorado, comprised the experimental subjects in this study. The experiment was conducted at the Uni-

versity of Colorado, Boulder, and also is discussed by Duvall and Chiszar (1989). These individuals were maintained on a diet of house mice (*Mus musculus*).

Procedures. This experiment was designed to manipulate the presence versus absence of house mouse chemicals in a 3 × 5-m seminatural indoor arena. Sex of snakes was not an independent variable in this experiment. The five snakes studied were individually placed into the enclosure and left there for two weeks. No prey odors were presented during this period. The floor of the arena was covered with a 4-cm-deep layer of dirt and gravel, and large rocks were distributed randomly throughout. A glass water bowl was centrally located. Ambient temperature in the arena was maintained at ca. 26°C by an electric heater and a 12 : 12 light–dark photoperiod was employed. The floor of the arena was marked so that 15, 1 × 1-m square zones could be distinguished. Records of particular squares occupied by snakes were made.

On days 15–20, two steel mouse cages with screen tops were placed into the enclosure. Each cage was placed into a randomly selected square. One of these contained clean shavings, the other shavings that had been soiled by house mice for one week. No mice were present in either container when placed into the arena. Squares occupied by snakes were recorded 10 times a day, for six consecutive days.

During the first two weeks snakes moved more or less randomly in the arena. There was a slight preference for corner squares, but each snake was observed to move throughout the arena and to visit the water bowl and most of the squares. After the third day, the rate of movement declined, but there remained a tendency for the snakes to make excursions through the arena. Since corner squares were preferred, the cages containing shavings were never placed in corners. This was the only restriction on the otherwise random selection of sites for cages.

When the clean and soiled containers were in place (days 15–20), it was observed that snakes initially positioned themselves next to or on top of the container with soiled shavings. This behavior disappeared over succeeding days, so data for days 15–17 and 18–20 were analyzed separately. We tallied all observations during which each snake was in the square containing soiled shavings, clean shavings, and all other squares. These tallies were converted to percents and averaged over the five snakes. Single sample t tests were used to analyze spatial preferences of snakes during days 15–17 and days 18–20.

Results. Descriptive statistics reflecting snakes' spatial preferences are presented in Table 4. An alpha of 0.05 was used as the acceptance level for all significant effects reported for experiment 4. During days 15–17, snakes were found more frequently than expected near the soiled cage [$t(4) = 11.30$], and less frequently than expected near the clean cage [$t(4) = -10.00$] and all other squares [$t(4) = -9.76$]. Since the snakes had a slight preference for corner

TABLE 4. PERCENT ($\bar{X} \pm$ SE) PREFERENCES OF *C. v. viridis* FOR TEST ARENA REGIONS CONTAINING HOUSE MOUSE-SOILED, UNSOILED, OR NO SHAVINGS[a]

	Preference for:		
Days	Soiled squares	Unsoiled squares	All other squares
15–17	70.0 ± 5.6[b] (6.7)	0.7 ± 0.6[b] (6.7)	29.1 ± 5.9[b] (86.7)
18–20	12.9 ± 7.0 (6.7)	4.1 ± 1.5 (6.7)	83.0 ± 12.2 (86.7)

[a] Expected percent spatial preference scores in parentheses. This experiment also is discussed by Duvall and Chiszar (1989).
[b] Deviates significantly from expected. See text for discussions of statistical significance.

squares during days 1–14, it is all the more interesting that soiled shavings located in noncorner squares were successful in attracting snakes during days 15–17. During days 18–20, however, snakes were no longer attracted to the soiled cages. Spatial preferences for clean and all other squares likewise did not differ significantly from expected. Finally, a paired t test revealed a significant reduction in mean percent attendance at the soiled container between days 15–17 and 18–20 [$t(4) = 4.58$].

DISCUSSION

As expected, *C. v. viridis* tested in the laboratory were attentive to prey-derived stimuli, and they reduced activity and came to reside in arena zones containing such cues. In contrast to behavior observed in the field (Duvall and Chiszar, 1989; King and Duvall, 1990), however, there were almost no differences detected between males and females in the laboratory experiments reported here. Whether mediated by chemical or other cues, the results are consistent with the functional hypothesis that the survival value of vernal migrations in nature is to find prey. Although this strictly applies only to the Wyoming snakes, since they had recently emerged from hibernation when tested, we expect the same for northeastern Colorado snakes in nature. In Wyoming, for example, we know that the major alternative functional explanations for vernal movements—finding mates and appropriate microrefugia for ecdysis—do not operate until much later in the season (Duvall et al., 1985; King, 1987; King and Duvall, 1990). Finding prey always precedes mating and almost always precedes shedding at the Wyoming site, even though intermittent but reduced feeding, especially among females, may continue throughout the active season (King and Duvall, 1990). Perhaps the sequence of survival "problem solving" exhibited

by Colorado snakes is similar. However, because of differences in community structure and key habitat variables in Colorado as opposed to Wyoming (e.g., a potentially more uniformly distributed prey base, longer growing seasons), it is possible that the sequence in which snakes confront the problems of finding food, mates, shedding sites, and so forth, may be more variable. The observation by Klauber (1936) that females in eastern Colorado can show annual reproductive cycles, supports the supposition that greater prey availability and increased seasonal warmth occur there (cf., Diller and Wallace, 1984).

Responses to prey chemicals were variable and complex. Preferences of Colorado snakes for arena zones containing house mouse odors were clear and unequivocal, but significance was detected in only one of several dependent measures among the Wyoming snakes exposed to deer mouse chemicals. The tongue–VNO system may have played a role in this effect. Although we do not view the latter as strongly supportive of a major role for deer mouse odors in signaling Wyoming snakes as to the presence or absence of prey in a particular area, those from northeastern Colorado probably do employ rodent chemicals to select foraging or ambushing sites. Field studies of foraging behavior and ecology of *C. v. viridis* occurring in certain portions of northeastern Colorado are needed.

Why are there differences in response to prey chemicals between *C. v. viridis* from northeastern Colorado and those from southcentral Wyoming? Several possible explanations exist. First, the animals studied in Colorado were long-term captives that were maintained on and tested with house mice. Conversely, the Wyoming snakes had just emerged from hibernation and were recently captured prior to experimentation, and they were tested with chemicals from a natural prey type. It is not clear how these factors may have given rise to the disparate results reported here. Second, deer mice on the Wyoming site are true desert rodents, in that they drink little water and urinate rarely, hence the two-week period to develop odorous deer mouse cages employed in the Wyoming experiments. House mice, on the other hand, urinate copiously and may be significantly more odorous than deer mice. Perhaps soiled house mouse cages represented a more potent chemical stimulus. Third, certain procedures differed between the two sets of experiments. For example, test arenas in Colorado were considerably larger than those used in Wyoming. Again it is not clear how this difference may have affected results, but it must be considered. And fourth, the Colorado snakes were maintained on one mouse every two weeks, while the Wyoming animals had not eaten for at least eight months prior to testing.

Another, perhaps more fundamental, factor is the different habitat and community selection regimes the two populations of snakes have encountered in their recent evolutionary histories. As noted above, it is possible that *C. v. viridis* from northeastern Colorado and southcentral Wyoming may be sit-and-

wait versus active foragers to varying extents. Based upon what we know about the two regions, we would predict that the Colorado animals would tend towards the "ambusher" end of a conceptual foraging continuum, with Wyoming snakes tending more towards the other "active, opportunistic forager" end. This is because simulation models indicate that a pure sit-and-wait ambushing foraging strategy among rattlesnakes is viable only when prey units are uniformly distributed and relatively close together (Duvall et al., unpublished data).

Rattlesnakes in Wyoming continue to move and search in the spring until rodents actually are encountered or captured (King and Duvall, 1990). Deer mouse exudates may not provide migrating snakes with sufficient information to make accurate decisions about the likelihood that these rodents are or are not present in an area. Perhaps the situation is different in northeastern Colorado, allowing snakes to select ambush sites that provide a good probability for success, based upon presence of prey chemicals alone. In this context, it is interesting that the preference Colorado snakes exhibited for soiled house mouse cages during days 15–17 disappeared by days 18–20. Although this may have been due to volatilization of important chemicals, the failure to actually capture prey might also have played a role. Perhaps the actual capture of prey determines the choice of foraging or ambushing sites.

Acknowledgments—We thank Charles W. Radcliffe and Alan J. Redder for their assistance in the work reported here. We also thank Paul Weldon for the invitation to present a version of this work at the 1988 ISCE meetings, University of Georgia, Athens. An earlier draft of the manuscript was much improved by the constructive criticisms of Paul Weldon and Jim Dixon. Experiments 1, 2, and 3 were supported by NSF grant RII-8610680. Some data discussed herein also were reported at the Fourth International Symposium on Chemicals Signals in Vertebrates, The University of Oxford, U.K., 1988.

Letter to the Editor

VOMEROLFACTION AND VOMODOR

The major chemical senses of vertebrates are gustation, olfaction, and the sense supported by the vomeronasal system. The vomeronasal system is widespread in the tetrapods, being absent or vestigial only in crocodilians, some arboreal lizards, some aquatic turtles, birds, and adults of aquatic mammals and higher primates (Bertmar, 1981). Oddly, there is no term to denote chemical perception by the vomeronasal sense. At present, one must resort to vomeronasal sense, vomeronasal olfaction, or similar phrases. To distinguish it from the vomeronasal sense, olfaction is sometimes called nasal olfaction. Such terms do not pose a great problem for occasional use, but with the steadily increasing volume of papers on the structure, function, and behavioral roles of the vomeronasal system, especially in mammals and squamate reptiles (see Duvall et al., 1986), a term distinguishing the chemical sense supported by the vomeronasal system from that supported by the olfactory and gustatory systems is needed. Similarly, a term equivalent to odor for the stimuli sensed by the vomeronasal system would be useful.

The vomeronasal sense is similar to olfaction, but its anatomical substrates and sensitivities are distinct (Parsons, 1970, Halpern, 1983). Briefly, the vomeronasal organ has a sensory epithelium that is histologically quite similar to the olfactory epithelium, although there are differences in numbers of bipolar cells, cellular structure (including lack of cilia in bipolar neurons of the vomeronasal epithelium), and binding of cells to monoclonal antibodies against lactoseries carbohydrates (Halpern, 1983; Wang and Halpern, 1980; Mori, 1987). The neural connections also differ. Whereas the olfactory nerves terminate in the primary olfactory bulbs, the vomeronasal nerves terminate in the accessory olfactory bulbs. A further distinction is that the vomeronasal and olfactory systems are most sensitive to substances having different molecular weights and appear to have different behavioral roles (e.g., Cowles and Phelan, 1958; Stoddart, 1980). At least in squamate reptiles, the vomeronasal system can detect volatile substances (Burghardt, 1980), but unlike the primary olfactory organ, it is quite sensitive to compounds of very high molecular weight (Stoddart, 1980, Burghardt et al., 1988). In squamate reptiles, the vomeronasal system detects molecules of high molecular weight, often sampled from substrates; the olfactory system detects mainly volatile airborne substances (Halpern, 1983).

0098-0331/90/0100-0103$06.00/0

Stimuli for the olfactory system are called odors and are usually restricted, in terrestrial animals, to volatile airborne substances (e.g., Geldard, 1972). Olfactory detection of volatiles by squamate reptiles may lead to activation of tongue-flicking to sample compounds of higher molecular weight that may contain greater information content useful in specific identification of the source (Cowles and Phelan, 1958; Duvall, 1981). Thus, the vomeronasal sense is important in precise identification of potential mates and their reproductive condition, potential sexual competitors, kin, prey, and important predators (numerous papers in and cited in Duvall et al., 1986, early papers reviewed by Burghardt, 1970).

It is therefore useful to make a distinction between primary olfaction and vomeronasal olfaction, ideally by a one-word descriptor equivalent to gustation and olfaction. Such a term should readily identify the sensory system in question, as does the simple description of animals unable to detect chemicals by the vomeronasal systems as avomic (Graves and Duvall, 1985). After considering various alternatives, we propose the term vomerolfaction. This term emphasizes the distinctness from olfaction, yet gives recognition to the similarity. To denote the largely nonvolatile chemical stimuli sensed by vomerolfaction, we propose the term vomodor.

INTRODUCTION TO BACTERIAL MOTILITY AND CHEMOTAXIS

MICHAEL D. MANSON

Department of Biology
Texas A&M University
College Station, Texas 77843

(Received February 1, 1989; accepted March 17, 1989)

Abstract—Bacteria swim by rotating semirigid, left-handed helical flagellar filaments; counterclockwise (CCW) rotation produces straight swims, known as "runs," and clockwise (CW) rotation generates abrupt changes in direction, known as "tumbles." As a cell moves through its environment, alternately running and tumbling, it detects spatial gradients of attractants and repellents by making temporal comparisons of their concentration. These chemicals bind to receptors in the cell envelope to modulate the activity of the chemotactic signal transducers, proteins that span the cytoplasmic membrane. Signals generated by the transducers control the motion of the flagella to promote migration up attractant gradients and down repellent gradients. Chemotactic adaptation, accomplished by methylation–demethylation of the transducers, cancels out these signals. Adaptation is an essential component of the "memory" that allows bacteria to use a temporal mechanism to detect spatial gradients. Both signaling and adaptation are mediated by changes in the level of phosphorylation of several cytoplasmic chemotaxis (Che) proteins. The activity of the transducers regulates the rate of autophosphorylation of the CheA protein, which then passes the phosphate on to other proteins. In particular, phosphorylated CheY protein controls the frequency of tumbling because it promotes CW flagellar rotation, and the CheB esterase modulates adaptation because its nonphosphorylated form removes methyl groups from the transducers much more slowly than its phosphorylated form.

Key Words—Flagella, motility, chemical gradients, temporal sensing, bacterial memory, chemoreceptors, signal generation, intracellular signaling, protein phosphorylation, protein methylation, adaptation, Bacterium.

INTRODUCTION

The intent of this article is to provide the nonspecialist with a brief overview of bacterial motility and chemotaxis. The acronyms for the various genes and proteins will be explained as they appear in the text. This field has been the subject of several recent and excellent reviews, to which I direct readers interested in a more detailed treatment (Macnab, 1987a,b; Stewart and Dahlquist, 1987; Adler, 1986; Ordal, 1985; Hazelbauer and Harayama, 1983; Koshland, 1980).

FLAGELLAR ROTATION AND THREE-DIMENSIONAL RANDOM WALK

Bacteria swim by rotating semirigid, helical flagellar filaments. This rotation is driven by a reversible electrostatic motor located at the base of each flagellum. The motors rotate in the plane of the cell envelope; the rotation is bent 90° around the body of the cell through a flexible coupling called the proximal hook. The hook connects the filament to the basal body of the flagellum.

In most bacteria, rotation is powered by an inward current of H^+ ions, which presumably passes through or between flagellar components associated with the cytoplasmic membrane. In some alkalophilic species, rotation is driven by an inward Na^+ current. Under contrived, nonphysiological circumstances, an outward flux of H^+ also causes flagella to turn.

In the enteric bacteria—the exclusive subject of the remainder of this essay—and in many other bacterial groups as well, flagella appear to arise at random sites on the surface of the cell. Evidence indicates that the chemoreceptors of these bacteria are also randomly distributed on the cytoplasmic membrane and are not associated with the flagella in any ordered way. This spatial separation of receptors and flagella requires that the two elements be coupled by a transduction mechanism that transmits information over the dimensions of a bacterial cell (several micrometers).

In the absence of environmental input, cells of *Escherichia coli* move in a three-dimensional random walk. This walk consists of alternating "runs" (periods of one to several seconds in which the cell swims in a continuous path) punctuated by "tumbles" (periods on the order of 0.1 sec when the cell actively, but randomly, changes its heading). During a run, counterclockwise (CCW) rotation of the flagellar motor causes the six to eight left-handed-helical flagellar filaments to coalesce into a bundle that pushes the cell along its path. During a tumble, clockwise (CW) rotation of the flagella causes the bundle to fly apart, leading to rapid reorientation of the cell. Resumption of CCW rotation allows the bundle to reform, and another run ensues.

E. coli cells respond to spatial gradients of attractant by extending the length of a run in the favorable direction—up an attractant gradient or down a repellent gradient. Thus, the primary response to an attractant is suppression of the CW flagellar rotation that generates tumbling, and chemotaxis is effected by altering the steady-state CCW to CW switching probability of the flagellar motor.

SPATIAL GRADIENTS SENSED BY TEMPORAL MECHANISM

Spatial gradients are sensed by comparing chemoeffector concentrations in time as the cell swims. (See the discussion by H.C. Berg, p. 119 in this issue). In effect, cells are able to compare the instantaneous chemoeffector concentration, measured by receptor occupancy, with the concentration over the last few seconds.

In receptors utilizing methyl-accepting chemotaxis proteins (MCPs), more commonly referred to as signal transducers, this "memory" component is the extent of carboxyl methylation of specfic glutamate residues in the cytoplasmic portion of the transmembrane transducer. Occupancy by attractants leads to increased methylation and occupancy by repellents to demethylation relative to the unstimulated level.

Since the methylation reaction is slow relative to ligand binding and dissociation, the degree of methylation reflects the receptor occupancy of the recent past. A transducer that is undermethylated with respect to its ligand occupancy signals the flagella to turn CCW. Conversely, a transducer that is overmethylated with respect to its ligand occupancy signals the flagella to turn CW. A transducer that is in balance generates a level of signal that leads to switching between the CCW and CW states. The level of methylation that creates a balanced situation is low, medium, and high for a repellent-saturated, unstimulated, and attractant-saturated MCP, respectively.

MOLECULAR NATURE OF CHEMORECEPTORS

Bacterial chemoreceptors can be of several types. The periplasmic portions of several of the transducers discussed in the previous section serve as primary receptors. Thus, the Tar (taxis toward aspartate and away from some repellents) protein binds aspartate directly, and the Tsr (taxis toward serine and away from some repellents) protein binds serine. Both of these amino acids are potent attractants for *E. coli*. They may interact with a positively charged "arginine pocket" in their respective transducers (Wolff and Parkinson, 1988; Dahl and Manson, 1989).

Other attractants first interact with substrate-binding proteins, which are

localized in the periplasmic space. The binding of ligand induces a conformational change in these proteins that increases their affinity for a specific signal transducer: Trg (taxis toward ribose and galactose) for the ribose- and galactose-binding proteins, Tap (taxis toward peptides) for the dipeptide-binding protein, and Tar for the maltose-binding protein. The latter transducer is unique in that it has both an amino acid (aspartate) and a protein as excitatory effectors.

Receptors for other attractants are less well characterized. Many sugars are sensed chemotactically by the phosphotransferase system (PTS). Unlike the transducer-mediated responses described above, however, the transport and concomitant phosphorylation of the substrate is essential. The nature of the signal and of the adaptation process during PTS chemotaxis is a matter of active investigation.

Oxygen taxis, also known as aerotaxis, also requires chemical modification of the chemoeffector, since the receptor in this instance appears to be cytochrome oxidase. It is believed that the signal generated by oxygen is an increase in the protonmotive force (PMF), but the manner in which this increase is monitored by the cell, and how it is used to regulate the flagellar switch, is unknown. It has been suggested that PMF taxis, in which the energy level of the cell is sensed, could be the ancestral taxis and thus exhibits the most fundamental mechanism of flagellar control.

The methyl-accepting transducers are involved in the responses to many repellents, but the nature of the stimulation is in general poorly understood and, unlike the situation for attractants, may in some cases be indirect. Weak organic acids seem to exert their effect by permeating the cell membrane in the protonated form, thereby lowering the cytoplasmic pH and affecting the degree of protonation of a critical histidine residue in the signaling region of the transducer.

NATURE OF INTRACELLULAR SIGNAL

Recent work in several laboratories has enormously increased our understanding of the chemotactic signal in bacteria. No detailed information is available about how the receptor and signaling domains of the transducers communicate across the membrane. However, based on the analysis of mutant transducers with locked signal outputs, Ames and Parkinson (1988) have proposed that an alteration in the conformation of the receptor portion of the transducer is transmitted to the signal domain through a membrane-spanning linker region. The resulting change in the conformation of the signal domain is then canceled by increased methylation.

A series of papers from the laboratory of Melvin Simon (Hess et al., 1987;

1988a,b; Oosawa et al., 1988) has demonstrated that the communication between the signaling domain of the transducers and the flagellar switch involves a phosphorylation cascade. The CheA protein (one of six soluble, cytoplasmic proteins required for any chemotaxis) autophosphorylates, using ATP as the phosphate donor. This phosphate is linked to a histidine residue in the N-terminal portion of the protein. The phosphate group can be transferred to the CheY protein. Phosphorylated CheY, in turn, interacts with the switch at the base of the flagellum to initiate CW rotation. The transducers, with the participation of the CheW protein, modulate the rate of CheA autophosphorylation. Mutants lacking any one of the CheA, CheW, or CheY proteins, or all of the major transducers, can rotate their flagella only in the CCW direction, and thus are "smooth swimmers."

The CheZ, CheR, and CheB proteins also play essential roles in signaling and adaptation. CheZ antagonizes the effect of CheY by accelerating the dephosphorylation of CheY, thereby canceling CW input to the flagellar switch. CheZ may also interact directly with the switch to promote CCW rotation, although this interaction has not been established unequivocally. A mutant defective in CheZ function has increased CW rotation of its flagella, and the mutant cells tumble incessantly.

Mutants lacking CheR, the transferase enzyme that adds methyl groups to specific glutamate residues in the cytoplasmic domain of the transducers, are defective in adaptation. Normally, the undermethylated transducers send out a CCW signal, and CheR mutants swim smoothly, but a repellent stimulus initiates an abnormally extended period of tumbling because of nonadapting CW rotation of the flagella. The methyltransferase uses S-adenosylmethionine as a methyl-group donor and seems to operate at a constitutive rate.

Changes in the net level of transducer methylation are generated by controling the activity of the CheB esterase, which removes methyl groups from the glutamyl-methyl esters. The N-terminal region of CheB is a another substrate for phosphorylation by CheA. CheB-phosphate has greatly enhanced esterase activity, which is catalyzed by the C-terminal portion of the protein.

Upon binding an attractant or ligand-associated binding protein, a conformational change initiated in the periplasmic domain of the transducers is propagated through the membrane to the cytoplasmic signaling domain. This attractant-activated state of the signaling domain, perhaps acting together with the CheW protein, inhibits the basal rate of autophosphorylation of CheA that is maintained by the transducers in the absence of external stimuli. The level of CheY phosphate falls rapidly because of the presence of CheZ protein, and the flagellar motors spin CCW. At the same time, however, the level of CheB phosphate also falls, and demethylation of the transducers is reduced. As a consequence, the extent of transducer methylation increases, which in turn

blocks the signal from the transducers that inhibits autophophorylation of Che A. The cell adapts, and its flagella return to the unstimulated pattern of alternating CCW-CW rotation.

Repellents presumably elicit a conformational change in the transducer that stimulates autophosphorylation of CheA, again perhaps with the mediation of CheW. The level of CheY phosphate increases rapidly, and CW rotation of the flagella ensues. At the same time the amount of CheB phosphate also is increased, leading to rapid removal of methyl groups from the transducer, which negates the stimulation of CheA autophosphorylation. Once again, the cell adapts, and the normal pattern of alternating CCW-CW rotation is restored. In general, cells respond to the removal of an attractant as they do to the addition of a repellent and to the removal of a repellent as they would to the addition of an attractant.

Not all aspects of this model have been verified by experiment. However, the scheme provides a good working hypothesis for directing future experiments.

METHYL-ACCEPTING CHEMOTAXIS PROTEINS: TRANSMEMBRANE RECEPTORS IN BACTERIA

Gerald L. Hazelbauer, Biochemistry/Biophysics Program, Washington State University, Pullman, Washington 99164. Methyl-accepting chemotaxis proteins are central components of the extensively studied chemotactic system of the enteric bacteria *Escherichia coli* and *Salmonella typhimurium*. These transmembrane receptor proteins, called transducers, consist of an amino-terminal, extracytoplasmic, ligand-recognition domain and a carboxy-terminal, cytoplasmic, signaling, and adaptation domain, connected by two transmembrane sequences. Adaptation is linked to methylation of specific glutamyl residues in the cytoplasmic domain. The four transducers in *E. coli* exhibit extensive sequence identity in the cytoplasmic domain, consistent with the common functions in sensory signaling and adaptation. Methyl-accepting chemotaxis proteins have been observed in a number of other bacterial species, and this laboratory became interested in their relationship to the transducer proteins in the enterics. Initial studies with antiserum that recognized transducers from *E. coli* indicated that methyl-accepting proteins from *Bacillus subtilis* and *Spirochaeta aurantia* were antigenically related to the enteric proteins. More recent immunoblot studies have identified candidate transducers in a number of eubacterial species. These observations prompted a detailed investigation of methyl-accepting taxis proteins in an archaebacterial species, *Halobacter halobium*. The results revealed that the basic themes observed in the study of methyl-accepting chemotaxis proteins from the enterics persist in this representative of the archaebacteria, although some interesting variations occur.

In collaboration with a number of other research groups, we are currently searching in a number of bacterial species for genes that code for methyl-accepting sensory proteins. A series of oligonucleotide probes, representing regions of conserved sequence among the transducer genes of *E. coli*, are being used to search for complementary sequences in chromosomal DNA or cloned frag-

ments. Promising candidate restriction fragments have been detected in *H. halobium*, *Rhizobium meliloti*, and *Pseudomonas putida*. Cloning and sequencing of the genes contained on these fragments should provide insight into the degree to which the structure of these sensory proteins has been conserved over the evolutionary distances that separate the diversity of bacterial species.

MOTILITY AND CHEMOTAXIS OF AN AQUATIC SPIROCHETE

E.P. Greenberg, Department of Microbiology, University of Iowa, Iowa City, Iowa 52242. *Spirochaeta aurantia* serves as the model for studies of spirochete chemotaxis. The natural habitat of *S. aurantia* is anoxic muds at the bottom of freshwater ponds. Like all spirochetes, *S. aurantia* is a slender helical bacterium possessing flagella enclosed entirely within the periplasmic space. In the case of *S. aurantia*, the flagella operate by working against components of the cell rather than working against the external environment as do the flagella of bacteria other than spirochetes. The unusual motility system of spirochetes allows these organisms to move through viscous gels that immobilize most other bacteria; this is thought to be important to the ecology of these organisms. Attractants for *S. aurantia* are sugars, while primary repellents include acids and alcohols. Because of the unique motility of spirochetes, it has been of interest to compare the mechanism of chemotaxis in *S. aurantia* to the well-characterized mechanism of chemotaxis in *E. coli*. Although many of the components of the motility and chemotaxis machinery are analogous in the two organisms, there appear to be some very interesting differences. In particular, the signals that coordinate motility are postulated to be different. Studies involving automated motion analysis and chemotaxis mutants will be particularly stressed during the talk.

THE ROLE OF BACTERIAL CHEMOTAXIS IN INITIATION OF *Rhizobium*/LEGUME SYMBIOSIS FOR NITROGEN FIXATION

Kostia Bergman, Department of Biology, Northeastern University, Boston, Massachusetts 02115. Many types of bacteria are equipped for chemotaxis, the movement toward or away from specific chemicals. Investigators of this behavior in enteric bacteria have often emphasized its importance as a model for sensory physiology, or even as a model for the central nervous system of higher organisms. Our long-term aim is to extend the powerful methods developed in such work toward an understanding of the role that bacterial chemotaxis has in microbial ecology.

It is now clear that initiation of the *Rhizobium*/legume symbiosis for nitrogen fixation involves the exchange of multiple signals between the host plant

and the microsymbiont. We have demonstrated that motile rhizobia accumulate at localized sites of attractant release on the surface of the plant root. The localized sites are found in the area of the root shown by others to be susceptible to the infection process which initiates symbiotic nitrogen fixation.

Studies with behavioral mutants of the rhizobia demonstrate that this response requires a functional system for the sensory and motor processes of chemotaxis. Furthermore, competition experiments with strains that are isogenic except for known mutations in their chemotaxis system suggest that this behavior has a role in the physiology of the interaction between the two organisms, presumably guiding the bacteria to potential infection sites.

We have used a soft-agar swarm-plate assay to test the attractant activity of purified chemicals and plant root extracts. This assay is made specific by the use of two mutants of *Rhizobium meliloti* strain SU47 that no longer detect any pure substance tested (primarily sugars and amino acids) but still detect the localized-site attractant. Partial purification of active substances has shown that they are related to amino acids and are distinct from the known *nod* gene activators found by other investigators. However, recently Caetano-Anolles et al. (*J. Bacteriol.* 170:3164–3169, 1988) have shown, using capillary assays, that at low concentrations luteolin, a *nod* gene activator, is also an attractant. The possible advantages of such a two-attractant system for fine-tuning the response will be discussed.

AUTOINDUCTION OF BACTERIAL BIOLUMINESCENCE: A MECHANISM FOR ENVIRONMENTAL SENSING

Kenneth H. Nealson[1] *and Reinhardt A. Ronson, Center for Great Lakes Studies, University of Wisconsin–Milwaukee, Milwaukee, Wisconsin 53204.*
Autoinduction is the process that controls enzyme synthesis, and thus total bioluminescence, in marine luminous bacteria. As the bacteria grow, they continuously produce a small autoinducer (AI) molecule, which accumulates in the medium. When AI reaches a critical concentration, it acts as the specific inducer for the bioluminescence (*lux*) system; luminescence is induced by a factor of 100 or more. The autoinduction phenomenon is outwardly similar for several species of marine bacteria but has been carefully characterized only for *Vibrio fischeri*. The AI for *V. fischeri*, [*N*-(3-oxohexanoyl)-3-aminodihydro-2[^{3}H]-furanone] has been isolated, identified, and synthesized. The addition of synthetic AI results in the rapid induction of the *lux* system in mutants lacking AI. Genetic experments have shown that the *lux* regulon from *V. fischeri* consists of seven genes, two of which are regulatory. One of these codes for a protein responsible

[1] Symposium participant.

for AI production, and the other codes for a protein necessary for AI to exert its effect. Taken together, these results can be assembled into a model that predicts that cells maintained at low density will be continuously dark, while those present at higher densities will be subject to autoinduction, and thus be bright. Experiments in chemostats have shown that cells maintained at low density remain dark unless AI is supplied in the medium, indicating that the induction mechanism involves an extracellular phase. This result supports the view that autoinduction acts as a mechanism for environmental sensing.

CELL-CELL INTERACTIONS IN *Myxococcus*

Dale Kaiser,[1] *Lee Kroos, Adam Kuspa, Yvonne Cheng, and Seung Kim, Department of Biochemistry, Stanford University, Stanford, California 94305.* When starved, 10^5 *Myxococcus* cells congregate to form a fruiting body within which some cells become spores. Many new proteins appear during fruiting body development. A transposable promoter probe, Tn*5 lac*, can express beta-galactosidase (BG) if it inserts with its left end downstream of an active promoter. Among 2374 independent insertions of Tn*5 lac* into *Myxococcus*, 37 were identfied that make at least three times more BG after fruiting body development starts than during growth. Each of these transcriptional fusion strains increases BG at a particular time in development, ranging from before aggregation to the time of sporulation. This set of fusion strains serves as an indicator of progress through the developmental program.

How is the time of morphological, biosynthetic, and gene expression events controlled? A set of mutants has been isolated that behave as if they are defective in cellular interactions necessary to development. Sporulation in fruiting bodies is restored to the mutants if they are mixed with developing wild-type cells. "Complementation" experiments with whole cells divide the mutants into four groups (A, B, C, and D). Particular sets of *lac* fusions depend on the normal function of complementation groups. For example, A^- strains containing 18 of the 21 different *lac* fusions tested fail to make BG, while the other three strains continue to make BG. The pattern of dependence of BG expression on the A, B, C, and D complementation groups is consistent with a branched-linear regulatory pathway (L. Kroos and D. Kaiser, *Genes Dev.* 1:840–854, 1987).

A-dependent and C-dependent *lac* fusions are being used to purify the molecules responsible for an early (A) and late (C) developmental signal. In crude extracts of developing wild-type cells, both activities are heat labile and nondialyzable (A. Kuspa et al., *Dev. Biol.* 117:267–276, 1986).

[1] Symposium participant.

ION CHANNELS IN *Paramecium* YEAST, AND *Escherichia coli*

Ching Kung, Laboratory of Molecular Biology and Department of Genetics, University of Wisconsin, Madison, Wisconsin 53706. Animal behavior is largely governed by biological electricity. Ions, the carriers of electric currents, cannot go through the hydrophobic lipid bilayer of the membrane. Instead, they go through a special class of integral membrane proteins called ion channels. Because open channels drain the electrochemical gradients, they are "gated" and only open upon sensing certain environmental signals. Thus, channels are switches that transduce the signals into electric or ionic information within the cells. Of the approximately 60 different ion channels now recognized, some are gated by external ligands, internal messengers, transmembrane voltages, or mechanical forces. Although ion channels have traditionally been studied in higher animals, we have chosen to study the channels in microbes.

Paramecium, the ciliated protozoan, is a giant among microbes and has been investigated with conventional electrophysiological procedures. At least eight electric currents, passing through eight distinct ion channels, can be recognized. Mutants defective in individual currents have been isolated and studied. For example, mutations in seven genes each result in a decrease or the disappearance of Ca^{2+} current. In the case of a group of mutants called *pantophobiacs*, which lack Ca-gated K^+ currents, the molecular defect has now been traced to calmodulin (Schaeffer et al., *Proc. Natl. Acad. Sci. U.S.A.* 84:3931–3935, 1987). *Pantophobiac A*, for example, was found to have a serine-to-phenylalanine substitution at residue 101 of calmodulin.

Smaller microbes now can be studied electrically using the patch-clamp technique. The budding yeast *Saccharomyces cerevisiae* has the ideal size for patch-clamp experiments. Removal of the cell wall with zymolase yields spheroplasts of 5–7 μm in diameter. We found two types of ion-channel activities in yeast. One is a voltage-gated K channel, which has a unitary conductance of 20 picoSiemens (pS). It opens when the membrane depolarizes and passes K^+ specifically. Based on gating mechanism, conductance, ion selectivity, and blocker spectrum, this channel is very similar to the voltage-gated K^+ channels that turn off the action potential in nerves and muscles. The second type of channel we found in yeast is gated by mechanical forces instead of voltages. These channels tend to open when a small suction is applied to the membrane patch. This type of channel has little ion selectivity.

Normal *E. coli* cells are too small even for the patch clamp. However, giant spheroplasts, 5–10 μM in diameter, can be generated for such studies. We found a voltage-gated channel that opens more frequently upon membrane depolarization. It has a unitary conductance of 450 pS and appears to have no ion selectivity. The second channel we encountered is gated both by voltage

and suction. It has a large unit conductance of nearly 1000 pS. It passes inorganic ions as well as organic ions as large as glutamate.

These are the first patch-clamp studies on yeast and *E. coli*. Although the physiological roles of ion channels in these microbes are not yet known, we hope that the combination of biophysical studies and the well-advanced genetics and molecular biology for these organisms will lead to a deeper understanding of the structures, functions, and evolutionary origins of ion channels.

PHYSICAL CONSTRAINTS ON MICROBIAL BEHAVIOR
How You Act if You Are Very Small

HOWARD C. BERG

Department of Cellular & Developmental Biology

(Received February 1, 1989; accepted March 17, 1989)

Abstract—Physical constraints limit the way in which an organism as small as *Escherichia coli* can interact with its surroundings. These constraints are listed, together with references to the relevant literature.

Key Words—Chemotaxis, sensory transduction, diffusion, viscous flow, *Escherichia coli*, Bacterium.

The bacterium *Escherichia coli* is remarkably small, some 10^{-4} cm in diameter. It swims by rotating about six thin helical filaments that arise at random points on its surface. The motor that drives each filament is embedded in the cell wall and the cytoplasmic membrane and is smaller in diameter than the cell by a factor of about 50. In the absence of a stimulus, *E. coli* swims steadily at speeds on the order of 20 diameters per second. It executes a random walk with runs (intervals during which it swims along a gently curved path) of about 1 sec duration and tumbles (intervals during which it moves erratically with little net displacement) of about 0.1 sec duration. During runs, the filaments turn counterclockwise and work coherently in a bundle that pushes the cell forward. During tumbles the filaments turn clockwise and work independently, moving the cell this way and that. When the cell swims in a spatial gradient of a chemical attractant, runs that happen to carry it up the gradient are extended, while those that happen to carry it down the gradient are not. Thus, the cell drifts in a favorable direction by executing a biased random walk. The bias is positive, not negative: the runs get longer, not shorter.

0098-0331/90/0100-0119$06.00/0

Physical constraints influence this sensory strategy in several ways—I quote from a recent survey (Berg, 1988): (1) The flagellar filaments are long, thin, and helical, because motion is dominated by viscous rather than inertial forces: it sounds contradictory, but thrust must be generated by viscous drag. (2) A cell is unable to run in a straight line, because rotational perturbations due to Brownian movement knock it off its path: *E. coli* forgets where it is going in about 10 sec. (3) A cell cannot improve its lot locally by swimming or stirring, because transport of small molecules is effected by diffusion rather than bulk flow: local displacements of the fluid do not increase the cells nutritional intake. (4) A cell must sense a chemical gradient temporally rather than spatially, because comparisons between concentrations in front or behind are overwhelmed by diffusive currents due to its rapid motion. Although the net increase in intake is very small, a cell always absorbs more molecules in front than behind. Therefore, with a spatial mechanism, any new direction is deemed favorable. Finally, (5) the precision with which a cell can make temporal comparisons is limited by statistical fluctuations. The counting statistics improve with the square root of the product of the concentration and the integration time. Therefore, a chemical cannot be sensed at an arbitrarily low concentration, because the integration time required would be prohibitively long.

For a brief review of bacterial chemotaxis with an emphasis on the physiology, see Berg (1988). For a taste of the physics in a back-of-the-envelope style, see Purcell (1977) and Berg (1985). For a more extensive textbook discussion, see Berg (1983). For a rigorous treatment of the counting problem, see Berg and Purcell (1977).

(Received February 1, 1989; accepted March 17, 1989)

Abstract—The flagellate male and female gametes of the aquatic fungus *Allomyces macrogynus* are each attracted to a sexual pheromone produced by the opposite gamete type. The sperm attractant, sirenin, causes chemotaxis to female gametes. Examination of sperm chemotaxis shows that the pheromone influences the frequency of directional changes and the duration of a chemotactic run. Physiological experiments using tertiary amine local anesthetics or calcium chelators such as EGTA demonstrate that sirenin stimulates the influx of calcium ions (Ca^{2+}) into the sperm cytoplasm. Radiological experiments with $^{45}CaCl_2$ have demonstrated this calcium flux directly. Structurally, sirenin is an oxygenated sesquiterpene that consists of a cyclopropyl ring attached onto an isohexenyl side chain. The pheromone displays a threshold concentration for attraction at 10 pM in chemotaxis bioassays. Structure-activity relationships with racemic sirenin and sirenin analogs indicate that biological activity requires a terminal hydroxymethyl group on the side chain. In addition, a hydrophobic group must be present at the other end of the sirenin molecule. Besides sirenin, the sperm cells of *A. macrogynus* produce a female attractant, parisin. While the molecular nature of this attractant is not completely resolved, some general features of the molecule suggest it may be similar structurally to sirenin.

Key Words—*Allomyces macrogynus*, sex pheromones, sesquiterpene, sirenin, parisin, analogs, calcium ions, chemotaxis, fungus.

INTRODUCTION

Overview of the Organism. Chemical communication is an important process in both prokaryotic and unicellular eukaryotic organisms (Taylor and Panasenko, 1984). In the fungi and algae, chemical communication between motile gametes can involve sexual pheromones that are produced to attract mating partners. Although several algal pheromones in the division Phaeophyta have been described (see Maier and Müller, 1986), few sexual pheromones have been discovered in the aquatic fungi (division Chytridiomycota). This paper discusses the sexual pheromones of the aquatic fungus *Allomyces macrogynus* and describes what is known about the chemical composition of these pheromones. For the sperm-attractant sirenin, its possible mode of action will be discussed.

The genus *Allomyces* (class Chytridiomycetes) is a subtropical water mold that grows as a saprophyte on decaying plant and animal matter (Emerson, 1941). In the sexual phase of *A. macrogynus*, multinucleate male and female reproductive structures, called gametangia, are formed at the tips of the growing vegetative hyphae. The two types of gametangia are easily discerned with a dissection or compound microscope. The male gametangia are terminal, orange, and smaller than the subterminal, colorless, female gametangia. Under conditions of nutrient starvation, each female and male gametangium undergoes cytoplasmic cleavage (Sewall and Pommerville, 1987) and differentiates approximately 50 female gametes and 100 sperm. Both types of gametes are uninucleate and swim using a posterior whiplash flagellum (Pommerville and Fuller, 1976). These motile cells also are easily identified with a compound microscope. The sperm cells are orange, highly motile, and about half the size (5 μm) of the colorless, sluggishly motile female gametes. Cell communication is exhibited only during this motile stage in the life cycle. Communication is important for efficient gamete mating and zygote formation (Pommerville, 1982; Pommerville and Fuller, 1976).

Overview of Chemotaxis. The sperm and female gametes of *A. macrogynus* each generate a specific pheromone to attract the opposite gamete type (Pommerville and Olson, 1987a). The effects of the female attractant, sirenin, on the sperm have been intensively studied, and the findings show that the sperm require a sensory system coupled to transduction processes (Carlile and Machlis, 1965a,b; Machlis, 1973; Pommerville, 1977, 1981).

Based on quantitative chemotaxis assays, Machlis (1973) suggested that sperm attraction required a pheromone gradient. However, the nature of the attraction process become clearer when sperm motility was studied by dark-field microscopy (Pommerville, 1978). In brief, sperm motility without sirenin is characterized by short, bending runs. Each run is interrupted by a brief period (<1 sec) when the sperm cell temporarily stops swimming and the cell body

pitches an average angular distance of 60°. Another run then occurs but in the direction determined by the pitch of the cell body (Pommerville, 1978).

Sperm undergoing chemotaxis in a gradient of sirenin (toward female gametes) exhibit longer runs and fewer pitches of the cell body. Furthermore, the addition of sperm to a uniform distribution of attractant results in continuous pitches of the cell body. These findings demonstrate that sirenin influences the frequency of directional changes (chemoklinokinesis) and duration of runs.

In the majority of eukaryotic microbes that exhibit chemotactic or phototactic behavior, the cells can undergo at least a temporary reversal of flagellar beat (backwards swimming). This usually results in negative chemotaxis when sensing potentially harmful compounds. The reversal of flagellar beat is due to the influx of Ca^{2+} (Holwill, 1980; Gibbons, 1982). With *Allomyces*, experimental analysis has shown that sirenin stimulates the influx of calcium ions ($[Ca^{2+}]$) into the sperm cytoplasm (Pommerville, 1981). This finding indicates that pitches of the cell body are due to increased levels of cytosolic Ca^{2+}. Removal of extracellular Ca^{2+} with EGTA results in circular swimming even when sirenin is present (Pommerville, 1981). Thus, the equivalent of flagellar reversal in sperm of *Allomyces* is pitching of the cell body. Once excess Ca^{2+} is sequestered or pumped out of the cell, another run can occur. Thus, the motile cells of *A. macrogynus* can undergo negative chemotaxis (Pommerville and Olson, 1987b), but this requires the cells to undergo several pitches of the cell body to turn around.

When sperm are placed in a solution containing tertiary amine local anesthetics (procaine or tetracaine), the sperm swim in circles without pitches of the cell body (Pommerville, 1981). The addition of sirenin to such a solution of sperm does not change the behavior of the cells. Removal of the anesthetic leads to recovery of normal motility and gamete attraction. These results can be understood based on known actions of procaine and tetracaine. These compounds displace Ca^{2+} from membranes (Low et al., 1979), interfere with normal membrane electrical properties, and act as antagonists to the normal functioning of calcium-binding proteins, such as calmodulin (Volpi et al., 1981). In summary, physiological and pharmacological experiments with chelators and anesthetics suggest indirectly that Ca^{2+} is important to the regulation of sperm chemotaxis in *A. macrogynus*.

Experiments with $^{45}CaCl_2$ have been used to demonstrate directly the influx of Ca^{2+} in *A. macrogynus*. The addition of sperm to a $^{45}CaCl_2$ solution results in the binding of $^{45}Ca^{2+}$ to the exterior of the plasma membrane (Figure 1). After washing these cells in distilled water or initially using lower concentrations of $^{45}CaCl_2$, the levels of radioactivity are reduced (Figure 1b). However, when sirenin is added to a suspension of sperm in a $^{45}CaCl_2$ solution, there is a 2.5-fold increase in radioactivity above that detected before sirenin was added (Figure 1a). The simultaneous addition of sirenin and $^{45}CaCl_2$ to a suspension

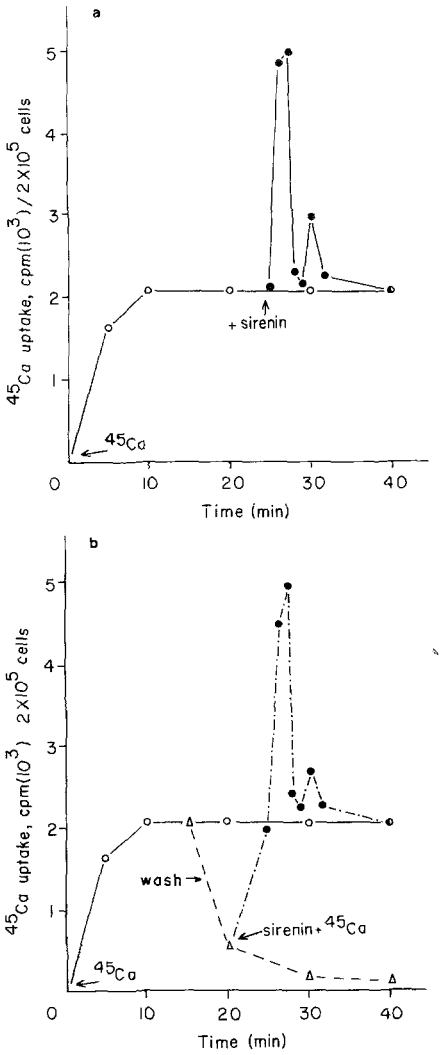

FIG. 1. Measurement of ^{45}Ca activity with and without sirenin addition. (a) Addition of sirenin to sperm incubated in ^{45}Ca resulted in a 2.5-fold increase in cell radioactivity. For these experiments, sperm in Eppendorf tubes were mixed with $^{45}CaCl_2$ in distilled water (○ —— ○) to give 2×10^5 sperm/0.4 ml (5 μM $CaCl_2$). The tubes were incubated for 24 min, at which time sirenin (● —— ●) or distilled water (○ —— ○) was added. At 1-min intervals, the solution from one tube was removed and layered over 12.5% sucrose, centrifuged for 30 sec, and the tube frozen. After a complete set of experiments, the tips of the tubes were cut off and the cell pellets placed in scintillation fluid. (b) Simultaneous addition of sirenin and ^{45}Ca to sperm that had been incubated in ^{45}Ca (○ —— ○) and washed with distilled water (△ -- △) before sirenin/^{45}Ca addition (● - · - ●). Note that addition of sirenin and $^{45}CaCl_2$ to washed cells still stimulated the same level of ^{45}Ca uptake. Radioactivity was determined as described in (a).

of washed gametes also results in a rapid influx of $^{45}Ca^{2+}$ (Figure 1b). When zoospores are substituted for sperm in these experiments, influx of $^{45}Ca^{2+}$ above membrane-bound levels is not detected.

SIRENIN, THE SPERM ATTRACTANT

Machlis et al. (1966) examined the molecular nature of sirenin by producing large quantities of the attractant from pure female strains of *Allomyces*. This provided sufficient material to isolate and purify the pheromone (Machlis et al., 1966), and to determine the structure of sirenin (Machlis et al., 1966, 1968; Nutting et al., 1968).

Sirenin is a sesquiterpenediol (Figure 2) of low molecular weight (236 daltons). Following the synthesis of *dl*-sirenin, a few isomers and analogs were generated (Bhalerao et al., 1970). When these synthetic products were tested for their ability to attract sperm cells (Machlis, 1973), only the synthetic *l*-enantiomer of sirenin was found to be active (Figure 2). The ability to exclude inappropriate synthetic sirenin analogs (the *d*-enantiomer and the *exo*-methyl diastereomer; Figure 2) was shown by their inability to attract sperm in chemotaxis bioassays (Machlis, 1973). When *d*-sirenin was mixed with *l*-sirenin, there was no decline in or interference with chemotaxis. These findings provided the first indirect evidence for pheromone receptors in *Allomyces*.

To understand receptor recognition further, we have synthesized several

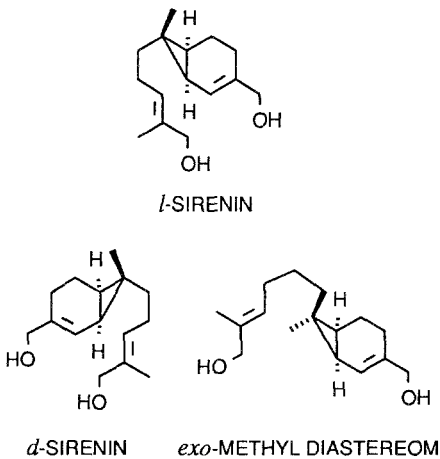

FIG. 2. Structure of *l*-sirenin and two of the analogs tested by Machlis (1973). Both the *d*-enantiomer and the *exo*-methyl diastereomer were inactive in attracting sperm in a chemotaxis bioassay.

active sirenin analogs and tested them for their ability to attract sperm in a bioassay (Pommerville, 1987; Pommerville et al., 1988). The most potent of these compounds is a monohydroxy analog (Figure 3A), which exhibits identical biological activity to the natural pheromone. Sperm respond to the monohydroxy analog and to racemic sirenin with threshold concentrations (i.e., the minimal concentration needed to stimulate male chemotaxis in a bioassay) of 10 pM. The other analogs we synthesized were either inactive or exhibited much higher threshold concentrations (10 μM or higher). However, sperm attraction at these higher analog concentrations still varied with their structural resemblance to sirenin (see Pommerville et al., 1988). Indeed, the benzyl ether of racemic sirenin (Figure 3B), which has a threshold activity of 10 μM, again supports the need for receptor recognition.

Important structure–activity relationships can be discerned by comparing the relatively inactive compounds (Figure 3B–E) with the monohydroxy analog (Figure 3A) and *l*-sirenin (Figure 2). First, the hydroxymethyl group attached on the bicyclic ring of sirenin is not necessary for activity (compare Figure 2 and Figure 3). The monohydroxy analog was as potent as sirenin. Second, replacement of the hydroxymethyl group on the ring with a large hydrophobic group (benzyl ether) reduces activity substantially (Figure 3). Thus, chemotactic activity in the 10 pM range requires a structure having a terminal hydroxy-

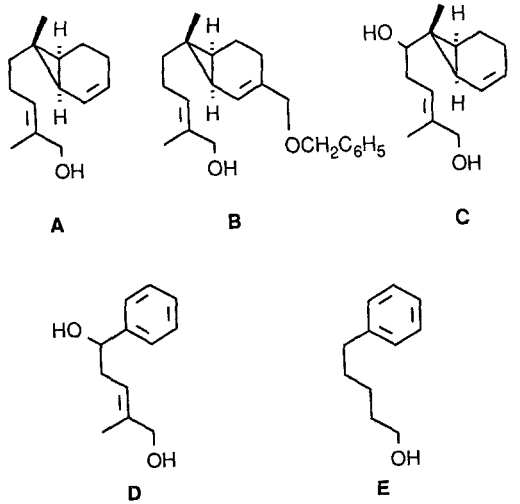

FIG. 3. Structures for several active analogs of sirenin. The monohydroxy analog (A) had a threshold concentration at 10 pM, identical to racemic sirenin. Analogs B–E all had threshold concentrations at 10 μM. See text for details. (Adapted from Pommerville et al., 1988.)

methyl group on the side chain and a large hydrophobic group at the other end of the molecule. Any structural change that leads to improper fit at the receptor's recognition site requires an attractant concentration of at least 10 μM for a chemotactic response—if indeed any response occurs (Pommerville et al., 1988).

Sirenin must bind in a conformation that distinguishes it from the *d*-enantiomer and other analogs. We postulate that when *l*-sirenin is bound, the hydroxymethyl group on the ring is located in a nonspecific hydrophilic region (Figure 4A). Thus, the monohydroxy analog is a potent attractant. *d*-Sirenin lacks activity because its hydroxymethyl group intrudes into a region of the receptor that must be occupied by the hydrophobic ring of *l*-sirenin (Figure 4b).

PARISIN, THE FEMALE ATTRACTANT

When sperm and female gametes are physically separated from one another in a bioassay, the sperm cells attract female gametes (Pommerville, 1977). With the generation of pure male and female strains of *A. macrogynus* (Olson, 1984), parisin can be isolated. A series of general chemical tests have been completed on parisin (Pommerville and Olson, 1987a).

In chemotaxis bioassays, sperm cells or a supernatant solution from these cells stimulated attraction of female gametes. Sperm cells and supernatant were without effect using zoospores in the bioassay (Pommerville and Olson, 1987a). The stability of parisin was examined using chemical tests originally designed to study the stability of sirenin (see Machlis, 1958, for methods). The activity of parisin is maintained after freezing, boiling for 10 min, or autoclaving for 20 min (Pommerville and Olson, 1987a). However, the product of hot acid or alkaline conditions had no chemotactic activity.

Machlis (1958) demonstrated that sirenin could be extracted with ether. Following this protocol, parisin activity also remained associated with the ether fraction (Pommerville and Olson, 1987a). Thus, in these preliminary tests, the pheromone behaves similarly to sirenin.

PERSPECTIVES

The previous research activities point to the next stage in understanding the role of sirenin during chemotaxis in *Allomyces*. It is now possible to determine if pheromone receptors are present on the plasma membrane or in the cytoplasm of the sperm cells. In addition, we can identify the pathway(s) responsible for the influx of $[Ca^{2+}]$ into the sperm cytoplasm.

The studies discussed above demonstrate the ability to synthesize sirenin and a variety of active sirenin analogs. Therefore, we now can measure the

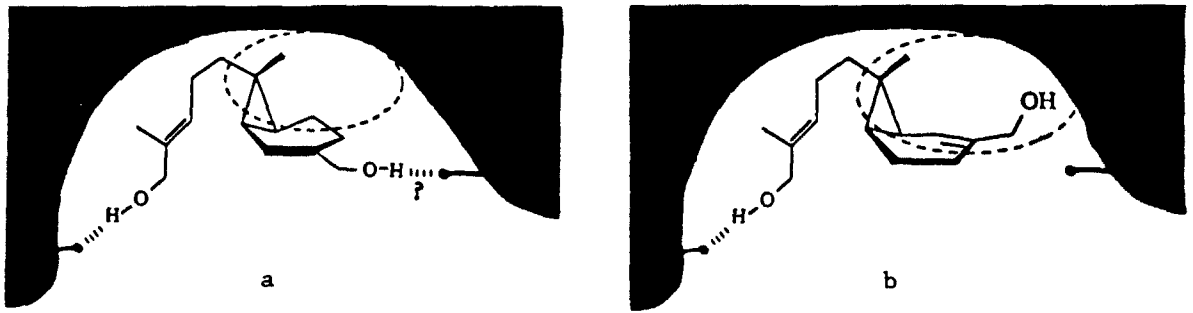

FIG. 4. A hypothetical model for the binding of *l*-sirenin (a) and the absence of binding for *d*-sirenin (b) with a presumptive sperm chemoreceptor. The *l*-enantiomer (a) would bind to the receptor by one or two hydrogen bonds (dashed lines) at the primary alcohol and the ring hydroxymethyl group, respectively. The bicyclic ring lies in a hydrophobic binding site of the receptor (dashed circle). *d*-Sirenin (b) would not bind due to inappropriate stereochemistry of the hydroxymethyl group.

binding of tritiated pheromone ([^{3}H]sirenin) or analogs to potentially small numbers of receptors. By using these radioligands, we can distinguish between actual receptors (specific binding sites) and nonspecific binding sites. In addition, since we have a better idea of the structure–activity relationships for sirenin, photoaffinity labeling can be carried out. Sirenin can be prepared with both a radiolabel and a photosensitive functional group to link covalently pheromone and receptor.

[^{3}H]Sirenin can be used to determine if the attractant enters the sperm cytoplasm. Uptake could involve the intact molecule or a labeled fragment. Absence of cytoplasmic radioactivity would suggest that stimulation of chemotaxis by sirenin requires Ca^{2+} as a second messenger system at the cell surface.

One process resulting from the binding of pheromones, hormones, or neurotransmitters to cell-surface receptors is the transduction of these signals into a change in cellular function or behavior. Ca^{2+} very often acts as a second messenger to transduce these signals (Rasmussen et al., 1985; Carafoli, 1987). How sirenin generates a transient rise in cytoplasmic Ca^{2+} needs to be determined. Because Ca^{2+} most often crosses the plasma membrane through channels, the existence of such channels on the sperm cell surface needs to be examined. Ligand binding to receptors can trigger potential-dependent channels that are responsible for the slow Ca^{2+} current or receptor-operated (mechanical) Ca^{2+} channels (Godfraind, 1985). Calcium and calmodulin antagonists can be used to identify the presence and types of calcium channels in *Allomyces*. Similar procedures have been used with other eukaryotic microbes, including the green alga *Chlamydomonas* and the protozoan *Paramecium* (Nultsch et al., 1986; Ehrlich et al., 1988), for the examination of calcium channels.

Finally, our findings point out some similarities between parisin and sirenin. Studies are in progress to determine the complete structure of parisin and to examine female gamete behavior in the presence of this attractant.

BEHAVIORAL STUDIES INTO THE MECHANISM OF EUKARYOTIC CHEMOTAXIS

DAVID R. SOLL

Department of Biology
University of Iowa
Iowa City, Iowa 52242

(Received February 1, 1989; revised March 17, 1989)

Abstract—Recent behavioral studies designed to elucidate the mechanism of chemotaxis to cAMP in the eukaroyte *Dictyostelium discoideum* are reviewed. In these studies, ambae were analyzed by the newly developed, computer-assisted dynamic morphology system while (1) chemotaxing in a spatial gradient of cAMP, (2) responding to repeated temporal waves of cAMP in the absence of a spatial gradient in a Sykes-Moore chamber, and (3) responding to rapid shifts in cAMP concentration. It is demonstrated that eukaryotic amebae do indeed have the capacity to assess the direction of a temporal gradient, which indicates that they must have a "memory" system for this purpose. It is also demonstrated that amebae regulate behavior in spatial and temporal gradients of chemoattractant through changes in: (1) velocity; (2) frequency of pseudopod formation; and (3) frequency of turning. Analogies to the bacterial system are apparent.

Key Words—Chemotaxis, ameba, *Dictyostelium discoideum*, cAMP, temporal gradient, spatial gradient.

INTRODUCTION

Although the general mechanism of bacterial chemotaxis is reasonably well understood (Berg and Brown, 1972; Koshland, 1980; Boyd and Simon, 1982; Macnab and Koshland, 1972; Brown and Berg, 1974; Springer et al., 1977), the basis for eukaryotic chemotaxis remains elusive. Controversy still exists as to whether ameboid cells, such as those of *Dictyostelium* and polymorphonuclear leukocytes, employ a temporal or spatial mechanism to assess the direction of a spatial gradient of chemoattractant, even though significant progress has been achieved in defining the molecular components involved in sensory trans-

0098-0331/90/0100-0133$06.00/0

duction. Without doubt, one of the major reasons for the slow progress in understanding how ameboid cells assess the direction of a chemical gradient is the prevailing attitude that behavioral studies are usually not definitive proof of mechanism and that all information on mechanism will ultimately emerge from molecular studies. Nothing could be further from the truth. In order to understand how chemotaxis really works in ameboid cells, three types of information must be used: (1) cell behavior; (2) biochemistry of receptors and sensory transduction; and (3) structural alterations in the cytoskeleton during the motile response. Behavioral studies can be designed that provide a very strong indication of mechanism (e.g., Zigmond et al., 1981; Varnum-Finney et al., 1978a,b) and that afford us with predictions concerning the mechanics of the sensory transduction machinery and the role of the cytoskeleton in the motile response (Wessels et al., 1988). In the discussion that follows, recent behavioral studies performed on individual amebae of the slime mold *Dictyostelium discoideum* will be reviewed. The studies demonstrate that amebae can assess the direction of a temporal gradient of chemoattractant in the absence of a spatial gradient and that amebae respond to temporal and spatial gradients of attractant in a fashion similar to bacteria, but substitute pseudopod formation for flagellar rotation in the motile response.

General Features of Aggregation in D. discoideum. When amebae of *D. discoideum* are washed free of nutrients and dispersed on an agar substratum, the cell carpet separates into distinct territories encompassing roughly 10^5 amebae. Within each territory, an alternating pattern of light and dark concentric bands can be visualized. Each light and dark bank originates in the center of the aggregation territory and travels outward to the edge of the territory without a significant change in width. Since band propagation exhibits the characteristics of a nondissipating wave, it is most easily described in wave parameters. The period varies from 10 min during early aggregation to 5 min during late aggregation (Alcantara and Monk, 1974; Durston, 1974). The velocity at which bands move remains constant throughout aggregation but is affected by cell density, varying from 43 μm/min for dense cultures (Gerisch, 1968) to 300 μm/min for cell monolayers (Alcantara and Monk, 1974; Gross et al., 1976). During aggregation, roughly 20 waves are propagated from the center to territory edge (Devreotes, 1982). At the very end of aggregation, cells in a territory separate into streams that channel rapidly into the final cell aggregate.

cAMP Wave. Bonner (1947) first demonstrated that aggregating amebae were attracted to a diffusible molecule emanating from aggregating cells. This "acrasin" was later identified as cAMP (Konijn et al., 1967, 1968). Utilizing a unique isotope dilution–fluorographic technique, Tomchik and Devreotes (1981) visualized waves of cAMP in aggregation territories. The waves were symmetrical and exhibited dimensions similar to those of cell movement bands (Devreotes et al., 1983). The concentration of cAMP in the peak and trough of

an average wave was calculated to be 10^{-6} M and less than 10^{-8} M, respectively.

Three components appear to be necessary for the genesis of cAMP waves (Shaffer, 1962): (1 autonomous secretion of pulses of cAMP from the aggregation center; (2 relay of the cAMP signal by outlying cells in the territory; and (3 degradation of the signal. Autonomous pulsing appears to begin in precocious cells in the population, and these cells have been considered by some investigators to be specialized (Ennis and Sussman, 1958), although evidence has been presented that suggests this is not always the case (Konijn and Raper, 1961). Once a pulse of cAMP is emitted from an aggregation center, a relay system ensures that the wave does not rapidly dissipate. In order to relay, outlying cells emit a signal of cAMP in response to the initial signal (Shaffer, 1975; Ross et al., 1975; Geller and Brenner, 1978; Devreotes et al., 1978), then remain insensitive to further stimulation during a refractory period to ensure that relay occurs only in an outward direction. To remove the signal so that amebae can respond to a new signal, cAMP is rapidly hydrolyzed by a membrane-bound phosphodiesterase (Dicou and Brachet, 1979; Kessin et al., 1979).

Directed Movement and the "Back of the Wave Paradox." An ameba must assess the direction of the aggregation center in order to move towards it in a directed fashion. In an aggregation territory, an ameba first encounters both a positive spatial (in relation to the aggregation territory center) and a positive temporal gradient of cAMP at the front of an outwardly traveling wave (Figure 1). In the positive spatial gradient, the concentration gradient of cAMP across the cell body is higher in the direction towards the aggregation center; in the positive temporal gradient, the concentration of cAMP in the immediate cellular environment increases with time. After the peak of a wave passes, an ameba encounters both a negative spatial and a negative temporal gradient in the back of the wave (Figure 1).

It has been assumed by many that an ameba simply assesses the spatial gradient in the wave in order to move in a directed fashion towards the aggregation center (e.g., Alcantara and Monk, 1974; Gerisch, 1968). Indeed, many of the original assays for chemotaxis employed relatively stable spatial gradients generated in agar substrates. These gradients were nonpulsatile, and groups of cells, when placed on the agar containing a spatial gradient of cAMP, exhibited a positive response in which single cells surged from the group in the direction of increasing concentration (e.g., Konijn et al., 1968; Mato et al., 1975; Varnum and Soll, 1984).

If directed movement is controlled exclusively by assessment of the spatial gradient, a paradox arises. Since it has been demonstrated that cells can change their direction of movement in a matter of seconds when challenged with a localized pulse of cAMP (Futrelle et al., 1982; Swanson and Taylor, 1982), amebae should change direction on average 180° when they experience the

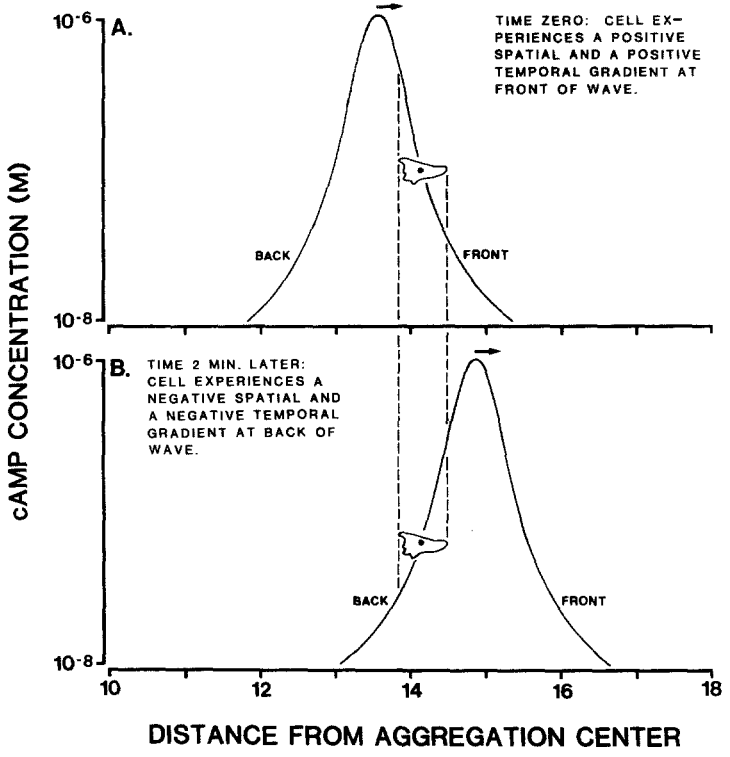

FIG. 1. Diagram of a wave of cAMP passing across a cell in a natural aggregation territory. The peak of the wave has been estimated to be 10^{-6} M cAMP and the trough less than 10^{-8} M. The front of the wave covers 3.5 min and the back 3.5 min. Distance from the aggregation center (source of wave) is in arbitrary units. The arrow at top of the wave indicates the direction of the moving wave. See text for a discussion of the wave paradox.

reversed spatial gradient at the back of the wave. A change in direction would negate net progress towards the aggregation center. They apparently do not. Therefore, a mechanism must exist for the inhibition of turning.

There are at least four possible mechanisms that may play a role in inhibiting turning. First, it is possible that the high concentration of cAMP that cells encounter at the peak of a wave may suppress turning and that a recovery period would be similar in length to the back of the wave. Second, the increasing temporal gradient in the front of the wave may inhibit turning by an adaptation process in which cells adapt through the increasing temporal gradient in the front of the wave but become unresponsive to the decreasing temporal gradient at the back of the wave. Third, the decreasing temporal gradient in the back of

the wave may directly inhibit turning. This mechanism requires that a cell be capable of measuring the direction of a temporal gradient. Unlike the prior alternative, adaptation in the increasing phase is not a component in this mechanism. Finally, the establishment of polarity in a cell during the front of the wave may retard a change in direction during the back of the wave. In the first three alternatives, inhibition could be accomplished by: (1) inhibiting the rate of motility; (2) inhibiting the capacity to read a spatial gradient; (3) decreasing the frequency of turning; or (4) decreasing the degree of turning.

Although it has been convincingly demonstrated that individual *Dictyostelium* amebae can assess the direction of a spatial gradient (Varnum and Soll, 1984), it is not known how they do so. The most obvious mechanism for assessing a spatial gradient would be for the ameba to measure the concentration differential across the entire cell body. This represents a spatial mechanism. However, if one employs the diffusion equation to calculate the concentration differential across a cell body in a Zigmond chamber, the percent difference between the ends of the cell is no more than 1–2%. If a spatial gradient is measured along the length of a pseudopod, the concentration differential would be far smaller.

Alternatively, amebae may assess a spatial gradient by a temporal mechanism comparable to that of a bacterium. By moving through a positive spatial gradient, a cell would experience an increase in attractant with time; by moving through a negative spatial gradient, a cell would experience a decrease in attractant with time. The capacity to assess the direction of a temporal gradient requires that the cell have a form of memory. It must know at any moment whether the concentration of attractant at a previous moment was higher or lower, a comparison which is probably receptor mediated (Green and Newell, 1975; Klein and Juliani, 1977; Zigmond, 1977).

Methods for Analyzing Cell Behavior in Spatial and Temporal Gradients of cAMP. In order to analyze the behavior of individual amebae in relatively stable spatial gradients and in increasing and decreasing temporal gradients of chemoattractant, we employed two chamber systems. The first, originally developed by Zigmond (1977), consists of a Plexiglass bridge bounded by two troughs. Amebae on the bridge or attached to the overlying cover slip experience a spatial gradient that flattens with time. Relatively accurate calculations of concentration at a cell location for a particular time can be made employing the diffusion equation (Varnum and Soll, 1984). The second chamber consists of two glass walls separated by a rubber O ring. In this Sykes-Moore chamber, cells attached to the glass wall are perfused with solution at rates high enough to ensure that cells cannot condition their microenvironment (Herman and Soll, 1984; Staebell and Soll, 1985). This chamber is excellent for generating temporal gradients in the absence of a spatial gradient and for mimicking the temporal dynamics of a natural wave (Varnum et al., 1985).

To monitor the behavior of cells in these chambers, the microscope field is continuously videorecorded. Originally, we analyzed the recordings with a digitizing pad attached to an IBM-PC programmed to calculate several simple parameters of motion. This was an extremely slow process. This process was accelerated at least 20-fold with a SUN II-driven Expertvision System purchased from Motion Analysis Corp. (Santa Rosa, California). This system allowed us to monitor up to 40 cells in parallel for linear velocity, angular velocity, turning, and directionality, with rapid statistical packages for each parameter. However, this system did not provide information on the morphological changes accompanying a cell's behavior. We therefore developed the dynamic morphology system (DMS), which can measure up to 30 parameters of cell movement and shape as frequently as every thirtieth of a second for up to 40 cells (Soll, 1988; Soll et al., 1988a,b). Parameters monitored by DMS include velocity, directional change, turns per unit time, angular velocity, width, length, roundness, polarity of pseudoped formation, frequency of pseudopod formation, expansion area per unit time, contraction area per unit time, concavity, and convexity (Soll et al., 1988a,b).

Constant Concentrations of cAMP Depress Cell Motility. The average rate of motility (measured as linear velocity and averaged over a 21-min period) is similar in buffer solution lacking cAMP and in buffer solution containing cAMP at 10^{-10} and 10^{-8} M, the estimated concentrations at the trough of the natural wave (Varnum and Soll, 1984). However, above 10^{-8} M cAMP, velocity is depressed in a concentration-dependent fashion, reaching a plateau of roughly 35% maximum velocity (measured in buffer alone) at 10^{-5} M cAMP (Figure 2). This response is observed in both a Zigmond chamber and a Sykes-Moore chamber at high perfusion rate. Therefore, no constant concentration of cAMP stimulates motility, and constant concentrations above 10^{-8} M actually depress motility (Varnum and Soll, 1984).

A rapid increase in cAMP concentration depresses motility, increases directional change, and causes disoriented pseudoped formation; this response exhibits adaptation. Shifting the concentration of cAMP from 0 M to concentrations ranging from 10^{-8} to 10^{-6} M in a Sykes-Moore perfusion chamber (shift time 15.8 sec) results in an immediate reduction in velocity (Varnum-Finney et al., 1988; see data for a representative cell in Figure 3A). After shifting from 0 M to either 10^{-8} or 10^{-7} M cAMP, velocity is inhibited, then rebounds, exhibiting a standard adaptation response (Figure 3A). However, a shift from 0 M to 10^{-6} M cAMP (the estimated peak concentration of a natural wave) results in inhibition without adaptation. A shift from 0 M to concentrations ranging from 10^{-8} to 10^{-6} M cAMP also results in: (1) an increase in directional change (Figure 3B); (2) an increase in roundness (Figure 3C); (3) a decrease in length (Figure 3D); and (4) a depression in positive flow (Figure

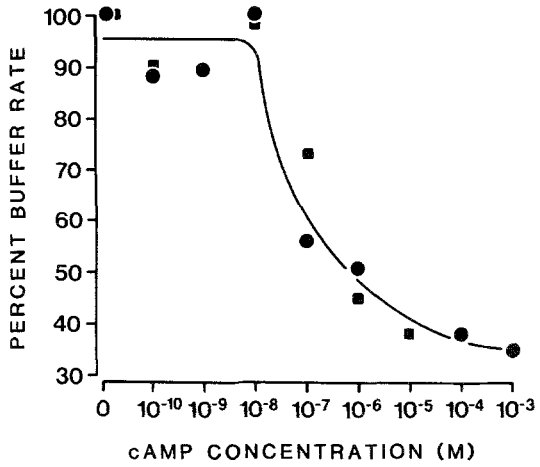

FIG. 2. The average rate of cell motility (presented in percent of the buffer rate) as a function of cAMP concentration. Each point represents the average rate measured over a period of 20 min for 50 cells. The filled circles represent amebae in homogenous solutions of cAMP (nongradient conditions) at the respective concentrations. The filled squares represent amebae in gradients of cAMP. In the latter case, the average concentration of cAMP at the position of the cell body was calculated by the diffusion equation. Details of these measurements are presented in Varnum and Soll (1984).

3F). In the case of a shift to 10^{-8} M cAMP, all parameters return to near-normal after adaptation, but in the case of a shift to 10^{-6} M cAMP, cells continue to exhibit these characteristics in the absence of adaptation. The increase in directional change following a shift reflects a decrease in cellular polarity and an increase in the number of expansion zones (filled areas) and contraction zones (hatched areas) visualized in "difference pictures" (Figure 4). Prior to a shift to 10^{-8} M cAMP (panels 13.17m to 14.67m in Figure 4), cells exhibit an elongate morphology and directional persistence (note direction of vectors). After a shift (panels 15.00m to 18.17m in Figure 4), the cells exhibit disorganized behavior, including the loss of polarity and multiple expansion zones. After adaptation, the cells regain their elongate shape, oriented behavior, and singular optical expansion zone.

It should be noted that most studies into the receptor-mediated effects of cAMP on cellular physiology, relay, and the cytoskeleton follow the general experimental format of a cAMP pulse or shift. However, rapid shifts lead to the inhibition of motility and most probably are never experienced by an ameba in a natural aggregation territory. Indeed, the increase in the cAMP concentration at the front of a natural wave occurs 14 times more slowly than it does

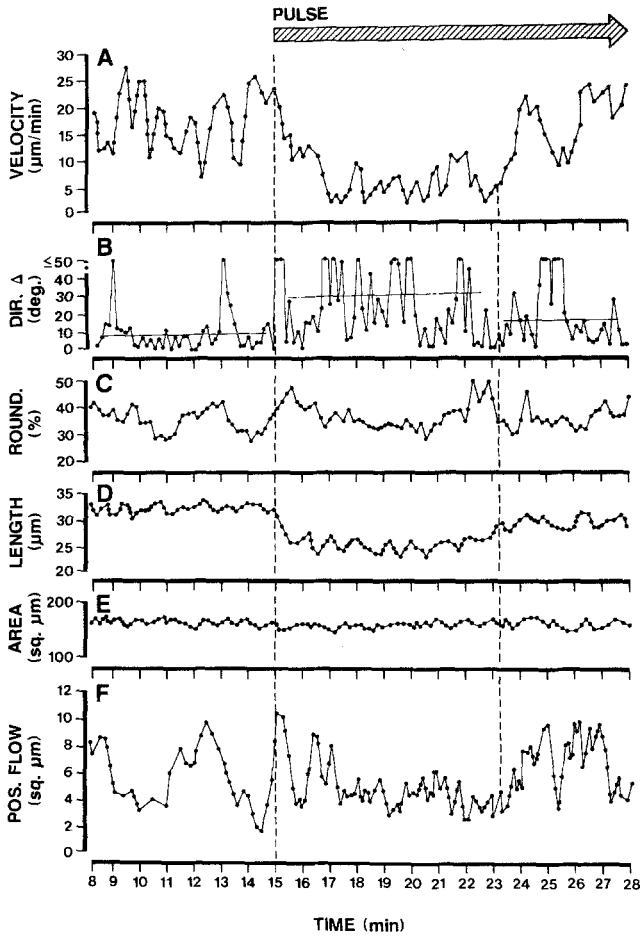

FIG. 3. Parameters monitored by the dynamic morphology system of a cell in a Sykes-Moore chamber perfused for 15 min with buffer lacking cAMP, then for 15 min with buffer containing 10^{-8} M cAMP. (A) velocity, measured as instantaneous velocity; (B) directional change; (C) roundness parameter (a perfect circle provides a roundness parameter of 100% and a straight line a parameter of 0%); (D) length; (E) area; and (F) positive flow (this measurement was assessed by differencing every 5 sec; see legend in Figure 4). Points are plotted for the final 7 min in buffer and initial 13 min after the shift. The first vertical dashed line represents the onset of the shift, and the second vertical dashed line the estimated time of adaptation. The horizontal hatched line at the top of the figure represents the time after shift.

during a shift in a Sykes-Moore chamber and probably two orders of magnitude more slowly than a pulse of cAMP administered to a rotating suspension culture.

Effects on Cell Behavior of Temporal Waves of cAMP that Mimic Temporal Dynamics of Natural Waves. Using a Sykes-Moore perfusion chamber, the temporal dynamics of natural waves can be mimicked in the absence of a spatial gradient (Varnum et al., 1985). The generated gradients are diagramed in Fig. 5E. In Figure 5A–D, the tracks of four individual cells perfused with repeated "temporal waves" of cAMP are presented; in Figure 5E, the interval velocities are presented for a single cell treated with repeated temporal waves. In almost every case, the velocity during the increasing and decreasing phase of the first wave was depressed. However, in subsequent waves, cell motility was stimulated in the increasing phase and dramatically reduced in the decreasing phase (Figure 5E). When a concentration range was selected for which the highest concentration was not inhibitory when constant, the rate of motility was stimulated during the increasing phases of waves 2–4 to levels slightly higher than the basal rate. These results demonstrate: (1) an ameboid cell can assess the direction of a temporal gradient in the absence of a spatial gradient and modify its velocity accordingly; (2) although no constant concentration of cAMP can stimulate motility, an increasing temporal gradient will do so; and (3) a memory system exists that allows a cell to compare the present concentration of an attractant with a prior concentration.

The results presented in Figure 5 suggest that the direction of the temporal gradient at the front and back of a wave regulates the rate of motility and therefore plays a role in the net movement of cells towards the aggregation center. The direction of a temporal gradient may affect pseudopod formation, cell shape, turning, and cell polarity, and in so doing enhances the effect on velocity. The results of studies on pseudopod formation during waves 2, 3, and 4 demonstrate that the direction of a temporal gradient does indeed affect pseudopod extension and turning (Table 1). During the first 35 sec of the increasing portions of waves 2–4, the mean frequency of new pseudopod formation was 15/10 min (± SD 7.6) and the mean frequency of turns resulting from new pseudopod formation was 10/10 min (± SD 7.5); therefore, 67% of new pseudopods resulted in turns. In contrast, during the remaining 17.5 sec of the increasing portion of the wave, the mean frequency of new pseudopod formation was 5.2/10 min (± SD 2.4) and only 15% resulted in turns. During the first 35 sec of the decreasing portion of the wave, mean frequency was 7.5 (± SD 7.0) and only 33% resulted in turns. The frequency and percent turns was roughly unchanged during the last 175 sec of the decreasing portion of the wave. Therefore, during the first

20% of the increasing phase of a temporal wave, the frequency of pseudopod formation and the proportion of pseudopodia that results in turns are high; however, both frequency and turning rapidly decrease and remain low during the last 80% of the increasing phase. During the entire decreasing phase, both the frequency of pseudopod formation and the proportion giving rise to turns remain at an intermediate level, very close to the values observed at a constant concentration of 10^{-8} M cAMP (Table 1).

Behavior of Cells in Spatial Gradients of cAMP. Individual amebae exhibit a strong positive chemotactic response to relatively stable gradients of cAMP generated in a Zigmond chamber. The chemotactic index is maximal when the average concentration at the position of the cell body is 10^{-9}–10^{-8} M cAMP. Gradients that result in average concentrations at the cell body above 10^{-8} M result in reduced chemotactic indices in the chamber. It should be noted that amebae respond maximally to concentrations that approximate the K_D of the high-affinity cAMP-binding site of *D. discoideum* (Green and Newell, 1975). Similar results were obtained in the response of leukocytes to pentapeptide chemoattractants (Zigmond and Sullivan, 1979).

When amebae are migrating towards the source in a gradient of cAMP (high chemotactant index), they move faster, extend pseudopodia at a dramatically reduced frequency, and turn far less often than when migrating away from the source (Figure 6A–C, respectively). For cells oriented at an angle to the source, the same number of pseudopods form in the correct direction (towards the source) as in the incorrect direction (away from the source), but cells more frequently turn in the direction of pseudopods oriented in the correct direction than in the direction of pseudopods oriented in the incorrect direction (Varnum-Finney et al., 1988b). These results suggest that a decision-making mechanism may be localized in the pseudopodial region (anterior half) of polarized cells.

Making Sense of Behavioral Studies. The behavioral studies reviewed in

FIG. 4. Difference pictures generated by the dynamic morphology system of a cell (the one analyzed in Figure 3) in a Sykes-Moores chamber perfused for 15 min in buffer, then 15 min in 10^{-8} M cAMP. In the genesis of each difference picture, the cell outline in the frame noted in the upper left-hand corner of each panel (time in minutes) is superimposed on the cell outline on a frame 10 sec earlier. The expansion zones are filled and the contraction zones hatched. To indicate direction of translocation between frames, an arrow is drawn from the centroid of the earlier frame (large filled circle) through the centroid of the later frame (small filled circle). The shift to 10^{-8} M cAMP begins at 15 min (panel 15.00m) and is noted in subsequent panels by a dashed horizontal line. This particular cell adapted between 23 and 24 min with an increase in velocity (see Figure 3A). This adaptation coincides with an elongation of cell shape (panels 23.67m to 24.17m).

[a] Details of simulated waves are presented in Figure 5. The means were calculated from the combined data from eight independent cells. Data were averaged for the last three of four simulated waves. The significance of the difference between the value for the first 35 sec and the value for the last 175 sec of each parameter was assessed by the *P* value test; NS, not significant. Details are presented in Varnum-Finney et al. (1987b).

this discussion can be separated into two categories: (1) those in which behavior is assessed before and after a single rapid shift in attractant concentration, and (2) those in which different aspects of the natural wave are mimicked. Both are important since they provide information on different aspects of chemotaxis. Rapid shifts have been employed in most analyses of receptors and receptor-mediated changes, including sensory transduction pathways and cytoskeletal changes. It is, therefore, important that we have as detailed a description of the behavioral effects as we do of the physiological effects, since the behavior must

FIG. 5. The behavior of amebae perfused with four temporal waves of cAMP that mimic the temporal dynamics of natural waves in the absence of spatial gradients. (A–D) Tracks of individual amebae during four temporal waves. Centroids of each cell were determined at 21-sec intervals during the increasing (●) and decreasing (○) phase of each wave. Concentric waves are numbered 1–4. The arrows represent the direction of movement. (E) The temporal dynamics of simulated waves 1–4 and the velocity of centroid translocation (calculated for each 21-sec segment of a single cell track) plotted during the increasing (●) and decreasing (○) phases of the four waves. Details of these data are presented in Varnum et al. (1985).

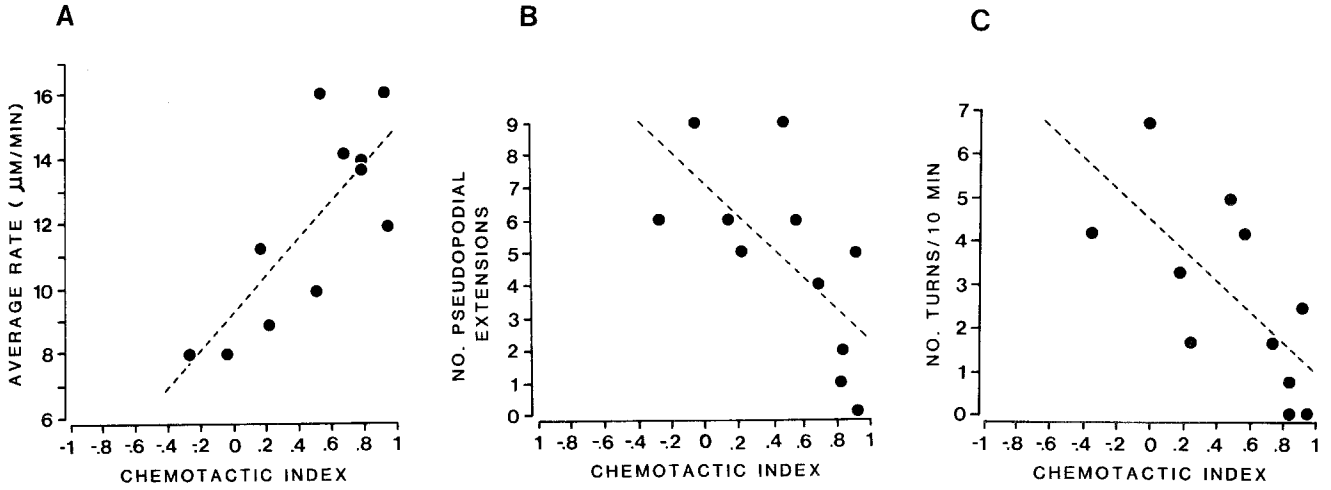

FIG. 6. Velocity (A), frequency of pseudopod formation (B), and frequency of turning (C) as functions of the chemotactic index. (A) The velocity was averaged for each cell over a 12-min period; (B) the number of pseudopodial extensions was measured for each cell for a 12-min period; (C) the number of turns was measured for each cell for a 12-min period. Cells were monitored during a 12-min period in a Zigmond chamber containing 10^{-7} M cAMP in one trough (source) and buffer in the other (sink). Chemotactic index was calculated by dividing directional distance (net distance toward source) by total distance (Varnum and Soll, 1984). Dashed lines represent regression lines calculated for the data of points.

provide a context for interpreting the physiology. Unfortunately, few researchers have attempted to assess physiological parameters in cells that are actively chemotaxing in a spatial gradient of attractant or in cells treated with temporal waves mimicking the temporal dynamics of natural waves. The differences we have demonstrated in the motile response of cells treated with a shift, cells treated with repeating temporal waves, and cells actively assessing a relatively stable spatial gradient argue very strongly for a reassessment of physiological parameters under the latter two sets of conditions.

Perhaps the most important experiments that we have reviewed are those in which the cellular response to repeating temporal waves of cAMP is examined in a Sykes-Moore chamber. These experiments demonstrate that *Dictyostelium* amebae are capable of assessing the direction of a temporal gradient of cAMP and adjusting: (1) the rate of centroid translocation (Varnum et al., 1985); (2) the frequency of pseudopod formation; and (3) the frequency of turning into, or retracting, lateral pseudopods (Varnum-Finney et al., 1987a). It is not clear why cells are not stimulated by the first of four temporal waves. However, it is clear that in the second wave motility is stimulated submaximally during the increasing phase and depressed during the decreasing phase and that in the third and fourth waves motility is stimulated maximally during the increasing phase and in the decreasing phase is depressed to the same extent as in the first wave (Varnum-Finney et al., 1988). The transition from the decreasing to increasing phase of consecutive waves results in a temporary stimulation of pseudopod formation and turning. As the increasing phase continues, both pseudopod formation and turning frequency are suppressed, which facilitates translocation with directional persistance. Extrapolating from the behavior observed in temporal gradients in the Sykes-Moore chamber to behavior expected in a natural wave, one would expect rapid and directionally persistent translocation at the front of the wave and depressed translocation and a higher frequency of turning at the back of the wave. Recent analyses of single cell behavior in natural aggregation territories indicate that this prediction is correct (Wessels and Soll, in preparation).

Temporal wave experiments may explain velocity, pseudopod frequency, turning frequency, and persistence, but they do not necessarily explain how cells orient towards the source of attractant. Experiments in spatial gradients indicate how this is achieved. When a cell is oriented in the wrong direction in a spatial gradient (negative chemotactic index), it moves slowly and exhibits higher frequencies of pseudopod formation and turning than cells oriented in the correct direction (Varnum-Finney et al., 1987b). This mechanism will lead to orientation, since it will trap cells as they orient in the correct direction. These results determine behavior as a function of chemotactic index, but they do not discriminate between temporal and spatial mechanisms. Two sets of observations, however, suggest that a temporal mechanism is functioning in a

spatial gradient. First, a cell oriented at an angle to the source produces pseudopods towards the source as frequently as it does away from the source, but turns two to three times more frequently in the correct direction than in the incorrect direction, suggesting that discrimination of direction is localized in the extending pseudopod at the anterior end of the cell. Second, if one mimics the increasing temporal gradient of cAMP that would be generated by a cell moving towards the source (chemotactic index of +1) in a Zigmond chamber, the frequency of pseudopod formation and the frequency of turning is depressed (Varnum-Finney et al., 1987a). Therefore, an ameba can assess the direction of a temporal gradient generated when it moves in a relatively stable spatial gradient.

We have begun to elucidate a chemoresponse system in eukaryotic amebae that includes a temporal mechanism analogous to that of bacteria for assessing the direction of a temporal change in attractant. Instead of affecting flagellar rotation (Macnab and Koshland, 1972; Berg and Brown, 1972), the motile response of an ameba involves cell polarity, pseudopod formation, turning, and pseudopod retraction. Although the behaviors in amebae are effected through the reorganization of the intracellular cytoskeleton, cytoplasmic flow, and membrane formation, the end results are similar to the bacterial system and no doubt represent the parallel evolution of temporal mechanisms in bacteria and eukaryotes. However, it should be noted that proving amebae have the capacity to assess the direction of a temporal gradient does not prove that this mechanism is uniquely employed in the chemotactic process (Varnum-Finney et al., 1987b). Considering the complexity of the chemotactic responses described in the studies reviewed here, it would not be surprising if both temporal and spatial mechanisms are involved in the chemotactic response of ameboid cells. Further behavioral studies of wild-type and mutant cells (Soll et al., 1988b; Wessels et al., 1988) will be instrumental in describing the mechanisms involved.

SEQUESTRATION OF DISTASTEFUL COMPOUNDS BY SOME PHARMACOPHAGOUS INSECTS

RITSUO NISHIDA and HIROSHI FUKAMI

Pesticide Research Institute
Faculty of Agriculture, Kyoto University
Kyoto 606, Japan

(Received February 1, 1989; accepted March 17, 1989)

Abstract—Several pharmacophagous insects have been shown to sequester specific kairomonal substances or their derivatives in their body tissues. Turnip sawflies, *Athalia rosae*, visit a plant, *Clerodendron trichotomum* (Verbenaceae), and feed voraciously on the leaf surface. Clerodendrins were characterized as the potent phagostimulants for *A. rosae* adults. The insect sequesters some of the analogs and becomes extremely bitter on its body surface. Some chrysomelid leaf beetles associated with cucurbitacins were found to store high concentrations of these bitter principles in their body. South American polyphagous beetles, *Diabrotica speciosa* and *Cerotoma arcuata*, are strongly arrested by root components from the cucurbit plant, *Ceratosanthes hilariana*, and selectively accumulate 23,24-dihydrocucurbitacin D, effectively gaining bitterness. Similarly, four species of Asian pumpkin leaf beetles belonging to the genus *Aulacophora* were shown to sequester the same compound in body tissue as the major bitter principle. Three phenylpropanoids closely related to methyl eugenol were found to accumulate in the rectal glands of the male Oriental fruit fly, *Dacus dorsalis*. One of the rectal gland components, 2-allyl-4,5-dimethoxyphenol was shown to be released in the air during courtship. In all of these cases, selectively sequestered compounds strongly deterred feeding by some predators, thus serving as allomones in this context. Kairomonal and pheromonal functions linked with allomonal sequestration by pharmacophagous feeding has also been suggested.

Key Words—Sequestration, pharmacophagy, kairomone, allomone, *Athalia* spp., *Diabrotica* spp., *Dacus dorsalis*, clerodendrin, cucurbitacin, methyl eugenol.

INTRODUCTION

A number of insects are strongly associated with specific chemicals produced by plants that are not their own host. Strong associations between pyrrolizidine alkaloids and several lepidopterous insects such as danaid butterflies (Meinwald et al., 1969; Boppré et al., 1978; Boppré, 1978) and arctiid moths (Conner et al., 1981; Schneider et al., 1982) have been extensively studied. By sequestering these plant metabolites, the insects gain protection from predators and precursors for the male pheromones (Boppré, 1986). These insects gather the chemicals not from their primary host, but from totally unrelated plants. Boppré (1984) proposed the redefined term "pharmacophagy" for this particular type of insect–plant association. However, very few additional examples of such interactions between insects and foreign plant chemicals have been discovered (Boppré, 1984, 1986; Ferguson and Metcalf, 1985).

We have studied three cases of pharmacophagous associations among important agricultural pest insects, including the turnip sawfly (Hymenoptera) –clerodendrins, dibroticite leaf beetles (Coleoptera) –cucurbitacins, and the Oriental fruit fly (Diptera) –phenylpropanoids (Figure 1). In all of these cases,

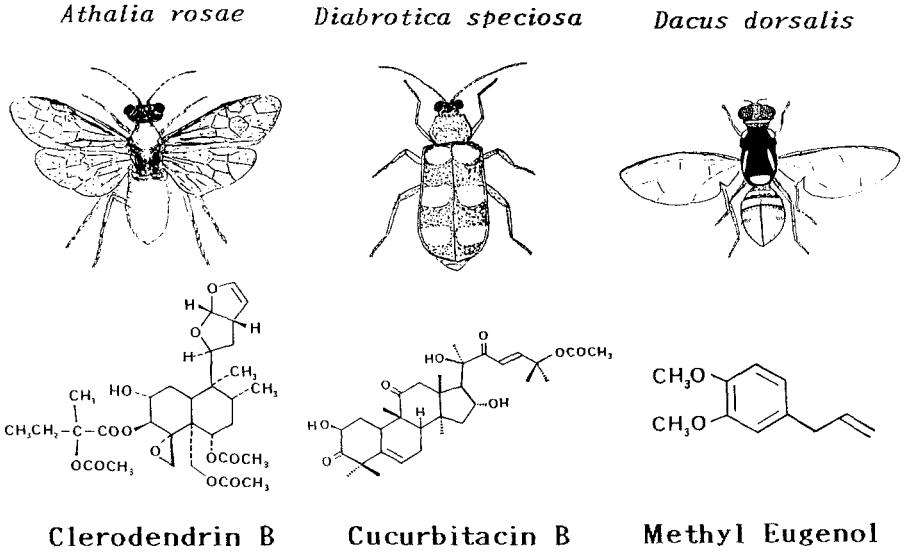

FIG. 1. Pharmacophagous insects and kairomonal substances associated with the insects. Left: A turnip sawfly, *Athalia rosae*, is stimulated to feed on leaves of *Clerodendron trichotomum* in response to the phagostimulant, clerodendrin B. Middle: *Diabrotica speciosa* and other related leaf beetles are stimulated by cucurbitacin B contained in various cucurbit plants. Right: Males of the Oriental fruit fly, *Dacus dorsalis* are attracted to methyl eugenol, and ingest the essential oil.

the insects are strongly stimulated to feed on the kairomonal substances and sequester the specific chemicals (or their derivatives), thereby utilizing them as allomones. Some pheromonal effects linked with pharmacophagous feeding are also suggested in some cases. Here, we describe the identification of the chemicals sequestered by pharmacophagous insects and the ecological significance of these substances.

TURNIP SAWFLY–CLERODENDRIN ASSOCIATION

A turnip saw fly, *Athalia rosae* (*ruficornis*), feeds exclusively on the plant family Cruciferae (Abe, 1988). The larvae infest many kinds of cruciferous vegetables, but the adult insects do not feed on the larval hosts. However, the adult flies frequently visit a shrubby plant, *Clerodendron trichotomum* (Verbenaceae), which is entirely unrelated to their host-plant family Cruciferae (Kitano, 1988). The sawflies eagerly feed on the leaf surface. Both sexes are attracted to the plants, and mating behavior commonly can be seen on the leaves. When the leaf surface was mechanically disturbed, an extremely bitter substance was exuded. The bitter substance appeared to serve as a phagostimulant for *A. rosae*.

Identification of Kairomones from C. trichotomum. The potent feeding stimulants were effectively extracted by quickly rinsing the leaves of *C. trichotomum* with a mixture of acetone and hexane (2 : 1) (Nishida et al., 1989). When the extract was dispensed on a piece of filter paper (8 × 8 mm^2), the sawflies eagerly fed on the surface if contacted with their mouthparts (Figure 2). Using this simple behavioral bioassay, two kairomonal substances, clerodendrin B and D, were characterized (Nishida et al., 1989). Clerodendrin B was previously identified from this plant together with a major component, clerodendrin A, as insect antifeedants (Kato et al., 1971, 1972). Although the plane structure of D is identical to that of ajugapitin (Hernández et al., 1982), the configuration of both D and ajugapitin at the 2-methylbutyryl moiety has yet to be determined (Figure 3). Clerodendrins B and D were strongly stimulating to both sexes of *A. rosae*, but clerodendrin A did not induce any feeding responses from the insects in spite of its predominance in the leaf extracts (Nishida et al., 1989).

Sequestration of Clerodendrins. It was noted that a large portion of the wild *A. rosae* population possesses an extremely bitter taste, while laboratory-reared adults did not taste bitter. The indoor females that were fed with *Clerodendron* leaves quickly gain the bitterness on their body surface. *Clerodendron*-fed sawflies were significantly rejected by a lizard, *Japalura polygonata* (Johki and Nishida, unpublished data). Figure 4 shows the thin-layer chromatograms (TLC) of the extracts from the bodies of *A. rosae* females fed (upper) and not fed (lower) *Clerodendron* leaves for at least three days before extraction and then fed with 10% sucrose solution. The extracts of *Clerodendron*-fed

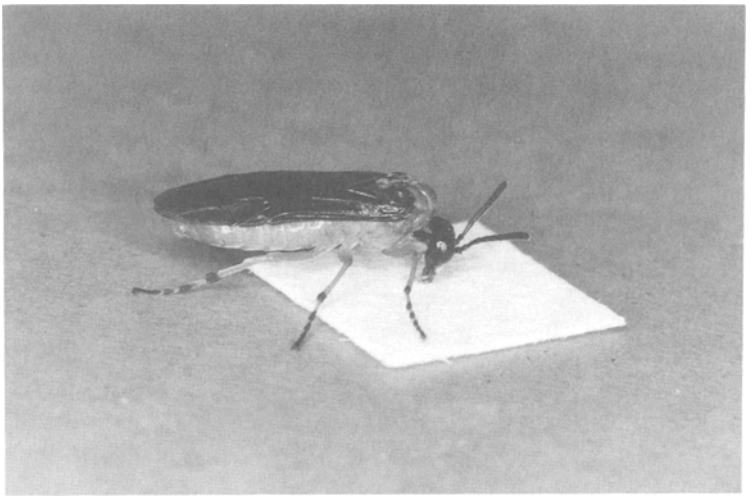

FIG. 2. Feeding test of turnip sawflies to an extract of *Clerodendron trichotomum*. A female insect is feeding on a square piece of filter paper treated with the sample.

females exhibited three clear spots (*Rf* = 0.61, 0.50, and 0.05) which were absent in those of unfed females. All three of these components, purified by HPLC (Nucleosil 100-5, 300 × 8 mm ID, 60% methyl acetate in hexane, 2 ml/min), showed a bitter taste. One of the components (TLC: *Rf* = 0.61) was identified as clerodendrin D from the retention time (*Rt* = 10.6 min) and from its diagnostic mass spectrum (MS: M^+, *m/z* 550) and proton NMR spectrum.

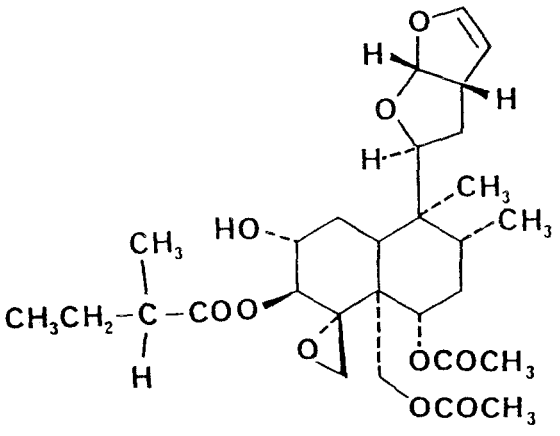

FIG. 3. Structure of clerodendrin D, a bitter substance sequestered by *Athalia rosae*.

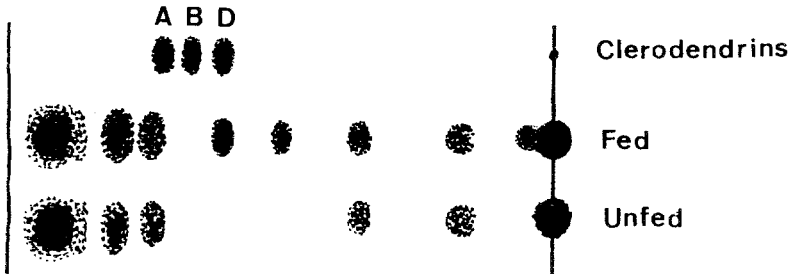

FIG. 4. Thin-layer chromatograms of clerodendrin A, B, and D (upper), body extracts of *Athalia rosae* females that were fed (middle) and not fed (lower) with *Clerodendron* leaves (HPTLC silica gel $60F_{254}$, nano-TLC, Merck, developed with benzene–ethyl acetate, 1 : 1, I_2 coloration).

Two other bitter components also appeared to be clerodendrin analogs (structural elucidations are in progress). The yield of clerodendrin D was estimated to be 8 μg/female. No significant amounts of clerodendrin A or B were present in the extract, even though clerodendrin D is a very minor component in the leaf extract. The external bitterness of *Clerodendron*-fed *A. rosae* bodies implies that a portion of the substances is being deposited on the cuticular surface. Sequestration of these components by the male insects has not yet been confirmed. Clerodendrin D deters birds, and its possible role as allomone will be discussed in the later section. In addition, females that have sequestered clerodendrins become more attractive to the males (Nishida, unpublished data), suggesting some pheromonal function involved in their courtship sequence.

CHRYSOMELID LEAF BEETLES-CUCURBITACIN ASSOCIATION

Many polyphagous chrysomelid leaf beetles (mainly diabroticites) show strong affinity to cucurbit plants that are not their ordinary hosts for the larvae. Curcurbitacins have been shown as the characteristic kairomones for these beetles (Chambliss and Jones, 1966a; Metcalf, 1979, 1986; Nishida et al., 1986). Above all, cucurbitacin B and D are extremely potent stimulants for several diabroticites (Chambliss and Jones, 1966b; Metcalf et al., 1982). These two compounds are present most commonly in various kinds of cucurbit plants and are known to be the source of the bitterness (Lavie and Glotter, 1971; Metcalf, 1979). It has been demonstrated that *Diabrotica* spp. accumulate the bitter principles by feeding on cucurbit plants during adulthood, thus effectively deterring feeding of a mantid (Ferguson and Metcalf, 1985). The fate of cucurbitacins in the bodies of the adult beetles has been examined by artificially feeding them with ^{14}C-labeled curcurbitacin B (Ferguson et al., 1985). The cucurbit plants,

however, contain a complex mixture of cucurbitacin analogs in varying quantity (Lavie and Glotter, 1971). The wild chrysomelid leaf beetles appeared to accumulate only a limited number of analogs, which are not always the major analogs in the plants (Nishida et al., 1990).

Sequestration of Cucurbitacins by Two Brazilian Leaf Beetles. Nishida et al. (1986) identified cucurbitacin B and 23,24-dihydrocucurbitacin B from the root of *Ceratosanthes hilariana* (Cucurbitaceae) as the major feeding stimulants of two Brazilian leaf beetles, *Diabrotica speciosa* and *Cerotoma arcuata*. By feeding the roots, the insects gain bitterness in the body tissue. 23,24-Dihydrocucurbitacin D (Figure 5, MS:$M^+ - H_2O$, *m/z* 500) has been isolated from both species as a major substance causing bitterness (Nishida et al., 1990). The insects were extracted at least two days after compulsive feeding on *C. hilariana* roots. The yields of the compound present in the tissues were as high as 20 μg/insect in *C. arcuata* and 6 μg in *D. speciosa*. The major analogs (cucurbitacin B and D) seemed not to be sequestered in significant quantities in their body tissues. *D. speciosa* was also found to sequester hexanorcucurbitacin D (M^+, *m/z* 402) (Nishida et al. 1990). Although both 23,24-dihyrocucurbitacin D and hexanorcucurbitacin D are known from several curcurbit plants (Lavie and Glotter, 1971; Doskotch and Hufford, 1970), as well as from *C. hilariana* roots as relatively minor constituents (Nishida et al., 1990), it has not yet been demonstrated whether these chemicals are sequestered as a consequence of selective accumulation directly from their food or are metabolities of major cucurbitacins such as B and D.

Sequestration of Cucurbitacins by Asian Leaf Beetles. Similar to North American diabroticites, Asian pumpkin beetles in the genus *Aulacophora* are strongly associated with cucurbit plants. *A. foveicollis* is induced to feed by cucurbitacin E (Sinha and Krishna, 1969, 1970), and *A. coffeae*, *A. femoralis*, and *A. nigripennis* are also phagostimulated by cucurbitacin B and some other

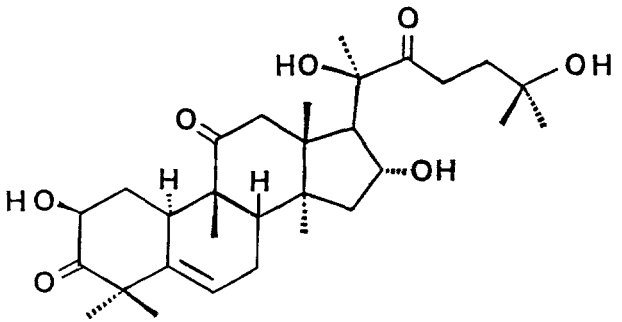

FIG. 5. Structure of 23,24-dihydrocucurbitacin D, a major cucurbitacin analog, sequestered by various chrysomelid leaf beetles associated with cucurbit plants.

analogs (Nishida et al., 1990). All four of these species store 23,24-dihydrocucurbitacin D in significant quantities in the body tissues (e.g., *A. coffeae*: 9 μg/insect; *A. foveicollis*, 3 μg/insect) (Nishida et al., 1990). Several analogs, including cucurbitacin B and D, were detected from overwintering *A. femoralis*, which had not fed at least a month. It is interesting that both the New and Old World leaf beetles are stimulated equally to feed by cucurbitacins (Metcalf, 1979, 1986) and selectively sequester the same compound, 23,24-dihydrocucurbitacin D, because many of the New World diabroticites are now polyphagous, while the Old World species remain oligophagous on Cucurbitaceae (Nishida et al, 1990).

ORIENTAL FRUIT FLY–METHYL EUGENOL ASSOCIATION

The Oriental fruit fly, *Dacus dorsalis*, is a polyphagous tephritid fly, infesting various kinds of fruit in the tropical and subtropical region. Methyl eugenol is known as an extremely potent kairomone for *D. dorsalis* males (Chambers, 1977). The insects are attracted to the chemical source and then feed on the intact chemical. *D. dorsalis* males visit various plants that contain methyl eugenol (Kawano et al., 1968; Shah and Patel, 1975; Fletcher et al., 1975). They probably ingest the essential oil components from the plant source. However, the biological significance of such specific attraction to methyl eugenol for the males has not yet been clarified. We have examined the volatile components in the male *D. dorsalis* body tissue and found that wild males possess varying quantities of two phenylpropanoid analogs, 2-allyl-4,5-dimethoxyphenol and coniferyl alcohol (Figure 6), while laboratory-reared males contain none of these components (Nishida et al., 1988a). *D. dorsalis* males

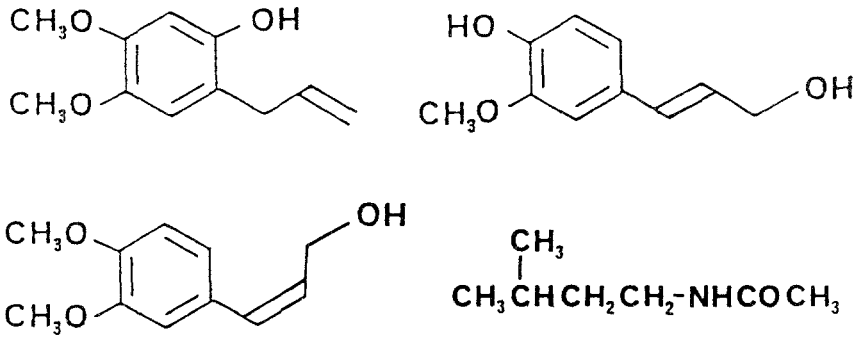

FIG. 6. Volatile components identified from rectal glands of *Dacus dorsalis* males. Upper left: 2-allyl-4,5-dimethoxyphenol. Upper right: coniferyl alcohol. Lower left: *cis*-3,4-dimethoxycinnamyl alcohol. Lower right: 3-methybutyl acetamide.

were shown to consume methyl eugenol in a short period and to convert this compound to these two components in their body tissue. Dissection of the male insect revealed that a large portion of the metabolites accumulated in the rectal glands, as much as 10 μg per gland. Males dissected within a few days after ingesting methyl eugenol also contained *cis*-3,4-dimethoxycinnamyl alcohol as a minor ingredient in the rectal glands (Figure 6). Besides these phenylpropanoids, 3-methylbutyl acetamide was also detected from the gland extracts of *D. dorsalis* males regardless of whether or not they fed on methyl eugenol (Nishida et al., 1988b). The gland complex of the male rectal sac has been suspected as the source of an olfactory pheromone (Kobayashi et al., 1978). *D. dorsalis* males produce a smokelike substance from the rectal glands, which has been shown to be attractive to virgin females (Ohinata et al., 1982). The volatiles from a chamber containing *D. dorsalis* males that had been fed methyl eugenol were collected on a short column of porapak-Q. The trap was replaced every 2 hr from noon until midnight. 2-Allyl-4,5-dimethoxyphenol was recovered from the aeration extract only during the time around sunset (1700–1900 hr), which coincides with the period when *D. dorsalis* males congregate and attract females (Figure 7). This evidence suggests a possible role of methyl eugenol as a pher-

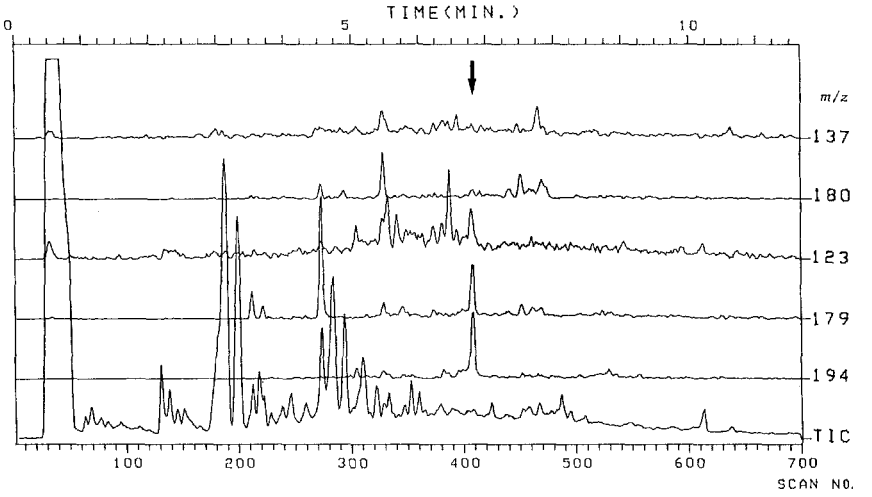

FIG. 7. Mass fragmentogram of an aeration extract in Porapak Q of *Dacus dorsalis* fed methyl eugenol around sunset (1700–1900 hr). This chromatography was done on a 23-m × 0.25-mm fused silica capillary coated with cross-linked-bonded methyl silicon (0V-101), 0.25 μm thick, programmed from 80°C (2 min holding) to 240°C at a rate of 10°C/min. The 70 eV spectra were used to plot *m/z* 194, 179, and 123 for 2-allyl-4,5-dimethoxyphenol, and *m/z* 180 and 137 for coniferyl alcohol. 2-Allyl-4,5-dimethoxyphenol is observed at a retention time of 6.8 min (scan number 409).

omone precursor in a courtship behavior, including male-to-male interaction. 2-Allyl-4,5-dimethoxyphenol also was found to attract male flies as potently as methyl eugenol in the field (Nishida et al., 1988a). Further behavioral study is needed to clarify the pheromonal function of the phenylpropanoids together with other ingredients found in the rectal secretions.

DETERRENT EFFECTS OF SEQUESTERED COMPOUNDS AGAINST PREDATORS

Preliminary observation suggested that *Athalia rosae* that had been fed with *Clerodendron* leaves taste extremely bitter and deter feeding of lizards (Johki and Nishida, unpublished data). The deterrent effect of clerodendrins to Japanese tree sparrows, *Passer montunus saturatus*, was tested as follows. Two square plates (16 × 16 cm) were placed next to each other in an outdoor bird-feeding arena in Kyoto City (Figure 8). Thirty rice grains treated with the test samples were placed in one plate, and 30 untreated grains were placed in the other plate. The activity was evaluated from the number of grains left from the initial 30 grains after exposure to sparrow feeding. Both clerodendrin B and D strongly deterred feeding of sparrows at 2 μg/grain (Table 1). Since the con-

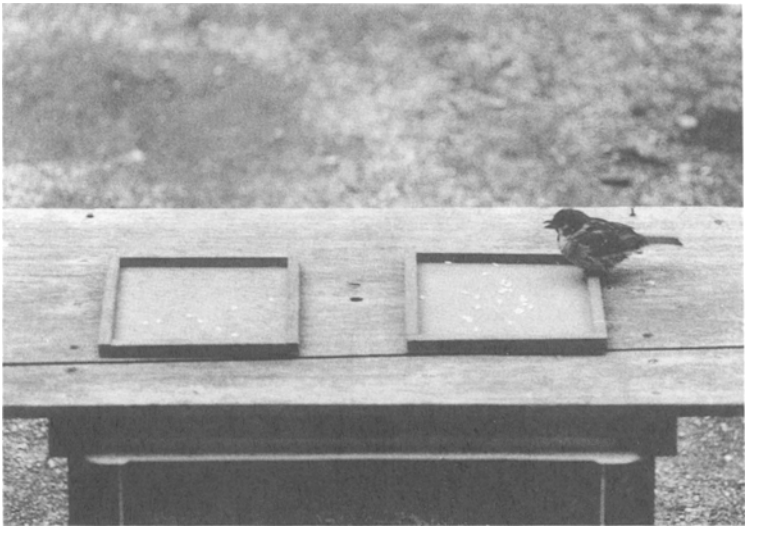

FIG. 8. Feeding deterrence bioassay of compounds sequestered by pharmacophagous insects against Japanese tree sparrows. Each tray contains 30 grains untreated (left) and treated with compounds (right). The number of grains remaining from the initial 30 grains was counted after exposure to sparrows.

TABLE 1. DETERRENT EFFECTS OF PLANT-DERIVED COMPOUNDS AGAINST SPARROWS IN RICE GRAIN FEEDING TEST

Sample	Effective dose (μg/grain)[a]
Clerodendrin B	2
Clerodendrin D	2
Cucurbitacin B	1
23,24-Dihydrocucurbitacin D	10
Hexanorcucurbitacin D	10
Methyl eugenol	10
2-Allyl-4,5-dimethoxyphenol	3
Coniferyl alcohol	>30

[a] Actual feeding counts and statistical comparisons for cucurbitacins and phenylpropanoids are given in Nishida et al., 1990 and 1988a, respectively.

centration of clerodendrins in female body tissue was found to be as high as 10 μg/insect and a portion appeared to be deposited on the cuticular surface, clerodendrins could effectively serve as a gustatory allomone.

The effective doses of cucurbitacin analogs sequestered by chrysomelid leaf beetles were determined similarly (Nishida et al., 1990). 23,24-Dihydrocucurbitacin, which is commonly sequestered by various kinds of beetles, was clearly rejected by sparrows. Cucurbitacin B, however, was shown to be the most deterrent, although it was detected only from *Aulacophora femoralis* in a relatively minor quantity (approximately 2 μg/insect).

In contrast to bitter clerodendrins and cucurbitacins, phenylpropanoid analogs found in the Oriental fruit fly do not taste bitter to humans. However, a significant deterrent activity against sparrows was observed for 2-allyl-4,5-dimethoxphenol at low levels. Conversion of methyl eugenol to more active oxidized forms might be adaptive in this insect. Strong rejection of methyl eugenol-fed *D. dorsalis* males by spiders and gekkoes also suggests a more general defensive role of the phenylpropanoids in the natural environment (K.H. Tan, personal communication).

DISCUSSION

Plants produce a wide variety of secondary metabolites to cope with various kinds of herbivorous attacks. Clerodane diterpenes have been shown to be potent antifeedands against several noctuid species (Kato et al., 1972; Kubo et al., 1976; Gueskens et al., 1983; Belles et al., 1985; Blarney et al., 1988), and

the triterpene cucurbitacins also act as deterrents against mites (DaCosta and Jones, 1971) and a chrysomelid beetle (Nielson et al., 1977). Some insects have not only overcome such chemical barriers after a long evolutionary history but also have developed the ability to sequester allomonal components originating from their specific host plants (Blum, 1981). In particular cases, a group of insects obtain nutrients from their host plants during larval stages and seek additional chemical substances from plants to protect themselves from predators during the adult stage. Here we have demonstrated three different cases of so-called pharmacophagous interactions. These insects are strongly attracted to the plant sources and gregariously engaged in feeding on the kairomones. Methyl eugenol is a potent attractant as well as a potent feeding stimulant for the Oriental fruit fly; however, clerodendrins and cucurbitacins are not likely to serve as airborne attractants because of their almost nonvolatile nature. They seem to act as feeding stimulants through the specific contact chemoreceptors located on the mouthparts of these insects (Metcalf, 1979). Pyrrolizidine alkaloids are also large molecules but apparently seem to attract a pharmacophagous moth species from distance (Boppré, 1986). The mechanisms of long-range attractions remain to be clarified.

It has been demonstrated that most of the chemicals sequestered by pharmacophagous insects are distasteful to sparrows. These "bitter" principles seem to act as defense substances against a wide variety of predatory animals, since some reptiles and spiders also rejected intact bodies of *Athalia rosae* fed with the *Clerodendron* plant and *Dacus dorsalis* fed with methyl eugenol. Ferguson and Metcalf (1985) have shown that the praying mantis, *Tenodera aridifolia sinensis*, rejects *Diabrotica* leaf beetles fed with bitter cucurbit fruits. However, some vertebrate predators obviously eat such bitter insects (Gould and Massay, 1984). Further work will be needed in order to know the "predatory spectrum" and allomonal mode of action of individual chemicals in their natural habitat.

The gregarious behavior of these pharmacophagous insects could be to effectively enhance their aposematic appearance against certain predators (Sillén-Tullberg, 1988) and could simultaneously serve as visual cues to congregate conspecifics. Three closely related turnip sawfly species, namely, *Athalia rosae*, *A. lugens infumata*, and *A. japonica* all look similar in that they each possesses orange-colored abdomens. All of these species are sympatric and feed together on *Clerodendron* leaves. They are regarded as Müllerian mimics. The plant seems to provide not only a chemical source, but also a rendezvous site for the sawflies, as mating behavior can be very frequently seen on the leaves (Kitano, 1988). Many cucurbitacin-associated chrysomelids also exhibit warning color patterns, some of the species resembling the color pattern of the turnip sawflies: black wings and a bright orange body. They also may be regarded as Müllerian mimics. Cucurbitacins and clerodendrins have been characterized as bitter principles in plants (David and Vallance 1955; Duncan et al., 1968; Lavie and

Glotter, 1971; Kato et al., 1971). In contrast, 2-allyl-4,5-dimethoxyphenol and coniferyl alcohol did not taste bitter to humans, although the former compound does repel sparrows. The male Oriental fruit flies seem to be chemically protected by foraging on methyl eugenol containing plants such as *Ocimum sanctum* (Labiatae), *Cassia fistula* (Leguminosae), and *Zieria smitii* (Rutaceae) (Shah and Patel, 1975; Kawano et al., 1968; Fletcher et al., 1975). The color pattern of the female fruit fly bodies is nearly the same as that of the male. It is postulated that females can be also protected if a large portion of the male population is unpalatable (automimicry, see Brower, 1969).

It has been suggested that the sequestered chemicals could trigger precopulatory behavior in the case of *Athalia rosae* and *Dacus dorsalis*. Similar relationships can be seen in danaid butterflies, in which the males utilize pyrrolizidine alkaloids as sex pheromone precursors (Boppré, 1978). Conner et al. (1981) suggested that hydroxydanaidal, accumulated in the coremata of a arctiid moth, *Utetheisa ornatorix*, might provide the means whereby the females assess the alkaloid content of the male and therefore his degree of chemical protection, in addition to its initial behavioral function as sex phermone. Males of the Oriental fruit moth, *Grapholitha molesta*, also have the ability to accumulate an additional quantity of one of the hairpencil pheromone components, ethyl *trans*-cinnamate, from their adult food, although it is uncertain whether the phenylpropanoid ester can serve as a defensive substance (Nishida et al., 1985). It would be of great interest to study further the pharmacophagous insects, because their apparently purposeless behavior might be explained by ecological adaptation mechanisms.

Acknowledgments—We thank Dr. M. Takeda and Mr. T. Miyata of Kobe University for a study on the turnip sawfly–clerodendrin associations, Drs. B.P. Magalhães and M. Yokoyama of National Research Center for Rice and Beans (EMBRAPA/CNPAF, Brazil) for a study on chrysomelid leaf beetles–cucurbitacin associations, and Dr. K.H. Tan and Mr. M. Serit of Universiti Sains Malaysia for a study on fruit fly–methyl eugenol associations. We are also grateful to Professor M.S. Blum of the University of Georgia for reviewing our manuscript.

LEPIDOPTERA AND PYRROLIZIDINE ALKALOIDS
Exemplification of Complexity in Chemical Ecology[1]

MICHAEL BOPPRÉ

Forstzoologisches Institut der Universität Freiburg

(Received February 1, 1989; accepted March 17, 1989)

Abstract—Pyrrolizidine alkaloids (PAs) are defensive secondary metabolites found in numerous plant groups. Various insects belonging to different orders have special requirements for these compounds and sequester them from such plants for their own defense and often as pheromone precursors. The fitness of these insects depends on PAs and, in some cases, PAs even act as regulators of androconial organ development. This article discusses selected behavioral, chemical, physiological, and phylogenetic aspects of insect–PA relationships, and raises questions about the complex interactions of the variety of PA-related adaptations as they occur among a diverse array of species. Although many superficial similarities are recognized, few generalizations can yet be drawn. However, insect–PA relationships not only exemplify basic features of chemical ecology but illustrate a multiplicity of aspects and adaptations, which we should expect to find in any thorough study of insect–plant relationship.

Key Words—Pyrrolizidine alkaloids, pharmacophagy, male pheromones, chemical defense, Lepidoptera, Danainae, Arctiidae, *Heliotropium, Senecio, Crotalaria*

INTRODUCTION

The large array of physiological, behavioral, chemical, and ecological phenomena involved in sequestration of secondary plant metabolites can, in practice, only be investigated in relatively few cases. Nonetheless, from this sample

[1] Paper presented at the Symposium "Sequestration of Natural Products by Insects" during the 5th Annual Meeting of the International Society of Chemical Ecology, Athens, Georgia, June 24–27, 1988.

0098-0331/90/0100-0165$06.00/0

we hope to discover basic mechanisms—or even rules—governing chemically mediated interactions among organisms. The producers and consumers of pyrrolizidine alkaloids (PAs) appear to be well suited for such studies because they exhibit many features similar to those found in other systems of insect–plant relationships: on the one hand, PAs occur in a great variety of plant species and PAs are chemically distinct but quite diverse; on the other hand, various unrelated insects exhibit relationships to PA plants, and these are phenomenologically similar but nevertheless of different kinds. The polyphyletic development of both PA plants and the insect groups that exploit them enables us to undertake a comparative approach, leading to insights into evolutionary developments and processes. Furthermore, the associations of insects with PAs raise challenging questions for research into sensory physiology, sociobiology, biochemistry, and other fields peripheral to chemical ecology.

A significant and increasing amount of data on relationships between insects and plants containing pyrrolizidine alkaloids is now available. For example, we have learned that insects gather PAs not only from their primary host plants but also independently from nutrient uptake; insects store PAs for their protection against predators; and much is now known about PAs as precursors for male pheromones. Two examples suffice to illustrate the attraction of the subject: (1) Male milkweed butterflies (Danainae) visit withered PA-containing plants and extract PAs. These substances are required as precursors for biosynthesis of the quantitatively dominant pheromone component danaidone (Figure 1A) necessary for courtship success. In addition, males store PAs for their defense and also transfer significant amounts in the spermatophores, causing protection of

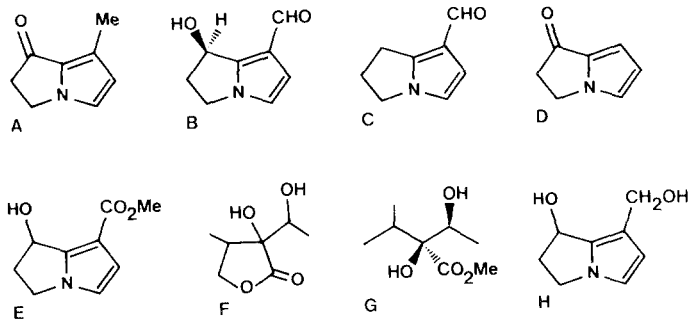

FIG. 1. Molecular structures of derivatives of pyrrolizidine alkaloids identified from androconial organs in Lepidoptera (see Table 4). A: danaidone, B: *R*-(−)-hydroxydanaidal, C: danaidal, D: nordanaidone (S. Schulz, personal communication), E: methylhydroxydanaidoate, F: ithomiine lactone [2-hydroxy-2-(1-hydroxyethyl)-3-methyl-γ-butyrolactone]; methylviridiflorate (G) and the necine pyrrole (H) are probably intermediates. G shows relative configuration.

females and eggs. (2) Larvae of *Creatonotos* (Arctiidae) are polyphagous but PAs alone can elicit feeding behavior. Those individuals that have PAs are protected from predators, and males with PAs also use them as precursors for biosynthesis of hydroxydanaidal (Figure 1B), which is emitted by coremata and appears to bring about the formation of mating assemblages. Thus there is an individual variation in the pheromonal strength of the males that is directly related to the amount of PAs gathered (as in the danaines, but here the amount per adult male is fixed for life); furthermore, in *Creatonotos* the development in size of the pheromone disseminating apparatus is also controlled by the amount of PA, i.e., PAs serve as organ-specific morphogens.

Neat as these brief summaries may sound, and although there is considerably more knowledge available than I have mentioned, our understanding of these phenomena is nonetheless superficial. Many aspects have yet to be investigated and, although many of the details involved might seem rather subtle, they are basic to our understanding not only of the two examples mentioned above, but also with respect to other organisms that sequester PAs.

This article addresses the multiplicity of phenomena involved in insect–PA relationships from a chemoecological perspective, and draws attention to some of the gaps in our knowledge that are rarely emphasized. Thus in the following sections, selected aspects are highlighted without comprehensive treatment of the subject and the respective literature. [For details and references on insects and PAs see reviews by Boppré (1986), Schneider (1987), Eisner and Meinwald (1987).]

PYRROLIZIDINE ALKALOIDS

PAs are chemically defined as ester alkaloids composed of an amino alcohol (necine; originating from 1-hydroxymethyl-pyrrolizidine) and mono- or dicarboxylic acids (necic acids; often C_7–C_{10} oxygenated and highly branched acids (Figure 2). Thus, saturated and unsaturated PAs are known that are mono- or diesters or macrocyclic diesters. PAs often occur as *N*-oxides; free-base alkaloids and their water-soluble *N*-oxides readily interconvert. To date, about 200 structures have been characterized, but many more have yet to be identified. [For details and references on PA chemistry see reviews by Bull et al. (1968), Robins (1982), Wróbel (1985), Mattocks (1986).]

PLANTS CONTAINING PAs

Plant species belonging to more than 60 genera in a dozen or so families have been recognized to produce PAs as secondary compounds. PAs have been found most widely in species of *Senecio* (Asteraceae), *Heliotropium* (Boragi-

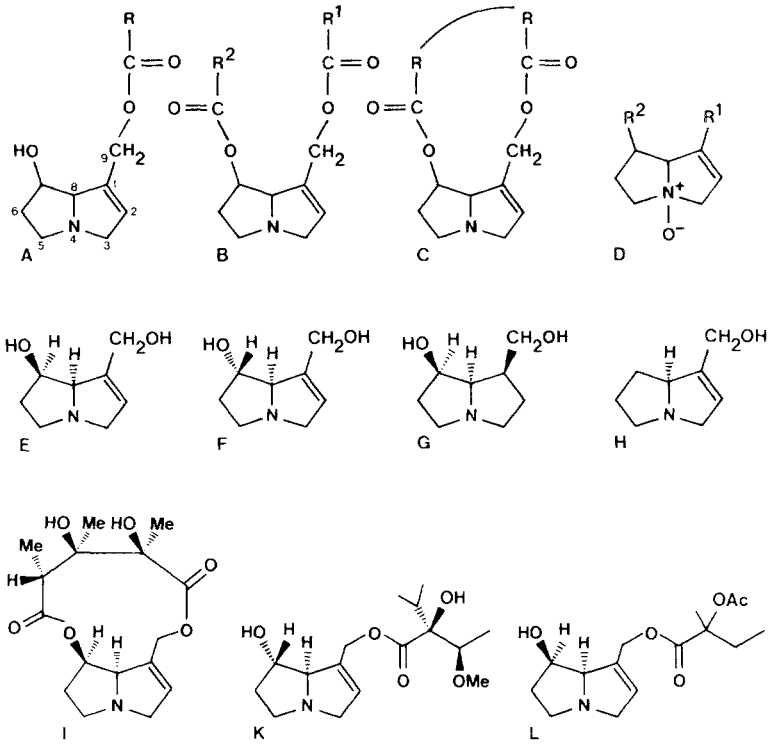

FIG. 2. General structure of pyrrolizidine alkaloids (A–C) and PA *N*-oxides (D) and molecular structures for examples of necine alcohols (E: retronecine; F: heliotridine; G: platynecine; H: supinidine) and of free bases (I: monocrotaline; K: heliotrine); L: the insect metabolite callimorphine. E–L show absolute configurations.

naceae), and *Crotalaria* (Fabaceae) (Smith and Culvenor, 1980), but these genera have been investigated much more thoroughly than others because of their importance for domestic animals and man. Their PAs usually consist of the necines retronecine and heliotridine (Figure 2E,F); retronecine appears as the most common amino alcohol in PAs.

Generally, a given plant species contains several PAs; such a set consists of PAs of similar structure, and these PAs tend to be characteristic of plant genera or even some higher groupings. Reported amounts of PAs are >5% (maximum: 17.99% dry weight in *Senecio riddellii*; Molyneux and Johnson, 1984) or as low as 0.001% of dry weight; a common figure is 0.1% or so. Considerable intraspecific variation also occurs (e.g., Johnson and Molyneux, 1985), involving both qualitative and quantitative composition as well as spatial

and temporal distribution of PAs, a result of the physiological state of the individual plant as well as of its environmental conditions.

Although we talk often about PA plants, from a chemoecological point of view they are anything but uniform. The (chemical) definition of PAs is quite broad, and our biological knowledge should forbid us to group all the different structures under one term; for convenience only, the general term is still employed. Provoked by the pathogenicity of (certain) PAs, an impressive amount of knowledge on PA chemistry and toxicology has been gathered, but ecological aspects have been relatively neglected. Most studies have focused solely on the identification of the molecular structures; thus for extraction and isolation of PAs standard techniques have been employed, which, on the one hand, usually involve dried plant material only and, on the other hand, carry the risk of chemical degradation (e.g., reduction of *N*-oxides; cf. Hartmann and Toppel, 1987) during the procedures.

Some valuable information is available on ecophysiological matters, but it is presently incomplete and too limited to permit an understanding of PA plants in a wide sense. Evidence from *Senecio* and *Crotalaria* favors the idea that *N*-oxides are the form by which PAs are synthesized, translocated, and accumulated, while seeds seem to contain free-base alkaloids exclusively (cf. Hartmann et al., 1988). Is this situation common to the entire spectrum of PA plants? Studies involving examples from a range of unrelated species and considering different physiological states are urgently required, since the physicochemical properties of free bases and *N*-oxides are quite different and must have different biological effects on insects in the context of perception, toxicity, degradation, solubility, and transportation. Further basic tasks include details on the occurrence of PAs in nectar, the changes in PAs when a plant is withering or drying, and the stability of PAs as well as their derivatives (see below).

PAs IN PLANTS—WHAT FOR?

The majority of known PAs cause serious diseases in domestic animals and man—the leading motive for most studies on PAs. In contrast to many other secondary plant metabolites, the noxious actions of PAs are not instantaneous but appear only after weeks or months of incubation and in an indirect way. In the vertebrate metabolism, unsaturated ester alkaloids (those with 1,2-dehydro-1-hydroxymethyl-pyrrolizidines) are converted into pyrroles (Figure 1H), which are responsible for hepatotoxic, mutagenic, oncogenic, and other deleterious effects. [For review and references on toxicological aspects see Bull et al. (1968), Mattocks (1986).] If PAs with other structures are harmless, what are their biological roles?

Although some domestic herbivores consume PA plants (particularly if there is shortage of other food), PAs actually protect their producers significantly from herbivory. Grazing animals usually avoid PA plants, apparently because of their deterrent taste; for humans, PAs taste bitter. One can speculate that it has to be a kind of gustatory "aversion receptor" that protects herbivores from uptake of PAs, i.e., from being poisoned. This receptor probably has low specificity, otherwise the great number of different PAs would not be explicable since one would have to expect selective pressure on the plants to synthesize PAs with less diverse structures. Is it a general "bitter receptor," with a wide reaction spectrum, i.e., does it sense other types of noxious compounds, too? If so, it might not have evolved as a response to the "invention" of PAs by plants but antedate this incident(s). Could we then propose that the (PA) plants have merely taken advantage of a sensory system generally present in animals? (See below on aversion in nonherbivorous vertebrates and insects.) Unfortunately, so far, this matter represents nothing but speculation.

To a great extent, PAs appear to protect plants from damage not only by vertebrates but also by insects. Comparatively few species are known to utilize PA plants as hosts, and the aversion receptor postulated above might be present in insects also: PA-contaminated but otherwise adequate food is rejected by locusts, many lepidopteran larvae, cockroaches, ants (Bernays and Chapman, 1977; Bentley et al., 1984; Boppré et al., in preparation)—even by species that naturally do not encounter PAs (e.g., *Periplaneta, Blatta*). PA-containing nectar is avoided by many nectar-foraging species, and insects storing PAs are protected from predators including invertebrates (see below). It must be emphasized, however, that we have no idea what would happen to an unadapted insect if it lacked the taste barrier and took up PAs. One cannot predict the physiological reactions of invertebrates from knowledge of the toxicology in vertebrate metabolism.

The undoubted protective role that PAs have for plants cannot explain the entire phenomenology of such compounds within the plant kingdom. Why do we find amounts of PAs that are much higher than required for deterring herbivores? For example, seeds of *Crotalaria* may contain as much as 5% PAs by dry weight. Of course, the reproductive organs may require the best protection possible, but the plant should not invest more energy in PA synthesis than needed. Toppel et al. (1988) have recently shown for *Crotalaria* that in the course of germination PAs are metabolized as a nitrogen source; the seedlings do not contain PAs at all. Thus, the secondary compounds are also relevant for primary metabolism, a fact that also can be inferred from the great variations observed in PA content of the plants (see below) but which by no means contradicts the role of PAs as defensive chemicals.

PA-ADAPTED INSECTS

Insects have selectively adapted to most of the defensive mechanisms of plants; a variety of species utilize PA plants as hosts, and yet others depend on PAs and gather them from plants independently of feeding. Not very many species have been investigated in detail. The following accounts focus on Lepidoptera and are further restricted to examples dealing with the Asteraceae, Boraginaceae, and Fabaceae, simply because other systems have hardly been looked at.

Considering the disjunct phylogeny of taxa making use of PA plants and the different types of PA insects, adaptations to utilize PAs must be polyphyletic in origin. As with PA chemistry, few other generalizations can be drawn, although the phenomena obviously exhibit similarities. In any case, one has to differentiate between three types of associations (Table 1): insects taking advantage of (1) the nutritional value only, (2) both the primary and the secondary metabolites, and (3) PAs alone.

Insects utilizing PA plants solely as food sources demonstrate, perhaps, the most original adaptation, apparently enabling them to exploit a food resource with limited competition. We know too little of the few species belonging to this category, but it seems that they are mostly polyphagous and handle PAs unspecifically by converting and/or excreting them.

Lepidoptera restricted to PA-containing host plants (e.g., *Tyria, Utetheisa, Nyctemera*) seem to take advantage of PAs themselves in one way or another. They have probably adapted to avoid harm and, apparently, they have means of recognizing PA plants. Since a PA plant is not only characterized by the possession of PAs, one can imagine a variety of cues that are capable of guiding an insect to its host, but critical investigations regarding this point are entirely lacking. Host records of insects using PA plants indicate, however, that different Lepidoptera do use different stimulus patterns for egg-laying and/or phagostimulation, because various species exhibit different host ranges (Table 2), indicating that PAs cannot be the only cues (but see discussion of pharmacophagy below).

Straightforward detection and recognition of PAs is a basic feature of pharmacophagous species. By definition, species of this category search for the allelochemics directly, take them up, and utilize them for a specific purpose other than primary metabolism or (merely) host recognition (Boppré, 1984b), i.e., they often gather secondary plant compounds independently of foraging for nutrients. Pharmacophagy with respect to PAs has been demonstrated for *Creatonotos* larvae (Table 2) but is most easily recognized in all those Lepidoptera (and other insects) that, in their adult stage, visit withered or decaying PA plants

TABLE 1. EXAMPLES OF LEPIDOPTERA AND OTHER INSECTS SHOWING DIFFERENT KINDS OF PA SEQUESTRATION

[c]See Table 2.

(Table 1) and extract PAs from the dry material by using a liquid released through their proboscides. In most of these species the larvae feed on PA-free hosts, but this need not necessarily be the case (see *Nyctemera*, Table 1). In experimental situations, they will also go for certain pure PAs, i.e., orientation to PA sources has to be mediated olfactorily and also be solely related to PAs and not to any other plant product.

We do not know much about preferred species of PA plants, but plants with structurally different PAs are attractive (Table 3). Because of their high molecular weight, intact esters are unlikely to have sufficient volatility to mediate attraction. But we must ask precisely what cue(s) enable PA pharmacophagous insects to recognize PA sources. Recently, two independent approaches to this question revealed that hydroxydanaidal (Figure 1B), previously well known as male pheromone (see below), is the airborne signal from a variety of PA sources (Krasnoff and Dussourd, 1989; Bogner and Boppré, 1989; compare Pliske et al., 1976). Discrepancies exist, however, since Krasnoff and Dussourd (1989) found *S*-(+)-hydroxydanaidal more attractive than the respective *R*-(−)-enantiomer, while Bogner and Boppré (1989) found the opposite. The latter authors put forward evidence that hydroxydanaidal is a spontaneous degradation product that emanates in minute quantities from all those PAs that have either retro-

necine or heliotridine as the necine and are present as free bases. This finding explains the given but not very high specificity of attraction and suggests why plants must be withered (or damaged) to be attractive and lure best if remoistened. The study also demonstrated receptor cells for the perception of secondary plant metabolites that have similar specificity and sensitivity as receptors for sensing female pheromones in moths (e.g., Mustaparta, 1984). (At close range to the source, gustation also seems to be involved: Lepidoptera probe with their proboscides before eventually applying liquid to extract and imbibe PAs.)

Field observations on the biology of Lepidoptera that gather PAs as adults have revealed that nectar can be a potential source of PAs. Chemically, PAs have been recognized in honey of *Senecio* and *Echium* (up to 3.9 ppm; Deinzer et al., 1977; Culvenor et al., 1981), and flowers of the Eupatoriae (Compositae) are considered to be a major source of PAs for Lepidoptera (e.g., Brown, 1984). The flowers of the PA plant *Gynura scandens* are exclusively visited by PA insects, and these exhibit the same sex bias as at withered plants or artificial baits; other Lepidoptera completely ignore these flowers (Boppré, unpublished). Some novel PAs were first found in *Euchromia* moths that had visited *Gynura* flowers (Boppré and Edgar, unpublished; compare Wiedenfeld, 1982). In contrast, flowers of other PA plants (e.g., *Heliotropium*) are utilized by a wide spectrum of nectar foraging insects. This suggests that the nectar of PA

TABLE 3. PLANT GENERA MOST FREQUENTLY USED AS PA SOURCES BY ADULT LEPIDOPTERA

Asteraceae	*Ageratum, Eupatorium, Senecio, Gynura*
Boraginaceae	*Heliotropium, Tournefortia*
Fabaceae	*Crotalaria*

plants does not necessarily contain these secondary products—an aspect requiring further investigation. Furthermore, some orchids (*Epidendrum* sp.) are pollinated exclusively by adult Lepidoptera that are pharmacophagous with respect to PAs; apparently, these plants do not provide PAs but cheat PA insects to take advantage of specialists for pollination (Goss and Adams, 1976; DeVries and Stiles, 1989).

How elaborate the gathering of PAs can be is shown by danaine butterflies that vigorously scratch plant tissue with their legs to get access to PAs (which they then suck up with their proboscides). They need, however, a starting point such as a hole made by beetles (Boppré, 1983); undamaged tissue is ignored, apparently lacking the volatile cue for attraction.

Foraging PAs can thus be of great cost with respect both to phylogenetic adaptations and to the time and effort invested by individuals. One may therefore expect that PAs play significant roles in the lives of PA insects.

PAs AND THEIR ROLES FOR INSECTS

PAs for Defense. The great majority of insects that utilize PA plants in one or another way are aposematically colored and behave conspicuously. This suggests, in combination with the information above on the protective role of PAs for plants, that insects do store PAs and use them for their own protection. Storage of PAs by Lepidoptera was first demonstrated by Aplin and Rothschild (1968, 1972), and numerous similar studies have been undertaken since; the analyses reported by Brown (1984a,b, 1987) are outstanding for their detail.

Most species related to PA plants that have been analyzed chemically have been found to store PAs in their bodies (Table 1); the amounts can be as high as 20% of the insect's dry weight (e.g., Brown, 1987). Detailed analyses on the qualitative and quantitative composition of PAs in insects reveal, however, many intra- and interspecific differences. PAs found in insects do not necessarily represent fingerprints of the PAs found in their host(s); rather, there are great differences in the patterns, both qualitative and quantitative (e.g., Culvenor and Edgar, 1972; Aplin and Rothschild, 1972); even sex differences occur in PA storage by larvae that had fed on the very same individual plant. Are we dealing with selective uptake, selective metabolism, or perhaps selective conversion due to selective use? What is the role of "callimorphine" (Figure 2L), a PA not known from plant sources but found in several arctiids jointly with host plant PAs (Aplin et al., 1968; Edgar et al., 1980; Wink et al., 1988; L'Empereur et al., 1989). Unfortunately, studies considering both plants and insects at the same time are rare. We also need many more qualitative and quantitative PA profiles of several insect species to learn about individual (and sex-specific) variation, selectivity of uptake and utilization in sympatric species, and differences among populations. Further questions of general importance include: do

adult Lepidoptera extracting PAs from withered material of a given plant obtain the same amounts and types of PAs as obtained by larvae feeding on the living tissues? Extracts of insects usually reveal a high percentage of PAs in their *N*-oxide forms; did the insects take up *N*-oxides or did they oxidize free bases? If the latter (as demonstrated for *Rhodogastria*; Wiedenfeld and Boppré, unpublished) is the case, is *N*-oxidation caused by an adapted mechanism or is it simply an obligatory metabolic process? Are the polar *N*-oxides more or less or equally defensive (and/or repellent) compared to free bases or are they better suited for transport within the body? Thus, merely recognizing that an insect is associated with a PA plant is insufficient to predict if and how it sequesters the plant chemicals.

Although storage of PAs does not inevitably imply a protective function, we know from the meticulous studies of Eisner (1980, 1982) and Brown (1984a,b, 1987) that Lepidoptera (*Utethesia* and Ithomiinae) can be protected from predation (by *Nephila* spiders) by stored PAs they had gathered, respectively, as larvae or adults. Both these workers also demonstrated that, in their examples, PAs alone were responsible for protection.

With several other species the situation is more complex since they possess self-manufactured, toxic secretions in addition to PAs (see Blum, 1981; Rothschild, 1985; for general accounts and references) and/or they store other chemicals sequestered from plants. For example, *Danaus plexippus* can store cardenolides from larval hosts and the adult butterflies gather PAs in a pharmacophagous way (e.g., Brower, 1969; Kelley et al., 1987);[2] however, Ithomiinae and *Euploea core*, for example, do not store the defensive compounds present in their host plants (Brown, 1984a,b, 1987; Malcolm and Rothschild, 1983) and seem to rely only on PAs obtained as adults. Are different (sets of) compounds effective against different predators, do they act synergistically, and/or are several chemicals utilized to ensure protection if one or the other type is not available at a given habitat or time? Last, but not least, the considerable intraspecific variation in PA storage, particularly in pharmacophagous species, and the resulting "palatability spectrum" is of great relevance and deserves detailed study—also in the context of (auto-)mimicry.

At this point we should consider the potential predators for PA insects. Since PA insects are diverse with respect to, among other factors, size, activity pattern, and habitat, the range of potential predators is great and includes organisms with quite different physiology and life-styles (vertebrates as well as invertebrates). As with plants (see above) the question of unpalatability vs. toxicity arises (see also discussion by Brower, 1984). Is the knowledge of the

[2] Interestingly, often (always?) the ability to utilize PAs is associated with the ability to utilize cardenolides, but no common denominator of PAs and these glycosides is recognized (e.g., Rothschild et al., 1970).

toxicology, indicated above and largely derived from studies of domestic animals, really applicable to insectivores such as birds, bats, lizards, and toads? Would, for example, amounts of PAs accumulated through insectivory fall below the poisoning threshold? Likewise, in this context it must be asked again: why do insects usually avoid PAs and what kind of harm do they risk with ingestion of these compounds?

Taste rejection of PA-storing insects by predators suggests that PAs are located on the prey's outer surface. Indeed, biological observations verify this: *Nephila* spiders release Ithomiinae and *Utetheisa* unharmed from their webs (Eisner, 1982; Brown, 1984a), and *Creatonotos* and *Rhodogastria* survive attacks by toads and lizards, which spit them out (Boppré, unpublished). From Brown's studies we know about the quantitative distribution of PAs/PA *N*-oxides in the various body parts of ithomiine butterflies (accumulation in exoskeleton and reproductive tissues), but we lack information as to how PAs are transported. If PAs are ingested by larvae, the problem of how PAs reach the cuticular surface is less intriguing than in those Lepidoptera that gather PAs as adults, i.e., after the cuticle has been formed. In many arctiid adults, malodorous froth exuded from prothoratic glands immediately after an attack seems to support instant taste recognition. If adults have access to PAs, the froth of *Rhodogastria* is loaded with PA *N*-oxides (Wiedenfeld and Boppré, unpublished).

The transport of PAs in insect bodies must relate to how PAs pass the gut membranes. Because PAs are large molecules, some kind of carrier molecules should be expected (Hartmann, 1985; Wink and Schneider, 1988). Surprisingly, experiments with *Creatonotos*, the larvae of which happily consume glass-fiber disks impregnated with PAs (Boppré, unpublished), indicate that if the insects had ingested pure PAs in this way the effect of these chemicals on morphogenesis (see below) is 10–100 times weaker than if PAs had been provided naturally, i.e., unextracted via plant tissue (Boppré, unpublished). This may suggest attachment of PAs in plants to other molecules, resulting in more efficient metabolism (translocation, storage, conversion?) in insects. Perhaps, we even should ask whether poisoning of vertebrates is greater if PAs are ingested with plant tissue then in pure form, implying that LD_{50} tests with pure chemicals might be misleading. Based on available evidence, storage for defense seems to be the primary function in most, if not all, insect–PA relationships, but in many it is not the only one.

PA-Derived Male Pheromones. In Lepidoptera, utilization of PAs as precursors for male pheromones is widespread although not general (Table 1). Figure 1 shows the structures of PA-derived compounds identified from androconial organs in Lepidoptera, and Table 4 links them to the respective genera. It shows that unrelated species end up with similar or even identical pheromone components, regardless of the stage in which PAs are consumed. Nevertheless, in chemoecological terms this is not a basis for establishing a rule. As the infor-

[b] PA uptake by adults.

[c] PA-uptake by larvae.

mation provided in Table 4 also indicates, the respective species differ strikingly in the quantities of PA-derived compounds, they have quite different courtship strategies, and their pheromones come into play in different behavioral contexts, suggesting different roles, i.e., broadcasting different messages to the female (Boppré, 1984a).

In *Danaus chrysippus* (and probably many other danaine butterflies), mechanical contacts between abdominal hairpencils and alar glands are required for synthesis of danaidone (Boppré et al., 1978). Thus, in addition to the costs of foraging for PAs (plus producing appropriate enzymes), the males employ two sets of glandular organs and perform a peculiar precourtship activity. Must danaidone synthesis occur outside the body in order to avoid poisoning by PA metabolites? Perhaps so, but other species (e.g., *Lycorea*) manage without alar organs. It is also puzzling why so many species utilize hydroxydanaidal as a male pheromone (component). The idea that this molecule might be less costly to synthesize than other PA derivatives (e.g., danaidone) receives some support

by finding that hydroxydanaidal appears as a spontaneous degradation product (see above).

There are two enantiomeric forms of hydroxydanaidal but the androconia of *Creatonotos* and (all?) other Lepidoptera that use PAs as precursors emit *R*-(−)-hydroxydanaidal only (Figure 1B, Table 4). This detail is by no means trivial in an ecological context because insect olfactory receptors usually discriminate between enantiomers and, according to textbook knowledge, the enantiomeric configuration should not be changed in the course of biosynthesis of hydroxydanaidal from PAs. It was completely unexpected to find, from feeding experiments, that *Creatonotos* can utilize PAs with retronecine or heliotridine, in the latter case converting the configuration at C-7 (Bell et al., 1984; Bell and Meinwald, 1986; compare Wink et al., 1988). This mechanism, in consequence, enables *Creatonotos* to take advantage of a wider spectrum of species of PA plants than it could otherwise do. What happens in such insects as *Euploea*, which gather PAs as adults?

Because hydroxydanaidal is not only a pheromone but also the volatile principle responsible for attraction of insects to PAs (see above), certain insects might get confused—PA sources smell like male androconia and, in turn, androconia smell like PA sources. In fact, coremata of *Pyrrharctia* and *Creatonotos* attract PA insects (Krasnoff and Dussourd, 1989; Boppré, unpublished).

Referring to the androconial secretions as male pheromones is not very meaningful because the messages male pheromones carry are generally little understood and certainly not uniform (Boppré, 1984a). In any case, it is very surprising that a diversity of Lepidoptera use derivatives of (defensive) plant metabolites as male pheromone precursors. Utilization of plant products for pheromone biosynthesis is not restricted to PAs; the bark beetles (Scolytidae) provide a well-known example (e.g., Borden, 1985). However, in certain PA insects the question has a special dimension because of the linkage between chemical defense and chemical communication.

Based on the fact that hydroxydanaidal-deficient males of *Utetheisa* are unsuccessful in courtship, Conner and Eisner suggested the females might sexually select for males with a high ability to sequester PAs, a trait that might be inheritable (Eisner, 1980; Conner et al., 1981). Finding that males also donate substantial amounts of PAs with their spermatophores (Brown, 1984, 1987) resulted in an even more plausible hypothesis: since the male pheromone is derived from the nuptial gift, it might indicate to the female the amount of protective chemicals she can expect to gain during copulation (Eisner and Meinwald, 1987; Dussourd et al., 1988). Although several of the assumptions lack confirmation as yet, for *Utetheisa* there is some good evidence in favor of the hypothesis (see also Conner et al., 1989). The hypothesis is also of great value for studies on other species utilizing PAs for both defense and chemical communication. However, considering the differences in courtship behavior, the

fact that some species have to make do with a fixed amount of PAs gathered as larvae while others can increase their drug budgets as adults, and considering the existence of additional chemicals (e.g., extracts of male danaine hairpencils revealed bouquets comprised of up to 50 volatiles found only in the androconia; Schulz, 1987), without modification the hypothesis is unlikely to be equally valid for the entire variety of species.

More thorough studies focusing on how male butterflies handle ingested PAs are required for our understanding of the chemoecological aspects. What is the order of priority and what are the budgets if PAs are used for pheromone biosynthesis, for protection, and for incorporation into spermatophores? This question is of particular importance if PA resources are limited, and the answer must be expected to differ among species of PA insects. Furthermore, are the various PAs obtained by an insect from different plant species used equally or are there differences such that, for example, only certain PAs are stored for defense while others are converted into pheromones? Is there a difference between utilization of *N*-oxides and free bases, and/or are pure PAs less efficiently used (see above)?

Further questions arise from sex-specific sequestration of PAs. Among those species gathering PAs as adults, there is often a male bias, but others have female and yet others no sexual bias (Table 1). In *Creatonotos*, there is a significant sexual difference in the amount of PAs taken by larvae in ad libidum experiments (Boppré, unpublished). Particularly informative might be comparative studies with closely related species that behave differently. For example, *Amauris ochlea* and *A. niavius* are sympatric congeners. In the former, males exclusively are found at PA baits or plants, but in the latter species, a high proportion of females also visit such PA sources (Boppré, unpublished). Again a sensory physiological aspect appears, which seems promising for a study on the evolution of receptor specificity.

PAs as Morphogens. A unique effect of PAs has been recognized in arctiid moths of the genus *Creatonotos*. The amount of PAs consumed by larvae not only determines the amount of male pheromone [*R*-(−)-hydroxydanaidal] but also the size of the coremata (Schneider et al., 1982; Boppré and Schneider, 1985, 1989). Morphogenesis of these androconial organs (and of these alone) is quantitatively dependent upon the amount of PAs ingested by a larva; there is no previous knowledge of a similar morphogenic effect generated by a secondary plant metabolite. Recently, however, we found considerable variation in the size of coremata in a field population of *Teracotona* (Boppré, unpublished), and we are curious to study if PAs (or other secondary plant substances) act as morphogens.

Other Functions? There are many further facets in insect–PA relationships, making the complex situation discussed above even more involved, but the subject cannot be treated comprehensively here. One could add that Pliske

(1975a,b) and Goss (1979) speculate on a nutritive function for PAs, but there is no evidence for such an idea. In the case of Danainae and Ithomiinae there is debate on the evolutionary origins of their relation to PA plants. However, the most significant increase in the complexity of the subject occurs when non-lepidopteran insects associated with PA plants are considered in addition; Table 1 lists just a few examples.

EPILOGUE

PAs belong to the best investigated natural products and many aspects of sequestration of these allelochemics by insects (mainly Lepidoptera) have been studied. Despite our present knowledge, many questions naturally arise that demonstrate we have seen only "the tip of the iceberg" so far. The many aspects described here are of unequal importance and cannot be considered at once; they are neither meant to cause confusion nor to discourage specific studies; rather, they are intended to stress the research challenge provided by insects and PAs. However, we have to consider the complexity which is, I think, the fascination of chemical ecology. We should increase detailed studies and stress comparative approaches but refrain from generalizing conclusions; as shown above, to date we know quite a few examples but there is no model representative for insect–PA relationships.

Raising open questions on insect–PA relationships should also illuminate the many tasks for biological disciplines not directly involved in chemical ecology. These include studying such different subjects as receptors, morphology, ethology, orientation, phylogenetics, and even developmental processes.

Acknowledgments—I am deeply indebted to R.I. Vane-Wright, L.E. Gilbert, Th. Hartmann, and S. Schulz for very stimulating discussions in the course of preparing the manuscript. Studies are supported by the Deutsche Forschungsgemeinschaft.

IRIDOID GLYCOSIDE CONTENT OF *Euphydryas anicia* (LEPIDOPTERA: NYMPHALIDAE) AND ITS MAJOR HOSTPLANT, *Besseya plantaginea* (SCROPHULARIACEAE), AT A HIGH PLAINS COLORADO SITE[1]

KAREN M. L'EMPEREUR and FRANK R. STERMITZ

Department of Chemistry
Colorado State University
Fort Collins, Colorado 80523

(Received February 1, 1989; accepted March 17, 1989)

Abstract—The checkerspot butterfly, *Euphydryas anicia*, utilizes mainly *Besseya plantaginea* and only occasionally *Castilleja integra* as a larval hostplant at Michigan Hill, a few kilometers from a site where *C. integra* is used by over 90% of the butterflies. The *B. plantaginea* leaves that are consumed contain 9–22% iridoid glycosides, composed mainly of catalpol and catalpol esters, while larvae from the same plants contain 6–18% iridoids, mainly catalpol and no esters. Field-collected adult butterflies contain 0.5–4.3% iridoids. Laboratory-reared adults secrete iridoids in the meconium upon eclosion and retain similar amounts. The adult and meconium iridoid content is considerably lower than in the larvae, and metabolism in the pupal stage may be occurring.

Key Words—*Euphydryas anicia*, Lepidoptera, Nymphalidae, *Besseya plantaginea*, Scrophulariaceae, iridoid glycosides, sequestration, plant-insect interactions, herbivory.

INTRODUCTION

We recently reported (Gardner and Stermitz, 1988) the first detailed study of iridoid glycoside sequestration patterns in a natural lepidopteran population: *Euphydryas anicia* (Nymphalidae) hosted by *Castilleja integra* and *Besseya*

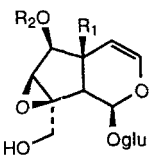
0098-0331/90/0100-0187$06.00/0

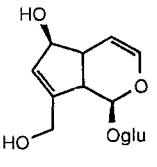
plantaginea (Scrophulariaceae) at a high plains Colorado site (Red Hill). A second localized population of the same checkerspot butterfly occurs on Michigan Hill, about 8 miles (13 km) east of Red Hill. Both host-plant species are also present at Michigan Hill. Preliminary analysis of field-caught adult butterflies from Michigan Hill showed that they contained the iridoid glycoside catapol, **1**, but lacked macfadienoside, **2**, an iridoid exclusive to *C. integra*, which was present in over 90% of the butterflies at Red Hill (Gardner and Stermitz, 1988) (Figure 1). Both host-plant species contain catapol and *B. plantaginea* contains catalpol esters that are hydrolyzed by the larvae to catalpol.

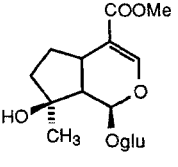
A detailed study of the Michigan Hill population was undertaken to establish firmly what appeared to be a major host-plant utilization difference at the two nearby sites. Such host-plant changes are well-documented for *E. editha* in California (Ehrlich et al., 1975; Singer, 1982, 1983). In addition, our first detailed study focused mainly on variation in the field-captured adult butterfly iridoid content, with less attention paid to host-plant or larval iridoid analyses. Therefore, we also used the Michigan Hill organisms to obtain data on the iridoid content of individual larval-consumed plants and iridoid content comparisons among these plants, larvae, pupae, excretion products and adult butterflies.

METHODS AND MATERIALS

Organisms and Site. Identification of the butterfly, *E. anicia* Doubleday and Hewitson, and the host-plants, *C. integra* Gray and *B. plantaginea* (James) Rydb., was as described previously (Stermitz et al., 1986). The study was con-







1: $R_1 = R_2 = H$ (catalpol)

3: aucubin

7: mussaenoside

2: $R_1 = OH$; $R_2 = H$ (macfadienoside)

4: $R_1 = H$; R_2 = benzoyl (veronicoside)

5: $R_1 = H$; R_2 = 3-hydroxy-4-methoxybenzoyl (isovanillylcatalpol)

6: $R_1 = H$; R_2 = 3,4-dihydroxybenzoyl (verproside)

FIG. 1. Structures of iridoid glycosides.

ducted on a south slope of Michigan Hill, 1 mi NW of US Highway 285 and 2 mi SW of Jefferson, Park County, Colorado (39°22′N, 105°50′W) at 9700 ft (2960 m) altitude. The butterfly population nectars on scattered *Potentilla* (Rosaceae) bushes within an approximately 50-m-wide dry depression and on several species of yellow composites growing alongside a dirt road that bisects the depression. *B. plantaginea* grows in this area with a few *C. integra* and with many more *C. integra* 50–100 m west across a dirt road. East and southeast a broad hill rises approximately 200 m from the ditch. This area of mainly low grasses contains some of the composite nectar plants as well as numerous *C. integra*, but no *B. plantaginea*. The host-plant species generally emerge from early to mid-May and larvae of *E. anicia* (which have overwintered in the second or third instar) can be found on *B. plantaginea* in late May or early June. Adult butterflies generally are flying from middle or late June to late July.

Adult butterflies were collected on July 4 and 26, 1986, in the depression area of the site, immediately placed in an ice chest, and frozen within one to two days. They were held in the freezer and then dried to constant weight for 15–20 hr at 50°C just before analysis. Previous work had shown no difference in iridoid content among fresh, air-dried, or 50° dried butterflies. On May 30, 1987, eight late-instar larvae were collected from plants of *B. plantaginea*, along with leaves from the same plants. The plant material and larvae were analyzed immediately. Twelve additional late-instar larvae were collected on June 7, 1987, from *B. plantaginea* and raised in the laboratory on the host-plant kept fresh in the refrigerator. Seven pupated between two and 15 days after capture. Three died for unknown reasons before pupation, while two did not survive due to parasitization by hymenoptera.

Frass, the meconium emitted after eclosion, and adults were analyzed for iridoid content. Additional *B. plantaginea* were collected on June 7, and these plants were also analyzed for iridoid content. They were used in an experiment designed to compare iridoid content determination on dried vs. fresh *B. plantaginea.*

Analytical Procedures. Iridoid glycoside analyses of adult butterflies, emitted meconium, and pupal cases were performed as previously described in detail (Gardner and Stermitz, 1988). The method essentially consisted of extraction into a polar solvent, clean-up with nonpolar solvent washes, evaporation of the purified mixture to dryness, conversion of the iridoid glycosides in the residue to trimethylsilyl ethers, and final quantitative analysis by gas–liquid chromatography using an internal standard.

Larvae from the field were not given food for 24 hr. They were then weighed, crushed into methanol, and refrigerated until analysis. The MeOH mixture was filtered through tared small polypropylene filters with a small cot-

ton plug into tared Erlenmeyer flasks. After filtration, the filters were dried overnight at 50°C. The MeOH was evaporated in vacuo from the flasks. The combined weight of the material on the filter and the MeOH residue was taken as the dry weight of the larvae. Iridoids in the MeOH residue were quantified by GLC as described previously (Gardner and Stermitz, 1988). Larvae raised to adulthood in the laboratory were individually fed fresh *B. plantaginea* each day. Frass was collected once a week and allowed to dry for later analysis. Pupae were placed in clean small vials with filter paper on the bottom. Six adults (five females and one male) emerged and were frozen 24 hr after emergence. The filter paper containing emitted meconium was shredded and allowed to stand in MeOH for 24 hr before iridoid analysis.

For leaf iridoid analysis, a weighed amount (about 0.30–1.00 g fresh or 0.060–0.30 g dry) was crushed in 20 ml of MeOH and the mixture allowed to stand at room temperature for 24 hr. The mixture was filtered as above through tared filters and into tared flasks. The filters were dried and the MeOH evaporated as above. To the residue 4.00 or 10.00 ml MeOH was added and the mixture was stirred until all residue had redissolved. A 1.00- or 2.00-ml aliquot was removed from the solution and the MeOH evaporated. Choice of quantities depended on the amount of original plant material extracted. Final analysis for iridoids was as previously described.

Two fresh undamaged leaves were obtained from two different plants, and each was cut approximately in half lengthwise. After being weighed, one half of a leaf was extracted immediately with methanol, the methanol was evaporated, and the residue was weighed. The marc remaining after the extraction was allowed to dry and weighed. The sum of the weights of residue and marc established the "dry weight" of the leaf half. Percent volatiles was the difference between fresh and dry weights of the leaf half. The other half of each leaf was weighed, allowed to dry for 14 days at 25°C and reweighed. The difference was the percent volatiles and the remainder the dry weight determined by this method.

RESULTS

Field-Collected Butterfly Analyses. The total iridoid content of the butterflies ranged from 0.5 to 4.3% on a dry weight basis (Tables 1 and 2). Catalpol, **1**, was found in all adults and was the major iridoid in 28 of the 31 analyzed; macfadienoside, **2**, was found in eight of the 31 and was the major iridoid in three of them. Small amounts of aucubin were present in 14 of the butterflies, but always at a very low level (less than 10% of the total iridoid content). Dry weight of the females (28 mg mean) was significantly higher ($P < 0.0001$; Student's t test) than that of males (19 mg mean). The percent total iridoid

content of the males was about twice that of the females for the July 4 collection ($P < 0.01$; Student's t-test), but not significantly different for the July 26 collection.

Iridoid Content of *Besseya plantaginea* and Insect Life Stages. Quantitative iridoid analyses performed on the residue from the methanol extraction of the fresh leaves and on a similar extract of the air-dried leaves showed that the percent volatiles and iridoid percentages determined by the two methods were similar, if not identical within experimental error (Table 3). The iridoid content of fresh leaves of six *B. plantaginea* plants varied from 9.1 to 22.3% of the dry weight, while iridoid content of larvae found consuming these plants varied from 7.1 to 18.0% (Table 4). Although the mean content was similar for plants and larvae, there was no direct correlation between the content of individual larvae and their consumed plants. For example, plant 2 had an abnormally high iridoid content and a high catalpol–catalpol ester ratio, but the larva consuming this plant had the lowest iridoid content. Two additional larvae (not in Table 4) were analyzed with similar results: 8.8 and 10.9% total iridoids (catapol and a trace of aucubin, **3**). Plant material for these individuals was not analyzed. One of the eight larvae analyzed contained macfadienoside even though it was collected on *B. plantaginea*. No catalpol esters, major components of the host-plant, were found in the larvae.

Iridoid analyses of frass, pupal cases, meconium, and adult butterfiles from the six field-collected and then lab-raised late-instar larvae showed little total iridoids in the frass and pupal case and relatively large amounts in the meconium and adults (Table 5). Total iridoid content (meconium and adult) was lower than that of the host-plants or larvae (Table 4), but comparable to that of field-collected adults (Table 1). Two of the larvae fed long enough so that frass could be collected in two batches, early and late. Comparison of these batches and

Aucubin (**3**)	0.0	0.2	0.1	0.1	0.0	0.2	0.1	0.1
Total iridoid %								
(Plants)	9.4	22.3	11.1	13.2	9.1	16.8	13.7	5.1
(Larvae)[b]	13.6	6.5	7.1	9.5	14.5	18.0	11.5	

[a] Percent, dry weight basis.
[b] All larvae had 0.1 or 0.2% aucubin. Larva 1 had 1.3% macfadienoside and 12.1% catalpol. None had verproside, isovanillylcatalpol, veronicoside, or mussaenoside.

the frass from larvae that pupated within the first days of collection showed that frass from less mature larvae contained some iridoids, indicating a less efficient sequestration than by the more mature larvae. The percent iridoid content of pupal cases was similar to that of the adults, but the dry weight of the cases is so small, they contribute little to the total iridoid content of the organism. One larva, although collected on and fed *B. plantaginea*, showed small amounts of macfadienoside in the frass and meconium.

DISCUSSION

Plant Analyses. Previous iridoid analyses of *B. plantaginea* (Stermitz et al., 1986; Gardner and Stermitz 1988), based upon actual isolation from whole plant material, had indicated a 2–4% iridoid content, although a few individual plant analyses via the GC method showed a much higher content (Gardner, unpublished results). The present work clearly establishes a much higher content (14% mean) when direct analyses by the GC method were conducted on leaf material at the time of larval consumption (Table 4). The iridoids of *B. plantaginea* are apparently stable during air drying of the plant material (Table 3), and hence one need not resort to freezing or immediate solvent extraction when collecting field samples. Individual plants may contain variable amounts of total iridoids, but the general pattern of individual iridoids is relatively con-

TABLE 5. IRIDOID CONTENT OF LAB-RAISED *Euphydryas anicia*

[a] Pupal cases for butterflies 1, 6, and 11 contained large amounts of meconium.
[b] Pupal case and meconium combined.

sistent from plant to plant (Table 4). An exception was that of plant 2, which had a catalpol content far exceeding the mean. Relative proportions of the catalpol esters **4–6** remained similar for the most part and mussaenoside, **7**, and aucubin were always very minor iridoids.

Butterfly Analyses. Field-collected adults (Table 1) showed fewer (8 of 31) containing macfadienoside than at Red Hill, where 92% in 1985 and 100% in 1986 contained that iridoid (Gardner and Stermitz, 1988). Thus, the major host-plant at Michigan Hill is *B. plantaginea* rather than *C. integra*. While Red Hill is a flat site, with both host-plants occurring together in most quadrants, Michigan Hill contains a variety of terrains and a much patchier distribution of the two hosts. A host-plant count of the Michigan Hill site and butterfly collections at varying portions of the site, such as the hilltopping area, will be needed as a first step to determining whether or not simple host-plant distribution and numbers can account for the different hostplant usage pattern at this site.

Larvae contain large amounts of iridoids (Table 4) relative to the adults, both field collected (Table 2) and lab raised (Table 5). The small total numbers of plants and larvae analyzed (Table 4) preclude a statistical treatment, such as was done recently (Martin and Lynch, 1988) for monarch butterflies and their host plants, but there is no indication of a relationship between larval and host-plant iridoid content. In the monarch case it was suggested that the butterflies were feeding on high cardenolide plants (comparable to the amount they stored) and had reached a saturation level. In our case, the iridoid content of both plant and insect is remarkably high. Catalpol esters represent a major part of the host-plant iridoids, but they were not found in larvae analyzed after 24 hr without food. Thus the esters are rapidly hydrolyzed. There is apparently little or no undigested plant material remaining in the larvae after 24 hr since esters were not found in the larval analyses.

One reason for the high larval content is that little is excreted in the frass (Table 5). There is some indication that very early instar larvae may not be as efficient in sequestration as later ones. Early frass from butterfly 5 showed more catalpol than later frass, although the total amount of frass collected from early instars was small. The meconium excreted upon eclosion contains considerable catalpol, often more than is finally present in the adult (Table 5). Meconium is sometimes left in the pupal case, but where the pupal case is clean iridoids are present even though the contribution to total iridoid content is minimal due to the small pupa case weight. Striking is our failure to correlate the large iridoid content of the larvae with that subsequently found in the adult and meconium, where most should appear. Two last skin casts were checked, but weights were very small and only traces of catalpol were present. This lack of material balance is not restricted to *E. anicia* on *B. plantaginea*, and occurs with some (but not all) other iridoid specialist–host-plant pairs being studied in our laboratories. Both larvae and host plants showed iridoid content comparably high to that

found in the present work, while adults again contain the same substantial, but considerably lower, iridoid content. The best hypothesis may be that metabolism is occurring during the pupal stage in these cases and that such metabolism is converting iridoid glycosides to noniridoid-like materials. Simple conversions such as hydroxylations or similar functional group changes would lead to materials that would show up in our TLC and GLC analyses, but do not. Cleavage of the glucose moiety, however, would lead to an aglycone whose physical, TLC, and GC properties would most likely be sufficiently changed so that it would not be detected in methods developed for glycoside analysis. In addition, iridoid aglycones are much less stable than the glycoside and might further degrade before or during analysis. In contrast to these results, studies on *Poladryas arachne* hosted by *Penstemon virgatus* have shown quite a good iridoid content balance between the consumed plant and life stage totals for the butterfly (L'Empereur, 1989; L'Empereur and Stermitz, in press).

Abstract—Scentless plant bugs (Heteroptera: Rhopalidae) are so named because adults of the Serinethinae have vestigial metathoracic scent glands. Serinethines are seed predators of Sapindales, especially Sapindaceae that produce toxic cyanolipids. In two serinethine species whose ranges extend into the southern United States, *Jadera haematoloma* and *J. sanguinolenta*, sequestration of host cyanolipids as glucosides renders these gregarious, aposematic insects unpalatable to a variety of predators. The blood glucoside profile and cyanogenesis of *Jadera* varies depending on the cyanolipid chemistry of hosts, and adults and larvae fed golden rain tree seeds (*Koelreuteria paniculata*) excrete the volatile lactone, 4-methyl-2(5H)-furanone, to which they are attracted. *Jadera* fed balloon vine seeds (*Cardiospermum* spp.) do not excrete the attractive lactone. Loss of the usual heteropteran defensive glands in serinethines may have coevolved with host specificity on toxic plants, and the orientation of *Jadera* to a volatile excretory product could be an adaptive response to save time.

Key Words—*Leptocoris, Jadera*, Heteroptera, Rhopalidae, Serinethinae, Sapindaceae, cyanogenesis, glucoside, sequestration, allomone, attractant, predation, pheromone, allelochemic.

INTRODUCTION

Rhopalidae (Heteroptera) are called scentless plant bugs because in adults of the Serinethinae the metathoracic scent gland is vestigial. However, this common name is misleading as serinethine adults retain the abdominal scent glands usually found only in immatures, and adults of the Rhopalinae actually do possess a metathoracic scent gland (Aldrich et al., 1979; Aldrich, 1988). Serinethinae prefer Sapindales, especially the Sapindaceae (Schaefer and Chopra, 1982; Schaefer and Mitchell, 1983), where they form aggregations of up to thousands of individuals (Carroll and Loye, 1987; Carroll, 1988; Wolda and Tanaka, 1987). Sapindaceae produce toxic cyanolipids in their seeds (Seigler and Kawahara, 1976); thus loss of the usual heteropteran defensive gland in serinethines may have coevolved with host specificity on these plants. This hypothesis is bolstered by the discovery that the aposematic bug, *Leptocoris isolata*, sequesters host cyanolipids as glucosides and can exude blood containing enough of these compounds to repel ants (Braekman et al., 1982).

Two serinethine species in the genus *Jadera* are common in the southern United States, *J. haematoloma* and *J. sanguinolenta*. In southern Florida, the balloon vine, *Cardiospermum corindum*, is the native host of *Jadera* (Carroll, 1988). Seeds of this plant contain cyanolipid **1** (Scheme 1) (Seigler, 1974; Seigler and Kawahara, 1976). Soapberry, *Sapindus saponaria drummondii*, the native host of *J. haematoloma* in the southwestern United States (Carroll and Loye, 1987), contains only **2** in its seeds (Seigler, 1974). The golden rain tree, *Koelreuteria paniculata*, is an introduced host of *J. haematoloma* in the southwestern and central states, and *K. elegans formosana* has likewise been introduced in Florida, where its seeds are fed upon by both *J. haematoloma* and *J. sanguinolenta* (Carroll and Loye, 1987; Carroll, 1988). *K. paniculata* seeds contain **2** and **3** (Mikolajczak et al., 1970) and *K. e. formosana* probably produces a similar cyanolipid blend (Seigler and Kawahara, 1976). We tested the acceptability of *Jadera* as prey for various predators and examined the sequestration of glycosides of cyanolipids in *Jadera* as a function of host species. Our results provide an insight into the chemical vocabulary of these semisocial bugs.

METHODS AND MATERIALS

Insects. Jadera spp. were collected by S.P.C. in 1985, and express-mailed to J.R.A. for dissection or rearing. Cultures of *J. haematoloma* and *J. sanguinolenta* were maintained on *K. paniculata* seeds for several generations and for one generation on *C. corindum* and *C. grandiflorum* seeds, plus water.

Two lycaenids (Lepidoptera) feeding on unripe seeds of *C. corindum* were

collected by S.P.C. at Plantation Key, Florida, in February 1988 and sent to J.R.A. for analysis: *Hemiargus thomasi* and *Clorostrymon simaethis*.

Chemical Analysis. Insect blood was collected in capillary tubes from amputated legs. Methanolic extracts were acetylated in pyridine–acetic anhydride (1 : 1), fractionated on silica gel, and monitored by TLC (silica gel 60 F_{254} nano plates). Gas chromatography (GC) was performed using a Varian 3700 GC with a Shimadzu C-R3A recorder, on a 15-m bonded methyl silicone capillary column (0.25 mm ID; DB-1, J&W Scientific, Folsom, California) with helium as carrier (40 cm/sec) at 145°C for 2 min to 240°C at 15°/min. Urine from bugs was extracted with methylene chloride (20 μl/100 μl CH_2Cl_2), and analyzed by GC (DB-1, 45°C for 2 min to 230°C at 15°/min). The volatile excretory product and acetylated glycosides were isolated in glass capillary tubes from a DB-1 column (15 m × 0.53 mm ID) in a Varian 3700 GC equipped with a thermal conductivity detector. GC–mass spectrometry was conducted using a Finnigan 4510 GC-MS system on a 30-m DB-1 column. NMR spectra were recorded at 60 MHz on a JEOL FX-60Q FT instrument and at 300 MHz on a General Electric QE-300 instrument with TMS as an internal standard. Decoupling experiments were performed for some samples at 300 MHz using single-frequency, low-pressure, on-resonance conditions to remove the target absorption. Infrared spectra were obtained in CCl_4 using a Perkin-Elmer 580B spectrometer and a UV spectrum of **4** (Figure 2 below) was recorded on a Perkin-Elmer 559 UV-VIS spectrometer. 4-Methyl-2(5H)-furanone (**4**) was synthesized according to published procedures (Price and Judge, 1973; Pelletier et al., 1975).

Cyanogenesis. A cupric acetate–benzidine acetate test solution on filter paper strips was used to check for release of HCN from crushed bugs and urine (Feigl, 1966). β-Glucosidase (40 μl, 4 mU/μl, 0.1 mM citrate/PO_4 buffer, pH 5.00; Sigma) was also added to preparations in conjunction HCN indicator tests.

Attraction Bioassay. Insects were anesthetized with CO_2 and placed in a 500-ml three-neck flask. A 250-ml splash-guard adapter was attached to each side arm, and the side arms were connected via silicone tubing to charcoal filtered and humidified air. The middle neck of the flask was connected to the house vacuum (20 ml/min), and the apparatus was positioned horizontally on a countertop in a room (23 ± 2.5°C) with bright fluorescent lights. Five, 10, or 50 μl of **4** (10 μg/μl in CH_2Cl_2) was applied to filter paper in the upwind end of one splash-guard and the other arm had filter paper with CH_2Cl_2 only. Treated and control sides were alternated between tests. The number of insects in each splash-guard was counted every 15 min for the first 2 hr, then hourly, and the next morning.

Predator Aversion. Jadera haematoloma from golden rain trees were offered to four toad species (*Bufo woodhousei, B. americanus, B. cognatus,*

and *B. speciosus*), the blue jay (*Cyanocitta cristata*), and praying mantids (probably Chinese mantids, *Tenodera ardifolia sinensis*).

RESULTS

Identification of Volatile Excretory Product. Urine from *J. sanguinolenta* adults or larvae fed *K. paniculata* seeds had a single volatile component (Figure 1A, **4**); bugs fed balloon vine seeds had no volatiles (Figure 1C). *J. haematoloma* adults and larvae also excreted **4** when fed golden rain tree seeds, but not when fed balloon vine seeds. The MS of **4** suggested a methyl-2(5H)-furanone structure. EI-MS *m/z* (%): 98(M^+, 33), 70(5), 69(100), 68(11), 55(1), 55(3), and 50(3); CH_4 CI-MS: 99($[M+H]^+$, 100); NH_3 CI-MS: 214($[2+NH_4]^+$, 2), 150($[M+(NH_3)_3H]^+$, 10). 133($[M+(NH_3)_2H]^+$, 100), and 116($[M+NH_4]^+$, 35). The identity of **4** as 4-methyl-2(5H)-furanone (3-methyl-2-butenolide) was deduced from spectral data: UV γ_{max} nm: 210; IR (CCl_4): γC=O 1755/1785 cm^{-1}, γC=C 1650 cm^{-1}; [^{1}H]NMR (60 MHz, $CDCl_3$) δ 2.16 (br s, 3H), 4.75 (br s, 2H), and 5.89 (br s, 1H); lit. (Liardon and Philippossian, 1978): IR (film): γC=O 1740/1775 cm^{-1}, δC=C 1640 cm^{-1}; [^{1}H]NMR (60 MHz, $CDCl_3$) δ 2.18 (m), 4.81 (m), and 5.94 (m). Insect-derived **4** coeluted with synthetic **4** by GC.

Identification of Blood Glycosides. Pinching the bugs usually caused them to bleed intersegmentally and eject scent secretion. Bleeding was most prevalent at the rostrum and, in adults, from the openings of the metathoracic scent gland. Methanol extracts of exuded fluid and of hemolymph showed the same components by TLC ($CHCl_3$–ethanol, 60:40) indicating that the externalized fluid is blood. Acetylation of 20 μl of blood extract from *J. sanguinolenta* larvae fed *K. paniculata* seeds confirmed by GC (Figure 1B) the pattern observed by TLC; compounds **6**, **8**, **12**, and **14** accounted for 0.5, 2.5, 88, and 4.5% of the total peak area, respectively. GC of an acetylated extract from *J. sanguinolenta* larvae reared on balloon vine seeds exhibited a new component (**10**, 69%) in addition to **12** (26%), and compounds **6**, **8**, and **14** were absent (Figure 1D).

The major blood component from six larvae and six adults of *J. haematoloma* reared on *K. paniculata* seeds (silica gel; 3 ml fractions of 10, 20, 40, 60, and 80% methanol–$CHCl_3$) gave CI-MS consistent with a monoglycoside having an aglycon of mol wt 275. The presence of the nitrile group in **11** was confirmed by the IR spectrum (γC≡N at 2228 cm^{-1}) and, since cardiospermin (=**9**) does not show IR absorption in the 2250 cm^{-1} region (Seigler et al., 1970, 1974), this structure was ruled out. The identity of **11** was confirmed by comparison to acetylated 4-β-D-glucopyranosyloxy-3-hydroxymethyl-2-butenylnitrile (=**12**, Figure 2) prepared from material isolated from *L. isolata*.

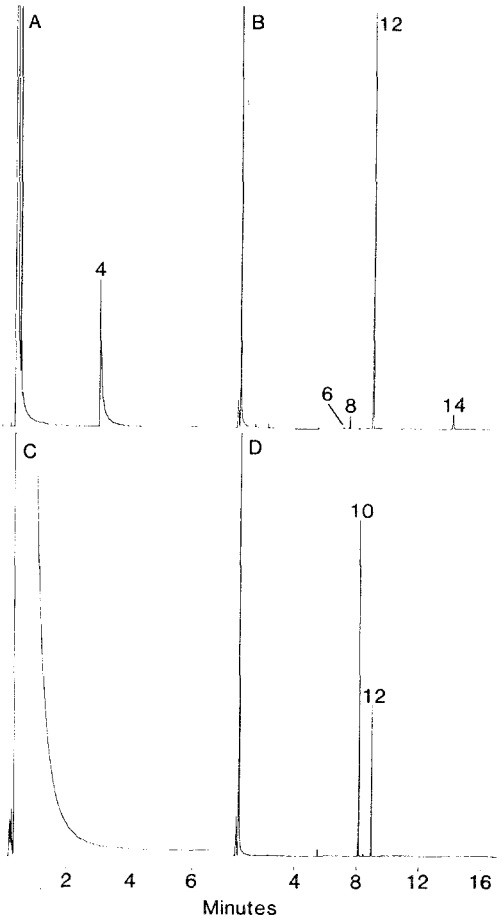

FIG. 1. Gas chromatograms of CH_2Cl_2 extracts of excreta and acetylated MeOH blood extracts from *Jadera sanguinolenta* adults reared on hosts with different cyanolipids (numbering of peaks follows Figure 2): (A) fed *Koelreuteria paniculata*/urine; (B) fed *K. paniculata*/blood; (C) fed *Cardiospermum cornindum*/urine (splitless GC injection); (D) fed *C. corindum*/blood.

For identification of minor bloodborne glycosides of *Jadera* reared on *K. paniculata* seeds, blood was collected from 166 male and female *J. sanguinolenta* in 3 ml of methanol and acetylated. Fractions (5 g silica gel) with material migrating above **11** by TLC were combined, as were those with material migrating below **11**. There were two prominent compounds in the fast-eluting fractions, one with an NH_3 CI-MS base peak at *m/z* 447 corresponding to a mol wt

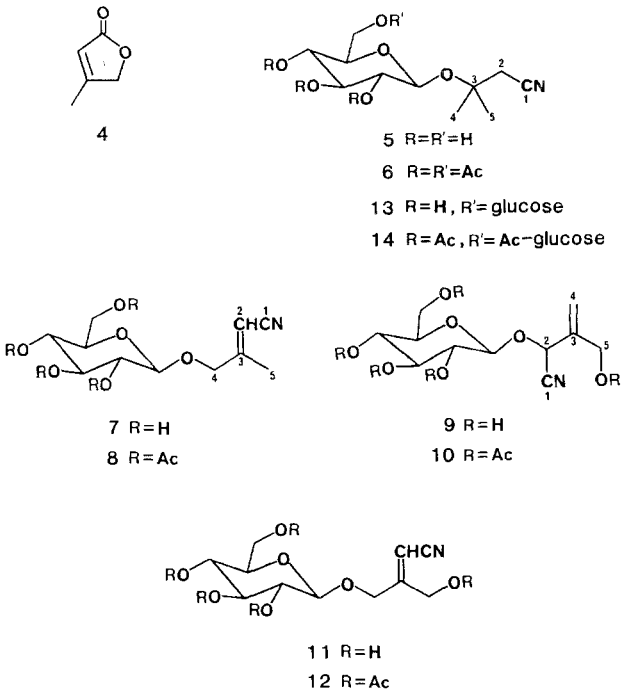

FIG. 2. Strucures of *Jadera* excretory lactone and blood-sequestered glucosides.

429 (Figure 1B, **6**) and the other with a base peak at *m/z* 445 corresponding to a mol wt 427 (Figure 1B, **8**). The [^{1}H]NMR of **8** differed characteristically from that of **12** by the absence of the H_2C-5 signal and the upfield shift of one methyl signal. Structure **7** (Figure 2) is proposed for this minor glycoside apparently derived from cyanolipid **3**. Compound **14** was isolated from the slow-eluting material by refractionating on silica gel (1:1, 3:1, and 6:1 $CHCl_3$–benzene) and recrystallizing from acetone–hexane (6:1 $CHCl_3$–benzene fraction). The NH_3 CI-MS of **14** exhibited a base peak at *m/z* 735 indicating a mol wt 717. This was substantiated by the CH_4 CI-MS (*m/z* (%) 718(20), $[M+H]^+$), and ions at *m/z* (%) 619(35) and 331(100) suggested the presence of a dihexose moiety. Two anomeric proton doublets (δ 4.57, J = 7.8 Hz; δ 4.70, J = 8.0 Hz) were observed in the [^{1}H]NMR, indicating a β-linked diglycoside structure. The signal at δ 4.08–4.30 integrated to two protons (H_2C-6″) whereas the signal at δ 3.58–3.84 integrated to four protons (HC-5′, HC-5″, and H_2C-6′), thus a β(1–6)disaccharide linkage was indicated. This interpretation was substantiated by comparisons to the [^{1}H]NMR spectra of amygdalin, sophorose, and melibiose. The EI-MS of **14** exhibited ions at *m/z* 702 ($[M-CH_3]^+$, <1%) and

677([M-CH_2CN]$^+$, 1%) consistent with a 3-glycoside of 3-methylbutyronitrile (Spencer and Daxenbichler, 1980). Decoupling experiments ruled out an aglycon corresponding to saturated **7** in favor of the dimethyl aglycon. Based on the CI-MS of **6** and the similarity of the EI-MS of **6** to that of **14**, structure **5** is proposed as the monoglucoside analog of **13**.

Compound **10** was the major glycoside of an acetylated methanolic extract of blood from *J. sanguinolenta* larvae reared on seeds of *C. corindum* (Figure 1D). The NH_3 CI-MS of **10** exhibited a base peak at *m/z* 503 indicating a mol wt 485, and the EI-MS showed an *m/z* 331 (9%) ion indicative of a hexose moiety. The IR of the isolated compound had no $\gamma C{\equiv}N$ and the [^{1}H]NMR spectrum had a pair of singlets at 5.54 δ and 5.66 δ (vinyl, 2H), a singlet at 5.20 δ (cyanohydrin H), and was otherwise identical to the published spectrum of acetylated cardiospermin (Seigler et al., 1974).

Aliquots of blood (5–15 μl) from the two lycaenid caterpillars collected from *C. corindum* showed no trace of the glycosides characteristic of *Jadera* feeding on balloon vine seeds.

3-Glucopyranosyloxy-3-methylbutyronitrile (5). Characterized as the tetraacetate **6**. NH_3 CI-MS *m/z* (%): 447 ([M+NH_4]$^+$, 100); $^{15}NH_3$ CI-MS: 448([M+$^{15}NH_4$]$^+$, 100); EI-MS: 331([M-C_5H_8ON]$^+$, 4), 242(26), 200(30), 169(33), 157(73), 140(39), 115(100), 98(90), 82(51), and 55(28).

4-β-Glucopyranosyloxy-3-methyl-2-butenylnitrile (7). Characterized as the tetraacetate **8**. NH_3 CI-MS *m/z* (%): 445([M+NH_4]$^+$, 100); $^{15}NH_3$ CI-MS: 446([M+$^{15}NH_4$]$^+$, 100); EI-MS: 331([M-C_5H_6ON]$^+$, 3), 265(9), 243(15), 200(23), 169(33), 157(49), 145(50), 112(65), 98(100), 81(97), 69(45), and 53(59); [^{1}H]NMR (300 MHz, $CDCl_3$) δ 1.95 (s, H_3C-5), 2.01–2.10 (4s, 12H), 3.72 (m, HC-3′), 4.16 (dd, HC-6′), 4.27 (dd, HC-6′), 4.48 (br s, H_2C-4), 4.52 (d, J = 7.8, HC-1′), 5.04 (dd, HC-2′), 5.10 (dd, HC-4′), 5.22 (t, HC-3′), and 5.27 (br s, HC-2).

Cardiospermin (2-β-glucopyranosyloxy-3-hydroxymethyl-3-butenylnitrile) (9). Characterized as the pentaacetate **10**. NH_3 CI-MS *m/z* (%): 503([M+NH_4]$^+$, 100); EI-MS: 331([M-$C_7H_8O_3N$]$^+$, 9), 271(2), 229(2), 211(3), 169(100), 138(19), 127(27), 109(92), 97(17), 81(15), and 69(11); IR (CCl_4) no $\gamma C{\equiv}N$; [^{1}H] NMR (300 MHz, $CDCl_3$) δ 2.02–2.10 (5s, 15H), 3.78 (m, HC-5′), 4.18 (dd, HC-6′), 4.27 (dd, HC-6′), 4.65 (br s, H_2C-5), 4.83 (d, J = 7.8, HC-1′), 5.03–5.14 (m, HC-2′, HC-4′), 5.20 (br s, HC-2), 5.26 (t, HC-3′), 5.34 (br s, HC-4), and 5.66 (br s, HC-4).

4-β-Glucopyranosyloxy-3-hydroxymethyl-2-butenylnitrile (11). NH_3 CI-MS (probe) *m/z* (%): 310([M+$(NH_3)_2$H]$^+$, 42), 293([M+NH_4]$^+$, 100), 215([hexose+$(NH_3)_2$H]$^+$, 26), and 198([hexose+NH_4]$^+$, 15); $^{15}NH_3$ CI-MS: 312(92), 294(100), 217(78), and 199(86); ND_3 CI-MS: 322(39), 302(100), 227(55), and 207(55); CH_4 CI-MS: 276([M+H]$^+$, 2); isobutane CI-MS: 332([M+C_4H_9]$^+$, 57), and 276(100); EI-MS: 155(2), 114(8), 97(16), 85(16),

73(72), 67(68), 60(100), and 57(51); IR(CCl_4): $\gamma C{\equiv}N$ at 2228 cm^{-1}. Further characterized as pentaacetate **12**. NH_3 CI-MS *m/z* (%): 503($[M+NH_4]^+$, 100); EI-MS: 331(2), 323(4), 292(2), 250(4), 242(11), 200(17), 169(25), 157(40), 145(37), 138(100), 115(45), 112(54), 98(58), 81(68), 70(34), 69(35), 61(7), and 52(6); [^{1}H]NMR (300 MHz, $CDCl_3$) δ 2.01–2.14 (5s, 15H), 3.73 (m, HC-5′), 4.17 (dd, HC-6′), 4.26 (dd, HC-6′), 4.55(d, J = 8.1, HC-1′), 4.59 (br s, H_2C-4), 4.74 (t, H_2C-5), 5.02 (dd, HC-2′), 5.09 (dd, HC-4′), 5.21 (t, HC-3′), and 5.54 (br s, HC-2); [^{13}C]NMR (300 MHz, $CDCl_3$) δ 20.0–20.2 (5C, $\underline{C}H_3COO$), 61.2 (C-6′), 62.3 (C-4), 66.6 (C-5), 67.7 (C-4′), 70.5 (C-2′), 71.8 (C-3′ or 5′), 72.2 (C-3′ or 5′), 97.2 (C-2), 99.6 (C-1′), 114.3 (C-1), 155.8 (C-3), and 168.8–170.1 (5C, $CH_3\underline{C}OO$). As the shift for the nitrile carbon (C-1) was at variance with that reported by Braekman et al. (1982) (δ 120.7), a [^{13}C]NMR (60 MHz, $CDCl_3$) spectrum of **12** derived from *L. isolata* supplied to us by Dr. Daloze was obtained on our instrument; the nitrile signal occurred at δ114.6. EI- and CI-MS of **12** from *L. isolata* were identical to **12** derived from *Jadera*.

*6-O-β-Glucopyranosyl-3β-glucopyranosyloxy-3-methyl-butyronitrile (**13**).* Characterized as heptaacetate **14** (2.6 mg, mp = 197–197.5°C). NH_3 CI-MS *m/z* (%): 735($[M+NH_4]^+$, 100); ND_3 CI-MS: 739(100); CH_4 CI-MS: 746($[M+C_2H_7]^+$, 9), 718($[M+H]^+$, 17), 619([dihexose]$^+$, 33), and 331([hexose]$^+$, 100); EI-MS: 677($[M\text{-}CH_2CN]^+$, 1) 370(2), 331(59), 317(16), 271(8), 215(11), 169(100), 157(15), 127(20), 109(51), 97(21), 81(48), 69(29), and 55(25); [^{1}H]NMR (300 MHz, $CDCL_3$) δ 1.39 and 1.40 (2s, H_3C-4 and H_3C-5), 2.00–2.10 (7s, 21H), 2.56 (d, J = 2.4, H_2C-2), 3.65 (d, HC-6′), 3.61–3.75 (m, HC-5′, HC-5″), 3.81 (dd, HC-6′), 4.12 (dd, HC-6″), 4.27 (dd, HC-6″), 4.57 (d, J = 7.8, HC-1′), 4.70 (d, J = 8.1, HC-1″), 4.85–5.09 (m, 4H; HC-4′, −4″, −2′, −2″), and 5.16–5.24 (m, HC-3′, HC-3″). [^{1}H]NMR (200 MHz, $CDCL_3$) of 3-methyl-3-(trimethylsiloxy)-butyronitrile lit. (Imi et al., 1987): 0.15 (s, 9H), 1.41 (s, 6H), and 2.47 (s, 2H).

Cyanogenesis. When five larvae and five adults of *J. haematoloma* reared on *K. paniculata* seeds were crushed separately in 4-ml vials, no HCN was detected even after addition of H_2SO_4. Single *J. haematoloma* larvae fed either *K. paniculata* or *C. grandiflorum* seeds were crushed in vials containing indicator paper and, after 10–15 min 40 μl of a β-glucosidase solution was added. Bugs reared on *K. paniculata* seeds showed no indication of HCN, and addition of β-glucosidase did not produce HCN. Larvae fed *C. grandiflorum* seeds tested negatively for HCN at first, but positively after addition of β-glucosidase. Urine (ca. 3 μl) collected from larvae fed *C. grandiflorum* was not cyanogenic even when β-glucosidase was added, nor was urine from larvae fed golden rain tree seeds. Last-instar *J. sanguinolenta* larvae were also tested as just described; *Cardiospermum*-fed bugs tested positively for HCN upon addition of β-glucosidase, but *K. paniculata*-fed bugs were acyanogenic within the observational time period (ca. 30 min).

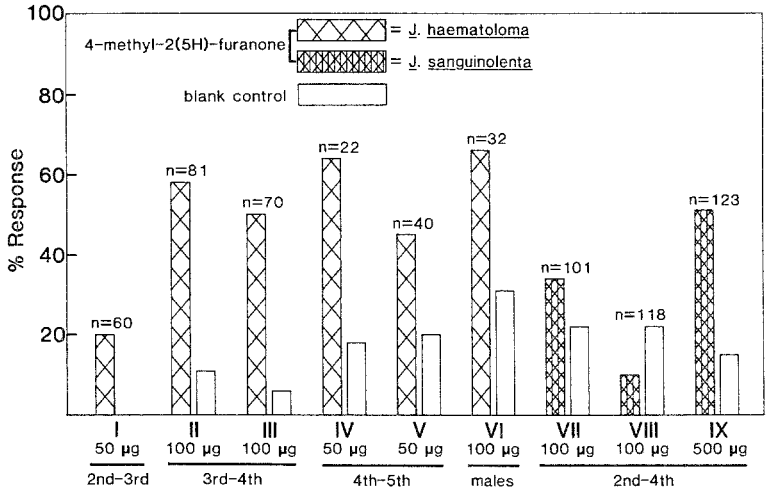

FIG. 3. Attraction of *Jadera* to 4-methyl-2(5H)-furanone.

Attraction Bioassay. J. haematoloma were attracted to **4** at the 50- and 100-µg dosages (Figure 3, tests I–VI; $X_1^2 > 3.84$, $p < 0.05$). Maximum response was usually recorded the morning after the test was started. For test I the maximum response occurred 2 hr after starting the test, but by the next morning the numbers of larvae in the treated versus control arms were not significantly different and the overall response was the lowest of all the *J. haematoloma* tests. Responses of *J. sanguinolenta* larvae to **4** were low at the 100-µg dosage and equivocal; in test VII the response was not significant from the control, and in test VIII more larvae occurred in the control arm (Figure 3). At a dose of 500 µg, *J. sanguinolenta* larvae were significantly attracted to **4** (Figure 3, test IX; $X_1^2 = 25.00$).

SCHEME 1.

Predator Aversion. Naive toads ate all 40 larvae offered, but later ate only two of 40 larvae and four of 40 adults (while readily eating mealworms) (Ribiero, 1989). Naive toads that initially ate adult bugs did not later avoid adults: 22 of 32 were eaten. However, toads ingesting adults in the second trial wiped their mouths and eyes and attempted to regurgitate. In tests with five captive, naive blue jays, each bird ate some or all of the three to four late-stage larvae offered initially, but only two ate bugs in a second trial; in a third trial, neither of these two birds would feed on bugs. One bird regurgitated after eating bugs. Experienced birds often tossed the bugs out of their cages. *Jadera* larvae offered to praying mantids were grasped and mandibulated for <5 sec and then thrown from the tree. Three larvae showed signs of pronotal damage, but none were permanently harmed. All five rejected larvae-emitted scent gland secretion and none of the mantids would accept another bug.

DISCUSSION

Serinethines are vividly marked, red insects that suck the seed oil of toxic Sapindales. They lack the stink glands common to most adult Heteroptera (hence the misnomer), yet still secrete, excrete, and bleed an impressive array of semiochemicals. A predator faces irritating vapors of α,β-unsaturated aldehydes, keto-aldehydes, and monoterpenes and, if it persists, is likely to have its mouth smeared with blood containing cyanogenic glucosides. For color-blind predators like shrews (Insectivora) (Huheey, 1984), scent gland odors may serve as aposematic signals associated with bloodborne toxins.

Our results show that HCN is released from crushed *Jadera*, but only in the presence of a β-glucosidase and only if the bugs are reared on balloon vine seeds. Sequestration of the glucoside cardiospermin by *Jadera* contrasts strikingly with the absence of this compound from the blood of lycaenid caterpillars that feed on balloon vine in which the concentration of cardiospermin is high (cf. Braekman *et al.*, 1982). Glucosides accumulated in the blood of *Jadera* fed soapberry or golden rain tree seeds are not truly cyanogenic; however, even acyanogenic cyanolipids exhibit insecticidal activity (Mikolajczak et al., 1984), and many predators reject bugs containing glucosides of these compounds.

The specialized *Jadera* mode of life is further highlighted by the ease with which the bugs exude blood. This capability is also reported for the serinethine *L. isolata* (Daloze et al., 1982) and is well known for *Oncopeltus fasciatus* (Heteroptera: Lygaeidae) and certain other lygaeine seed predators of cardenolide-containing Apocynales (Scudder et al., 1986). Notwithstanding the congeneric status of *L. isolata* and *L. trivittatus* (the boxelder bug), the latter species failed to ooze blood even after very rough handling (Aldrich, unpublished). In

fact, the glycoside chemistry of the former species is much more closely allied to that of *Jadera* than boxelder bugs. Certainly this is because *L. isolata* and *Jadera* feed on sapindaceous plants.

Analysis of the excreta of *J. haematoloma* and *J. sanguinolenta* for volatiles revealed a heretofore unknown dietary effect with intriguing ecological ramifications. 4-Methyl-2(5H)-furanone (**4**) is excreted by adults and larvae only if the bugs feed on golden rain tree (or soapberry?) seeds, and the bugs are attracted to this lactone. In southwestern North America, soapberry and golden rain trees typically mature thousands of seeds per tree at once in August and September, compared to the more continuous maturation of usually no more than several hundred seeds for balloon vine in the Florida Keys (Carroll, 1988). These phenological idiosyncrasies apparently have been paramount for evolution of *J. haematoloma* adults in Florida that are larger and produce larger eggs that take longer to hatch than do *Jadera* from Oklahoma (Carroll, 1988). For populations of Serinethinae on soapberry and golden rain trees, the limiting "resource" may be time rather than food (Carroll, 1988), so the orientation of *Jadera* individuals to a volatile excretory product could be an adaptive response to save time.

Acknowledgments—We thank Dr. D. Daloze (Université Libre de Bruxelles) for spectra and a sample of compound **12** from *L. isolata*, Dr. Jenella Loye (University of Utah) for assistance in field collections, and Ms. Sonjia Ribierro (University of Oklahoma) for permission to cite then unpublished data. Mr. Derek Hayes isolated compound **4** during summer employment in the INHL. S.P.C. was supported by grants from the University of Utah Research Council, the Smithsonian Tropical Research Institute, and Sigma Xi.

TOXINS IN CHRYSOMELID BEETLES
Possible Evolutionary Sequence from De Novo Synthesis to Derivation from Food-Plant Chemicals

(Received February 1, 1989; accepted March 17, 1989)

Abstract—In the Chrysomelinae, it appears that de novo synthesis of chemicals for defense is the primitive state, and the sequestration of plant chemicals for defense the derived state. The derived state evolved through both the morphological and biochemical preadaptiveness of the homologous defensive glands. In the adults, we discuss one unique case of sequestration in exocrine defensive glands of host-plant pyrrolizidine alkaloids by *Oreina cacaliae*. However, hypericin is not sequestered either in the glands or elsewhere in the body of *Chrysolina* spp. feeding on *Hypericum*, which contradicts an earlier claim. In the larvae, we examine in more detail how the phenolglucoside salicin can be used as the precursor of the salicylaldehyde present in the defensive secretion of *Phratora vitellinae* and *Chrysomela* spp. with minimal changes in the biochemical mechanisms involved in the biosynthesis of iridoid monoterpenes in related species.

Key Words—Coleoptera, Chrysomelidae, beetle, sequestration from plants, defense, pyrrolizidine alkaloids, salicin, salicylaldehyde, iridoid monoterpenes, hypericin, *Oreina cacaliae*, *Phratora vitellinae*, *Chrysomela* spp.

INTRODUCTION

Leaf-beetles provide us with striking examples of brilliant coloration. In many chrysomelid species, this conspicuousness is clearly fortified by unpalatability derived from chemical defense in both larval and adult stages. Upon alarm, these defensive chemicals can be released from specialized exocrine glands, by reflex bleedings, or by enteric discharges. In some cases, it is the mechanical action of the predator itself that causes the defensive substance to ooze from wounds of the prey.

The morphology, biology, and chemistry of such defenses in the Chrysomelidae has recently been reviewed (Pasteels et al., 1988) and will not be discussed in further detail here. The major point of interest in this paper is the derivation of chemical defense from host plants from a biochemical as well as evolutionary point of view. The Chrysomelidae are a relatively well-studied group that are known to biosynthesize their own chemical defenses (e.g., iridoids, cardenolides, isoxazolinones) (Pasteels et al., 1988) or to sequester their defenses from a food plant (e.g., salicylaldehyde, juglone, cucurbitacins) (Ferguson and Metcalf, 1985; Pasteels et al., 1989a). This base of comparative knowledge provides a platform from which we can begin to assess the processes involved in the evolution of the diversity of chemical defenses found in the taxon.

Here we review our recent work on plant-derived toxins in the defensive secretion of the Chrysomelinae. More particularly, we postulate the biochemical mechanisms that have allowed the replacement of autogenous compounds by plant-derived toxins by some taxa in the course of evolution.

Some general information on the nature and occurrence of the defensive glands is required before a more detailed discussion of the derivation of defense can be given. Defensive exocrine glands are found in both larval and adult leaf beetles. However, these two sets of glands are not homologous, and their distribution is restricted to certain taxa (Deroe and Pasteels, 1982; Pasteels et al., 1988). Moreover, when they occur in both larval and adult stages of the same species, they secrete toxins of completely different chemical natures. So far, no species is known in which plant-derived toxins occur in the defensive glands of both larvae and adult defensive glands. Yet, in both adults and larvae of genetically closely related species, the same morphological structures are utilized either to synthesize autogenous toxins or to store plant-derived toxins. This genetic relatedness, in conjunction with differences in the identity of chemical defenses, particularly in homologous glands, provides an opportunity to determine the influence of the host plant on defensive chemistry.

In the first part of this paper we report on a previously undescribed and striking example of host-plant influence on the exocrine secretions of adult Chrysomelinae (*Oreina* and pyrrolizidine alkaloids) and reconsider briefly a

previous report of sequestration (*Chrysolina* and hypericin). In the second part, we examine how plant toxins are sequestered in larval secretion (e.g., *Phratora* and *Chrysomela*, and phenolglucosides) and relate this to the probable mode of evolution of this habit.

HOST-PLANT INFLUENCE ON ADULT DEFENSE

In adults of the subfamily Chrysomelinae, the defensive glands are situated in the pronotum and the elytra, especially along the lateral margins. After physical disturbance, the secretion oozes from the gland pores and collects in marginal grooves as well as pronotal and elytral depressions, which help to retain the secretion on the insect. Each gland is formed from a group of secretory cells opening into a common duct. The secretion accumulates within the gland cells themselves, as there is no glandular reservoir. Within this taxon, these glands are morphologically very similar and undoubtedly homologous (Deroe and Pasteels, 1977, 1982). Comparative chemical studies have demonstrated a remarkably diversified defensive chemistry, including cardenolides, dipeptides, and isoxazolinone glucosides. The types of defensive compounds found in the different subtribes studied are summarized in Table 1. There is a close parallel between current classification and the type of compound secreted (see Pasteels et al., 1988).

In this section we will consider only the adults of the subtribe Chrysolinina, which, with few known exceptions to date, produce cardenolides and ethanolamine. In most species of the two European genera of this subtribe, the secretion contains a diversity of cardenolides (Table 2). The structure of 22 different cardenolides has been elucidated (Van Oycke et al., 1988). These cardenolides differ either in their aglycones, of which six are structurally identified,

TABLE 1. DISTRIBUTION OF ADULT DEFENSIVE COMPOUNDS MOST FREQUENTLY FOUND IN SUBTRIBES OF CHRYSOMELINAE (Chrysomelidae, Coleoptera)

Chrysomelinae subtribes	Defensive compounds
Chrysolinina 2 genera, 21 spp.	Cardenolides and ethanolamine
Doryphorina 1 sp.	γ-Glutamyl dipeptide
Chrysomelina 6 genera, 9 spp.	Isoxazolinone and nitropropionic acid glucosides
Phyllodectina 1 genus, 3 spp.	

TABLE 2. DEFENSIVE CHEMISTRY OF ADULT CHRYSOLININA PRODUCING CARDENOLIDES

Beetles	Host plants	Secretions
Oreina	Apiaceae	22 cardenolides identified
8 spp.	Asteraceae	6 aglycones
		8 sugars or esterified derivatives
Chrysolina	Lamiaceae	
13 spp.	Ranunculaceae	up to 138 μg/insect
	Plantaginaceae	(2×10^{-1} M to 4×10^{-1} M)
	Scrophulariacae	also present: ethanolamine
	Hypericaceae	

or in their sugar moieties, of which eight have been elucidated. Cardenolides are found in at least eight species of *Oreina* and 13 species of *Chrysolina* (Pasteels et al., 1988). This widespread occurrence suggests that this is the plesiomorphic condition in the taxon. The host plants of the beetles belonging to these two genera are quite diverse, including seven different families of plants (Table 3). None of these host plants contains cardenolides. Van Oycke et al. (1987) were able to demonstrate that in *C. coerulans* the cardenolides are biosynthesized from cholesterol, following a metabolic pathway that is identical to that found in plants. The function of ethanolamine may be to increase the solubility of the cardenolides in the secretion to reach concentration greater than 10^{-1} M.

TABLE 3. HOST-PLANT RELATIONSHIPS AND CHEMICAL DEFENSES OF ADULT CHRYSOLININA

Beetles	Host plants	Secretions[a]
12 spp. of *Chrysolina*	*Mentha, Lycopus, Rosmarinus, Galeopsis, Glechoma, Ranunculus, Plantago, Linaria*	Cardenolides
Chrysolina dydimata	*Hypericum*	Cardenolides
3 other spp. of *Chrysolina*	*Hypericum*	6-Oxosteroids
7 spp. of *Oreina*	*Chaerophyllum, Peucedanum, Centaurea*	Cardenolides
Oreina speciosissima	*Senecio, Adenostyles, Petasites*	Cardenolides
Oreina cacaliae	*Senecio, Adenostyles, Petasites*	Pyrrolizidine alkaloids

[a] Ethanolamine is also present in all secretions independently of the type of compound secreted.

There are, however, two striking exceptions to this pattern: three species of *Chrysolina* feeding on *Hypericum* secrete 6-oxosteroids and one species of *Oreina* feeding on various Asteraceae secretes pyrrolizidine alkaloids, in addition to ethanolamine. None of these insects secrete cardenolides.

In *Oreina cacaliae*, the major component of the secretion is seneciphylline *N*-oxide (Pasteels et al., 1989b). This species feeds on three genera of Asteraceae, all known to contain the pyrrolizidine alkaloid seneciphylline in its *N*-oxide form. Although sequestration has not yet been demonstrated unambiguously, the presence of exactly the same compound in the plant and in the beetle is unlikely to be a mere coincidence. Thus, secretion of autogenous cardenolides appears to have been replaced by sequestration of plant toxins; but ethanolamine is still produced by the beetle. More mystifying is *O. speciosissima*, a closely related sympatric species, which feeds on the same set of plants but secretes cardenolides rather than pyrrolizidine alkaloids. There are at least three possible alternative and not exclusive hypotheses to account for this. First, it may be advantageous to keep the secretions as chemically diverse as possible to avoid adaptation of specialized predators. Second, the secretion of cardenolides may be the more primitive condition, and thus, *O. speciosissima* has not yet developed the ability to sequester plant toxins. Thirdly, the defensive secretions may also have some species-specific pheromonal function.

Three of four species of *Chrysolina* feeding on *Hypericum* form the second exception to the rule of secretion of autogenous cardenolides (see Table 3). *Chrysolina* feeding on *Hypericum* produce as their main chemical defense polyoxygenated steroids characterized by a ketonic function on carbon 6 as in ecdysone (Daloze et al., 1985; Randoux et al., in preparation). The metabolic origin of these compounds is still unknown, although it is reasonable to hypothesize that they are metabolites of sequestered plant sterols.

There is a persistent claim in the literature that *C. brunsvicensis* sequesters the plant quinone hypericin. This claim is based on a short report by Rees (1969), which states that the quantity of hypericin found in the beetle was too high to be contained solely in the gut. Hypericin, however, is present neither in the defensive secretions containing polyoxygenated steroids, nor is it present in the hemolymph or other body parts of *C. brunsvicensis*, *C. varians*, *C. hyperici*, and *C. geminata* in amounts that could significantly contribute to defense (<0.5 μg/beetle) (Duffey and Pasteels, in preparation).

Thus, it seems that certain beetle species have evolved to replace their primitive de novo secretion with sequestered plant toxins. The reasons for this replacement are not yet known and await a better understanding of both the ecological and metabolic factors involved. This information is not yet available for adult beetles but, as we will see in the next section, it is starting to emerge for the larvae.

HOST-PLANT INFLUENCE ON LARVAL DEFENSE

The larvae of the subtribe Chrysomelina and of the genus *Phratora* possess nine pairs of segmental exertile glands (Pasteels et al., 1984). Many species produce highly reactive iridoid monoterpene aldehydes and ketones (Table 4). These species feed on a great diversity of host plants (seven families). The plants are not known to contain iridoid precursors, and the iridoid monoterpenes must be synthesized de novo by the larvae. Following the same reasoning as for adult defenses, we suggest that this widespread occurrence of autogenous iridoid monoterpenes represents the primitive condition. Some species, however, produce aromatic compounds such as salicylaldehyde, juglone, and phenylethyl esters, instead of iridoid monoterpenes. The metabolic origin of the phenylethyl esters produced by the North American *Chrysomela interrupta* remains to be clarified (Blum et al., 1972). The other shifts in defensive chemistry can be correlated with host-plant influence. For example, species producing salicylaldehyde feed on *Salix* and *Populus*, which are rich in salicin and from which salicylaldehyde is derived (Rowell-Rahier and Pasteels, 1982; Pasteels et al., 1983; review in Rowell-Rahier and Pasteels, 1986; Pasteels et al., 1989a). Note that in the genus *Phratora*, some species produce autogenous iridoid monoterpenes, but *Phratora vitellinae* derives salicylaldehyde from host-plant salicin, although all species feed on Salicaceae. Thus, as observed in the adults (see above), species belonging to the same genus and feeding on the same host plants may either derive their toxins from host plants or biosynthesize them de novo. The hypotheses advanced to explain this double origin of toxins in the

TABLE 4. DISTRIBUTION OF DEFENSE COMPOUNDS IN CHRYSOMELINAE LARVAE

Beetles	Host plants	Secretions
Subtribe Chrysomelina		
6 genera, 11 spp.	Salicacae Betulaceae Ranuncalaceae Apiaceae Polygonacae Scrophulariaceae Cruciferae	Iridoid monoterpenes
Chrysomela interrupta	Betulaceae	Phenylethyl esters
6 spp. of *Chrysomela*	Salicaceae	Salicylaldehyde ± benzaldehyde
Gastrolina depressa	Juglandaceae	Juglone
Subtribe Phyllodectina		
3 spp. of *Phratora*	Salicaceae	Iridoid monoterpenes
Phratora vitellinae	Salicaceae	Salicylaldehyde

adults are also valid for the larvae. Finally, *Gastrolina depressa* probably derives its juglone (Matsuda and Sugawara, 1980) from the host plant *Juglans*.

To derive salicylaldehyde from salicin, only two enzymes are needed; first, a β-glucosidase to hydrolyze the β-glucoside salicin to the aglycone saligenin and glucose; second, an oxidase to transform saligenin into salicylaldehyde. To derive juglone from the plant toxin, exactly the same two kinds of enzymes are necessary. Likewise, we hypothesized that in the species that secrete iridoid monoterpenes, these chemicals are, initially, produced as glucosides; these are less toxic, more stable, and easier to transfer across membranes (from gland cells to lumen of exertile gland). In the second step, after secretion of the glucosides into the lumen, it is hypothesized that the glycoside is enzymatically hydrolyzed to the hemiacetal and then subsequently oxidized to the dial (e.g., plagodial) (Figure 1). In all these above cases, the common factor is the concurrent action of a β-glucosidase and an oxidase upon a glucoside and an alcohol, respectively, to liberate a carbonyl-containing defensive chemical. Hence, if one views the de novo synthesis of defense chemicals as the primitive state, the enzymes are already (i.e., preadaptively) present that would permit the evolution of the use of plant-derived glucosides for defense. Such an evolution only requires changes in the specificity of the two enzymes, particularly that of the oxidase.

This evolutionary scheme has been tested indirectly (Duffey and Pasteels, in preparation) by comparing the enzymatic specificity of the β-glucosidase and oxidase in the gland fluid of *Plagiodera versicolora*, a species that feeds on

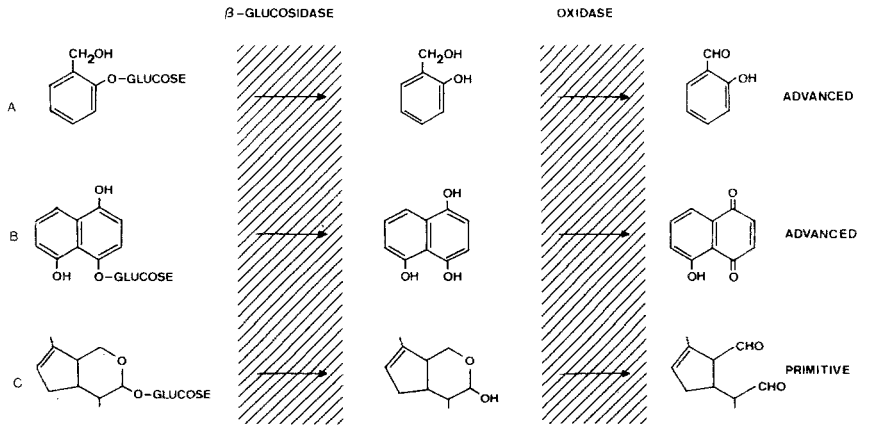

FIG. 1. Final steps in the production of toxins in chrysomelid larvae; A and B examplify the derivation of toxins from plant precursor; C, de novo biosynthesis. B and C remain putative.

Salix and secretes autogenously monoterpenes, and of *Chrysomela populi*, a species that also feeds on *Salix* and by sequestration secretes salicylaldehyde.

Let us consider *Plagiodera versicolora* first; a hypothetical schematic representation of the glands and associated organs and processes involved in the production of iridoidal defenses of larvae is given in Figure 2. The gland cells supposedly biosynthesize and secrete into the lumen of the gland the β-D-glucoside of monoterpene iridoid. Up to now we have not been able to detect the glycosidic or aglyconic hemiacetal form of the monoterpene in the defensive secretion. However, glucose is readily detectable, which supports the hypothesis that a glucoside is a precursor. Moreover, significantly high levels of nonspecific β-glucosidase activity have been detected in this fluid. This activity is able to hydrolyze a wide variety of phenolic and terpenoid glucosides (including salicin). We have not been able to prove the existence of the oxidase, possibly because of its specificity (see below for salicin) and of a lack of appropriate substrates. The secretion was not able to oxidize saligenin to salicylaldehyde or to oxidize the aglycone of the iridoid glucoside mussaenoside.

Another aspect of the scheme deserves attention. The lumen of the gland is filled with a biphasic fluid comprising an aqueous component containing the enzymes and glucose and a nonmiscible phase containing the monoterpene aldehydes. The aqueous phase permits the solution of the postulated glucoside as well as of the aglycone. We assume that once the glucoside is secreted into the

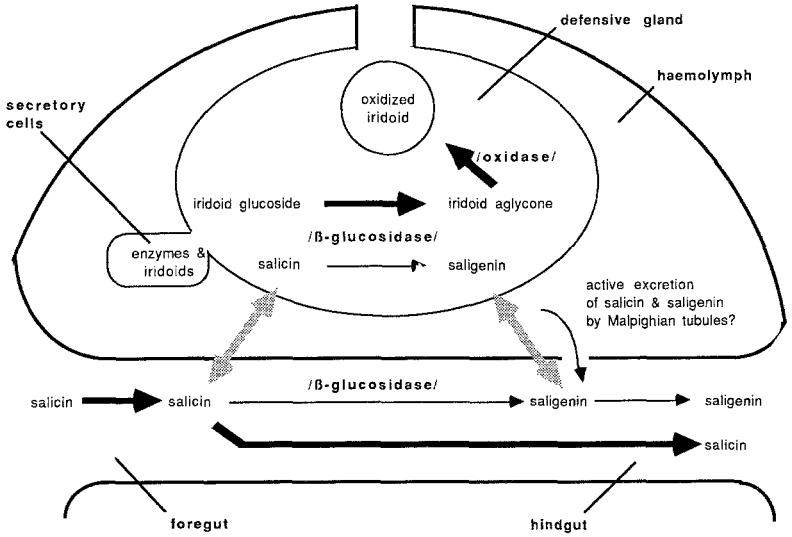

FIG. 2. Schematic representation of the biosynthesis of defensive iridoid monoterpenes in the larvae of *Plagiodera versicolora*. (Adapted from Duffey and Pasteels, in preparation.)

lumen, it is rapidly hydrolyzed, and the resulting aglycone rapidly oxidized to the dial, which is the reason the former two are not detectable. However, once the dial is formed, it rapidly forms the second phase (an oil) because of its immiscibility with the aqueous phase.

Based on the evidence from *Plagiodera versicolora*, we suspect that the major biochemical determinant of the chemical nature of the defensive secretion is the oxidase, rather than the glucosidase. In other words, a change in the specificity of the oxidase, say the acquisition of the ability to oxidize saligenin, would permit an insect to develop a switch from de novo biosynthesis of iridoid monoterpenes to sequestered defense via the utilization of the plant glucoside salicin. In *Chrysomela populi*, we believe we have evidence for this switch in defensive strategy.

In species such as *C. populi*, which produces salicylaldehyde (Figure 3), the defensive secretion is biphasic and readily emulsifiable. The aqueous phase contains not only high levels of both nonspecific β-glucosidase activity (it will hydrolyze many phenolic terpenoid glucosides) and specific oxidase activity (O_2-dependent, NAD-independent activity against a limited number of analogs and homologs of saligenin), but also contains traces of salicin and saligenin (Duffey and Pasteels, in preparation). The determining enzyme, the oxidase, which shows high specificity, rapidly converts saligenin to salicylaldehyde but is unable to oxidize the aglycone of mussaenoside to the aldehydic form; the

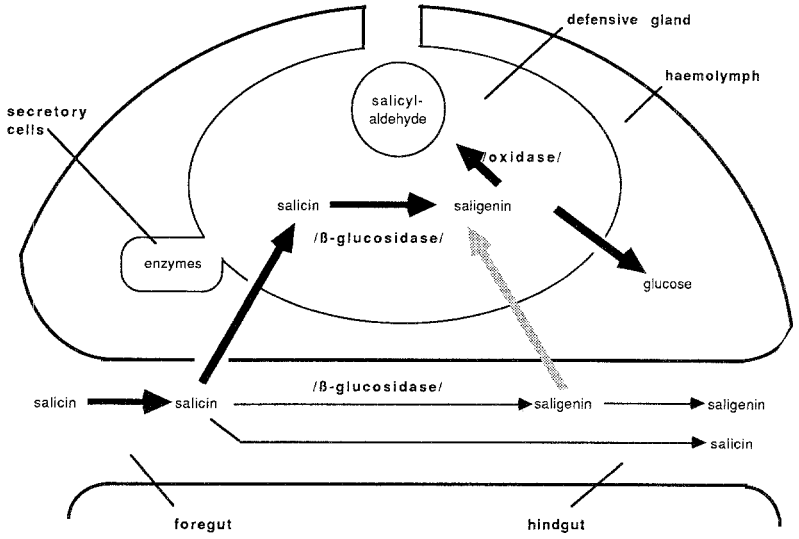

FIG. 3. Schematic representation of the biosynthesis of defensive salicylaldehyde derived from host-plant salicin in the larvae of *Chrysomela populi*. (Adapted from Duffey and Pasteels, in preparation.)

glucosidase, by contrast, effectively hydrolyzes mussaenoside. Once the salicylaldehyde is produced in the gland fluid, it forms a distinct organic phase because of its lipophilic nature and its immiscibility with the aqueous phase. The formation of a water-insoluble phase within the confines of the gland restricts the diffusion of toxic salicylaldehyde to the body in general.

There is another salient aspect of the scheme (Figure 2) that relates to how a change in the specificity of the oxidase could lead to a switch from de novo synthesis of monoterpenes to production of salicylaldehyde from a sequestered precursor. Note again that both *P. versicolora* and *C. populi* feed upon *Salix* and both ingest salicin. Some β-glucosidase activity is present in the gut of *C. populi* and *C. tremulae* (Duffey and Pasteels, in preparation; Pasteels et al., 1983); the ingested foliage does not contribute meaningfully to the production of saligenin. However, only the glands of *C. populi* produce salicylaldehyde. Both salicin and saligenin probably diffuse passively through the bodies of the insects into the gland fluid because of their water solubility. With a change in enzyme specificity towards metabolism of saligenin, resulting from gland glucosidase activity, salicylaldehyde can be accumulated rapidly because of the constant inward diffusion of plant substrates. The conversion of saligenin to salicylaldehyde may also be of benefit, considering that saligenin is toxic and must probably otherwise be eliminated by reglucosylation, excretion by Malpighian tubules, or other mechanisms. It is worth noting that the feces of *C. populi* contain only traces of salicin and saligenin, whereas the feces of adults of *C. populi* and larvae of *P. versicolora*, neither of which sequester salicylaldehyde, have very high levels of salicin and saligenin.

Thus we propose that a single change in the specificity of the oxidase is very likely the only prerequisite to the utilization of plant precursors by the larvae. The process could be further refined by an increased permeability of the gut to salicin and/or saligenin and the reduction of its active excretion by the Malpighian tubules. Additionally, more glucose will be recovered by the larvae as the quantity of salicin hydrolyzed increases, thus giving the species utilizing salicin a net energetic advantage compared to those synthesizing iridoid monoterpenes (Rowell-Rahier and Pasteels, 1986). According to our hypothesis, sequestration of plant-derived toxins is a secondary event that has replaced the more costly autogenous synthesis of toxins.

It is reasonable to suppose that those larvae that secrete juglone underwent an analogous switch in the specificity of the oxidase.

CONCLUSIONS

Our results suggest that during the evolution of leaf-beetles, the colonization of new host plants by these specialized herbivores had major consequences on their chemical defenses. On at least four independent occasions

(once in the adults and three times in the larvae), the sequestration of plant toxins or the derivation of toxins from host-plant precursors has replaced the production of autogenous compounds, although the defensive glands, used both as storage and releasing organs, remained basically unchanged.

Our present understanding of the metabolic processes involved during the derivation of toxins from plant precursors in larval secretions not only illuminates their probable evolution, but also points to the likely limitations of plant influence on larval chemical defense.

Evolutionary success was probably the result of lower defensive costs. Preexisting glands and enzymes (β-glucosidase and oxidase), only slightly modified in their specificity, are used to derive toxins from plants, and thus no additional cost is required for the metabolism of plant precursor by the larvae, and, additionally, there is an economy in toxin biosynthesis and, possibly, in active excretion of the plant toxin. Moreover, the plant toxin acquires a nutritive value due to the glucose released during its metabolism. This is possible only if the plant precursor is a glucoside, the aglycone of which can be transformed by oxidation into a nonpolar toxin. Host-plant influence on larval secretion may be restricted to glucosides. So far, only plant glucosides are known to be used for defense by the larvae, and twice (in *Chrysomela* and *Phratora*) it is the same glucoside, salicin, that is used.

The adult glands must function on completely different principles, which remain poorly understood; plant glucosides are not metabolized in those glands, even in the species that use these glucosides for defense in their larval stages. At present it is impossible even to guess why the sequestration of pyrrolizidine alkaloids is possible in glands that originally biosynthesized cardenolides from cholesterol or why sequestration of pyrrolizidine alkaloids has evolved repeatedly in insects (review in Boppré, 1986).

Acknowledgments—We thank J.C. Braekman, D. Daloze, L. Koechlin, and H. Rowell for fruitful discussion and comments on previous drafts of this manuscript. M. Rowell-Rahier thanks the Schweizerischer Nationalfonds for financial support. We wish to thank Dr. Stermitz for the sample of mussaenoside he kindly gave us.

Abstract—Adults of a generalist herbivore, the lubber grasshopper, *Romalea guttata*, can be converted to functional specialists by feeding them exclusively on catnip, *Nepeta cataria*. No obvious adverse effects on adult development resulted from this enforced monophagy. Notwithstanding the fact that *R. guttata* has had no coevolutionary relationship with this Eurasian mint, it readily sequesters compounds that are identical to or derived from the terpenoid lactones that are characteristic of *N. cataria*. *R. guttata* appears to both biomagnify minor allelochemicals and to sequester metabolites of the *Nepeta* terpenes in its paired defensive glands. The levels of autogenously produced phenolics are not affected by feeding on *N. cataria* and the defensive secretions of catnip-fed grasshoppers are more repellent to ants than those of wild-fed acridids. Metabolites of the *N. cataria* monoterpenes are sequestered in the defensive glands when catnip is added to the natural diet of *R. guttata*. The ability of a generalist, *R. guttata*, to facilely bioaccumulate a potpourri of foreign allelochemicals when feeding in a specialist mode is

0098-0331/90/0100-0223$06.00/0

analyzed in terms of its biochemical, physiological, and functional significance. Sequestration is examined as a response to the enteric effronteries represented by the phytochemicals that can be characteristic of the "overload" in a monophagous diet.

Key Words—Lubber grasshopper, *Romalea guttata* (*microptera*), Orthoptera, Acrididae, sequestration, catnip, *Nepeta cataria*, cyclopentanoid monoterpenes, phenolics, generalist herbivore, defensive secretion.

INTRODUCTION

Herbivores have evolved a variety of mechanisms for coping with the diverse allelochemicals that fortify their host plants. These include excretion, metabolism, and sequestration (Rothschild, 1972; Blum, 1981, 1983), but the particulars of how a species processes the natural products in its diet are very idiosyncratic and it has been emphasized that each herbivore and the phytochemicals in its host plant must be regarded as a distinct evolutionary case (Blum et al., 1987). Furthermore, the abilities of many species of phytophagous insects to feed on plants containing potentially toxic natural products have considerable consequences vis-à-vis the chemical defenses of these arthropods, especially against vertebrate predators.

Many species of specialist phytophages sequester plant-derived compounds or their metabolites, and these insects are often aposematic (Rothschild, 1972). These acquired compounds are often of considerable defensive value, rendering their possessors either unpalatable or toxic to predators. In addition, these specialists may synthesize intrinsic toxins (Rothschild et al., 1975) that considerably augment the message of deterrency carried by the sequestered allelochemicals. Although some generalists can biomagnify ingested plant natural products, in general these species act like specialists by temporarily feeding on a single plant species that often contains high concentrations of sequestrable compounds (Rothschild and Aplin, 1971).

While most specialist herbivores sequester plant allelochemicals in nonsecretory structures (Duffey, 1980), species in a few taxa bioaccumulate these compounds in exocrine glands, some of which are identified with the de novo synthesis of potent defensive allomones. Lygaeids may biomagnify cardenolides in their aldehyde-rich defensive glands (Scudder and Duffey, 1972; Duffey and Scudder, 1974), in contrast to certain milkweed-feeding acridids whose defensive exudates are dominated by these steroidal allelochemicals (von Euw et al., 1967). The generalist acridid, *Romalea guttata*, appears to represent a unique case because it not only produces a large variety of allomonal constituents in its defensive glands (Eisner et al., 1971; Jones et al., 1988), but when forced to feed on a single species of host plant behaves like a sequestrative

specialist (Jones et al., 1989). The consequences of this enforced monophagy are considerable.

The secretions of *R. guttata* are dominated by phenolics and quinones (Eisner et al., 1971), but great individual variation in the compositions of the secretions are characteristic of this species (Jones et al., 1986). Furthermore, the autogenous defensive compounds in the secretions may be quantitatively and qualitatively diminished when diet breadth is restricted (Jones et al., 1987). Significantly, when diet was reduced to a single species, wild onion (*Allium canadense*), allelochemicals characteristic of this plant were sequestered in the defensive glands, whereas autogenous compounds were either absent or present in reduced concentrations (Jones et al., 1989). However, the secretions of the onion-fed acridids were more repellent to foraging ants than those derived from wild-fed grasshoppers.

Recently, we demonstrated that adults of *R. guttata* fed readily on catnip, *Nepeta cataria*, as a sole food plant, and apparently sequestered some compounds from this mint (Blum et al., 1987). In the present report, we have determined the fates of the ingested monoterpenes characteristic of *N. cataria* (Regnier et al., 1967a,b; Tucker and Tucker, 1988), when *R. guttata* was in a specialist feeding mode. In addition, we studied the effect that this enforced monophagy had on the concentrations of autogenous defensive compounds and whether this dietary specialization affected adult survivorship. Finally, we compared the repellency of the secretions from *Nepeta*-fed acridids to those collected from wild-fed individuals as a further measure of the consequences of monophagy for this eminent polyphage.

METHODS AND MATERIALS

Rearing of Insects. Groups of 15 field-collected female larvae (fifth instar) were placed in cages maintained at 25 ± 2°C with 60 ± 10% relative humidity and a 12 : 12 hr light–dark cycle. Larvae and the subsequent adults were either fed a control diet consisting of romaine lettuce, *Latuca sativa longifolia*, and dried oatmeal or experimental diets made up of (1) freshly cut leaves and stems of catnip, (2) a natural diet (wild fed) that included many of the 26 species of plants readily fed upon in this area, and (3) natural diet plus catnip as a minor constituent. Survivorship was recorded 14 days after the adult molt.

Secretion Collection. The defensive exudate is eliminated at each molt and subsequently regenerated. Two-day-old adults were milked with microcapillaries (10 μl), and these secretions were discarded. Secretions were again collected when the adults were 14 days old, and the total volume of secretion was recorded (±0.25 μl). The capillaries were immediately sealed and were stored at −10°C until the secretions were analyzed.

Bioassay of Romalea *Secretions as Feeding Deterrents.* The repellencies of the metathoracic exudates were determined by utilizing the fire ant *Solenopsis invicta* in feeding tests. Bioassays were undertaken by introducing into the foraging arena of colonies ($N = 8$) 25 × 75-mm glass slides to which were added two 25-μl droplets of 2.5% sucrose solution. One droplet contained 0.5 μl of a secretion from lubbers that had been fed on a single host plant (e.g., lettuce, catnip). The second droplet served as a standard and contained 0.5 μl of secretion obtained from wild lubbers that had consumed a generalist diet (Jones et al., 1987). Tests were undertaken by presenting the different secretions in a randomized order and at different times of the day. The number of ants at each droplet was recorded at 5-min intervals until a droplet had been consumed. Data were analyzed by Friedman two-way analysis of variance.

Analysis of Defensive Exudates, Feces, and Catnip Leaves. Fresh catnip leaves and feces from grasshoppers that had fed exclusively on catnip were analyzed for the presence of *Nepeta*-derived compounds or their metabolites. Leaf or fecal samples were placed in 3-dram vials and covered with methylene chloride (Burdick and Jackson) and stored at −10°C for at least 30 days. Prior to examination by gas chromatography (GC) or gas chromatography–mass spectrometry (GC-MS), the samples were warmed to room temperature, shaken, and a 250-μl aliquot in a tapered test tube was concentrated under nitrogen to 5 μl. The extract was treated with 100 μl of a 1:1 mixture of *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) and dimethylformamide (DMF), capped, heated for 45 min at 76°C in a capped tapered test tube and, after cooling, a 1-μl aliquot was removed for gas chromatographic (GC) analysis. Derivatization of compounds in the defensive secretions was effected by adding the BSTFA–DMF mixture to a 5-μl aliquot of the exudate in a microsampling vial, which was treated as above.

GC and GC-MS analyses were conducted on a Hewlett-Packard 5985B GC-MS system equipped with a cold on-column injection port (Arrendale and Chortyk, 1985) with a 0.32-mm-diam. × 30-m SE-54 0.5-μm film thickness fused silica capillary column (Arrendale and Martin, 1988), and a flame ionization detector (FID) and an open split GC-MS interface (Arrendale et al., 1984) using a temperature program of 100°C for 1 min followed by 3°C/min increase to 280°C. Samples were first analyzed with the column connected to the FID and then switched to the open-split interface for GC-MS analysis. Mass spectrometer conditions were as follows: ion source temperature 200°C, electron multiplier voltage 2400 V, electron energy 70 eV, scan range 40–400 dalton, scan rate 266.7 dalton/sec, and GC-MS interface zone temperature 300°C.

Synthesis of Nepetalactone Metabolites. Potential metabolites of nepetalactone (**Ia,** Figure 1) were prepared by isolating the lactone from *N. cataria.* Leaves and small stems (285 g) were extracted by dipping into 200 ml of methylene chloride and, after filtration and solvent removal, a 2.5-g cuticular extract

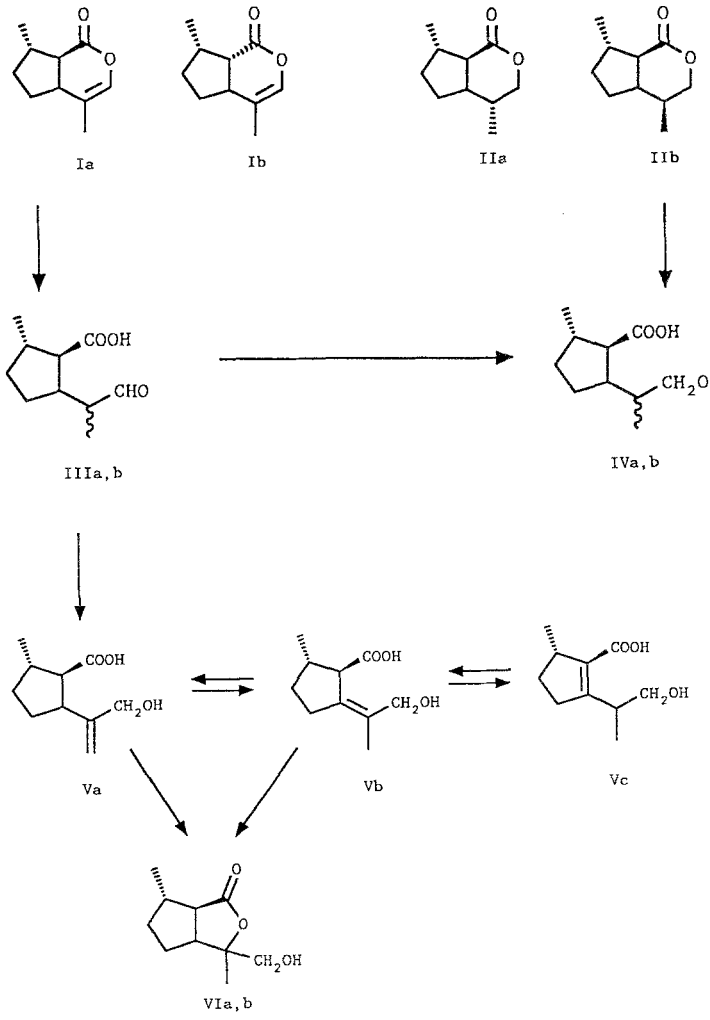

FIG. 1. Cyclopentanoid monoterpenes from *N. cataria* and their metabolites in lubber secretions.

was obtained. A portion of the extract (0.85 g in hexane) was placed on a 30-g silicic acid column (Unisil, 100–300 mesh, activity grade I) and eluted stepwise with hexane–CH_2Cl_2 gradient (100 ml hexane; 200 ml, 1:9 CH_2Cl_2–hexane; 200 ml, 1:4 CH_2Cl_2–hexane; and 200 ml, 1:1 CH_2Cl_2–hexane). About 122 mg of 93+% I was isolated in the 1:1 CH_2Cl_2–hexane fraction.

A portion of the isolate was subjected to preparative GC on HP 5830

equipped with a 2-mm-ID × 1.8-m glass column packed with 10% Carbowax 20 M on 80–100 mesh Chromosorb W-AW and thermoconductivity detector using a temperature program of 100–200°C at 5°C/min to yield 98% Ia.

*Conversion of **Ia** to Dihydronepatalacone (**IIa**) and Isodihydronepatalactone (**IIb**).* About 1.0 mg of **Ia** was hydrogenated using palladium on charcoal in 95% ETOH under H_2 at atmospheric pressure. A mixture of products similar to those isolated by Regnier et al. (1967b) was obtained: 82% 2-isopropyl-5-methylcyclopentanoic acid, 2% **IIa** (Figure 1, MW = 168), and 16% **IIb** (Figure 1, MW = 168).

*Conversion of **Ia** to Nepetalic Acids (**IIIa** and **b**) and Nepetolic Acids [**IVa** and **b** = 2-(2-Hydroxyisopropyl)-5-methylcyclopentanoic Acids].* About 1 mg of **Ia** (Figure 1) was hydrolyzed with 1.5 ml of 1 N KOH for 1 hr in an ultrasonic bath (Regnier et al., 1967a), and the hydrolysate was extracted with hexane (3 × 1 ml). Half the water-soluble portion was adjusted to pH 2 and was extracted with CH_2Cl_2 (3 × 1 ml) to yield a mixture of **IIIa** and **b,** which was converted to silyl ethers and subjected to GC and GC-MS analysis (MW_{TMS} = 256). The nepetalic acids were not observed in the defensive secretions of *R. guttata*.

The other portion of the **Ia** hydrolysate was directly treated with excess $NaBH_4$. After 24 hr in the dark at room temperature, the sample was treated as described above to yield ditrimethylsilyl derivatives of dihydroisonepetolic acid (**IVa,** MW = 330) and dihydronepetolic acid (**IVb,** MW = 330) in about a 1:2 ratio. Hydrolysis of the hydrogenation products (**IIIa** and **b**) from **Ia** produced about a 1:6 ratio of **IVa** to **IVb.**

RESULTS

7-Methylcyclopentapyranones and Other Phytochemicals in N. cataria *Leaves.* The capillary gas chromatogram of the CH_2Cl_2 whole-leaf extract of catnip is shown in Figure 2. The majority of the compounds eluting before 12 min are artifacts of the silylation reagents. In good agreement with other reports (Regnier et al., 1967a,b), the terpenoid lactones associated with the extract were 92% **Ia** (nepetalactone), 7.4% **Ib** (epinepetalactone), 0.1% **IIa** (dihydronepatalactone), and 0.3% **IIb** (isodihydronepatalactone) (see Figure 1 for structures).

Ib was characterized using retention time and GC-MS data obtained from the analysis of an essential oil sample from *Nepeta mussini*; the major terpene in this oil is **Ib** (Regnier et al., 1967b). The presence of the saturated lactones **IIa** and **IIb** was confirmed by hydrogenation of **Ia** and reported GC retention data (Regnier et al., 1967a,b).

Other components identified by GC-MS were the typical plant fatty acids

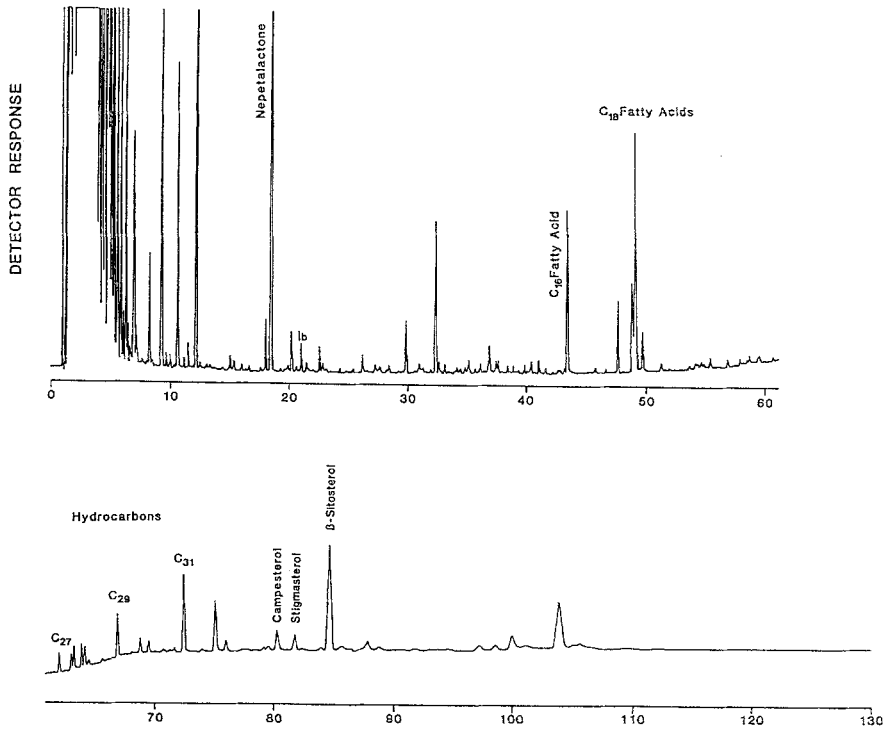

FIG. 2. Capillary gas chromatogram of the silylated methylene chloride extract of *N. cataria* leaves.

and a series of aliphatic hydrocarbons dominated by the C_{27}, C_{29}, and C_{31} alkanes (Figure 2). Typical phytosterols were also identified in this extract. None of the phenolics (e.g., catechol, hydroquinone) that dominate the defensive secretion of *R. guttata* were detected.

Phytochemicals Identified in Feces of Lubbers Fed Leaves of N. cataria. Gas chromatographic analysis of the fecal extracts of catnip-fed lubbers (Figure 3) indicated that most of the hydrocarbons, fatty acids, and phytosterols were excreted directly after ingestion of leaf material. On the other hand, major qualitative and quantitative changes in the cyclopentanoid monoterpenes of *N. cataria* were readily evident.

The major terpene present in catnip leaves **Ia,** was reduced from a relative abundance of more than 90% of the monoterpene mixture to a relative abundance of less than 20% in the fecal extract (Figure 3). Indeed, none of the five terpenes detected in the feces exceeded 25% of the monoterpene mixture and both the unsaturated (**Ia, Ib**) and saturated lactones (**IIa, IIb**) were of similar

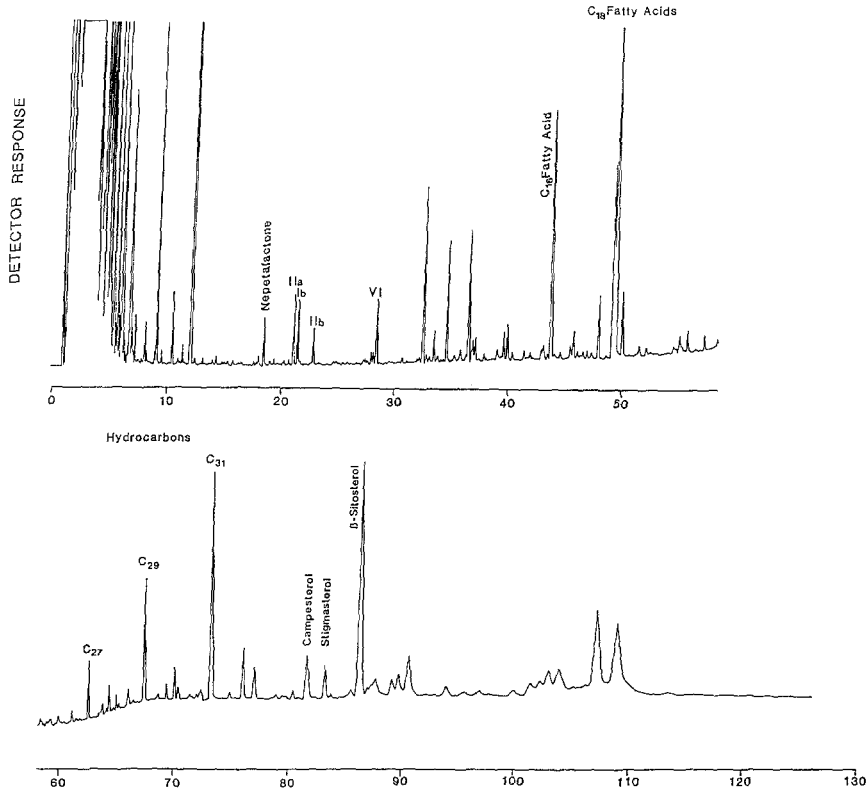

FIG. 3. Capillary gas chromatogram of the silylated methylene chloride extract of the feces of lubbers fed on *N. cataria* leaves.

concentrations. On the other hand, a terpene not detected in *N. cataria* leaves was present in the feces of catnip-fed grasshoppers. This lactone, **VI,** is described in the next section.

Neither the characteristic cyclopentanoid monoterpenes of *N. cataria* nor their metabolites are excreted in appreciable quantities. For example, based on unitary detector response, the ratio of **Ia** and the C_{31} cuticular hydrocarbon in the leaf was 176:1, whereas the ratio in the feces was 1:5.

Compounds Identified in Secretions of Lubbers Fed N. cataria. The capillary gas chromatogram of the defensive secretion (TMS) of lubbers fed on catnip is shown in Figure 4. The major compounds detected by GC-MS appeared to be a mixture of silylated hexoses that were present in all exudates analyzed, host plants notwithstanding. The structures of these compounds were not further characterized.

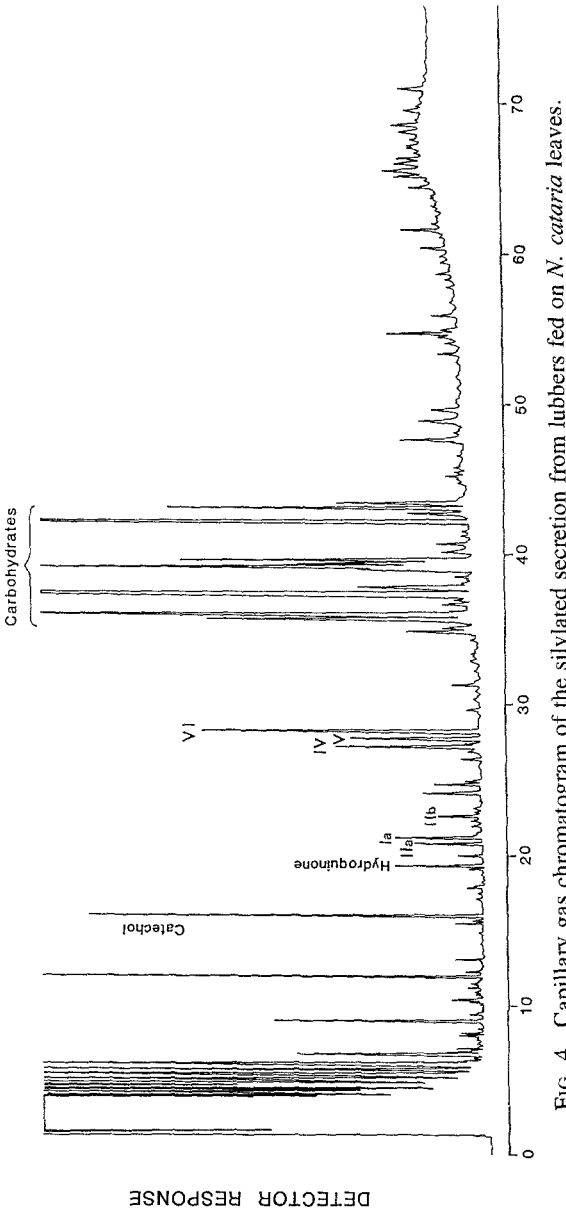

FIG. 4. Capillary gas chromatogram of the silylated secretion from lubbers fed on *N. cataria* leaves.

Two of the phenolics characteristic of lubber defensive exudates, catechol, and hydroquinone, were consistently identified in the lubber defensive secretions (Figure 4). For adult lubbers fed solely on *N. cataria*, the catechol–hydroquinone ratio was about 5 : 1, as was the case for the secretions of grasshoppers that had consumed a natural diet (wild fed). Approximately the same ratio was present in secretions of lubbers that had been fed an extract of *N. mussini* applied to oatmeal. When *R. guttata* adults were fed their natural diet plus about 10% catnip leaves, the ratio of these two phenolics increased to approximately 20 : 1. On the other hand, the ratio of catechol–hydroquinone varied from 1 : 4 to 1 : 10 when the acridids were fed a control diet of lettuce leaves and oatmeal.

Six monoterpenes were identified in the defensive exudates of catnip-fed adults, three of which consisted of minor compounds present in the catnip essential oil. **Ib, IIa,** and **IIb** were biomagnified in the secretion, increasing from about 10% of the monoterpenes in the leaf to about 25% (Figure 4). A comparison of the mass spectral data for synthetic **IIa** and **IIb** with those found in the exudate is presented in Figures 5 and 6. The mass spectrum of **Ib** from the defensive secretion is shown in Figure 7. Although **Ia,** the major terpene produced by *N. cataria* (Figure 2) was not detected, three metabolites of this lactone, designated **IVb, V,** and **VI,** which constituted about 75% of the detected terpenes, were found.

The basic structure of these hydroxy-acids, **IV** (Figure 1), consisting of about 20% of the terpenoid mixture, was confirmed by the hydrolysis of **Ia** to a mixture of nepetalic acids, **IIIa** and **b,** and reduction with sodium borohydride to yield a mixture of nepetalic acids **IVa** and **b** (Figure 1). They were also prepared by the hydrolysis of the mixture of reduced lactones **IIa** and **IIb**. Only one isomer of **IV** was observed in the secretion. Based on relative abundance of synthetic products and relative retention data, the compound in the secretion was assumed to be dihydronepatalic acid. The mass spectrum of the ditrimethylsilyl derivative of the synthetic compound and the compound in the exudate are compared in Figure 8.

The mass spectrum of secretory component **V,** also representing about 20% of the terpenoid mixture, is shown in Figure 9. The molecular weight (328) and fragment ions at *m/z* 73 and 147 indicated that two methylsilyl groups were present (Draffan et al., 1968), suggesting that **V** was an isomerization product of **III** (Figure 1). Three probable structures for this compound, the methylhydroxyisopropenylcyclopentanoic acid (**Va**), the methylhydroxyisopropylidenecyclopentanoic acid (**Vb**), and the methylhydroxyisopropylcyclopenetenoic acid (**Vc**), could result.

Based on the MS fragmentation pattern (Figure 10), the most probable structure for **V** is **Vb** (Figure 1). Abstraction of the proton from the β-carbon of the cyclopentane ring would result in the *cis* elimination of the trimethylsilyl

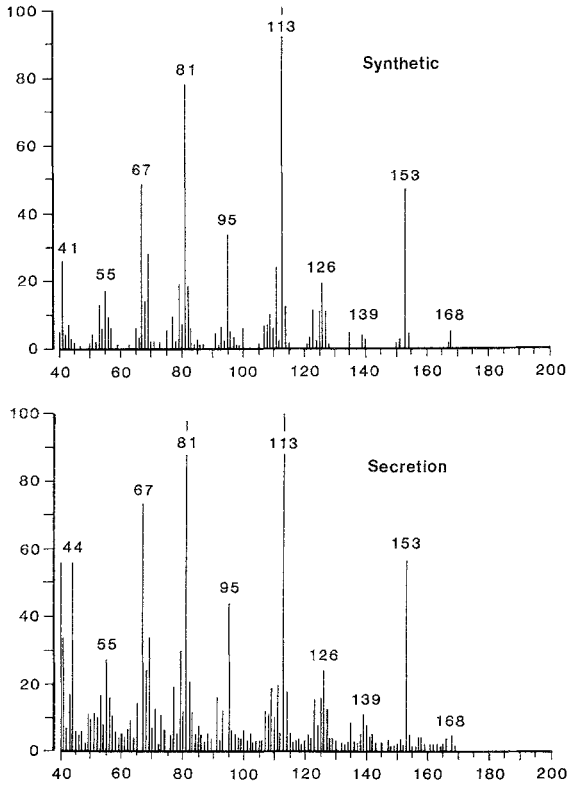

FIG. 5. Comparison of the mass spectra of synthetic dihydroisonepetalactone (**IIa**) and **IIa** from the secretions of lubbers fed on *N. cataria* leaves.

ether of formic acid and the formation of the very stable ion at *m/z* 210, which is the second most abundant ion in the mass spectrum (Figure 9). A similar loss from the M-15 ion or the loss of a methyl radical from the 210 ion would yield the third most abundant ion of *m/z* 195. Abstraction of the active proton alpha to the carboxyl group and double bond by the silyl ether moiety would eliminate the HOTMS and produce the stable ion at *m/z* 238.

The mass spectrum of compound **V**, the major terpene in the secretion (≈40%), is shown in Figure 11. The proposed structure can be formed from **V**, and **VI** clearly fits the mass spectral data. All major fragment ions are explained by the proposed fragmentation scheme (Figure 12). The key to the characterization of this compound was the base peak at *m/z* 153.

Metabolites **IV**, **V**, and **VI** are sequestered in the defensive glands of lub-

bers that had fed on a natural diet to which was added catnip leaves. As was the case for lubbers that had fed exclusively on catnip as adults, compound **VI** was the major terpenoid present. On the other hand, the concentrations of the three terpene metabolites were considerably lower in these secretions than those of grasshoppers that had specialized on *N. cataria*.

Efficacies of Defensive Secretions as Feeding Deterrents. Secretions from lubbers that had fed exclusively on catnip were very repellent to hungry ant workers. Utilizing solutions fortified with secretions from wild lubbers that had fed on a natural diet as a standard, it was determined that exudates from catnip-fed acridids were about three times as repellent. In comparison, secretions from lettuce- and oatmeal-reared acridids were about two thirds as repellent as the standard. Among secretions bioassayed from lubbers fed on 13 single-host diets, only that of wild carrot, *Daucus carota*, was of approximately equivalent repellency to that of catnip both in terms of ant repellency and time taken for the sucrose-fortified droplets to be eaten (unpublished data).

Survivorship and Secretory Volumes of Lubbers Fed on Different Diets. Larvae and adults of *R. guttata* fed as readily on catnip leaves as they did on those of the natural generalist diet. No significant difference in 14-day mortality resulted in adults that had fed exclusively on catnip compared to the control diet of lettuce plus oatmeal or the natural polyphagous diet. Thus, as far as we

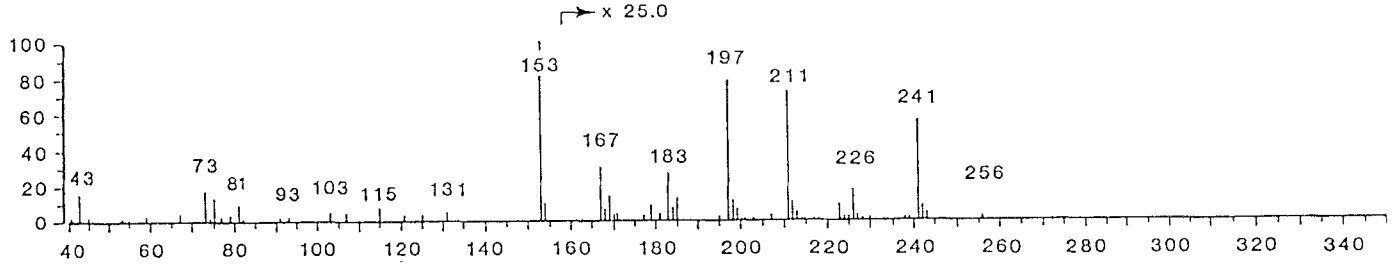

FIG. 11. The mass spectrum of the trimethylsilyl derivative (**VI**) from the secretion of the lubbers fed on *N. cataria* leaves.

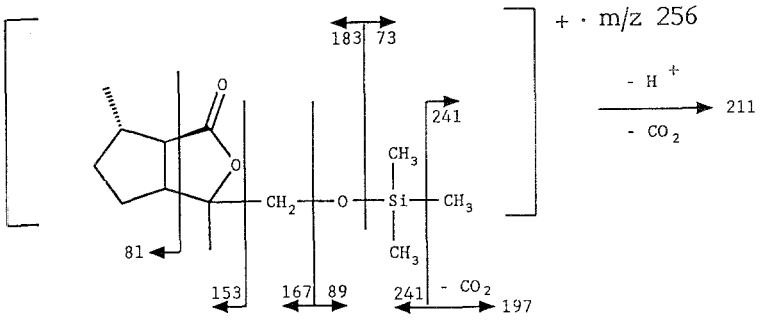

FIG. 12. The mass spectral fragmentation of the trimethylsilyl derivative of **VI.**

can determine, *N. cataria* is an eminently acceptable host plant for the developing adults.

We have found that there is a positive correlation between the amount of secretion generated by adult *R. guttata* and fitness characteristics such as survivorship, weight, and rate of development (Whitman, Jones, and Blum, unpublished data). Ingestion of catnip as the sole host plant resulted in the highest average secretion obtained with lubbers that had fed on 13 different diets. Individuals that had fed exclusively on catnip produced an average of 4.5 μl secretion/individual, whereas control grasshoppers that ingested solely lettuce and oatmeal produced an average of about 2 μl of secretion each. Indeed, only grasshoppers that had utilized tansy, *Tanacetum vulgare*, as their sole food plant produced secretions that averaged more than 4 μl/individual. For the 13 single host-plant diets, an average of 2 μl of secretion/individual was obtained.

DISCUSSION

R. guttata is an eminent generalist that considerably enhances its polyphagous propensity by exhibiting obligate host-plant switching that includes feeding on different plant tissues of different ages. By nature a nibbler, this acridid samples many of the plant species in its habitat, switching frequently from one to another, as is the case for some other grasshopper species (Waldbauer and Friedman, 1988). We suggest that this obligate switching of host plants is an adaptation that results in reducing the physiological stress that could occur from the ingestion of inordinately high levels of the characteristic allelochemicals produced by a single species of host plant. On the other hand, it is possible that the pronounced polyphagy of *R. guttata* may reflect selection for a diet that is optimal for rapid growth and development as well as fitness (Waldbauer and Friedman, 1988). However, even if we do not comprehend the *raison*

d'être for the pronounced polyphagy of this acridid, we recognize that the results of its idiosyncratic feeding behavior may affect its survivorship.

The defensive efficacies of the metathoracic secretions of *R. guttata* may be significantly correlated with diet breadth. The secretions produced by lubbers feeding on a diet consisting of lettuce or an artificial diet lacking fresh plant material were less repellent to ants than those derived from acridids reared on a natural polyphagous diet. Furthermore, the concentrations of phenolics in exudates produced by lubbers reared on the above restricted diets were reduced compared to exudates from lubbers reared on a natural generalist diet (Jones et al., 1989). However, the reduction in autogenous phenolics observed with secretions from onion-reared lubbers was accompanied by the sequestration of low concentrations of onion-derived sulfides with a concurrent increase in the deterrency of the exudates so that they were more repellent than those generated by lubbers on a natural wild diet. Similarly, lubbers feeding solely on catnip sequestered compounds derived from this mint, resulting in an increase in ant deterrency of the exudate. However, the secretory and sequestrative specifics of catnip monophagy differ strikingly from those observed with wild onion.

Specialization on onion results in secretions that contain sulfur volatiles with a concentration about 300-fold less than the natural phenolics, whose mean concentrations were about 37 times lower than those from exudates of wild-fed lubbers (Jones et al., 1989). By contrast, secretions of lubbers specializing on catnip did not contain reduced levels of phenolics such as catechol and hydroquinone. Furthermore, the combined concentrations of the sequestered monoterpenes were about a third greater than the two phenolics (Figure 4). Therefore, the increase in deterrency of the secretions from lubbers specializing on catnip may reflect the added repellent impact of high levels of the mint-derived phytochemicals in combination with the normal levels of proven deterrents, the autogenous phenolics. Thus, reduction in diet breadth, as exemplified by *N. cataria*, does not appear to depress the concentrations of autogenous defensive compounds in lubber secretions, in contrast to what has been observed for secretions produced by lubbers reared on an artificial diet or another single-host plant, wild onion (Jones et al., 1987, 1989). Since catnip and wild onion appear to differ considerably in their effect on autogenous phenolics in defensive secretions, it seems appropriate to determine how sensitive the concentrations of these compounds (i.e., catechol, hydroquinone) are to enforced monophagy in other cases. Beyond that it is appropriate to ask how important these phenolics are to the observed repellencies of the defensive exudates.

The ratio of catechol to hydroquinone in secretions of lubbers feeding solely on catnip was about 5 : 1, as was the case for these compounds in the exudates of lubbers that had fed on a natural polyphagous diet. Since the concentrations of these two phenolics are similar in both secretions, the fact that the secretions of catnip-fed lubbers are about three times more repellent to ants as those derived

from insects fed on natural diets must reflect the presence of compounds other than catechol and hydroquinone in the former exudates.

We have also noted that in the case of secretions produced by lubbers feeding on a control diet of lettuce and oatmeal, the phenolic ratio was about 1:7, with hydroquinone predominating. This secretion is considerably less repellent than the wild diet. In the case of a single-host plant diet consisting of garlic, *Allum sativum*, a relative of wild onion, neither catechol nor hydroquinone could be detected in the defensive exudate. The defensive efficacy of these secretions was very similar to that of lettuce and oatmeal. It thus appears that both the ratio and concentration of autogenously derived phenolics may affect the repellencies of the defensive secretions of lubbers feeding on different diets.

The ability of diet to affect the concentrations of catechol and hydroquinone in the metathoracic exudates raises the question of the origin of these so-called autogenous defensive compounds. Adults of *R. guttata* produce low concentrations of these two phenolics when they are reared on an artificial diet lacking polyphenolic compounds that could serve as precursors (Jones et al., 1987). On the other hand, a portion of the catechol and hydroquinone could well be derived from aromatic amino acids (e.g., tyrosine), as are phenolics produced in the defensive secretions of millipedes (Duffey and Blum, 1977). By contrast, the ability of diverse host plants to effect the levels of these two phenolics in the secretions makes it seem probable that phytochemicals such as polyphenolics (e.g., chlorogenic acid) may also serve as precursors of catechol and hydroquinone. Thus, these autogenously produced defensive allomones appear to have two unrelated origins, one of which (e.g., phytochemicals) may be of much greater significance than the other. Indeed, if catechol and hydroquinone are each administered as 10% solutions on oatmeal along with lettuce, the resulting defensive secretions contain abnormally high levels of the administered phenolics. Obviously, ingestion of free phenolics in plant tissues and their subsequent sequestration in the defensive secretions could serve admirably to increase their concentrations in the exudates.

Phenolic concentrations are also drastically affected when catnip is added to the natural polyphagous diet. The catechol–hydroquinone ratio of the secretions of acridids feeding on a catnip-fortified natural diet was about 20:1, in contrast to the 5:1 ratio that prevails when catnip was the sole food plant. In addition, lubbers sequester terpenes in their defensive exudates when feeding in a generalist mode that includes catnip, thus demonstrating that biomagnification can occur even in a generalist that is ingesting a polyphagous diet. No evidence for allelochemical sequestration when feeding in a generalist mode was detectable when adults of *R. guttata* fed on a natural diet that included sulfide-rich wild onion (Jones et al., 1989).

Although selected generalist herbivores can sequester allelochemicals (Rothschild and Aplin, 1971), these phytophages are feeding on a single host

plant when this occurs, and thus are functional specialists. Conceivably, *R. guttata*, a species of low vagility, may manifest temporary specialization as new species of host plants become available as a consequence of plant successional changes that occur in its limited habitat during its two- to three-month developmental period. Such temporary specialization could serve to fortify its defensive secretions with additional defensive allomones. The nepetalactone metabolites in the exudates of lubbers feeding on a polyphagous diet including catnip are at a low concentration relative to their levels in secretions derived from grasshoppers feeding only on catnip. Although increased diet breadth appears to result in dilution of sequestered plant natural products (Jones et al., 1989), fortification of the exudates with catnip metabolites undoubtedly provides them with an increased defensive "punch."

The sequestration of specific terpenoids by *R. guttata* emphasizes that insects can be highly selective in terms of the allelochemicals that are biomagnified. Nepetalactone, the major monoterpene lactone produced by *N. cataria*, does not appear to be sequestered, whereas three minor compounds constituting about 10% of the available lactones, are biomagnified so that they represent 25% of the stored terpenoids. Significantly, about 75% of the sequestered monoterpenes are degradation products of the lactones produced by *N. cataria*. About 50% of the stored metabolites are made up of nepatolic and nepetolic acids (Figure 1), whereas a novel lactonic metabolite constitutes the remaining half of the sequestered compounds. The sequestrative strategy of *R. guttata* is similar to that of arctiid species that biomagnify some minor allelochemicals while metabolizing others that are subsequently stored (Aplin and Rothschild, 1972). While the sequestrative fingerprint of *R. guttata* may be correlated with the physical properties (e.g., lipophilicity) of the compounds, it is important to recognize that some biomagnified compounds (e.g., metabolites) may also represent true detoxification products. In essence, the processing of these allelochemicals by the lubber, while unpredictable, may ultimately be demonstrated to reflect the ability of this insect to both sequester some compounds directly from the plant and to detoxify others to metabolites that can be facilely biomagnified.

The great efficiency of *R. guttata* as a sequestrator of the cyclopentanoid monoterpenes of catnip is evidenced by their low concentrations in feces (Figure 2). For example, the major terpene produced by catnip, nepetalactone, which is not sequestered in the defensive secretion, is excreted in the feces as a very minor constituent. Other catnip terpenes such as isodihydronepetalactone and dihydronepetalactone, which constitute about 2% of the leaf monoterpenes (Figure 2), represent nearly 40% of the fecal terpenoids (Figure 3). The major terpene metabolite in the defensive secretion is also detectable in the feces, but in considerably reduced concentration. In contrast, the leaf cuticular hydrocarbons, sterols, and fatty acids (Figure 2) appear to have been excreted in con-

centrated form (Figure 3). It thus appears that *R. guttata*, in common with arctiid larvae (Aplin and Rothschild, 1972), is a very efficient—and selective—sequestrator of allelochemicals.

Finally, the ability of this North American acridid to readily sequester the cyclopentanoid monoterpenes of an Eurasian plant, *N. cataria*, with which it has had no coevolutionary relationship, raises the question of how selective sequestration is vis-à-vis allelochemicals. Duffey (1980) has emphasized that sequestration is a common phenomenon in herbivores, encompassing a multitude of compounds belonging to diverse chemical classes. We have found that the secretions of lubbers fed single host plants are often enriched with a variety of nonautogenous compounds and that these exudates are often considerably more repellent than those from wild-fed grasshoppers. In short, the pronounced mithridatism of *R. guttata* often results in the sequestration of a variety of plant natural products, or their metabolites, with a concomitant increase in defensive efficacy of the exudates. Our results suggest that sequestration of specific allelochemicals may not reflect any previous adaptation on the part of the herbivore, but rather a concatenation of biophysical and biochemical processes that follows the ingestion of intrusive natural products. Ultimately, the sequestration of plant-defensive compounds by herbivores may be explained as the inevitable consequence of a herbivorous life-style associated with the pharmacopoeia represented by the host-plant arsenals.

Abstract—We investigated the potential role of defensive chemicals in the avoidance of watercress (*Nasturtium officinale*) by the cooccurring amphipod, *Gammarus pseudolimnaeus* at two spring brooks: Carp Creek, Michigan and Squabble Brook, Connecticut. We conducted observations and laboratory experiments on the consumption of watercress, the toxicity of damaged (frozen) watercress, and the toxicity of damage-released secondary chemicals. Field-collected yellowed watercress typically lacked the bite and odor characteristic of green watercress and was consumed by *G. pseudolimnaeus*. *G. pseudolimnaeus* strongly preferred yellowed watercress to green watercress despite the higher nitrogen content of the latter (2.7 vs 5.4%), and usually consumed five times more yellowed watercress (>50% of yellowed leaf area vs. <8% of green leaf area presented). Fresh green watercress contained seven times more phenylethyl glucosinolate than yellowed watercress (8.9 mg/g wet vs. 1.2 mg/g). Cell-damaged (frozen) watercress was toxic to *G. pseudolimnaeus* (48-hr LC_{50}s: ca. 1 g wet/liter), and the primary volatile secondary chemicals released by damage were highly toxic. The predominant

[3]Present address: Fisheries and Wildlife, 1980 Folwell Ave., University of Minnesota, St. Paul, Minnesota 55108.

0098-0331/90/0100-0245$06.00/0

glucosinolate hydrolysis product, 2-phenylethyl isothiocyanate had 48-hr LC_{50}s between 0.96 and 3.62 mg/liter, whereas 3-phenylpropionitrile was less toxic, with 48-hr LC_{50}s between 130 and 211 mg/liter. These results suggest that live watercress is chemically defended against consumption. The glucosinolate-myrosinase system, recognized as the principle deterrent system of terrestrial crucifers, is also possessed by *N. officinale* and may contribute to defense from herbivory by aquatic crustaceans. This system may be just one of many examples of the use of defensive chemicals by stream and lake macrophytes.

Key Words—*Nasturtium officinale, Rorippa nasturtium-aquaticum, Gammarus pseudolimnaeus*, freshwater, streams, herbivory, chemical defense, glucosinolates, phenylethyl isothiocyanate.

INTRODUCTION

Invertebrate herbivory on live macroscopic plants is conspicuously rare in freshwater systems (Otto and Svensson, 1981; Wetzel, 1983; for exceptions see Gaevskaya, 1969; and Sheldon 1987). Vascular macrophytes are important as both invertebrate habitats and as substrata for epiphytic periphyton (e.g., Hutchinson, 1975; Gregg and Rose, 1985). When these plants die or senesce, i.e., when tissues rapidly decompose (Webster and Benfield, 1986), they contribute directly to the particulate energy base of aquatic systems, providing energy to detritivores or decomposers (Wetzel, 1983; Mann, 1988).

Despite low herbivory on macrophytes, few have investigated plant–animal interactions from a chemical standpoint, which has resulted in a common opinion that chemical defenses are relatively unimportant in freshwater macrophytes (McClure, 1970; Hutchinson, 1975). Recently, Lamberti and Moore (1984) noted that there is insufficient information available to assess the importance of antiherbivore chemicals in freshwater plants, although Otto and Svensson (1981) and Ostrofsky and Zettler (1986) have argued for a greater role of secondary chemicals in freshwater plant defense. Most recently, Hay and colleagues (see Hay and Fenical, 1988, for a review) have shown that secondary chemicals are very important determinants of seaweed use by marine herbivores. Our study of watercress [*Nasturtium officinale* R. Br. – synonym: *Rorippa nasturtium-aquaticum* (L.) Hayek], a common spring-brook macrophyte, and *Gammarus pseudolimnaeus* Bousfield, a commonly cooccurring amphipod, suggests that this macrophyte is chemically defended from herbivory and that the defensives act in a manner comparable to terrestrial relatives.

Watercress is a crucifer that possesses glucosinolates and myrosinase, which are common to the family (Kjaer, 1976). It was introduced to North America in the 1700s from Europe and is now widely distributed in the United States (Green, 1962) in alkaline springs and spring-fed streams, where it often establishes extensive beds (Howard and Lyon, 1952; Voss, 1985). Because of

its use as a food for humans, much information is available on watercress aroma and taste-related chemistry. Glucosinolate and myrosinase are stored separately in the plant, but upon tissue damage, glucosinolate hydrolysis is mediated by myrosinase to yield characteristic isothiocyanates and nitriles (Van Etten and Tookey, 1979; Larsen, 1981). In watercress, 2-phenylethyl isothiocyanate and 3-phenylpropionitrile are the predominant hydrolysis products (MacLeod and Islam, 1975; Spence and Tucknott, 1983) and constitute 25–55% of the volatile compounds. The 2-phenylethyl isothiocyanate is considered the predominant flavor component and imparts the characteristic "hot" taste of watercress (Freeman and Mossadeghi, 1973).

In terrestrial studies, glucosinolates and corresponding isothiocyanates of crucifers are considered classical examples of chemical defense (Feeny, 1976, 1977). These compounds are deleterious to nonadapted herbivores (e.g., Lichtenstein et al., 1964; Blau et al., 1978) and will reduce herbivore damage (Louda and Rodman, 1983; Louda et al., 1987). Moreover, isothiocyanates are released as a response to direct damage of tissues, underscoring the causal relationship with herbivory. Isothiocyanates are especially noxious and can be quite toxic (Lichtenstein et al., 1964; Lowe et al., 1971; Åhman, 1986). However, we know of no research on the ecological implications of the mustard oil system in aquatic plants such as watercress.

Amphipods are also commonly found in alkaline spring streams and often occur among watercress (Howard and Lyon, 1952; Hynes and Harper, 1972; Gregg and Rose, 1985). In particular, *Gammarus* are generalist consumers in that they eat other animals, terrestrial leaf litter, algae (Marchant and Hynes, 1981; Sutcliffe et al., 1981), and are able to digest cellulose (Bärlocher and Porter, 1986). *Gammarus* also readily consumes decomposing macrophytes (e.g., Newman et al., 1987), including watercress (Newman, unpublished manuscript).

In this study, we report the results of feeding choice tests with watercress leaves, the concentrations of isothiocyanate yielding glucosinolates in watercress, and the toxicity of frozen watercress and glucosinolate degradation products to *Gammarus pseudolimnaeus*. We suggest that the lack of aquatic herbivory on North American watercress is in large part due to a chemical defense system. Watercress may represent one of many emergent macrophytes that have carried defensive systems into the aquatic environment.

METHODS AND MATERIALS

Observations were made in Connecticut (Squabble Brook, East Canaan, Connecticut; 42°1′N, 73°16′W) and Michigan (Carp Creek, 45°33′N, 84°41′W; T36N, R3W, S4, Cheboygan County, Michigan). Both streams were spring

fed, and typically maintain temperatures of 7–13°C. The waters were alkaline with conductivities between 200 and 300 μS/cm and support extensive watercress beds.

In the course of detritivory experiments, we discovered that watercress possesses noxious compounds that are harmful to *Gammarus* and hypothesized that glucosinolate hydrolysis products (2-phenylethyl isothiocyanate and 3-phenylpropionitrile) were the harmful agents, because senescing yellow leaves have less of the characteristic watercress aftertaste. To evaluate this hypothesis, we performed feeding choice tests with fresh and yellow (senescent) watercress leaves to determine the extent that watercress was palatable to *G. pseudolimnaeus*.

Feeding Choice Test. To determine if *Gammarus* would readily consume fresh watercress, we conducted feeding choice tests, comparing yellowed watercress leaves with fresh green leaves. Preliminary field observation had suggested some damage to senescent yellowed leaves. For these experiments, most yellowed leaves were obtained by keeping leaves in the dark at 10°C for about one week, but some yellowed leaves were collected from plants in the streams. Eight amphipods (ca. 5 mg dry wt. each) were placed into choice chambers (modified 100 × 20-mm Petri dishes, divided into four pie-shaped compartments that were open to one another) with 60 ml filtered stream water. The amphipods were allowed to acclimate to the chambers (10°C) without food for 12 or 48 hr, which resulted in two levels of starvation. Leaf disks (ca. 105 mm^2; 25 mg wet) were cut from fresh and yellowed leaves with a cork borer. Disks were randomly assigned to choice chambers, one disk per compartment, in one of four categories: 3 green disks; 2 green + 1 yellow disk; 1 green + 2 yellow (CT); or 1 green + 1 yellow disk (MI); 2 green + 2 yellow disks. Disks were held in compartments by pinning the disks with insect pins to silicon knobs in each compartment. The amphipods were allowed to feed for 24 hr, the disks were removed, and disk area remaining was computed (by planimeter or digitizer). During each experiment, a set of four green and four yellow disks were placed in chambers without amphipods and served as controls to estimate initial areas. For each choice type there were 6–12 replicates at 12- and 48-hr starvation periods.

Damaged Tissue Tests. Toxicity tests were conducted with frozen watercress to determine the presence of harmful chemicals. Mustard oils are typically in minute concentrations prior to plant damage. Freezing, however, produces extensive plant damage and, upon thawing, promotes the hydrolysis of glucosinolates to the corresponding isothiocyanates and nitriles.

Fresh watercress leaves were clipped from the plants, washed, blotted dry, and then frozen at ca. −15°C. Toxicity tests were conducted in 100 × 15-mm plastic Petri dishes containing 40 ml of filtered stream water. Ten amphipods (ca. 5 mg dry wt. each) were placed in each Petri dish and acclimated for 24

hr in an environmental chamber at ambient stream temperature (ca. 10°C). The frozen leaves were thawed and predetermined wet weights of leaf tissue were randomly placed into each dish, which was then covered. Triplicate dishes of each of five concentrations (a control and four levels of watercress) were used in each toxicity assay. Mortality was observed over time for 48 hr. Lethal concentrations (LC_{50} values) and confidence intervals were computed with the trimmed Spearman-Karber method (Hamilton et al., 1977).

Toxicity of Secondary Compounds. Toxicity tests were also conducted with the two secondary compounds known to be prevalent in watercress: 2-phenylethyl isothiocyanate and 3-phenylpropionitrile (Aldrich Chemical Co., Milwaukee, Wisconsin). Experimental conditions were identical to the damaged tissue tests. Because the compounds were volatile oils, serial dilutions were made with absolute ethanol and appropriate concentrations were applied to inert filter disks (Reeve Angel Cellulose disks). Filter disks with the appropriate amount of compound were placed in each Petri disk (concentrations of 0.1–25 mg/liter for 2-phenylethyl isothiocyanate and 25–375 mg/liter for 3-phenylpropionitrile), three replicate dishes per concentration. Filter disks with an amount of ethanol equal to that in the lowest concentration (highest dilution) were placed in the control dishes. The experiments were then conducted and analyzed in the same manner as the frozen watercress experiments.

Chemical Analyses. Watercress was analyzed for carbon, hydrogen, nitrogen, and isothiocyanate-yielding glucosinolates during summer 1988 in Michigan. Fifteen subsamples (2–4 mg, dry) of yellowed and green leaves were dried (65°C) and analyzed for carbon, hydrogen, and nitrogen with a Perkin-Elmer 24000 CHN Total Elemental Analyzer. The subsamples were taken from leaflet material remaining after disks were cut for the choice experiments and represent the range of material used in the choice tests. A sample of watercress roots as also analyzed.

Glucosinolate content was analyzed for frozen leaves as well as fresh green and yellowed leaves used in the choice experiments. Samples of fresh and yellowed leaves (0.8–2.6 g wet) were obtained from leaf material remaining from different choice tests and immediately boiled for 10 min in 70% methanol. Glucosinolate analyses were done (within three months) according to the methods described by Blua (1984) and Blua and Hanscom (1986), except that phenylethyl isothiocyanate was used as the standard for isothiocyanate concentration determination. Results are expressed as milligrams of phenylethyl isothiocyanate-yielding glucosinolate (IYG) per gram (wet) watercress. Concentrations of phenylethyl isothiocyanate from the tissues can be determined by multiplying the IYG concentrations by 0.371. Frozen watercress was analyzed for phenylethyl isothiocyanate directly, without fixation or the standard myrosinase treatment. Subsamples of thawed, frozen watercress (0.8–2.6 g wet) were placed in 40 ml cold water, and 10 ml methylene chloride was then added and the bottles

were shaken vigorously to extract the released isothiocyanates. The methylene chloride phase was later processed (within three months) and analyzed by GC for isothiocyanate content in the same manner as done for the fresh and yellowed samples. Standard extraction procedures and analysis (e.g., Blua and Hanscom 1986) of the thawed leaf tissue remaining after methylene chloride extraction revealed no detectable glucosinolates. A set of standards prepared on filter disks (similar to the toxicity test disks) was treated in the same way as the frozen watercress samples; analysis showed almost 100% recovery.

RESULTS

Watercress Chemistry. Fresh green watercress contained the highest concentrations of carbon, hydrogen, and nitrogen, with total nitrogen >5% and C/N ratio of 7.27 (Table 1). Yellow leaves had significantly lower carbon and nitrogen (2.7%) with a C/N ratio of 12.7. Roots had the lowest nitrogen and the highest C/N ratio (16).

Fresh green watercress also had much higher concentrations of phenylethyl glucosinolate (8.9 mg/g) than yellowed leaves (1.2 mg/g; $P < 0.001$) (Table 2). Frozen green watercress yielded phenylethyl isothiocyanate concentrations nearly identical to fresh watercress ($P > 0.5$), which suggests that freezing and thawing resulted in nearly complete hydrolysis of the phenylethyl glucosinolate to isothiocyanate.

Choice Tests. Amphipods readily consumed yellowed leaf disks (typically 40–60% of the area offered), but rarely consumed more than 10% of the fresh green disks (Figures 1 and 2). For each choice type (e.g., two fresh and two

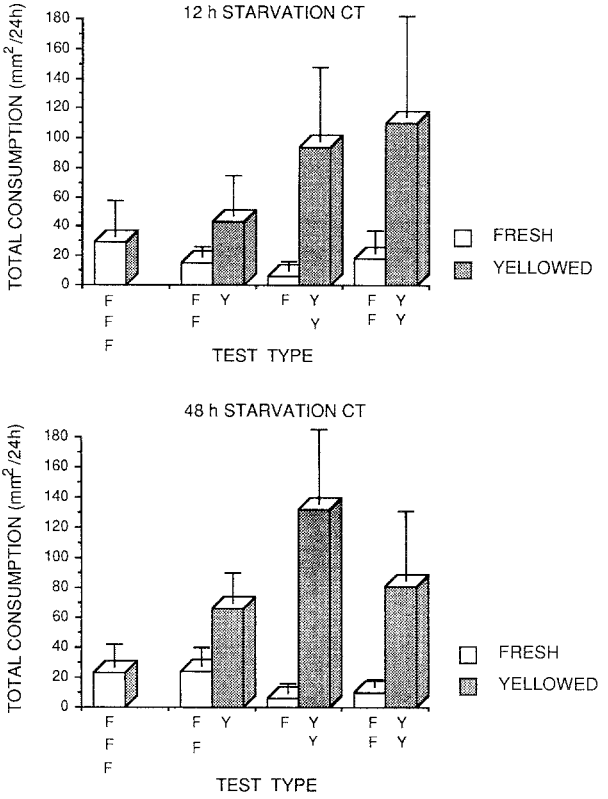

FIG. 1. Consumption (area/24 hr) of fresh green (F) and yellowed (Y) leaf disks by *Gammarus pseudolimnaeus* in Connecticut, November 1987, after 12- and 48-hr starvation periods. Test type indicates the number of fresh and yellow disks offered. Vertical lines represent +2 SEs.

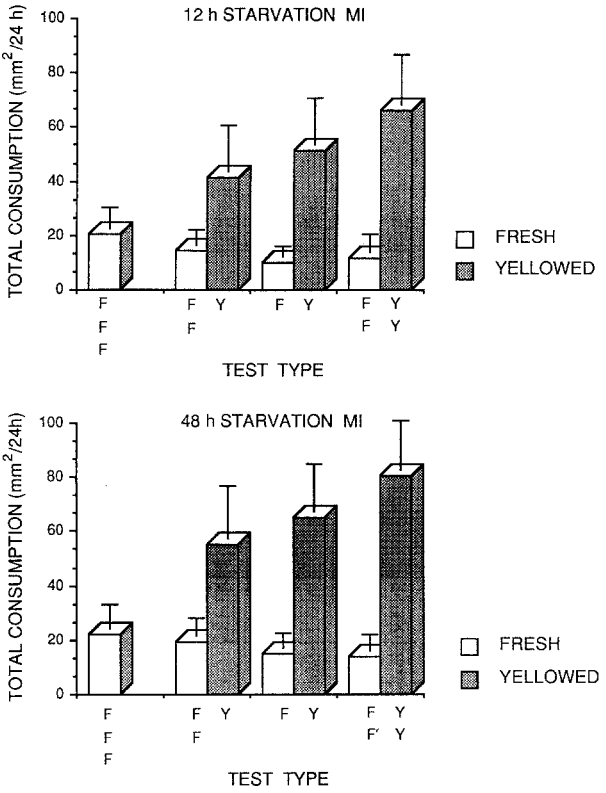

FIG. 2. Consumption (area/24 hr) of fresh green (F) and yellowed (Y) leaf disks by *Gammarus pseudolimnaeus* in Michigan, July–August 1988, after 12- and 48-hr starvation period. Test type indicates the number of fresh and yellow disks offered. Vertical lines represent +2 SEs.

yellow disks), both total consumption and mean consumption (an average disk) of yellowed disks was significantly higher than that of green disks (*t* tests; all $P < 0.01$). Even when *Gammarus* was starved for 48 hr and provided only green disks, total consumption was less than half that of yellow disks. Starvation duration (12 or 48 hr) did not increase the consumption of leaf disks in Connecticut but did increase consumption significantly in Michigan ($P < 0.05$). Consumption of cress (both green and yellow) by amphipods in Michigan and Connecticut was not significantly different ($P > 0.05$).

Damaged Tissue Tests. Frozen watercress was toxic to the amphipods. Amphipod mortality showed typical dose–response curves, with no mortality at the lowest concentrations, partial mortality at intermediate concentrations, and

complete mortality at the highest concentrations. The 48-hr LC_{50} values for leaves ranged from 475 to over 1000 mg (wet)/liter (Table 3). Toxicity of roots was similar to leaves. Observations during the tests suggested that most mortality occurred within 24 hr; 24-hr LC_{50}s were $<30\%$ larger than 48-hr LC_{50}s. Toxic levels of frozen cress appeared to result in abnormally high rates of gut evacuation, which were not seen at low and control levels. New amphipods introduced into the highest concentrations after the 48-hr experiments were also killed, but the toxic action was reduced.

Toxicity of Secondary Compounds. Previous research demonstrated that 2-phenylethyl isothiocyanate and 3-phenylpropiontrile are predominant glucosinolate hydrolysis products in watercress (MacLeod and Islam, 1975; Cole, 1976; Spence and Tucknott, 1983). Forty-eight-hour LC_{50} values for 2-phenylethyl isothiocyanate were <4 mg/liter (Table 4). 3-Phenylpropionitrile was not as toxic, giving LC_{50} values over 100 mg/liter (Table 4). Toxic effects were similar to frozen watercress; mortality occurred rapidly and high rates of defecation were noted. The 24-hr LC_{50} values were not significantly different from 48-hr LC_{50} values. With 3-phenylpropionitrile, however, amphipods at intermediate concentrations appeared partially paralyzed, but did not die even after 96 hr.

DISCUSSION

Field-collected yellowed watercress typically lacked the bite and odor characteristic of green watercress and was consumed by *G. pseudolimnaeus*, which strongly preferred yellowed watercress to green watercress, despite the

higher nitrogen content of the latter, and usually consumed five times more yellowed watercress. Fresh green watercress, however, had phenylethyl glucosinolate concentrations that were seven times higher than yellowed watercress. Cell-damaged green watercress was toxic to *G. pseudolimnaeus*. The primary volatile secondary chemicals released by damaged watercress were also highly toxic to *G. pseudolimnaeus*. These results, although only correlative, suggest that live watercress is chemically defended against consumption and that the glucosinolate–myrosinase system (recognized as the principle deterrent system of terrestrial crucifers) is also active against aquatic crustacean herbivores. Further work is needed to determine if other possible explanations that we did not test for, such as mechanical defense or other chemicals, can be eliminated.

Gammarus and watercress both occur in spring-fed alkaline streams. *G. pseudolimnaeus* is often most abundant in the watercress beds, living among the roots and submerged leaves (Hynes and Harper, 1972; Newman, personal observation). These crustaceans are generalist feeders, consuming algae, other animals, and terrestrial leaf litter (Sutcliffe et al., 1981). Moreover, *Gammarus* reportedly possesses the ability to digest cellulose (Bärlocher and Porter, 1986). Therefore, *G. pseudolimnaeus* has the potential to consume watercress, yet little plant damage was observed on green leaves, only on senescing yellow leaves. Others have reported occasional feeding. For example, Minckley (1963) reported that *G. minus* and *G. bousfieldi* contained watercress in their guts, but did not identify whether the material was from living tissue or senescent leaves.

H.B.N. Hynes (personal communication, University of Waterloo) notes that in England, after commercial watercress beds are cleared for replanting, *G. pulex* (indigenous to Europe) will consume newly planted watercress cuttings; however, all other food sources are removed during clearing. Sutcliffe et al. (1981) found poor to moderate growth of *G. pulex* on watercress in laboratory trials but also noted high (up to 95%) mortality. The only reported aquatic pest of watercress known to us is the trichopteran *Limnephilus lunatus*, which is indigenous to Europe (Gower, 1967).

As mentioned earlier, in our work, the yellowed cress usually lacked the bite and odor characteristic of fresh watercress and had greatly reduced levels of glucosinolates. Frozen watercress leached in the stream for two days was not toxic to the amphipods and was consumed. Likewise, Feeny and Rosenberry (1982) noted that yellowed senescent leaves of the terrestrial crucifer *Dentaria* sp. had no detectable glucosinolates. Loss of toxic volatile compounds conicided with marked increase in consumption. *G. pseudolimnaeus* strongly preferred yellow leaves to green leaves, typically consuming over 50% of a yellowed leaf disk, but rarely more than 15% of a green disk. The yellowed disks often lost large areas, whereas *G. pseudolimnaeus* only sampled the edges of green disks, even when no other food was available. The average amount of consumption of individual green leaf disks was similar among test types, further suggesting a sampling of each disk rather than sustained consumption.

Food quality does not appear to explain the lack of consumption of the green leaves. Most aquatic invertebrates, including *Gammarus*, prefer food with high nitrogen and low C/N ratios (Bird and Kaushik, 1981). Fresh leaves had a high nitrogen content (higher than most terrestrial and aquatic plants reported by Otto and Svensson, 1981) and a low C/N ratio (yet similar to the ratio of 7.5:1 reported for watercress by Dawson, 1980), which suggest a high food quality. In contrast, yellowed cress had significantly lower nitrogen and higher C/N ratios. Therefore, choice seems unrelated to food quality.

In our experiments, cell damage via freezing leached substances toxic to *G. pseudolimnaeus*. Freezing damaged the plant tissue and resulted in high production of glucosinolate hydrolysis products (phenylethyl isothiocyanate) upon thawing. Freezing and thawing apparently resulted in complete hydrolysis of the glucosinolate. The primary products of glucosinolate hydrolysis in watercress are 2-phenylethyl isothiocyanate and the corresponding nitrile (3-phenylpropionitrile; Freeman and Mossadeghi, 1973; MacLeod and Islam, 1975; Spence and Tucknott, 1983). Cole (1976) determined that, after autolysis, watercress produced 74 μg of 2-phenylethyl isothiocyanate per gram of watercress and reported no other isothiocyanates or nitriles. Our results showed much higher levels of phenylethyl isothiocyanate, about 3.3 mg/g. Others have reported additional volatiles, but in all cases, 2-phenylethyl isothiocyanate was the predominant compound (Freeman and Mossadeghi, 1972, 1973; Spence and

Tucknott, 1983). Moreover, Freeman and Mossadeghi (1972) confirmed that 2-phenylethyl isothiocyanate was the chemical responsible for the characteristic odor and "hot" taste of watercress. By comparing our toxicity results to plant phenylethyl isothiocyanate concentrations, it can be seen that the toxicity of frozen cress corresponds well (within a factor of 3) with the toxicity and amount of phenylethyl isothiocyanate that would be released upon thawing (Table 2).

The isothiocyanates have been proposed to be the primary defensive agent in terrestrial crucifers (e.g., Feeny, 1977; Louda and Rodman, 1983). Studies with terrestrial invertebrates, mostly insects, have shown 2-phenylethyl isothiocyanate to be quite toxic (e.g., Lichtenstein et al., 1964; Åhman, 1986); Lowe et al. (1971) reported the toxicity to dipteran larvae (*Inopus rubriceps*) to be at the level of DDT toxicity (a highly toxic insecticide). Our toxicity tests with 2-phenylethyl isothiocyanate and 3-phenylpropionitrile confirm that both are quite toxic to crustaceans. The 48-hr LC_{50} for 2-phenylethyl isothiocyanate (ca. 1 mg/liter) is comparable to the level of toxicity of moderately toxic insecticides to *G. pseudolimnaeus* (Mayer and Ellersieck, 1986). Toxicity, feeding, and chemical analyses suggest that *G. pseudolimnaeus* food choice may be influenced by the presence of defensive chemicals such as 2-phenylethyl isothiocyanate that are released from watercress upon tissue damage. This would appear to be an aquatic analog to the terrestrial crucifer defense system often cited as a classic example of plant defense. We do not know the toxicity of consumed watercress, however. Neither can we rule out mechanical or other chemical differences that may be correlated with senescence and loss of glucosinolates. Thus, more work is needed to determine more positively if the glucosinolate system is the defensive agent.

The subject of chemical defenses in freshwater systems is largely unexplored. A few incomplete studies suggest that chemical defenses may be highly important. For example, LaLonde et al. (1979) showed that the freshwater alga *Cladophora* possesses fatty acids toxic to dipteran larvae but did not look at food choice or consumption. Similarly, Ostrofsky and Zettler (1986) showed that many aquatic macrophytes possess significant concentrations of alkaloids, but did not relate chemistry to defense. Finally, Otto and Svensson (1981) suggested that the lack of herbivory on aquatic macrophytes was due to defensive chemicals, but they did not relate chemistry to feeding observations. We believe that chemical defenses may be more important in aquatic plants than previously thought and suggest that watercress is only one example of many chemically defended freshwater plants.

This suggestion has important implications for detritivory. Stream invertebrates are quite adept at using detrital material of both autochthonous and allochthonous origin. Aquatic macrophytes decay quite rapidly compared to terrestrial leaf litter (Bird and Kaushik, 1981; Webster and Benfield, 1986) and can be an important component of aquatic energy budgets (Wetzel, 1983; Car-

penter and Lodge, 1986). One possible reason that macrophytes are not consumed until senescence or death is that they are chemically defended (Smock and Stoneburner, 1980). Watercress has a very rapid decay rate (Bird and Kaushik, 1981; Webster and Benfield, 1986), which is in large part influenced by abundance of shredders such as *G. pseudolimnaeus* (Newman, unpublished manuscript). Our results suggest that the reason watercress contributes directly to stream invertebrate energetics only upon senescence and death is that this potentially nutritious food source is chemically defended while alive. The loss of noxious compounds after senescence permits rapid decay and high consumption by stream invertebrates.

Acknowledgments—We thank Drs. Frances Chew, Paul Feeny, and Svata Louda for sharing their insights into crucifer–herbivore interactions; and Drs. K.W. Cummins, H.B.N. Hynes, M.E. Power, and V.H. Resh for their insights on stream plants and invertebrates. Dr. W.A. Ellis permitted access to Squabble Brook. Drs. R.D. Fogel, S.F. Hedtke, D.B. Schroeder, F.A. Streams, J.A. Weber, D.A. White, and W.W. Whitworth lent supplies, equipment, or space to R.M.N. S.P. Hendricks performed the CHN analyses at the University of Michigan Biological Station (UMBS). Drs. D.J. Gerhart, R.G. Wetzel, and an anonymous reviewer made many helpful comments on the manuscript. R.M.N. was supported by the Naturalist Ecologist Training Program (UMBS), funded by the Andrew W. Mellon Foundation, and the Department of Renewable Natural Resources, University of Connecticut. Voucher specimens of *G. pseudolimnaeus* and *N. officinale* were deposited with the University of Connecticut, Museum of Natural History, Storrs, Connecticut. PEPTIDE-MEDIATED BEHAVIORS IN MARINE ORGANISMS
Evidence for a Common Theme

DAN RITTSCHOF

Duke University Marine Laboratory
Pivers Island
Beaufort, North Carolina 28516

(Received February 1, 1989; accepted March 17, 1989)

Abstract—Biology has many common themes such as DNA, RNA, the other biopolymers, and their building blocks. Chemical communication systems have similar common themes. An example is the common usage of amino acids, sugars, and nucleotides as food cues. It is likely that communication systems began with the evolution of specific meanings for preexisting molecules. One class of molecules used in specific communication is peptides. These peptides are generated as part of the body odor of organisms in aquatic environments and can act at a distance or by contact. Evidence is given for a common type of peptide receptor system. Four peptide-mediated behaviors, three in diverse crustacean groups and one in a mollusc, are discussed. The behaviors are of major survival importance, are cued by nanomolar concentrations of peptides generated by serine proteases, and the basic carboxy terminal amino acid is required. The behaviors include attraction to new shells, attraction to living prey, release of larvae, and induction of larval settlement behavior. Studies with pure di- and tripeptides show the same molecules evoke larval release behavior, shell attraction responses, and larval settlement behavior. The pure compounds are effective at nanomolar or lower concentrations. Similar peptides function as specific cues in vertebrates in response to wounding. Thus, peptide communication using serine protease-generated peptides appears to be a common theme.

Key Words—Trypsin, behavior, crustaceans, pheromones, molluscs, predator–prey interactions, peptides, serine proteases.

INTRODUCTION

Aquatic chemical ecology excels in studies using polar comopunds. Recent technological advances in the synthesis, sequencing, and analysis of peptides facilitate studies and use of these polar compounds in studies of novel roles of peptides. This area should be a very productive one in the next decade.

The extensive regulatory roles of peptides in human metabolism are one aspect of their bioactivity. Other aspects are less well understood. The mediation of behavior by peptides is a new frontier. This phenomenon has been clearly demonstrated in isolated behaviors of aquatic crustaceans and molluscs. That similar mediation of events is observed in the defensive events that occur in response to wounding of vertebrates suggests that there may be classes of peptide receptors that are comparable to those analogous to amino acid receptors. However, the peptide receptors function to cue behaviors other than feeding. It should be emphasized that the examples presented are marine, but that any interaction that enables communication by polar compounds (licking or touching or eating, for example) provides the potential for peptide mediation of behavior. Examples are not yet available from other than the systems discussed today.

Pivotal events in the lives of organisms are not left to chance. Frequently, critical events in an organism's life are associated with stereotyped or precisely timed behaviors. Chemical signals coordinate many such stereotyped behaviors and precisely timed events. For terrestrial organisms, many of the coordination chemicals are volatile compounds (Wilson, 1970). In contrast, most of the chemicals known to coordinate behavior in aquatic organisms are polar compounds, and many of these are peptides (Rittschof and Bonaventura, 1986).

Peptides coordinate a potpourri of behaviors for aquatic organisms. These include gregarious settlement and metamorphosis of many marine invertebrate larvae (Crisp, 1984; Burke, 1984; Morse, 1984; Rittschof, 1985); precisely timed larval release by crustaceans (Forward et al., 1987); location of the population limiting resource (empty gastropod shells) for anomuran crustaceans (McClean, 1974); alarm responses in gastropods (Snyder, 1967; Atema and Burd, 1976); and location of living, intact prey by predatory snails (Rittschof et al., 1984).

The biological events listed above are highly specific and stereotyped responses mediated by peptides, but other similarities are not obvious at the organismal level. Some of the behaviors, however, are related by the mechanism responsible for their coordination. The gregarious settlement of barnacles, larval release behavior in mud crabs, hermit crab shell attraction, and creeping responses of predatory snails have striking similarities in the molecular mechanisms that coordinate them. Those behaviors are all mediated by peptides that can be generated by trypsinlike serine proteases. It appears that this provides a

common theme: the use of peptides, generated by degradative processes, that contain a number of neutral residues and a basic residue (arginine or lysine) at the carboxy terminus.

This theme of a common mediation system will be documented by the presentation of five biological examples. Four are the marine invertebrate examples mentioned above. The fifth is the mammalian complement system and the functions of C3a–C5a peptides. The mammalian example is included because it is well understood and extends the notion of the common theme to the vertebrates. Because each example is dependent upon a different biological system, the information communicated is slightly different in each case. All of the individual stories are fragmentary; however, the aggregate information suggests that there is a common theme in the generation and detection of these peptide signal molecules. One should not lose sight of the fact that the examples are a selected subset and that a variety of equally important behaviors do not work by the proposed mechanism.

The biological examples supporting the theme are diverse. In the short sections that follow, thumbnail sketches of each system are included as a frame of reference. Emphasized in each sketch is the benefit of the biological response to the organism.

SHELL LOCATION BY ANOMURAN CRUSTACEANS

In marine environments, death by predation is the rule rather than the exception. Events such as the death of a snail have added significance because the vacant shell is cycled and recycled through communities as habitats for fish, octopuses, fouling organisms, and crabs (McClean, 1974). Shells are the population-limiting resource for the first marine example, hermit crabs (Vance, 1972).

Hermit crabs use shells for protection. The fit of the shell can influence growth (Frotheringham, 1976) and reproduction (Childress, 1972; Bach et al., 1976). Searching for and acquiring new and better-fitting shells dominates the life of juvenile and adult crabs. In addition to complex behaviors related to assessing and trading shells (Hazlett, 1966, 1981), hermit crabs can chemically locate the source of a new shell from a distance. Molecules released by the flesh of the snail attract hermit crabs, generally those whose shells are not adequate (Rittschof, 1980a), and those belonging to species that usually occupy that type of shell (Rittschof, 1980b; Gilchrist and Abele, 1984). The crabs do not feed on the snail flesh. Rather, they interact with other attracted crabs, take a position in a size hierarchy of the crabs, and wait for the new shell to be released by the predator (McClean, 1974, 1975). When the new shell is released, all crabs in shells smaller than the new shell switch to the next larger shell. This ritual is

repeated whenever a snail loses its life and is a major route of influx of new shells into the population (Wilber and Herrnkind, 1982, 1984).

PREY LOCATION BY GASTROPOD *Urosalpinx cinerea*

Unlike terrestrial predators, many marine predators are slow moving and do not depend upon vision for prey location. Oyster drills, *Urosalpinx cinerea* are slow-moving, virtually blind predatory snails (Frederighi, 1931). The prey of *U. cinerea* are sessile and gregarious. Where prey occur, they are often dense and occur in continuous sheets or reefs. Predators such as oyster drills prey upon these sessile prey much as ungulates graze upon grass. These snails locate living intact prey from a distance by their odors (Carriker, 1955). The type of prey consumed determines the reproductive output of the snail (Frederighi, 1931). The crawl-away juvenile oyster drill is attracted only to barnacles (Rittschof et al., 1985). Survival of juvenile snails is strongly dependent upon locating prey.

AGGREGATIONS OF THE BARNACLE *Balanus amphitrite*

Acorn barnacle adults, *Balanus amphitrite*, are simultaneous hermaphrodites that do not generally self-fertilize (Holm, personal observation). Gregarious settlement in barnacles increases the probability that an individual will reproduce. Settlement is mediated via chemical cues. Larvae respond to chemical cues in two ways: (1) they alter their behavior; or (2) they attach permanently to a surface to which the chemical cue is adsorbed. The biochemical events of metamorphosis are then initiated (Crisp and Meadows, 1962, 1963; Rittschof, 1985).

LARVAL RELEASE BY BRACHYURAN CRABS

Mud crabs, *Rhithropanopeus harrisii*, are the best understood of any brachyuran crustacean with respect to larval release behavior (Forward, 1987). Female crabs extrude and glue fertilized eggs to their abdomens. Embryos are carried until the time of hatching. Hatching is synchronous and precisely timed with respect to lunar, diurnal, and tidal cycles. Females perform a stereotyped larval release behavior in response to pheromones originating from hatching eggs (Forward and Lohmann, 1983; Rittschof et al., 1985; Forward et al., 1987). The synchrony of larval release is thought to reduce the risk of predation and to ensure that the physiologically delicate larvae are introduced into environmental conditions that maximize the probability of successful development.

MAMMALIAN COMPLEMENT CASCADE

In mammals, wounding or infection result in a cascade of biochemical responses. Peptides resulting from proteolytic activation of the complement cascade have a variety of functions (for review, Schiffman, 1982). These peptides induce anaphylaxis, smooth muscle contraction (C3a; Unson et al., 1984), and attract neutrophils (C5a; Chenoweth and Hugli, 1978). These responses, as well as several others, are central to defense against microbial invasion (Schiffmann, 1982).

SYNTHESIS

The stereotyped responses in each example described above have been used as bioassays. Table 1 summarizes the measures used in each bioassay and provides references for the details of each assay. These bioassays have been used to direct the purification of the chemical signals, and to ask questions about the nature, origin, and specificity of the cues mediating responses.

The biological responses to chemical stimulation in the context of Table 1 are all extremely simple. Although the measures examine such basic characteristics as movement, they are extremely sensitive and effective because each response is highly specific. For example, studies of simulated gastropod predation sites show that hermit crabs respond only to flesh from gastropods and that the species of hermit crab attracted is dependent upon the species of snail used to generate the peptide cues (McClean, 1975; Rittschof, 1980a,b; Hazlett and Hernnkind, 1980). Similarly, oyster drills are stimulated to creep only by the odor of balanoid barnacles (Rittschof, 1985). This snail has been placed in the outflow of a biochemical separation column and used as a detector because

TABLE 1. ASSAY MEASURES IN FIVE BIOLOGICAL SYSTEMS

Organism	Assay	Reference

Vertebrate wounding	White cell movement Skin swelling Ileum muscle contraction	Schiffmann, 1982 Hugli and Erickson, 1977 Unson et al., 1984
Snails	Directed movement in flow	Rittschof et al., 1983

it will sit for hours in flow without moving until stimulated chemically to creep (Rittschof et al., 1984). Similar extreme specificity is observed in the responses of barnacles (Larman et al., 1982), ovigerous crabs (Forward and Lohmann, 1983; Forward et al., 1987), and the responses to C5a and C3a peptides (Schiffmann, 1982).

In the four marine examples, the behavioral response to chemical stimuli generally requires additional sensory input (Table 2). The best studied example of this is the response of *Urosalpinx cinerea* (Brown and Rittschof, 1984). In this case, either chemical cues alone or flow alone do not evoke creeping. Rather, snails creep only in response to certain levels of flow and certain levels of chemical stimulus. At flows above a certain level or amounts of chemical above a certain concentration, the creeping response is inhibited.

In many instances the precise protein source of the peptide cue has not been identified. It is clear, however, that these cues are generated by trypsinlike serine proteases. In the vertebrate examples the enzymes generating the peptides are known. Digestion of protein sources with trypsin generates biologically active peptides that attract hermit crabs (Rittschof, 1980b), induce metamorphosis in barnacles (unpublished data), and induce hatching and larval release behavior in ovigerous crabs (Rittschof and Forward, 1988). Similar enzymes are responsible for the generation of biologically active peptides in the mammalian complement system (Schiffmann, 1982).

Additional evidence supports the conclusion that proteolytic clips are gen-

TABLE 2. COMPARISON OF RESPONSES, CUE TYPE, AND CUE GENERATION IN FIVE EXAMPLES[a]

	System				
Topic	Hermit crab	Predatory snail	Barnacle larvae	Ovigerous crab	Vertebrate wound

[a]References in which the original work was presented are given in the text.

erated by trypsinlike enzymes. Carboxypeptidases that degrade arginine or lysine carboxy termini rapidly destroy biological activity in the snail creeping assay (Rittschof et al., 1984), the barnacle settlement assay (Tegtmeyer and Rittschof, 1988), and the crab pumping assay (Rittschof et al., 1985). Removal of the carboxy terminus greatly reduces the effectiveness of the leukocyte attractant peptide (Schiffmann, 1982). Carboxy terminal arginine is required for ileum contraction and the anaphylaxis response associated with the C3a peptide (Unson et al., 1984) (Table 3).

The concentration threshold of leukocyte attractant peptides is in the picomolar range (Chenoweth and Hugli, 1978). Because analysis of the other biologically active peptides is not complete, only conservative estimates can be made for the potency of the native peptides in the marine examples. The threshold concentration for the peptides in the marine examples is in the nanomolar range in all instances where sufficient information is available to make the determination (Rittschof et al., 1983, 1985; Rittschof, 1985).

In a similar fashion, molecular size estimates of the native compounds are imprecise due to limitations of the bioassays and the ongoing nature of the studies. However, there is no doubt that barnacle and snail attractants are 3000- to 5000-dalton peptides, while the crab larval release pheromones are <500 daltons. Molecular size may be related to the biochemical complexity of the environment and the effective distance over which the cue must transmit information. Although all the peptides are relatively stable chemically, they have very short half lives in the marine environment due to biological consumption (Rittschof et al., 1983; Forward and Lohmann, 1983).

In addition to work with native peptides, synthetic peptides have been used to probe the responsiveness of barnacle larvae (Tegtmeyer and Rittschof, 1988), ovigerous crabs (Forward et al., 1987; Rittschof et al., 1988), and the vertebrate system (Schiffmann, 1982; Unson et al., 1984) (Table 4). The vertebrate systems have the most stringent requirements for large peptides. The most effective of these peptides, however, evoke responses in the bioassays at the level of the native compounds (Unson et al., 1984).

Of the restricted number of synthetic di- and tripeptides tested for induction of metamorphosis of barnacles, peptides of the general form of neutral–basic or basic–basic are effective at subnanomolar concentrations (Tegtmeyer and Rittschof, 1988).

In bioassays of larval release from ovigerous crabs, neutral–basic and neutral–neutral–basic peptides have effectiveness that is highly composition-dependent (Forward et al., 1987; Rittschof et al., 1988). Peptides possessing arginine at the carboxy terminus are more effective than carboxy terminal lysine peptides. Carboxy terminal arginine tripeptides containing isoleucine and glycine are most potent. Response thresholds to pure peptides span nine orders of magnitude, from femtomolar for the most effective compound (isoleucyl-glycyl-arginine) to submicromolar for the carboxy terminal lysine compounds (Rittschof et al., 1988).

Several biological assays have been used to probe responses to mixtures of amino acids. Micromolar to millimolar binary mixtures of free amino acids elicit biological responses in the ovigerous crab and hermit crab system. In the case of the ovigerous crab, only binary mixtures containing a neutral and a basic

amino acid are effective (Forward et al., 1987; Rittschof et al., 1988). In the hermit crab system, tests conducted on two species of hermit crab demonstrated that one species responds only to neutral–basic binary mixtures similar to the ovigerous crabs. For this species, the most attractive mixtures contain isoleucine or leucine and lysine. The other species, however, responds to binary mixtures containing leucine and either arginine or lysine. In the latter case, high concentrations of a single amino acid, leucine, are also attractive.

Thus, cleavage products generated by the action of trypsinlike enzymes upon structural proteins (flesh, egg membranes, complement proteins, and possibly upon the exocuticle or cement of barnacles) coordinate highly specific responses. The evolution of cues and pheromones generated from hydrolysis of structural components by one of the most common classes of hydrolytic enzymes, the serine proteases (Desnulle, 1960), is mechanistically simple. The raw materials—enzymes and cleavage products—are integral to life itself. What is required is selection pressure for the ability to detect and respond to the peptide cue. Events that are critical to survival and that are closely associated with cue production are subject to extreme selection pressure. All five of the examples discussed have exactly these characteristics.

It could be argued that the common theme of these chemical signals could lead to confusion of responses or cross-talk between organisms. In fact, both the predatory snail and the barnacle appear to use the same cue for different purposes as both animals respond to the same highly purified material (Rittschof, 1985). In contrast to this long-distance cue, the mud crab pheromone is essentially a very personal pheromone. It is effective at very low concentrations and over very short distances because of rapid dilution due to mixing, and because it is released as a pulse. These features, coupled with the fact that eggs cannot be made to hatch prematurely by the pheromone, ensures that this system is virtually fail-safe. Confusion may also be avoided by spatial separation of sensitive organisms or by high levels of receptor discrimination. In certain instances there is a strong possibility that the simultaneous utilization of a cue by several species may occur. For example, one possibility currently under investigation is that compounds released from snail flesh simultaneously cue both hermit crab attraction and settlement of fouling organisms on the newly available shell.

If all the signal receptor systems have evolved from a common pathway, then other aspects of the best studied systems may also apply to the less well studied systems. For example, leukocytes contain receptors for prostaglandin-like compounds (Schiffman, 1982), and prostaglandin-like substances have also been implicated in crustacean larval release (Clare et al., 1982). This may be more than a coincidence. Studies are currently being conducted to determine if these types of parallels exist.

Indirect actions of enzymes (the generation of biologically active peptides)

are well accepted events in endocrinology. This is exemplified by the brain–gut peptides and the plethora of bioactive hormones possessing a carboxy terminal arginine. The concept that internal communication systems have evolved from external systems is gaining credibility in marine systems (Carr et al., 1987). Demonstration that the biochemistry of some external communication systems is identical to that of the internal systems in the evolutionarily more advanced forms would be strong support for this hypothesis.

In summary, one theme in peptide communication between marine organisms appears to be the use of peptides generated by serine proteases to cue highly specific behaviors. Similar events appear to occur in internal regulation in vertebrates. The hypotheses drawn in this study suggest that similar biochemical processes may also use degradative enzymes to produce chemicals with high information potential for use in internal and external communication.

LACK OF PREDICTABILITY IN TERPENOID FUNCTION
Multiple Roles and Integration with Related Adaptations in Soft Corals[1]

Abstract—Terpenoids are commonly found in alcyonacean soft corals of the Great Barrier Reef (Coelenterata, Octocorallia), but they are highly variable in their distribution within this order. Such secondary metabolites in these organisms vary widely in type, concentration, and function. Thus far, they have been found to play roles in predator defense, competitor defense, antifouling, and reproduction. The effectiveness of compounds derived from individual species also varies widely with respect to interactions with other members of the community. These chemical characters function in concert with other morphological, physiological, behavioral, or developmental adaptations that have similar functions. Integration of these adaptations is highly species-specific. The multiple functions of terpenoid compounds and the high degree of species specificity in their ecological roles greatly reduces the ability to predict either the presence or absence of a terpenoid from other related characters. In addition, simple indicators of terpenoid function appear not to exist. If such indicators do exist, they are more likely to be found at higher levels of taxonomic resolution (within families or genera).

Key Words—Terpenoids, soft coral, Alcyonacea, Coelenterata, Octocorallia, defense, predator–prey interaction.

INTRODUCTION

Secondary metabolites have long been known to play an important role in the ecology of plants and animals (Sondheimer and Simeone, 1970; Rice, 1984). Early accounts of secondary compounds and their functions in nature were drawn from terrestrial ecological studies examining antiherbivore interactions (e.g., Janzen, 1969, 1970, 1971; Harper, 1976; Rosenthal and Janzen, 1979; Rhoades, 1985). In early studies, an antipredator role was often assumed for secondary compounds. Later, other functions were considered, including anticompetitor adaptations such as allelopathy (Muller, 1966) that reduced germination rate in neighboring plants, mate attractants (i.e., pheromones in insects and higher animals; Riddiford and Williams, 1967; Bronson, 1971), trail markers (e.g., in ants; Wilson, 1965), and insect attractants (e.g., Edgar and Culvenor, 1975).

When natural products chemistry was extended to the marine environment (see Scheuer, 1973, 1978a, b, 1980, 1981, 1983), secondary metabolites again were initially assumed to be associated with predator defense and antibiosis/antifouling. Chemical communication, however, also was believed by some to be important in the sea, helping to structure marine and aquatic planktonic communities (Kittredge, 1974; Lucus, 1947, 1949, 1955; Saunders, 1957). Later studies lent support to this hypothesis (e.g., Jackson and Buss, 1975; Strickler, 1982, 1984; Kerfoot, 1982; ses Bakus et al., 1986, for review).

In early chemical ecological studies, it was common that a single role was identified for a given secondary metabolite or set of metabolites. In some cases, the roles of compounds were related to morphological structure or behavior (e.g., Bakus, 1976). Janzen (1979), however, has pointed out that such an approach may be too simplistic.

Alcyonacean soft corals (Coelenterata, Octocorallia) are known to be rich in secondary compounds, especially terpenes (Faulkner, 1977, 1984, 1986, 1987), and this richness is now understood to contribute to their ecological and evolutionary success (Fishelson, 1970; Bakus, 1981; Dinesen, 1983; Coll and Sammarco, 1986; Sammarco and Coll, 1988). These secondary metabolites have a multitude of functions, and enough is now known about the chemical ecology of the Alcyonacea to consider how their secondary metabolites integrate with other adaptations that perform a similar function (Sammarco, 1986, 1987).

In this analytical review, we show how terpenoids in the Alcyonacea and their multiple ecological functions integrate with functionally related adaptations (physiological, morphological, behavioral, etc.) in a highly complex manner. We also demonstrate how this high interspecific variability in chemical function coupled with a similar high variance in related adaptations greatly reduces the ability to predict a priori the ecological role of a secondary compound.

ICHTHYOTOXICITY IN ALCYONACEAN SOFT CORALS

Chemical studies have revealed a richness and diversity of terpenoids in Great Barrier Reef soft corals (Coll et al., 1980, 1985, 1986). Ichthyotoxicity bioassays using the fish *Gambusia affinis* (Yamanouchi, 1955) performed on ~400 specimens from the northern, central, and southern regions of the Great Barrier Reef revealed a consistent frequency of 50% ichthyotoxicity for common, exposed soft corals (Coll et al., 1982b; Coll and Sammarco, 1983, and unpublished data). In most instances, ichthyotoxicity was associated with the presence of terpenoid compounds. (Such tests on "evolutionarily naive" fish, of course, are used simply to detect the presence or absence of toxins. More refined tests performed on ecologically relevant species are used to answer detailed questions about roles of the compounds in their own habitat; see Alino et al., 1988).

Surveys of Great Barrier Reef soft corals have also revealed high interspecific and intergeneric variance in ichthyotoxicity. Within some genera (e.g., *Lemnalia* and *Sarcophyton*), toxicity levels of extracts were consistently high, while those derived from species within other genera (e.g., *Cladiella* and *Anthelia*) were generally nontoxic. Extracts from species within another set of genera (e.g., *Lobophyton* and *Sinularia*) spanned the entire range of toxicity. In addition, there appears to be no obvious relationship between the occurrence of toxicity and characteristics of the environment, biological or physical, from which they were sampled. In short, variance in the frequency of occurrence of ichthyotoxicity in the group is high, and simple indicators of its presence are absent.

ICHTHYOTOXICITY AND ANTIPREDATOR ADAPTATIONS

Relationships between Ichthyotoxicity and Feeding Deterrence. Numerous examples of chemical predator defense may be found in both the terrestrial (Whittaker and Feeny, 1971; Feeny, 1975) and marine (Halstead, 1978) literature. Recent field surveys indicate that soft corals of the Great Barrier Reef are rarely preyed upon by generalist predators, including many fish and crustaceans (Sammarco, unpublished data; P. Alino, work in progress). Yet in an experiment assessing 36 soft corals, we found no significant correlation between ichthyotoxicity (as defined above) and feeding deterrence (La Barre et al., 1986). Toxic characteristics were not correlated with olfactory or palatability responses, nor were these two types of responses correlated with each other. In support of this, recent laboratory feeding experiments have demonstrated that *Chaetodon melanotus* (Pisces), a reef fish specialized to feed on polyps of soft and scler-

actinian corals, responds to visual cues from soft corals, not chemical ones (Alino et al., 1988).

If the secondary metabolites of soft corals are playing a role in taste or olfaction (also see Jones, 1962; Schwartz et al., 1980; Faulkner and Ghiselin, 1983; Rowell et al., 1983), their specific effects could have been masked or augmented by other molecules, such as feeding stimulants, steroidal glycosides (Lucas et al., 1979), or prostaglandins (Gerhart, 1984). Soft corals possess a wide range of primary and secondary metabolites, including those mentioned above (see Pawlik et al., 1987), the effects of which have not been isolated in this context from those of the terpenes. Herein lies fertile ground for future experimentation.

Thus, the presence of ichthyotoxicity in a soft coral is a poor indicator of feeding deterrence.

Relationship between Ichthyotoxicity and Morphological Antipredator Adaptations. Feeding deterrence can also be manifested through morphological adaptations. The Alcyonacea exhibit a wide range of morphological variability (Bayer, 1956). Colonies vary in form from flat and encrusting to erect and branching, and their tissues may be hard and impenetrable, soft and fleshy, or spikey, with the polyps completely protected from predators. If the terpenoids discussed above were functioning as antipredator defenses, one might intuitively expect to find a negative correlation between their presence and the occurrence of physical defense against predators (Bakus, 1974, 1976; Bakus and Thun, 1979).

Soft corals from 19 genera spanning numerous families were assessed for ichthyotoxicity and 16 morphological characters assumed to possess antipredator functions. No negative correlation was found between these two sets of characters. Morphological characters considered included gross colony form, colony texture, presence of mucus, colony color, polyp retractility, and sclerite morphology and distribution. Pattern-seeking analyses also revealed no significant negative associations. In fact, two positive associations emerged, possibly implying multiple (or synergistic) predator defenses.

Reduction of the data set to 56 species drawn only from the genus *Sinularia* and the family Nephtheidae (both of which exhibit a wide range of toxinological and morphological variation) yielded more insightful results. Here, only five characters that were clearly potentially related to predator defense were considered: polyp armament, mineralization of the polypary (upper polyp-bearing portion of the colony), mineralization of the coenenchyme (colony interior), tissue consistency and polyp retractility. The first three were found to be significantly negatively correlated with the presence of ichthyotoxicity. Separate analyses of data from the two sets of taxa further clarified these relationships. Association between toxicity and the first two characters occurred only in the Nephtheidae;

the negative association involving mineralization of the coenenchyme was attributable solely to the genus *Sinularia*.

Thus, the presence of morphological antipredator characters can act as an indicator of the absence of toxicity (also see Fenical and Harvell, 1988; Harvell and Fenical, 1989; Harvell et al., 1989) and vice versa. There is, however, measurable variance in this relationship, and the relationship only becomes apparent at high levels of taxonomic resolution.

ADAPTATIONS TO INTERSPECIFIC COMPETITION FOR SPACE

Competition between Alcyonaceans and Scleractinians. The ecological and evolutionary success of soft corals in the Indo-Pacific is evidence of the fact that they are effective competitors for space (see Jackson, 1977). Unlike scleractinian corals, however, alcyonaceans possess neither stenoteles (penetrant nematocysts; Barnes, 1974), sweeper tentacles (Richardson et al., 1979), or similar specialized anticompetitor defense apparati. Some soft corals (e.g., *Sinularia flexibilis* Quoy and Gaimard and various *Sarcophyton* spp.), however, possess particularly high concentrations of terpenoid toxins (flexibilide, FLX; Kazlauskas et al., 1978; and sarcophytoxide, SX, Tursch, 1976; Bowden et al., 1978a), accounting for up to 1% of their dry weight (Bowden et al., 1980).

Field experiments have demonstrated that some soft coral terpenoids cause tissue necrosis and mortality in scleractinian corals without contact. Investigations were made into three species of soft corals (*Lobophyton pauciflorum* Ehrenberg, *Sinularia pavida* Tixier-Durivault, and *Xenia* sp. affin. *danae*) competing for space with two scleractinian species (*Porites andrewsi* Vaughan and *Pavona cactus* Forskal). It was found that the occurrence and efficacy of allelopathic effects of soft corals on scleractinians varies species specifically between soft corals. Also, scleractinian corals vary in their susceptibility to these detrimental effects.

The involvement of terpenoids in this allelopathic interaction has been confirmed in laboratory studies. Pure terpenoids (FLX and FN-45) cause 100% mortality in two scleractinians (*Acropora formosa* Dana and *Porites andrewsi*) at concentrations as low as 5–10 ppm (Coll and Sammarco, 1983). But, again, the response curves vary species specifically with respect to both the toxin and the target species.

Experiments have also confirmed that terpenoids are present in the water column around the soft corals. A submersible sampling apparatus with a reversed-phase Sep-Pak was placed around undisturbed colonies of *Sinularia flexibilis* and *Sarcophyton crassocaule* in the field. Ambient concentrations of 1–5 ppm of the toxic diterpenes FLX and SX, respectively (Coll et al., 1982a).

Thus, the secondary metabolites present in soft corals can be transmitted as allelopathic agents, most likely accumulating in the lipid-rich tissues of neighboring organisms such as scleractinian corals.

Not all species with allelopathic capabilities, however, export their toxins (also see Gerhart, 1986). Field experiments examining similar interactions between three different soft corals (*Sarcophyton ehrenbergi* Maranzella, *Nepthea brassica* Kukenthal, and *Capnella lacertiliensis* MacFayden and Forskal) and the same two species of scleractinians examined earlier (*Pavona cactus* and *Porites andrewsi*) revealed that the highest degree of mortality in the latter occurred in this case as a result of contact (Sammarco et al., 1985). The amount of toxin released appears to be low in some soft corals, despite high concentrations of terpenes in the tissues (Sammarco et al., 1985; Bowden et al., 1978a, 1979).

Other adaptations can assist soft corals in competition for space. They may either complement the allelopathic capabilities of the octocoral or, on the other hand, obviate the need for chemical defense. Certain soft corals secrete a polysaccharide layer (cuticle) in the vicinity of the scleractinian, protecting them from damage from stinging nematocysts (Sammarco et al., 1985). In one case, this allows a soft coral (*Nephthea brassica*) to attach to the surface of a living scleractinian coral (*Acropora hyacinthus* Dana) and grow across it (La Barre and Coll, 1982).

Interspecific Competition between Alcyonaceans: Chemical, Behavioral, and Developmental Responses. Although competitive interactions between alcyonaceans and scleractinians are commonly observed in the field, similar interactions between alcyonaceans themselves appear to be infrequent. Tissue necrosis can be experimentally induced in interspecific interactions between alcyonaceans (*Alcyonium molle* Dean, *Sinularia flexibilis*, and *Nepthea brassica*) in both contact and noncontact situations (La Barre et al., 1986), but the response is a short-term one (on the order of weeks), decreasing in intensity with time. By shifting hydrostatic pressure within the colony, the organism can bend to avoid contact with its neighbor. Also, in the longer term (6–12 months), colonies move from their neighbors through directed growth and establish something akin to an individual distance (Conder, 1949) from their neighbors, thereby reducing the frequency of further interaction.

Growth and movement responses like these help to explain the paucity of interactions between alcyonaceans observed to occur naturally in the field. In fact, observed soft coral distribution patterns may be partially explained by the outcomes of historical competitive interactions. These interactions add another dimension to adaptations that have evolved in this group in response to competition for space.

OTHER ACTIONS OF SECONDARY METABOLITES

Antifouling. Although alcyonacean corals are generally characterized by the absence of fouling epibiota (e.g., bryozoans, filamentous algae, sessile polychaetes, etc.), fouling has occasionally been observed (Patton, 1972; Hartnoll, 1975; Morse et al., 1977; Goldberg and Makemson, 1981; Coll et al., 1987). One mechanism by which soft corals maintain their clean surfaces is the secretion of mucous sheets that are sloughed off. These sheets often harbor microalgae, which occasionally attach themselves to the colony in a more permanent manner. Slow release of terpenes from the colony may ultimately assist in their removal. This premise is supported by the finding that a number of terpenes derived from soft corals inhibit the growth of filamentous algae in unialgal culture (Coll et al., 1987; also see Targett et al., 1983) and prevent settlements of barnacle larvae (Standing et al., 1982; Rittschof et al., 1985, 1986, 1988; Keifer et al., 1986; Gerhart et al., 1988). Antifouling represents another ecological role of terpenes in the Alcyonacea.

Reproduction. Recent studies have opened questions about potential roles for secondary compounds in the reproduction of alcyonacean corals. In common with many scleractinian corals, Great Barrier Reef alcyonaceans have a mass spawning period during the early summer months (Babcock et al., 1986; Alino, work in progress). Many species are dioecious, releasing eggs and sperm simultaneously. The terpene composition of eggs released from several alcyonacean species is, in some cases, different from that of the tissue of the parent colony (Bowden et al., 1985; Coll et al., 1986, 1988). Thus far, compounds present in the eggs have not been shown to play a role in defense against planktonic or pelagic parasites or predators (P. Alino, work in progress), nor do they possess antibiotic properties against a range of marine bacteria.

Sperm chemotaxis has been demonstrated to occur in several species, but the chemicals responsible for this do not appear to be the egg-specific terpenoids (Coll et al., 1987). Although eggs may be present in the parent organism for up to 23 months, synthesis of terpenes within the eggs occurs only during the month immediately preceding spawning (Coll et al., 1988). The question as to whether these terpenes play some role in egg release remains open.

DISCUSSION AND CONCLUSIONS

Although secondary metabolites, particularly terpenes, occur commonly with the Alcyonacea, they exhibit high variability in their distribution. These terpenes may play multiple ecological roles. Although these may include anti-

predator adaptations, there does not appear to be any direct correlation between ichthyotoxicity and feeding deterrence. Other classes of molecules may well be more effective in this capacity.

Ichthyotoxicity is negatively correlated with morphological antipredator characteristics, but the association is only detectable at a high level of taxonomic resolution (e.g., genus or perhaps family) and only when a small number of morphological traits clearly related to predator defense are considered.

Many selection forces may operate differentially on each of the characteristics considered here, be they chemical or morphological. At a high level of taxonomic resolution, an adaptive response to predation, whether toxinological or morphological, is more readily discerned, and the range of variability in such a response is more restricted. At too low a level of resolution (e.g., across families), such responses in the same characteristics are easily counterbalanced and blurred by concurrent adaptations to other selection forces (Table 1). Colony morphology also evolves in response to such factors as food capture (Lewis, 1982), resistance to physical environmental stress (e.g., Fishelson, 1970; Dinesen, 1983), competition for space (Jackson, 1977; La Barre and Coll, 1982; Sammarco et al., 1983, 1985; La Barre et al., 1986a), optimization of photoreception by endosymbiotic zooxanthellae (e.g., Dustan, 1975), resistance to siltation (Fishelson, 1970; Schuhmacher, 1975; Dinesen, 1983), etc. Any one of these factors may act as a strong selection force in one species but becomes less important in others (Sammarco et al., 1987; Sammarco and Coll, 1988). Thus, an association between any two antipredator adaptations may be obscured by one or more other adaptations performing the same function.

Secondary metabolites play a complex role in competition for space between alcyonaceans and scleractinians. Concentrations of terpenoid compounds vary species specifically within the Alcyonacea as does the efficacy of the compounds against scleractinians. Some compounds are released more readily by some species than by others; some competitors are less susceptible to a given compound than others; and survival of competitors may be enhanced by other structural or behavioral anticompetitor defense adaptations. The roles that terpenoids play in alcyonacean soft corals are highly sophisticated, and their integration with other functionally related adaptations must be considered if one is attempting to explain variance in their distribution.

With respect to competition for space, the Alcyonacea exhibit a variety of chemical, developmental, and behavioral adaptations that are conplementary in function. Functional adaptations, whether chemical, morphological, behavioral, or developmental, are also highly species specific in their effectiveness. The presence of a toxic secondary metabolite is not a good indicator of an allelopathic agent nor does it necessarily imply any function in competition for space (Sammarco et al., 1985). The terpenes occurring in these organisms func-

	Emetic response
	Synergistic effects (positive or negative) with other classes of compounds
Morphological[1,4]	Soft coral traits
	Microarmament of individual polyps
	Armament of polypary
	Mineralization of coenenchyme
	Sclerite sharpness?
	Color?
	Consistency of tissue?
	Colony flexibility?
	Growth form?
	Encrusting
	Stoloniferous
	Branching
Behavioral/physiological[1,4]	Polyp retractility
	Mucus secretion

[a] Evidence for functions determined through experimentation or observations; "?" denotes function yet to be confirmed. Superscripts refer to the following references: (1) La Barre, 1984; (2) Coll et al., 1982b; Coll and Sammarco, 1983; unpublished data; (3) La Barre et al., 1986b; (4) Sammarco et al., 1987.

tion in many different ways, depending on the soft coral species in question and the set of species—predators and competitors—with which it has interacted through evolutionary time. Each soft coral species has evolved in response to its own set of primary selective pressures. This has resulted in a given molecule derived from the same class of secondary compounds—the terpenes—serving different functions in different species.

Chemical characteristics functioning in competitor defense may or may not act in concert with other morphological or behavioral adaptations that serve a similar function (Table 2). In addition, these same morphological or behavioral characters may have other secondary or even primary functions that have evolved

TABLE 2. ANTICOMPETITOR CHARACTERISTICS IN ALCYONACEAN SOFT CORALS[a]

Characteristic	Trait
Chemical	Effects on Competitors[1,5–7]
	Allelopathic capabilities
	Contact
	Noncontact (waterborne)
	Growth inhibition/stunting
	Bleaching (expulsion of zooxanthellae)
	Induction of neoplasms
Morphological	Soft coral traits
	Sclerite density?
	Sclerite sharpness/abrasion?
	Basal polysaccharide cuticle[1,6,7]
	Colony flexibility[1,6,7]
Behavioral/physiological	Polyp retractility?
	Mucus secretion?
	Avoidance response (bending)[1,8]
	Movement (through growth)[1,8]

[a] "?" denotes function yet to be confirmed. Superscripts refer to the following references: (1–4) see Table 1; (5) Sammarco et al., 1983; Coll and Sammarco, 1983; (6) Sammarco et al., 1985; (7) La Barre and Coll, 1982.

in response to other selective forces (Table 1). The relative intensity of these selective forces varies greatly between species and thus, once again, the predictability of the occurrence of a toxin in a given alcyonacean, its function, and its association—negative or positive—with other functionally related adaptations decreases with further investigation.

TABLE 3. ANTIFOULING FUNCTIONS OF CHARACTERS IN ALCYONACEAN SOFT CORALS[a]

Characteristic	Trait
Chemical	Effects of epibiota
	Growth inhibition[9]
	Antibacterial activity[10]
	Antifungal activity[10]
	Antiviral activity[10]
Morphological	Soft coral traits
	Colony flexibility?
	(inhibition of colonization or attachment)
Behavioral/physiological	Mucus sheet formation[9]
	Ciliary action?

[a] "?" denotes function yet to be confirmed. Superscripts refer to following references: (1–7) see Tables 1 and 2; (8) Sammarco et al., 1985; (9) Coll et al., 1987; (10) Rinehart et al., 1981.

It is also possible that terpenes play a role in antifouling and enhancement of reproductive success, although their specific role(s) in the latter remains to be determined. Even these adaptations are tied to specific physiological or behavioral adaptations, and these latter adaptations themselves may have multiple roles (Tables 3 and 4). There may also be other functions that have not yet been considered, such as negative or positive settlement or association cues for larvae (sensu Rittschof et al., 1985; Morse et al., 1979, respectively).

Secondary compounds such as terpenes in alcyonaceans may play a role in any of these ecological processes, but the mere presence of the compound does not imply any particular role. It may play one or more different ecological roles

TABLE 4. FUNCTIONS OF CHARACTERISTICS IN ALCYONACEAN SOFT CORALS THAT ENHANCE REPRODUCTIVE SUCCESS[a]

Characteristic	Trait
Chemical	Toxic Effects
	Allelopathy[11]
	(increase success of larval settlement)
	Predator deterrents
	Eggs?[12,13]
	Whole colony during most fecund period?[12,13]
	Nontoxic effects
	Chemotaxis?[14]
	Sperm attractant?[14]
	Associate settlement cues?
	Spawning release factor?[13]
Morphological	Soft coral traits
	Growth form
	Encrusting
	Stoloniferous
	Branching
Behavioral/physiological	Surface brooding in mucus sheets[15]
	Synchronous spawning of gametes/ "predator swamping"—eggs[16]
	Nocturnal spawning[16]
	Brooding[16]
	Buoyancy of eggs and planulae (lipid content)[12,13,16]
	Taxis, planular?
	Phototaxis?
	Geotaxis?
	Thigmotaxis?

[a] "?" denotes function yet to be confirmed. Superscripts refer to following references: (1–10) see Tables 1–3; (11) personal observation; unpub. data; (12) Bowden et al., 1985; Coll et al., 1986; (13) Coll et al., 1988; (14) Coll et al., 1987; (15) Z. Dinesen, personal communication; (16) P. Alino, work in progress.

within a single species and is often highly species specific in action. A priori prediction of a function for a given secondary metabolite in an alcyonacean is virtually impossible because of the multiplicity of potential roles it can play. In addition, the presence or absence of a particular morphological or behavioral trait is a poor indicator of the presence or absence of chemical adaptation, and vice versa. This is due to similar confounding effects and evolutionary tradeoffs that have occurred between traits performing similar functions.

In any one species, the role of a secondary compound is integrated with various other adaptations (morphological, behavioral, reproductive, etc.), but such integration is complex, subtle, and highly species specific. Thus, if predictable relationships are to be found between secondary chemical characters and other functionally related attributes in a set of organisms, this is most likely to occur at high levels of taxonomic resolution.

Acknowledgments—P.W.S. thanks the Western Society of Naturalists (1986 Conference, University of Hawaii at Hilo), the National Science Foundation (Biological Oceanography Section), the Department of Marine Sciences—University of South Florida at St. Petersburg, the St. Petersburg Progress Committee, and the International Society of Chemical Ecology for the opportunity to develop, formalize, and present these ideas. He also thanks W. Fenical, M. Hay (WSN), P. Betzer, and L. E. Davis (USF St. Petersburg), and D. Gerhart (ISCE) for helping to make such presentations possible. C. Johnson, D. Alongi, and A. Wood provided helpful comments on the manuscript. Both authors thank the Australian Marine Science and Technologies Council, the Australian Research Council, and the Australian Institute of Marine Science for their support of our research.

(Received November 29, 1988; accepted February 6, 1989)

Abstract—The behavioral response of female alfalfa seed chalcids is dependent on the polarization of sky light when exposed to olfactory stimuli between 1100 and 1500 hr. Females made no orientation flights to or landings on eight unbaited targets, but when half the targets were baited with the host-plant odor of hexyl acetate, they did make orientation flights to and landed on baited targets. Female preference for baited targets disappeared when natural sky light was plane polarized (at right angles to natural sky light polarization at 1200 hr). When natural sky light was passed through a diffuser filter to completely depolarize the light, females made numerous orientation flights but displayed no preference for baited targets. Any alteration of the natural wavelengths of sky light between 345 and 425 nm with various Kodak Wratten filters that excluded certain wavelengths produced similar results wherein females had no preference for baited or unbaited targets. The hypothesis that chalcid response was controlled by the polarization characteristics of sky light was confirmed when females again preferred baited targets in tests that were conducted 6 hr after sunrise, but they displayed no preference for baited targets when exposed to the mixture of polarized and nonpolarized light present in the sky 1–2 hr after sunrise or 1–2 hr before sunset. The possibility that chalcid response was due to a circadian rhythm was eliminated by exposure of insects to different sequences of light-dark regimes prior to the olfactory test.

Key Words—Alfalfa seed chalcid, *Bruchophagus roddi*, Hymenoptera, *Eurytomidae*, Chalcidae, olfactory behavior, polarization vision, insect behavior.

INTRODUCTION

The classic work of von Frisch (1949) showed that honeybees (*Apis mellifera* L.) use the celestial pattern of polarized light as a compass. They also have trichromatic color vision composed of ultraviolet (345 nm), blue (440 nm), and green (550 nm) with a predominance of blue receptors (Menzel, 1975). Many herbivorous species of insects respond to the pattern, dimension, and spectral quality of plants. Spectral reflectance of plant buds, bracts, blossoms, seeds, fruits, stems, twigs, and thorns may be similar or different in reflectance (Prokopy and Owens, 1983). How phytophagous species perceive and use polarized light to assess plants is unknown for most species.

Polarization vision, like color vision, is three-dimensional but for different reasons and requires three types of receptors (Bernard and Wehner, 1977). Polarizational states are analogous to colors that can be described by intensity, angle of polarization (*e* vector orientation), and degree of polarization. The percentage of polarized sky light increases from the sun, where it is zero, to an angular distance of 90° from the sun (Wehner and Rossel, 1985). Also, a patch of sky is characterized not only by the degree of polarization, but also by its spectral composition. Those portions of the sky that exhibit maximum polarization also have the highest content of short-wavelength light. These characteristics of celestial light may influence the way insects perceive and evaluate plant stimuli.

The effect of polarized light has not been investigated for most phytophagous insects, but certain components of light are known to affect host-finding. For example, the fruit fly, *Rhagoletis pomonella* (Walsh), detects its host fruit by intensity contrast of dark fruit against a bright background of light transmitted through foliage (Owens and Prokopy 1987). One also cannot rule out an interaction of light and odor perception in phytophagous insects (Visser, 1986), as occurred in tests with tsetse flies (*Glossina* spp.) (Green, 1986).

During flight and host-finding tests with alfalfa seed chalcids, *Bruchophagous roddi* (Gussakovsky), females responded differently to the same olfactory stimuli in the laboratory and greenhouse. Reported herein are tests with different types of light that changed the way female chalcids responded to olfactory stimuli.

METHODS AND MATERIALS

Experimental insects were reared in the laboratory in controlled environment chambers as described elsewhere (Kamm and Buttery, 1986). Females were collected the day of emergence and put into vials (95 × 24 mm diam.) provisioned with a 10% solution of sugar water, 25 per vial. The rearing regime

was 16 : 8 light–dark at 24°C with lights programmed to begin at sunrise. Once in vials, females were exposed to 30°C in one of the following pretest light regimes of 16 : 8 light–dark for 48–72 hr where the lights in the chambers came on; 6 hr before sunrise, 6 hr after sunrise, or sunrise. The latter was used unless specified otherwise.

To obtain a relatively uniform distribution of light, the bioassay chamber (Kamm, 1988) was used inside a large plywood box (1.2 × 1.2 × 2.4 m long) with an open top (Figure 1). Parallel observation ports (5 × 65 cm) were cut in the sides of the box, positioned 68 cm from the top and 60 cm from the ends. The observer viewed the tests from under black shading cloth attached to the box so light did not enter through these ports. The chamber was used in a greenhouse room, half of which had a thin layer of shading compound to reduce the intensity of direct sunlight and avoid heat build-up inside the greenhouse. Otherwise, test insects had a 160° view of the sky from east to west during bioassays. No plants were grown in the bioassay greenhouse. One end of the plywood box was fitted with an intake fan and the other with an exhaust fan mounted in openings 20 cm in diam. These fans were used to move fresh air through the chamber and to exhaust test odors out of the greenhouse after a test.

Test choices consisted of eight wax targets (previously illustrated; Kamm, 1989) deployed in the chamber in two rows and spaced 17 cm apart. Hexyl acetate, a known host-plant attractant (Kamm and Buttery, 1986), was used as bait by dispensing 25 μl of 0.1% hexyl acetate in hexane onto a piece of cotton

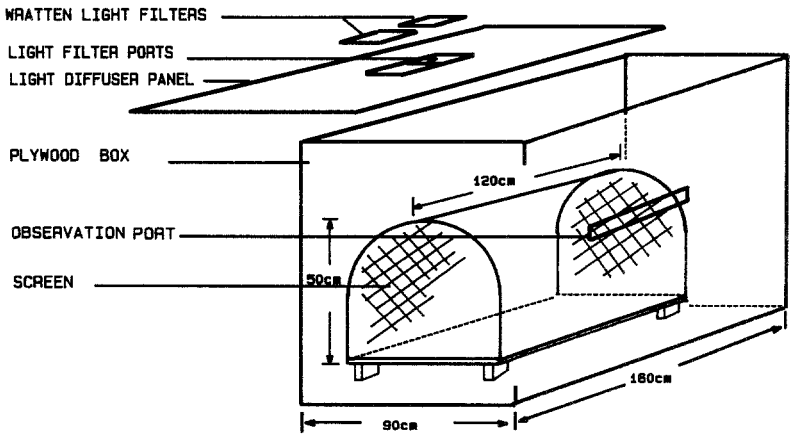

FIG. 1. Diagram of bioassay chamber inside a large plywood box (painted white). Either the light diffuser panel (shown) or the polarized filter (not shown) was taped to the top of the box to conduct a test. The Kodak Wratten filters were taped over the ports cut in the diffuser panel.

dental roll 1 cm long. Blank targets had similar dental rolls impregnated with 25 μl of hexane. After the solvent evaporated, the rolls were suspended and hidden inside the wax target as described (Kamm, 1989). Half the targets were baited with hexyl acetate and half with hexane (blank). Test odors dispersed through the chamber by diffusion to form a concentration gradient around each source of odor.

Filters were used to obtain certain types of light. A light diffuser (No. 444 luminous panel, Armstrong Corp., Seattle, Washington) was used to completely depolarize incoming light. Two adjacent ports (110 × 110 mm) were cut out of the center of the 61 × 122-cm diffuser panel so either one or two Kodak Wratten light filters could be used simultaneously. When one filter was used, the other port was covered with a piece of the diffuser panel. The polaroid filter (HN 35 neutral color, 48 × 128 cm long) was a cellulose acetate butyrate linear polarizer obtained from Polaroid Corp. (Norwood, Massachusetts). This filter was used in place of the light diffuser panel shown in Figure 1. Both the Polaroid filter and diffuser panel were taped to appropriate-sized tagboard frames that were then secured to the plywood box to exclude all other light. Kodak Wratten filters 0, 2B, 2E, and 18A (125 × 125 mm) were used in combination with the diffuser filter as illustrated (Figure 1). Each filter excluded specific wavelengths and permitted others to pass through the filter. All filters were gelatin except 18A, which was glass and permitted entry of specific wavelengths of light between 345 and 355 nm. Only four targets (two of which had hexyl acetate) were used in tests with Kodak filters because of the relatively small area beneath the filters. The light intensity was measured with a light meter prior to a test and ranged from 28,000 to 52,000 lx inside the bioassay chambers.

To conduct a test, eight vials (95 × 24 mm diam.) of 25 females were placed upright in the bioassay chamber and the stoppers removed so females could exit and disperse within the chamber. After the insects had acclimated to the chamber environment (29°C) for 30 min, the targets were introduced and the insects observed for 1 hr. This procedure was replicated three times for each test. The observer monitored only that air space within 10 cm of the array of targets (delineated by parallel lines along the side of the chamber) for the number of orientation flights, orientation landings, and direct landings. Females were not removed after an orientation flight because they tend to stay where they land 2–10 min and then fly off in a different flight mode. Orientation flights were considered terminated when the insect lost interest in the stimuli and flew out of the monitoring zone or landed on the stimuli. How the observer distinguished these behaviors is described elsewhere (Kamm, 1989). Briefly, the test criteria were: (1) Orientation flight—chalcid slowly flew around and/or directly toward specific targets with the antennae thrust forward while the abdomen was held vertically. These flights usually occurred within 10 cm of the array of test

stimuli and were often punctuated by hovering flight when close to the target. (2) Orientation landing—chalcid hovered close to or circled the target and then gently landed on it. (3) Direct landing—chalcid flew swiftly to and landed forcefully on a target without close-range evaluation. χ^2 analysis was used to analyze all test data with the hypothesis that the ratio of chalcids that responded to baited and unbaited targets was 1 : 1. No analysis was done in tests where fewer than six insects responded in a given category.

RESULTS AND DISCUSSION

When females were exposed to a randomized array of baited and unbaited targets in unfiltered naturally polarized sky light, they preferred targets baited with hexyl acetate to unbaited targets (blank) as indicated by the numerous orientation flights and landings (Figure 2A). When exposed to only unbaited targets, females made no orientation flights and landings but instead made numerous direct landings on the targets (Figure 2B). These tests clearly indicated that the odor stimulus was the factor that elicited an orientation response directed toward the targets, a process that commonly occurs in other insects (Kennedy, 1977). Similar results were obtained when a Polaroid filter was used but aligned (visually positioned to permit entry of maximum natural polarized

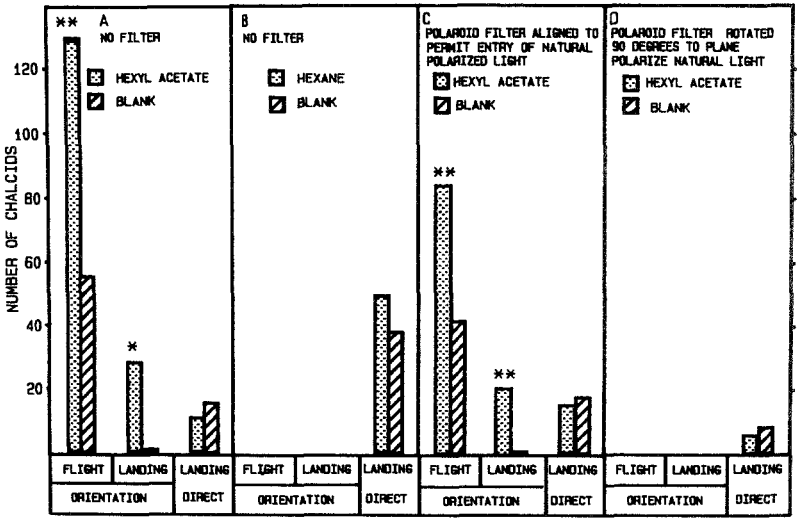

FIG. 2. Total number of female alfalfa seed chalcids that responded when exposed to olfactory stimuli in unfiltered sky light or sky light passed through a polaroid filter between 1100 and 1500 hr. $*P < 0.05$; $**P < 0.01$, χ^2.

light) so it did not alter the natural polarization of sky light (Figure 2C). However, when the Polaroid filter was rotated 90°, it blocked certain light vibrations and permitted entry of polarized light aligned only in a single plane. Then the chalcids made no orientation flights to or orientation landings on targets (Figure 2D). Females clearly required the celestial pattern of polarized light to respond to the hexyl acetate bait. Although light intensity was greatly reduced by the Polaroid filter, it was the same in tests C and D of Figure 2.

A different approach was used to confirm the previous results by using a light diffuser (Figure 1) that completely depolarized the sky light entering the bioassay chamber. First, evidence was obtained that light passing through the diffuser was depolarized by placing it between two Polaroid sheets. Light was transmitted equally when both Polaroid filters were aligned and also when the top filter was rotated 90°. This indicated the light was completely depolarized (a uniform random scattering of light) because the latter arrangement would not have transmitted light had light been polarized in a single plane. Light was not transmitted by the combination of Polaroid filters without the diffuser between them when the top filter was rotated 90°. When the diffuser was used to depolarize natural sky light, females made numerous orientation flights but displayed no preference for baited targets (Figure 3A). Thus, females again displayed no olfactory preference when the natural polarization of light was altered using a procedure other than Polaroid filters. When unfiltered light entered through ports in the center of the diffuser, chalcids regained their preference for baited targets (Figure 3B). Similar results were obtained when Kodak Wratten filter 0 (essentially unfiltered light through gelatin) was used in the port (Figure 3C). However, when Kodak filters 2B, 2E, and 18A were used alone and in different combinations to exclude specific wavelengths of light between 345 and 425 nm, females displayed no preference for targets baited with hexyl acetate (Figure 3D–H). This indicated that the natural color of light also plays an important role in the olfactory behavior of chalcids.

Because the degree and angle of polarization changes as the earth changes position relative to the sun, tests were made to determine how such gradients influence response of females to olfactory stimuli. When females were exposed to a regimen of 16:8 light–dark where the photophase began 1 hr before sunrise, females displayed no olfactory preference when the test began 1 or 10 hr after sunrise, but they preferred the baited targets when the test began 5 hr after sunrise (Figure 4A–C). The chalcids may have responded because they were trained to a lights-on signal that evoked a circadian response instead of a response to the natural polarization of light. Thus, to determine whether or not the response was circadian, females were exposed to the same 16:8 light–dark regimen as in previous tests but the light period began 5 hr before sunrise. Again females displayed no olfactory preference when the test began 1 hr after sunrise but preferred baited targets when the test began 5 hr after sunrise (Figure 4D

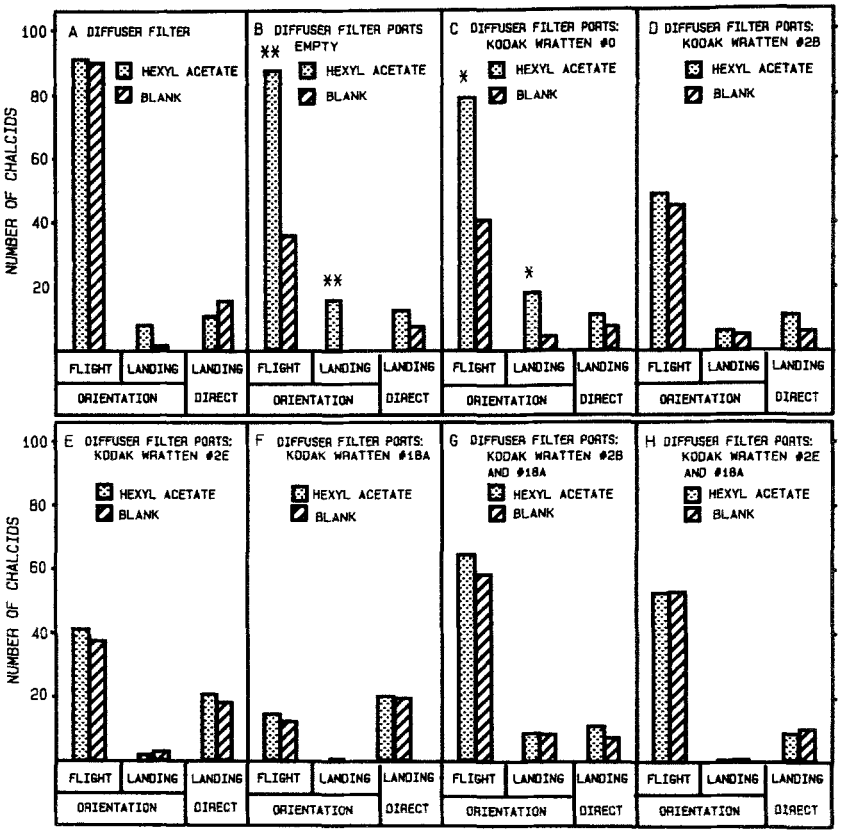

FIG. 3. Total number of alfalfa seed chalcids that responded to olfactory stimuli when sky light was completely randomized by a diffuser filter used alone and in combination with Kodak Wratten filters. $^{*}P < 0.05$; $^{**}P < 0.01$, χ^2.

and E). In yet another test, females were exposed to 16:8 light–dark where the dark period began 4 hr before and continued 4 hr after sunrise. Females were exposed to the targets 2 hr after the beginning of the light period (6 hr after sunrise), and again females preferred baited targets (Figure 4F). Thus, a circadian response was not the mechanism that influenced olfactory response in chalcids.

In summary, chalcids made inflight maneuvers toward and landed on targets baited with hexyl acetate when tests were conducted under natural wavelengths and polarization of sky light. Any alteration of these parameters eliminated female preference for baited targets. As Dethier (1982) pointed out, the use of behavior as a criterion of recognition does not necessarily mean

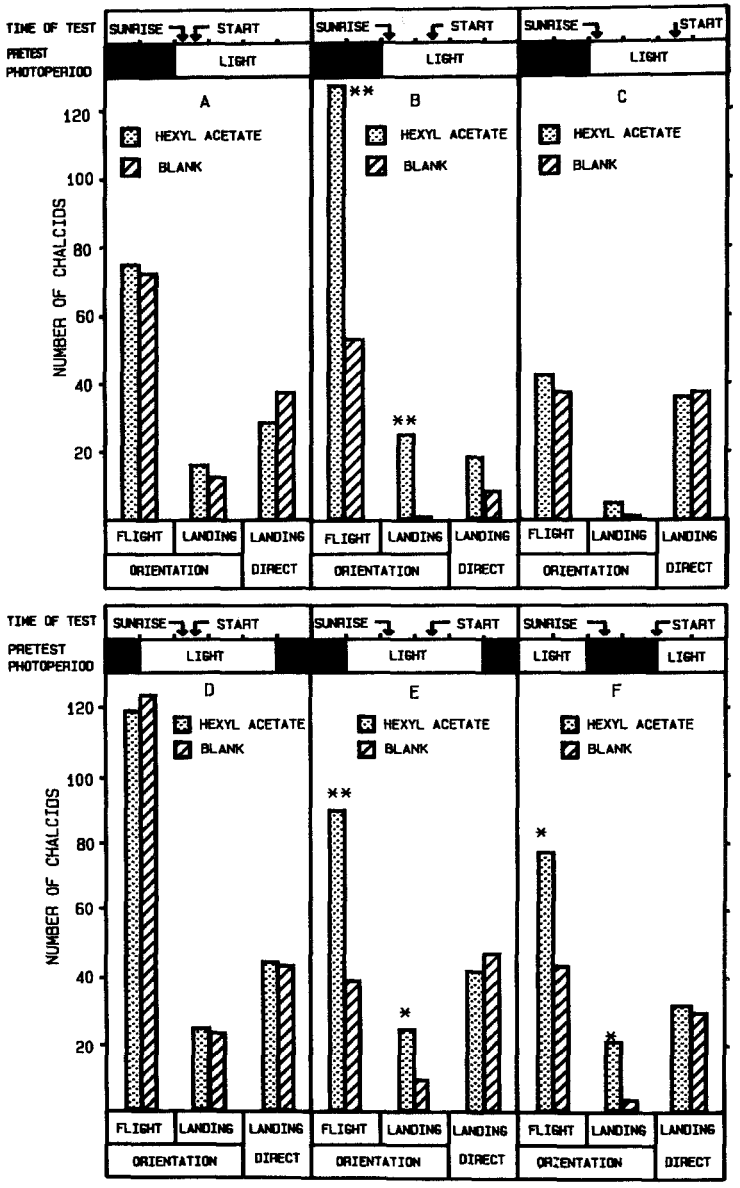

FIG. 4. Total number of alfalfa seed chalcids that responded when exposed to different light-dark regimens prior to testing female response to olfactory stimuli in unfiltered natural sky light when tests began 1, 5, or 10 hr after sunrise. $*P < 0.05$; $**P < 0.01$, χ^2.

absence of recognition when the behavior is absent. Nevertheless, alteration of natural light changed the way chalcids responded to olfactory cues during flight. Previously (Kamm and Buttery, 1986), the absence of natural light and the use of artificial light in no-choice tests did not prevent chalcids from identifying hexyl acetate as an active component of alfalfa. However, these tests did not consider inflight evaluation of the chemical stimuli. Here, natural light was essential for chalcids to evaluate visual and olfactory stimuli during flight if they were to display a preference when confronted with a choice. Important behaviors of other insects may be inhibited when bioassays are conducted in the laboratory without the natural color and/or the polarized gradient of sky light. In general, it is difficult to stimulate insects to fly upwind in response to plant odors (Finch, 1986), and natural light may be required to induce such behavior in some insects.

The mechanism chalcids use to perceive light cues is probably similar to that of honeybees, where the spatial arrangements of ultraviolet receptors in the eye read the point of maximum polarization in the sky (Wehner and Possel, 1985). Direct sunlight contains less than 10% ultraviolet radiation, while scattered sky light may have up to four times more. Chalcids failed to display a preference for baited targets when exposed to a light spectrum that excluded ultraviolet light below 390 nm using Kodak Wratten filter 2B. Ultraviolet light functions as a primary color for many insects (Brunner and Labhart, 1987; Kevan and Baker, 1983). The chalcid may use the color of light and the degree and angle of polarization to determine the time of day it engages in olfactory and visual search behavior. Although temperature clearly plays an important role in chalcid flight (Strong et al., 1963), the natural polarization of light may confine olfactory activity to midday in areas where night temperatures stay above 21°C.

CORRELATION OF PHENOLIC ACID CONTENT OF MAIZE TO RESISTANCE TO *Sitophilus zeamais*, THE MAIZE WEEVIL, IN CIMMYT'S COLLECTIONS

(Received June 7, 1988; accepted February 6, 1989)

Abstract—The (*E*)-ferulic acid content of the grain of nine populations of land races of maize derived from CIMMYT's collections was found to be negatively correlated to susceptibility characteristics towards the maize weevil *Sitophilus zeamais*. Correlation coefficients for six susceptibility parameters and (*E*)-ferulic acid content were significant and ranged from −0.58 to −0.79. A multiple regression analysis by the SAS forward procedure using the primary seed characteristics associated with susceptibility indicated that the ferulic acid content was the only significant factor in explaining variation in at least two susceptibility parameters: the Dobie index and adult preference. In 15 CIMMYT pools, correlations between four susceptibility parameters and (*E*)-ferulic acid content were also significant (−0.76 to −0.81). The results suggest that phenolic acid content is a leading indicator of grain resistance or susceptibility to insects and may represent a newly identified mechanism of resistance.

Key Words—Phenolic acids, resistance, susceptibility, maize, maize weevil, *Sitophilus zeamais*, Coleoptera, Curculionidae.

INTRODUCTION

Sitophilus zeamais Motsch., the maize weevil, is both a preharvest and a postharvest pest of maize. Infestations can occur in the field while the grain is still in the husk or in storage after the maize is shelled. Races of maize vary greatly

0098-0331/90/0200-0301$06.00/0

in susceptibility to attack by the corn weevil (Eden, 1952; Dobie, 1977; Serratos et al., 1987). The husk cover does provide some protection from attack (Dobie, 1977), but other factors contribute to the resistance of shelled grains.

In maize, variation in seed characteristics related to nutritional quality such as sugar and starch content, protein, fat, oil, hardness, and ash have been assessed for a possible role in susceptibility to either *S. zeamais* or *S. oryzae* (Dobie, 1977; Eden, 1952; Singh and McCain, 1963; Gomez et al., 1982, 1983; McCain and Eden, 1965). Many of these factors are correlated in some way with susceptibility.

A previous study by this group using two susceptible and two resistant maize populations suggested a possible role for maize phenolics as deterrents to *S. zeamais* (Serratos et al., 1987). The resistant maize populations had significantly higher phenolic acid levels in the pericarp than susceptible varieties, and feeding studies with maize extracts and pure phenolic acids added to artificial diets suggested the antifeedant effects of these compounds.

The purpose of the present study was to investigate the role of phenolic acids in maize within the context of other nutritional and physical factors that are known to affect susceptibility of grain to maize weevil. Two sets of maize from CIMMYT's (International Centre for Wheat and Maize Improvement, El Batan, Mexico) collections were studied. A set of land races was examined because in our previous study (Fortier et al., 1982), two land races were identified as having exceptionally high resistance and because land races have a high degree of variability useful for determining factors associated with resistance. In addition, 15 CIMMYT pools were examined to determine if the results extended to modern improved germplasm.

Susceptibility of maize populations to maize weevil was assessed by standardized tests for the number of oviposition sites, number of progeny produced, consumption by adults and a related stability parameter, an adult preference test (choice), and a life-cycle index of susceptibility (the Dobie index). Initially, hardness, the principal phenolic acid [(*E*)-ferulic acid], sugar and protein contents were examined in the land races. A more detailed analysis of individual maize phenolics [(*Z*)-ferulic, *p*-coumaric and sinapic acids, Figure 1] was carried out with the pools.

METHODS AND MATERIALS

Plant Material

Nine collections of Mexican land races and 15 pools from CIMMYT's collection were multiplied at El Batan, Tlaltizapan, and Poza Rica field sites from germ-plasm bank material held at CIMMYT (Table 1). The Mexican land races represent rare germ plasm of maize described by Wellhausen et al. (1951).

The chemical analyses were done on flours, and hardness was assessed using intact whole grains.

Assessment of Resistance

The following procedure was used with CIMMYT pools: cultures of *Sitophilus zeamais* were reared in 1-liter screened Mason jars and maintained in an environmental chamber at 27°C, 70% relative humidity, and 16-hr photoperiod on a diet of Ritchies Recleaned Corn, a locally available feed corn. Prior to use in the resistance tests, all corn was stored in a cold room at 4°C. Varieties to be tested were placed in 1.5-liter screened Mason jars and kept under the same conditions as *S. zeamais* for a minimum of six weeks before beginning resistance tests (Widstrom et al., 1978). After this time, average moisture content of each variety was determined by accurately weighing three 5-g samples of seed, taken randomly from different levels in the Mason jar. The samples were dried in an oven at 130°C for 16 hr and reweighed (Fortier et al., 1982).

Seed sample size and infestation of *S. zeamais* were determined following the recommendations of Widstrom et al. (1978): there was 1 g seed per adult weevil and more than the minimum of 20 weevils required to avoid sex determinations. All tests were carried out in the dark at 27°C, 70% relative humidity by placing the vials in a black cloth bag in the environment chamber. Ritchies Recleaned Corn and Cacahuacintle, a high-altitude, floury, Mexican corn susceptible to *S. zeamais* were used as controls (Van Der Schaaf et al., 1969; Dobie, 1977). A resistance test was performed on each variety plus controls using the following technique developed by Dobie (1977) with some modifications. For each variety, two subsamples of 200 seeds each (50+ g) were placed in screened 40-g plastic vials. Each sample was infested with 50 adult *S. zeamais* weevils, 0–7 days old. These first infestations were known as the conditioning replicates, and their purpose was to allow the weevils to adjust to any short-term affects. After seven days, moisture content of each variety was determined and adult mortality recorded. Two more samples of 200 seeds were counted, weighed, and placed in vials (test replicates). Surviving weevils from the conditioning replicates were transferred to the test replicates, and the test replicates were returned to the chamber for one more week. Adult mortality was again noted (only this mortality figure is reported in the results).

At the end of the second week, one test replicate of each variety was returned to the chamber to await emergence of progeny adults. Once emergence began, progeny adults were counted and removed daily for approximately 28 days. Upon termination of the test (no further emergence), frass was removed from the sample by blowing the seeds with a stream of compressed air before weighing. The mean number of progeny per 50 adults or 200 seeds represents the parameter "progeny." The second test replicate of each variety was placed

in the refrigerator after removal of the adult weevils in preparation for counting of egg plugs. Frass was removed from the samples prior to staining with 20 ppm berberine hydrochloride for counting (Milner et al., 1950). All 200 seeds were examined and egg plugs counted under UV light. Presence of stained egg plugs was confirmed by examining some seeds under a dissecting microscope. For each variety, the entire procedure was repeated four times and the mean number of eggs/50 adults (or 200 seeds) represents the parameter "egg number."

The Dobie (1977) index of susceptibility (I) was determined from the data where:

$$I = \ln \frac{F}{D} \times 100$$

and F = total number progeny adults and D = mean development time (days).

The methods for determining and other susceptibility parameters (stability factor based on rate of consumption, consumption of grain, choice test) are described in Serratos et al. (1988).

Determination of Phenolic Acid and Fatty Acid Content

Alkaline Hydrolysis (4 and 18 hr). The total content of the phenolic acids and fatty acids in 1 g of ground grain was hydrolyzed in 30 ml of 2 N sodium hydroxide in an enclosed flask in an atmosphere of nitrogen. The flask was placed on a shaker for 4 or 18 hr and subsequently acidified to pH 2.0 with 6 N hydrochloric acid. The slurry was centrifuged at 750g for 10 min, and the supernatant was decanted into a separatory funnel. The pellet was rinsed twice with water and centrifuged after each wash. All supernatants were combined, and the phenolic acids and fatty acids were extracted with 40 ml of ethyl acetate. The upper organic layer and the lower aqueous layer were collected separately. The aqueous layer was reextracted with 40 ml of ethyl acetate. The upper ethyl acetate layer from this second extraction was combined with the upper layer from the first extraction and extracted with 40 ml of water. The ethyl acetate layer from the final extraction, including any emulsion that formed between the upper and lower layers, was collected and dehydrated over sodium sulphate (anhydrous). The extract was dried in vacuo and the residue was redissolved in 3 ml of ethyl acetate.

Acid Hydrolysis. The acid hydrolysis procedure used was based on the method of Pussayanawin and Wetzel (1987). The flour was hydrolyzed in a test tube with 35 ml of 0.2 N sulfuric acid in a boiling water bath for 30 min. The tube was cooled under running water and 5 ml of a 2% (w/v) suspension of a fungal amylase (Sigma) in 2.5 M aqueous sodium acetate was added to digest the starch in the sample and to simplify subsequent procedures. The mixture

was incubated in a water bath at 55°C for 60 min with periodic agitation. The sample was centrifuged at 750*g* for 10 min. The supernatant was collected and the pellet was washed twice with water and centrifuged. The supernatants from all three centrifugations were combined and adjusted with water to a volume of 50 ml. The phenolic acids were extracted three times with 100 ml ethyl acetate. The upper (ethyl acetate) layers were combined and dehydrated over sodium sulphate (anhydrous). The extract was dried in vacuo and redissolved in 3.0 ml of ethyl acetate.

Separation by Gas Chromatography. To prepare the samples, all samples were filtered (0.45 μm filter) and an aliquot of 1 ml from each extract was dried under nitrogen. Hydroxybenzoic acid was used as an internal standard, and 20 μg was added to each sample and dried under nitrogen. The samples were derivatized prior to injection with *N*, *O*-bistrimethylsilyl acetamide (Serva) and diluted with methylene chloride.

The Vista Varian 6000 gas chromatography system with a flame ionization detector was used. One or five microliters were injected onto a 10-m bonded phase vitreous silica capillary column (ID 0.22 mm, OD 0.33 mm) with a flow rate of 3.0 ml/min. The initial oven temperature was 150°C. After 2 min, the oven temperature was increased at a rate of 10°C/min for 12 min and then held at 250°C for 3 min. The peaks were recorded on a Hewlett-Packard Integrator. The areas under the peaks were integrated and corrected for the volume of sample injected and dilution. The areas of the peaks for the individual components were divided by the area of the peak for the internal standard to correct for any variation in injection volume. The areas were converted to micrograms of compound according to a standard curve constructed using standards of (*E*)-ferulic acid and hydroxybenzoic acid. Phenolic acids and fatty acids were separated using this procedure.

Identification. Identification of the components was made by gas chromatography–mass spectrometry (GC-MS) and by comparison with standards. The GC-MS analysis was performed on derivatized samples and under similar chromatographic conditions to those used to obtain the quantitative data.

Determination of Hardness

The grain was equilibrated for six weeks in a growth chamber at 27°C and 70% relative humidity before determining hardness. The Instron system for determining hardness was made up of two parts. The testing system consisted of a model 4201 Instron (Canton, Massachusetts) with a strain-gauge indicator (Daythonic, model 3170, Dayton, Ohio) and a load cell of 0–1000 lb capacity (Strainsert model FLIU-35PKT, West Conshocken, Pennsylvania). The computer system consisted of an Apple II Plus microcomputer with a real-time clock

card, a video display monitor, a matrix printer (Apple dot matrix), and two disk drives. A description of the entire system and the program can be found in Buckley et al. (1984).

Each sample unit was tested at room temperature and force peak (newtons) was averaged per each variety. Since hardness is defined as the height of the force peak on the first compression cycle (first bite) (Borne, 1982), this measure was taken.

Determination of Protein and Sugar Content. Total sugar was analyzed by a modified Dubois method as described previously (Serratos et al., 1987) and protein in whole grain was estimated by a kjeldahl nitrogen analysis procedure using an automated kjeltec (Decator) analyzer and 6.25 as conversion factor.

RESULTS

Phenolic Extraction

A review of the literature suggested at least three major variations on phenolic acid extraction methodologies; 4-hr base hydrolysis (Sosulski et al., 1982), overnight base hydrolysis (Ribereau-Gayon, 1972), and a 30-min acid hydrolysis (Pussayanawin and Wetzel, 1987). As seen in Table 2 overnight (18-hr) base hydrolysis resulted in the highest recoveries of (*E*)-ferulic acid with 4-hr base hydrolysis providing near equivalent amounts. The acid hydrolysis pro-

duced very low values. Both overnight and acid hydrolysis were incompatible with accurate analysis of the minor phenolic acids [(*Z*)-ferulic acid, *p*-coumaric acid, and sinapic acid] because of either isomerization and release of interfering fatty acids by saponification (18-hr base hydrolysis) or extremely poor recoveries (acid hydrolysis). For these reasons, the 4-hr base hydrolysis was adopted as the best method for varietal comparisons of all phenolics.

Excellent separation of maize phenolics from extracts was obtained by a gas chromatographic method developed using a capillary column (Figure 2). (*E*)-Ferulic acid, (*Z*)-ferulic acid, *p*-coumaric acid, and sinapic acid as well as the fatty acid palmitic acid were identified by GC-MS.

Correlations in Land Races

Five physical and chemical parameters for nine collections of land races of maize are given in Table 3. Means of six susceptibility parameters for the same land races are reported elsewhere (Serratos, 1988). All the susceptibility parameters are highly ($r \geq 0.58$) and frequently ($r \geq 0.79$) and significantly ($P \leq 0.05$) correlated with each other (data not shown). In Table 4 simple correlations between some of these parameters are given. There was a signifi-

cant negative correlation between all the susceptibility parameters and the following physical chemical characteristics: (*E*)-ferulic acid, protein, or hardness ($r = -0.5$ to -0.9). Palmitic acid showed a negative correlation with the Dobie index.

In order to assess the significance of (*E*)-ferulic acid in susceptibility with respect to other physical–chemical parameters, a multiple regression was undertaken using the SAS forward selection procedure, entering only parameters with $P \leq 0.1$ into the model. The six susceptibility parameters were taken in turn as the independent variable, with the physical–chemical parameters as dependent variables. Multiple regression coefficients, r^2, F, and P values are given in Table 5. Ferulic acid is the only significant factor in explaining variation in the choice test (adult preference) and Dobie index (life-cycle index) while protein is significant for the other parameters (egg number, emergence, consumption, and stability parameter).

Correlations in CIMMYT Pools

Generally similar results were found in the correlations for the 15 CIMMYT pools. However, these were further analyzed for phenolic acid content [(*Z*)-ferulic, (*E*)-ferulic acid, *p*-coumaric acid, and sinapic acid] as measured by gas chromatography analysis (Table 6). Highest correlations ($r \geq -0.75$) were found between all susceptibility parameters and the content of the principal phenolic acid, (*E*)-ferulic acid (Table 7, Figure 3). These were highly signifi-

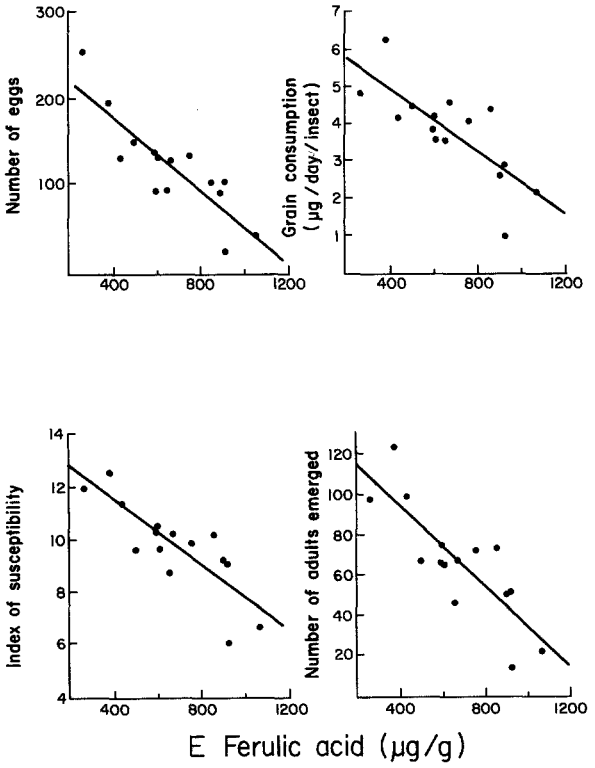

FIG. 3. Relationship between four susceptibility parameters and (*E*)-ferulic acid content of 15 CIMMYT pools.

DISCUSSION

Populations of maize with high phenolic acid content are more resistant to attack by *Sitophilus zeamais* than those with low phenolic acid content. The principal phenolic acid associated with resistance is (*E*)-ferulic acid. (*Z*)-Ferulic, *p*-coumaric, and sinapic acids may make a minor contribution. The strong negative correlation between the susceptibility parameters and the level of (*E*)-ferulic acid was observed with both land races and CIMMYT pools. Also, correlations between (*E*)-ferulic acid and susceptibility parameters were found to be of a similar magnitude as the correlations between susceptibility and the leading parameters, protein and hardness, identified in previous studies (Dobie, 1977; Eden, 1952; Singh and McCain, 1963) and confirmed in the present trials. Clearly ferulic acid can be taken as a good indicator of resistance.

Palmitic acid may play a minor role in resistance. The palmitic acid detected in the study of the land races was probably a by-product of the saponification of fats and oils and therefore reflects differing levels of these constituents. This fatty acid was significantly correlated (at $P \leq 0.05$) with only one of the susceptibility parameters, the Dobie index. Singh and McCain (1963) and Gomez et al. (1983) have reported that fat content did not affect resistance and that oil did not influence the number of eggs laid or the number of adults attracted in a free choice test. Therefore, the role of palmitic acid or fats and oils is still unclear.

In our previous study (Serratos et al., 1987) fluorescence microscopy revealed that phenolic acids are located in high concentration in the pericarp and to a lesser extent in the cell walls of the endosperm. Schoonhoven et al. (1976) have demonstrated that susceptibility increases after the removal, damage, or ether extraction of the pericarp. The importance of the pericarp, a maternally derived tissue, may also be reflected in the genetics of weevil resistance (Widstrom et al., 1975) which is known to display maternal inheritance.

At this time the mechanism by which phenolic acids contribute to resistance is unknown. While direct antifeedant effects of free ferulic acid have been demonstrated (Serratos et al., 1987), free and soluble esterified phenolic acids are a small component of the total phenolic acid content of grain. Bound phenolics form the bulk of total phenolics in maize grain (Sosulski et al., 1982), and recent [^{13}C]NMR studies (Lewis et al., 1987) have revealed that these may be linked in complex ways to carbohydrates in plant cells. It has been suggested (Fry, 1983) that bound ferulate has a strengthening effect on the structure of the cell wall and provides initiation sites for lignification. Bound ferulate is correlated with and undoubtedly contributes to seed hardness. However, further work is required on both the chemistry of phenolics in maize and their effect on stored-products insects if this interactive system is to be fully understood.

Acknowledgments—The technical assistance of J. Gale, N. Donskov, S. Luther, and S. Séguin is greatly appreciated. We would also like to thank C. Kazimov for the GC-MS analyses. Funding of the project was provided by IDRC and NSERC. We are grateful to J. Mihm, D. Jewell, and C. James (CIMMYT) as well as M. Loevinsohn (IDRC) and G. Fulcher (Agriculture Canada) for encouraging the project. We thank M. Koeck (Agriculture Canada) for his assistance with the Instron measurements.

(Received October 24, 1988; accepted February 7, 1989)

Abstract—Extracts of the sex pheromone glands of female *Cydia caryana* were evaluated by electroantennography and gas chromatography–mass spectrometry. These studies suggested the following compounds were potential sex pheromone components: (*Z*)-8- and/or (*E*)-9-dodecenyl acetate (50 pg/female), dodecyl acetate (40 pg/female), and (*E*, *E*)-8,10-dodecadienyl acetate (25 pg/female). In field tests only the diene produced trap catch, and when the other components were added to the diene, trap catch was not increased. When the diene was formulated in red natural rubber septa, only transient and low catches were obtained, but when gray halobutyl isoprene elastomeric septa were used, high and consistent catches were obtained for eight weeks. Catches depended on the ratio of (*E*, *E*)-8,10 to (*E*, *Z*)-8,10

0098-0331/90/0200-0317$06.00/0

isomers. High catches were obtained for an *EE* to *EZ* ratio of 100 : 0.6, and insignificant catches were obtained when the ratio was 100 : 3. Equivalent catches were obtained for dosages of 50, 100, and 200 μg/septum.

Key Words—Sex pheromone, sex attractant, *Cydia caryana*, Lepidoptera, Tortricidae, Olethreutinae, (*Z*)-8-dodecen-1-ol acetate, (*E*)-9-dodecen-1-ol acetate, dodecanol acetate, (*E*, *E*)-8,10-dodecadien-1-ol acetate, (*E*, *Z*)-8,10-dodecadien-1-ol acetate.

INTRODUCTION

The hickory shuckworm, *Cydia caryana* (Fitch) (Lepidoptera: Tortricidae: Olethreutinae) is found throughout southeastern United States from Texas and Oklahoma in the west, to South Carolina, Georgia, and Florida in the east. *C. caryana* is one of the most destructive insect pests on pecan. Crop losses are caused by early season nut abortion and mid- to late-season hindrance of proper kernel deposition and shuck dehiscence (Payne and Heaton, 1975).

The presence of a sex pheromone in female *C. caryana* was established by Anderson (1972). Subsequently, Smith et al. (1987) determined electroantennogram (EAG) profiles of male response to monounsaturated 12- and 14-carbon alcohols and acetates and conducted studies of behavioral responses of males in a flight tunnel to the compounds that evoked the stronger EAG responses. These studies produced several candidates for use in traps.

The present study was undertaken to identify components from the female sex pheromone gland and to develop an effective field lure.

METHODS AND MATERIALS

Insects. C. caryana were obtained as full-grown overwintering larvae within pecan shucks from a pecan orchard in Sparks, Oklahoma. Larvae were maintained in a controlled environmental room, at a temperature of 22–24°C, 65% relative humidity under a 14-hr light/10-hr dark regimen. Emergent adults were collected daily, sexed, and placed in separate holding cages provided with a solution of 5% sugar-water.

Extraction of Pheromone. Female moths (two to three days after eclosion) were collected 45 min to 1 hr after the initiation of scotophase and placed in a refrigerator for 10–30 min prior to dissection. The glandular area, which lies dorsally between the 8th and 9th abdominal segments as a modified intersegmental membrane, was everted under pressure, excised, and extracted in dichloromethane at room temperture for 15 min. The solution was removed and stored at −20°C.

Gas Chromatography. The following gas chromatographic column was

used for collecting fractions of *C. caryana* female sex pheromone gland extract: a nonpolar, silanized glass column (1.8 m × 2.3 mm OD) packed with 3% dimethyl silicone (SE-30) on 80–100 mesh Gas Chrom Q and operated at 110°C for 8 min and then temperature programmed at 4°C/min to 200°C and held at that temperature.

The following capillary GC column was used for chemical analysis of biologically active fractions: a nonpolar, capillary column (60 m × 0.25 mm ID) of fused silica with cross-linked methyl silicone (DB-1) was operated at 80°C for 2 min and then temperature programmed at 20°C/min to 170°C and held at that temperature.

Collection of Sex Pheromone. Components from extract of *C. caryana* sex pheromone glands were collected from a gas chromatograph equipped with a flame ionization detector (FID) and effluent splitter. The FID to splitter ratio was 1 : 9. Effluent was collected in glass tubing traps cooled in a mixture of Dry Ice and acetone. Collection efficiency was 80%. The biological activity of collected fractions was measured by the electroantennal response of 2- to 4-day old *C. caryana* male moths.

Gas Chromatography–Mass Spectrometry (GC-MS). A quadrupole mass spectrometer (Hewlett-Packard 5970) with a GC inlet (Hewlett-Packard 5790) was used. A dimethyl silicone (DB-1) capillary column (60 m × 0.25 mm ID) was held at 80°C for 2 min and then temperature programmed at 20°C/min to 190°C and then held at that temperature.

Field Tests. Test compounds in dichloromethane were impregnated into red rubber or gray halobutyl isoprene elastomeric septa (Brown and McDonough, 1986) size 1F (The West Co., Phoenixville, Pennsylvania).

Field tests were conducted in pecan orchards in Oklahoma, Georgia, Alabama, and Kansas. Wing traps (Pherocon 1C, Trecé Corp., Salinas, California) were suspended approximately 6.2 m above ground level, within the lower to middle canopy of the pecan trees. Traps were set out in rows (replicates), with treatments assigned at random within each replicate. Traps were at least 20 m from any other trap and were separated by at least one pecan tree. Traps were checked daily; the number of *C. caryana* was recorded, and the moths were removed. Trap catch data were transformed to $(X_i + 1)^{1/2}$, and submitted to analysis of variance by Duncan's multiple-range test.

RESULTS

Identification of Sex Pheromone Gland Components. Six fractions of 94 *C. caryana* female equivalents (FE) in the volatility range of 10- through the 16-carbon acetates were collected from the packed nonpolar GC column. Electroantennograms of each fraction showed that only fractions 3 (13.5–16.5 min) and 4 (16.5–19.5 min) elicited significant responses.

Subsequent capillary GC analysis of fraction 3 showed a peak with the retention time of 12 : Ac [t_R (peak) = 14.38 min; t_R (12 : Ac) = 14.39 min]. A second peak in fraction 3 was also detected at a retention time indicative of a dodecenyl acetate (t_R = 14.26 min). Capillary GC analysis of fraction 4 indicated a peak with the same retention time as *E*8, *E*10–12 : Ac [T_R (peak) = 15.94 min; t_R (*E*8, *E*10–12 : Ac) = 15.94 min].

GC-MS analysis (selective ion monitor mode) of 18 FE of *C. caryana* whole extract gave evidence of: a dodecenyl acetate at t_R = 15.98 min and m/z = 166(M^+ − 60) and 61($CH_3CO_2H_2$), with retention time coincident with *Z*8–12 : Ac and/or *E*9–12 : Ac; 12 : Ac at t_R = 16.16 min and m/z = 168(M^+ − 60) and 61($CH_3CO_2H_2$); and a dodecadienyl acetate at t_R = 17.46 min and m/z = 224(M^+) and 164(M^+ − 60). The t_R of *E*8,*E*10–12 : Ac was also 17.46.

Quantitative evaluation of peak areas indicated that dodecenyl acetate, dodecyl acetate, and dodecadienyl acetate were present at 1.0, 0.75, and 0.5 ng in the extract of 18 female glands.

Field Tests. When trap catches provided by *E*8, *E*10–12 : Ac, *Z*8–12 : Ac, and mixtures of these compounds in gray septa were determined (Table 1, test 1), *E*8,*E*10–12 : Ac alone produced significant trap catch while *Z*8–12 : Ac did not and mixtures were less effective than *E*8,*E*10–12 : Ac alone. In test 2 (Table 1), trace quantities of *Z*8–12 : Ac(0.03–3% of *E*8,*E*10–12 : Ac) were tested. Again no lure was more effective than the one containing *E*8,*E*10–12 : Ac alone. *E*9–12 : Ac (Table 1, test 3) neither increased nor decreased trap catch provided by *E*8,*E*10–12 : Ac alone. 12 : Ac (Table 1, test 4) appeared to provide a small (44% greater) improvement in catch over *E*8,*E*10–12 : Ac alone, but the difference was not statistically significant. Dosages of *E*8,*E*10–12 : Ac of 50, 100, and 200 μg produced equivalent catches (Table 1, test 4).

When *E*8,*E*10–12 : Ac was tested in red rubber septa after aging for 0, 1, or 2 weeks, the fresh septa produced borderline catch and the older septa were ineffective (Table 2). Cotesting of the same quantity of *E*8,*E*10–12 : Ac in gray septa produced significant catch for lures aged from 0–8 weeks (Table 2).

The effect of *E*8,*Z*10–12 : Ac on efficiency of *E*8,*E*10–12 : Ac is shown in Table 3. Trap catch was high when the *EZ*% was ca. 0.6% but 3% *EZ* and higher eliminated significant catch.

DISCUSSION

Although there was not enough natural pheromone available to allow rigorous chemical proof of identity of the diene, there can be little doubt that *E*8,*E*10–12 : Ac is the principal sex pheromone component for this species.

[a]Gray elastomeric septa were used as the controlled release substrate. Tests were conducted in 1986, and there were five replicates per test. Letters after the numbers indicate significance according to Duncan's multiple range test ($P = 0.05$).

The flight tunnel and EAG studies (Smith et al., 1987), the present GC-MS and field trapping studies, and taxonomy collectively confirm this conclusion. The sex pheromones of three other *Cydia* species have been identified, and all three contained the (*E*,*E*)-8,10-dodecadienyl structure [alcohol: *C. pomonella* (Roelofs et al., 1971), and acetate: *C. latiferreanus* (Davis et al., 1984) and *C. nigricana* (Greenway, 1984)].

Although dodecyl acetate, when added to the diene did not produce sig-

nificantly increased trap catch over the diene alone, it cannot necessarily be ruled out as a possible sex pheromone component. In what may be an analogous situation, dodecanol was found to be a constituent of the sex pheromone gland extract of *C. pomonella* (Einhorn et al., 1984) and generally would not increase trap catch of *E*8,*E*10–12 : OH, but was behaviorally active at certain ratios and dosages (Arn et al., 1985).

The dodecenyl acetate, which was either *Z*8 or *E*9, did not increase trap catch when added to the diene, although it apparently accounted for the EAG activity of GC fraction 3. *Z*8–12 : Ac in combination with *E*8, *E*10–12 : Ac

TABLE 3. EFFECT OF RATIO OF *E*8,*E*10– TO *E*8,*Z*10–12 : Ac ON TRAP CATCH (10 REPLICATES/TREATMENT FOR 31 DAYS IN GRAY SEPTA)[a]

Ratio of *EE* to *EZ* (μg/septum)	Mean total catch/replicate
50 : 0.3	184.9a
50 : 1.5	11.0b
50 : 5.0	6.2b
50 : 15.0	3.2b
0 : 0	0.6b

is the sex pheromone of another Olethreutinae, *Hedya nubiferana* (Frerot et al., 1979). The reason for its presence in *C. caryana* in such large amount coupled with its inactivity in field tests is not known. Perhaps the dodecenyl acetate has the *E*9 structure and is a biosynthetic precursor to the diene. In an analogous situation *E*9–12 : OH was shown to be the biosynthetic precursor of *E*8,*E*10–12 : OH in *C. pomonella* (Löfstedt and Bengtsson, 1988).

In red rubber septa *E*8,*E*10–12 : Ac is ineffective as a lure to monitor *C. caryana* populations, most likely because of isomerization of the conjugated diene structure (Davis et al., 1984; Guerin et al., 1983; Hoffman et al., 1983). Gray septa allow much slower rates of isomerization (Brown and McDonough, 1986) and here provided an effective, long-lasting lure.

The (*E*,*Z*)-8,10-dodecadienyl structure may be as important in *Cydia* species as (*E*,*E*)-8,10-dodecadienyl. In *C. latiferreanus* (formerly *Melissopus latiferreanus*; Brown, 1983) *EZ* is the major component (*EZ* : *EE* is 80 : 20) and the pure *EE* isomer is not attractive (Davis et al. 1984). In *C. pomonella* sex pheromone gland extracts, the *EZ* : *EE* ratio is 5 : 95 (Einhorn et al., 1984). Roelofs et al. (1972) have shown that higher levels of *EZ* cause a moderate reduction in trap catch of *C. pomonella* males but the attractancy or nonattractancy of pure *EE* has not been reported. In *C. caryana* an *EE* : EZ ratio of 100 : 0.6 was very attractive in field tests, while a ratio of 100 : 3 was equivalent to blank traps. Thus, as with *C. pomonella*, it remains to be seen whether the pure *EE* isomer is attractive and whether a small quantity of *EZ* is required for best trap catch.

IDENTIFICATION OF HOST-PLANT CHEMICALS STIMULATING OVIPOSITION BY SWALLOWTAIL BUTTERFLY, *Papilio protenor*

KEIICHI HONDA

Seishô Biological Laboratory
1-3-11 Naka-cho, Odawara 250, Japan

(Received October 26, 1988; accepted February 7, 1989)

Abstract—The ovipositional response of a Rutaceae-feeding papilionid butterfly, *Papilio protenor*, to *Citrus* host plants was evoked by the synergistic action of L-(−)-stachydrine, D-(−)-quinic acid, (−)-synephrine, and L-(−)-proline that characterize the chemical compositions of the leaves and epicarp of *Citrus* plants (*C. natsudaidai* and *C. unshiu*). The stimulatory activity of their mixture was enhanced by the addition of flavanone glycosides, naringin and hesperidin, which coexist in these plants and have previously been demonstrated to serve as oviposition stimulants. However, sugars such as sucrose, glucose, and inositols, which abound in plant tissues, exerted no effect on egg-laying by the females. On the other hand, chlorogenic acid present in the leaves of another host plant, *Fagara ailanthoides*, was found to act as an excellent synergist. However, there existed significant qualitative dissimilarities between the chemical compositions of the leaves of *C. unshiu* and *F. ailanthoides*. This strongly suggests that *P. protenor* is likely to utilize different categories of compounds as chemical cues in recognizing each plant as a host.

Key Words—Oviposition stimulant, *Papilio protenor*, Lepidoptera, Papilionidae, D-(−)-quinic acid, L-(−)-stachydrine, (−)-synephrine, L-(−)-proline, chlorogenic acid, *Citrus natsudaidai*, *C. unshiu*, *Fagara ailanthoides*.

INTRODUCTION

Some butterfly species depositing eggs directly on the plant where the larvae later grow have been reported to utilize primarily visual and/or olfactory cues to distinguish potential larval food plants among mixed vegetation (Vaidya, 1969; Rausher, 1978; Saxena and Goyal, 1978; Stanton, 1982; Feeny et al.,

0098-0331/90/0200-0325$06.00/0

1983; Chew and Robbins, 1984). Earlier work on host selection in Pieridae and Papilionidae clearly demonstrates that plant metabolites serve in the final step of oviposition behavior as the cues permitting females to discriminate and to recognize their hosts (David and Gardiner, 1962; Nishida, 1977; Ichinosé and Honda, 1978; Saxena and Goyal, 1978; Rodman and Chew, 1980; Abe et al., 1981; Feeny et al., 1983). Plant chemicals are perceived by foretarsal chemotactile sensory hairs during drumming, which is essential for females to assess the suitability of the plant on which they landed (Ma and Schoonhoven, 1973; Ichinosé and Honda, 1978; Stanton, 1979).

Recently, vicenin-2, narirutin, hesperidin, rutin (flavonoids), adenosine, and 5-hydroxy-*N*, ω-methyltryptamine have been identified in the leaves of *Citrus unshiu* as oviposition stimulants for *Papilio xuthus*, which infests principally *Citrus* plants in nature (Ohsugi et al., 1985; Nishida et al., 1987). However, each of them had little or no effect on oviposition when tested alone, and only their mixture exhibited sufficient ovipositional activity.

Similar topics on the synergy of multiple components in egg-laying have also been dealt with in the cabbage butterfly, *Pieris rapae* (Renwick and Radke, 1983), and in the swallowtail butterfly, *Papilio protenor*, in which two flavanone glycosides, naringin and hesperidin, present in the epicarp of sour orange (*Citrus natsudaidai*), elicited ovipositional response from the females in combination with other unidentified water-soluble compounds (Honda, 1986). Furthermore, recent work by Feeny et al. (1988) has revealed that egg-laying in an umbellifer-feeding swallowtail butterfly, *Papilio polyxenes*, is stimulated by the synergistic action of luteolin 7-*O*-(6″-*O*-malonyl)-β-D-glucoside and *trans*-chlorogenic acid. In contrast, Pereyra and Bowers (1988) have shown that a single iridoid glycoside, catalpol, was sufficient to induce oviposition by the nymphalid butterfly, *Junonia coenia*, at levels similar to that of the host plant.

P. protenor is an oligophagous butterfly, which in nature feeds on several specific plants in the genera *Citrus* (main), *Fagara*, *Poncirus*, and so on. The present paper reports on oviposition stimulants for *P. protenor* newly identified from *Citrus* and *Fagara* host plants.

METHODS AND MATERIALS

Insects. Butterflies used for behavioral assays were 3- to 10-day-old gravid females derived from stock cultures or collected in the field in Kanagawa Prefecture.

Extraction and Fractionation of Active Components. The epicarp of sour orange, *C. natsudaidai* (760 g), which evokes potent ovipositional response (Honda, 1986), as do its leaves, was extracted with methanol (3 liter) at room temperature for one month. Young fresh leaves of *C. unshiu* and *Fagara ail-*

anthoides, which are the principal host plants of the population used in this study, were also extracted with methanol in a similar manner. Each methanolic extract was concentrated in vacuo below 50°C, and the residue, after being mixed with water, was extracted successively with chloroform and isobutanol. Since previous work (Honda, 1986) and preliminary experiments showed that the aqueous fraction derived from each extract was highly effective in releasing oviposition behavior, the water-soluble fraction was examined for chemical constituents, monitoring their oviposition stimulatory activities.

The aqueous fraction of *C. natsudaidai* was evaporated to dryness, and the residue was reextracted with hot methanol to remove resinous substances. The methanolic extract obtained (designated fraction IV) that provoked strong positive response was then subjected to TLC analysis and fractionated by means of preparative TLC (Merck PLC plate Silica gel 60).

Bioassay for Ovipositional Activity. Behavioral bioassays to evaluate the stimulatory action of test samples were conducted employing artificial green plastic foliage according to the method given in a previous paper (Honda, 1986). The rate of response was expressed by the ratio of the number of positive responses to that of alighting on the leaves that was accompanied with drumming. The appraisal of positive response was based on the following criteria: release of the ordinary sequential oviposition behavior, which consists of drumming on a leaf with the forelegs and subsequent abdominal curling, followed by settling of the ovipositor in contact with the underside of the leaf.

Instrumentation for Chemical Analyses. [^{13}C]NMR (CMR) spectra were measured at 67.8 MHz in D_2O, unless otherwise noted, with a JEOL JNM-GX 270 FT-NMR spectrometer by proton-decoupled operation. Chemical shifts were represented by δ unit from the downfield of tetramethylsilane as the external standard. The multiplicity of signals determined, by means of INEPT or off-resonance technique, was abbreviated as follows: singlet (s), doublet (d), triplet (t), quartet (q).

Fast-atom-bombardment mass spectra (FAB-MS) were recorded on a JEOL JMS-DX 303 mass spectrometer. The target was bombarded with 6.0 kV Xe atoms using glycerine as a matrix, and positive and/or negative ions were recorded.

High-pressure liquid chromatography (HPLC) for the separation of optical isomers was carried out with a Hitachi 635S liquid chromatograph equipped with a wavelength-tunable spectrophotometer using a stainless column (4.6 mm ID × 250 mm) packed with Chiralpack WH (Daicel Chemical Industries, Ltd.). Mobile phase was 0.25 mM aq. $CuSO_4$ solution, and the column eluate was monitored at 225 nm. The system was operated at 40°C, and the flow rate was regulated at 1 ml/min.

The optical rotation was measured with a Horiba SEPA-200 polarimeter at 25°C in H_2O.

RESULTS

Oviposition Stimulants in the Epicarp of C. natsudaidai. Fraction IV, which was derived from the hydrosoluble part of the methanolic extract of the epicarp and which exhibited potent stimulatory activity for egg-laying, was separated by preparative TLC developing with methanol–acetone (60:40) into three fractions: A (R_f = 1.00–0.58), B (R_f = 0.58–0.27), and C (R_f = 0.27–0.00). The rates of ovipositional response of individual fractions assayed at the concentration of 0.2% were 0, 0.32, and 0.75, respectively. The most polar fraction C seems to contain some compounds of substantial importance responsible for egg-laying.

Fraction C was further fractionated by preparative TLC developed with methanol into four fractions: CA (0.68–0.45), CB (0.45–0.25), CC (0.25–0.05), and CD (0.05–0.00). The ovipositional responses of these fractions tested at a concentration of 0.5% were 0.13, 0.67, 0.17, and 0, respectively. The ovipositional activity of each fraction apparently diminished; however, the recombined sample of individual fractions resumed activity almost the same as that of the original fraction (C). This indicates that oviposition is elicited by a synergy of multiple compounds.

Since fraction CD seemed to be composed mainly of resinous substances and it induced no oviposition behavior, this fraction was discarded. An examination of the CMR spectrum of fraction CA revealed that it consists of a carboxylic acid (compound 4) and inositol isomers. Similarly, fraction CB was found to contain a large amount of another carboxylic acid (compound 1) and small quantities of compound 4 and compound 3, which was a predominant component of fraction CC. From these fractions, compounds 1, 3, and 4 were isolated by repetitive TLC as white or pale yellow crystals.

On the other hand, fraction B was shown by CMR measurement to be a mixture of an aromatic compound (compound 2), glucose, sucrose, inositols, and compound 4, while only sucrose and glucose were the major constituents of fraction A. Fraction B was subjected to TLC on silicic acid with methanol, and compound 2 was obtained as white crystals.

Structural elucidation of the four compounds 1, 2, 3, and 4 was thus attempted on the basis of the following characteristic spectral and physicochemical information:

Compound 1. Mp: 226°C. FAB-MS: $(M + H)^+$ at *m/z* 116. CMR, δ (ppm): 23.8 (t), 29.0 (t), 46.2 (t), 61.4 (d), and 174.5 (s). $[\alpha]_D^{25}$: −85.1°. This compound, of molecular weight 115 and seeming to contain one nitrogen and five carbon atoms, one of which constitutes a carboxyl group, was determined to be L-(−)-proline. To examine whether the D-isomer of proline is coexistent in fraction CB from which L-(−)-proline was isolated, fraction CB was subjected to HPLC on Chiralpack WH, which enabled the separation of the two

optical isomers. However, no peak corresponding to D-isomer (R_t = 37.0 min) was observed. Therefore, the epicarp of *C. natsudaidai* was considered to exclusively produce L-isomer (R_t = 22.5 min).

Compound 2. Mp: 169°C. FAB-MS: $(M + H)^+$ at *m/z* 168. CMR (0.1 N HCl/D_2O), δ (ppm): 33.2 (q), 54.6 (t), 68.3 (d), 115.8 (d), 127.7 (d), 131.3 (s), and 155.8 (s). $[\alpha]_D^{25}$: −50.5°. The mol wt of this substance should be 167, which is indicative of the presence of nitrogen atom(s) in its molecule. Four signals (six carbons) appearing between 110 ppm and 160 ppm represent an aromatic ring, and the resonance at 33.2 ppm appears to be a methyl group attached to the nitrogen atom. From these data compound 2 was identified as (−)-synephrine, which had already been reported in *Citrus* plants (Stewart et al., 1964; Namba et al., 1985).

Compound 3. Mp: 279°C. FAB-MS: $(M + H)^+$ at *m/z* 144. CMR, δ (ppm): 18.9 (t), 25.4 (t), 46.4 (q), 52.5 (q), 67.4 (t), 76.7 (d), and 171.0 (s). $[\alpha]_D^{25}$: −38.4°. This compound has a mol wt of 143, which is larger by just two methyl equivalents than that of proline, and it exhibits two additional resonances at 46.4 ppm and 52.5 ppm, which may be assignable to *N*-methyl carbons. These data strongly suggest that the compound is *N,N*-dimethyl betaine of proline. On the analogy of the data of L-(−)-proline, compound 3 was considered to be L-(−)-stachydrine, and the identity was confirmed by comparison with an authentic sample (Mp: 287°C, $[\alpha]_D^{25}$: −42.8°) prepared by the reaction of L-(−)-proline with two equivalents of methyl iodide in the presence of potassium carbonate in methanol.

Compound 4. Mp: 167°C. FAB-MS: $(M - H)^-$ at *m/z* 191. CMR, δ (ppm): 37.4 (t), 40.6 (t), 67.1 (d), 70.4 (d), 75.2 (d), 76.9 (s), and 180.9 (s). $[\alpha]_D^{25}$: −45.1°. This compound, of mol wt 192, possesses two methylene carbons, four hydroxyl-substituted carbons, and one carboxyl carbon, which is suggestive of a cyclic compound. Taking account of the optical rotation, compound 4 was identified as D-(−)-quinic acid.

The oviposition-stimulatory activity of the identified compounds to the females was examined next. Since sugars such as sucrose, glucose, and inositol are ubiquitous in plants, compounds 1, 2, 3, and 4 were tested first. As shown in Table 1, each substance was entirely ineffective when bioassayed alone. Furthermore, no binary mixtures were observed to display sufficient activity to release egg-laying by the females. However, the ovipositional response was markedly enhanced when an equivalent mixture of the four compounds was tested, although the stimulatory activity of this quaternary system did not reach the level of fraction IV.

Another experiment was carried out to estimate the degree of contribution to the oviposition of individual compounds and two flavonoid compounds, naringin and hesperidin, both of which have already been reported to act as synergists in the oviposition of *P. protenor* (Honda, 1986). Because a sufficient

quantity of optically active natural (−)-synephrine was not available, commercial D,L-synephrine was used in this test. The results are given in Table 2.

The remarkable synergistic action of naringin and/or hesperidin on oviposition was reconfirmed through this experiment. At first the author underestimated the function of flavonoids in egg-laying; however, they proved of significant influence. The effectiveness of quinic acid and stachydrine was also prominent, whereas that of synephrine was moderate, and proline was found to

[c] Eighteen females were tested.

be much less responsible for oviposition. The comparatively weaker activity of synephrine may be due to the coexistence of a (+)-isomer, which is deemed to be absent in the original plant. This problem should be resolved by further investigation. At any rate, it is evident that all of these compounds, including flavanones, concurrently display significant stimulatory activity for egg-laying by *P. protenor*.

Oviposition Stimulants in Leaves of C. unshiu. Although these substances derived from the epicarp of *C. natsudaidai* synergistically induce oviposition by the females, it is not yet elucidated if they are the real oviposition releasers present in the leaves of the host plant, for the females in nature ordinarily deposit eggs not on fruit but exclusively on leaves and, sometimes, on twigs. To elucidate this question, analysis of the chemical composition of young leaves of *C. unshiu* was conducted of the water-soluble fraction. As shown in Figure 1, the compounds found in the epicarp of *C. natsudaidai* were also detected from the leaves of *C. unshiu* and in much higher concentration. Despite the great difference between the two in the absolute concentrations of the individual components, the overall profile of the relative proportion of each constituent in the leaves was quite similar to that of the epicarp, except for L-(−)-proline, which exhibited weak ovipositional activity. Therefore, it was definitely substantiated that compounds 1 to 4 are the actual oviposition stimulants in the leaves of *C. unshiu*, although other unidentified compounds would also play an important role in host discrimination and preference.

Oviposition Stimulants in Leaves of Fagara ailanthoides. *P. protenor* occa-

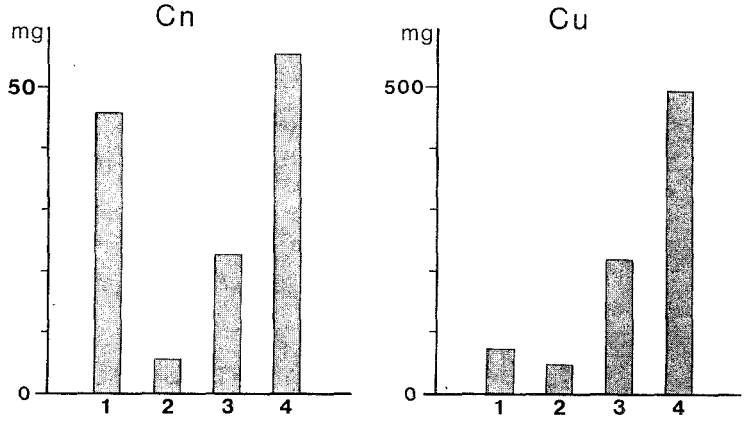

FIG. 1. Concentrations of some characteristic compounds in *Citrus* plants (per 100 g of fresh weight) that stimulate oviposition by *Papilio protenor*. Cn: *C. natsudaidai* (epicarp), Cu: *C. unshiu* (leaf). 1: L-(−)-proline, 2: (−)-synephrine, 3: L-(−)-stachydrine, 4: D-(−)-quinic acid.

sionally utilizes *F. ailanthoides* as a host in a habitat abundant in this plant. By analogous extraction and separation procedures to those presented for the epicarp of *C. natsudaidai*, another substance (compound 5) showing the following spectral characteristics was obtained as crude crystals. FAB-MS: $(M + H)^+$ at *m/z* 355. CMR (0.1 N KOH/D_2O), δ (ppm): 37.0 (t), 38.0 (t), 70.3 (d), 70.9 (d), 72.5 (d), 76.3 (s), 114.1 (d), 115.0 (d), 116.0 (d), 122.6 (d), 126.8 (s), 144.0 (s), 146.0 (d), 146.9 (s), 168.8 (s), and 179.8 (s). Although purification of this compound was unsuccessful, compound 5 was concluded to be chlorogenic acid by comparison of its spectral data with those of an authentic compound. The concentration of this compound in young leaves of *F. ailanthoides* was estimated at ca. 230 mg/100 g of fresh weight.

Further investigation on the chemical constituents in the leaves of *C. unshiu* and *F. ailanthoides* revealed the existence of large amounts of sugars, such as sucrose, glucose, and inositols. Thereupon, the effect of these sugars and chlorogenic acid on the ovipositional response of *P. protenor* was examined in combination with the oviposition stimulants so far identified. In this experiment, females that made little or no response to sample C (Table 3), but which responded positively to the leaves of *C. unshiu*, were chosen selectively to

appraise the influence of these compounds. Such females were found in a proportion of 10–20% in the population studied. They are not anomalies, and individual variation in oviposition preference in which chemical stimuli appear profoundly involved is quite commonplace in many butterflies (Tabashnik et al., 1981; Wiklund, 1981; Moore, 1986; Thompson, 1988). The results are summarized in Table 3. It is apparent that a sugar mixture composed of sucrose, glucose, and inositols exerts neither a stimulatory nor a synergistic effect on egg-laying (samples H and J), despite their abundance in the host plants. The combination of sugars and chlorogenic acid also did not evoke any ovipositional response by themselves (sample L), and inactivity of these compounds was further corroborated by carrying out an assay with normal females that responded positively to both samples A and C. Unlike sugars, chlorogenic acid notably enhanced the activity for egg-laying when admixed with sample A or C (sample I or K), which undoubtedly demonstrates that chlorogenic acid is also an oviposition stimulant acting synergistically. Moreover, the rate of ovipositional response to sample K was found to run up to approximately 1.0 ($N = 14$) when bioassayed with normal females.

Besides these compounds, two other compounds, neohesperidin and caffeic acid, which are related to hesperidin and chlorogenic acid, respectively, were tested for their ovipositional activity. Neohesperidin has been reported to be one of major flavanone glycosides present in the leaves and peel of *C. natsudaidai* (Nishiura et al., 1969; Tosa et al., 1988), and caffeic acid corresponds to the aglycone of chlorogenic acid, although the presence of caffeic acid in *F. ailanthoides* has not yet been ascertained. Neither of these compounds, however, affected oviposition behavior at concentrations of 0.05 or 0.1%. Consequently, seven compounds in total, including two flavanone glycosides, were reckoned as active for egg-laying by the females of *P. protenor*. The chemical structures of oviposition stimulants newly identified in this study are shown in Figure 2.

DISCUSSION

These results, combined with previous work (Honda, 1986), substantiate that host recognition in *P. protenor* is mediated by a variety of secondary plant metabolites in wide categories of chemical compounds such as sugar acid, amino acid, alkaloid, flavonoid, and so on. It is interesting that plant metabolites that would be of little nutritional importance to larvae are dominant determinants of host selection, whereas sugars, which are essential nutrients, do not exert a synergistic effect on oviposition at all. This appears true with other systems of host selection in the Pieridae (David and Gardiner, 1962), Papilionidae (Ohsugi et al., 1985; Nishida et al., 1987; Feeny et al., 1988), and Nymphalidae (Per-

FIG. 2. Chlorogenic acid was found in *Fagara ailanthoides*, and other compounds, in *Citrus unshiu* and *C. natsudaidai*.

eyra and Bowers, 1988). Taking into account the fact that the nutritional profiles of most plants are more or less the same, the history of host selection in butterflies might be the evolutionary process of defensive tactics focused on avoidance or detoxification of harmful plant allelochemicals, rather than a process of positive exploitation of a new host range.

Among the compounds presently appraised as active in oviposition behavior, synephrine, to the best of our knowledge, is specific to Rutaceae, and *Citrus* plants are excellent producers (Stewart et al., 1964; Namba et al., 1985). On the other hand, stachydrine occurs also in several genera other than *Citrus*, and quinic acid and proline are ubiquitous in the plant kingdom. Even so, these substances, which, by quantitative examination, proved to be major components in the water-soluble fraction of the leaves of *C. unshiu*, characterize the chemistry of the plant. Upon further investigation, the leaves of *C. natsudaidai* also contained all these compounds in somewhat different proportions, thereby suggesting that they are specific oviposition stimulants for *P. protenor*, which certain *Citrus* plants have in common. In this respect, it is highly likely that host recognition in *P. protenor* is governed by both series of compounds,

including two flavanones, that are qualitatively specific to and quantitatively characteristic of *Citrus* plants. Similar instances implicating multiple components for host discrimination or host preference have been demonstrated for *Papilio xuthus* (Nishida et al., 1987), *Papilio polyxenes* (Feeny et al., 1988), and *Pieris rapae* (Renwick and Radke, 1983, 1987, 1988). By contrast, in a nymphalid butterfly, *Junonia coenia*, a single iridoid glycoside (catalpol) suffices to elicit oviposition (Pereyra and Bowers, 1988).

Since chlorogenic acid found in *F. ailanthoides* markedly enhanced ovipositional response when added to the mixture based on *Citrus* plant materials, the acid can be regarded as a potent synergistic stimulant. The synergy of chlorogenic acid in oviposition is also known in *P. polyxenes* (Feeny et al., 1988). Although chlorogenic acid displayed striking stimulatory activity, there was no evidence of its existence in *Citrus* plants. Therefore, it is questionable whether chlorogenic acid is a real key substance acting concurrently with *Citrus* chemicals in nature. In addition, a brief chemical analysis revealed that the chemical compositions of *C. unshiu* and *F. ailanthoides* were quite different in quality from each other. In fact, young leaves of *F. ailanthoides* contained no appreciable amounts of quinic acid, stachydrine, synephrine, hesperidin, and naringin, and, except for sugar components, chlorogenic acid was one of principal constituents of this plant. These facts provide a piece of evidence that egg-laying on *F. ailanthoides* is triggered by a distinct group of compounds that include chlorogenic acid from the active compounds identified in *Citrus* plants.

P. protenor and *P. xuthus* are sympatric in most localities, and either species intrinsically depends on *Citrus* plants for larval feeding. However, the compounds with ovipositional activity to *P. protenor* are somewhat different from those reported for *P. xuthus* (Nishida et al., 1987), notwithstanding that the plant species from which oviposition stimulants were identified was actually the same (*C. unshiu*). Among the compounds shown to serve as oviposition stimulants for *P. xuthus*, 5-hydroxy-*N*,ω-methyltryptamine and adenosine were found entirely inactive to *P. protenor* (Honda, unpublished). While *P. protenor* shows positive response only to certain specified flavanone glycosides (Honda, 1986), diverse flavonoid compounds are stimulatory to *P. xuthus* (Nishida et al., 1987). It is very intriguing that host discrimination in these related butterflies utilizing virtually the same plant as a host is mediated by different groups of plant chemicals. This finding seems to give us new insight into chemical factors as a major element underlying the evolution of host selection and coevolution with plants in butterflies.

NATURAL PRODUCTS PHYTOTOXICITY
A Bioassay Suitable for Small Quantities of Slightly Water-Soluble Compounds[1]

D.L. DORNBOS, JR., and G.F. SPENCER

USDA/ARS Northern Regional Research Center
1815 N. University Street
Peoria, Illinois 61604

(Received September 19, 1988; accepted February 7, 1989)

Abstract—A large variety of secondary metabolites that can inhibit germination and/or seedling growth are produced by plants in low quantities. The objective of this study was to develop a bioassay capable of reliably assessing reductions in germination percentage and seedling length of small-seeded plant species caused by exposure to minute quantities of these compounds. The germination and growth of alfalfa (*Medicago sativa*), annual ryegrass (*Lolium multiflorum*), and velvetleaf (*Abutilon theophrasti*) were evaluated against six known phytotoxins from five chemical classes; cinmethylin (a herbicidal cineole derivative) was selected as a comparison standard. Each phytotoxin, dissolved in a suitable organic solvent, was placed on water–agar in small tissue culture wells. After the solvent evaporated, imbibed seeds were placed on the agar; after three days, germination percentages and seedling lengths were measured. Compared to a commonly used filter paper procedure, this modified agar bioassay required smaller quantities of compound per seed for comparable bioassay results. This bioassay also readily permitted the measurement of seedling length, a more sensitive indicator of phytotoxicity than germination. Seedling length decreased sigmoidally as the toxin concentration increased logarithmically. Phytotoxicity was a function of both compound and plant species. Cinmethylin, a grass herbicide, reduced the length of annual ryegrass seedlings by 90–100%, whereas that of alfalfa and velvetleaf was inhibited slightly. The agar bioassay facilitated the rapid and reliable testing of slightly water-soluble compounds, requiring only minute quantities of each compound to give reproducible results.

[1] The mention of firm names or trade products does not imply that they are endorsed or recommended by the U.S. Department of Agriculture over other firms or similar products not mentioned.

Key Words—Alfalfa, *Medicago sativa*, benzylisothiocyanate, cinmethylin, cinnamaldehyde, coumarin, germination, juglone, nigericin, plumbagin, ryegrass, *Lolium multiflorum*, seedling length, velvetleaf, *Abutilon theophrasti*.

INTRODUCTION

The phytotoxicity of various compounds, as demonstrated by reductions in germination and seedling growth, has been evaluated in Petri dishes with filter paper (Lehle and Putnam, 1982; Shilling and Yoshikawa, 1987; Tang and Young, 1982; Wolf, 1986), sand (El-Deek and Hess, 1986), and water agar (Pederson, 1986). Although the germination percentage (defined as the proportion of seeds with a protruded radicle) is typically measured to assess the phytotoxic response to a compound, root length and root fresh weight were found to be more sensitive growth parameters (Cope, 1982; Pederson, 1986; Shilling and Yoshikawa, 1987). Because bubbles form under filter paper when wetted, small seeds often received a nonuniform supply of moisture and gave inconsistent results. Pederson (1986) found that differences in white clover (*Trifolium repens*) root length were more readily detected when grown on agar treated with aqueous extracts from tall fescue (*Festuca arundinacea*) leaves than on germination paper.

The majority of phytotoxicity studies have been conducted with water-soluble compounds such as the phenolics. These materials are typically applied to a growth medium in aqueous solution (Leather and Einhellig, 1985; Lehle and Putnam, 1982; Tang and Young, 1982). Pederson (1986) combined liquid agar and aqueous leaf extracts and then allowed them to solidify prior to assay. Other phytotoxic compounds, such as nigericin, are poorly soluble in aqueous systems (Heisey and Putnam, 1986). These toxins are normally dissolved in organic solvents and applied to filter paper. After the solvent is evaporated, water is added to induce germination (Shilling and Yoshikawa, 1987; Wolf et al., 1984; Wolf, 1986). The application of slightly water-soluble compounds to an agar surface may facilitate the accurate measurement of their toxic effects on the seedling length of small-seeded plant species.

The application of phytotoxins to a relatively large surface area, such as 100-mm-diameter Petri dishes (Wolf et al., 1984; Pederson, 1986), requires substantial quantities of test materials. By reducing the area of the test surface, a greater proportion of the slightly water-soluble compound is in contact with the seedling. The quantity of material available for study is often limited in natural products research, precluding the accurate bioassay of toxic effects. A reduction in the dimensions of the germination container might reduce the quantity of compound required for replicated bioassay. The objective of this study was to develop a bioassay capable of reliably assessing effects of minimum

quantities of phytotoxin on germination and seedling growth of several small-seeded plant species. The toxicity of six phytotoxins from five chemical classes, and the grass herbicide cinmethylin, was evaluated on three plant species with an agar germination medium in small tissue culture wells.

METHODS AND MATERIALS

Source of Materials. Alfalfa (*Medicago sativa* L., cv. Vernal, Kelly Seed Co., Peoria, Illinois), annual ryegrass (*Lolium multiflorum* L., Kelly Seed Co.), and velvetleaf (*Abutilon theophrasti* Medic., Azlin Weed Seed Service, Leland, Mississippi) seeds were obtained from cold storage (1°C) at the Northern Regional Research Center (NRRC), Peoria, Illinois). Cinmethylin {*exo*-1-methyl-4-(1-methylethyl)-2-[(2-methylphenyl)methoxy]-7-oxabicyclo[2.2.1] heptane} was supplied by E. I. du Pont de Nemours and Co., Inc., Wilmington, Delaware. *trans*-Cinnamaldehyde, coumarin, and nigericin were obtained from Aldrich Chemical Co., Inc., Milwaukee, Wisconsin; juglone and plumbagin from Sigma Chemical Company, St. Louis, Missouri; and benzylisothiocyanate from ICN Pharmaceuticals, Inc., Plainview, New York. Cluster24 tissue culture dishes were obtained from Costar, Cambridge, Massachusetts. All solvents were reagent grade.

Solvent Optimization. Water agar was prepared by autoclaving 4.4 g Bactoagar (Difco Laboratory, Detroit, Michigan) in 400 ml distilled water for 20 min, and then diluted with an additional 400 ml of distilled water. One milliliter of agar was placed in each of the 24 3-ml wells, arranged in four rows of six columns each, in each disposable tissue culture dish. The volumes 0.0, 0.2, 0.4, 0.6, 0.8, or 1.0 ml of four solvent mixtures (100:0, 10:90, 1:99, or 0:100 of chloroform–hexane) were layered on solidified agar in each tissue culture well. The solvent was allowed to passively evaporate from the agar surface in a ventilated hood, typically requiring 4 hr, before seeds were placed on the agar.

Alfalfa and velvetleaf seeds were surface-sterilized in 10% Clorox for 15 m, thoroughly rinsed with distilled water, and imbibed for 4 hr on two layers of filter paper that were saturated with water. Five seeds of imbibed alfalfa and velvetleaf, and of unimbibed annual ryegrass, were placed on the agar in each well. The dishes were placed in a growth chamber at constant 25°C. After three days, seeds with a radicle protruding through the seed coat were counted as germinated. The seedling length (root plus shoot) of germinated seeds was measured after being frozen. Freezing over night softened the seedlings and facilitated the measurement of length. Seeds that did not germinate were not considered in seedling length measurements.

Agar Bioassay Method. A stock solution of each test compound was made

by dissolving the desired quantity in 1 ml chloroform and diluting to 100 ml with hexane. A dosage series of each compound was made by diluting the stock solution with 1:99 chloroform–hexane (v/v). One milliliter of each solution was carefully layered on the agar in each appropriate tissue culture well. Five imbibed alfalfa, annual ryegrass, or velvetleaf seeds were placed in each well. Germination percentages and seedling lengths were recorded according to the procedure described above.

Filter Paper Bioassay Method. Filter paper germination bioassays were conducted as described by Wolf et al. (1984). Two pieces of Whatman No. 1 filter paper were placed in each 9.0-cm-diameter glass Petri dish. Two milliliters of each compound, dissolved in 1:99 chloroform–hexane (v/v) as before, were pipetted on the filter paper. Approximately 1 hr after evaporating to dryness, the filter paper was rewetted with 4 ml distilled water and 20 imbibed seeds were spaced on the filter paper. The dishes were wrapped in aluminum foil and placed in a growth chamber maintained at 25°C. After three days, the number of germinated seeds was counted according to the procedure described previously.

Experimental Design. Solvent and germination bioassays were conducted as split-plot completely randomized designs. Toxin or solvent mixture represented the main plots, and the dose represented the split plot. All experiments were replicated at least four times. The data were analyzed by general linear model and linear regression procedures of the Statistical Analysis System (SAS Innstitute Inc., Cary, North Carolina 27511-8000) and the curvilinear regression procedure of SigmaPlot (Jandel Scientific, Corte Madera, California 94925). Treatment effects were considered significant when $P \leq 0.05$.

RESULTS AND DISCUSSION

Solvent Optimization. Many biologically active compounds isolated in natural products research are insoluble or slightly soluble in water, but are soluble in organic solvents. Because chloroform and hexane are inexpensive solvents that can readily dissolve a wide variety of poorly water-soluble compounds, an optimum solvent or solvent mixture for compound delivery was identified using these solvents. Alfalfa and velvetleaf germination and seedling length were equally affected by the solvent treatments (Figure 1). Only 0.2 ml chloroform reduced the germination percentage of alfalfa and velvetleaf by 80% (Figure 1). A volume of 0.4 ml chloroform or greater reduced the germination percentage by 100%. Seedling length was reduced 77% by 0.2 ml of chloroform, and 100% by 0.4 ml or more chloroform (Figure 1). Chloroform dissolved the surface of the polystyrene wells leaving a layer impervious to water movement between the seed and agar. Chloroform also penetrated the agar because its

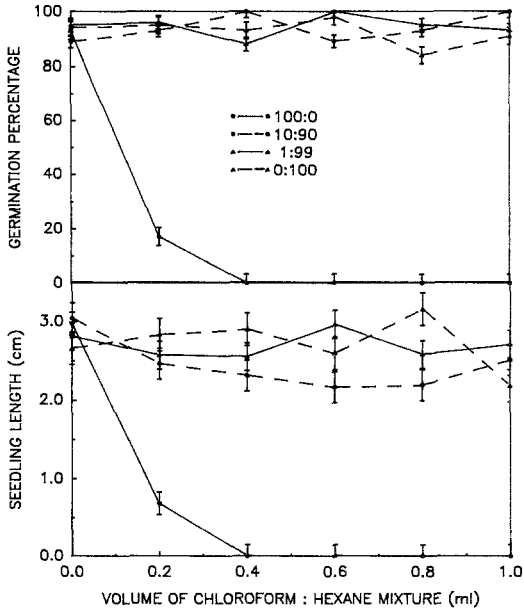

FIG. 1. The effect of chloroform, hexane, and representative mixtures of chloroform and hexane on alfalfa and velvetleaf seed germination and early seedling growth in polystyrene tissue culture wells ± 1 SE.

density is greater than that of water, preventing its complete evaporation from the agar.

Germination percentage was not affected by absolute hexane or either of the chloroform–hexane mixtures (Figure 1). Seedling length was reduced by 25% at all volumes of 10:90 chloroform–hexane, but was not reduced by hexane or 1:99 chloroform–hexane (Figure 1). Absolute hexane did not affect germination or seedling growth in the bioassay after evaporation but was incapable of dissolving several of the test compounds. A small proportion of chloroform (10:90, chloroform–hexane, v/v) proved nontoxic to germination, but reduced seedling length slightly. The optimum solvent was a 1:99 mixture of chloroform–hexane (v/v), which was nontoxic to both germination and seedling growth. When dissolved in a small volume of chloroform and diluted to the desired volume with hexane, all the test compounds, plus numerous others not reported here, could be solubilized and tested for phytotoxicity using the agar bioassay without an adverse solvent effect.

Agar versus Filter Paper Bioassay. All five compounds submitted to filter paper and agar bioassays reduced the germination of alfalfa, annual ryegrass, and velvetleaf to at least 20%, except for benzylisothiocyanate against vel-

vetleaf on filter paper (Tables 1–5). Both bioassay techniques indicated that juglone, plumbagin, and coumarin were more phytotoxic against germination than benzylisothiocyanate and cinnamaldehyde. A statistically significant curvilinear regression equation was fitted to the data for each plant–compound combination, indicating that the germination percentage was reduced linearly as the concentration of phytotoxin decreased. Using the agar bioassay, the LD_{50} (mg/replication) of juglone and plumbagin against velvetleaf was 20- and fourfold less, respectively, than the filter paper bioassay (Table 1). Similarly, between three- and sixfold less juglone or plumbagin was required to reduce the germination percentage of alfalfa or annual ryegrass with the agar bioassay (Table 2). With coumarin, the LD_{50} (mg/replication) values for alfalfa and annual ryegrass were six- and ninefold less with the agar bioassay (Table 3). Much lower doses of benzylisothiocyanate and cinnamaldehyde (26- to 187-fold) were required by the agar bioassay to reduce the germination percentages of alfalfa, annual ryegrass, and velvetleaf comparably to that of the filter paper bioassay (Tables 4 and 5). Without exception, the agar bioassay described herein

required smaller quantities of the compounds tested to reduce the germination percentage comparably to that of the typical filter paper bioassay.

The agar bioassay provides a sensitive method for screening the phytotoxicity of both water- (Pederson, 1986) and organically soluble compounds that are available in limited quantity. One reason less compound was required for a similar effect is because of the smaller dimensions of the tissue culture wells in comparison to that of the Petri dishes. Poorly water-soluble compounds can be absorbed by seeds or seedlings through direct root contact or at dilute concentrations in the bulk flow of water to the root. A larger proportion of poorly water-soluble or insoluble molecules placed on the agar would be available for absorption by the seedlings because a greater proportion of the agar surface is in contact with a seedling, improving the efficiency of phytotoxin contact with, and uptake by, the seedlings.

A second reason for the requirement of less compound was because the efficacy of several compounds, namely benzylisothiocyanate and cinnamaldehyde, was enhanced in the agar bioassay. The LD_{50} values in mole per seed units for benzylisothiocyanate and cinnamaldehyde were approximately 10-fold less in the agar bioassay than the filter paper bioassay. The LD_{50} values (mole/seed) of juglone, plumbagin, and coumarin varied from sixfold less to no different in the agar bioassay than the filter paper bioassay. The interaction between compound and bioassay medium may be due to differences such as compound solubility and polarity.

Germination Percentage and Seedling Length. The agar bioassay can capably detect reductions in seedling length by phytotoxin doses lower than those required to detect reductions in the germination percentage, further minimizing the quantity of compound required for bioassay. After seedlings are killed and

softened by freezing, seedling length can be readily and reliably measured using the agar bioassay. The roots are restricted to the filter paper surface and can be difficult to remove from the paper without breaking, whereas they readily penetrate the agar and are easily removed. The germination percentage LD_{50} and the seedling length ID_{50} in the agar bioassay, when averaged across the plant species tested, were 8 and 6 $\times$ 10^{-8} mole/seed for juglone and plumbagin, and 7 and 2 $\times$ 10^{-8} mole/seed for coumarin (Tables 1–5, Figure 2), respectively. Others have also shown that many compounds can reduce seedling length (Cope, 1982; Pederson, 1986) and root length (Shilling and Yoshikawa, 1987) by a greater extent than germination at toxic concentrations.

In addition to improving the sensitivity of the bioassay, the measurement of seedling length permits identification of certain compounds as being toxic that would be overlooked if considering germination percentage alone. Rela-

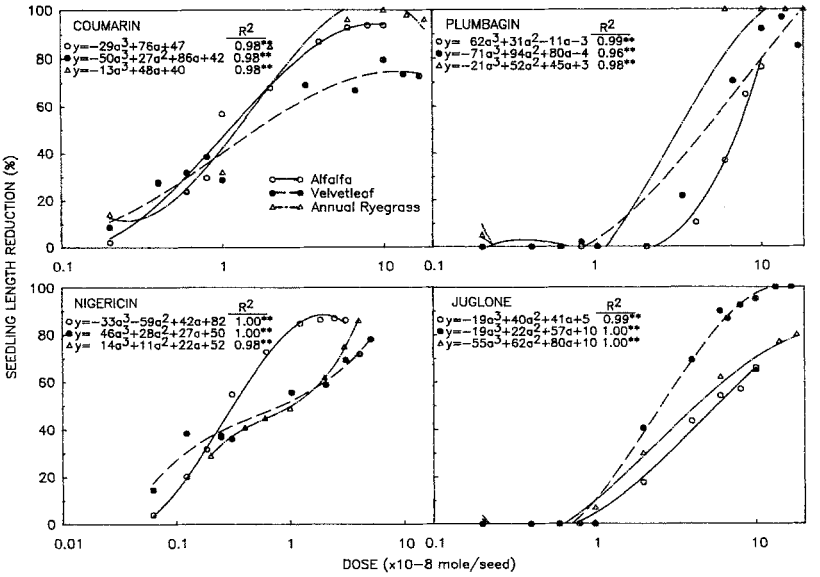

FIG. 2. Reductions in the seedling growth of alfalfa, annual ryegrass, and velvetleaf resulting from increased dosages of several phytotoxins delivered using the modified bioassay (** indicates significance at the 1% level).

tively few compounds directly inhibit the germination process. Many compounds, however, inhibit one or more aspects of seedling growth and metabolism. Nigericin did not inhibit the germination of alfalfa, annual ryegrass, or velvetleaf at the highest doses (data not shown), but was substantially more inhibitory to seedling growth than any of the other compounds tested (Figure 2). Greater potential for identifying inhibitory compounds may be realized by measuring a general parameter of seedling growth such as length.

A sigmoidal reduction in alfalfa, annual ryegrass, and velvetleaf seedling length was caused by coumarin, juglone, nigericin, and plumbagin in the agar bioassay (Figure 2). Low and high doses of each compound caused little change in seedling length. The curvilinear regression equations were significant and described the dose response for each compound and plant species. Dose-response characteristics differed among phytotoxins. The ID_{50} values for nigericin, coumarin, juglone, and plumbagin were, respectively, 0.5, 2.0, 6.6, and 7.2×10^{-8} mole/seed for alfalfa; 1.2, 1.2, 7.4, and 4.0×10^{-8} mole/seed for annual ryegrass; and 1.7, 3.9, 3.6, and 5.6×10^{-8} mole/seed for velvetleaf. Nigericin exhibited the greatest phytotoxicity against seedling length, followed by coumarin, juglone, and plumbagin. Heisey and Putnam (1986) reported that

nigericin strongly inhibited radicle elongation of garden cress (*Lepidium sativum* L.). The agar bioassay is useful for determining the dose–response characteristics of a large variety of compounds.

Germination percentage was often positively correlated with reduced seedling length. Correlation coefficients between germination percentage and seedling length were 0.80 ($P = 0.01$), 0.91, and 0.61 for coumarin, juglone, and plumbagin with alfalfa; and 0.49, 0.94, and 0.89 with velvetleaf. In contrast, nigericin reduced alfalfa and velvetleaf seedling length but did not affect germination. Lower germination percentages were associated with reduced seedling length in the agar bioassay, even though only germinated seeds were considered in seedling length measurements. Phytotoxins that caused the largest reductions in germination percentage did not necessarily cause the largest reductions in seedling length.

Selectivity. The agar bioassay was capable of detecting differences in phytotoxicity among compounds and plant species. Alfalfa and velvetleaf germination were unaffected by cinmethylin. Cinmethylin (0.6×10^{-8} mole/seed) reduced the germination percentage of annual ryegrass by 70%. The germination of velvetleaf was reduced by 89% and 82% by 10×10^{-8} mole/seed of juglone and plumbagin, respectively (Table 1), whereas that of alfalfa was reduced by 26% and 39%, and annual ryegrass by 50% and 100% (Table 2). In contrast, 10×10^{-8} mole/seed coumarin reduced the germination of alfalfa and annual ryegrass by 84% and 100%, respectively, but did not reduce that of velvetleaf. Both naphthoquinones inhibited the germination of alfalfa and annual ryegrass more than that of velvetleaf, whereas coumarin did not reduce that of velvetleaf.

Cinmethylin reduced alfalfa and velvetleaf seedling length maximally by 30% and 18%, respectively, but that of annual ryegrass was reduced 97% by 1×10^{-9} mole/seed cinmethylin (Figure 3). Velvetleaf seedling length was inhibited more by plumbagin and juglone than was alfalfa (Figure 2). Juglone reduced alfalfa and velvetleaf seedling length by 66% and 95% at 1×10^{-7} mole/seed. Plumbagin reduced alfalfa and velvetleaf seedling length by 76% and 85% at 1×10^{-7} mole/seed. In contrast, the highest test doses of nigericin and coumarin reduced alfalfa seedling length by 86% and 94%, and velvetleaf by 78% and 73%.

Summary. The use of sensitive organisms such as garden cress (*Lepidium sativum* L.) in bioassaay is suggested as a way to identify toxic compounds. While useful in some applications, they may be too sensitive in others. The agar bioassay represents an alternative method able to test the effects of compounds on small-seeded agronomic, horticultural, or weed species, thereby emphasizing agricultural relevance.

An agar bioassay method is described that requires smaller quantities of plant growth inhibitors than the frequently used filter-paper bioassay to dem-

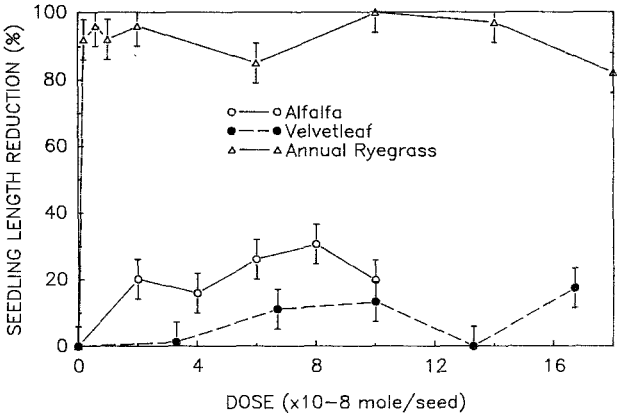

FIG. 3. The dose-response of cinmethylin on early seedling growth of alfalfa, annual ryegrass, and velvetleaf using the agar ± 1 SE.

onstrate comparable reductions in germination percentage. The use of agar as a growth medium in small tissue culture wells permits the accurate, reliable, and fast measurement of both the germination percentage and seedling length. The agar bioassay indicated that seedling length was more responsive than germination to compound phytotoxicity and was sensitive to selectivity among species. Dosage response dynamics of various compounds and plant species can be evaluated rapidly and analyzed statistically with the agar bioassay, permitting the rapid evaluation of poorly water-soluble organic compounds available in limited quantity.

(Received December 22, 1988; accepted February 10, 1989)

Abstract—2,2′-Oxo-1,1′-azobenzene (AZOB), a compound with strong herbicidal activity, was isolated and characterized from a soil supplemented with 2,3-benzoxazolinone (BOA). A parallel experiment with 6-methoxy-2,3-benzoxazolinone (MBOA) yielded AZOB as well as its mono- (MAZOB) and dimethoxy- (DIMAZOB) derivatives. These compounds were produced only in the presence of soil microorganisms, via possible intermediates, I and II, which may dimerize or react with the parent molecule to form the final products. In the case of MBOA, it was shown that demethoxylation precedes the oxidation step. Although BOA and 2,4-dihydroxy-1,4(2H)-benzoxazin-3-one (DIBOA) were leached out of rye residues, there were no detectable amounts of the biotransformation products in the soil. When BOA was mixed with soil and rye residue, either under field conditions or in vitro, AZOB was detected. Levels of free BOA in the soil were greatly reduced by incubation with rye residue. AZOB was more toxic to curly cress (*Lepidium sativum* L.) and barnyardgrass (*Echinochloa crusgalli* L.) than either DIBOA or BOA.

Key Words—Allelopathy, benzoxazolinones, benzoxazinones, BOA, DIBOA, hydroxamic acids.

INTRODUCTION

Cubbon (1925) reported that a rye (*Secale cereale* L.) crop, grown simultaneously with a grape crop, reduced the grape's growth relative to a control. The high nutrient content of the soil and abundant water supply suggested that com-

[1] Journal Article No. 12943 of the Michigan Agricultural Experiment Station.

0098-0331/90/0200-0353$06.00/0

petition was not the cause of the reduced grape growth. Virtanen et al. (1957) isolated a cyclic hydroxamic acid, 2,3-benzoxazolinone, from rye seedlings. The same authors later isolated 6-methoxy-2,3-benzoxazolinone (MBOA) from wheat and corn (Virtanen et al., 1957) simultaneously with Loomis et al. (1957). These compounds were isolated and purified based on their biological activity against fungi (*Fusarium nivale*) and European corn borer (*Ostrinia nubilalis*). They also reported a glucoside precursor, 2-*O*-glucosyl-1,4(2H)-benzoxazin-3-one (GDIBOA) from rye, and a methoxylated analog, 2-*O*-glucosyl-7-methoxy-1,4-benzoxazin-3-one (GDIMBOA) from corn and wheat. Treatment of the glucoside with a crude enzyme preparation from rye caused hydrolysis to glucose and a second precursor, 2,4-dihydroxy-1,4(2H)-benzoxazin-3-one (DIBOA) in rye and 7-methoxy-2,4-dihydroxy-1,4(2H)-benzoxazin-3-one (DIMBOA) in corn and wheat (Virtanen and Hietala, 1960; Hietala and Virtanen, 1960). Hofman and Hofmanova (1969) showed that when intact tissue was carefully extracted, using liquid nitrogen as a fixative to prevent all enzyme activity, only the glucoside derivatives were extracted. This indicated that there was no free aglycone or benzoxazolinone in living intact tissue. Upon injury to the plant, β-glucosidases are released and rapidly hydrolyze the glucoside to the aglycone, which in turn decomposes in water to form the benzoxazolinone (Virtanen and Hietala, 1960). Naturally occurring benzoxazinones have also been reported from two other species, Job's tears (*Coix lachryma jobi*) (Koyama et al., 1955) and bears breech (*Acanthis mollis* L.) (Wolf et al., 1985). These are the only known instances of 1,4-benzoxazinone production in higher plants, although production by microorganisms is fairly common (Tipton et al., 1967).

Chou and Patrick (1976) studied the phytotoxic compounds released during the degradation of corn and rye residues. Plant material was combined with soil and allowed to decompose for up to 30 days. In the aqueous extracts of decomposing corn residue, they detected 18 phytotoxic compounds, mostly low-molecular-weight organic acids such as benzoic, phenylacetic, and 4-phenylbutyric acids, along with cinnamic acid derivatives such as ferulic, caffeic, *o*-coumaric, *p*-coumaric, *trans*-cinnamic, and vanillic acid. The cinnamic acid derivatives are frequently implicated in allelopathy by many species and are one of the fundamental groups of allelochemicals (Rice, 1984). Barnes and Putnam (1983, 1986, 1987) examined the allelopathic potential of residues and aqueous extracts of rye, and implicated the benzoxazinones, 2,4-dihydroxy-1,4(2H)-benzoxazin-3-one (DIBOA) and 2,3-benzoxazolinone (BOA), cyclic hydroxamic acids, as the toxic agents produced by rye.

Patrick and Koch (1958) conducted a study of the toxic substances produced as a result of microbial decomposition of plant residues, including rye. They found that unless decomposition of the residues occurred, no toxic substances were present in the soil extract. If, however, decomposition had taken place, the extract of the soil–residue mixture was extremely toxic to the respi-

ration, oxygen uptake, and growth of tobacco (*Nicotiana tabacum* L.) seedlings (Patrick and Koch, 1958). They did not determine whether the toxins were of plant or microbial origin.

Once in the soil system, the benzoxazinones produced by rye would be susceptible to microbial transformation by various soil microbes. For the benzoxazinones to be involved in long-term allelopathic activity, they must be sufficiently resistant to such microbial transformations. Alternatively, if the parent compounds are metabolized, it is conceivable that biologically active metabolites may be involved in the overall process of allelopathy by rye residues. This paper describes the isolation and characterization of potent allelochemicals from soil previously supplemented with benzoxazinones and the detection of the levels of BOA and DIBOA in both residues and underlying soil over a period of time.

METHODS AND MATERIALS

Experimental. [^{1}H]- and [^{13}C]NMR analyses were performed on a Varian XL-300 spectrometer, 300 MHz for proton and 75 MHz for carbon. Electron impact mass spectral (EI-MS) analysis was done on a Hewlett Packard model 5895 quadruple mass spectrometer at 70 eV. Chemical ionization (CI) and high-resolution mass spectra (HRMS) were generated on a Jeol model HX-110 mass spectrometer. Ultraviolet (UV) absorption analyses were performed on a Gilford Response II ultraviolet spectrophotometer and infrared (IR) spectra, on a Perkin Elmer model 1170 FTIR spectrophotometer. Melting points were determined on a Thomas model 40 Micro Hot Stage apparatus and are uncorrected. HPLC analyses were performed on a Waters Radial Pak 8 mm ID $\times$ 10 cm, radially compressed C18 column (Waters Assoc., Division of Millipore Inc., Milford, Massachusetts), using KH_2PO_4 (0.01 M, pH 3.0)–acetonitrile (80:20 v/v). Unless specified, flash chromatography was performed on a silica gel column (Merck silica gel G, grade 60) and thin-layer chromatography, on silica gel plates (Merck silica gel G F-254, 0.250 mm layer). 2,3-benzoxazolinone (BOA) was obtained commercially from the Aldrich Chemical Co., Milwaukee, Wisconsin. Soil used was a Spinks loamy sand (Psammentric, hapludalf, sandy, mixed, mesic), collected from a field site at Michigan State University for use in the greenhouse, and stored in large bins under dry conditions for approximately one year. Soil was sterilized when necessary by autoclaving (1 hr on three successive days).

Spray Reagents for TLC Detection. DIBOA was detected on thin-layer plates with a spray reagent consisting of 5% $FeCl_3$ in 95% ethanol, acidified with conc. HCl. A spray reagent consisting of 1% ceric sulfate in conc. H_2SO_4 was used to detect BOA and MBOA.

Isolation of 6-Methoxy-2,3-benzoxazolinone (MBOA). Ten-day-old maize seedlings (Pioneer 3737) were harvested and frozen at −20°C overnight (592 g). The thawed plant material was homogenized in a Waring blender with distilled water (1.4 liters). This was kept at room temperature (1 hr) to ensure hydrolysis of the glucoside, 2-*O*-glucosyl-7-methoxy-1,4-benzoxazin-3-one (GDIMBOA) to 7-methoxy-2,4-dihydroxy-1,4-benzoxazin-3-one (DIMBOA) and refluxed (2 hr) to cause the conversion of DIMBOA to MBOA. After cooling, the extract was strained through cheesecloth and the filtrate was acidified with conc. HCl (pH 1.0). The acidified extract was filtered through Whatman No. 4 filter paper and extracted with diethyl ether (5 × 300 ml). The ether fraction was washed once with distilled water (300 ml), dried over anhydrous $MgSO_4$, and the solvent was removed in vacuo. The crude extract thus obtained (720 mg) was initially purified by flash column chromatography ($CHCl_3$—MeOH 5 : 1) followed by TLC check with ceric sulfate detection. The fractions positive to ceric sulfate were pooled, and the solvent was removed *in vacuo*. This partially purified fraction (451.0 mg) was further chromatographed by TLC ($CHCl_3$—MeOH 6 : 1). The ceric sulfate-positive band was removed, eluted ($CHCl_3$—MeOH 2 : 1), and the solvent was removed by rotary evaporation. The colorless compound (129.8 mg) thus obtained was recrystallized from hexane–acetone, yielding needlelike crystals (70.8 mg) mp 144–148°C; UV (MeOH) 232.5 nm (9420), 290.0 nm (5050); IR (KBr) 3200, 1790, 1638, 1500, 1318, 1210, 1140, 1100, 1025, 970 cm^{-1}; [^{1}H]NMR (CD_3OD) δ 3.56 (3H, s, OCH_3), 7.80 (1H, d, J = 8.2 Hz), 7.65 (1H, d, J = 2 Hz), 7.58 (1H, d, J = 8.7 Hz); EI-MS, *m/z*: 165 (100, M^+), 150 (80).

Isolation of 2,4-Dihydroxy-1,4(2H)-benzoxazin-3-one (DIBOA). Seedlings of rye (Wheeler, 25 days old) were lyophilized at 15°C (101.5 g), homogenized in a Waring blender with distilled water (1 liter), and kept at room temperature (1 hr) to ensure enzymatic hydrolysis of the glucoside 2-*O*-glucosyl-1,4-benzoxazin-3-one (GDIBOA) to 2,4-dihydroxy-1,4-benzoxazin-3-one (DIBOA). After filtering through cheesecloth, the filtrate was heated in a water bath until the temperature of the extract reached 70°C. It was then cooled immediately in an ice bath. Coagulated components were removed by vacuum filtration using Whatman No. 1 filter paper. The filtrate was acidified with conc. HCl (pH 1.0) and extracted with diethyl ether (4 × 300 ml). The ether fraction was washed once with distilled water (300 ml), and the solvent was removed *in vacuo*. The crude extract thus obtained (355.8 mg) was initially purified by column chromatography ($CHCl_3$—MeOH 4 : 1), followed by TLC check with ferric chloride detection. The fractions positive to ferric chloride were pooled, and the solvent was removed at reduced pressure. This partially purified fraction (187.2 mg) was further chromatographed by TLC ($CHCl_3$—MeOH 6 : 1). The ferric chloride positive band was eluted ($CHCl_3$—MeOH 2 : 1), and removal of the solvent by rotary evaporation afforded a pale yellow residue (89.2 mg). This residue

was extracted with diethyl ether and filtered through a sintered glass filter (fine). Recrystallization from ether–cyclohexane afforded colorless needles (22.4 mg), mp 151–155°C; IR (KBr) 3400, 3200, 2380, 1670, 1590, 1280, 1220, 1040, and 750 cm^{-1}; [^{1}H]NMR (CD_3OD) δ 5.70 (1H, s), 7.35 (1H, dd, J = 1.0, 8.0 Hz), 7.10 (3H, m); HRMS, *m/z*: 181.0476 ($C_8H_7O_4N$, M^+).

Isolation of 2,2'-Oxo-1,1'-azobenzene (AZOB). 2,3-benzoxazolinone, (20 mg) was mixed thoroughly with soil (50 g), and the mixture was transferred to a 250 ml Erlenmeyer flask. Distilled water (5.0 ml) was added to the above and incubated at 26°C for 10 days. Soil for sterile controls was autoclaved. BOA and filter-sterilized (0.22-μm membrane) water (5.0 ml) were added aseptically to the soil, and the system was incubated at 26°C for 10 days. The control and experimental soil, as described above, were extracted with methanol (4 × 100 ml each). The methanol extract of the control soil was pale yellow, while the experimental extract was intensely orange. Both extracts were filtered, separately, through a sintered glass filter (fine), and the solvent was removed by rotary evaporation. A preliminary TLC analysis of the extracts indicated the presence of an orange band, only in the experimental soil. This orange compound (19.8 mg) was purified by TLC ($CHCl_3$—MeOH—HCOOH 20:1:1). Repeated purification was carried out by TLC (toluene—EtOAc—NH_4OH 5:4:1) until the resulting dark red compound (1.8 mg) gave only one spot by TLC. Recrystallization from hexane–acetone yielded AZOB as orange-red needles, mp 223–228°C (decomp.); UV (MeOH) 237 nm (ϵ = 28,268), 432 nm (ϵ = 23,711); IR (KBr pellet) 760, 1574, 1587 cm^{-1}; [^{1}H]NMR (DMSO) δ 7.75 (2H, d, J = 8.4 Hz, H-6, H-6'), 7.55 (6H, m, H-3, -4, -5 and H-3', -4', -5'); [^{13}C]NMR (DMSO) δ 99.87 (d, ×2), 104.86 (d, ×2), 117.25 (d, ×2), 126.60 (d, ×2), 129.19 (s, ×2), 130.34 (s, ×2); EI-MS, *m/z*: 212 (100, M^+), 185 (60), 184 (33); CI-MS, *m/z*: 212 (100, M^+), 185 (28) 184 (18); HRMS, *m/z*: 212.0588 ($C_{12}H_8N_2O_2$, M^+); FAB-MS (+) *m/z*: 213 (M^++H).

A similar experiment with DIBOA was carried out as in the case of BOA, and the work-up and purification yielded two compounds that proved to be BOA and AZOB, as well as unreacted DIBOA.

Isolation of AZOB from Field Soil to which BOA was Added. A commercial sample of BOA (1.0 g) was mixed with the top 13 mm of soil in a small plot (1.22 m) at the location from which soil used for in vitro conversion of BOA to AZOB was obtained. A soil sample (390 g) was taken from the center of the plot after seven days and extracted with methanol as above (105.5 mg). Removal of the solvent at reduced pressure gave an orange residue. Analysis of this extract by TLC confirmed the presence of AZOB. A control plot of the same size and location, but not supplemented with BOA, was also extracted for comparison and showed no benzoxazinones or diazoperoxides present.

Isolation of 4-Methoxy-2,2'-oxo-1,1'-azobenzene (MAZOB) and 4,4'-Dimethoxy-2,2'-oxo-1,1'-azobenzene, (DIMAZOB). The experiment with

MBOA was carried out as in the case of BOA and work-up and purification yielded a single component. Recrystallization from hexane–acetone afforded MAZOB as red-orange needles, mp 218–220°C (decomp.); UV (MeOH) 231 nm (ϵ = 23,591), 450 nm (ϵ = 21,122); IR: 2860, 2830, 1650; [^{1}H]NMR (DMSO) δ 3.70 (3H, s, OMe), 7.74 (1H, J = 8.4 Hz), 7.64 (1H, d, J = 8.8 Hz), 7.52 (3H, m), 7.11 (1H, J = 2 Hz), 7.01 (1H, J = 6 Hz); EI-MS, m/z: 242 (100, M^+); FAB-MS, m/z: 243 (M^+).

A small amount of 4,4′-dimethoxy-2,2′-oxo-1,1′-azobenzene, (DIMAZOB) was detected by both EI- and FAB-MS at 272 (M^+) and 273 (M^++H), respectively.

An additional experiment was carried out in which a 1 : 1 mixture of BOA and MBOA was added to soil and incubated as above. Work-up, purification, and analysis by EI-MS gave AZOB, MAZOB, and DIMAZOB. EI-MS, m/z: 212 (72%), 242 (26%), and 272 (1.5%) respectively.

Microbial Ecology of Transformation Reaction. Several attempts were made to isolate the organism(s) responsible for the biotransformation of BOA. Soil (1 g) was mixed with physiological saline (0.85% NaCl, 9 ml) and vortexed. Serial dilutions (1 : 10) were then plated on NZ-amine agar (NZ-amine A, 3 g; agar 18 g, distilled water 1 liter). The plates were sealed in a polyethylene bag and incubated at 25°C. After 72 hr, individual colonies were removed and inoculated into screw-capped test tubes containing sterile soil (5 g), and BOA (2 mg). These were wet with sterile distilled water (0.5 ml) and incubated as above.

Leaching Experiments with Rye Residue. Rye seedlings (Wheeler, 35 days old) were harvested at the soil level (900 g), placed on a flat (25 × 50 cm) of soil and watered over the top at 72-hr intervals. Residue and underlying soil samples were taken at 0, 1, 2, 3, 6, 10, 17, and 27 days, respectively. Methanol extracts (4 × 100 ml) of the soil samples were stored at −20°C. The lyophilized residue samples were homogenized in a Waring blender with distilled water (300 ml), kept at room temperature (1 hr), and strained through cheesecloth. The pH of the extract was adjusted to 1.0 with conc. HCl. The acidified extract was filtered through Whatman No. 1 filter paper under vacuum and extracted with diethyl ether (4 × 100 ml). The solvent was removed in vacuo and the dried samples were stored at −20°C.

Several experiments were also conducted in which lyophilized rye residue (10 g) was cut into 2 cm pieces and mixed into dry soil (1 kg) with distilled water (100 ml). Three such systems were set up in 2-liter beakers, each comprising a sample, that was extracted at 24, 72, and 240 hr respectively. Soil and residue were separated after drying at 45°C (1 hr). Methanol extraction of soil (3 × 500 ml) and removal of the solvent yielded dry samples that were stored at −20°C. The lyophilized residue was homogenized in a Waring blender with

distilled water (200 ml), kept at room temperature (1 hr), strained through cheesecloth, and acidified with conc. HCl (pH 1.0). The extracts were processed as above and stored at −20°C. All samples were analyzed simultaneously. Preliminary analysis of the samples was carried out by TLC ($CHCl_3$–MeOH 5 : 1). DIBOA and BOA were detected with the ferric chloride and ceric sulfate spray reagents, respectively. Samples that did not contain BOA or DIBOA by TLC were not analyzed further. Samples containing BOA or DIBOA were partially purified by TLC ($CHCl_3$—MeOH 5 : 1) and analyzed by HPLC. Both compounds were quantified respective to external standards by monitoring at 230 nm.

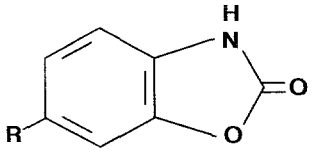
An additional experiment was conducted in which BOA (10 mg), rye tissue (5 g fresh), and distilled water (2.5 ml) were added to soil (25 g) and incubated at 26°C (10 days). An identical system, lacking residues, was used as a control.

Herbicide Bioassays. Phytotoxic activity was evaluated in terms of seedling growth inhibition. Stock solutions (1 mg/ml methanol) of purified compounds were applied to Whatman No. 1 filter paper in plastic Petri dishes (60 × 15 mm) to obtain doses ranging from 6.25 to 200 g/dish. Pure methanol was also added to a control plate. The plates were left open to allow the methanol to evaporate completely (20 min). Ten indicator seeds (curly cress and barnyardgrass) were then placed on the filter paper and distilled water (1.5 ml) was added. The plates were wrapped with parafilm to prevent drying and incubated in the dark (26°C for 72 hr). After incubation, seedling root length was measured and compared to the control. The experiments were designed as randomized complete blocks, with three replicates.

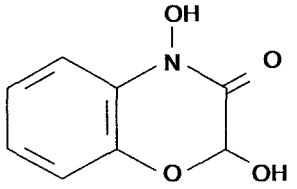
RESULTS AND DISCUSSION

AZOB (2,2′-oxo-1,1′-azobenzene), isolated as a biotransformation product of 2,3-benzoxazolinone (BOA) (Figure 1) from nonsterile soil, gave the molecular formula of $C_{12}H_8N_2O_2$ by HRMS. The doublet at 7.75 ppm, integrated for two protons was assigned to the 6 and 6′ hydrogens ortho to the nitrogen in the aromatic ring. The only other signal observed in the [^{1}H]NMR spectrum was a multiplet at 7.55 ppm, integrated for six protons. The [^{13}C]NMR spectrum of AZOB gave only six signals for 12 carbon atoms, indicating a symmetrical structure for this molecule. The strong IR absorption at 760 cm^{-1}, indicative of an aromatic system with four adjacent hydrogens, was in full agreement with the NMR data and confirmed the proposed structure (Figure 2).

Incorporation of DIBOA into soil also resulted in the formation of AZOB. Addition of methoxylated BOA (MBOA) gave MAZOB and DIMAZOB, characterized by spectral methods (Figure 2). It is interesting to note that the most



BOA: R = H
MBOA: = OMe



DIBOA

FIG. 1. Benzoxazolinones and benzoxazinones isolated from rye or corn plants.

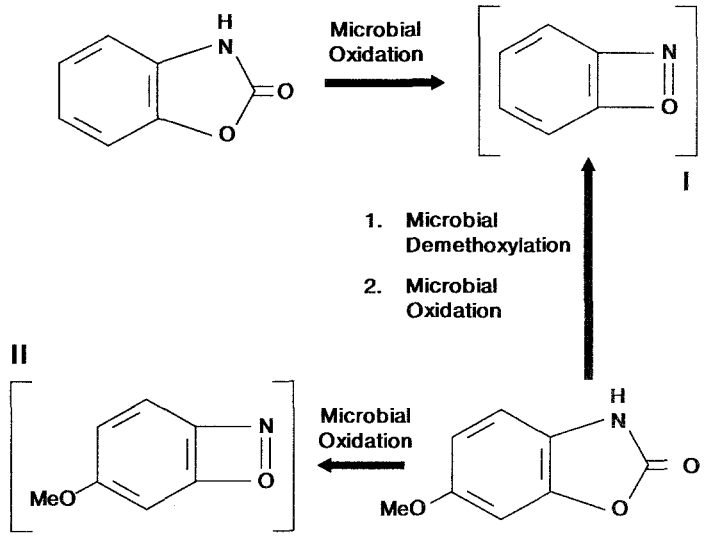
abundant product of MBOA transformation is MAZOB (95%), with DIMAZOB present as a minor species, as evident by mass spectral data. Trace amounts of AZOB were also present in the above mixture.

Formation of AZOB in the soil could be the result of an intermediate **I** (Scheme 1), produced enzymatically from BOA, which in turn reacts with another molecule of BOA. Alternatively, this intermediate could undergo dimerization to afford AZOB. In the case of MBOA, the major product was

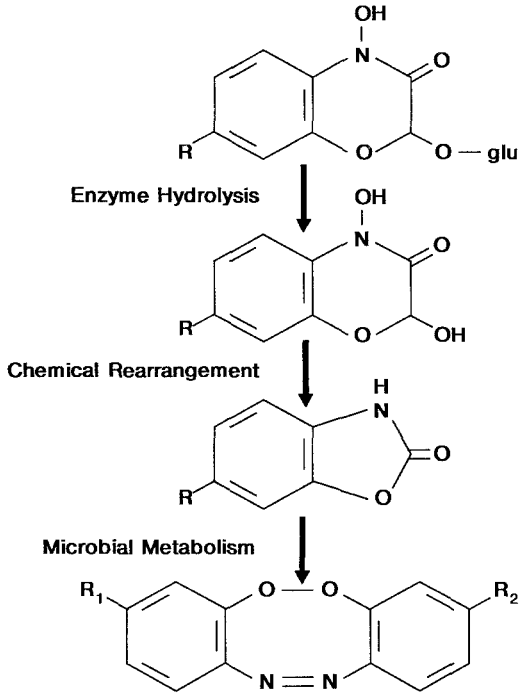


SCHEME 1. Probable transformation scheme for conversion of BOA to AZOB.

MAZOB, a monomethoxy analog of AZOB. This indicated that prior to the enzymatic oxidation leading to intermediate **II** (Scheme 1), there is a demethoxylation step involved. That is, an enzymatic demethoxylation, followed by enzymatic oxidation, would also yield intermediate **I**, which in turn would react with MBOA, to give MAZOB. The dimethoxy derivative (DIMAZOB) should result from the reaction of intermediate **II** with MBOA or from dimerization of intermediate **II**. The experiment with equal amounts of BOA and MBOA gave AZOB as the major product (72%), MAZOB (26%), and DIMAZOB in very small quantity (1.5%). Therefore, it is evident that intermediate **II** is less abundant than intermediate **I** and that the demethoxylation occurs prior to the enzymatic oxidation. Based on these results, it is possible to extend the breakdown scheme for benzoxazinones proposed by Virtanen et al. (1960) (Scheme 2).

Addition of BOA or MBOA into sterile soil did not produce any of the azobenzenes, suggesting that these compounds are produced by soil microbes. To isolate the total microbial population, a saline extract of the soil was added to soil containing BOA, and resulted in production of AZOB after incubation for seven days.

Experiments to isolate the organism(s) responsible for the transformation were inconclusive. None of the colonies isolated to date was capable of transforming BOA. It appears as if the transformation reaction does not provide a



SCHEME 2. Extension of the degradative scheme for BOA proposed by Hietala and Virtanen (1960).

selective advantage to those microbes capable of carrying it out. That is, the reaction is probably not an energy-yielding reaction, but perhaps, instead, is catalyzed by an extracellular oxidase enzyme. Production of AZOB was also demonstrated in the field, using commercial BOA, indicating that these organisms are present in the environment. Although trace amounts of BOA and DIBOA were isolated from the soil in laboratory leaching experiments using rye residue, AZOB was apparently not present in this soil. In order to verify this result, an in vitro experiment with rye residue and BOA was conducted and the products were quantified. Only trace amounts of AZOB were observed by TLC from the soil containing BOA and fresh rye residue. It was also interesting to note that most of the added BOA in the residue sample (92%) had disappeared. The control sample, containing no residue, produced the normal amount of AZOB as mentioned earlier, yet contained approximately 9.7 times as much of the added BOA as did the residue treatment. These results indicated that either some enzymatic inhibitors had leached from the rye residue into the soil, or that the leachate had killed the microbe(s) responsible for the conversion.

Since the microbes responsible for the production of azobenzenes have not yet been identified, it is difficult to argue that the leachate has killed these organisms. Chemical reaction between BOA and the leachate is a possible explanation for the diminished production of AZOB, as well as the disappearance of most of the added BOA. The above results were repeated in large-scale experiments as well.

Barnes and Putnam (1987) found dicotyledonous species to be approximately 30% more sensitive to BOA and DIBOA than were monocotyledonous species. Initial assays, conducted with garden cress and barnyardgrass as indicators, indicated a high degree of toxicity of AZOB to radicle elongation of both species (Figure 3). AZOB was much more toxic than either BOA or DIBOA. This compound could contribute to the overall toxicity of rye residues, for which Barnes could only attribute a small portion (12%) to the hydroxamic acids.

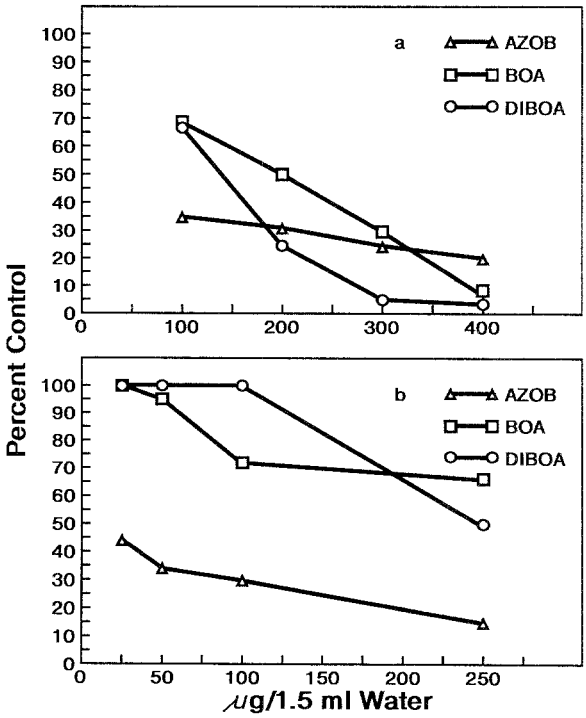


FIG. 3. Relative toxicities of 2,2′-oxo-1,1′-azobenzene and the parent benzoxazinones, BOA and DIBOA, as measured by inhibition of radicle elongation of (a) garden cress and (b) barnyardgrass. All points are significantly different from control at the 0.05 level by LSD.

Our results suggest a role for soil microorganisms in the overall process of allelopathy by rye. The primary allelochemicals produced by rye, BOA, and DIBOA have been shown to be present in the soil by in vitro leaching experiments. Once in the soil, these compounds undergo microbial transformation, resulting in the diazoperoxide, AZOB. Although these compounds were not detected in either *in vivo* or *in vitro* experiments using rye residues, the biological activity of AZOB clearly demonstrates the potential role of these compounds in allelopathy if a suitable microbial population is present in soil to perform their synthesis.

(Received September 1, 1988; accepted February 21, 1989)

Abstract—The antifeedant activity of a series of 21 chalcones, flavanes, and flavanones isolated from the genera *Lonchocarpus* and *Tephrosia* (Leguminosae) was assessed by behavioral and electrophysiological bioassays against larvae of *Spodoptera littoralis* and *S. exempta*. The antifeedant activity is related to the molecular structure of the compounds, and possible modes of interaction with the insect taste receptors are discussed.

Key Words—*Spodoptera littoralis*, *Spodoptera exempta*, Lepidoptera, Noctuidae, *Lonchocarpus*, *Tephrosia*, antifeedant, feeding behavior, gustatory codes.

INTRODUCTION

Many species of the plant family Leguminosae are protected from attack by insects by the presence of allelochemicals that have toxic or antifeedant properties, or both, against a range of insects that are major pests of crop plants (Birch et al., 1989). This article is one of a series in which we are assessing the antifeedant activity of naturally occurring compounds and synthetic com-

0098-0331/90/0200-0365$06.00/0

pounds derived from them (Simmonds and Blaney, 1984; Simmonds et al., 1985; Blaney et al., 1987, 1988). In doing so, we are also exploring facets of insect feeding behavior and, in particular, the sensory physiology of the receptor systems principally deployed by insects in host plant selection.

The compounds tested in this paper are flavanones, flavanes, and chalcones, belonging to a homogeneous group of C-15 derivatives characterized by the presence of one isoprenyl group. These compounds may represent intermediate stages in the biosynthesis of the insect-toxic rotenoids, which occur in the genera *Lonchocarpus* and *Tephrosia*, belonging to the family Leguminosae, from which the present compounds are isolated or derived (Delle Monache et al., 1973, 1978, 1986; Goncalves de Lima et al., 1975; Lupi et al., 1975; Cuca Suarez et al., 1980).

In studying the structure–function relationships of plant compounds with antifeedant activity, we have found it constructive to compare the behavioral and electrophysiological responses of lepidopterous larvae that differ in their feeding specificity (Simmonds and Blaney, 1984; Blaney et al., 1987, 1988). In this article we use the oligophagous larvae of *Spodoptera exempta* (Walker), which feed almost exclusively on Gramineae, and the polyphagous larvae of *Spodoptera littoralis* (Boisduval).

METHODS AND MATERIALS

Insects

Larvae of *S. littoralis* were reared on a bean-based diet (Dimetry, 1976) and those of *S. exempta* on wheat seedlings. All the insects were reared at Birkbeck College in a 16 : 8 hr light–dark photoperiod at 26° ± 1°C. Larvae, 24–36 hr into the final stadium, were deprived of food for 4 hr before being used in a bioassay.

Chemicals

The compounds used and their origins are listed in Table 1, and their molecular structures are shown in Figure 1. In order to facilitate comparison between the assays, the same test solutions were used for both behavioral and electrophysiological assays. Thus, since the electrophysiological assay requires the presence of an electrolyte, all solutions contained 0.05 M sodium chloride. The compounds were first dissolved in 95% ethanol, then made up with distilled water so that the final concentration of ethanol was never more than 0.5%. At that concentration, these solvents do not affect the sensory responses (Simmonds and Blaney, 1984, and unpublished results). The test compounds were presented at the concentrations shown in Tables 2 and 3 below.

TABLE 1. NAME AND ORIGIN OF PLANT FLAVONOIDS

[b] Derived from plant compound.

Bioassay

Four different bioassays were used to test the compounds.

Dual-Choice Test (A). Individual larvae were confined for up to 5 hr in a Petri dish (9 cm diameter) containing two glass-fiber disks (GFD). Both disks (Whatmans GB/A, 1 cm) were treated with 50 μl of a solution containing 0.05 M sucrose (to make the disk palatable) and 0.05 M sodium chloride. The application of this amount of solution to each disk ensures that the compound is evenly distributed over the disk. One disk served as the control (C); the other, the treatment disk (T), received additionally, when dry, a 50-μl aliquot of the

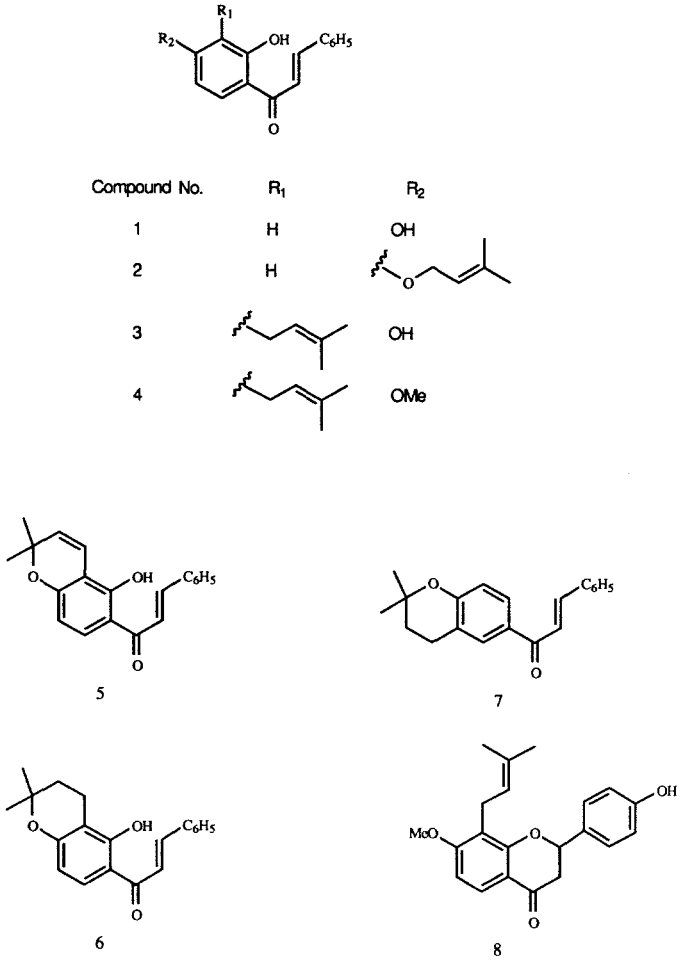

FIG. 1. Structures of the 21 compounds tested.

test solution. The disks were dried and weighed before being presented to the larvae. The experiments were terminated after 5 hr, or when 50% of any disk had been eaten. The disks were then weighed, and the amount of each disk eaten was used to calculate the antifeedant index $[(C - T)/(C + T)]\%$. This index distinguishes phagostimulants (negative values) and deterrents (positive values).

Dual-Choice Leaf Disk Test (B). This test was similar to test A, but leaf disks were used instead of GFD. For *S. littoralis* disks (1 cm diameter) of cotton leaves were used, and for *S. exempta* an equivalent area of wheat leaf blade was used. The treatment leaf disks (T) were painted with a 30-μl aliquot of test

solution, and the control disks were treated with solvent solution only. Both solutions contained 0.1% Tween 80. The bioassay was for 1 hr or until 50% of either disk was eaten. The amount eaten was assessed visually to the nearest 5% by comparing the remaining leaf material with a template of the original plant material. The antifeedant index was calculated using the percentage eaten.

No-Choice Leaf Disk Test (C). Disks were painted with the test solution,

as in test B, and each larva was left with a disk for 1 hr (no larva consumed more than 70% of a disk).

Electrophysiological Bioassay (D). A description of this bioassay can be found in Blaney et al. (1987). Briefly, the paired maxillary sensilla styloconica are stimulated with a range of solutions using a standard tip-recording technique (Hodgson et al., 1955). Each larva was stimulated with the control solution, 0.05 M sodium chloride, and up to five of the test solutions. All compounds were tested on three to five larvae, with one to five replications for each lateral and medial styloconic sensillum. All compounds, except 8 and 21 (Table 1), were tested against both species in the dual-choice GFD bioassay at 100 ppm. However, in the other bioassays, because of the limited amounts of compounds available, the concentration used and the number of compounds tested varied.

RESULTS

The results of the dual-choice bioassay with GFD are given in Table 2. The antifeedant effect was generally much greater against *S. exempta* than against *S. littoralis*. The 4-methoxyflavanes (9 and 10) and the flavanones (11, 12, 13, and 16) were significantly more active against *S. exempta* than *S. littoralis*, at 100 ppm. Fourteen of the 20 compounds tested at 100 ppm against *S. exempta* had significant antifeedant activity, and 13 of them were still active at 10 ppm. The flavanones were more active than the chalcones, indeed, only flavanone (17) did not have a significant level of activity against *S. exempta.*

Of the 11 compounds available in sufficient quantity to be tested at 500 ppm against *S. littoralis*, six (1, 5, 6, 12, 13, and 14) had significant antifeedant activity, but only two of them (5 and 14) were still active at 100 ppm. Of the other compounds tested at 100 ppm, five (4, 15, 18, 19, and 20) had significant antifeedant activity, and four of them (4, 15, 19, and 20) were still active at 10 ppm. Of these four, the three flavanones (15, 19, and 20) were more active than the chalcone (4). Flavanone (21) was the only compound to significantly increase feeding.

The results of the dual-choice test with leaf material are given in Table 3. The two chalcones (5 and 6) and all the flavanones (11, 12, 13, 14, and 17) tested against *S. exempta* were significant antifeedants at 100 ppm. Of the six chalcones tested against *S. littoralis*, three (1, 5, and 6) were significantly active at 500 ppm, and two of them (5 and 6) retained activity at 100 ppm. Chalcone (7) was active at 100 ppm but not at 500 ppm. Of the five flavanones tested, only one (14) was active. Generally, the antifeedant activity on the leaf disks was lower than on the GFD (see statistics in Table 3). There was one exception, however: with *S. littoralis*, chalcone (6) was more active on leaf disks than on GFD.

The results of the no-choice leaf disk bioassay have been correlated with those of the electrophysiological bioassay and are presented in Figures 2 and 3. Of the 11 compounds tested, those most active behaviorally against *S. exempta* were the flavanones 11, 12, 13, and 14, and against *S. littoralis* the most active were the chalcones 2, 6, and 7.

In the electrophysiological bioassay, the responses of the two species differ

in important respects. In *S. exempta*, a single neuron in the medial sensillum responded to the test compounds, and its firing rate was significantly negatively correlated with the amount of plant disk eaten (Figure 2; $r = -0.9784$; $P < 0.001$); the firing rate increased as the amount eaten decreased. In *S. littoralis* the compounds stimulated one, two, or three neurons in the medial sensilla (identified as neurons A, C, and D, see discussion and Blaney et al., 1987, 1988). The output of each neuron was identified by the shape and height of its action potentials. There was found to be a significant correlation between the total firing rate of the medial sensilla during the first second of stimulation with the compounds and the amount of plant disks eaten (Figure 3; $r = 0.8775$; $P < 0.001$). An interesting result from this experiment is that the more unpalatable the test solution, the lower the firing rate elicited.

The compounds did stimulate one to two neurons in the lateral sensillum of both species, but their total response was low (5–15 impulses/sec) and sporadic. As this response did not correlate with the feeding behavior, it has been excluded.

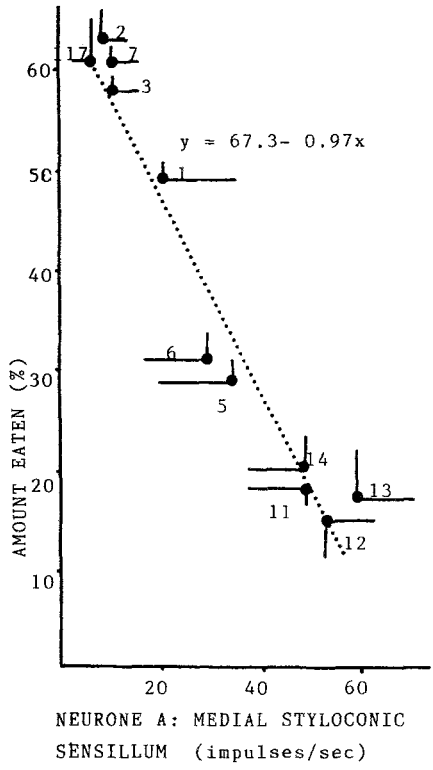

FIG. 2. The relationship between the amount eaten by larvae of *S. exempta* in the no-choice bioassay, using leaf disks coated with 30 μl of test compound at 100 ppm, and the firing rate of neuron A in the medial styloconic sensillum when stimulated with the same test compounds. Numbers = compounds in Figure 1: range bars = SEM; replications: behavior = 10–15; electrophysiology = 3–5 larvae.

Clearly, the sensory code for taste quality mediated by the styloconic sensilla is either more complex or more obscure in *S. littoralis* than in *S. exempta*. A further analysis of the performance of individual neurons in *S. littoralis* has been undertaken (Table 4 and Figure 4). Compounds 2, 3, 11, 12, 13, and 17 stimulated neuron C more than neuron A, and neuron A was stimulated more than neuron C by compunds 1, 5, 6, 7, and 14 (Table 4). Another neuron, D, which was stimulated strongly by the control solution, sodium chloride, was active in all the recordings, although it represented a low percentage of the total response. The response of neuron A, when taken as a percentage of the total firing of the medial sensillum during the first second of stimulation, correlates significantly with the antifeedant index from the GFD bioassay (Figure 4; r =

FIG. 3. Numbers = compounds in Figure 1: range bars = SEM; replications: behavior = 10–15; electrophysiology, see Table 4.

0.8243; $P < 0.001$), the antifeedant index from the leaf disk bioassay ($r = 0.7610$; $P < 0.001$), and the amount eaten in the no-choice ($r = 0.5576$; $P < 0.01$).

DISCUSSION

In general, the antifeedant effect of the compounds was greater with the oligophagous *S. exempta* than with the polyphagous *S. littoralis*. A similar difference in susceptibility has been found previously with these species, both with natural plant compounds and with synthetic derivatives of them (Blaney and Simmonds, 1983; Simmonds and Blaney, 1984; Simmonds et al., 1985; Blaney et al., 1987).

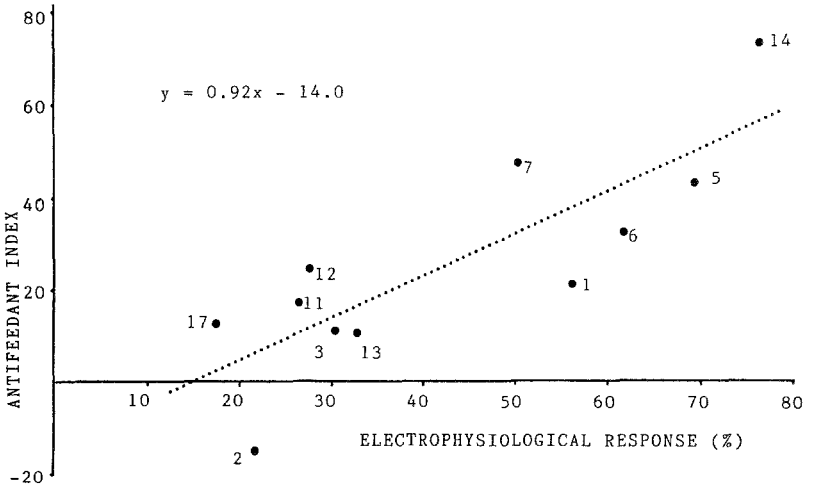

FIG. 4. The relationship between the antifeedant index $[(C - T)/(C + T)]\%$ with larvae of *S. littoralis* in the glass fiber disk bioassay and the electrophysiological response, represented by the firing rate of neuron A given as a percentage of the total firing in the medial styloconic sensillum. Numbers = compounds in Figure 1.

The type of feeding bioassay used affects the results obtained and influences particularly the assessment of a compound as an antifeedant with potential for practical application. Leaves of host plants are generally more palatable to phytophagous insects than glass-fiber disks, even with sucrose added. It is therefore not surprising to find that, overall, the antifeedant activity was lower on leaf disks than on glass-fiber disks. This effect is important, and care should be taken when comparing activity obtained with different bioassays (Simmonds et al., 1985; Lewis and Van Emden, 1986; Blaney et al., 1987).

The fundamental moiety of all these compounds is the C6—C—C—C—C6 system found in chalcones, which may cyclize to give flavanones and other flavonoids including flavanes (Goodwin and Mercer, 1983). The 4-methoxy-flavanes (9 and 10) differ fundamentally from the flavanones and should be considered separately.

Consideration of antifeedant activity in relation to molecular structure indicates that the flavanones were generally more active than the chalcones. There are some interesting structure–activity relationships in which the same substitutions, in both the chalcones and flavanones, are associated with antifeedant activity. Thus the chalcones and their corresponding flavanones most active against both species are 4 and 14 and 5 and 15, respectively.

For *S. littoralis*, a comparison of the antifeedant activity associated with the flavanones 14 and 13 and chalcones 4 and 3 shows that the methoxy substitution at R2 (14 and 4) is more active than the hydroxy substitution at R2 (13 and 3). However, the picture is not so clear for *S. exempta*: in the chalcones, the methoxy substitution (4) is more active than the hydroxy substitution (3), but in the flavanones 13 and 14 both are equally active substitutions. Differences such as this suggest that, while both species have neurons that respond to these compounds, the receptor sites on the relevant neurons of *S. exempta* differ in structure and/or function from those of *S. littoralis*.

In *S. littoralis* the presence of a double bond in the dimethyl chromene ring of flavanone (15) and chalcone (5) appears to be important in determining antifeedant activity because the reduced compounds 16 and 6 are less active. Within the angular 4-methoxy-flavanes (9 and 10), the isopropenylfuran ring in compound 9 is associated with poor antifeedant activity, whereas in compound 10 the dimethyl chromene ring with a double bond conjugated with the aromatic ring is associated with low but increased antifeedant activity. However, the chromene ring is also present in the active phagostimulant (21), although in the presence of an hydroxy substitution at R5.

The introduction in the molecule of a methoxy group at C-5 (compound 15 versus 20) does decrease activity in *S. littoralis* but not in *S. exempta*, whereas the introduction of a hydroxy group at C-3 makes the compound a phagostimulant for *S. littoralis* (21 versus 15).

An important and intriguing consideration in studies such as this is the way

in which information on the palatability status of compounds and mixtures is conveyed to the insect by means of the sensory code for taste quality. In this respect there are fundamental differences between the oligophagous *S. exempta* and the polyphagous *S. littoralis*.

When the maxillary styloconic sensilla of *S. exempta* and *S. littoralis* are stimulated with antifeedant compounds, responses may be evoked from both medial and lateral sensilla (Simmonds and Blaney, 1984; Blaney et al., 1985, 1987, 1988), but, most commonly, it is the response from the medial sensilla that is dose-dependent and correlates best with antifeedant activity. Each sensillum contains four neurons, and all four may be active during a given stimulation, but often only one neuron is entirely or predominantly responsible for the dose-dependent response. In order to discourage prejudgement of the roles and activities of these neurons, we have refrained from identifying them exclusively in terms of the stimulants to which they give the greatest magnitude of response (i.e., "sugar best" or "salt best" neuron) and have called them simply neurons A, B, C, and D. However, in *S. exempta* there is one neuron, neuron A, in the medial sensillum that responds to the majority of compounds that deter feeding, and we, like Ma (1976), refer to this neuron as the "deterrent" neuron.

In the present study with *S. exempta*, the compounds all stimulate predominantly the deterrent neuron in the medial sensillum. However, it is possible that more than one receptor site is involved. Examination of Figure 2 suggests that the compounds fall into two categories. Flavones 11, 12, 13, and 14 elicit similar firing rates, and the resulting behavior is similar, as seen by the amount eaten in the no-choice bioassay or by the antifeedant index in the GFD bioassay. Flavanone 17 and chalcones 1, 2, 3, and 7 constitute another group, stimulating a low rate of firing from neuron A, producing little reduction in the amount eaten in the no-choice bioassay and having no significant longer-term antifeedant activity, as seen in the results of the dual-choice GFD bioassay. The two groups are composed principally of chalcones in the one case and flavanones in the other. It may be that these two groups of compounds stimulate different receptor sites on the same neuron or the same sites with differing effectiveness.

In *S. littoralis*, the fact that the total neural response from the medial styloconic sensillum decreased as the amount eaten decreased is difficult to explain. However, when the neural input is examined in more detail, the response can be explained in terms of the concept of antifeedant compounds stimulating specific neurons (see review by Schoonhoven, 1986). Previous experiments with *S. littoralis* have shown that when a test solution contains both an antifeedant, such as azadirachtin, and a phagostimulant, such as sucrose, dissolved in sodium chloride, the response from the medial sensillum will be lower than that obtained with either the antifeedant or phagostimulant alone (Simmonds and Blaney, 1984). In that particular case, an interaction appeared to occur between neuron

A, responding to the deterrent, and neuron C, responding to the phagostimulant. Whether that interaction occurred between the receptor sites and the compounds or between neurons is not known. The effect seen in the present experiments is likely to be of a different nature since the compounds were dissolved in sodium chloride solution only, and no phagostimulant such as sucrose was present. Nevertheless, a more complex variant of the general theme of a specific deterrent neuron may apply with *S. littoralis*, with two possible modes of action being involved.

First, the decrease in firing with decreased palatability involves a decrease in the firing of both neuron A and neuron C. Compounds 2, 3, 11, 12, 13, and 17 stimulated predominantly neuron C, and compounds 3, 12, 13, and 17 yielded relatively high rates of firing from this neuron, whereas compounds 1, 5, 6, and 14 stimulated predominantly neuron A with relatively low rates of firing (Table 4). In all cases, neuron D was also firing, but at a lower rate than occurred with the control solution, sodium chloride. In general, as palatability decreased, the rate of firing of neuron A increased as a proportion of the total firing. Thus the lack of palatability of some of the compounds is signaled by the response of neuron A. The importance of neuron A in the gustatory code for antifeedant activity has been shown previously for *S. littoralis* with the clerodane diterpenoid compounds (Blaney et al., 1988) and the alkaloidal glycosidase inhibitors (Simmonds et al., 1989).

Second, it is possible that the different levels of response seen in Figure 4 actually derive from the same neuron, rather than two neurons. However, we have been very aware of this possibility and have studied spike height histograms, spike shape profiles, and temporal sequences meticulously in identifying spikes from neurons A, C, and D (Frazier and Hanson, 1986; Blaney et al., 1987, 1988).

Given the fact that we are dealing with a group of structurally similar compounds, it is interesting that, with *S. littoralis*, they appear to be able to stimulate receptors on at least two neurons, and a slight change in the ratio with which they stimulate these neurons correlates with their ability to affect feeding behavior.

The level at which the receptors on each neuron respond to a specific compound may be related to how the compounds engage in stimulus–receptor–ionophore interactions. These interactions would result in different levels of response specific to the receptor sites on the different neurons. The present results suggest that there are at least two different receptor types involved, each having a different structure–function type of response; in *S. exempta* they are situated on one neuron, whereas in *S. littoralis* they are situated on different neurons. However, of the compounds studied here, no aspects of their molecular structure known to us allow us to identify which receptor they would stimulate without exceptions.

Acknowledgments—We thank Miss S. Machin for technical assistance and Dr. F. Hanson for helpful criticism. This work was carried out under MAFF licence No. PHF1020/10 issued under the Import and Export (Plant Health Great Britain) Order 1980 and Plant Pests (Great Britain) Order 1980.

Abstract—A volatile kairomone emitted from lima bean plants (*Phaseolus lunatus*) infested with the spider mite *Tetranychus urticae*, was collected on Tenax-TA and analyzed with GC-MS. Two components were identified as the methylene monoterpene (3*E*)-4,8-dimethyl-1,3,7-nonatriene and the methylene sesquiterpene (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, respectively, after purification by preparative GC on a megabore column and recording of UV, IR, and [^{1}H]NMR spectra. The response of two species of predatory mites towards the identified chemicals was tested in a Y-tube olfactometer. Four of the compounds tested, linalool (3,7-dimethyl-1,6-octadien-3-ol), (*E*)-β-ocimene [(3*E*)-3,7-dimethyl-1,3,6-octatriene], (3*E*)-4,8-dimethyl-1,3,7-nonatriene, and methyl salicylate attracted females of *Phytoseiulus persimilis*. Linalool and methyl salicylate attracted females of *Amblyseius potentillae*. The response of *A. potentillae* to these two kairomone components was affected by the rearing diet of the predators in the same way as was reported for the response to the natural kairomone blend: when reared on a carotenoid-deficient diet, the predators responded to the volatile kairomone of *T. urticae*, but when reared on a carotenoid-containing diet they did not. The identified kairomone components are all known from the plant kingdom. They are not known to be produced by animals de novo.

0098-0331/90/0200-0381$06.00/0

In addition to biological evidence, this chemical evidence suggests that the plant is involved in production of the kairomone. Based on the present study and literature data on the response of *T. urticae* to infochemicals, it is concluded that the kairomone component linalool is also a component of a volatile spider-mite dispersing pheromone.

Key Words—Kairomone, spider mites, predatory mites, lima bean leaves, tritrophic system, methylene monoterpene, methylene sesquiterpene, rearing diet, carotene, identification.

INTRODUCTION

Since the first report on volatile kairomones (sensu Dicke and Sabelis, 1988) in interactions between phytophagous mites and predatory mites (Sabelis and Van de Baan, 1983), a lot of biological information has been obtained on many aspects of these acarine allelochemicals. Volatile kairomones have been reported from 13 acarine prey–predator interactions (Sabelis and Van de Baan, 1983; Sabelis and Dicke, 1985; Dicke and Groeneveld, 1986; Dicke et al., 1986, 1988; Dong and Chant, 1986; Dicke, 1988). Studies have concentrated on the effect of predator condition on the response (Sabelis and Van de Baan, 1983; Dicke and Groeneveld, 1986; Dicke et al., 1986; Dong and Chant, 1986; Dicke, 1988), the type of behavior elicited in the predator by the kairomone (Sabelis et al., 1984a), kairomone preference (Dicke and Groeneveld, 1986; Dicke, 1988), and extraction of the compounds from leaves with methylene chloride and study of their origin (Sabelis et al., 1984b).

As a result of the increased biological knowledge on volatile kairomones in spider mite—predatory mite interactions, questions have arisen that can only be answered by identification of the chemicals involved:

1. Do different predator species, which all respond to the same prey species, use the same chemicals as a source of information? The phytoseiid species *Phytoseiulus persimilis* Athias-Henriot, *Typhlodromus occidentalis* (Nesbitt), *Amblyseius potentillae* (Garman), and *Typhlodromus pyri* Scheuten, all respond to a volatile kairomone of the two-spotted spider mite, *Tetranychus urticae* Koch (Sabelis and Van de Baan, 1983; Dicke et al., 1986; Dicke, 1988). *Tetranychus urticae* is a valuable prey species to the first two predator species, but the latter two are severely hindered by the dense web structure of this prey, which reduces predator reproductive success (Sabelis, 1981; Overmeer, 1981; McMurtry et al., 1970). This difference in profitability is reflected in the response of the predators to a volatile kairomone of *T. urticae*. *Phytoseiulus persimilis* and *T. occidentalis* respond to the kairomone when satiated or starved for 24 hr, respectively (Sabelis and Van de Baan, 1983), but severe quantitative or qualitative food deficiencies are needed to demonstrate the response of *A.*

potentillae and *T. pyri* to the volatile kairomone of the two-spotted spider mite (Dicke et al., 1986; Dicke, 1988; Dicke, unpublished data). It is interesting to know whether the different effects of *T. urticae* on reproductive success of these four phytoseiid species are also reflected in differences in the chemical information used by the predators.

2. What is the function of the volatile kairomone to the prey mite itself? The predators may cue in on any spider mite-related chemical, but as a result of natural selection, only a response to a chemical that is indispensable or inevitable to the prey mite will last long on an evolutionary time scale. From leaves infested with *T. urticae*, a volatile spider-mite dispersing pheromone is emitted, the biological characteristics of which suggest that it may be (partly) identical to the kairomone (Dicke, 1986). However, only identification of the chemicals involved in the intraspecific and interspecific interactions may demonstrate this.

3. What is the origin of the kairomone? An interaction of the host plant and the spider mite is a prerequisite for demonstration of a response by *P. persimilis* (Sabelis et al., 1984a; Dicke, unpublished data). The kairomone in the current tritrophic system is present on previously infested leaves from which all spider mites and visible spider-mite products have been removed (Sabelis et al., 1984a). This indicates that the kairomone may have been produced by the plant and/or by the spider mites that deposited it on the plant. Chemical identification of the kairomone may assist in revealing the origin of the kairomone and the role of the plant and the spider mite in its production.

Here we report on the isolation, by collection of airborne chemicals, and identification of components of the volatile *T. urticae* kairomone.

METHODS AND MATERIALS

Mites. The two-spotted spider mite (*T. urticae*) was reared on lima bean plants (*Phaseolus lunatus* L.) at 20–30°C, 50–70% relative humidity under continuous fluorescent light that was added to the natural daylight regime.

The predatory mite *P. persimilis* was obtained from Koppert BV (Berkel en Rodenrijs, The Netherlands) six years ago. It was reared at ca. 20°C on lima bean leaves infested with *T. urticae*, either on wet cotton wool or on clay flower pots that were put upside down in a water basin.

The predator *A. potentillae* was reared on either of two diets: *Vicia faba* (broad bean) pollen or *T. urticae*. In both cases, the food was provided on plastic arenas (McMurtry and Scriven, 1965; Overmeer, 1985). The predators of these two cultures will be indicated by the suffixes (Vf) and (Tu) respectively. For additional information on rearing history, see Dicke et al. (1989).

Isolation of Kairomone for Analytical Purposes. Twenty lima bean plants, with two to three leaves per plant, were cut and immediately placed in a 5-liter

glass jar with 1 cm of freshly distilled water at the bottom. Care was taken not to damage the plants except for cutting the stem. Three plant treatments were used: clean, infested with spider mites, or damaged mechanically by rubbing the leaves with carborundum on a wet cotton wool pad. A Pyrex glass tube (161 × 6.4 mm OD; ID 3 mm) with 90 mg of Tenax-TA in the center, held in place by two plugs of silanized glass wool, was connected to the outlet of the jar, and a charcoal filter to the inlet. Air was sucked through the system with a membrane pump at ca. 15 ml/min, for 1, 3, 5, 15, or 60 min.

The collected volatiles were released from the adsorbent by heating in a Thermodesorption Cold Trap Unit (Chrompack, Middelburg, The Netherlands) at 250°C for 3 min, with an N_2 flow of 20 ml/min. The desorbed compounds were collected in a cold trap (SIL5CB-coated, fused silica capillary) at −100°C. Flash heating of the cold trap provides sharp injection of the compounds into the capillary column of the gas chromatograph to which the cold trap is connected.

This desorption procedure is inapplicable when thermolabile compounds are present, but that was not the case here: no qualitative differences were observed between the chemicals identified with thermodesorption and those identified after solvent extraction of Tenax on which volatiles were collected from plants infested with *T. urticae*. Thermodesorption was used here because it provides a more sensitive analysis method: all desorbed volatiles are injected into the GC at the same time.

Isolation of Kairomone for Preparative Purposes. Two compounds that could not be identified by analytical GC and GC-MS were collected in larger amounts and purified by preparative GC for subsequent analysis by GC-IR and NMR.

Freshly picked infested lima bean leaves (500–600 g) were put in a stainless-steel cylinder (24.7 cm ID, 40.4 cm high) and flushed with 2.5 ml purified air per second overnight. The air was first pumped through glass tubes containing KOH pellets, mixed molecular sieves 5A and 13X, activated charcoal, and Tenax-TA before entering the cylinder at the center top. The kairomone-containing air left the cylinder at the bottom through a perforated stainless-steel ring near the wall of the cylinder. Via a Teflon tube, the air was led through a glass trap (4.8 mm ID) containing Tenax-TA (ca. 200 mg). The Tenax was cleaned before use by overnight extraction in a Soxhlet apparatus with MeOH, EtOAc, and hexane, respectively. The Tenax with the collected volatiles was extracted with 4 ml pentane–acetone (4 : 1) for 30 min in a micro-Soxhlet on a glass frit. The extract was poured in a conical 5-ml flask and an insulated 25-cm Vigreux column was put on top of the flask. The solution was concentrated to 0.3 ml in a water bath of ca. 42°C. The above procedure was repeated nine times. All the concentrated extracts were combined and concentrated to 0.6 ml. In ca. 20 injections of 25 μl each, the compounds were separated on a megabore

column. The two compounds of interest were trapped in two glass traps cooled to −70°C (the FID was disconnected during trapping). When the traps were not connected to the GC, they were closed with teflon tubing.

Instruments Used. For analytical GC a Varian 3500 gas chromatograph equipped with a 30-m DB-17 (J&W) column was used; split ratio 1 : 100, carrier gas nitrogen; temperature program 60°C (0 min hold) to 210°C (0 min hold) with 2.5°C/min; FID. For preparative purposes a Carlo Erba gas chromatograph equipped with a 30-m DB-1 (J&W) column was used; 0.53 mm ID; 3.0 μm film thickness; no split; carrier gas nitrogen; temperature program 60°C (0 min hold) to 150°C at 5°C/min, then to 210°C at 10°C/min, 10 min hold.

All volatiles were analyzed by GC-MS using a Chrompack SIL19CB column (25 m × 0.25 mm ID). The column temperature was held at ambient for 2 min, then at 40°C for 4 min, and then programmed to 280°C at a rate of 4°C/min. Electron impact ionization was carried out at 70 eV on a VG MM7070F mass spectrometer (resolving power 1000).

The 300-MHz [^{1}H]NMR spectra were recorded in $CDCl_3$ on a Bruker CXP300. The $C\underline{H}Cl_3$ signal was used as an internal reference (7.26 ppm). Assignments were confirmed by homo-nuclear decoupling experiments.

For GC-IR, a Carlo-Erba gas chromatograph equipped with a 30-m DB-1 (J&W) column (film thickness 1 μm, split 1 : 5) connected with a Bruker IFS-85 FT-IR detector was used.

For HPLC, a Gilson 303 pump and a Gilson 116 UV detector were used in combination with a Rainin C18 column, 10 cm × 4.6 mm, 3 μm particle size. Solvent: MeOH–H_2O (9 : 1); flow rate 1 ml/min; detection UV 220 nm.

Synthesis. To synthesize (3*E*)-4,8-dimethyl-1,3,7-nonatriene, geraniol was oxidized with CrO_3 pyridine to geranial, which was converted to the desired product with the Wittig reagent methyltriphenylphosphonium iodide.

To synthesize (3*E*, 7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, (2*E*, 7*E*)-3,7,11-trimethyl-2,7,10-dodecatriene-1-ol (Aldrich) was oxidized with CrO_3 in pyridine to the corresponding aldehyde. This aldehyde was submitted to a Wittig reaction using CH_2I_2, Zn, and $TiCl_4$, yielding the desired product.

Solvents. All solvents used were of analytical or HPLC quality.

Separation of (*Z*)- and (*E*)-β-Ocimene. β-Ocimene (3,7-dimethyl-1,3,6-octatriene) could only be obtained as a mixture of the *Z* and *E* isomers. This mixture was separated by preparative GC on a 9.8% Carbowax on Chromosorb W-HP 100–120 column (200 × 0.2 cm), with a TCD detector and a column temperature of 80°C. The desired isomer was collected in a capillary tube which was cooled in Dry Ice. The ratio of the two isomers in the collected fractions was determined on the same column.

Bioassay. To determine whether extracts or synthetic chemicals had kairomonal activity, a Y-tube olfactometer was used. A glass Y-shaped tube held a Y-shaped iron wire in the center. At the end of both arms of the olfactometer,

filter paper (15 cm^2) with test or control solutions was placed in PVC cages. Air was sucked out at the base of the tube and led to the outside of the climate room in which the olfactometer was positioned. The air speed in both arms of the olfactometer was measured with a hot wire anemometer and standardized at 0.7 ± 0.1 m/sec by adding dry cotton wool in the PVC cages and/or changing the total airflow speed with a valve. Female predators were placed on the wire in the basal tube and observed individually. When the predator walked upwind and reached the far end of one of the arms, the experiment was terminated. A sign test was used to analyze the results ($\alpha = 0.05$). The experiments were performed at $25 \pm 1°C$ and $60 \pm 10\%$ relative humidity.

Only female predators were tested in the olfactometer. In the case of *P. persimilis*, they were well-fed, but unless stated otherwise, *A. potentillae* females were tested after a 20-hr period of starvation in a plastic tube at 25°C.

The chemicals were dissolved in dichloromethane [(*Z*/*E*)-β-ocimene, linalool (3,7-dimethyl-1,6-octadien-3-ol) and methyl salicylate], paraffin oil [1-octen-3-ol, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexen-1-yl acetate, 4,8-dimethyl 1,3,7-nonatriene] or hexane [(*Z*/*E*)-β-ocimene]. Aliquots of 0.1 ml of diluted chemicals were poured onto a piece of filter paper outside the climate room and transferred to the olfactometer immediately. A filter paper with 0.1 ml solvent served as control. In these tests, new filter papers were prepared for each predator tested. All chemicals were obtained from Aldrich except for (*Z*)-3-hexen-1-yl acetate, which was a Roth product; β-ocimene, which was obtained as a mixture of isomers from International Flavor and Fragrances Industries or from Dr. J. H. Tumlinson (USDA, Gainesville, Florida) and (3*E*)-4,8-dimethyl-1,3,7-nonatriene isomers and (3*E*, 7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, which were synthesized (see above). All chemicals, except (*Z*/*E*)-β-ocimene (see Results) and the methylene terpenes, were ≥ 98% pure. The methylene terpenes were ca. 90% pure, as a result of rapidly occurring racemization.

RESULTS

Collection of Kairomone and Identification. The suitability of Tenax-TA to collect the volatile kairomone of *T. urticae* was demonstrated in the olfactometer with satiated females of *P. persimilis*: 31 of 49 predators chose the arm with solvent extract of Tenax on which volatiles of spider mite-infested plants had been collected ($P = 0.04$). By GC-MS analysis of the mixture of volatiles collected from spider mite-infested plants on Tenax-TA, many components could be distinguished (Table 1, Figure 1). Only three of these (2-butanone, 2-hexanal 1-octen-3-ol) have been found in samples collected from clean intact bean plants (Table 1). Some others, such as the general green leaf volatiles (*Z*)-3-hexen-1-

[a] *P. persimilis* were tested as satiated females, *A. potentillae* as females that were starved for 24 hr at 25°C. Data on *T. urticae* are based on the data of Dabrowski and Rodriguez (1971), Rodriguez et al. (1976) and Dicke (1986).
[b] Uncertain because pure isomer was not tested.

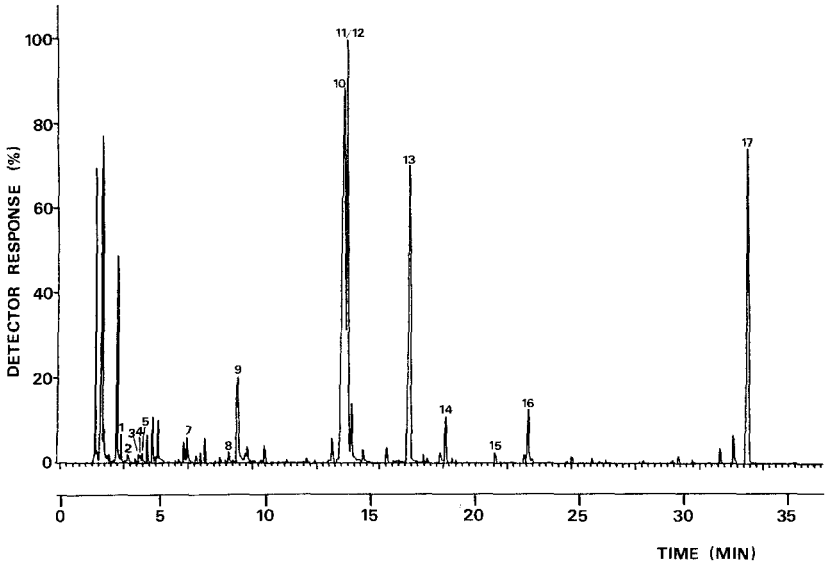

FIG. 1. Gas chromatogram of volatiles from spider mite-infested bean plants collected on Tenax-TA. Peak numbers correspond to numbers given in Table 1. Most unlabeled peaks are artifactual peaks.

ol and (Z)-3-hexen-1-yl acetate are expected to be emitted by lima bean plants, but if so, the quantities were very small compared to the amounts of these compounds that were obtained from spider mite-infested bean plants. An analysis of the volatiles released by artificially damaged plants revealed several compounds that are also emitted by spider mite-infested plants (Table 1). Thus, emission of these compounds from spider mite-infested plants presumably is the result of mechanical damage of the plant. The other volatiles emitted from *T. urticae*-infested bean plants are caused by other spider-mite activities or are emitted from the spider mites themselves.

Two major components of the volatile kairomone could not be readily identified. Their mass spectra showed the molecular ion at *m/z* 150 and *m/z* 218, respectively, with similar fragmentation patterns (base peak for both at *m/z* 69). The difference between the two compounds was most likely one isoprene unit. Initially they were thought to be the furanoterpenes perillene and dendrolasin because of the almost identical mass spectra. However, a sample of a ginger oil, which was investigated at the same time, contained both perillene and the unknown compound. As it was not possible to deduce the correct structures from MS alone, we tried to isolate the two compounds in larger quantities and to record [^{1}H]NMR and IR spectra.

Initial attempts to separate and purify these two compounds by means of GC on a packed column failed. However, no separation could be obtained. The reason for this could be the low sensitivity of the TCD or the low inertness (leading to excessive tailing or decomposition of the compounds involved) of the column used. A separation by reverse-phase-HPLC was successful, but during isolation of the very small quantities of apolar pure compounds from the aqueous solvents, too many impurities were introduced for recording of high-quality NMR spectra. Also, evaporation of the solvent inevitably resulted in loss of the volatile compounds. Separation and purification of the two compounds was successful by preparative capillary GC on a megabore column, a relatively new technique. This technique combines good inertness with high separation power and a relatively high loadability. [^{1}H]NMR spectra showed that the resulting samples consisted of pure compounds. Altogether an estimated 300 μg (mol wt = 150) and 200 μg (mol wt = 218) were collected. The IR spectra, recorded immediately before NMR analysis, most closely resembled the IR spectra of monoterpene hydrocarbons. No evidence for the presence of any oxygen-containing functional group could be found. The most likely molecular formulas were thus $C_{11}H_{18}$ and $C_{16}H_{26}$ instead of $C_{10}H_{14}O$ (perillene) and $C_{15}H_{22}O$ (dendrolasin). From the NMR data, structure **1** (Figure 2) or its *Z* isomer followed for the lower molecular weight compound. Especially the signal at 6.58 ppm with coupling constants of 17, 10.5, and 10.5 Hz (corresponding with H-2) was most helpful in elucidating the structure. As it was not possible to determine whether the compound possessed the *E* or *Z* configuration, both were synthesized. By comparison of the spectral data and retention times of the isolated compound and the synthesized isomers, it was clear that the isolated compound had the *E* configuration. The higher-molecular-

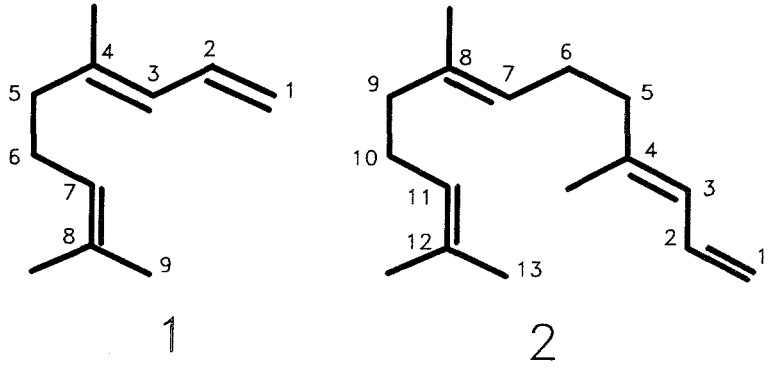

FIG. 2. Structures of the methylene terpenes (3*E*)-4,8-dimethyl-1,3,7-nonatriene (**1**) and (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (**2**).

weight compound was now assigned structure **2** (Figure 2). The configuration around the 3,4 double bond is the same as in **1**, because of the identical chemical shifts and coupling constants. The configuration around the 7,8 double bond was deduced to be *E* from the chemical shift of the 7-methyl group at 1.61 ppm. In the case of the opposite configuration, the 7-methyl group would have appeared around 1.68 ppm. The structure of compound **2** was also confirmed by synthesis.

Bioassay of Identified Components. The effect on the predatory mite *P. persimilis* of those identified chemicals that were available was tested in the Y-tube olfactometer. Figure 3 shows that linalool is attractive to *P. persimilis* females at a wide dose range, whereas methyl salicylate proved to be attractive only when offered at an amount of 20 μg. The dose range was based on the finding that the amounts of each compound recovered from 20 plants during 60 min of sampling were in the range of one to several tens of micrograms. (*Z*)-3-Hexen-1-ol, (*Z*)-3-hexen-1-yl acetate, and 1-octen-3-ol did not attract the predators. These latter compounds had been identified in samples obtained from both artificially damaged and spider mite-infested plants.

The data for ocimene are presented in Figure 4. β-Ocimene was obtained as mixtures of the *E* and *Z* isomers at ratios of 90:10 and 70:30. Gas chromatography on 3% OV-17 showed that some minor compounds were also present. When tested in the olfactometer, only the 90:10 (*E*, *Z*)-β-ocimene mixture proved attractive to *P. persimilis*, either when 20, 2, or 0.2 μg were offered. When the dose offered was only 0.02 μg, no response was observed. The difference in response of *P. persimilis* to the two β-ocimene samples could be

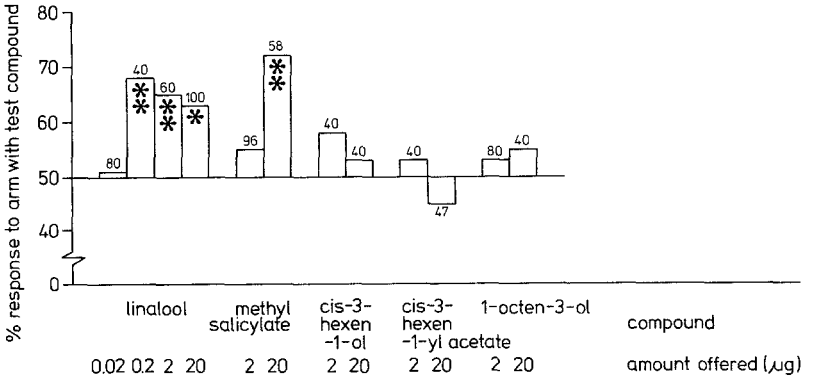

FIG. 3. Choice of *P. persimilis* females in Y-tube olfactometer to various doses of chemicals identified after collection of volatiles emitted from *T. urticae*-infested lima bean plants. Numbers under and above columns indicate the number of predators tested. **$0.001 < P < 0.01$; *$0.01 < P < 0.05$.

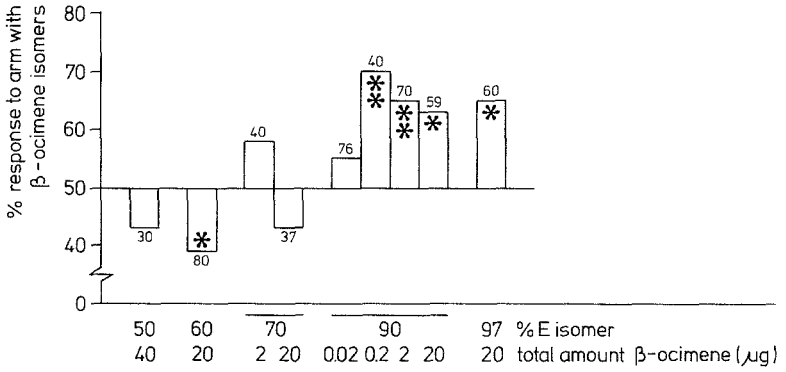

FIG. 4. Choice of *P. persimilis* females in Y-tube olfactometer to β-ocimene, offered at various *E*/*Z* ratios and various doses. Numbers under and above columns indicate the number of predators tested. For explanation of asterisks, see Figure 3.

caused by the impurities or by the difference in *E*/*Z* ratio. To investigate this, *E*/*Z* ratios of 50:50 and 60:40 were prepared from the 90:10 sample and a 97:3 *E*/*Z* ratio from the 70:30 sample. The 97:3 sample was attractive, but the 50:50 sample was not. The 60:40 *E*/*Z* ratio was even repellent. These data show that (*Z*)-β-ocimene reduced the attractivity of (*E*)-β-ocimene to *P. persimilis*.

Experiments with the methylene terpenes (3*E*)-4,8-dimethyl-1,3,7-nonatriene and (3*E*, 7*E*)-1,4,8-trimethyl,1,3,7,11-tridecatetraene show that 20 μg of the former compound is also attractive to *P. persimilis*, whereas its *Z* isomer is not (Figure 5). No response of *P. persimilis* towards (3*E*, 7*E*)-1,4,8-trimethyl-1,3,7,11-tridecatetraene was recorded (Figure 5).

Amblyseius potentillae responded to the natural kairomone blend when reared on a carotenoid-deficient diet such as *V. faba* pollen, but not when reared on the carotenoid-containing spider mite *T. urticae* (Dicke et al., 1986). Predators that differed in qualitative feeding history were offered the identified chemicals. The results (Figure 6) show that when amounts of 20 μg were offered, no chemical was attractive to *A. potentillae* (Tu). However, when the predator was reared on *V. faba* pollen, methyl salicylate and linalool were attractive, which resembles the data obtained for *P. persimilis*. However, in contrast to *P. persimilis*, *A. potentillae* (Vf) did not respond to 90:10 *E*/*Z* β-ocimene. Either (*E*)-β-ocimene is not attractive or the presence of 10% of the *Z* isomer or the other impurities disturbed the response of *A. potentillae* to the *E* isomer.

The response of *A. potentillae* to linalool was studied in more detail (Figure 7). Three different concentrations were tested: 20, 2, and 0.2 μg. When reared on *V. faba* pollen, all three concentrations attracted predators that were

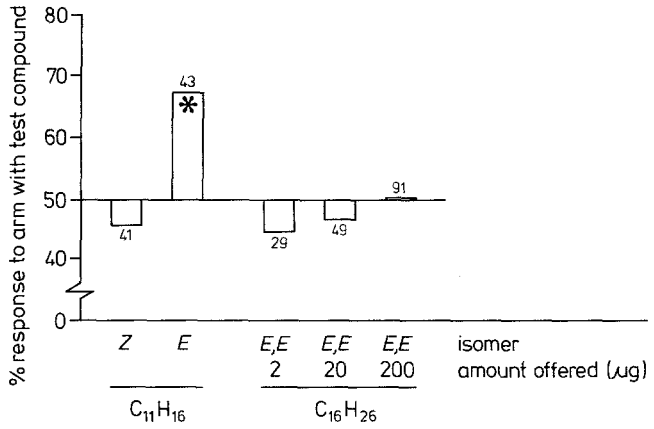

FIG. 5. Choice of *P. persimilis* females in Y-tube olfactometer to 4,8-dimethyl-1,3,7-nonatriene isomers and (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene. Numbers under and above columns indicate the number of predators tested. For explanation of asterisks, see Figure 3.

starved for 20 hr. When satiated, these predators also responded to 2 µg linalool. A response to the volatile *T. urticae* kairomone in well-fed *A. potentillae* has only been observed when the predators were reared on *V. faba* pollen (Dicke, unpublished data). In contrast to the data for *A. potentillae* (Vf), amounts of

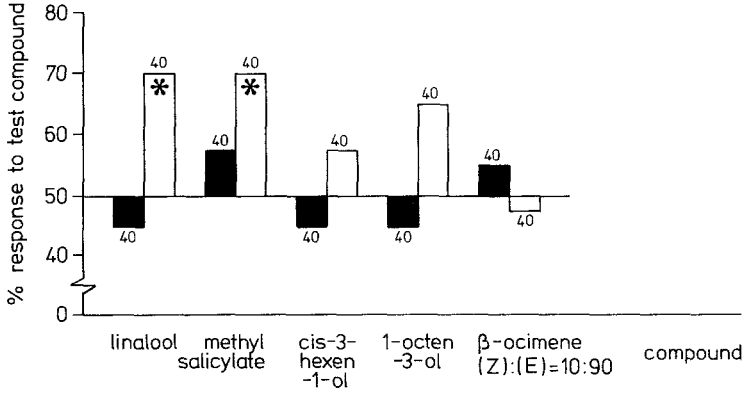

FIG. 6. Choice of starved female *A. potentillae* (Tu) (black bars) and *A. potentillae* (Vf) (white bars) in Y-tube olfactometer to synthetic chemicals (dose: 20 µg), identified after collection of volatiles from *T. urticae*-infested lima bean plants. For explanation of asterisks, see Figure 3. Numbers under and above columns indicate the number of predators tested.

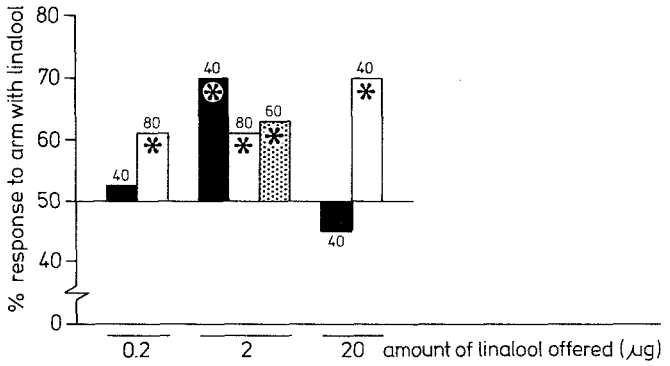

FIG. 7. Choice of starved female *A. potentillae* (Tu) (black bars) and starved and satiated *A. potentillae* (Vf) (white bars: starved; shaded bar: satiated) in Y-tube olfactometer to linalool at various doses. For explanation of asterisks, see Figure 3. Numbers under and above columns indicate the number of predators tested.

20 and 0.2 μg linalool were not attractive to *A. potentillae* (Tu) that were starved for 20 hr, but when 2 μg linalool was offered, a significant response was observed in these predators. The data for the responses of both predator species are summarized in Table 1.

DISCUSSION

Damage inflicted on lima bean plants by rubbing the leaves with carborundum or by infestation with spider mites caused emission of many volatiles. However, a clear difference was observed between the volatile mixture emitted from plants damaged in either way. Most of the major volatiles emitted from clean lima bean plants, plants damaged mechanically, or plants infested with *T. urticae* were identified. The amounts of volatiles emitted from spider mite-infested plants were large enough to allow short sampling times in our investigation. However, minor compounds may have been missed.

Shortly after our identification of the two methylene terpenes (Figure 2), Maurer et al. (1986) reported the isolation of these compounds from *Elettaria cardamomum* (cardamom) oil, which, like ginger, is a species from the Zingiberaceae family. The spectral data reported by Maurer et al. (1986) are identical to the data recorded by us. In 1987, independent of our work, the same compounds were reported by Kaiser (1987) from flowers of many night-scented plant species of different families that are pollinated by moths.

The odor differences observed between plants that are in different condition, will allow many organisms to distinguish between them. This will be discussed according to the three questions posed in the Introduction.

1. Do different predator species use similar chemicals as volatile *T. urticae* kairomone? Four compounds elicited a significantly attractive response from at least one of the predator populations tested: these compounds are the terpenes linalool and (*E*)-β-ocimene, the methylene terpene (3*E*)-4,8-dimethyl-1,3,7-nonatriene, and methyl salicylate.

All four compounds attracted *P. persimilis* females although methyl salicylate only elicited this response when offered at a dose of 20 μg. The effect of linalool and methyl salicylate on *A. potentillae* (Vf) is similar to that on *P. persimilis*. With respect to (*E*)-β-ocimene, no definitive conclusion can yet be made, because it is not known whether the presence of 10% *Z* isomer affected the behavior of *A. potentillae* (Vf) towards (*E*)-β-ocimene.

With regard to the kairomone components linalool and methyl salicylate, the data obtained for *A. potentillae* reared on either of the two diets are in agreement with those of Dicke et al. (1986) and Dicke (in preparation) on the response of *A. potentillae* to the volatiles emitted by *T. urticae*-infested plants. The only exception is the response of *A. potentillae* (Tu) to 2 μg linalool. This may indicate that *A. potentillae* (Tu) are sensitive to this component of the volatile *T. urticae* kairomone, although much less than *A. potentillae* (Vf), which respond much more consistently to linalool.

Our observations provide no reason to suppose that different predator species use different volatiles emitted from *T. urticae*-infested plants as kairomone. Investigations with other phytoseiid species, such as *T. occidentalis* or *T. pyri* are needed.

2. Do kairomone components function as dispersing pheromone for spider mites? The spider mite *T. urticae* also distinguishes between undamaged and *T. urticae*-damaged lima bean plants. Clean leaves emit a volatile kairomone that attracts spider-mite females. After infestation with *T. urticae*, the leaves emit a dispersing pheromone in addition. At a high ratio of dispersing pheromone to plant kairomone, the spider mites are repelled (Dicke, 1986).

It is interesting to investigate whether the chemicals that act as a kairomone to predatory mites act as a spider-mite dispersing pheromone. Some indications for this can be found in a study on host plant–spider mite interaction. Dabrowski and Rodriguez (1971) studied the response of *T. urticae* females to essential oil components of strawberry foliage. In a static air olfactometer, linalool repelled the mites at several concentrations. Methyl salicylate was indifferent, whereas (*E*)-β-ocimene or (3*E*)-4,8-dimethyl-1,3,7-nonatriene were not included in their study. In a later study by Rodriguez et al. (1976), mixtures of compounds were used. A mixture resembling strawberry essential oil attracted *T. urticae* females. An increase in the proportion of nonanal, one of the components, reduced the attractive effect. However, an increase in the proportion of methyl salicylate had no effect. Unfortunately, the effect of a change in the proportion of linalool was not studied.

In the context of the present study and the one by Dicke (1986), the data of Dabrowski and Rodriguez (1971) indicate that linalool is not only a component of the *T. urticae* kairomone that attracts predatory mites, but also of the *T. urticae* dispersing pheromone. This supports the hypothesis that the dispersing pheromone and the spider-mite kairomone have components in common (Dicke, 1986). There is no evidence that the kairomone component methyl salicylate is a component of the dispersing pheromone (Rodriguez et al., 1976). These data on the identity of components of the *T. urticae* dispersing pheromone are incorporated into Table 1. It will be interesting to investigate the effect of (*E*)-β-ocimene and (3*E*)-4,8-dimethyl-1,3,7-nonatriene on *T. urticae* females to know whether these kairomone components are also a component of the dispersing pheromone.

3. What is the origin of the volatile kairomone? The above considerations raise the question of the origin of the allelochemicals that function in plant–spider mite–predatory mite interactions. The chemicals presumably are of plant origin, as can be inferred from the classes of compounds identified (e.g., Karrer, 1976; Maurer et al., 1986). However, it cannot be concluded yet that the plant has active control over the production or emission of the volatiles or that the plant offers a substrate for spider-mite enzymes that subsequently produce the kairomone components. Investigation of, e.g., site and moment of production and possible storage of precursors are needed for that. Chemical identification of kairomone components was an essential first step for this.

(Received September 19, 1988; accepted February 22, 1989)

Abstract—Using gas chromatography–mass spectrometry 33 constituents of the preorbital gland of the grey duiker, *Sylvicapra grimmia*, were identified as unbranched alkanes, 2-alkanones, alkanals, alkanoic acids, alkan-4-olides, as well as 3-methyl-3-buten-1-ol, (Z)-9-octadecenoic acid, benzyl cyanide, diethyl sulfoxide, 2-isobutyl-1,3-thiazole, 2-isobutyl-4,5-dihydro-1,3-thiazole, and 3,4-epoxy-2-dodecanone. Determination of the relative concentrations of these components in a limited number of secretion samples taken from males and females revealed that in these samples the two thiazole derivatives and the epoxy ketone were present in consistently and significantly higher concentrations in male than in female secretions. This suggests that they could act as sex recognition cues.

Key Words—*Sylvicapra grimmia*, Bovidae, semiochemicals, pheromones, exocrine secretion, preorbital secretions, thiazoles, epoxy ketone, mammalian gland secretion, antelope, grey duiker.

INTRODUCTION

In many groups of mammals odoriferous substances that act as semiochemicals are produced by cutaneous glands. These glands are common in carnivores and rodents and in most ungulate groups, but are also found in many other orders (Schaffer, 1940). Volatile substances may be released into the atmosphere by diffusion directly from the glands, but in most cases that have been described, objects are marked with secretions from these glands.

Scent marking with glandular exudate is often associated with territorial behavior (Eisenberg and Kleiman, 1972) and several bovid species, such as the grysbok, *Raphicerus melanotis*, and the grey duiker, *Sylvicapra grimmia*, employ secretions from their preorbital glands for this purpose. These small antelope cause damage of some economic significance in vineyards, orchards, and pine plantations in parts of South Africa (Bigalke, 1974). A research program was therefore initiated to identify the semiochemicals produced in these preorbital glands and to investigate the feasibility of reducing damage by the use of synthetic pheromones.

This research program was started with the chemical characterization of the preorbital gland secretion of the grysbok, *Rhaphicerus melanotis* (Burger et al., 1981). A total of 27 straight-chain compounds, which can be classified as alkanols, alkenols, alkadienols, alkanyl methanoates, alkenyl methanoates, and alkanoic acids, were identified in the secretion.

Although the ritual involved in marking objects with preorbital gland secretions undoubtedly plays an important part in the behavior of male grysbok, there is no experimental evidence to indicate whether the olfactory stimuli released from the deposited material serve as deterrents signalling territorial occupancy to other males (Novellie et al., 1984). It is, however, possible that olfactory cues play a more important part in the territorial behavior of more primitive species than in that of the grysbok. The grey duiker, *Sylvicapra grimmia*, a small cephalophine antelope, is considered by some authors to fall into this category (Estes, 1974) and was selected for investigation. In this paper the identification of the volatile organic constituents of the preorbital gland secretion of the grey duiker, and the results of the quantitative determination of these constituents in individual males and females, are reported.

METHODS AND MATERIALS

General. Dichloromethane (Merck, Residue Analysis Grade) was analyzed gas chromatographically and found to be pure enough for extraction purposes when used in small quantities. All Pyrex glassware used in the handling of biological material and extracts thereof was heated to 500°C in an annealing

oven to remove traces of organic material. Syringes, stainless-steel needles, etc., that were used to handle material, were cleaned by rinsing with the dichloromethane specified above.

Analytical Methods. Gas chromatographic analyses (GC) were carried out with a Carlo Erba 5300 (Mega) gas chromatograph equipped with a flame ionization detector, a Grob split–splitless injector and a 45-m Pyrex capillary column (ID 0.32) coated with a 1.0-μm film of PS-089-OH (Petrarch Systems, Bristol, Pennsylvania) which is a silanol-terminated (95%)–dimethyl–(5%)–diphenylsiloxane copolymer. The column was manufactured according to procedures developed by Blum (1985) for similar silanol-terminated phases. Helium was used as carrier gas at a linear velocity of 28.6 cm/sec at 40°C. The flame ionization detector was operated at 260°C. The injector was normally used at 200°C. Samples were injected in the splitless mode and the split valve was opened after 1 min. The volatiles entering the column were thermally focused and subsequently analyzed using the following temperature program: 25°C (1 min), programmed at 25°C/min to 40°C (5 min) and programmed at 2°C/min to 240°C (hold).

GC data were stored and processed with a Hewlett-Packard XTRA CHROM II Data System using a Nelson Analytical 192-K interface. Electron-impact (EI) mass spectra were recorded at 70 eV on a Finnigan MAT 4500 GC-MS instrument, using the GC column and conditions described above. Chemical-ionization (CI) mass spectra were obtained with methane as reactant gas. High-resolution mass-spectral data were obtained with a Varian MAT 311A mass spectrometer and a Kratos DS90 data system. [^{1}H]- and [^{13}C]NMR spectra were recorded at 300 MHz and 75 MHz, respectively, on a Varian VXR-300 spectrometer using a probe temperature of 26°C.

Sample Preparation and Analysis. Preorbital gland secretion was collected individually from netted or culled, sexually mature male and female animals by scooping the exudate with Reacti-Vials from the row of preorbital pores through which it is released from the underlying preorbital gland. To avoid handling the very sensitive duikers, material was also collected from territorial marks, freshly deposited on precleaned aluminum foil. The organic volatiles were extracted by vigorously shaking each collected sample (0.4–1.0 g) with dichloromethane (0.5–1.2 ml) in a mechanical flask shaker for 6 hr, centrifuging the resulting emulsion for 2 hr at 3000 rpm, removing the dichloromethane extract from underneath the supernatant water and mucus layer with a 1000-μl syringe and transferring it to a clean Reacti-Vial. These extracts were further concentrated in an inert, purified (activated charcoal) nitrogen atmosphere for GC-MS analysis. For quantitative comparison of the secretions of individual grey duikers, these extracts were diluted with dichloromethane to approximately the original volume of the collected material. Thus, an extract was diluted to, for instance, 430 μl if 430 mg of material had initially been collected from an animal. The

extracts obtained by this procedure were used without further concentration to obtain quantitative gas chromatographic data.

To avoid the introduction of artifacts into the extracted organic material by the use of a solvent, the authenticity of the constituents identified in the secretion was verified by collecting secretion in glass capillaries that were introduced into the inlet of the gas chromatograph without any further sample preparation. This was achieved by using a slightly adapted version of the solventless injection technique described by Burger et al. (1985). A strand of glass wool was inserted very loosely into the first section (25 mm) of a glass capillary (80 mm × 1.0 mm ID). This section of the capillary was cooled (ca. −50°C) with a small copper heat sink, which had been precooled in liquid N_2. Secretion (ca. 10 μl) was carefully drawn into this part of the capillary, which was then sealed off at a point about 30 mm from its inlet end. The heat sink was removed and the sample-containing end of the capillary introduced to a depth of ca. 50 mm into the injector, maintained at a temperature of 200°C (splitless mode) of the gas chromatograph through an otherwise stoppered hole in the septum, while keeping the column at room temperature. After 1 min the capillary was replaced by a glass stopper, the split valve opened, and the temperature program started. In an alternative procedure, in which the sample is not subjected to excessively high temperatures, the crude secretion was introduced into the injector at a low temperature (60–100°C), whereafter the injector was ballistically heated to 200°C, thus allowing volatile material to evaporate and be transported onto the column at the lowest possible temperature. The final injector temperature was maintained for 2 min, whereafter the split valve was opened, the injector heater switched off and the capillary with involatile residue replaced by a glass stopper. In this procedure the temperature program was adapted to allow for an isothermal period of 2 min at ambient temperature, although using a shorter isothermal period did not materially affect the efficiency of the GC separation.

Synthetic Reference Compounds. Synthetic samples of some of the compounds identified in the preorbital gland secretion of the grey duiker were obtained from Merck (Darmstadt), Fluka (Buchs), and Aldrich (Milwaukee, Wisconsin). Compounds that are not commercially available were synthesized. Melting and boiling points are uncorrected.

Octadecan-4-olide was prepared from 1-hexadecene according to the method of Heiba et al. (1974). The reaction product was purified by distillation at 158°C/2 torr (yield 43%) and recrystallization to give the pure lactone as fine colorless needles, mp 48.5–49.5°C (EtOH); [^{13}C]NMR ($CDCl_3$): δ 177.24 (s, C-1), 28.87 (t, C-2), 28.03 (t, C-3), 81.06 (d, C-4), 35.62 (t, C-5), 25.25 (t, C-6), 29.71 (t, C-7), 29.70 (t), 29.68 (t), 29.68 (t), 29.64 (t), 29.55 (t), 29.49 (t), 29.38 (t), 29.37 (t) (C-8 to C-15), 31.95 (t, C-16), 22.71 (t, C-17), 14.12 (q, C-18).

Hexadecan-4-olide was prepared in an analogous manner from 1-tetrade-

cene. Distillation and crystallization from ethanol gave the γ-lactone as colorless crystals (yield 46%) bp 121°C/0.01 torr, mp 41–43°C; [^{13}C]NMR ($CDCl_3$): δ 177.24 (s, C-1), 28.87 (t, C-2), 28.04 (t, C-3), 81.06 (d, C-4), 35.63 (t, C-5), 25.26 (t, C-6), 29.68 (t, C-7), 29.65 (t), 29.65 (t), 29.55 (t), 29.49 (t), 29.37 (t), 29.37 (t)(C-8 to C-13), 31.94 (t, C-14), 22.71 (t, C-15), 14.12 (q, C-16).

3-Dodecen-2-one (Scheme 1 below, **3**) was prepared by a crossed aldol condensation of acetone and nonanal (**1**) followed by an acid catalyzed elimination of water from the resulting hydroxy ketone **2,** according to the method given by Tishchenko and Stanishevskii (1963) for the preparation of 3-nonen-2-one. Nonanal trimer (14.2 g) was depolymerized by stirring it with 6 M HCl (2 ml) for 2 hr, whereafter acetone was added to the reaction mixture and the resulting solution slowly added to a stirred solution of 2.5 M NaOH (10 ml) in acetone (16 ml) over a period of 2 hr at a temperature that did not exceed 12°C. After another hour at room temperature, the reaction mixture was diluted with ice (40 g), neutralized with 6 M HCl, and the acetone removed on a rotary evaporator. The organic material was extracted with ether and the combined extracts washed with saturated $NaHCO_3$ and saturated saline solution. The ether solution was dried and after filtration and evaporation of the solvent, the residue was distilled (123°C/0.001 torr) to give the condensation product (3.3 g), which was refluxed in benzene (13 ml) with *p*-toluenesulfonic acid (7 mg) in the presence of anhydrous Na_2SO_4 (1.3 g) for 1 hr. The drying agent was removed by filtration and the filtrate washed with saturated $NaHCO_3$, whereafter the benzene solution was dried, filtered, and the solvent removed under reduced pressure. Distillation of the resulting residue gave 3-dodecen-2-one (**3**) (1.97 g, 65%) as a colorless liquid, bp 82°C/0.01 torr; [^{1}H]NMR ($CDCl_3$): δ 6.808 (1H, H-4, dt, $J_{3,4}$ = 16.0, $J_{4,5}$ = 6.9), 6.070 (1H, H-3, dt, $J_{3,4}$ = 16.0, $J_{3,5}$ = 1.5), 2.236 (3H, H-1, s), 2.223 (2H, H-5, m), 1.469 (2H, H-6, m), 1.274 (10H, H-7 to H-11, CH_2 envelope), 0.883 (3H, H-12, t, $J_{11,12}$ = 6.7); [^{13}C]NMR ($CDCl_3$): δ 26.80 (q, C-1), 198.68 (s, C-2), 131.32 (d, C-3), 148.63 (d, C-4), 32.52 (t, C-5), 28.16 (t, C-6), 29.24 (t, C-7), 29.24 (t, C-8), 29.40 (t, C-9), 31.89 (t, C-10), 22.69 (t, C-11), 14.10 (q, C-12).

Dodecen-2-one-3,4-epoxide (Figure 1 below, 6294) was prepared according to the method of Wasson and House (1957). A solution of 3-dodecen-2-one (**3**) (1.9 g) in methanol (12 ml) was treated with H_2O_2 (35%, 2.4 ml) and 6 M NaOH added over a period of 55 min at 15°C. The reaction mixture was stirred at 20–25°C for a further hour, whereafter it was diluted with water (13 ml) and extracted with ether. The combined ether extracts were washed three times with water and once with potassium iodide solution (3%). The usual work-up procedure gave the epoxy ketone 6294 as a colorless oil (1.24 g, 61% yield), bp 80°C/0.07 torr; [^{1}H]NMR ($CDCl_3$): δ 3.176 (1H, H-3, d, $J_{3,4}$ = 2.0), 3.074 (1H, H-4, ddd, $J_{3,4}$ = 2.0, $J_{4,5a}$ = 5.9, $J_{4,5b}$ = 5.0), 2.057 (3H, H-1, s), 1.620

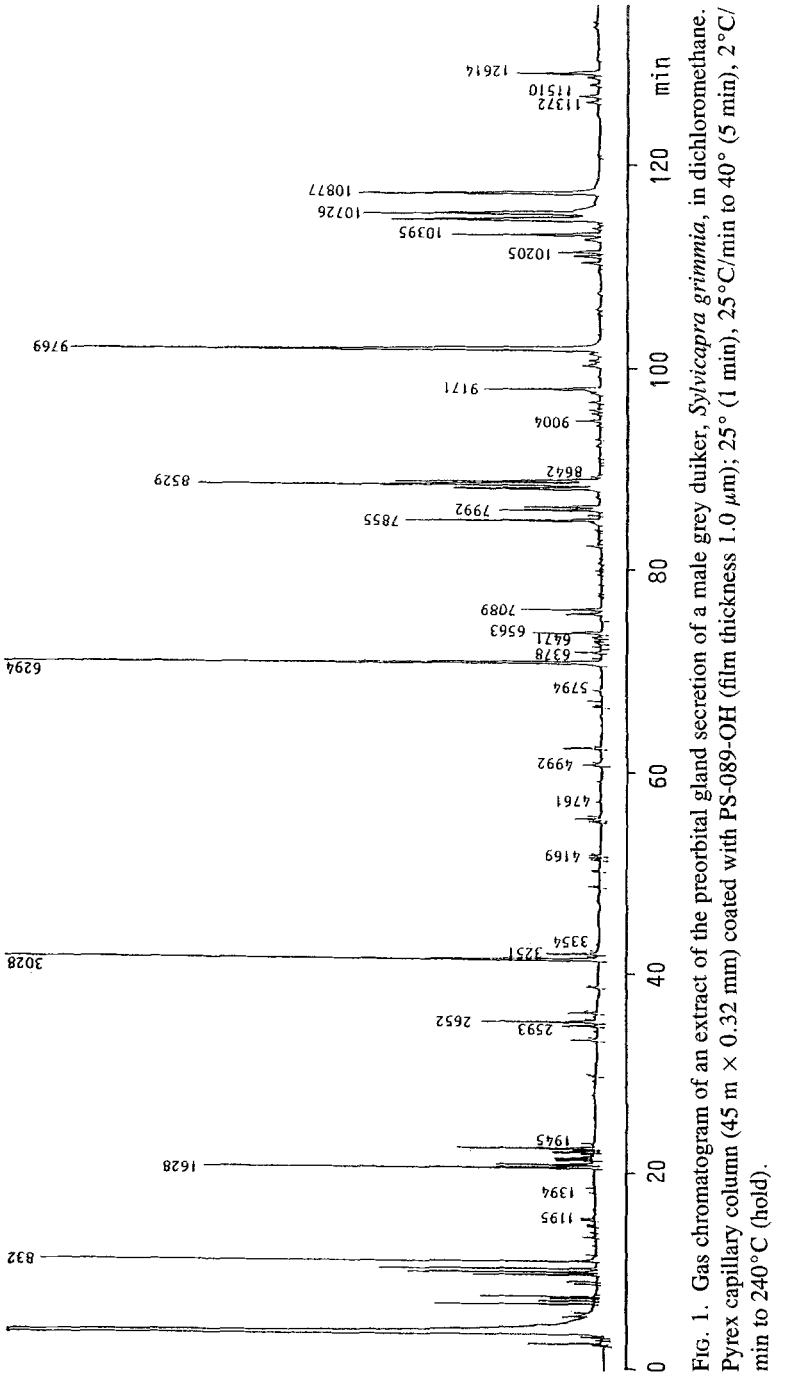

FIG. 1. Gas chromatogram of an extract of the preorbital gland secretion of a male grey duiker, *Sylvicapra grimmia*, in dichloromethane. Pyrex capillary column (45 m × 0.32 mm) coated with PS-089-OH (film thickness 1.0 μm); 25° (1 min), 25°C/min to 40° (5 min), 2°C/min to 240°C (hold).

(2H, H-5, m), 1.466 (2H, H-6, m), 1.275 (10H, H-7 to H-11, CH_2 envelope), 0.883 (3H, H-12, t, $J_{11,12} = 6.7$); [^{13}C]NMR ($CDCl_3$): δ 24.31 (q, C-1), 205.99 (s, C-2), 59.97 (d, C-3), 58.08 (d, C-4), 31.82 (t, C-5), 25.81 (t, C-6), 29.18 (t, C-7), 29.29 (t, C-8), 29.44 (t, C-9), 31.85 (t, C-10), 22.67 (t, C-11), 14.09 (q, C-12).

2-Isobutyl-4,5-dihydro-1,3-thiazole was synthesized (Burger et al., 1988) according to the procedure described by Wenker (1935) for 2-methyl-4,5-dihydro-1,3-thiazole. In the final step of this synthesis phosphorus pentasulfide (8.9 g, 20 mmol) and *N*-(2-hydroxyethyl) isovaleramide (14.5 g, 100 mmol) were mixed in a distilling flask fitted with an efficient cooler. The mixture was heated in an oil bath at 180°C, at which temperature the reaction took place and the required reaction product distilled from the flask at reduced pressure (110 torr). The crude product was dried on KOH and distilled to give the pure 2-isobutyl-4,5-dihydro-1,3-thiazole in a yield of 28%, bp 79°C/10 torr [lit. 70–73°C/10 torr (Meyers and Durandetta, 1975)]; [^{1}H]NMR ($CDCl_3$): δ 0.94 (6H, d, $J = 6.5$ Hz), 2.03 (1H, m, $J = 6.8$ Hz), 2.40 (2H, dt, $J = 6.8$ Hz; $J = 1.7$ Hz), 3.28 (2H, t, $J = 8.2$ Hz), 4.22 (2H, tt, $J = 8.4$ Hz; $J = 1.6$ Hz). [^{13}C]NMR ($CDCl_3$): δ 22.32 (2C, q), 27.52 (d), 33.65 (t), 43.16 (t), 64.14 (t), 171.29 (s).

2-Isobutyl-1,3-thiazole was prepared by the dehydrogenation of 2-isobutyl-2,5-dihydro-1,3-thiazole with chloranil according to Dubs and Pesaro (1974). The product of this reaction was distilled to give 2-isobutyl-1,3-thiazole in a yield of 59%, bp 60–62°C/14 torr [lit. 66°C/10 torr (Dubs and Pesaro, 1974)]; [^{1}H]NMR ($CDCl_3$): δ 0.98 (6H, d, $J = 6.6$ Hz), 2.12 (1H, m, $J = 6.8$ Hz), 2.88 (2H, d, $J = 7.2$ Hz), 7.16 (1H, d, $J = 3.3$ Hz), 7.66 (1H, d, $J = 3.3$ Hz); [^{13}C]NMR ($CDCl_3$): δ 22.04 (2C, q), 29.52 (d), 41.96 (t), 117.71 (d), 142.00 (d), 169.80 (s).

RESULTS AND DISCUSSION

The grey duiker is adaptable and widely distributed in sub-Saharan Africa except in deserts and dense forests. They are normally present in savanna and woodlands and also flourish on cultivated land (Kingdon, 1982) where they are a nuisance in orchards and plantations.

As in the case of grysbok, grey duiker males mark actively with their preorbital glands, while this behavior is rare in females (Dunbar and Dunbar, 1979). Unlike grysbok, grey duiker do not maintain dung heaps so that preorbital secretion appears to be the major medium of olfactory signaling. They live in individual home ranges with the ranges of males overlapping those of one or more females. Females' ranges may overlap to some extent but they drive intruders of the same sex out. Males occupy more discreet ranges, the boundaries of which they defend (Dunbar and Dunbar, 1979).

The preorbital gland structure of the grey duiker has been described by Richter (1973). It is more complex than in most other duikers (*Cephalophus* spp.) and consists of pigmented and unpigmented areas. The secretion consists of a thick black melanin-containing component and a thin, yellowish clear liquid. Preliminary bioassays indicate that grey duiker respond to fresh preorbital marks as well as to those up to about two weeks old by sniffing or marking over them. No response was elicited by marks exposed to the air for four weeks. Whether or not signals deter potential rivals remains to be determined.

Although young hand-reared grey duikers are quite docile, the males in particular tend to become dangerous when adult. The captured animals are, on the one hand, extremely aggressive, while, on the other, they are also easily stressed and regular handling may result in a high stress-related mortality. This complicated the present project, since it was impossible to obtain material for analytical purposes on a regular basis or to collect material in sufficiently large quantities for the preparative gas chromatographic isolation of specific components.

As noted above, the preorbital gland secretion of the grey duiker is heterogeneous. It consists of water, mucus, a thin yellowish oil, and large concentrations of heavy waxy material in varying proportions. In contrast to the preorbital secretion of the grysbok, which, when introduced into the injector of a gas chromatograph without any preliminary clean-up, left only a solid dry residue, the grey duiker secretion left an oily residue that contaminated the injector liner and was also particularly detrimental to capillary columns. Getting quantitatively reproducible gas chromatograms was further complicated by the heterogeneous nature of the secretion, since it was virtually impossible to control the concentration of organic volatiles in a sample and thus the loading of the column with these volatiles. The quantitative comparison of the secretion of individual animals was therefore carried out with extracts of the organic material. A number of analyses, in which direct introduction of the pure secretion into the injector was employed, were nevertheless carried out, using a series of injector temperatures from 150°C up to 240°C, in order to determine the thermal stability of the volatile organic compounds in the secretion. The quantitative results of these analyses did not show any variations that could be correlated with the injector temperature, and the compounds under investigation were therefore expected to survive the GC separation and transfer through the GC-MS interface. A typical gas chromatographic analysis of an extract of the preorbital gland secretion in dichloromethane is shown in Figure 1.

Initial tentative identification of a number of the volatile organic constituents of the secretion was based on their mass spectra and the results of a comparison of their spectra with those in the available spectra library. Further corroboration of the molecular mass of the compounds was obtained by chemical ionization mass spectrometry and final proof of the proposed structures was

provided by the coinjection of the extract with authentic synthetic material. In a few cases where some of the members of a homologous series were not available, careful use was made of the retention time increments obtained under temperature programming conditions for the neighboring positively identified members of such a series. Since the mass spectra of some of the constituents contained insufficient or ambiguous information, some of the even relatively prominent constituents remained unidentified. The stereochemistry of the chiral components was not investigated in the present study.

The mass spectrum of component 6294 (Figure 2) has a weak (1.0%) ion at *m/z* 198, which, according to the M + 1 ion at *m/z* 199 in its CI spectrum, is the molecular ion of this compound. By high-resolution mass measurements this ion was found to correspond to the molecular formula $C_{12}H_{22}O_2$, while the ion at *m/z* 85 has the elemental composition $C_4H_5O_2$. The presence of these ions in the spectrum can be interpreted in terms of component 6294 being a γ-substituted γ-lactone. In the spectra of such long-chain γ-lactones, however, the ion *m/z* 85 carries a much higher proportion of the total ion current, while the ion at *m/z* 43 is slightly weaker. The relatively high abundance of the *m/z* 43 ion in the mass spectrum of component 6294 can also be interpreted in terms of the presence of a methyl ketone function in the compound which, to satisfy the elemental composition of the *m/z* 85 ion, would require the presence of an

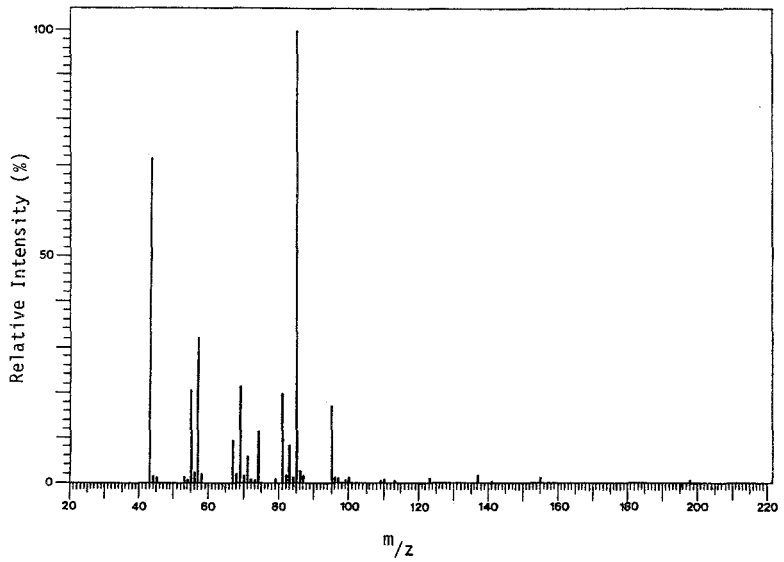

FIG. 2. Mass spectrum of component 6294 from the preorbital gland secretion of the grey duiker, *Sylvicapra grimmia*.

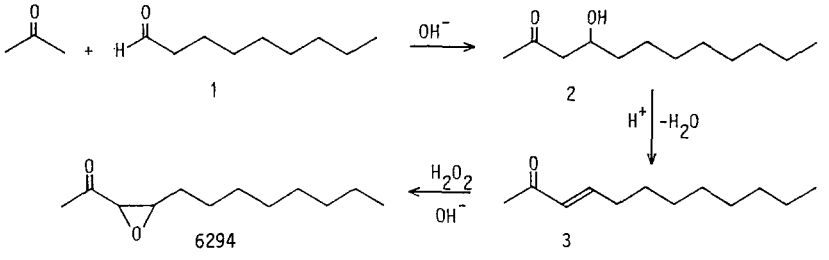
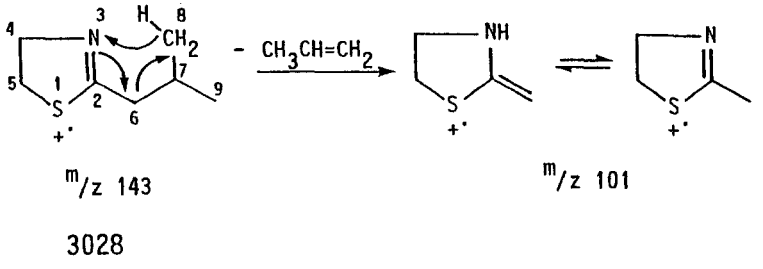
oxygen atom on one of the next two carbon atoms in the chain. 3,4-Epoxy-2-alkanones are known to have abundant ions at *m/z* 43 and 85 and weak molecular ions (Reusch and Djerassi, 1967), and component 6294 was therefore tentatively identified as 3,4-epoxy-2-dodecanone. In order to substantiate this assignment, this epoxy ketone was synthesized as shown in Scheme 1. The synthetic compound had a mass spectrum identical to that of the natural compound.



SCHEME 1.

The identification of 2-isobutyl-1,3-thiazole (2652) and 2-isobutyl-4,5-dihydro-1,3-thiazole (3028) in the preorbital secretions of the grey duiker and the red duiker (*Cephalophus natalensis*) has been discussed in detail in the preceding paper (Burger et al., 1988) in this series on mammalian pheromones. In summary, the assignment of these structures to the two compounds hinged on the presence of base peaks at *m/z* 99 and *m/z* 101 in the mass spectra of the compounds 2652 and 3028, respectively. The presence of the ion at *m/z* 101 in the spectrum of compound 3028, for example, was interpreted in terms of the rearrangement shown in Scheme 2, which can take place with either *n*-butyl or isobutyl in position 2 of a 4,5-dihydro-1,3-thiazole ring.



SCHEME 2.

The alkyl substituent in position 2 was finally unequivocally established to be an isobutyl group in both compounds by comparison of the mass spectra and gas chromatographic retention times of the natural compounds with those of authentic synthetic samples. Structural conclusions drawn from the mass spectra of these two thiazole derivatives were further substantiated by confirmation of their molecular ions by chemical ionization mass spectrometry and the determination of the elemental composition of the most abundant ions in the spectrum of the 4,5-dihydro-1,3-thiazole by high-resolution mass measurements.

The mass spectrum of 2-isobutyl-4,5-dihydro-1,3-thiazole, with a base peak at *m/z* 101, is distinctly different from that of 2-*sec*-butyl-4,5-dihydro-1,3-thiazole, which was found in urine of male mice (Liebich et al., 1977; Schwende et al., 1986) and has an abundant ion at *m/z* 115 instead of a base peak at *m/z* 101. The mechanism proposed for the formation of the base peak in the mass spectrum of the 2-isobutyl derivative can also be invoked to explain the presence of the ion at *m/z* 115 in the spectrum of the 2-*sec*-butyl derivative. This not only proves that these two compounds are distinctly different, but also lends support to the proposed fragmentation mechanism. As expected, these ions do not appear in the mass spectrum of the 2-isopropyl derivative, which is also present in male mouse urine.

Hexadecan-4-olide and octadecan-4-olide were prepared by the radical addition of acetic acid to 1-tetradecene and 1-hexadecene, respectively; oxidation of the resulting adduct radicals and cyclization of the carbocations was according to the method of Heiba et al. (1974) for the preparation of saturated γ-substituted γ-lactones.

The volatile compounds identified in the preorbital gland secretion are listed in Table 1. The majority of these compounds belong to one of four compound classes, viz. unbranched alkanes, 2-alkanones, alkanoic acids or alkan-4-olides, members of which have been identified in many mammalian secretions (Albone, 1984). Benzyl cyanide has been found in the chest gland secretion of the bush baby, *Galago crassicaudatus* (Crewe et al., 1979), and it has been suggested that in this animal it may have a function in short-term territorial marking. Based on the fact that this nitrile, the two γ-lactones, and the three sulfur-containing compounds, diethyl sulfoxide, 2-isobutyl-1,3-thiazole, and 2-isobutyl-4,5-dihydro-1,3-thiazole, as well as 3,4-epoxy-2-dodecanone are uncommon in mammalian exocrine secretions, they are expected to give the secretion a distintive character, although it cannot be ignored that some of the minor unidentified components of the secretion may be even more essential to its function. Since a reliable behavioral or electrophysiological bioassay is at this stage not yet available, it was impossible to use a response-guided strategy (Albone, 1984) for the identification of the compounds that influence the territorial behavior of the grey duiker. Although the alternative chemical image strategy was

complicated by the limited number of animals available for this research, the variations in the composition of the preorbital gland secretions from individual animals were studied as a first step in this direction. The results obtained by quantitative analysis of the secretions from three males are given in Table 2. To obtain secretion from the male M1, the animal was netted on three occasions over a period of three weeks for the collection of material. The samples were pooled for analysis. The animal appeared to be sexually active during this period and was very aggressive. As a result of the collection of the material, the animal

died of stress. Consequently material was obtained from the second male M2 by collecting freshly deposited territorial marks. A single sample of secretion was also obtained from a culled male M3. Since fresh secretion, collected directly from the animals, contains large and varying proportions of water in addition to the organic material, whereas deposited territorial marks appear to contain very little water, using an internal standard would have produced misleading results. Hexadecanoic acid, which is present in high concentrations in the secretions of both males and females, was therefore used as a quasiinternal standard, and the quantitative data were normalized with respect to this component of the secretion, taken as 100%. With the exception of a few components, such as 3,4-epoxy-2-dodecanone, tetradecanoic acid, and 2-nonadecanone, which are present in much lower concentrations in the secretion from the culled male M3 than in that from the male M1, the secretions from these two animals are similar. The standard, hexadecanoic acid, was apparently present in a slightly higher concentration in the secretion from the male M3, resulting in lower relative concentrations for almost all other constituents. The sample prepared by extracting the territorial marks deposited by the male M2 shows little resemblance to the other two samples. Diethyl sulfoxide, for instance, is present in a much lower concentration in this sample, whereas the two thiazole derivatives are the two major constituents of this secretion. Octadecanoic acid was present in a barely detectable concentration. Although some of the volatile material may have been lost by evaporation before the material could be collected, it is unlikely that this factor could account for these differences between this and the other two samples. Not too much significance can be attached to the results obtained from such a limited number of samples, but it is possible that in an attempt to collect as much material as possible, larger proportions of certain components are forced from the secretion-emitting pores than by the gentle rubbing motion with which the material is deposited by the animal. When the secretion is collected manually, the first material to emerge from the pores is a thin yellowish liquid, whereas a thicker black suspension is forced out of the pores when pressure is applied to the gland. Analysis of the territorial marks deposited by the animals is therefore expected to provide a more accurate volatile organic constituent profile of the secretion as it is employed for territorial marking by the grey duiker.

Although it was, unfortunately, impossible to carry out a full investigation of the seasonal variations in the quantitative composition of the preorbital secretion of male animals, analyses of the territorial marks deposited by the male M2 were carried out once a week over a period of eight weeks, the results of which are given in Table 3. This part of the study was undertaken two months after the analysis reported in Table 2. Once again hexadecanoic acid was used as quasiinternal standard. There does not seem to be a marked trend in the

[a] The quantitative data are normalized with respect to an arbitrary concentration of 100% for the hexadecanoic acid present in the deposited material.
[b] Components are numbered as in Figure 1 and are given in order of elution from the gas chromatographic column.

relative concentrations of the components of the secretion except for diethyl sulfoxide, 2-nonadecanone, and 2-tricosanone, which reached a peak at about the sixth week with concentrations between 25 and 30 times as high as the lowest concentrations recorded in one of the previous weeks. One further point of interest is the remarkably parallel variation of the concentration of the two thiazole derivatives. The ratio of the relative concentrations of 2-isobutyl-1,3-thiazole and 2-isobutyl-4,5-dihydro-1,3-thiazole remained almost constant throughout the eight-week period.

Samples of material collected directly from seven culled females were likewise compared (Table 2). All the samples have very similar quantitative compositions. The differences that were found are considered to be too small to be of any significance in a semiochemical context. This result was anticipated since, as mentioned above, female grey duikers do not use their preorbital gland secretion for territorial marking.

A comparison of the data in Tables 2 and 3 reveals that 2-pentadecanone is present in higher concentrations in the female secretions than in the male secretions, whereas the situation is reversed in the case of 2-heptadecanone and 2-nonadecanone. The only consistent and significant difference between the secretions from the two sexes appears to be the much higher concentrations of the two thiazole derivatives and the epoxy ketone in the male preorbital secretions.

The dihydrothiazole derivatives, 2-isopropyl-4,5-dihydro-1,3-thiazole and the 2-*sec*-butyl-substituted analog, which are both closely related to 2-isobutyl-4,5-dihydro-1,3-thiazole, were identified as major constituents of the urine of male mice and were found to be either absent from the urine of females or present only in trace amounts (Liebich et al., 1977). The production of these compounds was found to be androgen dependent (Jemiolo et al., 1985; Schwende et al., 1986), to influence the frequency of estrus cycles in the females (Jemiolo et al., 1985), and to provoke male aggression (Novotny et al., 1985). It is unlikely that compounds such as the long-chain alkanes, ketones, and fatty acids, which are ubiquitous in mammalian exocrine secretions, play more than a supporting semiochemical role in the secretion and until evidence to the contrary has been obtained, no special significance can be attached to the observed variations in the concentrations of these constituents of the secretions. Further work on the territorial behavior of the grey duiker will therefore be concentrated on an investigation of the semiochemical as well as the physiological function of the two thiazole derivatives and the epoxy ketone that were identified in this secretion.

METABOLISM AND EXCRETION OF THE FURANOCOUMARIN XANTHOTOXIN BY PARSNIP WEBWORM, *Depressaria pastinacella*

JAMES K. NITAO[1]

Department of Entomology,

(Received November 29, 1988; accepted February 22, 1989)

Abstract—The parsnip webworm, *Depressaria pastinacella*, feeds on plants containing high concentrations of furanocoumarins, compounds toxic to many organisms. Parsnip webworm larvae were fed radiolabeled xanthotoxin to quantify the detoxification of this furanocoumarin. They metabolized approximately 95% of the ingested xanthotoxin, indicating that metabolic detoxification is important in their tolerance to this allelochemical. Excretion of xanthotoxin and its metabolites was not restricted to the frass but also occurred by means of the silk glands. The silk glands contained half as much of the tritiated compounds as the rest of the body. Because of the feeding habits of this insect, such an excretory pathway may have implications for interactions with predators and pathogens.

Key Words—*Depressaria pastinacella*, parsnip webworm, xanthotoxin, detoxification, furanocoumarins, silk, plant secondary compounds, plant-insect interactions, Oecophoridae, Lepidoptera.

INTRODUCTION

Furanocoumarins are plant secondary compounds most commonly found in the families Rutaceae and Umbelliferae (Murray et al., 1982). Upon exposure to long-wave ultraviolet light, many of these compounds are photoactivated and

[1] Present address: Department of Entomology, 243 Natural Science Building, Michigan State University, East Lansing, Michigan 48824.

0098-0311/90/0200-0417$06.00/0

can bind covalently to nucleic acids and generate highly reactive oxygen species (Murray et al., 1982; Knox and Dodge, 1985). Because these processes can damage fundamental biological systems, furanocoumarins are toxic to a broad spectrum of organisms (reviewed in Murray et al., 1982).

A growing body of evidence indicates that furanocoumarins can be significant in herbivore–plant interactions. Not only are several furanocoumarins phototoxic to insect and mammalian herbivores (Berenbaum, 1978; Berenbaum and Neal, 1985; Ashkenazy et al., 1985), some also exhibit acute toxicity independent of photoactivation (Berenbaum, 1978; Berenbaum and Neal, 1985). Chronic toxicity as manifested by reduced fecundity can occur as well (Berenbaum and Feeny, 1981). In addition to postingestive effects, these compounds are frequently phagodeterrent (Yajima et al., 1977; Muckensturm et al., 1981). At a broader level of interaction, patterns of herbivore species distributions are correlated with furanocoumarin content in the Umbelliferae (Berenbaum, 1981). Moreover, the within-plant distribution of furanocoumarins is related to the relative value of the reproductive parts in one umbellifer species, suggesting that these toxins are allocated against herbivores in accordance with optimal defense theory (Nitao and Zangerl, 1987).

A well studied herbivore–plant interaction involving furanocoumarin chemistry involves the parsnip webworm, *Depressaria pastinacella* (Duponchel) (Lepidoptera: Oecophoridae). The larvae feed exclusively on plants in three genera of the Apiaceae, all of which contain furanocoumarins (Murray et al., 1982; Berenbaum, 1983). One of the webworm's major hosts in North America is the wild parsnip, *Pastinaca sativa* L. (Umbelliferae) (Hodges, 1974). In central Illinois, the wild parsnip generally produces six furanocoumarins, two of which, bergapten and sphondin, are associated with resistance of this plant against *D. pastinacella* (Berenbaum et al., 1984, 1986). Xanthotoxin, a furanocoumarin highly toxic to polyphagous insect herbivores (Berenbaum, 1978; Berenbaum and Neal, 1985), apparently is not a resistance factor against the parsnip webworm despite its abundance in the plant (Berenbaum et al., 1986). In fact, when bioassayed against the webworm in an artificial diet, xanthotoxin had no detectable effect on larval survivorship or development; in vitro studies suggested that *D. pastinacella* tolerance to xanthotoxin is due at least in part to metabolism by cytochrome P-450 monooxygenases (Nitao, 1989).

In this paper, I present the results of in vivo experiments ascertaining the extent to which the parsnip webworm detoxifies xanthotoxin and the physiological fate of ingested xanthotoxin and its metabolites. Previous studies on taxonomically unrelated insects that regularly feed on furanocoumarin-containing plants have found extensive in vitro and in vivo enzymatic degradation of xanthotoxin (Ivie et al., 1983; Bull et al., 1984, 1986; Ashwood-Smith et al., 1984). The mechanism by which the parsnip webworm tolerates this compound

should provide further information on how different herbivores cope with identical plant secondary chemicals.

METHODS AND MATERIALS

Metabolic Fate of Xanthotoxin. To quantify furanocoumarin metabolism by *D. pastinacella*, larvae were fed tritiated xanthotoxin (8-[*methoxyl*-^{3}H]psoralen, Amersham Corporation, Arlington Heights, Illinois; radiochemical purity of >99% verified by TLC). The tritiated furanocoumarin was diluted with unlabeled xanthotoxin (Sigma, St. Louis, Missouri) to a specific activity of 2.09×10^3 mCi/mmol in ethanol. Radiolabeled material in artificial diet (Nitao and Berenbaum, 1988) was presented to larvae in glass scintillation vials. One piece of artificial diet weighing approximately 0.2 g fresh mass was placed into each vial, and onto each piece was pipetted 10 μCi of [^{3}H]xanthotoxin in ethanol. The ethanol was evaporated with a stream of air, and a final (sixth) instar larva was placed into the vial. Larvae had been reared on artificial diet lacking xanthotoxin and were less than one day into the sixth instar when used; experimental individuals were offspring from field-collected insects (Champaign County, Illinois) (Nitao and Berenbaum, 1988). Rearing conditions were 25°C, 16:8 hr light–dark.

After three days, three larvae were dissected for quantification of the distribution of tritium in the body parts. The silk glands, the gut and its contents, the remaining carcass (including the fat body), and the frass from each larva, as well as the uneaten diet remaining in the vial, were frozen until analysis. The silk glands were briefly rinsed in 1.15% KCl in 0.05 M Tris HCl buffer (pH 7.8) prior to freezing to wash off hemolymph. Scintillation fluid was added to the used, empty vials and residual tritium quantified using standard liquid scintillation counting (LSC) procedures. The liquid scintillant consisted of dioxane, 300 g/liter naphthalene, and 15 g/liter PPO (2,5-diphenyloxazole). All readings were corrected for quench.

Xanthotoxin and its metabolites were extracted and quantified by using a procedure modified from Bull et al. (1984). Body parts and frass were homogenized in 1 ml of distilled water acidified to pH 2 with HCl. This homogenate was then extracted three times with 1-ml aliquots of ethyl acetate. The ethyl acetate fractions were combined, and aliquots were taken from both aqueous and ethyl acetate fractions for LSC. Preliminary work with unlabeled compound indicated that xanthotoxin partitions completely into the ethyl acetate phase as measured by high-pressure liquid chromatography. Hence, to determine the amount of unmetabolized xanthotoxin in the frass and body parts, only the ethyl acetate fractions were further analyzed. Ethyl acetate fractions were evaporated

to dryness, and the residues were redissolved in a small volume of ethyl acetate for spotting on silica gel thin-layer chromatography (TLC) plates (Eastman Chromagram sheet 13181). Extracts were cospotted with unlabeled xanthotoxin. TLC plates were developed in 75:25:1 ethyl acetate–methanol–acetic acid and visualized under long-wave UV to establish the R_f of xanthotoxin. TLC lanes for each extract were cut at 0.5-cm intervals and counted for tritium using LSC. The amount of radiolabel ingested was determined by subtracting the quantity of tritium in the uneaten diet and the residue remaining in the feeding vial from the initial amount given to the larva.

Excretion of Xanthotoxin and Metabolites in Silk. Parsnip webworms normally web together the flowers of their host plants and therefore produce large amounts of silk. Preliminary observations suggested that furanocoumarin and metabolites were excreted into the silk. Xanthotoxin and its major metabolites fluoresce under long-wave ultraviolet light (Bull et al., 1984); the presence of these compounds in webworm silk was suggested by the fluorescence of silk spun by furanocoumarin-fed larvae, whereas silk from larvae fed diet totally lacking in furanocoumarins did not fluoresce.

To verify that the presence of metabolites and furanocoumarin in the silk was not due simply to regurgitation or contamination from frass, the dispersion of these compounds in the silk was examined qualitatively. Silk was collected from the sides of a plastic cup in which three to five larvae had spun silk. These larvae were raised on 0.3% xanthotoxin (w/w) fresh mass diet from egg hatch through the early ultimate instar, starved for 8 hr to maximize clearance of the digestive tract, and then allowed to spin silk onto the sides of clean 28-ml cups. The silk was then collected and placed under long-wave ultraviolet light to visualize fluorescent metabolites and xanthotoxin. Dispersion of fluorescent material in globules or highly localized patches would indicate regurgitate or frass; uniform fluorescence throughout the silk fibers would suggest excretion of the compounds through the silk glands. Silk from larvae raised on control diet lacking xanthotoxin was also examined. The silks were placed under long-wave ultraviolet light and photographed through a No. 8 medium yellow correction filter.

To quantify the xanthotoxin and its metabolites in the silk, three larvae were fed [^{3}H]xanthotoxin for three days as described earlier. At the end of the three days, larvae were transferred to clean 28-ml plastic cups where they spun silk onto the cup wall. Prior to transfer, larvae were ligated with thread to close off the anus so as to avoid contamination of the silk with frass. After 8 hr, larvae were removed carefully so as to prevent defensive regurgitation, which would contaminate the silk, and the silk was collected. The silks were extracted sequentially for 1 hr each in 1 ml of ethyl acetate at room temperature, followed by 1 ml of 70% aqueous ethanol at 60°C. Silks were then solubilized by digestion in 100 μl of protease type XXV (Sigma, St. Louis, Missouri) (4 mg pro-

tease/ml 10 mM Tris buffer pH 7.6, 1 mM EDTA) at 37°C overnight. The radiolabeled material was quantified in all three fractions. The ethyl acetate extracts were evaporated to dryness and brought back up in a small volume of the same solvent to spot on TLC plates. The 70% ethanol extracts were also evaporated to dryness but were redissolved in absolute ethanol for application onto TLC plates. Plates were developed and analyzed as described earlier.

RESULTS

Metabolic Fate of Xanthotoxin

Recovery efficiency of the ingested tritium from larval body parts and the frass was approximately 90%. Nearly 95% of the ingested [^{3}H]xanthotoxin was metabolized; most of the unmetabolized [^{3}H]xanthotoxin was excreted with the frass (Table 1). Metabolites excreted in the frass accounted for approximately 80% of the recovered radiolabeled compounds out of the total tritium consumed. Xanthotoxin constituted less than 0.5% of the total ingested radiolabel present in the body exclusive of gut and gut contents; the silk glands by themselves contained half as much radiolabeled as the rest of the carcass. Most of the tritium in the silk glands was present in the form of metabolites.

Approximately 70% of the metabolites were recovered in the aqueous fraction, indicating that xanthotoxin was converted primarily into products of greater polarity. TLC analysis of the ethyl acetate fractions revealed that most metabolites partitioning into the organic phase had lower R_f values than that of xanthotoxin (R_f 0.70–0.75) (Figure 1). The lower R_f values on silica gel suggest that the ethyl acetate soluble metabolites were also generally more polar than

TABLE 1. DISTRIBUTION OF TRITIATED XANTHOTOXIN AND METABOLITES IN BODY PARTS AND FRASS OF *Depressaria pastinacella* SIXTH-INSTAR LARVAE[a]

	Ethyl acetate fraction			
	Unmetabolized [^{3}H]xanthotoxin	^{3}H metabolites	Aqueous fraction ^{3}H metabolites	Total
Silk glands	0.02 ± 0.008	1.76 ± 0.613	0.18 ± 0.117	1.96
Gut and contents	0.10 ± 0.058	5.46 ± 1.640	0.68 ± 0.118	6.24
Carcass	0.41 ± 0.220	2.81 ± 0.010	0.75 ± 0.175	3.87
Frass	6.41 ± 2.911	16.63 ± 4.976	62.83 ± 8.674	85.87
Total	6.94	26.66	64.44	

[a] Values are mean percent ± SE of ingested [^{3}H]xanthotoxin, $N = 3$.

xanthotoxin. The carcass, however, contained compound(s) having an R_f of 0.81 as well.

Excretion of Xanthotoxin and Metabolites in Silk. Silk collected from sixth-instar larvae raised on xanthotoxin diet fluoresced under long-wave ultraviolet light whereas silk from larvae reared on control diet did not (Figure 2). Moreover, the fluorescent compounds were dispersed uniformly throughout the silk and were not in localized patches or blotches, as would be expected if the compounds originated from regurgitant or frass.

The silk of larvae fed [^{3}H]xanthotoxin contained 0.10% ± 0.009 SE of the total tritium consumed and was mostly extracted in the hot 70% ethanol extract. Approximately 30% of this tritium was in the form of xanthotoxin (Table 2). No radiolabeled compounds were found in the protease digest, indicating that the ethyl acetate and 70% ethanol treatments extracted all of the detectable xanthotoxin and its radiolabeled metabolites; hence, there was no indication that tritiated metabolites were bound to the silk in an unextractable

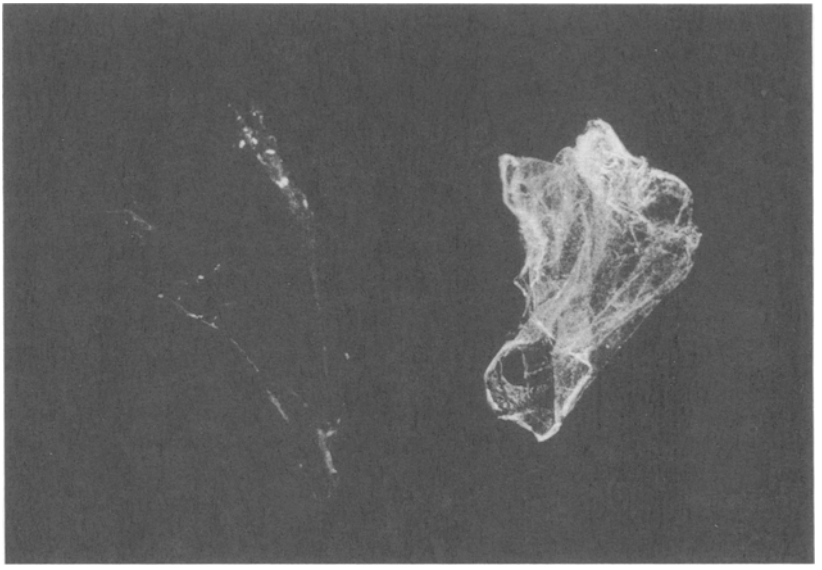

FIG. 2. Fluorescence under long-wave ultraviolet light of silk collected from *Depressaria pastinacella* fed control diet lacking xanthotoxin (left) and diet containing 0.3% w/w fresh mass xanthotoxin (right).

form. The mean mass of the collected silk was 0.21 mg ± 0.027 SE. Assuming that unlabeled and radiolabeled xanthotoxin are excreted into the silk in equal proportion, the estimated concentration of unmetabolized xanthotoxin in the silk was 1.16×10^{-4}%. As with the frass and body parts, most of the metabolites had lower R_f values than xanthotoxin (Figure 3).

DISCUSSION

Insect herbivores avoid the deleterious effects of toxic plant secondary compounds through a variety of mechanisms. They may rapidly excrete the toxin unaltered, sequester the compound in specialized structures, metabolize the compound to an excretable form, or possess target sites physiologically insensitive to the toxin (Brattsten, 1986). In the parsnip webworm, biochemical metabolism appears to play a major role in conferring resistance to xanthotoxin. Approximately 95% of the ingested tritium recovered from larvae and frass was in the form of metabolites. These results are consistent with in vitro studies demonstrating that *D. pastinacella* microsomal enzymes possess high specific activity towards xanthotoxin (Nitao, 1989). The occurrence of unmetabolized

xanthotoxin in the body still presents the potential for toxicity; Lee and Berenbaum (in preparation) have found antioxidative enzymes in this insect and suggest that these enzymes protect against reactive oxygen species formed by furanocoumarin photoactivation.

Duffey (1980) discusses the possibility that the physiological fate of ingested plant secondary compounds is determined by the physical and chemical properties of the compound (e.g., polarity, solubility, binding constants). In other words, compounds may be predisposed to certain resistance mechanisms because of their inherent chemical properties. An expected outcome of this hypothesis is that taxonomically unrelated specialists will possess similar resistance mechanisms against the same compounds. Consistent with this prediction, sequestration is widespread in the various insect herbivores that feed on plants containing iridoid glycosides (Bowers and Puttick, 1986), cardenolides, and pyrrolizidine alkaloids (reviewed in Duffey, 1980). In contrast to these compounds, metabolic detoxification is common in the insects examined regularly feeding on furanocoumarin-containing plants. The black swallowtail, *Papilio polyxenes* (Lepidoptera: Papilionidae) (Ivie et al., 1983; Bull et al., 1984, 1986), and an agromyzid leaf miner, *Phytomyza spondylii* (Diptera) (Ashwood-Smith et al., 1984), as well as the parsnip webworm metabolize xanthotoxin. This toxin may therefore be more prone to oxidative metabolism and less amenable to sequestration.

In *D. pastinacella*, the metabolism of xanthotoxin is typical of xenobiotic detoxification in that it results in products more polar than the original compound. The presence in the carcass and silk of metabolites with slightly higher R_f than xanthotoxin on silica gel TLC is difficult to interpret since polarity and small differences in R_f are not perfectly correlated. A time–dose study would clarify the pharmacokinetics of xanthotoxin metabolism and help to ascertain whether these metabolites are intermediates in the detoxification process.

Xanthotoxin and its metabolites were found in the silk and silk glands; in fact, the silk glands by themselves contained as much of the ingested tritiated compounds as the rest of the body, which included the fat body and much of the hemolymph. Because the silk glands constitute only a minor fraction of the total body mass, the amount of xanthotoxin and metabolites was disproportionately high in these organs. As in many lepidopterous larvae, the glands were elongate, extending posteriorly along the digestive tract and terminating in the hindgut region. The extensive exposure to the hemolymph and orientation alongside the gut may predispose the silk-forming organs to absorb ingested allelochemicals and metabolites. Bergapten, another furanocoumarin, is also excreted in the silk (unpublished data), indicating that this process is not limited to xanthotoxin in *D. pastinacella*.

The larvae of hymenopterous parasitoids excrete nicotine and α-terthienyl in their cocoon silk when their lepidopteran hosts have been fed these plant

secondary compounds (Barbosa et al., 1986; McDougall et al., 1988). Other lepidopteran larvae are also known to excrete plant compounds into their silk (Brunet and Coles, 1974; Stermitz et al., 1988). This excretion pathway for allelochemicals therefore may be widespread in silk-producing insects that encounter xenobiotics. However, contamination by regurgitant, frass, or meconium can be a confounding factor in determining the occurrence of silk gland excretion (e.g., McDougall et al., 1988). In the study presented here, such contamination was unlikely. Visual examination of the silk under ultraviolet light revealed that the xanthotoxin and metabolites were dispersed uniformly throughout the silk strands and not in globules. Moreover, thin-layer chromatograms of the silk extracts in the radioisotope studies did not correspond with those of the gut and gut contents (Figures 1 and 3) as would be expected if the presence of radiolabel in the silk was due to regurgitant.

The incorporation of plant secondary compounds into silk may have functions other than as an elimination mechanism. Even the seemingly low xanthotoxin concentration of $1 \times 10^{-4}\%$ found in this study can have ecological implications. In nature, parsnip webworm larvae reside within silk-webbed flowers. Because the larvae are especially sensitive to ultraviolet light (personal observation), the incorporation of UV-absorbing compounds into the silk may serve to shield webworms from harmful solar radiation. Moreover, low concentrations of xanthotoxin inhibit fungal growth (Johnson et al., 1973; Camm, et al. 1976). The excretion of an antimicrobial agent in both frass and silk may produce a pathogen-free zone for the larva. Insect pathogens are known to spread and reside in the silk of some lepidopteran larvae (Jeffords et al., 1987), so that the presence of an antibiotic in the silk may prevent the establishment of deleterious microbes. Antimicrobial agents may be especially important in the high-humidity and frass-filled environment of the webs. Furthermore, the concentration of xanthotoxin in the floral parts of *P. sativa* can be over 300 times higher than that fed to larvae in the radioisotope experiments reported here. Thus, if the incorporation of xanthotoxin in the silk is dependent on dietary concentration, the levels in silk from a caterpillar feeding on a plant may be much higher. Finally, Stermitz et al. (1988) suggest that the presence of allelochemicals in silk may have antipredator functions. At higher concentrations, furanocoumarins may make the silk a chemical barrier as well as a physical one, deterring predators and parasites that probe or chew through the silk to reach larval or pupal hosts.

Abstract—Diastereomers of the spiroacetal, 2,8-dimethyl-1,7-dioxaspiro[5.5]undecane, represent main components of the cephalic secretion from males of the solitary bee, *Andrena wilkella*. The major compound proved to be of high enantiomeric purity, showing (2*S*,6*R*,8*S*) configuration. Only the naturally occurring enantiomer attracted patrolling males in the field; its antipode was behaviorally inactive and in a racemic mixture did not inhibit response. The (*E*,*Z*) diastereomers were also found to be almost inactive. EAG studies gave the same result as the behavioral tests. The biological function of the spiroacetal is discussed in view of the evolution of the mating behavior in *A. wilkella*.

Key Words—Enantiomer discrimination, male patrolling, odor marking, Hymenoptera, Apoidea, *Andrena wilkella*, bee, EAG, spiroacetal, absolute configuration, 2,8-dimethyl-1,7-dioxaspiro[5.5]undecane.

INTRODUCTION

Chemical signaling plays an important role in the mating strategies of insects. In many species, the enantiomeric composition of chiral compounds released in volatile secretions is essential for species-specific signaling. Striking examples are reported from bark beetles. The ambrosia beetle *Gnathotrichus sulcatus* (Le Conte) uses a 65:35 mixture of (*S*)- and (*R*)-6-methyl-5-hepten-2-ol (sulcatol) and needs both enantiomers for full response (Borden et al., 1976), while the closely related *G. retusus* (Le Conte) produces (*S*)-sulcatol in at least 99% optical purity and does not respond to the racemate (Borden et al., 1980). In the case of *Ips pini* (Say), interpopulational differences in pheromone biology are based on different enantiomeric mixtures of the principal aggregation pheromone, ipsdienol (Lanier et al., 1980).

Males of the palaearctic bee, *Andrena wilkella*, deposit odor marks along their patrol routes using a volatile cephalic secretion. This is a complex mixture of spiroacetals, alcohols, hydrocarbons, and terpenes (Bergström et al., 1982), among which (*E*,*E*)-2,8-dimethyl-1,7-dioxaspiro[5.5]undecane [(*E*,*E*)-DSU] (**1** in Figure 1, which shows structures of oxygen-containing heterocycles mentioned in this paper), accompanied by minor amounts of its *E*,*Z*-isomer, is one of the main components. 2-Methyl-5-pentyl-3,4-dihydro-2H-pyran (2HPYR) (**2** in Figure 1) (Francke, 1984), biogenetically probably closely related to the spiroacetals, also occurs in major amounts.

The objectives of our study were to determine the absolute configuration of DSU in *A. wilkella* and to test whether males discriminate between the enantiomers of (*E*,*E*)- and (*E*,*Z*)-DSU. We report results from long-term field experiments on the behavioral responses elicited in patrolling bees and from electrophysiological (EAG) studies of the reactions of primary odor receptors to these oxygen-containing heterocycles.

METHODS AND MATERIALS

Investigations were carried out in May–June of 1983–1985 on Öland, an island close to the southeastern coast of the Swedish mainland. A small grazed meadow surrounded by deciduous woodland served as the arena for the behavioral studies. The electrophysiological analyses were performed at the Ecological Research Station.

Pure enantiomers and racemates of (*E*,*E*)- and (*E*,*Z*)-2,8-dimethyl-1,7-dioxaspiro[5.5]undecane, as well as racemic 2-methyl-6-pentyl-3,4-dihydro-2H-pyran served as test compounds. Pure hexane was used as a control. The compounds were prepared according to previously described methods (Francke et al., 1980b; Mori and Tanida, 1981; Isaksson et al., 1984). All samples were

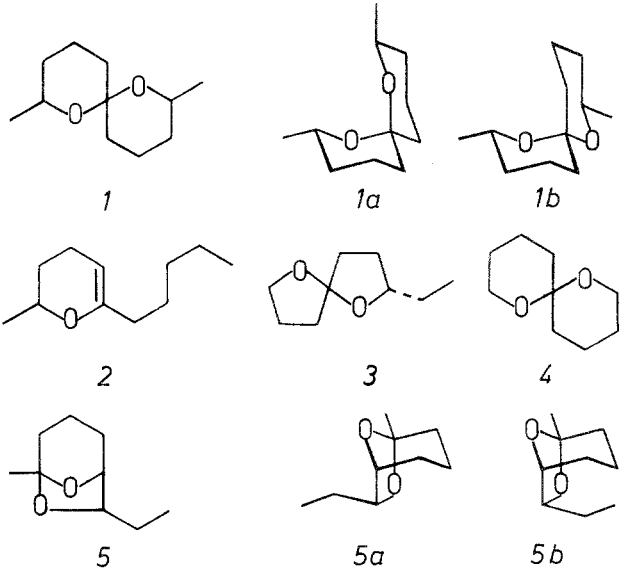

FIG. 1. Structural formulas of oxygen-containing heterocycles mentioned: **1** = 2,8-dimethyl-1,7-dioxaspiro[5.5]undecane (DSU); **1a** = (−)-(2*S*,6*R*,8*S*)-DSU [(−)-(*E*,*E*)-DSU]; **1b** = (−)-(2*R*,6*R*,8*S*)-DSU [(−)-(*E*,*Z*)-DSU]; **2** = 2-methyl-6-pentyl-3,4-dihydro-2H-pyran [2HPYR]; **3** = (2*S*,5*RS*)-ethyl-1,6-dioxaspiro[4.4]nonane (2*S*-chalcogran); **4** = 1,7-dioxaspiro[5.5]undecane (olean); **5** = 7-methyl-5-methyl-6,8-dioxabicyclo[3.2.1]octane (brevicomin); **5a** = (+)-*exo*-brevicomin; **5b** = (+)-*endo*-brevicomin.

stored at −20°C prior to use. While the dihydropyran proved to be a little sensitive, the spiroacetals were stable under neutral conditions at ambient temperatures and showed no tendency to racemize. Despite the fact that complexation gas chromatography (Weber and Schurig, 1984) separates mostly enantiomers of bicyclic acetals, attempts to resolve (*E*,*E*)-DSU failed. Resolution was improved through the use of a modified cyclodextrin as a stationary phase (König et al., 1988a,b). More specifically in our case, successful separation was obtained by using perhexyl-α-cyclodextrin; conditions are given in the legend to Figure 2.

For the behavioral experiments, synthetic compounds (as 1% v/v solutions in hexane) were presented in test series to patrolling *A. wilkella* males. Each substance was included in either 16 or 23 test series replicates, depending on whether it was tested over two or three seasons, respectively. During a single test series, all test substances were presented successively and in random order for 5 min each. A velvet strip (6 × 10 mm) attached to an insect pin was

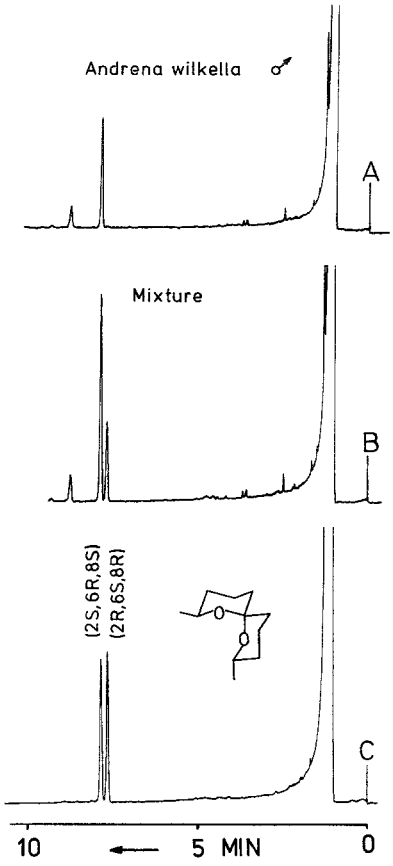

FIG. 2. Determination of the absolute configuration of DSU from *A. wilkella* by gas chromatography: per-*n*-hexyl-α-cyclodextrin; 35-m glass capillary; 0.25 mm ID; 80°C isothermal; 0.8 bar H2. (A) Natural extract; (B) natural extract spiked with racemic DSU; (C) resolution of racemic DSU.

impregnated (by soaking) with 0.1 ml of a test substance immediately before the experiment and was placed on a twig frequently patrolled by males. The behavioral responses of male bees were registered during the 5-min period, using the classification of Kullenberg (1973) and Tengö (1979): unaffected passage, quick approach, or pendulating/hovering inspection. The latter class represents the highest mood of excitement and thus reflects the highest biological activity of the test substance.

All experiments during each year were performed by one investigator. Two test series were carried out in parallel at sites 20 m apart by alternating test

periods between the sites. To minimize bias, the identity of the tested odor was never revealed to the investigator (blind test).

The number of males patrolling the test area differed between years, ranging approximately from 40 to 100. Individual males passed within a few meters of the test twig up to three times each 5-min period. Only test series with a minimum of five males passing within 10 cm of the odor source each 5 min were included in statistical analyses.

The attraction capacity of each substance was defined as the sum of the observations of hovering inspections (weighted with a factor 2) and quick approaches (unweighted), divided by the total number of behavioral events observed per substance. The resulting figure was standardized by assigning the substance with the highest attraction a value of 100 and the substance with the lowest attraction (i.e., the control) a value of 0. The behavioral patterns from the three years were tested for homogeneity using a χ^2 contingency test.

The response of four *A. wilkella* males to each of the test substances was electrophysiologically analyzed using electroantennogram techniques. The males were collected at midday and kept at 4–6°C for 1–3 hr until tested. The test substances were dissolved in distilled hexane (1 : 1000, v/v) and stored at −25°C between experiments. The antennograms were obtained by standard methods (Borg-Karlson et al., 1988). For sample preparation, 10 μl of each solution (equilibrated at ambient temperature) were applied to a piece of filter paper, which (after evaporation of hexane) was put into a glass vial placed inside a disposable plastic syringe; the odor-impregnated filter papers were replaced every hour. The EAG tests were performed at a temperature of 22.9–27.7°C and a relative humidity of 34–40%; hexane was used as the control, octanol as the standard.

Calculations of electrophsiological responses followed the method of van der Pers (1981), which corrects for the decreasing sensitivity of the antenna and for differences in sensitivity between animals, electrodes, and electrode positions.

The correlation between the behavioral and electrophysiological responses was evaluated using the Spearman rank method.

RESULTS

Gas chromatographic analyses revealed (*E,E*)-DSU to be secreted by *A. wilkella* males only as the (−)-enantiomer (Figure 2). The average amount per male ranged between 5 and 30 μg.

The behavioral data were similar over all three years (χ^2 contingency test, $P > 0.05$) and were consequently pooled for subsequent analyses (Figure 3). Each test substance differed significantly from the control in terms of the three

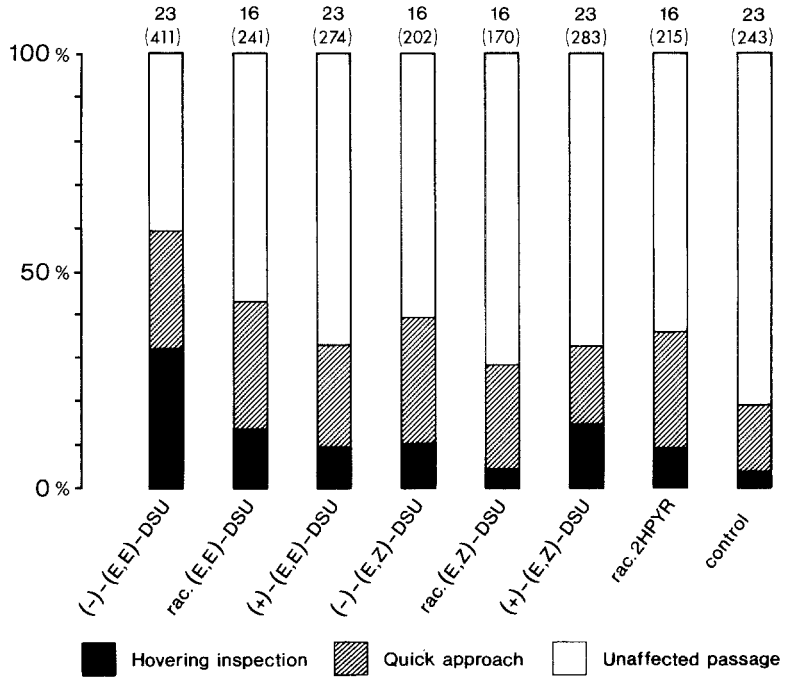

FIG. 3. Percentage of different behavioral responses (hovering inspection, quick approach, and unaffected passage) evoked by each odor substance in *A. wilkella* in field experiments. Number of test series replicates and total number of behavioral responses (in parentheses) are shown at the top of each bar.

behavioral response classes elicited in *A. wilkella* males (χ^2 test, $P < 0.05$, Table 1, Figure 3), and all evoked differing levels of excitement. When the substances were arranged in order of decreasing attraction capacity (Table 1), (−)-(*E*,*E*)- and racemic (*E*,*E*)-DSU took prominent positions. The responses evoked by each of these two compounds differed significantly from those of the other substances (χ^2 test, $P < 0.001$). The racemate elicited a slightly, but not significantly, weaker response in comparison with the (−)-enantiomer. The bees responded very weakly to (+)-(*E*,*E*)- and (+)-(*E*,*Z*)-DSU.

The behavioral response shown to racemic 2HPYR was significantly stronger than to racemic (*E*,*Z*)-DSU (χ^2 test, $P < 0.01$), but weaker than to racemic (*E*,*E*)-DSU (χ^2 test, $P < 0.05$, Figure 3).

EAG responses were highest to (−)-(*E*,*E*)- and racemic (*E*,*E*)-DSU (Table 1). Responses to the other substances were markedly lower; in only one case [racemic (*E*,*Z*)-DSU] were they significantly different from the control. The

TABLE 1. ATTRACTION CAPACITY (IN DECREASING ORDER) OF ODOR SUBSTANCES TESTED IN THE FIELD AND RELATIVE EAG RESPONSES

Odor substance[a]	Attraction capacity (%)[b]	Relative EAG response (concentration 1:1000)[c]		
		Mean[d]	S.D.	P^e
(−)-(*E*,*E*)-DSU	100	1.13	0.38	0.01
rac-(*E*,*E*)-DSU	84.3	1.07	0.43	0.025

[d] Values from four males.
[e] Probability of error that the relative EAG response differs from the control (*t* test) (N.S. = not significant).

relative EAG response to each substance was positively correlated with the behavioral attraction capacity, showing the highest values for (−)-(*E*,*E*)- and racemic (*E*,*E*)-DSU (Spearman rank correlation, $r_s = 0.81$, $N = 8$, $P = 0.015$).

The short seasons only permitted tests at one concentration. However, single test series replicates using 0.1 and 0.01% v/v solutions in hexane showed the same trend as 1% solutions.

DISCUSSION

Bicyclic Acetals in Systems of Chemical Communication. Bicyclic acetals are widespread among insect volatiles and have been reported as pheromone components of beetles, flies, bees, and wasps. As in many other cases, the enantiomeric composition of these compounds plays a major role in the generation of an efficient olfactory signal. Some of these compounds originate from the acetate pool, since they show an unbranched carbon skeleton.

The *exo*- and *endo*-isomers of brevicomin, 7-ethyl-5-methyl-6,8-dioxabicyclo[3.2.1]octane (**5** in Figure 1), were first identified from frass of female western pine beetles, *Dendroctonus brevicomis* (Silverstein et al., 1968). Natural *exo*-brevicomin, the female-released aggregation pheromone of *D. brevi-*

comis, was found to have (1*R*,5*S*,7*R*) configuration (Stewart et al., 1977), and the beetles were shown to be able to discriminate between the enantiomers (Wood et al., 1976). Complexation gas chromatography (Weber and Schurig, 1984) of abdominal volatiles of male mountain pine beetles, *D. ponderosae*, revealed the presence of (1*R*,5*S*,7*R*)-(+)-*exo*-brevicomin (**5a** in Figure 1) of high enantiomeric purity; enantiomeric proportions of the additionally produced (1*R*,5*S*,7*S*)-(+)-*endo*-isomer (**5b** in Figure 1) ranged between 65 and 75% enantiomeric excess, with some variation evident between populations (Schurig et al., 1983). In *Dendroctonus frontalis*, (1*R*,5*S*,7*S*)-*endo*-brevicomin is the natural attractant in the male-produced aggregation pheromone (Redlich et al., 1987); its antipode inhibits response (Vité et al., 1985).

A spirocyclic acetal, a component of the male pheromone in the bark beetle, *Pityogenes chalcographus*, is 2-ethyl-1,6-dioxaspiro[4.4]nonane (chalcogran, **3** in Figure 1), which occurs as a mixture of diastereomers (Francke et al., 1977). The natural product shows (2*S*) configuration (Schurig and Weber, 1984), and the racemate is attractive in the field. In the olive fly, *Dacus oleae*, the active constituent of the sex pheromone is 1,7-dioxaspiro[5.5]undecane (**4** in Figure 1) (Baker et al., 1980). The females produce a racemate; however, males and females react differently to the enantiomers (Haniotakis et al., 1986).

Enantiomeric Discrimination in Hymenoptera. Although many chiral compounds have been identified from Hymenoptera (Blum, 1981), the absolute configurations have been determined in only some. Still less is known about enantiomeric discrimination at the receptor site. In ants, the classical case is 4-methyl-3-heptanone, an alarm pheromone of *Atta* spp.: the ants produce the (*S*) enantiomer, and only this isomer is active (Riley et al., 1974). Certain *Myrmica* spp. produce (3*R*)-octanol of high enantiomeric purity and react only to the natural product (Attygalle et al., 1983; Attygalle and Morgan, 1984).

Few cases of enantiomer discrimination are known from bees. Recently, it has been reported that enantiomeric composition of (2*E*)-9-hydroxy-2-decenoic acid is important for the retinue response to queen honeybees (Slessor et al., 1988; Winston et al., 1982). The stingless bee, *Scaptotrigona postica*, produces methylcarbinols of high optical purity (Engels et al., 1987) and the bees react differently to the enantiomers (W. Engels, personal communication).

2,8-Dimethyl-1,6-dioxaspiro[5.5]undecane (**1** in Figure 1) seems to be particularly widespread as an insect volatile (Francke et al., 1980b; Tengö et al., 1982; Davies and Madden, 1985; Dettner and Schwinger, 1986; Kitching et al., 1986); nevertheless its biological function is still largely unknown. The present study clearly shows both a central role of the (2*S*,6*R*,8*S*) isomer [(−)-(*E*,*E*)-DSU] (**1a** in Figure 1) in the communication systems of the bee *A. wilkella* and the males' ability to discriminate between the enantiomers (which also smell different to the human nose). To our knowledge, this is the first time that

enantiomeric discrimination has been demonstrated in solitary bees. In the natural secretions, (*E,E*)-DSU is accompanied by its *E,Z* isomer in a proportion of approximately 3 : 1 (Bergström et al., 1982). Although the absolute configuration of the latter remains to be determined, the bioassay clearly showed that the attractivity of this minor compound was inferior and that here, too, there were distinguishable differences between its enantiomers.

Since the attractivity of single compounds to male bees can be enhanced in some *Andrena* species by the addition of compounds identified from the cephalic secretion (Tengö, 1979), we have also tested a mixture of racemic spiroacetals, terpenes, and open-chain acetogenins, which resemble the natural blend found in *A. wilkella* (Bergström et al., 1982). Comparative experiments with this mixture and (−)-(*E,E*)-DSU revealed no significant differences in attraction capacity (Tengö, unpublished data) and thus no synergism in male attraction.

Biological Function. Communication between mating partners in bees and wasps has evolved in parallel with the temporal and spatial distribution patterns of the sexes. In the cases where sexually receptive female bees form aggregates, males normally wait at the aggregation areas and often compete for the most optimal territories (Alcock et al., 1978; Eickwort and Ginsberg, 1980; Thornhill and Alcock, 1983). By contrast, when females are randomly distributed within the habitat, males may exhibit different searching strategies (Alcock et al., 1978). For example, males may aggregate at prominent landmarks—such "hilltopping" behavior is reported from several species by Alcock (e.g., 1987)—or may display a spatially more extended patrolling, as in many *Andrena* species (Tengö, 1979).

Andrena wilkella bees nest in a random pattern within areas where both preferred flowers and prominent landmarks are also randomly dispersed. Thus, the probability of a male finding a place with receptive females is low. *Andrena wilkella* males patrol distinctly separated bushes, shrubbery, or curtains of deciduous trees, such that their flight is confined to a specific part of available vegetation (Tengö, unpublished). Flight routes often overlap extensively, with males frequently passing a place simultaneously, in small swarms. The same mating-flight areas are patrolled year after year, as are the landmarks used by hilltopping species (Alcock, 1984).

Andrena males mark spots along their mating-flight routes with secretions from the mandibular glands (Tengö, 1979). Such odor marks, as well as behavior-releasing synthetic compounds, have been found to attract patrolling *Andrena* males in field tests (Tengö, 1979). It seems plausible that *A. wilkella* males enhance the chances of aquiring mates by announcing their presence with odor marks, despite the fact that both females and copulation initiations are rarely seen at the patrolled areas. Likewise, when several males mark the same area,

hence increasing the total odor emittance, and when receptive females are randomly dispersed within the habitat, this chemical advertising may increase the mating chances of each male.

A male repeatedly visits the spots he marks, an investment for successful mating. When he deposits his own odor marks near those of other males, this odor should optimally be species-specific, especially in cases when males of more than one bee species occur in the same habitat. Males of up to five *Andrena* species, all specific in the composition of their cephalic secretions, have been observed patrolling the same shrubbery at a single time (Tengö, 1979). Comparative analyses of *A. wilkella* and two other species of the subgenus *Taeniandrena* showed distinct differences in odor bouquets, although all contain DSU as a major component (Bergström et al., 1982).

The transmission of a unique odor signal at the intraspecific level can arise from either specific blends or the presence of unique substances, including enantiomeric compositions of chiral compounds. The cephalic secretions of *A. wilkella* fit both possibilities. The high optical purity of natural (−)-(*E*,*E*)-DSU, its attractivity to males, as well as the ability of males to discriminate between its enantiomers, emphasize the importance of this unique compound in male patrolling behavior.

In this context, it is noteworthy that males of an ichneumonid wasp, *Meringopus titillator*, sometimes found patrolling the same bushes as *A. wilkella* males, also secrete (*E*,*E*)-DSU (of unknown absolute configuration) from their cephalic glands (Tengö, Francke and Hinz, unpublished data). DSU and 2HPYR have been found in other ichneumonids (Davies and Madden, 1985).

The complexity of the cephalic secretion in *A. wilkella* (ca. 50 components; Bergström et al., 1982) points to multifunctionality; intraspecifically, it may act as an individual odor, containing information used in kin recognition (Greenberg, 1979; Smith, 1983). Indeed, careful gas chromatographic analyses of cephalic secretions shows variation between individuals (Francke and Tengö, unpublished data).

In conclusion, males of *A. wilkella* discriminate both behaviorally and electrophysiologically between the enantiomers of the major component of their cephalic secretion, (*E*,*E*)-DSU, thereby allowing acuity in the inter- and intraspecific communication to operate in their mating behavior.

Acknowledgments—We acknowledge the help of Birgitta Malmberg and Mats W. Pettersson in the field experiments and of Barbro Holmlund for preparing the test substances. We also thank Dr. Paul Westrich for the bee determinations, Dr. Murray S. Blum and an anonymous reviewer for helpful comments on the manuscript, and Dr. Heidi Dobson for linguistic advice. We are indebted to the Swedish Natural Science Research Council (J.T.), the Bank of Sweden Tercentenary Foundation (L. Å.), the Axel and Margaret Ax:son Johnson Foundation (L. Å.), Deutsche Forschungsgemeinschaft (W.F.), and Fonds der Chemischen Industrie (W.F.) for financial support.

IMPACT OF ATMOSPHERIC POLLUTION ON LINEAR FURANOCOUMARIN CONTENT IN CELERY

WILHELM DERCKS, JOHN TRUMBLE, and CARL WINTER

Department of Entomology
University of California
Riverside, California 92521

(Received December 2, 1988; accepted March 1, 1989)

Abstract—In a series of laboratory studies, a single 4-hr acidic fog at pH levels associated with commercial celery (*Apium graveolens* L.) production near major population centers in California was found to stimulate development of psoralen, bergapten, xanthotoxin, and isopimpinellin within 24 hr and for at least 120 hr after exposure. At 120 hr posttreatment, the concentrations of phototoxin furanocoumarins (psoralen + bergapten + xanthotoxin) increased 540% in the leaves (to 135 μg/g fresh weight) and 440% in the petioles (to 55.56 μg/g fresh weight) of celery exposed to a pH 2.0 fog as compared to plants exposed to control fogs (pH 6.3–6.5). Concentrations of these compounds in test plants were 7.5 times higher than the amount known to produce contact dermatitis. The nonphototoxic isopimpinellin increased more than threefold in the leaves (to 39.23 μg/g fresh weight, 120 hr) and petioles (to 25.88 μg/g fresh weight) as compared to control plants. In contrast, a single ozone fumigation at 0.20 ppm for 2 hr generally reduced concentrations of phototoxin furanocoumarin in leaves of celery within 24 hr (ozone-treated plants = 37.9, controls = 69.5 μg/g fresh weight), but levels of these chemicals in leaves of ozone-fumigated plants increased rapidly and concentrations were not significantly different at 120 hr. Isopimpinellin concentrations in foliage followed a similar trend (at 24 hr, control = 25.11, ozone treated = 10.96 μg/g fresh weight, no difference at 120 h). In petioles, none of the linear furanocoumarin levels differed significantly at 120 hr posttreatment.

Key Words—Celery, *Apium graveolens*, atmospheric pollution, ozone, acidic fog, furanocoumarins, bergapten, xanthotoxin, psoralen, isopimpinellin.

INTRODUCTION

Phototoxin dermatitis caused by contact with celery infected with a *Sclerotinia* fungi has been reported since the early 1900s (Austad and Kavli, 1983; Ashwood-Smith et al., 1985). Since the mid-1970s, the causal agents of the dermatitis have been definitively identified as linear furanocoumarins. When exposed to long-wave UV light, the phototoxic linear furanocoumarins (psoralen, xanthotoxin, and bergapten) rapidly alkylate DNA (Scott et al., 1976). These chemicals: (1) have proven lethal and carcinogenic in in vitro bioassays of bacterial and mammalian cells (Ashwood-Smith et al., 1980, 1982; Igali et al., 1970), (2) pose substantial toxicological risks for humans (Scott et al., 1976), and (3) have been recognized as causally related to skin cancer by the World Health Organization (IARC, 1983). The presence of high concentrations of psoralens in other *Apium* spp. and in related genera in the Apiaceae (Umbelliferae) also have been reported (Berenbaum, 1981b; Chaudhary et al., 1986).

Although the linear furanocoumarins were originally thought to be mycotoxins produced by *Sclerotinia*, Beier and Oertli (1983) demonstrated that the phytoalexin response also was initiated by general elictors including copper sulfate, UV light, and cold temperatures. Mechanical damage occurring during harvesting and storage also has been shown to increase concentrations from about 2 ppm to 95 ppm (Chaudhary et al., 1985). In addition, Berenbaum (1981a) and Zangerl and Berenbaum (1987) demonstrated that distribution of psoralens in wild parsnip was significantly correlated with nitrogen content. Thus, induction of psoralens appears to be stress-related while nitrogen levels influence within-plant distribution.

In coastal California, where well over 50% of the celery produced in the United States is grown (Ivey and Johnson, 1986), acidic fogs and ozone are significant stress factors that influence the content and form of nitrogen in plants. Acidic fogs with a pH of 3.6 or lower can cause visible foliar damage and deposit nitrogenous compounds directly on plant surfaces (Shriner, 1986). In the Los Angeles basin, fogs with a pH of 1.69 have been recorded (Hoffman, 1984). However, fogs between pH 2.0 and 3.0 are more common. Although urban encroachment has reduced the total acreage of farmland in Orange and Los Angeles counties, the areas most commonly exposed to high nitrogen acidic fogs, total value of field-grown celery exceeds $5 million dollars (U.S.) annually (Ivey and Johnson, 1986). Atmospheric ozone, which typically reaches concentrations exceeding 0.20 ppm on 20 or more days each year, visibly damages many plant species and significantly reduces total nitrogen content and increases soluble protein levels in tomatoes. Therefore, the purpose of our study was to investigate the psoralen concentrations occurring in a commercial celery variety exposed to stressful atmospheric conditions (ozone and acidic fog) associated with celery production in some areas of coastal California.

METHODS AND MATERIALS

Simulated Acidic Fogs. Simulated acidic fogs were prepared by adjusting distilled water to pH 2.0 and 3.0 with reagent-grade nitric and sulfuric acid mixed at a 2.5 : 1 (v/v) ratio. This acid ratio is typical of fogs in California, but lacked other ionic components of ambient moisture (Waldman et al., 1982). The pH levels also are consistent with fogs occurring near Los Angeles (Hoffman, 1984). Control fogs consisted of distilled water with a pH of 6.3–6.5. Fogs were created within a 1-m^3 chamber using a fogging apparatus designed by Musselman et al. (1985), which operated at 7.03 kg/cm^2 and produced droplets averaging 20 μm in diameter. Temperature at treatment averaged 22–26°C. Shade cloth was used to reproduce incident radiation levels consistent with coastal fogs of no more than 300 $\mu E/m^2/sec$. Three randomly selected celery plants (*Apium graveolens* L., var Tall Utah 52-70) each for control and test fogs were exposed for 4 hr, and then placed in a shaded location to dry for at least 4 hr (22–26°C). These plants were extracted and examined by HPLC (Beier et al., 1983a,b) at 0, 24, and 120 hr posttreatment. This experiment was replicated three times (nine test plants per pH and nine control plants each for 24- and 120-hr measurements, nine untreated plants were analyzed at time 0). To reduce chamber effects, the replicates were run sequentially on three different dates, alternating fogs at pH 2.0, 3.0, and 6.3–6.5. Linear furanocoumarin contents in plants were compared between treatments and controls at 24 and 120 hr postfumigation using Student's *t* tests.

Ozone Treatments. Eight celery plants were exposed to a single 2-hr ozone fumigation at 0.20 ppm in an 0.78-m^3 (interior space) environmental chamber equipped with a fan providing a complete air exchange every 45 sec. Ozone was added after input air was first scrubbed with a charcoal filter. Ozone was generated using an OREC OV35-O ozonator (Ozone Research & Equipment Corp., Phoenix, Arizona) and monitored within the chamber by a model 1008 ozone analyzer (Dasibi Environmental Corp., Glendale, California). Eight control plants also were exposed for 2 hr in the same chamber but without the ozone input. This experiment was replicated three times (24 test plants and 24 control plants). To reduce any chamber effects, the replicates were run sequentially, alternating control and ozone fumigations. Linear furanocoumarin contents in plants were compared between treatments and controls at 24 and 120 hr postfumigation using Student's *t* tests.

Extraction and Quantification. Extraction of the linear furanocoumarins psoralen, bergapten, xanthotoxin, and isopimpinellin was modified from a technique reported by Beier (Beier, 1985; Beier et al., 1983a,b). The frozen plant material was immersed in liquid nitrogen and crushed to a fine powder with a mortar and pestle. The powder was transferred into a 40-ml Ten Broeck homogenizer and further ground in 15 ml of deionized H_2O. The homogenate was

poured into centrifuge tubes, the volume brought up to 25 ml with deionized H_2O, and the samples centrifuged for 6 min at 570*g*. The supernatant was passed into separatory funnels through several layers of cheesecloth and the sediment discarded.

The aqueous phase was extracted once with 20 ml and three times with 10 ml of diethyl ether. Ether fractions were combined, centrifuged at 110*g* to break emulsions, and decanted into a round-bottomed flask. The samples then were reduced to dryness by rotary evaporation. The residue was dissolved in 0.6 ml acetonitrile and 0.4 ml H_2O was added; this flask washing step was repeated four times.

The combined flask rinses were passed through a C18 Sep-Pak cartridge (Waters Associates, Inc., Milford, Massachusetts) which was previously washed with 15 ml MeOH and rinsed with 15 ml H_2O), and the eluate collected. The Sep-Pak cartridge then was washed with 8 ml 60% acetonitrile in H_2O, and the eluates were combined. Fifteen milliliters of anhydrous EtOH was added to the sample to facilitate azeotropic distillation of the water, and the sample subsequently was reduced to approximately 1 ml by rotary evaporation. The remaining water was poured into a test tube and extracted twice with 5 ml ethyl acetate by vigorously shaking the tubes.

After phase separation, the ethyl acetate layers were drawn off with a Pasteur pipete, combined, and passed through a silica Sep-pak cartridge (previously washed with 15 ml of chloroform) to remove polar impurities. The Sep-Pak cartridge was then eluted with 8 ml of 7.5% ethyl acetate in chloroform and the combined eluates were concentrated to dryness by rotary evaporation. The samples were taken up to 1 ml in chloroform and stored at −70°C until analyzed. In all cases, extraction recoveries of standard solutions were equal to or greater than 83%.

Linear furanocoumarins were resolved on a 25-cm Ultrasphere 80 Å pore silica column, preceded by an Ultrasphere 5-μm guard column on a model 334 liquid chromatograph (Beckman, Fullerton, California). The solvent system consisted of HPLC grade chloroform (Aldrich, Milwaukee, Wisconsin) pumped at a flow rate 1.5 ml/min (modified from Beier, 1985). Eluting components were monitored with a Beckman 160 UV detector set at 254 nm; sample peaks were recorded and integrated on a model 3392A integrator (Hewlett Packard, Avondale, Pennsylvania). Recovery of standards always exceeded 83%. Elutants were identified using mass spectrometry performed on a 7070E mass spectrometer (VG Analytical, Ltd., Wythenshawe, U.K.). Samples were analyzed using a solid probe (200–250°C) under electron ionization conditions (70 eV, source temperature = 150°C). A mass range of 100–300 daltons was scanned. The standards used in this study were psoralen, bergapten (5-methoxypsoralen), and xanthotoxin (8-methoxypsoralen), and isopimpinellin (5,8-methoxypsoralen) (Figure 1). The first three were purchased from Aldrich, and the last was

RESULTS AND DISCUSSION

Mass Spectrometry. The most important fragment ions for psoralen included: *m/z* 187 (24%); 186 (71%, $[M]^+ \cdot$); 159 (22%); 158 (100%); 130 (23%); 129 (45%); 103 (11%); 102 (53%); and 101 (27%). Key fragment ions for bergapten *m/z* 217 (26%); *m/z* 216 (72%, $[M]^+ \cdot$); 201 (42%); 188 (27%); 187 (19%); 174 (22%); 173 (94%); 146 (21%); 145 (74%); 144 (20%); 102 (22%); and 100 (19%). Identifying fragment ions for xanthotoxin included: *m/z* 217 (26%); *m/z* 216 (72%, $[M]^+ \cdot$); 201 (60%); 188 (45%); 174 (40%); 173 (100%); 158 (22%); 145 (92%); 129 (37%); 117 (21%); 116 (23%); 102 (25%); and 101 (21%). Key fragment ions for isopimpinellin included: *m/z* 246 (39%, $[M]^+ \cdot$); 231 (100%); 203 (27%); 188 (39%); 175 (33%); 160 (30%); 147 (25%); 143 (23%); 104 (49%); and 103 (21%). No other linear furanocoumarins were detected.

Simulated Acidic Fogs. Leaves from plants exposed to acidic fogs with a pH of 2.0 had significantly higher concentrations of the phototoxic furanocoumarins than plants treated with control fogs within 24 hr posttreatment (Figure 1). At 120 hr after exposure, all linear furanocoumarins reached significantly higher levels after exposure to 2.0 pH fogs. In contrast, fogs of 3.0 pH did not increase the levels of any furanocoumarins at 24 hr. However, all compounds except psoralen increased significantly in leaves at 120 hr. Foliar and petiole lesions were observed on all plants exposed to fogs with a pH of 2.0, but not on plants treated with control fogs or with fogs of pH 3.0.

Leaves consistently had higher concentrations than petioles and the linear

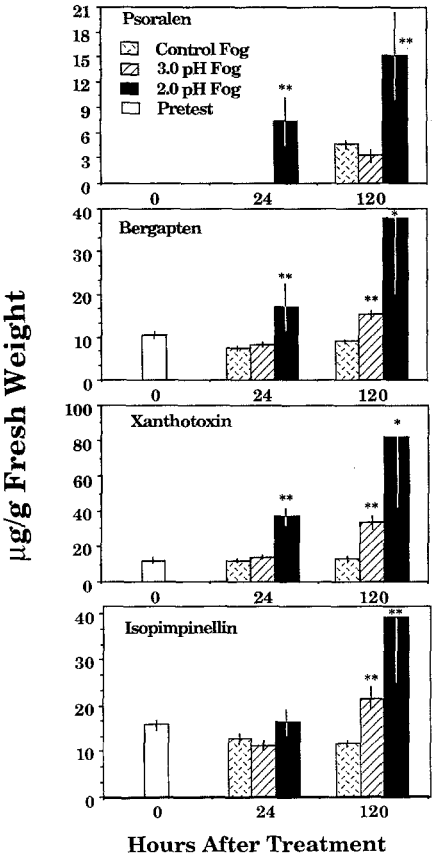

FIG. 2. Acute impact of acidic fogs of pH 2.0 and 3.0 and control fogs (pH 6.3–6.5) on linear furanocoumarin content in celery leaves. Bars delineate standard errors. furanocoumarins psoralen, bergapten, xanthotoxin, and isopimpinellin (Figures 1 and 2). Although this trend has been reported previously, the levels of psoralen, bergapten, and xanthotoxin (phototoxic furanocoumarins) from control plants in our test were sixfold higher in leaves and stems than observed by Beier et al. (1983a) (mean from leaves or petioles for psoralen ≤ 0.15, bergapten ≤ 1.5, xanthotoxin 3.5 ppm), but were similar (ca. 1.4-fold greater) to the concentrations reported by Berkley et al. (1986) (phototoxic furanocoumarins = 11.2 ppm in petioles and = 20.4 ppm in leaves). Such increases may be due

to varietal effects (Berkley et al., 1986), but direct comparisons with previous studies were not possible because the cultivars tested were not reported.

The foliar concentrations of the phototoxic furanocoumarins in our study are of considerable concern because of a new trend in marketing intact celery plants (leaves not trimmed) (T. Batkin, manager, California Celery Research Advisory Board, Dinuba, California, personal communication) rather than the more common "topped" celery (most leaves removed). Even in our control plant foliage, levels of the phototoxic furanocoumarins were more than twice (ca. 30 μg/g fresh weight) the critical level of 18 μg/g fresh weight known to cause phototoxic dermatitis (Austad and Kavli, 1983). Foliage from plants exposed to an acidic fog with a pH of 3.0 exceeded 50 μg/g fresh weight. The foliar concentrations of these compounds in plants exposed to a single fog of pH 2.0 reached 140 μg/g fresh weight and should be considered hazardous.

The concentrations of phototoxic furanocoumarins in petioles (59.7 μg/g fresh weight) of plants exposed to fogs of pH 2.0 exceeded the critical level of 18 μg/g by over 300%. Thus, even celery marketed with the leaves trimmed may have considerable potential for human health concerns if exposed to highly acidic fogs. However, petioles from plants treated with a control fogs or a fog with a pH of 3.0 contained concentrations of these chemicals below the critical level.

Ozone Fumigations. In general, ozone fumigation had a markedly different effect on content of linear furanocoumarins than did acidic fogs. Ozone fumigation was conducted at 20 ppm, a level which is reached in excess of 20 or more days each year in agricultural areas near Los Angeles. Foliage of plants exposed to ozone had significantly reduced concentrations of psoralen, bergapten, and isopimpinellin; xanthotoxin levels were not significantly reduced (Figure 3). At 120 hr posttreatment, no significant differences were evident between treatments. Levels of these compounds in petioles at 24 hr followed similar trends but were not significant at the $P < 0.05$ level (Figure 4). No differences in concentration were detected at 120 hr following ozone fumigation. Several mechanisms for the observed reductions in furanocoumarin concentrations appear possible: (1) the ozonolysis of the olefinic bonds in the furan or lactone rings found on these compounds, (2) the induction of degradation enzymes is inhibited, and/or (3) the inhibition of biosynthetic enzymes is occurring. Additional research will be required to document the critical mechanism(s).

Although the plants examined in the acidic fog and ozone trials were all from the same seedlot, planted at the same time, and agronomically treated the same, the control plants in the ozone tests developed consistently higher quantities of the linear furanocoumarins. This could have been caused by a reduction in concentration following control fogs, or more likely, an increase in furanocoumarin content occurring as a result of plant size (Austad and Kavli, 1983).

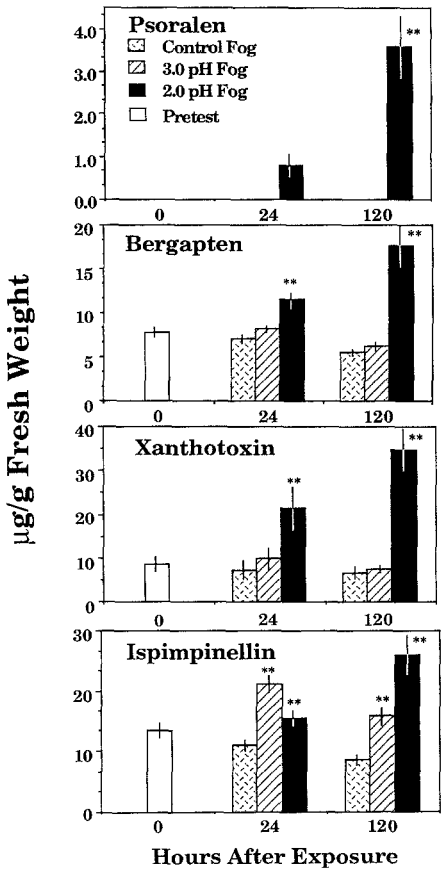

FIG. 3. Acute impact of acidic fogs of pH 2.0 and 3.0 and control fogs (pH 6.3–6.5) on linear furanocoumarin content in celery petioles. Bars delineate standard errors. Asterisk(s) next to points indicate significant differences from plants treated with a control fog (*$P \leq 0.05$, **$P \leq 0.01$, Student's t test, 16 df).

The plants used in the ozone trial were about eight weeks older than those used in the acidic fog tests and had reached the 36/carton stage. Nonetheless, the foliar contents of these chemicals were above the levels required to cause contact dermatitis. Because contact dermatitis in celery handlers is common [19 cases in 48 handlers in the most recent study (Seligman et al., 1987)], we suspect that the concentrations of phototoxic furanocoumarins found in our study are not unusual. At the least, the effects of atmospheric pollutants will help

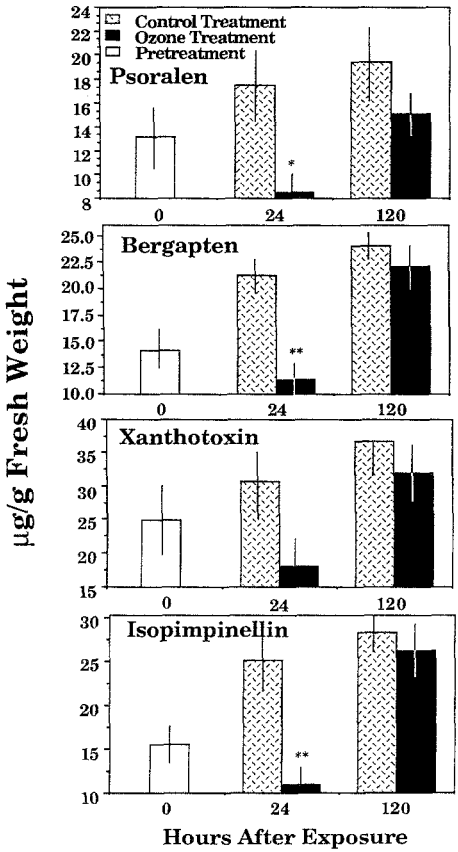

FIG. 4. Acute effects of 2-hr ozone fumigation of celery at 20 ppm on linear furanocoumarin content in foliage of a commercial celery variety. Bars delineate standard errors. Asterisk(s) next to points indicate significant differences from plants not treated with ozone (*$P \leq 0.05$, **$P \leq 0.01$, Student's t test, 16 df).

account for some of the variability in furanocoumarin contents reported in the literature.

The concentrations of linear furanocoumarins found in our study may be conservative. None of the plants used in any portion of this study exhibited symptoms of disease or were subjected to mechanical damage or cold temperatures, which could increase furanocoumarin content (Austad and Kavli, 1983; Ashwood-Smith et al., 1985; Beier and Oertli, 1983; Chaudhary et al., 1985). In addition, plants in our study were subjected to only acute exposure to atmo-

spheric pollutants. The impact of longer or chronic exposures to acidic fogs or ozone in combination with other environmental stresses on the production of linear furanocoumarins is worthy of additional study. To our knowledge this is the first report of anthropogenic air pollutants inducing production of plant metabolites which can be injurious to human health. These results raise the intriguing possibility that continuing production of atmospheric air pollutants could be having deleterious effects on our food supply beyond simply decreasing yields (Leung et al., 1982) or increasing insect damage (Trumble et al., 1987). This, in turn, leads to the possibility that certain geographic areas subject

to acidic fogs may be less desirable for production of celery for human consumption.

INHIBITION OF CUCUMBER LEAF EXPANSION BY FERULIC ACID IN SPLIT-ROOT EXPERIMENTS[1]

KRISTOFER KLEIN and UDO BLUM

Department of Botany
North Carolina State University
Raleigh, North Carolina 27695-7612

(Received December 6, 1988; accepted March 2, 1989)

Abstract—Experiments were conducted to determine how the proportion of a root system in contact with an allelopathic compound may affect seedling responses. Cucumber seedlings grown in a split-root nutrient culture system were given either single (1 mM) or multiple applications (0.5 mM) of ferulic acid. Seedlings receiving single applications were left in the treatment solutions for two days and then harvested, while seedlings receiving multiple applications had their solutions changed every other day for a total of three changes. Leaf areas were determined daily starting with the initial ferulic acid treatment. Mean absolute and mean relative rates of leaf expansion were inversely related to the proportion of the root system in ferulic acid solution. Leaf expansion was inhibited primarily during the first 24 hr after each treatment. A partial recovery of growth occurred during the second 24-hr period following each treatment. Root length was reduced by ferulic acid. These results suggest that information on root and allelochemical distribution in soils is important when assessing the potential of allelopathic interactions between plants.

Key Words—Allelopathy, ferulic acid, cucumber seedlings, *Cucumis sativus*, split-root treatments, leaf expansion, mean absolute growth rate, mean relative growth rate, growth inhibition.

INTRODUCTION

Many allelopathic compounds have been identified in soils that may affect the growth and development of plants (Whitehead, 1964; Wang et al., 1967; Whitehead et al., 1982). These are derived primarily from organic debris and living roots, which are normally unevenly distributed on or in the soil. Thus, for any given point in time, only a portion of a root system may be in contact with allelopathic compounds, and the proportion of the root system in contact with such agents will vary with time as the roots grow in the soil. Most bioassay studies, however, treat the whole root system (Patterson, 1981; Rice, 1984; Blum and Dalton, 1985). How plant growth may be affected by the proportion of the root system in contact with allelopathic agents has not been investigated. Several authors, however, have suggested that this may substantially affect plant response (Patrick et al., 1964; Lynch, 1985; Blum and Rebbeck, 1989).

The objective of this investigation, therefore, was to determine how seedling responses to allelopathic agents may be modified by varying the proportion of the root system in contact with an allelochemical. We chose ferulic acid and cucumber seedlings (*Cucumis sativus* cv. Early Green Cluster) for this study. Ferulic acid has been identified as an allelopathic compound (Wang et al., 1967; Rasmussen and Einhellig, 1977; Patterson, 1981) that affects cucumber seedling growth in a predictable manner (Blum and Dalton, 1985).

METHODS AND MATERIALS

A nutrient culture system was chosen for these experiments because contact between ferulic acid and roots can be easily controlled and every molecule in the solution in which the roots are immersed has the potential to interact with the roots. In soil systems both roots and ferulic acid are subject to uneven distribution. Absolute and relative growth rates were used because they provided a sensitive measure of ferulic acid effects on cucumber seedlings. In addition, Blum and Dalton (1985) observed that leaf area of cucumber seedlings and dry weight were directly related.

Single Ferulic Acid Treatment. Cucumber seeds (*Cucumis sativus* cv. Early Green Cluster) were placed in trays containing vermiculite and Hoagland's solution (pH 5.6) (Hoagland and Arnon, 1950). The seeds were allowed to germinate in the dark at 25°C for four days. On the fourth day, emerging seedlings were exposed to light for 8 hr before being transferred to containers with 110 ml of Hoagland's solution. The seedlings were suspended by foam collars through the lids of the containers. The plants were grown for an additional eight days under light banks (twelve 40-W cool white fluorescent and six 25-W incandescent bulbs). Seedlings received 140 $\mu E/m^2/sec$ over a 12-hr photoperiod

(Blum and Dalton, 1985). The growth temperatures ranged from 21 to 30°C. Water lost via evapotranspiration was replaced daily with deionized water. Nutrients supplied by the 110 ml were adequate since Blum and Dalton (1985) had previously demonstrated that 110 ml of 1/4 to 1/2 strength Hoagland's nutrient solution supplied adequate nutrition for cucumber seedlings over a 17-day growth period under these light banks. On day 12 the seedlings were suspended by foam collars through lids of 700-ml containers ($N = 25$). The seedling root systems were suspended into smaller containers within the 700-ml containers. The smaller containers were filled with 110 ml of Hoagland's solution (CONT) or a 1 mM ferulic acid–Hoagland's solution (FA). Containers were covered with aluminum foil to exclude light. Deionized water was added daily to each container to compensate for evapotranspiration. The initial pH of all solutions was 5.6.

Root systems of seedlings were placed in either a single container (100% CONT or 100% FA) or split between CONT and FA (~25, 50, or 75% FA) containers. The primary root was placed in the container with the largest root mass. In cases of 50:50 split, the primary root was randomly placed in either CONT or FA. For each seedling, the percentage of root length in each container was calculated based on root length measurements (see data analysis below). Only one container was used for the 100% CONT (controls) and 100% FA treatments since the Hoagland's solution supplied was more than adequate for normal growth of cucumber seedlings (Blum and Dalton, 1985).

Length and width measurements (mm) of the leaves on each plant were recorded daily starting on day 12. On day 14, roots were severed from the shoots and placed into 70% ethanol until they could be measured. The CONT and FA treated roots were stored separately. To measure total root length, all secondary lateral roots were severed from the primary root, and the primary and secondary roots were measured to the nearest centimeter. Root systems of five seedlings were also harvested on day 12 to provide an estimate of the average starting root length.

Multiple Ferulic Acid Treatments. The general procedures and growth conditions of this experiment were the same as the previous experiment. In this case, however, roots were treated three times with 0.5 mM ferulic acid solution ($N = 25$). This lower concentration was used because the 100% FA (1.0 mM) plants in the first experiment wilted.

Seedlings were treated on days 13, 15, and 17 by replacing all solutions. Leaf areas were measured daily starting with day 13 and ending with day 19, when the seedlings were harvested. In addition, sets of five seedlings with 100% of their root systems in CONT or FA were harvested on days 13 (CONT only), 15, 17, and 19.

Data Analyses. For both experiments, the daily leaf area (cm^2) of each seedling was determined from length (L) and width (W) measurements (mm)

of each leaf using the following formula: leaf area = $-1.457 + [0.00769 * (L * W)]$ (Blum and Dalton, 1985). Mean absolute and mean relative rates of leaf expansion (AGR and RGR, respectively) were then calculated (see Radford, 1967) by the following equations:

$$AGR = \text{leaf area at day}_{x+1} - \text{leaf area at day}_{x}$$

and

$$RGR = \ln(\text{leaf area at day}_{x+1}) - \ln(\text{leaf area at day}_{x})$$

where AGR is in cm^2/day and RGR is in cm^2/cm^2/day.

Root growth of control plants (100% CONT) was greater, on average, than root growth of plants in ferulic acid (100% FA). This suggested that for the split-root systems the proportion of roots in ferulic acid changed with time. To adjust the proportions, we assumed (1) that roots of the split-root system in CONT and in FA grew independently and (2) that root growth in the 100% CONT or FA was representative of the corresponding root portions of the split-root system.

Average root lengths for the 100% CONT or FA treatments (roots were harvested on days 12 and 14 of the first experiment and days 13, 15, 17, and 19 of the second experiment) were used to calculate appropriate coefficients for each time interval. The coefficients were calculated, for example, by taking the average root length for day 17 (a) and 19 (b) and solving for x (where $x = a/b$). These coefficients in conjunction with final root lengths (day 14 or 19) were used to back-calculate the ratio of roots in FA and CONT for the split-root seedlings on day 12 for experiment 1 and days 13, 15, and 17 for experiment 2. Data were analyzed using the Statistical Analysis System (SAS) programs for linear and multiple regressions (SAS Institute Inc., 1985).

RESULTS

Single Ferulic Acid Treatment. As the proportion of roots of cucumber seedlings treated with 1 mM ferulic acid increased, absolute (AGR) and relative (RGR) growth rates declined (Figure 1). When 100% of the root system of these seedlings was placed in FA, they wilted shortly after treatment but became turgid again within 24 hr. Leaf area data for these seedlings were deleted from the analysis since there was such an abrupt change in growth rates because of wilting. We felt, however, that root adjustments could be based on these seedlings because all roots in the 1 mM ferulic acid would be similarly affected. The slopes of the regression lines for both the AGR and RGR (slopes for growth periods 12–13 and 13–14 were -0.0947, -0.0470 for the AGR and -0.0024,

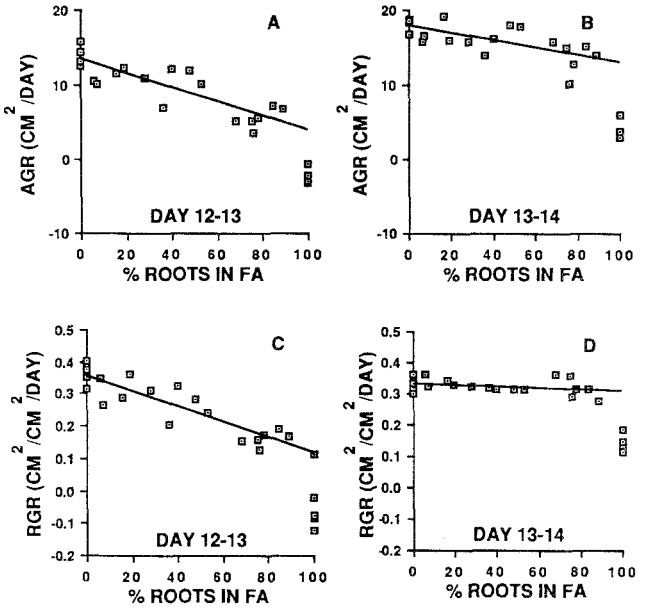

FIG. 1. Mean absolute (AGR) and mean relative (RGR) rates of leaf expansion of cucumber seedlings for which various proportions of roots (% ROOTS IN FA) were treated with 1 mM ferulic acid on day 12. R^2 values for A, B, C, and D were 0.86, 0.81, 0.85, and 0.76, respectively.

−0.00026 for the RGR) shifted significantly during the second 24-hr period after treatment, indicating a recovery of leaf expansion for the treated seedlings (Figure 1). The mean pretreatment root length for both CONT and FA ± standard error (SE) on day 12 was 157.76 ± 13.7 cm. The mean root lengths ± SE for the two treatments on day 14 were 203.9 ± 11.6 and 309.1 ± 17.3 for FA and CONT, respectively.

Multiple Ferulic Acid Treatments. The leaf area of seedlings for which the entire root system (100% FA) was treated with ferulic acid was significantly less than the controls (100% CONT) one day after the second treatment (day 16; Figure 2A), while a significant reduction in the rate of leaf expansion was observed 24 hr after the first treatment (i.e., growth period 13–14; Figure 3). All subsequent ferulic acid treatments reduced leaf area and leaf expansion during the first 24-hr period after treatment. Recovery of growth rates was evident during the second 24-hr period after each 0.5 mM ferulic acid treatment (Figure 3). This was particularly evident for the RGR. A significant reduction in mean

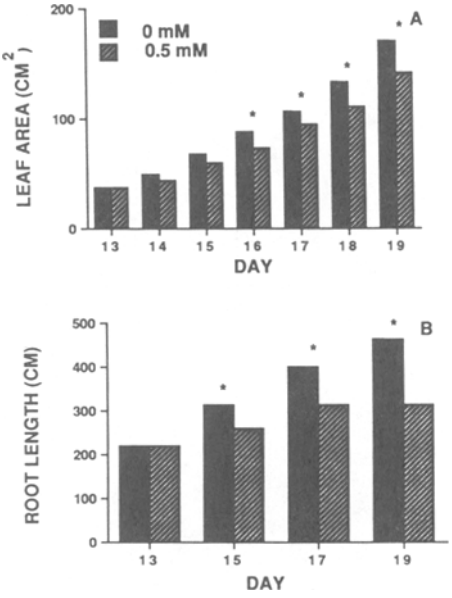

FIG. 2. Mean leaf area and root length of cucumber seedlings treated (100% of the roots in CONT or FA) with 0 or 0.5 mM ferulic acid solution on days 13, 15, and 17. Asterisks indicate significance at 0.05 levels.

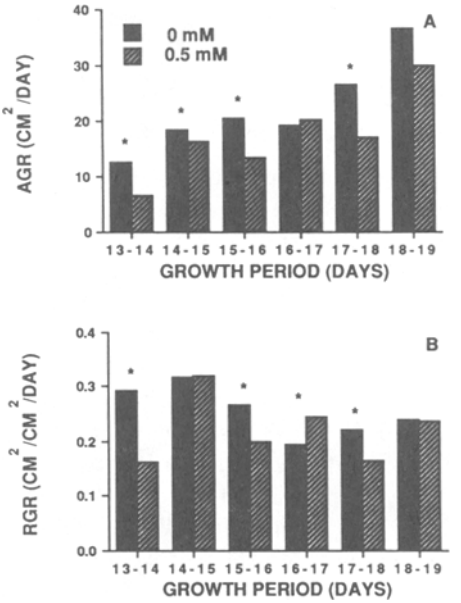

FIG. 3. Mean absolute (AGR) and mean relative (RGR) rates of leaf expansion of cucumber seedlings treated (100% of the roots in CONT or FA) with 0 or 0.5 mM ferulic acid solution on days 13, 15, and 17. Asterisks indicate significance at 0.05 level.

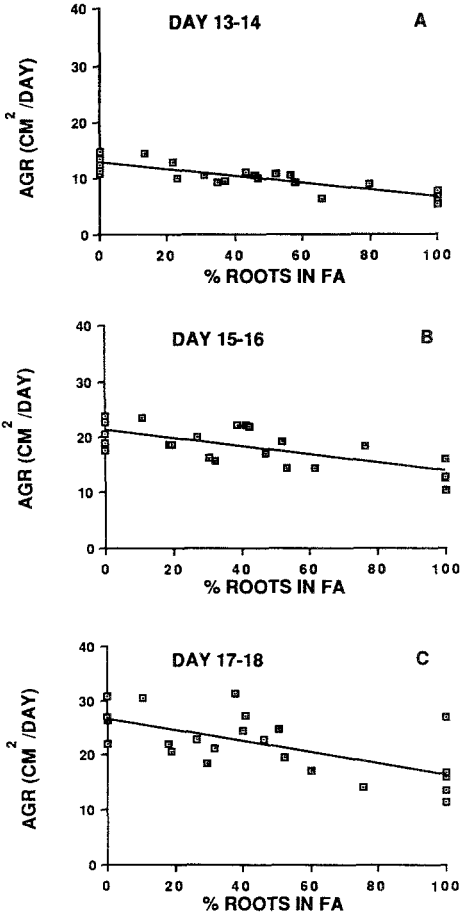

FIG. 4. Absolute (AGR) rates of leaf expansion of cucumber seedlings for which various proportions of roots (% ROOTS IN FA) were treated with 0.5 mM ferulic acid on days 13, 15, and 17. R^2 values for A, B, and C were 0.74, 0.50, and 0.42, respectively.

root length was observed when 100% FA roots were compared to 100% CONT roots 48 hr after each treatment (Figure 2B).

As the proportion of the root system treated with 0.5 mM ferulic acid increased, the growth rates of leaves declined (Figures 4 and 5). The best models were generated for the 13 to 14-day growth period. The scatter of the data along the regression lines increased for the subsequent growth periods. R^2 values for the AGR declined from 0.74 (day 13–14) to 0.42 (day 17–18) and the R^2 values for the RGR declined from 0.79 to 0.35.

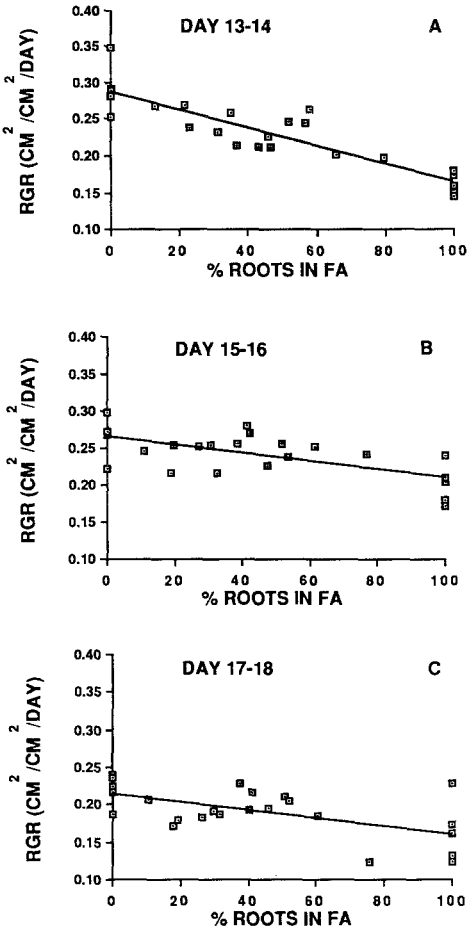

FIG. 5. Mean relative (RGR) rates of leaf expansion of cucumber seedlings for which various proportions of roots (% ROOTS IN FA) were treated with 0.5 mM ferulic acid solution on days 13, 15, and 17. R^2 values for A, B, and C were 0.79, 0.41, and 0.35, respectively.

DISCUSSION

The transitory effects of ferulic acid were apparent from the initial reduction of leaf expansion during the first 24-hr period and the observed recovery of leaf expansion during the second 24-hr period after each treatment. Similar transitory effects of ferulic acid were observed by Blum and Rebbeck (1989). They noted that inhibitory effects of ferulic acid on cucumber seedling growth

required the continued presence of the acid in the nutrient solution. Once ferulic acid was removed from the nutrient solution, "normal" root and leaf growth resumed.

Leaf expansion (i.e., AGR, RGR) was inversely related to the proportion of the root system in ferulic acid solution for both the 1.0 and 0.5 mM ferulic acid treatments. This is the first experimental evidence that the proportion of a plant root system in contact with a known allelopathic compound may indeed affect the level of growth inhibition. These observations, if confirmed for other species and other allelopathic compounds, suggest that a knowledge of the concentration and distribution of allelopathic compounds in the rhizosphere of a plant may be more meaningful in determining potential allelopathic interactions between plants than concentrations and distributions determined from bulk soil samples.

Acknowledgments—The authors wish to thank Drs. R.C. Fites, A.D. Worsham, and A.G. Wollum for review of this manuscript.

(Received September 21, 1988; accepted March 5, 1989)

Abstract—Responses by adult *Oryzaephilus surinamensis* (L.) and *Oryzaephilus mercator* (Fauvel) to various food volatiles were assessed by means of a two-choice, pitfall olfactometer. The individual experimental stimuli, all potential products of lipid oxidation, had a range of attractive doses of $\leq$ 1000-fold over the test dose ranges of 0.001–100 μg, or 0.01–1000 μg. Of 13 aliphatic C_3–C_{14} aldehydes and benzaldehyde tested for *Oryzaephilus* spp., 10 C_3–C_{10} aliphatic aldehydes and benzaldehyde showed some attractiveness for both species. For *O. mercator*, nonanal had the lowest lower threshold for positive response at 0.01 μg. The addition of small amounts of nonanal or of a 1 : 1 : 1 mixture of hexanal, octanal, and nonanal to small amounts of cucujolide aggregation pheromones enhanced response by mixed-sex *O. mercator* to the pheromones. Eleven aliphatic C_2–C_9 free fatty acids showed some attractiveness for both *Oryzaephilus* spp. Isovaleric acid and valeric acid had the lowest lower thresholds for positive response at 0.1 μg for *O. mercator* and *O. surinamensis*, respectively. Four olefinic oat volatiles were found to possess various degrees of attractiveness for both *Oryzaephilus* spp. The data suggest that food volatiles in this study might be used by *Oryzaephilus* spp. as host-finding kairomones in nature.

Key Words—*Oryzaephilus surinamensis* (L.), *Oryzaephilus mercator* (Fauvel), Coleoptera, Cucujidae, attractants, aliphatic C_3–C_{14} aldehydes, benzaldehyde, aliphatic C_2–C_9 free fatty acids, 2(*E*),4(*E*)-heptadienal, 2(*E*),4(*E*)-nonadienal, 3(*E*),5(*E*)-octadien-2-ol, 3(*E*),5(*E*)-octadien-2-one, oat volatiles.

INTRODUCTION

The sawtoothed grain beetle, *Oryzaephilus surinamensis* (L.), and the merchant grain beetle, *O. mercator* (Fauvel), are cosmopolitan pests of stored products. *O. surinamensis* is one of the most common pests of stored grain and processed cereals in Canada, United States, Britain, Australia, Asia, Africa, and South America (Sinha and Watters, 1985). *O. mercator* has become firmly established as a household pest in North America, especially on cereal products (Loschiavo and Sabourin, 1982).

Identification of attractive semiochemicals for *Oryzaephilus* spp. could contribute to the development of integrated control programs (Levinson and Levinson, 1979; Burkholder, 1981). Feeding males of both *Oryzaephilus* spp. produce macrolide aggregation pheromones, a class of pheromones given the trivial name cucujolide because of its prevalence in the family Cucujidae (Oehlschlager et al., 1988). These cucujolides have been identified as 3(*Z*),11(*R*)-dodecen-11-olide [(*R*)-II] and 3(*Z*),6(*Z*),11(*R*)-dodecadien-11-olide [(*R*)-IV] for *O. mercator*, and (*R*)-IV, 3(*Z*),6(*Z*)-dodecadienolide (IX), and 5(*Z*),8(*Z*),13(*R*)-tetradecadien-13-olide [(*R*)-V] for *O. surinamensis* (Pierce et al., 1985, 1987). In addition, males and females of both *Oryzaephilus* spp. maintained at low population densities produce another aggregation pheromone, (*R*)-(−)-1-octen-3-ol (Pierce et al., 1989).

Pierce et al. (1981) reported that *Oryzaephilus* spp. were attracted to Porapak Q-trapped volatiles from rolled oats or brewer's yeast. Unpublished analyses of these volatiles by coupled gas chromatography–mass spectroscopy (GC-MS) revealed the presence of hexanal, heptanal, octanal, nonanal, decanal, dodecanal, and benzaldehyde in the rolled oat volatiles, while benzaldehyde and isobutyric, 2-methylbutyric, isovaleric, and valeric acids were detected in brewer's yeast volatiles. Hexanal and nonanal comprised ~10% and ~14%, respectively, of the Porapak Q-trapped volatiles from rolled oats. Mikolajczak et al. (1984) have identified a number of volatile attractants from rolled oats for *O. surinamensis*. Additionally, some attractants from carobs also have been identified for *O. surinamensis* by O'Donnell et al. (1983) and Stubbs et al. (1985).

Our current objective was to screen various host-produced volatiles (primarily aldehydes and free fatty acids) as potential attractants for both *Oryzae-*

philus spp. Such attractants could be candidates for the formulation of a more cost-effective field bait containing host volatiles as well as cucujolides.

METHODS AND MATERIALS

Experimental Insects. O. mercator and *O. surinamensis* were reared on large-flake rolled oats and brewer's yeast (95:5, w/w) in 3.8-liter glass jars in an environmental chamber maintained at 28–30°C and 40–60% relative humidity in darkness.

Experimental Stimuli for Bioassay. Fatty acids, aldehydes, 2(*E*),4(*E*)-heptadienal, and 2(*E*),4(*E*)-nonadienal were purchased from commercial supply houses, and all but the fatty acids were distilled before use. Compounds were checked by gas chromatography (GC) before use and found to be ≥99% pure. Macrocyclic lactones for bioassay were racemic cucujolide II (Oehlschlager et al., 1983) and racemic cucujolide IV (Millar and Oehlschlager, 1984). Addition of methyllithium in ether to an etheral solution of freshly distilled 2(*E*),4(*E*)-heptadienal (Aldrich Chemical Company, Inc., Milwaukee, Wisconsin) gave, after aqueous work-up and bulb-to-bulb distillation, 3(*E*),5(*E*)-octadien-2-ol in 88% yield, which was 95% pure by GC analysis. Oxidation of 3(*E*),5(*E*)-octadien-2-ol with active MnO_2 in pentane gave, after removal of MnO_2 by filtration, evaporation of solvent, and bulb-to-bulb distillation, 3(*E*),5(*E*)-octadien-2-one in 81% yield, which was 95% pure by GC analysis. Analyses of the dienol and dienone by GC-MS indicated that the impurity in each was an isomer of unknown double-bond configuration.

Instrumental Methods. A Hewlett-Packard 5830A gas chromatograph equipped with a 18835B capillary inlet system and a flame-ionization detector was employed for analyses by GC. Helium was the carrier gas, and the injection port and detector temperatures were 260°C and 270°C, respectively. Samples were analyzed on an open-tubular glass column (40 m × 0.5 mm ID) coated with SP-1000 (Supelco Canada Ltd., Oakville, Ontario, Canada). The temperature program for analytical GC was 70°C for 2 min, then 4°C/min to 180°C, holding for 30 min or less.

GC-MS was performed on a Hewlett-Packard 5895B GC-MS-data system fitted with a fused silica column (30 m × 0.25 mm ID) coated with Carbowax 20 M (J&W Scientific, Folsom, California) with helium as the carrier gas.

Bioassay Procedures. Bioassays were conducted at 23°C and 60% relative humidity using mixed-sex beetles 5–12 weeks posteclosion. To ensure a uniform state of preconditioning for *O. mercator*, each replicate of 12 beetles was held in a 60-ml glass vial without food for 20 hr at 23°C darkness prior to a bioassay (Borden et al., 1979). To obtain maximum responsiveness from *O.*

surinamensis, up to 1500 beetles were preconditioned without food for 48 hr at 23°C in darkness in a 6-liter Erlenmeyer flask, through which charcoal-filtered, humidified air was drawn at 1.5 liters/min (Pierce et al., 1985). Since response by *O. surinamensis* to olfactory stimuli is extremely sensitive to population density (Pierce et al., 1983), test beetles were maintained at a low density of 1000 beetles/kg medium for at least one week before bioassays commenced.

A two-choice, pitfall olfactometer (Pierce et al., 1981) was utilized to test attractiveness of experimental stimuli. Filter paper disks, treated with a 10-μl aliquot of either an experimental stimulus in purified pentane or purified pentane as a control, were put singly into the bottoms of two glass vials suspended from holes in the bottom of a plastic Petri dish arena. (All test compounds dissolved completely in pentane at the concentrations used.) Twelve beetles were released into the dish, and the lid was replaced. Bioassays for each test solution were replicated 12 times (i.e., 12 olfactometers), using 12 fresh beetles in each replicate. After 2 hr in darkness, the numbers of beetles in experimental and control vials were recorded. For the compounds in Tables 1, 3, and 4 (below), all doses for a particular test compound were done in the same bioassay session, beginning with 12 replicates of the lowest dose and proceeding in sequence to the highest dose. The responsiveness of the test beetles was checked by bioassaying a standard low dose of cucujolides at the start of a bioassay session.

The untransformed data were analyzed by the paired-sample t test (Zar, 1984). For some experiments, the data also were analyzed by ANOVA followed by the Newman-Keuls test. Results were expressed as mean percent response = 100 (experimental − control)/N where experimental and control were the number of beetles in the vials containing the experimental and control disks, respectively, and N was the total number of insects released into the dishes. For each test solution, the number of responding insects was $\geq 90\%$ of those released.

RESULTS

For *O. mercator*, nonanal was the aldehyde having the lowest threshold for positive response, with significant positive responses demonstrated at experimental doses ranging from 0.01 to 10 μg (Table 1). Hexanal, octanal, 2-methylpropanal, and benzaldehyde had the next lowest thresholds for positive response at 0.1 μg. Over the test dose range examined, nonanal, hexanal, and 2-methylpropanal had the greatest attractive ranges of 1000-fold each.

For *O. surinamensis*, hexanal, pentanal, 2-methylpropanal, and nonanal were the aldehydes having the lowest thresholds for positive response at the

	0.02		0.1	66.8***c

[a] Each experiment was completed in a separate 2-hr session.
[b] Significant response (t test) to experimental stimulus indicated by: *$P < 0.05$, **$P < 0.01$, ***$P < 0.001$. $N = 12$ replicates per treatment, 12 adults per replicate. Means within experiments 2 or 3 followed by the same letter not significantly different (Newman-Keuls test, $P < 0.05$).

tive ranges of 1000-fold each over the test dose range examined. Valeric acid induced the lowest threshold for positive response by *O. surinamensis* at 0.1 μg; and acetic, octanoic, and nonanoic acids gave the greatest attractive ranges, each of 1000-fold, over the test dose range examined. All but heptanoic, octanoic, and nonanoic acids were repulsive or elicited no significant response at the highest dose for *O. mercator* (Table 3). For *O. surinamensis*, all fatty acids in high amounts were repulsive except for acetic, heptanoic, octanoic, and nonanoic acids, which were attractive at the 1000-μg dose.

Of four olefinic oat volatiles tested (Table 4), 2(*E*),4(*E*)-heptadienal, 3(*E*),5(*E*)-octadien-2-ol, and 3(*E*),5(*E*)-octadien-2-one had attractive ranges of 0.1–10 μg for *O. mercator*. 2(*E*),4(*E*)-Heptadienal and 3(*E*),5(*E*)-octadien-2-ol were attractive at 0.1–10 μg for *O. surinamensis*. Over the dose range examined for both *Oryzaephilus* spp., 2(*E*),4(*E*)-nonadienal was attractive at 1–100 μg. 3(*E*),5(*E*)-Octadien-2-one was attractive only at the 10-μg dose for *O. surinamensis*.

TABLE 3. RESPONSE BY *O. mercator* AND *O. surinamensis* IN TWO-CHOICE, PITFALL BIOASSAY TO FREE FATTY ACIDS

Test species	Fatty acid[a]	$\bar{X}$% response[b]					
		0.01 μg	0.1 μg	1 μg	10 μg	100 μg	1000 μg

DISCUSSION

Biological Implications. The positive responses to host volatiles in this study suggest that some of these compounds might be used by *Oryzaephilus* spp. as host-finding kairomones in nature. Compared to the cucujolide pheromones and 1-octen-3-ol (A.M. Pierce et al., 1985, 1987, 1989), however, the potential kairomones had relatively higher thresholds for positive response.

The aldehydes and free fatty acids listed in Tables 1 and 3 are ubiquitous natural products in cereals (Maga, 1978) and are common products of lipid oxidation. An increase in levels of free fatty acids is often used as an indicator of deteriorating grain stores (Zeleny, 1954), since grain-infesting fungi (Zeleny, 1954) and bacteria (Kaminski et al., 1980) are well-known producers of free fatty acids. Infestation by *O. surinamensis* in wheat plus dockage resulted in high levels of fat acidity and in infestation by *Penicillium* spp. and bacteria (Sinha, 1983). Because *Oryzaephilus* spp. are commonly associated with a wide variety of stored products of high oil content, it is evidently of adaptive advantage to utilize products of lipid oxidation as host-finding kairomones.

2(*E*),4(*E*)-Heptadienal, 2(*E*),4(*E*)-nonadienal, and 3(*E*),5(*E*)-octadien-2-one have been identified in rancid oat groats (Heydanek and McGorrin, 1981b), while 2(*E*),4(*E*)-nonadienal and 3(*E*),5(*E*)-octadien-2-one have been found in rolled oats (Mikolajczak et al., 1984) and dried oat groats (Heydanek and McGorrin, 1981a), respectively. The above three compounds are probable lipid-autooxidation products (Heydanek and McGorrin, 1981b); 3(*E*),5(*E*)-octadien-2-ol is a likely precursor of 3(*E*),5(*E*)-octadien-2-one.

In their study of oat volatile attractants for *O. surinamensis*, Mikolajczak et al. (1984) found that 2(*E*),4(*E*)-nonadienal was attractive to *O. surinamensis* at only two doses, 0.1 and 1 μg, with repulsion at 100 μg. In the same study, heptanal, hexanal, octanal, and benzaldehyde were moderately attractive, and nonanal was not attractive. Our results (Table 1) indicate lower threshold concentrations and greater active dose ranges than found by Mikolajczak et al. (1984), with the exception of the opposite trend for propanal.

At one test dosage for each compound, propanal, hexanal, hexanoic acid, and nonanoic acid were attractive to *O. surinamensis*, while nonanal and propionic acid were not attractive (O'Donnell et al., 1983). The authors noted that it is unwise to make conclusions about the relative attractancy of such compounds without testing them over a range of doses. In a study of volatile attractants for *O. surinamensis* from carobs, hexanoic acid was more attractive than acetic, isobutyric, butyric, or 2-methylbutyric acids over a range of stimulus dilutions (Stubbs et al., 1985), whereas we found little attraction of *O. surinamensis* by hexanoic acid (Table 3). However, the use of a bioassay based on an insect activity detector in the studies by O'Donnell et al. (1983) and Stubbs et al. (1985) makes comparisons with our results difficult.

Short- and medium-chain aldehydes and fatty acids have been implicated as kairomones for other stored-product insects. Octanal and octanoic acid induced aggregation of larval *Trogoderma glabrum* (Herbst) (Nara et al., 1981). Adults of *Tribolium castaneum* (Herbst) and *Trogoderma granarium* Everts were repelled by C_5–C_9 and C_5–C_8 fatty acids, respectively; valeric acid was a phagostimulant for larvae of *T. granarium* and *Dermestes maculatus* De Geer, while octanoic acid and nonanoic acid were feeding deterrents (Cohen et al., 1974). In comparison with our experiments, these assays were conducted over a very narrow dose range, and further experimentation could well alter the above conclusions.

Practical Implications. The data in Table 2 suggest that, for *O. mercator*, adding nonanal or a mixture of hexanal, octanal, and nonanal to field traps containing cucujolides might be an economical way of lowering the response threshold for the less volatile cucujolides. Adding the highly volatile (*R*,*S*)-1-octen-3-ol to cucujolide mixtures also enhanced the response to the cucujolides in laboratory bioassays for *O. mercator* and *O. surinamensis* (Pierce et al., 1989) and in field traps for *O. surinamensis* (Pierce et al., 1990). Hexanal, octanal, and nonanal in mixture did not interfere with response by *O. mercator* to the individual aldehydes since the response to the three-part aldehyde mixture extended over a greater range, 0.01–100 μg, than response to any of the three individual aldehydes (Tables 1 and 2). Thus, in the absence of pheromones, the three-part aldehyde mixture would be a better trap bait for *O. mercator* than the individual aldehydes.

Other attractive compounds in this study might be more effective as field baits when presented as mixtures. The more volatile, shorter-chain aldehydes such as 2-methylpropanal and pentanal might function over longer distances as useful attractants, while the less volatile, longer-chain compounds such as heptanoic, octanoic, and nonanoic acids might be effective at short range. Because of the limited attractive ranges of some of the potential kairomones, however, release rates would have to be carefully controlled.

(Received November 1, 1988; accepted March 7, 1989)

Abstract—When electroantennographic responses of male *Yponomeuta malinellus* Zeller to model compounds were determined at dosages of 0.3–30 ng, the strongest responses were obtained from (*Z*)-9-dodecen-1-ol acetate (*Z*9–12 : Ac). Also, strong responses were obtained from (*Z*)-11-tetradecenal (*Z*11–14 : Al) and (*Z*)-11-tetradecen-1-ol (*Z*11–14 : OH). At a dosage of 0.3 ng, *Z*11–14 : Al produced a stronger response than *Z*11–14 : OH, while at a dosage of 30 ng, *Z*11–14 : OH and *Z*11–14 : Al produced equal responses. Gas chromatographic and mass spectral analysis of extracts of female sex pheromone glands showed the presence of *Z*9–12 : Ac, tetradecan-1-ol (14 : OH), (*E*)-11-tetradecen-1-ol (*E*11–14 : OH), *Z*11–14 : OH, hexadecan-1-ol, and hexadecan-1-ol acetate in a ratio of 0.6 : 200 : 37 : 100 : 140 : 35. In field tests, *Z*9–12 : Ac and *Z*11–14 : OH together were required for trap catch, and addition of *Z*11–14 : Al, *E*11–14 : OH, 14 : OH, or (*Z*)-11-tetradecen-1-ol acetate did not increase catch. Ratios in rubber septa of 0.5 : 99.5 to 1.5 : 98.5 (*Z*9–12 : Ac/*Z*11–14 : OH) captured the most males and captures were statistically equivalent for dosages of 10–1000 μg/rubber septum. Traps baited with the synthetic lure produced better catches than those baited with females.

Key Words—Lepidoptera, Yponomeutidae, *Yponomeuta malinellus*, sex pheromone, apple ermine moth, (*Z*)-9-dodecen-1-ol acetate, (*Z*)-11-tetradecen-1-ol.

[1] Lepidoptera: Yponomeutidae.

INTRODUCTION

The apple ermine moth, *Yponomeuta malinellus* Zeller, is a member of a European group of small ermine moths (*Yponomeuta*) that have been studied in recent years in order to clarify taxonomic and evolutionary relationships among species within this genus. This group consists of nine species, of which five are classified as members of the "*padellus* complex" (Wiebes, 1975). The *padellus* complex consists of *Y. padellus*, *Y. cagnagellus*, *Y. mahalebellus*, *Y. malinellus*, and *Y. rorellus*. The other four species are *Y. evonymellus*, *Y. irrorellus*, *Y. plumbellus*, and *Y. vigintipunctatus*. Species of the *padellus* complex are difficult to distinguish morphologically and other features such as feeding preference and sex pheromones may be used for positive identification (Van der Pers and Den Otter, 1978). In flight-tunnel and field tests, attractants have been established for seven of the nine species. Compounds that are involved in the sex pheromones of these species include (*Z*)- and (*E*)-11-tetradecen-1-ol acetates (*Z*11- and *E*11–14 : Ac) and their corresponding alcohols (*Z*11- and *E*11–14 : OH), tetradecyl acetate (14 : Ac) and corresponding alcohol (14 : OH), (*Z*)-11-hexadecen-1-ol acetate (*Z*11–16 : Ac), and hexadecyl acetate (16 : Ac) (Löfstedt and Herrebout, 1988; Löfstedt et al., 1986; Löfstedt and Van der Pers, 1985). Attractants have not been established for *Y. mahalebellus* and *Y. malinellus*.

Although the actual sex pheromone has not been reported for *Y. malinellus*, some studies of its sex pheromone system have been carried out. In flight-tunnel tests, Hendrikse (1986) found that *Y. malinellus* males flew upwind to *Y. evonymellus* females, but terminated response when about 20 cm from them. In measurements of electrophysiological responses to model compounds of single sensilla trichodea of male *Y. malinellus*, van der Pers and den Otter (1978) reported the strongest response was obtained from *Z*11–14 : OH and moderate responses were obtained from *Z*11–14 : Ac, *E*11–14 : Ac, and *Z*9–14 : Ac. In an electroantennographic (EAG) profile of all the normal, monoene, 14-carbon acetates, Hendrikse et al. (1982) reported that *Z*11–14 : Ac gave the strongest response. Although a response profile for the corresponding 14-carbon alcohols or other series was not reported, they reported that *Z*11–14 : OH produced a stronger response than *Z*11–14 : Ac. In single-cell analysis, they found the strongest response from *Z*11–14 : OH and obtained moderate responses from *Z*9,*E*12–14 : Ac, *Z*11–14 : Ac, *Z*11–14 : Al, *Z*11–13 : Ac, *Z*9–13 : Ac and *Z*9–12 : Ac. C. Löfstedt (personal communication) has found *Z*11-, *E*11–14 : OH, and 14 : OH in extracts of female sex pheromone glands, but these compounds did not produce trap catch in field tests. In field tests, *Y. malinellus* have been reported to be captured in traps baited with *Z*11–14 : Ac (Arn et al., 1974; Stockel, 1981).

Y. malinellus occur in both Europe and Asia. Our interest in *Y. malinellus*

developed because of its detection in nursery stock in British Columbia, Canada, in 1981 and subsequently in Washington State, U.S.A in 1985 (Douglas J. Parker, personal communication). Thus, an effective attractant was needed to detect and monitor populations of *Y. malinellus* as part of a program attempting to prevent its spread into commercial apple orchards. Here we report the development of a highly effective lure based on a mixture of *Z*11–14 : OH and *Z*9–12 : Ac.

METHODS AND MATERIALS

Insects. Larvae and pupae of *Y. malinellus* in their tents were collected from an infested apple tree near Bellingham, Washington, U.S.A., placed in sealed containers, and transported to a quarantine rearing facility in Yakima. The tents were divided into parts, each containing several cocoons, and each part was placed on moist peat moss in a closed container. The room was maintained at 50% relative humidity and 20°C with a 16 : 8 light–dark cycle. Adults were collected daily 3 hr after onset of photophase and sexed. The females were maintained in separate glass vials while the males were maintained together in cages, and both sexes were provided with a 10% sugar solution.

Collection of Pheromone. Calling female moths (6–7 days old) were collected 3–4 hr into photophase and chilled in a refrigerator for about 10 min to inactivate them. Terminal abdominal segments were severed and steeped for 15 min in dichloromethane, and the solution was removed with a syringe and stored at −20°C until used.

EAG. The experimental apparatus was the same as previously described (McDonough et al., 1980). Test cartridges for the EAG profiles were loaded with 60 μg of model compound. Duplicate determinations were made for each datum point both in the EAG profile and in the concentration study. The model compounds were available commercially or were prepared and purified by established synthetic methodology (Voerman, 1988). They were at least 98% pure by gas chromatographic analysis, and contained 1% or less of the geometrical isomer.

GC-EAG. Fractions of female sex pheromone gland (SPG) extract for EAG analysis were collected from a GC equipped with a megabore capillary column (methyl silicone; DB-1; 15 m × 0.53 mm ID; J & W Scientific, Folsom, California) connected to a glass-lined splitter sending one part of effluent to the detector and nine parts to the collector. The GC was programmed at 2°/min from 120 to 210°C. Ten fractions encompassing the retention time of 10 : OH through 18 : Ac were collected as follows, (fraction) time interval in min: (1) 5–15.5; (2) 15.5–18; (3) 18–21; (4) 21–24; (5) 24–27.5; (6) 27.5–32; (7) 32–37.5; (8) 37.5–43; (9) 43–47; (10) 47–53. The retention times in minutes, of synthetic reference compounds were: 10 : OH, 5.5; 12 : OH, 7.9; 12 : Ac, 17.3;

Z11–14:OH, 21.8; 14:Ac, 31.0; 16:Ac, 42.2; 18:OH, 47.1; 18:Ac, 51.7. GC analysis of SPG extract was accomplished with a capillary column (methyl silicone; DB-1; 60 m × 0.25 mm; J & W Scientific) operated at 180°C.

LC. An extract of 150 female SPG was chromatographed on a column of silica gel (0.6 g). The column was eluted successively with hexane, hexane–dichloromethane (70:30), and dichloromethane. The hexane–dichloromethane (70:30) and dichloromethane fractions containing esters and alcohols were combined and concentrated for GC-MS analysis.

GC-MS. A Hewlett-Packard (Avondale, Pennsylvania) gas chromatograph (model 5790) with a quadruple mass selective detector (model 5970) was equipped with a capillary column (DB-Wax; 60 m × 0.25 mm ID; J & W Scientific). When the gland extract of 10 female *Y. malinellus* was analyzed, the column was held at 80°C for 2 min and programmed at 20°/min to 200°C and maintained at that temperature. Total ion abundance from $m/z = 15$ to $m/z = 300$ was monitored. When the cleaned-up extract of 150 females was analyzed in the single ion monitor (SIM) mode, the same temperature program was used, but ions 61 and 166 were monitored between 12 and 17 min (Z9–12:Ac at 12.78 min); ions 68, 166, and 194 were monitored between 17 and 20 min (Z11–14:OH at 18.10 min); and ions 81 and 210 were monitored between 20 and 28 min (*E*10,*E*12–14:OH at 24.03 min).

Field Tests. Field tests were conducted in a block of 18 apple trees near Bellingham, Washington. Test chemicals were dissolved in rubber septa (West Co., Phoenixville, Pennsylvania), and placed in Pherocon 1C traps (Trece, Corp., Salinas, California). The traps were hung in the upper one-third of the canopy of each tree. Three replicates of six test lures were randomly drawn for trap positions. Each week the number of males in the traps was counted and the traps were replaced. In the test with female *Y. malinellus* as the bait, three females in a screened cage were placed in each trap.

RESULTS

EAG. EAG response profiles of male *Y. malinellus* to the *n*-alkyl and *n*-alkenyl 12- and 14-carbon alcohols and acetates are given in Figure 1. The values are expressed as a percent of the response to Z9–12:Ac, which produced the strongest response. Z11–14:OH was comparable to, but not as strong as, Z9–12:Ac (87%). Z11–14:Ac produced a stronger response than other 14-carbon acetates (76%) but was weaker than Z11–14:OH. The EAG profile for the 14-carbon acetates has been reported previously (Hendrikse et al., 1982), and our results are in agreement with theirs. A few other compounds were also available for testing. These were the (Z)- and (*E*)-7-, 9-, and 11-tetradecenals and hexadecenals and the (Z)- and (*E*)-7-, 9-, and 11-hexadecenyl alcohols and

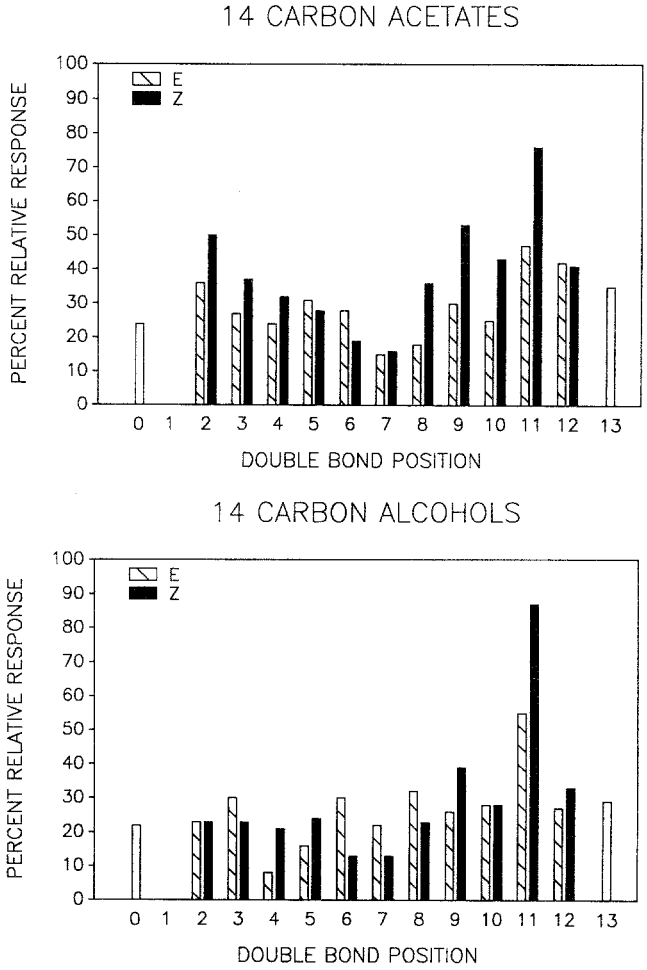

FIG. 1. Electroantennographic responses of male apple ermine moth (*Yponomeuta malinellus*) to model compounds. Numbers indicate double-bond position; zero indicates saturated.

acetates. Of this group, only Z11–14 : Al produced a strong response (85% of Z9–12 : Ac).

To better evaluate the relative potency of the compounds producing strong EAG responses, EAG measurements were made at dosages of 0.1, 0.3, 1.0, 3.0, 10.0, and 30.0 ng/test cartridge. Z11–14 : Al, Z11–14 : OH, and Z9–12 : Ac gave excellent linear correlations for EAG response versus logarithm of the dosage (Table 1). The intercepts (y_0), which are the responses in mV at a dos-

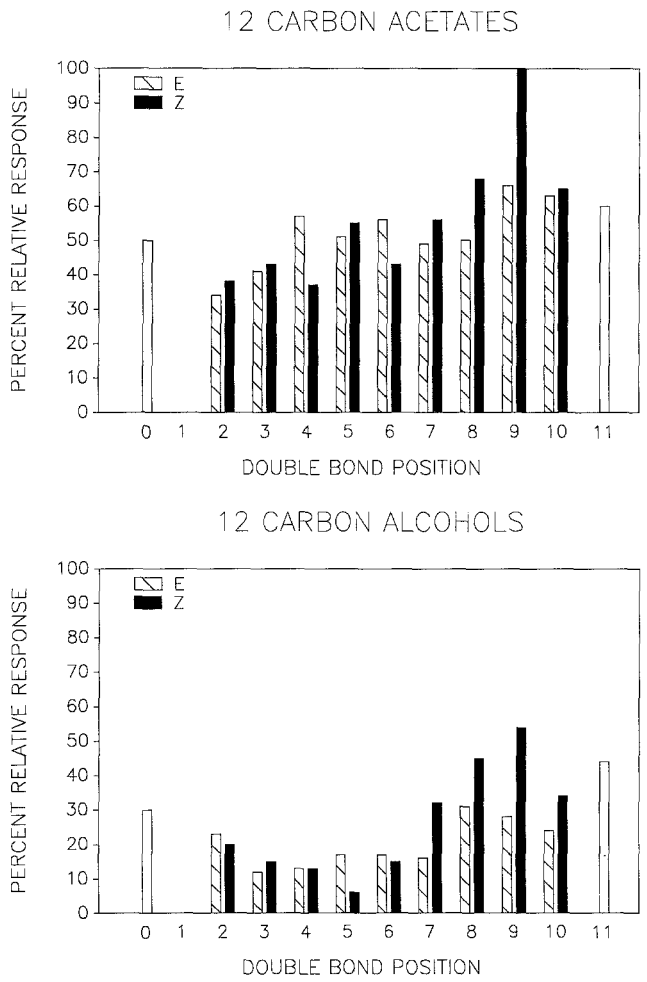

FIG. 1. (*Continued*)

age of 1 ng, showed the order to be Z9-12:Ac > Z11-14:Al > Z11-14:OH > Z11-14:Ac. Because of the differing slopes (*m*), Z11-14:OH and Z11-14:Al produced approximately equivalent responses at dosages above 30 ng.

GC-EAG and GC-MS. Gas chromatographic fractions of extract of sex pheromone glands of 59 female *Y. malinellus* covering the volatility range from the retention time of 10:OH through 18:Ac were collected from a methyl silicone column, and the EAG response to each fraction was determined. Fraction 4, containing the 14-carbon alcohols, produced the strongest response (0.8 mV above the blank). A capillary GC trace (methyl silicone column) of extract indicated the presence of 14:OH, *E*11-14:OH, and Z11-14:OH in this frac-

TABLE 1. LINEAR REGRESSION PARAMETERS FOR EQUATION $E = m \ln d + y_0$[a]

Compound	y_0	m	r^2
Z11-14:OH	0.442	0.200	0.96
Z11-14:Al	0.620	0.152	0.996
Z9-12:Ac	0.960	0.234	0.992
Z11-14:Ac	0.287	0.074	0.82

[a] E is the electroantennographic response in millivolts, m is the slope of the line, ln d is the natural logarithm of the dosage (over the range 0.3–30 ng) and y_0 is the intercept.

tion. The other fractions produced responses ranging from 0.2 to 0.4 mV. Fraction 2, which would contain Z9-12:Ac and Z11-14:Al if present, produced the 0.2-mV response.

A GC-MS analysis of the extract of SPGs from 10 females showed the presence of the following compounds in the given ratios: 14:OH (2.0), E11-14:OH (0.37), Z11-14:OH (1.0), 16:OH (1.4), and 16:Ac (0.35). The amount of Z11-14:OH in the extract was 5.8 ng. An extract of SPGs from 150 females was partially purified by liquid chromatography. The alcohol and ester fractions were combined, concentrated, and analyzed by GC-MS (SIM). The ions monitored were chosen so as to be able to detect Z9-12:Ac, Z11- and E11-14:OH, and E10,E12-14:OH. The analysis indicated 14.9 ng of Z11-14:OH, 6.5 ng of E11-14:OH, 0.09 ng Z9-12:Ac (0.6% of Z11-14:OH; retention time 12.794 min; ratio of 61/166 ions = 43:57; retention time of Z9-12:Ac standard was 12.795 min; ratio of 61/166 ions = 45:55; limit of detection 0.05 ng), and no E10,E12-14:OH.

Field Tests. In test 1 (Table 2), traps baited with Z11-14:OH + E11-14:OH, did not catch significant numbers of males, whereas traps baited with the three-component lure, Z11-14:OH + E11-14:OH + Z9-12:Ac caught large numbers of males. When the dosage was 100:30:1, catches exceeded those of traps baited with females. All of the females were alive at the end of the test. Traps baited with the three-component lure caught as many males as the traps baited with the three components plus Z11-14:Al (test 2). Test 3 showed that both Z11-14:OH and Z9-12:Ac must be present to produce trap catch, but the presence or absence of E11-14:OH had no effect on trap catch. Various combinations of Z11-14:OH + E11-14:OH + Z11-14:Ac did not produce trap catch even though Z11-14:OH + E11-14:OH + Z9-12:Ac produced a very high capture (test 4). Dosages of Z11-14:OH + Z9-12:Ac (100:1), ranging over a factor of 100, produced equivalent catch (test 5). Also, ratios of Z11-14:OH to Z9-12:Ac of 99.5:0.5 to 98.5:1.5 and perhaps to 97.5:2.5 produced equivalent trap catch (test 6), and ratios of 99.7:0.3 and 97:3 produced lower catch (test 1).

[a] There were three replicates per test lure. In each test numbers followed by the same letter were not significantly different ($P = 0.05$) by Duncan's multiple-range test.

DISCUSSION

The EAG studies of model compounds, GC-EAG, GC-MS, and field tests, indicate *Z*11–14 : OH and *Z*9–12 : Ac are sex pheromone components of *Y. malinellus*. The failure of the GC-EAG experiment to show a strong response to the fraction containing *Z*9–12 : Ac is not inconsistent with this conclusion. Based on the 0.8-mV response of the GC-EAG fraction containing *Z*11–14 : OH, the percentage of *Z*9–12 : Ac relative to *Z*11–14 : OH in the GC-MIS (SIM) experiment, and the parameters of Table 1, a value of 0.2 mV, the same as was found, would be predicted for the GC-EAG fraction containing *Z*9–12 : Ac. Although *E*11–14 : OH was present in SPG extracts, it had no effect on trap catch. Thus, its possible significance in the communication system is not clear. Because *E*11–14 : OH could be a biosynthetic precursor to *E*10,*E*12–14 : OH (Roelofs and Brown, 1982; Löfstedt and Bengtsson, 1988), the GC-MS (SIM) experiment was designed to detect its possible presence, but with negative results.

It is not known whether the North American *Y. malinellus* was introduced from Europe or Asia. It is also not known whether populations from these two areas differ, since studies of the sex pheromone system of *Y. malinellus* from Asia have not been reported. In Europe *Y. malinellus* is very closely related to *Y. padellus* (Nei's genetic distance is 0.083), and therefore these species are considered to have undergone evolutionary divergence from a *padellus*-like ancestor rather recently (Arduino et al., 1983; Arduino and Bullini, 1985). From their study of the sex pheromones of several *Yponomeuta* species, Löfstedt and Van der Pers (1985) suggested that *Z*11- and *E*11–14 : Ac + *Z*11–14 : OH comprised the sex pheromone of the ancestor to the present *Yponomeuta*. The structure of the sex pheromone of the American *Y. malinellus* appears to be consistent with these proposals. Slight redirections in the actions of the Δ11 desaturase and chain-shortening enzymes (Roelofs and Brown, 1982) of the *padellus*-like ancestor would be sufficient to develop the new pheromone systems of *Y. padellus* and *Y. malinellus*.

Lure longevity was not tested. However, it is possible to estimate the field life of the lure based on half-lives and effect of temperature on half-lives (Butler and McDonough, 1979, 1981; McDonough et al., 1989). In Bellingham, Washington, the average temperature during the 1988 summer was 17.5°C (Bellingham Public Works Department, private communication). Taking $t_{1/2}$ = 33 day at 20°C for *Z*9–12 : Ac and $t_{1/2}$ = 117 days at 20° for *Z*11–14 : OH and assuming lure longevity is limited by the time for the *Z*11–14 : OH/*Z*9–12 : Ac ratio to change from 98.5 : 1.5 to 99.5 : 0.5, we calculated longevities of 73 days at 20°C. Thus, a lure consisting of 200 μg *Z*11–14 : OH + 3 μg *Z*9–12 : Ac should provide a field life of 10 weeks without loss of efficiency.

Acknowledgments—We thank Mr. Eric LaGasa, Washington State Department of Agriculture, Dr. Charles Schwalbe, Animal and Plant Health Inspection Service, USDA, for helpful dis-

cussions, Dr. Ernest C. Bay, Washington State University Experiment Station, for providing the larvae and pupae of *Y. malinellus*, and Dr. Gerald Kraft, Bellingham, Washington, for use of his apple orchard.

(Received November 7, 1988; accepted March 7, 1989)

Abstract—Removal of type B trichome exudate from *Solanum berthaultii* leaflets leads to a decrease in tarsal gumming and mortality and an increase in feeding by the green peach aphid, *Myzus persicae*. Type B trichome exudate of the *S. berthaultii* accession PI 473331 is composed of a complex of 3′,3,4,6-tetra-*O*-acyl sucroses containing primarily short-chain branched carboxylic acids. The acyl constituents are primarily derived from 2-methylpropanoic, 2-methylbutyric, and 8-methylnonanoic acids but constituents derived from *n*-decanoic and dodecanoic acids are also present. Sucrose esters inhibit settling and probing by aphids in glass feeding cages.

Key Words—*Solanum berthaultii*, *Myzus persicae*, green peach aphid, Homoptera, Aphididae, sucrose esters of carboxylic acids, glandular trichome exudate, plant resistance to insects.

INTRODUCTION

The wild potato, *Solanum berthaultii* Hawkes, is defended against a variety of arthropod pests by the presence of two types of glandular trichomes on its foliage (Dimock and Tingey 1985; Gibson 1971, 1974; Tingey and Laubengayer, 1981, 1986; Tingey and Sinden, 1982). Type A trichomes are 120–210 μm in length with 50- to 70-μm diameter tetralobulate heads (Gregory et al., 1986).

[3]Present address: Purdue University, Department of Entomology, West Lafayette, Indiana 47907.

0098-0331/90/0200-0487$06.00/0

Upon rupture, these trichomes release an exudate that rapidly polymerizes (Ryan et al., 1982) and adheres to the tarsi and mouthparts of insects (Gibson and Turner, 1977; Tingey and Gibson, 1978). Small insects such as aphids may become entrapped on the leaf surface. The longer type B trichomes are 600–950 μm in length and secrete a viscous fluid that forms a droplet up to 45 μm in diameter on the tip of each stalk (Tingey, 1985). Type B exudate is important in the resistance of *S. berthaultii* to the green peach aphid, *Myzus persicae* (Sulzer). Transfer of type B exudate to foliage of the susceptible cultivated potato, *Solanum tuberosum* L., results in fewer probes, increased time to first probe, and reduced total feeding activity by *M. persicae* (Lapointe and Tingey, 1984). Type B exudate also has an interactive effect with type A trichomes. Aphids are more likely to rupture type A trichomes if their tarsi are coated with viscous type B exudate (Tingey and Laubengayer, 1981).

Trichomes of other plants of the family Solanaceae also produce viscous exudates that affect aphid behavior. Exudate from type IV trichomes of *Lycopersicon pennellii* Corr. (D'Arcy), a wild relative of the cultivated tomato, deters settling by the potato aphid, *Macrosiphum euphorbiae* (Thomas) (Goffreda et al., 1988). The active components of this exudate are glucose esters of branched chain carboxylic acids (Burke et al., 1987; Goffreda et al., 1988, 1989). Sucrose esters of carboxylic acids present in glandular trichomes of tobacco, *Nicotiana tabacum* L. are toxic to larvae of the tobacco budworm, *Heliothis virescens* (F.) (Cutler et al., 1986).

Recently, several tri- and tetra-*O*-acylated sucroses have been identified in exudate of *S. berthaultii* type B glandular trichomes (King et al., 1986; 1987a,b). We report here the performance of *Myzus persicae* on *S. berthaultii* after removing type B trichome exudate; the collection, isolation, and identification of carboxylic acid sucrose esters from type B exudate of *S. berthaultii* accession PI 473331; and describe the influence of sucrose esters on the behavioral activity of the green peach aphid.

METHODS AND MATERIALS

Identification and Isolation of Sucrose Esters. Seed of *Solanum berthaultii* (PI 473331) was obtained from the Interregional Potato Introduction Station (Sturgeon Bay, Wisconsin) and germinated in the greenhouse using peat–vermiculite media. Seedlings were transplanted in late May to field plots of Rhinebeck slit loam at the H.C. Thompson Vegetable Research Farm, Freeville, New York. Two bands of NPK fertilizer (168-168-168 kg [AI]/ha) were applied to each row before planting. EPTC (Eptam 10G) granules were applied at 67 kg/ha in July for weed control. Chlorothalonil (Bravo 500) was applied at 2.3

liters/ha with a hydraulic boom sprayer at 10-day intervals throughout the growing season for control of late blight.

Exudate of type B trichomes was collected in August by briefly dipping excised foliage in methanol. The leaf rinse was filtered, reduced to dryness *in vacuo* at 35°C, and partitioned between 25% aqueous methanol and hexanes. The aqueous phase was taken to dryness, dissolved in a minimal volume of chloroform, and fractionated by flash column chromatography (Still et al., 1978) on a 3 × 15-cm silica gel column eluted with a gradient from chloroform to 30% methanol. The fraction containing sucrose esters was fractionated further by a second passage over a silica gel column 1.5 × 15 cm, eluted with a gradient from chloroform to 10% methanol. Individual sucrose esters were purified by reverse-phase HPLC (Waters 5μ C18 radial compression; 17% aqueous acetonitrile, at 2 ml/min; detection at 210 nm).

Carboxylic acid compositions were determined from sucrose esters transesterified in ethanol using a J&W Scientific (Folsom, California) 30-m DB-FFAP capillary column. [^{1}H]- and [^{13}C] NMR experiments were performed on a Varian XL-400 instrument in $CDCl_3$. COSY spectra were recorded using double precision acquisition with a 4000-Hz spectral width, 128 τ_1 increments, and the spectra were zero-filled to a 512 × 512 data point set. Recycle time was 2 sec between each four transients per τ_1 increment. Fast atom bombardment collisionally activated dissociation (CAD) positive ion mass spectra were acquired on a Finnigan triple quadrupole mass spectrometer. The sample was bombarded with a beam of 6–8 kV cesium ions generated from a cesium ion gun. High-resolution fast atom bombardment spectra were acquired on a VG Instruments 70-250 SEQ in positive ion mode.

Aphid Rearing. A colony of *Myzus persicae* was initiated from a single nymph collected in July 1987 from field plots of the cv. Katahdin at Freeville, New York. The colony was maintained in a controlled environment chamber at 25°C, 16:8/light-dark photoperiod (250 μE/mm^2/sec) on excised terminal mainstems of *S. tuberosum* cv. Katahdin.

Removal of Type B Exudate Droplets. A number of solvents were tested for ability to rapidly and quantitatively remove the exudate droplets from type B trichomes while minimally disrupting the leaflet. Halogenated solvents are effective in removing trichome exudate but also remove cuticular components (King et al., 1987a,b) and cause rapid wilting and death of the leaflet. Type B droplets extract poorly in water (Holley et al., 1987). Alcohols (methanol or ethanol) are effective in type B droplet removal and cause minimal disruption of the leaf; type B trichome droplets begin to regenerate within 48 hr after removal with ethanol. Ethanol treatment does not affect polyphenol oxidase activity (Avé et al., 1986) of the type A trichome, while methanol causes a 10–15% decrease in oxidative activity (Neal and Tingey, unpublished data).

Biological Activity of Type B Droplets. Field grown plants (*S. berthaultii* accession PI 473331) were propagated by nodal cuttings and grown in a greenhouse under high intensity illumination (3600 E/mm^{2}sec) and 16:8/light–dark photoperiod. *S. tuberosum* cv. Katahdin plants (which lack type B droplets) were grown from tubers. Pairs of opposite leaflets on 10 leaves from three *S. berthaultii* plants were selected. For each pair, one leaflet was untreated, while type B droplets were removed from the other by dipping in ethanol for about 5 sec. As a control, the effects of the ethanol dip were measured using paired leaflets (one of each pair was dipped) on five leaves of a cv. Katahdin plant. Aphid nymphs were caged (2/cage) in 16-mm-diameter glass ring cages and held for 73 hr. The position of the aphids relative to the leaflet, whether or not they were in a feeding position, and mortality were recorded hourly for the first 8 hr and two to three times daily on days 2 and 3. Mortality and fraction feeding were compared by *t* test with single cages as replicates. After 73 hr, all aphids were evaluated for the presence of type A trichome exudate on the tarsi, and the diameter of the exudate accumulation measured at 30× magnification using an optical micrometer. The numbers of tarsi with exudate for aphids on dipped and untreated leaflets were compared by *t* test. The diameters of the exudate (for coated tarsi only) were compared for aphids on treated and untreated leaflets and for dead aphids and live aphids irrespective of treatment by *t* test.

Biological Activity of Sucrose Esters. Fourth instars and apterae were confined in groups of five using glass ring cages 25 mm diameter × 20 mm high. A Parafilm membrane stretched over a second ring cage served as the top of the chamber. Aphids were placed in each cage and allowed to probe inverted through the membrane for feeding on a solution of 20% sucrose. Ten cages were prepared for each treatment.

Behavioral activity of sucrose esters was determined by applying acetone solutions of the sucrose ester mixture to the membrane surface adjacent to the aphid. Control areas were treated with acetone alone (4 μl/cm^2). The acetone solution was spread as it dried to produce a uniform surface coating. For choice tests, a contiguous half of the surface was treated. Six concentrations of the sucrose ester mixture (100, 30, 10, 3, and 1 μg/cm^2) were tested. This is within the range present on the leaf; 10–20 μg/cm^2 were recovered from the leaf surface.

A second series of experiments was designed to determine the site of action of the sucrose esters on the green peach aphid. In these studies, the membrane was treated on the side opposite the aphid so that contact would be limited to the stylets. A choice test (concentration of 100 μg/cm^2) was compared to a sham-divided acetone-treated control, and a no-choice treatment (100 μg/cm^2) was compared to acetone alone and sucrose esters (100 μg/cm^2) on the side of the membrane adjacent to the aphid.

In both experiments, two parameters, i.e., settling and number of stylet sheaths, were measured. Settling was scored as the mean fraction of aphids resting on a membrane surface at each observation period. At least four observations were made at intervals not less than 2 hr apart during each 48-hr experiment. After the last observation, the sucrose diet solution was decanted and replaced with a solution of safranin O in methanol to stain stylet sheaths red. The parafilm membranes were inverted onto a grid, excess safranin removed with water, and the number of sheaths in a 50-mm^2 area counted at 25× magnification.

RESULTS

Effect of Type B Droplet Removal on Myzus persicae. Ethanol dip of *S. tuberosum* leaflets had no effect on feeding or mortality of aphids. Overall 72-hr mortality on *S. tuberosum* was 5% ($N = 19$). Removal of type B droplets from *S. berthaultii* significantly increased the fraction of aphids feeding for 36 hr after treatment (Figure 1). At 48 hr, type B trichome droplets began to regenerate on the dipped leaflets, and the fraction of aphids feeding declined. The 72-hr mortality on *S. berthaultii* was significantly higher ($P = 0.003$) on the untreated leaflets (67%) than on the dipped leaflets (20%). The average number of tarsi encased with type A trichome exudate per aphid was significantly higher ($P = 0.024$) for aphids on untreated leaflets (2.8) than aphids on dipped leaflets (1.4). There was no difference in the average diameter of the exudate residue ($P = 0.17$) for aphids on dipped and untreated leaflets. However, the size of the exudate accumulation was greater ($P = 0.0002$) on dead aphids (57 μm/coated tarsus) than on live aphids (35 μm/coated tarsus). All dead aphids were found on the cage and had left the leaf surface before expiring.

Identification of Sucrose Esters in Type B Trichome Exudate. HPLC analyses demonstrate that sucrose esters are the predominant components in type B trichome exudate of *S. berthaultii.* The primary acyl constituents were 2-methylpropanoic (45%), 2-methylbutyric (28%), 8-methylnonanoic (23%), *n*-decanoic (2%), and dodecanoic acids (2%) and were identified as their ethyl esters. Although the ester complex is heterogeneous by HPLC, [^{1}H]-NMR spectra of the region δ 5.5–3.0 of both the sucrose ester complex and purified sucrose esters were identical, showing that all members of the complex were similarly esterified. COSY spectra were effective in identification of overlapping coupled spin systems. Three positions of esterification were indicated by three downfield shifted resonances besides H-1 of glucose (δ 5.48, d, $J = 3.4$ Hz) in [^{1}H] NMR spectra: δ 5.25, t, $J = 9.6$ Hz (H-3); δ 5.1, t, $J = 9.6$ Hz (H-4); δ 5.15, d, $J = 8.0$ Hz (H-3′). Although cross-peaks from H-5 to H-6 were not detected in

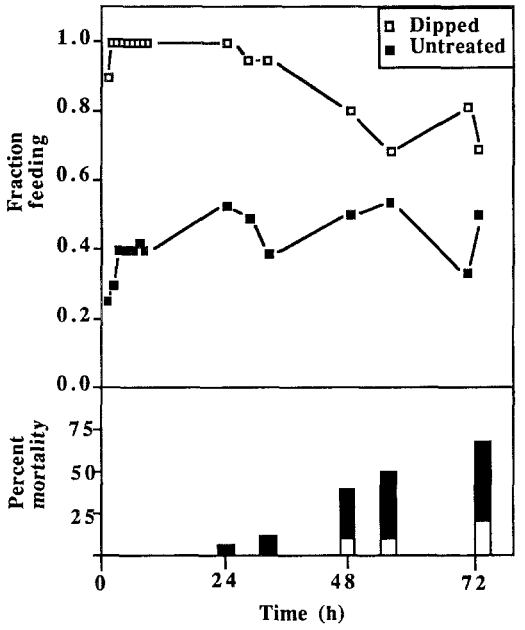

FIG. 1. Mortality and fraction of aphids feeding on *Solanum berthaultii* leaflets from which the type B exudate has been removed. Mortality at all time intervals and fraction feeding at 1 through 32 hr is significantly different for treated versus untreated leaflets (G test of independence, $P = 0.05$). At 48 hr, droplets on treated leaflets began to reappear.

COSY spectra, the singlet at δ 4.20 suggested an additional point of acylation at C-6 (King et al., 1987a). Four carbonyl resonances were apparent in ^{13}C spectra of a purified sucrose ester (δ 176.47, 174.95, 174.56, and 173.44). Other ^{13}C signals for the sucrose skeleton were nearly identical to those reported by King et al. (1987a) for 3',3,4,6-tetra-*O*-acyl sucroses in other *S. berthaultii* accessions.

Fast atom bombardment (fab) mass spectra (positive ions) of the sucrose ester complex gave major high-mass ions (Na^+ adducts) at *m/z* 757, 743, and 729. High-resolution fab of *m/z* 743 confirmed tetra-*O*-acylation (*m/z* 743.3859, $C_{35}H_{60}O_{15}Na^+$, calc. 743.3829); GC analysis indicated the presence of 3-methylpropanoic, 2-methylbutyric, and 8-methylnonanoic acids. CAD (positive ions) of the *m/z* 703 ion ($M + H - H_2O$) in a triple quadripole mass spectrometer gave a fragment of *m/z* 471 representing the triacylated glucopyranosyl cation bearing 3-methylpropanoic, 2-methylbutyric, and 8-methylnonanoic sub-

stituents; losses of the neutral acids were evident as ions *m/z* 383 (13%), 369 (22%), and 299 (13%). CAD of the *m/z* 743 Na^+ adduct further indicated that the fructose moiety was acylated with 3-methylpropanoic acid by the appearance of the *m/z* 273 (87%) 3-methylpropanoic acid fructose ester Na^+ adduct ion. Neutral loss of the 3-methylpropanoic acid fructose ester fragment gave rise to the tri-O-acylglucose Na^+ adduct bearing 2-methyl-propanoic, 2-methylbutyric, and 8-methylnonanoic acids (*m/z* 511, 60%). Other significant ions in the CAD spectrum of *m/z* 743 were *m/z* 655 (10%), 641 (8%), 493 (92%), 423 (12%), 409 (8%), 405 (20%), 391 (19%), and 255 (10%).

Activity of Sucrose Esters against Myzus persicae. In all artificial feeding cage trials, aphid survival over the 48-hr observation period exceeded 95%. At a concentration of 100 $\mu g/cm^2$, sucrose esters on the side adjacent to the test aphids significantly deterred aphid settling and reduced probing in both choice (Table 1) and no choice tests (Table 2). Deterrence declined with decrease in concentration; significant deterrent activity was still present at 33 $\mu g/cm^2$, but not at 10 $\mu g/cm^2$. While a concentration of 30 $\mu g/cm^2$ provided uniform membrane coverage, coverage was splotchy at 10 $\mu g/cm^2$. Sucrose esters coated on the membrane side opposite the aphids did not influence settling or probing in either choice (Table 3) or no choice assays (Table 2). Settling and probing behaviors were affected only when aphids were in physical contact with the sucrose esters.

DISCUSSION

While the sucrose esters from glandular trichomes of *N. tabacum* are toxic to *H. virescens* (Cutler et al., 1986), there is no evidence of acute toxicity of *S. berthaultii* sucrose esters to *M. persicae*. Ingestion may be a requirement for toxicity. Aphids are able to avoid ingestion of these compounds because of their method of feeding. The probable cause of death is starvation. *M. persicae* suffers significant mortality after 72 hr of starvation, which is consistent with the

results of our experiments. Sucrose esters were not toxic to the green peach aphid during 48 hr of exposure in feeding cages. Aphids avoided the treated surface and did not feed. When caged on plants, aphids that eventually died were found off the leaf surface for one or more observations prior to death, and dead aphids were always found on the cage and not on the plant.

Despite the lack of toxicity, sucrose esters are effective deterrents of settling and probing by aphids. Our results suggest that contact with organs other than the stylets is required for behavioral activity. The behavioral activity of these compounds could be due to either chemosensory or tactile responses. Sucrose esters are tacky when applied to a parafilm membrane. Other tacky materials such as Tween 80 also inhibit aphid settling (Neal and Tingey, unpublished data; 4 mg/cm^2 reduced settling at 24 hr from 60% to 0%, $N = 10$). However, chemosensory-based avoidance of Tween 80 is also possible. Although little is known about the gustatory properties of sucrose esters from *S. berthaultii*, sucrose octaacetate, an ester used to denature alcohol, is intensely bitter to humans (Windholz et al., 1976) and may be perceived similarly by aphids.

While previous studies have demonstrated immobilization of aphids by type A exudate (Gibson and Turner, 1977), aphids were not immobilized in our study. Perhaps the design of the cage allowed the aphids a convenient exit from the leaf surface before they ruptured sufficient type A trichomes. Consistent with previous reports (Tingey and Laubengayer, 1981), the presence of sucrose ester droplets led to an increase in the number of tarsi that accumulated type A exudate.

King et al. (1987b) have shown that several tuber-bearing *Solanum* spp. possessing secretory type B trichomes accumulate sucrose esters as the primary component of trichome exudate. These species have also been described as insect resistant (Lapointe and Tingey, 1986; see also Tingey, 1981). Based on the physiological properties of both free fatty acids and their esters toward insects (Shepard, 1951), and on the biological activity of sucrose esters from *Nicotiana tabacum* (Cutler et al., 1986) and glucose esters of *L. pennellii* (Goffreda et al., 1988), it is likely that all the reported acyl sucroses contribute significantly to the aphid resistance reported in these species.

Investigation of the 2,3,4-tri-*O*-acyl glucose complex of *L. pennellii* trichomes indicates that individual glucose esters varying in carboxylic acid constituents do not differ in deterrent activity against potato aphid, *Macrosiphum euphorbiae*, in feeding cages (Goffreda et al., 1989). However, mixtures may be important in determining the viscosity or adhesive properties of the trichome droplets. Highly purified sucrose esters are less viscous than mixtures (personal observation). Water content or minor components of the droplets may also affect physical properties of the exudate. Optimum resistance to insects may depend on the physical characteristics of the droplet because proper adhesion to the

insect is required for optimum rupture of type A trichomes (Tingey and Laubengayer, 1981).

Commercial aphid-resistant potato cultivars bearing glandular trichomes containing sucrose esters may eventually be developed. Although commercial *S. tuberosum* cultivars lack the glandular trichomes necessary to deliver sucrose esters to the leaf surface, some *S. tuberosum* × *S. berthaultii* hybrids (Mehlenbacher et al., 1983) produce type B trichomes bearing droplets of sucrose esters (King et al., 1987b; Steffens et al., in preparation). In addition to deterring feeding by aphids, recent work indicates that 3,4,6-tri-*O*-acylsucrose contributes to late blight (*Phytophthora infestans*) resistance of *S. berthaultii* PI 473340 (Holley et al., 1987). Synthetic sucrose esters may also prove useful in foliar application for protection against aphids, aphid-borne diseases, and *P. infestans*.

Acknowledgments—We are grateful to an anonymous reviewer for bringing an alternative interpretation of the data to our attention. We thank J. Finnerty for excellent technical assistance and Drs. Carter Cook and Jeffrey Shabanowitz for acquiring high-resolution fab-MS and CAD-MS, respectively. (Received January 19, 1989; accepted March 7, 1989)

Abstract—The response of the parasitoid *Eucelatoria bryani* Sabrosky to fresh plant material and several plant extracts was examined in an olfactometer. The plants tested can serve as a food source for hosts (*Heliothis* spp.) of the parasitoid. Females responded positively to 13 of the 19 fresh plant tissues tested, and all of the extracts tested. Males responded to only two of the fresh plant tissues and to none of the extracts. The significance of plant variety, morphology, and phenology on the host habitat-selection behavior of this parasitoid is discussed.

Key Words—Behavior, biological control, *Eucelatoria bryani*, Diptera, Tachinidae, parasitoid, habitat selection, semiochemical, *Heliothis* spp., Lepidoptera, Noctuidae.

INTRODUCTION

Host habitat location is one of the critical first steps in the host selection behavior of many entomophagous insects (Vinson, 1976), many of which, particularly hymenopterous and dipterous parasitoids, will search extensively for hosts on some plants, while ignoring others. In some species, this searching has been shown to occur in habitats whether or not host insects are present

[1] Present Address: USDA, ARS, Insect Biology and Population Management Research Laboratory. P.O. Box 748, Tifton, Georgia 31793.

(Vinson, 1981). In addition, some parasitoids may be attracted only to certain parts of the same plant (Varley, 1941; Smith, 1943). Thus, it is apparent that plant-produced chemicals are extremely important in the orientation and searching behavior of many entomophages.

Eucelatoria bryani Sabrosky is one of the most common tachinid parasitoids of larval *Heliothis* spp. in the southwestern United States (Bryan et al., 1972). Currently, an artificial diet is under development in the hope that *E. bryani* can be economically mass produced and used in inundative releases to control *Heliothis* spp. (Nettles et al., 1980; Nettles, 1986). In order to utilize this parasitoid effectively as a biological control agent, information concerning its host habitat-selection behavior is needed. Nettles (1979, 1980) has shown that *E. bryani* females are attracted to volatiles from cotton and okra plants. The present study was conducted to further elucidate the role of plant-produced semiochemicals in the host habitat-location behavior of *E. bryani*. This information should assist in determining the most appropriate times and locations for mass releases of this parasitoid.

METHODS AND MATERIALS

Insects. E. bryani were reared on cotton bollworm, *Heliothis zea* (Boddie), larvae as described by Nettles (1980). The rearing room was maintained at ca. 27°C, ambient relative humidity, and the flies were kept under a 14:10 hr light–dark photoperiod. Bollworm larvae were reared in large grids on a Nutrisoy diet (Shaver and Raulston, 1971) without corncob grits.

Plants. Most of the plant materials chosen for this study are listed as hosts of *H. zea* or *Heliothis virescens* (F.), or both, by Tietz (1972). Pigeonpea, *Cajanus cajans* (L.), and the unicorn plant, *Martynia louisianica* Mill., are not listed in Tietz (1972) as hosts for *Heliothis* spp.; however, flowering piogeonpea is extremely attractive to ovipositing *Heliothis* spp. (Lopez, 1982), and the unicorn plant was reported as a host for *Heliothis* spp. in the delta of Mississippi (Stadelbacher et al., 1986). In addition, the unicorn plant is frequently searched by *Cardiochiles nigriceps* Viereck, an important hymenopteran parasitoid of *H. virescens* (personal observation). Plant materials used in this study were carefully inspected for signs of *Heliothis* spp. infestation, briefly rinsed in distilled water, and blotted dry prior to their use. The plant materials tested against *E. bryani* are listed in Table 1.

Preparation of Extracts. Hexane extracts of pigeonpea flowers (two varieties), velvetleaf leaves, and sorghum head branchlets were prepared using the following procedure. Fresh material was soaked in hexane for 5 min, homogenized for 2 min in a Waring blender, and the resulting macerate filtered through Whatman No. 1 filter paper. The extracts were then evaporated to ca. 100 ml

TABLE 1. PLANT MATERIAL TESTED AGAINST PARASITOID *Eucelatoria bryani* IN AN OLFACTOMETER

[a] Plant material was obtained either from field- (F) or greenhouse- (G) grown plants.
[b] Indeterminate variety. Seed obtained from India.
[c] Determinate variety. Prior to our obtaining seed, this line had been selected for short season characteristics.

on a rotary evaporator, passed through anhydrous Na_2SO_4 crystals, and brought up to a concentration equivalent to 1 g plant material/ml hexane.

Parasitoids did not respond to hexane extracts of corn silks, but did respond to a water-soluble fraction of a chloroform–methanol extract. Fresh corn silks were soaked in a solution of chloroform–methanol (2 : 1) for 5 min, homogenized for 2 min in a Waring blender, and the resulting macerate was filtered through Whatman No. 1 filter paper into a large separatory funnel. The extract was then partitioned by vigorously mixing in a volume of distilled water,

approximately equal to that of the methanol, and allowing the extract to settle overnight at room temperature. Methanol from the methanol–water fraction was removed on a rotary evaporator, and the water-soluble component was concentrated to 1 g plant material/ml water. All extracts were stored in culture tubes at ca. −20°C until used.

Bioassay. Response of *E. bryani* to the plant material was tested in a Plexiglas olfactometer (99 × 30.5 × 50.8 cm) as described by Nettles (1980). During the test, each of the entry ports was fitted with two glass tubes (20 cm long, 5.1 cm ID) joined in series with duct tape. Each of the inner glass tubes (those closest to the olfactometer) was fitted with a flat aluminum screen at the outer end and a funnel-shaped screen (pointing inward) at the other end, so that flies entering the tube would be trapped. Both of the outer glass tubes were lined with heavy chromatography paper (Whatman, 3 MM) moistened with distilled water. Plant material (1–5 g) was placed in one of the outer tubes, while the other served as a control and contained only the moist filter paper. Air was passed through an activated charcoal filter and entered the glass tube arrangement at a velocity of ca. 1.2 m/sec. Air exited the opposite end of the olfactometer directly into the room through a large (25 × 45 cm) rectangular opening covered with a fine wire screen.

Plant extracts were applied to small (5.5 × 7.5 cm) sections of chromatography paper (Whatman, 3 MM), allowed to dry under a fume hood for ca. 10 min, then placed into the test chamber as described above. An equal volume of the appropriate solvent was applied to a second section of chromatography paper, allowed to air-dry, and placed in the control tube. Preliminary tests indicated that, depending on the extract used, different amounts were required to elicit a consistent response from the parasitoids. One gram equivalent was used for each assay of velvetleaf and both varieties of pigeonpea; 2-g equivalents of sorghum, and 5-g equivalents of the water-soluble corn silk extract were used for each test.

Since *E. bryani* are positively phototactic, the olfactometer was centered directly under the only light in the room. Illuminance at the top of the olfactometer was measured at 646 lux. In addition, a 28.5 × 46.5 cm section of white filter paper was placed on each side of the front end of the olfactometer, so that light intensity would be the same on both sides. Photoperiod, temperature, and humidity in the olfactometer room were kept the same as the rearing room, described above.

About 300–350 flies of both sexes, 7–11 days old, were released into the olfactometer at least 12 hr prior to the beginning of testing. Flies were provided with sugar cubes and moistened Cellucotton at all times. At the end of the 1-hr test period, flies that were caught in the trap tube were N_2-anesthetized, counted, sexed, and returned to the olfactometer. Between experiments, the glass tubes

were washed with a detergent solution, rinsed in acetone, and heated to 75°C for at least 2 hr.

We initially tried to conduct three to four experiments per day but found that the flies did not respond well under these conditions, possibly because of excessive handling and anesthetization. The best results were obtained when we conducted two runs per day in the olfactometer, one in the morning and one in the afternoon. Any bias that may have existed between the two entry ports was eliminated by alternating the port that received the treated and control tubes. Each material was tested against two or more separate groups of flies, and data are based on 10 replicates of each material. Data were analyzed using the *t* test procedure of SAS (SAS Institute, 1985).

RESULTS AND DISCUSSION

Overall, *E. bryani* females responded positively to the plant materials tested (Table 2). Positive responses to 13 of the 19 fresh plant tissues tested, and all five of the plant extracts were recorded. Males, on the other hand, responded positively only to fresh corn silks and leaves of velvetleaf. Curiously, none of the plant extracts, including those of these two plants elicited a positive response from males. Because of the taxonomic diversity of the plant materials tested, female flies may be responding to a general class of plant-produced chemicals.

Cotton was the only plant from which none of the tissues tested elicited a positive response from female flies. This is in contrast with Nettles (1980), who found that, under certain conditions, both male and female *E. bryani* responded to fresh cotton leaves. However, Nettles (1980) used the Deltapine 15 variety of cotton, and this discrepancy may be due to varietal differences in plant chemistry. Werner and Butler (1979) found that *Eucelatoria* sp. were one of the most abundant tachinid parasitoids collected in flight traps in an unidentified variety of short-staple cotton in Arizona. Franklin and Holdaway (1966) demonstrated that the tachinid parasitoid *Lydella grisescens* Robineau-Desvoidy is much more effective against the European corn borer, *Ostrinia nubilalis* (Hübner), on one corn hybrid than on another. Since *L. grisescens* is primarily attracted to plants of its host and secondarily to the host itself, this is likely a result of differences in plant-produced stimuli (Franklin and Holdaway, 1966).

Varietal differences in plant-produced chemicals have been shown in many plants, including cotton (Elzen et al., 1986). Generally, agronomic varieties are bred with characteristics such as high-yield, standability, quality, and resistance to disease and insects, with no thought given to effects on organisms in the third trophic level. Since plant-produced chemicals appear to play a vital role in the host selection process of many entomophagous insects (Nordlund et al., 1988),

TABLE 2. MEAN NUMBER (±SEM) OF *Eucelatoria bryani* RESPONDING PER HOUR TO VARIOUS PLANT TISSUES AND TISSUE EXTRACTS IN AN OLFACTOMETER[a]

Plant material	Females		Males	
	Treated tube	Control tube	Treated tube	Control tube
Cotton

the development of varieties that encourage and that are compatible with entomophagous insects should also be an important goal of plant breeders.

With the exception of early-season (ca. six weeks postplanting) leaves from ICPL 131, all tissues tested from both varieties of pigeonpea elicited a positive response from *E. bryani* females. In general, however, in terms of the number of flies responding, the Norman variety appears to be a slightly more attractive plant. Further, all tissues from Norman, including early-season leaves, were attractive to female flies (because Norman has been selected for short-season characteristics, plants were flowering at 12 weeks postplanting, which was the time interval established for testing mid-season leaves from ICPL 131). This is further evidence that varieties of the same plant species may affect parasitoid behavior in different ways.

In some of the plants tested, female *E. bryani* responded positively only to certain parts of the plant. Flies did not respond to leaves from nonflowering tobacco and unicorn plants, nor to leaves from flowering tobacco plants, but did respond to flowers from these plants. Although plant nectar is a component of the flies' natural diet, the positive response to these flowers was not likely food-oriented since: (1) only females responded in a positive manner, and (2) flies were provided sugar cubes and water at all times. Nettles (1979) reported that significantly more *E. bryani* females responded to okra flowers than to leaves of the same plant.

Similarly, flies did not respond to early-season (ca. six weeks postplanting) leaves of pigeonpea (ICPL 131), but leaves from more mature plants (ca. 12 weeks post-planting) did elicit a positive response. Thus, response by this parasitoid to plant material is dependent not only on the plant tissue in question but also on the age of that plant tissue. These may be general mechanisms by which the parasitoid is synchronized with its host population on certain host plants. Although there are undoubtedly many components involved in the synchronization between host and parasitoid, it is likely that plant phenology plays a role in this complex interaction. The life cycles of the tachinid parasitoid *Eucarcelia rutilla* Vill., and its host, *Bupalus piniarius* L., are so closely synchronized that the parasitoid almost exclusively attacks caterpillars feeding on pine needles between mid-July and the end of August (Herrebout, 1969).

Results from this study suggest that *E. bryani* may be a useful agent for control of *Heliothis* spp. in sorghum. Fresh sorghum head branchlets as well as extracted material elicited a strong response from female flies. Sorghum has also been shown to be highly attractive to *Campoletis sonorensis* (Cameron), an ichneumonid parasitoid of *Heliothis* spp. (Elzen et al., 1983). Because *Heliothis* spp. larvae are particularly vulnerable to parasitoid attack in open-headed sorghums (Young and Teetes, 1977), it is possible that one or both of these entomophagous agents could effectively control this pest.

E. bryani females also responded to fresh corn silks and a water-soluble corn silk extract. This attraction to corn has been observed in Arizona, where adult *E. bryani* are frequently collected via sweep net in corn fields (C. G. Jackson, personal communication). Biological control of *Heliothis* spp. larvae in silking corn is somewhat difficult because the majority of larval feeding occurs within the ear and thus, the larvae are rarely exposed. Because *E. bryani* is highly attracted to corn, it may prove to be important in the control of *H. zea* in this crop in certain geographic areas. Another tachinid, *Archytas marmoratus* (Townsend), is a major parasitoid of large *H. zea* larvae in corn grown in the southeastern United States (Gross and Young, 1984).

It is interesting to note that *E. bryani* were attracted to flowers and/or leaves of the two weed species that we tested. *Heliothis* spp. will oviposit heavily on velvetleaf in central Texas (personal observation), and has been reported to be a good host plant for *Heliothis* spp. development in the delta (flood plain) region of Mississippi (Stadelbacher, 1981). Although we never observed *Heliothis* spp. on unicorn plant in central Texas, it has been reported as a host of *H. virescens* in Mississippi, albeit a poor one (Stadelbacher et al., 1986). Weeds are a normal component of agroecosystems and have been shown to be important in the buildup of early-season *Heliothis* spp. populations (Stadelbacher et al., 1986). In addition, it has been suggested that these early-season populations of *Heliothis* spp. could be suppressed via habitat management and augmentative releases of predators and parasites (Stadelbacher et al., 1986). In certain areas, *E. bryani* may prove to be one of these parasites.

The data presented here indicate that female *E. bryani* are attracted to volatile chemicals from certain plants and that these chemicals may be important cues in the host habitat selection behavior of this parasitoid. This study also shows that response by this parasitoid can be affected by plant variety, plant morphology, and plant phenology. These factors likely influence the behavior of many parasitoids. Elzen et al. (1986) found that the parasitoid *C. sonorensis* exhibited a greater response to glanded cotton cultivars than glandless cultivars. In addition, there may be other factors, such as geographic variability, that influence host–parasitoid interactions. Lanier et al. (1972) found that the parasitoid *Tomicobia tibialis* preferred the kairomone produced by *Ips pini* (Say) from California and Idaho to that produced by beetles from New York. Herbivore defense against natural enemies can also vary geographically (Price, 1981). This variability in parasitoid behavior should be considered when exploring for new biological control agents and when evaluating the performance of these agents under specific conditions.

Acknowledgments—This research was conducted in cooperation with the Texas Agricultural Experiment Station, Texas A&M University, College Station, Texas 77843. We thank J. Bernardino and C. Menn for maintaining colonies of the parasitoid. E.H. Baehrecke, G.W. Elzen, and

T.N. Shaver provided helpful reviews of the manuscript. Mention of a proprietary product does not constitute an endorsement of the product by the USDA.

INTERPOPULATIONAL VARIATION IN EMITTED PHEROMONE BLEND OF CABBAGE LOOPER MOTH, *Trichoplusia ni*

K.F. HAYNES and R.E. HUNT

Department of Entomology
University of Kentucky
Lexington, Kentucky 40546-0091

(Received November 4, 1988; accepted March 10, 1989)

Abstract—Female cabbage looper moths, *Trichoplusia ni*, from laboratory colonies initiated from three locations across the United States emitted similar quantities and blend ratios of the six known pheromone components. In contrast, females from a long-established laboratory colony emitted a greater proportion of four of the five minor components relative to the major component, (*Z*)-7-dodecenyl acetate; only the relative proportion of 11-dodecenyl acetate was similar in all of the populations sampled. Females from this population emitted (*Z*)-7-dodecenyl acetate at a rate similar to that from females from field-collected colonies. Within each population there were highly significant correlations among the quantities of pheromone components of similar molecular weights. Correlations between components of different molecular weights were not as great, but often were significant. Similarities of blend ratios among field populations may indicate that the chemical signal in this species is conservative. The difference of the blend ratios in our laboratory population from the other populations may indicate a decrease in the intensity of selection pressure that usually would maintain these values.

Key Words—Sex pheromone, (*Z*)-7-dodecenyl acetate, (*Z*)-5-dodecenyl acetate, 11-dodecenyl acetate, dodecyl acetate, (*Z*)-9-tetradecenyl acetate, (*Z*)-7-tetradecenyl acetate, Lepidoptera, Noctuidae, *Trichoplusia ni*.

INTRODUCTION

Studies of communication systems of insects have sometimes documented genetically based geographical variation in the emitted blend of pheromone components within certain species (e.g., European corn borer, *Ostrinia nu-*

0098-0331/90/0200-0509$06.00/0

bilalis, Klun and Cooperators, 1975; *Ips pini*, Lanier et al., 1972; European turnip moth, *Agrotis segetum*, Lofstedt et al., 1986). Such divergence may be explained by directional selection and/or genetic drift. In contrast to these cases, the pheromone blend emitted by some species maybe fairly constant throughout their geographic range (e.g., Haynes and Baker, 1988). This consistency may be favored by gene flow between populations and mutually imposed stabilizing selection between signaler and responder (e.g., Ryan and Wilczynski, 1988).

When populations are maintained in continuous culture under laboratory conditions, these evolutionary forces may be quite different. Gene flow between a laboratory population and other populations is usually absent. Genetic drift resulting from founder effects and genetic bottlenecks may be more likely. Potential selection on the communication system imposed by heterospecifics is eliminated. The close proximity of many males and females may reduce the potential stabilizing selection imposed by signalers on responders and responders on signalers.

The sex pheromone of the cabbage looper moth, *Trichoplusia ni*, was identified as (Z)-7-dodecenyl acetate (Z7–12 : Ac) (Berger, 1966), but is now known to consist of this major component and dodecyl acetate (12 : Ac), (Z)-5-dodecenyl acetate (Z5–12 : Ac), 11-dodecenyl acetate (11–12 : Ac), (Z)-7-tetradecenyl acetate (Z7–14 : Ac), and (Z)-9-tetradecenyl acetate (Z9–14 : Ac) (Bjostad et al., 1984; Linn et al., 1984). We investigated interindividual and interpopulational variation in the pheromone blend emitted from sex pheromone glands in this species. Included in our analysis was a colony of *T. ni* that has been maintained in culture for over 100 generations without the reintroduction of insects from field-collected populations.

METHODS AND MATERIALS

Adult *T. ni* were collected in the field by using inverted cone traps (Scentry) that were baited with phenylacetaldehyde (a presumed floral attractant). Collection sites were in Riverside, California; Lexington, Kentucky; and Gainesville, Florida. At least 40 individuals were trapped at each collection site over the course of several weeks. Collected males and females were placed together in 1-gal cartons and females oviposited on paper towels. Eggs laid by females from California and Florida were sent by overnight mail to Kentucky where separately maintained colonies were established. Thereafter, rearing procedures followed the same protocol as those used for the laboratory colony that originated from populations near Riverside, and has been maintained using the procedures of Shorey and Hale (1965). Pupae were separated according to sex. Female pupae were housed in 1-pint (473-ml) paper cartons with nylon-screen lids. Emerged adults were removed daily and transferred to additional cartons.

Just prior to the onset of scotophase, when females were 3–5 days old, they were placed individually in 4 cm diameter × 4 cm height hardware cloth (3-mm mesh) cages closed with aluminum lids.

Collection of pheromone from females followed the procedures described by Baker et al. (1981), except that intact females were used. During the second through eighth hour of the scotophase, a period during which calling behavior was observed under the experimental conditions, a female was removed from an environmental chamber and inserted abdomen first into a glass female-holder. The holder was 5.5 cm long, 0.6 cm in diameter, and had a ca. 1-mm hole at the distal end that allowed the ovipositor and associated sex pheromone gland to extrude out of the holder when pressure was applied to the head of the female with a pipe cleaner. Females could then be removed from the holder and usually would survive for several days. The holder was then inserted into the all-glass collector described by Haynes et al. (1984). A stream of nitrogen gas flowed through the collector at a rate of 120 ml/min. After the 10-min collection period, 10 ng of an internal standard [(*E*,*Z*)-4,7-tridecadienyl acetate] was added to the adsorbent glass wool surface at the distal end of the collector which was then rinsed with two 50-μl aliquots of CS_2. This volume was reduced to ca. 1 μl before it was injected into a 30 m Carbowax 20 M capillary column in a Hewlett-Packard 5890A GC linked to a Hewlett-Packard 5970B Mass Selective Detector. The sensitivity of this instrument was optimized by manual tuning on ion 69 (*m*/*z*) of the tuning standard perfluorotributylamine, and subsequently using selective ion monitoring of ions 54, 55, and 67 (*m*/*z*), which are abundant in all of the reported pheromone components. Standard curves that related peak area (*m*/*z* 54 + 55 + 67) to the mass of each pheromone component were established because the relative abundance of these ions was not the same for all molecules of interest. The lower analytical limit using this technique was ca. 0.01 ng for *Z*9–14 : Ac (the least abundant component).

To determine the relative accuracy of the emission rates and blend ratio obtained using the extruded gland technique, a comparison was made to collections from free-calling females. A disposable pipet (Gold Seal No. 4642) was cut 1 cm before it starts to taper and 2 cm from the tip of the stem, thus leaving a 4-cm funnel-shaped collector. The stem of the collector was packed with 10 mg of glass wool. When a female began to call, the narrow end of this funnel collector was connected to a regulated vacuum system that allowed 120 ml/min to flow through the system. The collector was then positioned so that the sex pheromone gland of the female was just within the wide end of the funnel, but did not touch any of the glass surface. The females usually were not disturbed by this procedure and generally continued to call for at least 10 min, at which time the collection was terminated. Collections from these free-calling females alternated with collection from females that had begun calling, but were immediately inserted into the other collection system. The use of an internal standard

and the procedures for extracting pheromone components were the same as for the extruded gland technique.

RESULTS

The volatile collection technique allowed us to determine both the emission rate and blend ratio emitted by individual females (Figure 1). There were no significant differences in the females' emission rate of

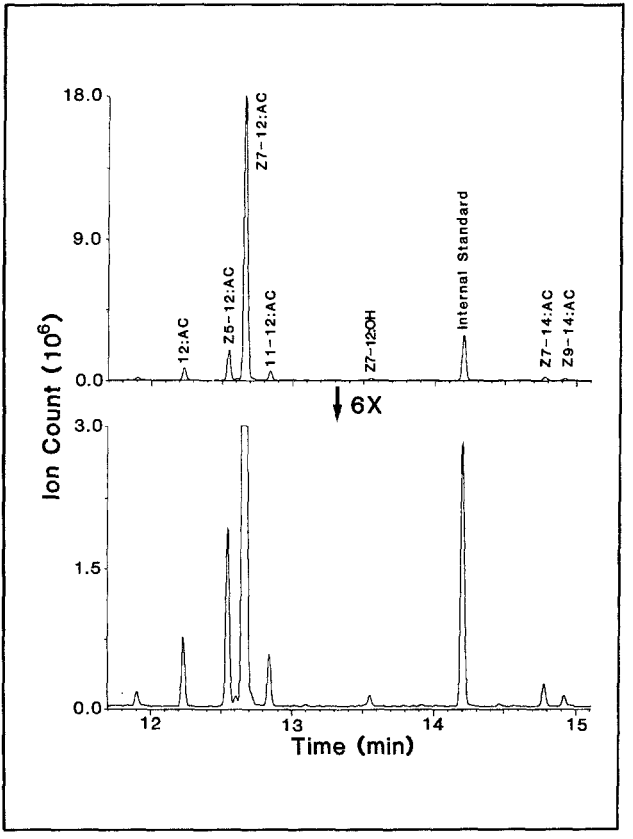

FIG. 1. Chromatogram obtained from the analysis of the compounds emitted from a single laboratory female. The lower trace is identical to the upper trace but is amplified sixfold to show the minor components. An internal standard [10 ng of (*E*,*Z*)-4,7-tridecadienyl acetate] was added to the collector before it was rinsed with carbon disulfide.

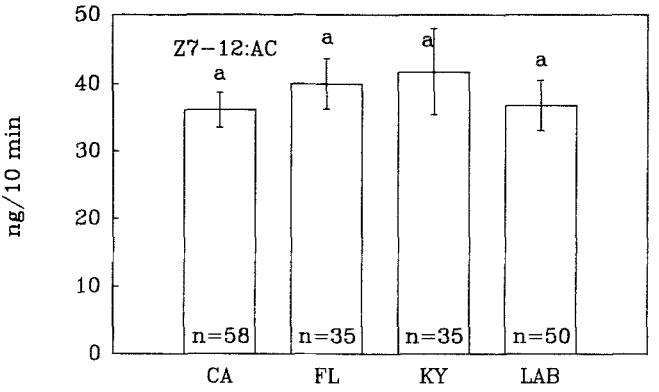

FIG. 2. Mean quantity (± SEM) of (Z)-7-dodecenyl acetate emitted during 10 min collection periods. There was no significant difference between populations of females ($P > 0.05$, one-way analysis of variance).

Z7-12:Ac, the major component, among the four populations sampled (Figure 2; one-way analysis of variance; $P > 0.05$). The low mean emission rate was 36.2 ng/10 min from females originating from the California colony, and the high mean emission rate was 41.8 ng/10 min from females originating in Kentucky. The measured emission rate of Z7-12:Ac was variable; for example, in females from the laboratory population it ranged from 1.26 ng/10 min to 124.1 ng/10 min.

The proportions of the minor pheromone components from volatile emissions were fairly consistent among females from the three field-originating populations, but their mean proportions of Z5-12:Ac, 12:Ac, Z7-14:Ac, and Z9-14:Ac were significantly lower than those of females from the laboratory population (Figure 3; one-way analysis of variance, Student-Newman Keuls multiple comparison test; $P < 0.05$). Z7-12:OH was detected in every volatile collection but was less abundant in the emitted volatiles of females from the laboratory population ($P < 0.05$).

In general the correlation between the quantities of the six pheromone components compared two at a time showed a significant positive relationship (Table 1). Exceptions were found within the Florida populations in which the relationships between some of the 12-carbon acetates and 14-carbon acetates were not significant. Within all four populations the correlations were greater with molecules of similar molecular weight (e.g., quantities of Z7-14:Ac and Z9-14:Ac were more highly correlated than Z7-12:Ac and Z9-14:Ac).

Collections from free-calling females and females with forced gland extrusions demonstrated that the techniques yielded similar results, with two excep-

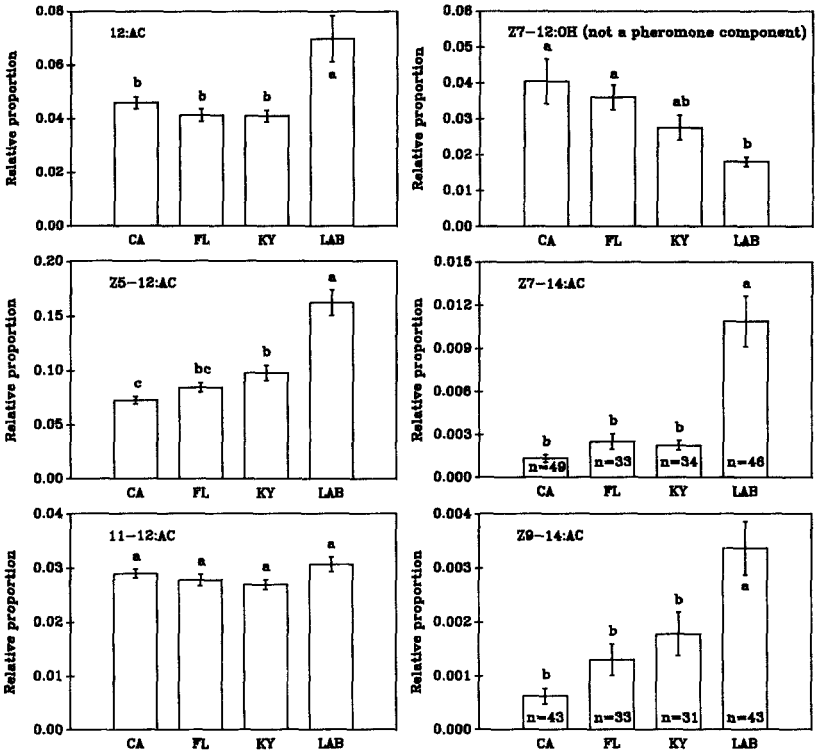

FIG. 3. Mean relative proportions (±SEM) of five minor pheromone components and (Z)-7-dodecenol emitted during 10-min collection periods. Number of individuals included for each mean was the same as in Figure 2, except where otherwise indicated. Means are significantly different when they do not share a letter in common ($P < 0.05$, one-way analysis of variance; Student-Newman-Keuls test for multiple comparisons).

tions (Table 2). First the emission rate from free-calling females was ca. 1.5 times higher than that measured from forced gland-extrusion collections (analysis of variance, $P < 0.05$). Second, no Z7-12:OH was detected from free-calling females.

DISCUSSION

The technique of obtaining volatile collections from forcibly extruded sex pheromone glands has proven to be an effective aid in identifying sex pheromone components (e.g., Bjostad et al., 1984; Dunkelblum et al., 1987). By allowing effective analysis of the blend emitted by individuals, these collections

[c] Z7-12:OH was absent or present below the limits of detection of this analysis.

have enabled us to gain a more realistic impression of interindividual variation and populational variation in pheromone blends (e.g., Haynes et al., 1984; Haynes and Baker, 1988). One assumption underlying the technique that we used in this study is that the moth emits the same quantity and quality of pheromone when the gland is forcibly extruded as when calling naturally. In moths that actively pump their sex pheromone glands, females may emit ca. 25 times more pheromone than would be indicated by forced collections (Schal and Cardé, 1985). Krasnoff and Roelofs (1988) documented that rhythmic protrusion and retraction of the pheromone gland by female *Pyrrharctia isabella* results in an extraordinarily high emission rate of its pheromone in aerosol form. The cabbage looper moth everts its pheromone gland for longer periods of time (Bjostad et al., 1980), and thus there appears to be no repetitive retraction and eversion of the gland. There was a predictable relationship between both the quantity and quality of the pheromone blend emitted by females as measured by free-calling and forced-extrusion techniques. Females were measured emitting only ca. 1.5 times more Z7–12 : Ac during calling compared to collections from forced extrusion of glands. However, using the forced-extrusion technique, we detected significant quantities of Z7–12 : OH, which is a potent interruptor of the males' behavioral response to sex pheromone (McLaughlin et al., 1974; Tumlinson et al., 1972). Emission of Z7–12 : OH has been noted earlier by Bjostad et al. (1984) and was considered at artifact of the technique. In another species, the tomato looper, *Plusia chalcites*, Z7–12 : OH was detected using the volatile collection technique. This compound has been found to interfere with the behavioral response of male *P. chalcites*. Dunkelblum et al. (1987) suggested that small amounts of Z7–12 : OH could be produced by the hydrolysis of Z7–12 : Ac by other tissues from the female. This explanation could be valid for *T. ni* since Z7–12 : OH is apparently not produced by free-calling females. The forced-extrusion technique appears to yield valid information on the blend ratio of pheromone components and a good approximation of the emission rate.

The technique of obtaining volatile collections from extruded glands has allowed us to compare pheromone emission by females from populations originating from three localities distributed across the United States and from a long-maintained laboratory population. The populations originating from these localities were very similar in both the quality and quantity of the pheromone components. *T. ni* is a very mobile insect, is subtropical in origin, and has no winter diapause (Lingren et al., 1979). In areas such as southern California and Florida populations may persist year-round, but in more northern states (such as Kentucky in this study) spring immigration is responsible for initiating the local populations. Prevailing weather patterns suggest that overwintering populations in Louisiana and Texas are likely sources for populations that later

establish in Kentucky (Riordan, 1979). Lingren et al. (1979) suggested that a fall southerly migration occurs in this species. Such mobility suggests that some gene flow between the three populations is possible and may be sufficient to prevent the establishment of geographically isolated populations in which divergence in the chemical signal might occur, as in the acoustical signals of cricket frogs (Ryan and Wilczynski, 1988). However, in another species of moth, *Pectinophora gossypiella*, Haynes and Baker (1988) have established that the pheromone blend was fairly consistent throughout the worldwide populations that were sampled. The blend emitted by one population from China was significantly different from all other populations sampled (Argentina, Brazil, Egypt, Pakistan, and the United States), but the difference was very small. Thus geographical isolation alone does not necessarily lead to divergence in the pheromone blend.

Given the apparent conservative nature of the pheromone blend in field populations of cabbage looper moths, an important question is why the ratio in laboratory populations was different. A simple explanation is that the individuals used to initiate the laboratory population were not representative of the population from which they were removed—a founder effect. Alternatively, the laboratory population may have gone through severe population crashes, which then could have led to a shift in the blend ratios—genetic bottlenecks. There were extreme individuals in the field populations that emitted blends similar to those produced by laboratory females. Normally one might expect that selection pressure for precise control of the pheromone blend might remove those individuals that deviated from the norm. In laboratory populations this selection pressure may be much less intense, because long-range mate location is no longer a prerequisite for mating, and selection for specificity in the pheromone blend is no longer critical when other species are not in the same environment.

A similar deviation in the pheromone blend between laboratory and field population was demonstrated in *Argyrotaenia velutinana* (Miller and Roelofs, 1980). Females from a field-collected population emitted 9.1% (*E*)-11-tetradecenyl acetate to (*Z*)-11-tetradecenyl acetate, whereas the laboratory females emitted a 7.0% *E*–*Z* ratio. Again, in this species, it was not possible to determine whether the change was due to directional selection in the laboratory population or genetic drift.

If this hypothesis of random change is correct, one would expect that blend ratios of females from other laboratory populations to be different from our laboratory population. If predictable directional selection is responsible for the divergence of the pheromone blend in laboratory and field populations, then all laboratory populations maintained in a similar way to ours might show similar differences. We cannot answer this question because only one laboratory population has been sampled.

Acknowledgments—We thank T.C. Baker, P.J. Landolt, and R.S. Vetter for providing us with cabbage looper eggs from field-collected moths. D. Campero and J. Clark reared most of the insects that were used in this study. Discussions with T.C. Baker concerning the potential roles of redundant pheromone components provided the impetus to conduct this study. This research was supported by USDA Competitive Grant 87-CRCR-1-2410. We acknowledge support of the University of Kentucky Major Research Instrumentation Bond Program in the purchase of equipment used in this study (ID Nos. 7E-8164-11, L-250-8A080, L-251-8A080, and L-252-8A080). The investigation reported in this paper (No. 88-7-285) was conducted in connection with a project of the Kentucky Agricultural Experiment Station and is published with the approval of the Director.

A KAIROMONE FOR *Trichogramma nubilale* (HYMENOPTERA: TRICHOGRAMMATIDAE) Isolation, Identification, and Synthesis[1]

SHENGQIANG SHU, PAUL D. SWEDENBORG, and RICHARD L. JONES

Department of Entomology
University of Minnesota
St. Paul, Minnesota 55108

(Received December 16, 1988; accepted March 13, 1989)

Abstract—A kairomone that effects host-seeking behavior in *Trichogramma nubilale* Ertle and Davis, an egg parasitoid of the European corn borer, *Ostrinia nubilalis* (Hübner), was isolated from moth scales of the European corn borer. The kairomone was identified as a mixture of 11,15-, 13,17-, and 15,19-dimethylnonatriacontanes. The three dimethylnonatriacontanes were synthesized, and bioassays showed that the 13,17 isomer was the most active in terms of klinokinetic and retention effects. The 11,15 isomer and the 15,19 isomer had some effect on klinokinesis, but they failed to effect retention of the wasps. The 13,17-dimethylnonatriacontane is considered to be the most important component of the kairomone.

Key Words—Behavior, hydrocarbons, kairomone, kinesis, *Ostrinia nubilalis*, Lepidoptera, Pyralidae, *Trichogramma nubilale*, Hymenoptera, Trichogrammatidae.

INTRODUCTION

Trichogramma nubilale Ertle & Davis is an important egg parasitoid of European corn borer (ECB), *Ostrinia nubilalis* (Hübner). In a Delaware study, parasitism of ECB egg masses on sweet corn ranged from ca. 5% in June to ca. 70% in September and, of more importance, 100% of the eggs are parasitized in ca. 90% of the parasitized egg masses (Ertle and Davis, 1975).

Kairomones play crucial roles in host-finding behavior of *Trichogramma* spp. Lewis et al. (1972) found that moth scales of female *Heliothis zea* (Boddie) were the source of a kairomone that elicited a host-finding response from female *Trichogramma evanescens* Westwood and that the parasitism rate of *H. zea* could be increased by spraying crops with the kairomones. Jones et al. (1973) identified tricosane as the most active of several active hydrocarbons. Other host-associated chemicals, such a sex pheromones and organic acids, also have been identified as kairomones for *Trichogramma* spp. (Lewis et al., 1982; Gueldner et al., 1984).

Shu and Jones (1989) demonstrated that kairomones in the scales of ECB adults could affect the klinokinetic and orthokinetic behavior of *T. nubilale* in a manner that retained the wasps in a kairomone-treated area and resulted in an increase in parasitism rates of ECB eggs and egg masses. The present paper reports the isolation, identification, and synthesis of the chemicals responsible for this activity.

METHODS AND MATERIALS

Insects and Bioassay. The rearing and handling of *T. nubilale* and procedures for bioassays were described by Shu and Jones (1989). The bioassay consisted of the measurement of female responses to a chemically treated 4.5-cm-diameter circle on filter paper. The subject chemicals were applied at rates equivalent to 5 μg of moth scales in a volume of 50 μl (100 ng/μl) (Shu and Jones, 1989). Observation was through a glass plate on which the movement of a female, after release in the center of the circle, was traced. A value of 0 was assigned when walking behavior was the same in the treated circle as in the clean area outside the circle. Values up to 10 were assigned quantitatively as the time (based on the paths drawn) allotted to the treated circle increased beyond the clean area outside the circle. There were 15 replications for each treatment. In the bioassay of the synthetic chemicals, the number of turns in the treated circle was recorded with a digital counter, and time spent inside and outside the treated circle was recorded with a cassette tape recorder in a way that an "in" or "out" voice indicated that the female was inside the treated circle or outside. The recorded tape was played back to quantify the time. Percentage of time inside the treated circle and turning rates (turns/min) inside the treated circle were calculated. The bioassay of synthetic materials was designed as a randomized-block design and five treatments were randomly assigned to each of nine blocks. A block was one day. The five treatments were: MSE (moth scales extract), 11,15-DMC39 (DMC39 = dimethylnonatriacontane), 13,17-DMC39, 15,19-DMC39, and control (hexane only). Concentration of each synthetic chemical was 50 pg/μl, the approximate concentration of the

active hydrocarbons in the 100 ng/μl moth scale extract. A treatment volume of 50 μl deposited 2.5 ng of synthetic chemical per treatment. The data were analyzed by analysis of variance followed by a check of model fitness and the multiple-range test by Duncan (1955).

Collection and Extraction. ECB moth scales (1.5 g) were collected from laboratory-reared moths after holding them at 0°C for immobilization. The immobilized moths were shaken in a jar to remove scales, which were collected with a hand vacuum cleaner. The collected scales were Soxhlet extracted for 6 hr with 100 ml nanograde hexane that subsequently was concentrated to 60 ml on a rotary flask evaporator.

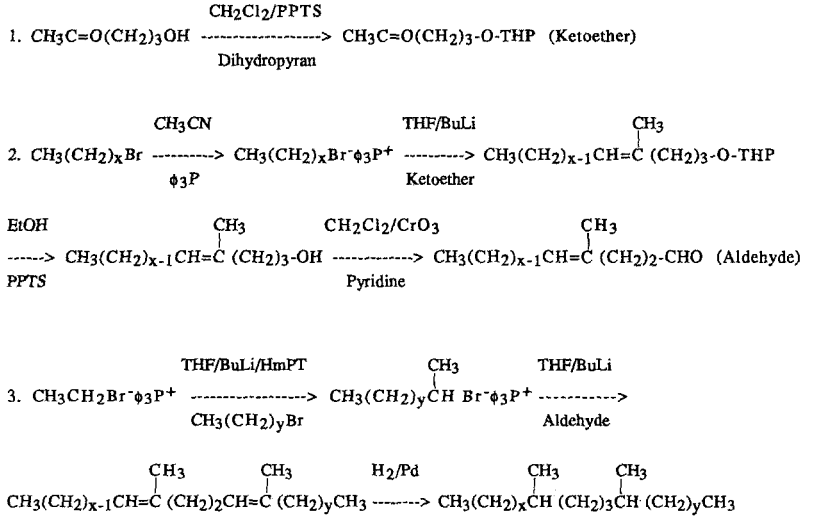
Isolation and Identification. A 50-ml aliquot of the 60-ml concentrated hexane extract was reduced to 1 ml under nitrogen and subjected to column chromatography on a 1.5 × 18-cm column containing Florisil (2% water by weight). The column was eluted successively with three void volumes (10 ml each) of hexane and two void volumes of: ether–hexane (2.5:97.5), ether–hexane (5:95), ether–hexane (7.5:92.5), ether–hexane (10:90), ether–hexane (25:75), ether-hexane (50:50), ether, acetone, and methanol. The 10 fractions were stored at −70°C.

Saturated and unsaturated hydrocarbons were separated by percolating the Florisil column hexane fraction through a 20% silver nitrate Florisil column (0.5 × 4 cm) with hexane to obtain the paraffins, followed by 2.5% ether in hexane to obtain the olefins. Straight-chain and branched hydrocarbons were separated with 5 Å molecular sieve (Hutchins and Martin, 1968).

Gas chromatography (GC) was performed with a 5830A Hewlett Packard GC equipped with a flame ionization detector (FID), effluent splitter, and thermal gradient collector (similar to that described by Brownlee and Silverstein, 1968). An all-glass column 1.9 m × 2 mm ID was packed with 3% Dexsil 300 on 80/100 Gas Chrom Q. The carrier gas was nitrogen at 20 ml/min. The temperature was programmed from 150° to 325°C with the first 12 min ramped at 8°C/min and thereafter at 3°C/min. Capillary gas chromatography was performed with a 5890 Hewlett Packard GC equipped with an FID and an effluent splitter that vented through a thermal conductivity detector (TCD) for collection. A glass capillary was connected to the TCD and cooled with Dry Ice. The column was a 0.53-mm × 30-m DB-5 column programmed to run isothermally at 300°C. The carrier gas was helium at 2.5 ml/min with a linear flow rate of 30 cm/sec and a column head pressure of 4.5 psig. All collected materials were rechromatographed to confirm purity and quantity.

Mass spectra were obtained on a Kratos GC-MS 25 equipped with a 0.53-mm × 15-m DB-5 column run at 290°C isothermal and using helium as a carrier gas at the rate of 3.5 ml/min. The mass spectrometer was operated at an ionization energy of 20 eV or 70 eV.

Synthesis. The synthetic route is outlined in Figure 1. All starting materials



Compound I. x=9, y=23. Compound II. x=11, y=21. Compound III. x=13, y=19.
PPTS=Pyridinium *p*-toluenesulfonate, THP=Tetrahydropyran, THF=Tetrahydrofuran, BuLi=n-butyllithium, HmPT=Hexamethylphosphoric triamide, ϕ_3P=triphenylphosphine.

FIG. 1. Synthesis route of three dimethylnonatriacontanes.

were commercially available except 1-bromotetracosane, which was synthesized from 1,12-dibromododecane and dodecyl aldehyde through a Wittig condensation. In all of the work we were guided by Sonnet (1976), Miyashita et al. (1977) for protection and deprotection of the hydroxy group of 5-hydroxy-2-pentanone, and Ratcliffe and Rodehorst (1970) for oxidation of the primary alcohol to the aldehyde. Synthetic materials for bioassay were purified on the 5830A GC described above. Collected materials were rechromatographed to check for purity and quantified by comparison with an internal standard.

RESULTS AND DISCUSSION

Isolation and Identification. The hexane Florisil fraction derived from the hexane extract of moth scales scored 8.3 of 10 in the bioassay. This was significantly higher than all other Florisil fractions (3.3) and the control (2.4).

Argentation chromatography of the active hexane Florisil fraction indicated the bioassay activity to be in the saturated hydrocarbon fraction. In addition, when the active Florisil fraction was subjected to 5 Å molecular sieve,

the excluded fraction retained activity indicating that the active chemicals were branched.

The active Florisil fraction was subjected to GC (3% Dexsil 300 column) analysis, and the effluent was collected in four fractions labeled A, B, C, and D from the first eluted GC peak to the last. Fraction C contained one peak and the other fractions contained more than one peak. Fraction C scored 8.0 of 10, while A, B, and D scored 2.4, 3.3, and 1.9, respectively. The control scored 2.1. The score of fraction C was significantly higher than the other fractions.

Fraction C was further subjected to GC (DB-5 column) analysis and showed the presence of four peaks labeled P-39A, 39B, 39C, and 39D. P-39A was not collected because it was a relatively small peak. P-39C and P-39D were incompletely resolved, so they were collected as one fraction. P-39B was collected in one fraction, and it scored significantly higher (7.9) than P-39C and P-39D (2.9) and the control (2.2).

The collected material in P-39B was rechromatographed with two internal standards, *n*-octatriacontane and *n*-tetracontane and was found to have an equivalent chain length of 39.5 (Miwa, 1963). The 39.5 equivalent chain length indicated that the compound(s) in P-39B could be dimethylnonatriacontane(s) (DMC39) (Nelson, 1978).

Sequential mass spectra during elution of P-39B demonstrated the presence of three components. Shown in Figures 2–4 are three 15× amplified spectra of P-39B taken at about 12 scans apart. These spectra had six odd mass peaks from secondary fragmentation [C_xH_{2x+1}-$(CH_3)CH$] at *m/e* 295, 379; 267, 407; and 239, 435, which were more intense than their preceding peaks of 14 mass units less. These peaks were also greater than the corresponding even mass peaks from secondary fragmentation with a hydrogen being transferred [C_xH_{2x}-$(CH_3)CH$] at *m/e* 294, 378; 266, 406; and 238, 434, an indication that the P-39B hydrocarbons were not internally branched monomethyl-alkanes (McCarthy et al., 1968; Nelson et al., 1972).

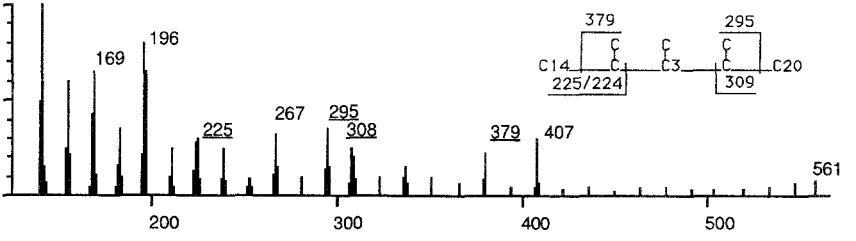


FIG. 2. Mass spectrum of a scan at 12 scans before the most intense scan with a mass range from 140 to 561: 15,19-dimethylnonatriacontane (most plausible structure). Ordinate, intensity; abscissa, *m/e*.

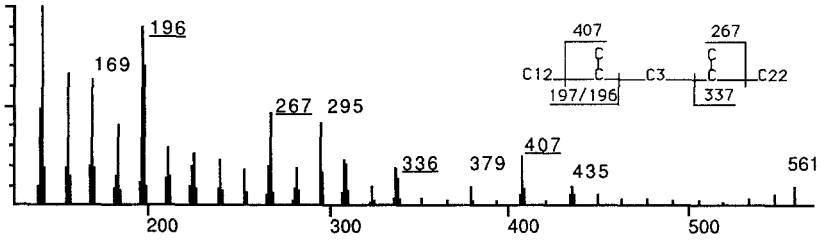

FIG. 3. Mass spectrum of the most intense scan with a mass range from 140 to 561: 13,17-dimethylnonatriacontane (most plausible structure). Ordinate, intensity; abscissa, *m/e*.

The presence of a significant odd mass peak at *m/e* 561 ($M^+ - 15$) and the equivalent chain length information supported a chemical of 41 carbon atoms. Three significant even mass peaks at *m/e* 224, 196, and 168 in the mass spectra (Figures 2–4) indicated that the branch points were positioned in the molecule so that secondary ion fragments with a long straight-chain tail could be formed. The presence of three predominant odd mass peaks at *m/e* 379, 407, and 435 confirmed three such methyl positions at the 15th, 13th and 11th carbon atoms. The three secondary ion fragments with the straight-chain tail could not be formed from one compound, thus the three even mass peaks at *m/e* 224, 196, and 168 must be from three different molecules (McCarthy et al., 1968). Although the mass peaks at *m/e* 168/169 and 196/197 could result from primary ion fragments (C_xH_{2x}/C_xH_{2x+1}) of different parent molecules, their intensities would be very small relative to the intensity of the secondary ion fragment with a hydrogen transferred (Nelson et al., 1972).

The presence of the predominant odd mass peaks at *m/e* 295, 267, and 239 indicated that each of these secondary ion fragments contained another methyl branch because an even mass peak of a secondary ion fragment with a straight-

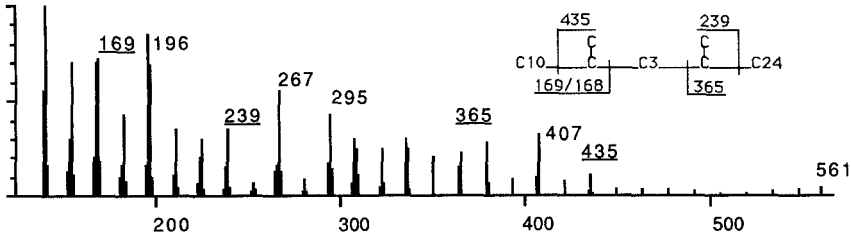

FIG. 4. Mass spectrum of a scan at 14 scans after the most intense scan with a mass range from 140 to 561: 11,15-dimethylnonatriacontane (most plausible structure). Ordinate, intensity: abscissa, *m/e*.

chain tail would be significant compared to the corresponding odd mass peak (McCarthy et al., 1968; Nelson et al., 1972). Therefore, these secondary ion fragments must have a methyl-branched tail. This agreed with the conclusion made from equivalent chain length determinations that two methyl branches were present. These three methyl positions were hypothesized to be at the 19th, 17th, and 15th carbon atoms. This was supported by the presence of the mass peaks at *m/e* 309 and/or 308, 337 and/or 336, and 365 since the molecular weight was 576. In addition, these three predominant odd mass peaks at *m/e* 259, 267, and 239 must come from three different molecules.

Generally, the internally multiple methyl-branched alkanes in the insects have isoprenoid spacing of the branch points (Nelson and Sukkestad, 1975; Nelson, 1978). Therefore, compounds in P-39B were postulated as three dimethylnonatriacontanes: 15,19-, 13,17-, and 11,15-dimethylnonatriacontane. Any one scan of the mass spectrum could not fully explain the existence of all three dimethylnonatriacontanes, but a survey of all the mass spectra scans revealed that the three dimethylnonatriacontanes existed. Based on the intensities of the specific mass peaks at *m/e* 196 and 407, and their appearance in almost all scans of P-39B, it seems that 13,17-dimethylnonatriacontane was the most abundant.

The characteristic fragments for the synthetic compounds are:

11,15-Dimethylnonatriacontane, EI mass spectrum at 70 eV [*m/e* (relative abundance)], 561[(0.8) M-15], 435[(5.3) $CH(CH_3)$-C_3H_6-$CH(CH_3)$-$C_{24}H_{49}$], 365[(4.2) $CH(CH_3)$-$C_{24}H_{49}$], 239[(7.9) $C_{10}H_{21}$-$(CH_3)CH$-C_3H_6-$(CH_3)CH$], 169[(5.2) $C_{10}H_{21}$-$(CH_3)CH$], 168[(9.6) $C_{10}H_{20}$-$(CH_3)CH$], 57[(base peak) C_4H_9].

13,17-Dimethylnonatriacontane, EI mass spectrum at 70 eV [*m/e* (relative abundance)], 561[(0.9) M-15], 407[(3.9) $CH(CH_3)$-C_3H_6-$CH(CH_3)$-$C_{22}H_{45}$], 337[(2.7) $CH(CH_3)$-$C_{22}H_{45}$], 336[(2.5) $CH(CH_3)$-$C_{22}H_{44}$], 267[(7.9) $C_{12}H_{25}$-$(CH_3)CH$-C_3H_6-$(CH_3)CH$], 197[(4.8) $C_{12}H_{25}$-$(CH_3)CH$], 196[(8.1) $C_{12}H_{24}$-$(CH_3)CH$], 57[(base peak) C_4H_9].

15,19-Dimethylnonatriacontane, EI mass spectrum at 70 eV [*m/e* (relative abundance)], 561[(0.9) M-15], 379[(4.2) $CH(CH_3)$-C_3H_6-$CH(CH_3)$-$C_{20}H_{41}$], 309[(3.4) $CH(CH_3)$-$C_{20}H_{41}$], 308[(3.8) $CH(CH_3)$-$C_{20}H_{40}$], 295[(8.7) $C_{14}H_{29}$-$(CH_3)CH$-C_3H_6-$(CH_3)CH$], 225[(4.0) $C_{14}H_{29}$-$(CH_3)CH$], 224[(6.1) $C_{14}H_{28}$-$(CH_3)CH$], 57[(base peak) C_4H_9].

Turning rates of *T. nubilale* females in areas treated with MSE, 13,17-DMC39, 15,19-DMC39, and 11,15-DMC39 were similar, and all but 11,15-DMC39 were significantly different from those in hexane treated areas (Table 1). Relative retention times in 13,17-DMC39-treated areas and in MSE-treated areas were the same and both retained the wasps significantly longer than the hexane control. Relative retention times in 11,15-DMC39- and 15,19-DMC39-treated areas were not significantly different from those in hexane-treated areas and were significantly lower than those in MSE- and 13,17-DMC39-treated

TABLE 1. MEAN TURNING RATE AND MEAN TIME SPENT BY *T. nubilale* IN AREAS TREATED WITH MSE AND SYNTHETIC HYDROCARBONS[a]

	MSE[b]	13,17-DMC39[b]	15,19-DMC39	11,15-DMC39	Hexane
Turning rate (turns/min)	23.3a[c]	24.5a	21.2a	19.3ab	14.2b
Time (%)	65.7a	70.5a	45.1b	43.4b	43.1b

areas. Although 11,15-DMC39, 13,17-DMC39, and 15,19-DMC39 had klinokinetic effects on *T. nubilale* behavior similar to MSE, 11,15-DMC39 and 15,19-DMC39 failed to retain *T. nubilale* wasps in the treated areas. Therefore, 13,17-dimethylnonatriacontane is considered to be the most influential kairomone present.

VARIABILITY IN PHEROMONE COMPOSITION AND PERIODICITY OF PHEROMONE TITER IN POTATO TUBERWORM MOTH, *Phthorimaea operculella* (LEPIDOPTERA: GELECHIIDAE)

T. ONO,[1] R.E. CHARLTON,[2] and R.T. CARDÉ

Amherst, Massachusetts 01003

(Received January 30, 1989; accepted March 13, 1989)

Abstract—The ratios and quantities of the pheromone components, (*E*,*Z*)-4,7-tridecadien-1-yl acetate (diene) and (*E*,*Z*,*Z*)-4,7,10-tridecatrien-1-yl acetate (triene), in the glands of individual female potato tuberworm moths (*Phthorimaea operculella*) originating from the United States (California) and Japan (Nagoya) were analyzed by gas chromatography. Quantities of gland-extracted pheromone components of Nagoya females fluctuated in a periodic fashion during the photoperiod. Maximal titers coincided with the onset of scotophase (and calling), then gradually declined to minimal levels soon after lights-on. The average daily pheromone quantities decreased significantly as females aged. Both populations exhibited considerable variation in the ratio of the two components. The proportions of triene in the blend ranged from 27% to 88% (triene $\bar{X}$ = 56 ± 13% SD; CV = 23%) for California females and from 16% to 71% (42 ± 13%; CV = 31%) for Nagoya females. Nagoya females also stored significantly higher amounts of pheromone in their glands (8.6 ± 3.9 ng) than did California females (2.7 ± 1.4). The differences between the populations, while substantial, would probably not be sufficient to impart a barrier to panmixis, given the wide range of component ratios favored by the males.

Key Words—Sex pheromone, individual variation, pheromone titer, periodicity, (*E*,*Z*)-4,7-tridecadien-1-yl acetate, (*E*,*Z*,*Z*)-4,7,10-tridecatrien-1-yl acetate, Lepidoptera, Gelechiidae, potato tuberworm moth, *Phthorimaea operculella*.

INTRODUCTION

The female-emitted sex attractant pheromones of most moth species examined to date consist of two or more components. However, among the moths, the degree of specificity associated with production of pheromone blends by females and male response to these mixtures can vary markedly. For some species such as *Argyrotaenia velutinana*, *Grapholita molesta*, or *Trichoplusia ni*, a relatively precise blend of compounds is required for mate-finding by the males, and the attendant variation in the ratio of pheromone components produced by individual females is minimal (cf. Miller and Roelofs, 1980; Baker et al., 1981; Bjostad et al., 1984; Linn et al., 1986). In other species, exemplified by *Pectinophora gossypiella*, the females produce and emit a narrow range of ratios (Collins and Cardé, 1985; Haynes et al., 1984), whereas the males respond to a comparatively wider array of blend ratios (Flint et al., 1979; Linn and Roelofs, 1985). Species subscribing to a third condition, however, appear to utilize a more broadly tuned signal, with females producing, and males responding to an extensive range of certain or all components of the blend (Löfstedt et al., 1985; Attygale et al., 1986; Guerin et al., 1986; Barrer et al., 1987).

The sex pheromone of the potato tuberworm moth, *Phthorimaea operculella*, is a blend of (*E*,*Z*)-4,7-tridecadien-1-yl acetate (diene) (Roelofs et al., 1975; Persoons et al., 1976) and (*E*,*Z*,*Z*)-4,7,10-tridecatrien-1-yl acetate (triene) (Persoons et al., 1976). As determined from pooled samples of female abdominal tips or whole female extracts, the ratio of these two compounds is approximately equal (Persoons et al., 1976; Toth et al., 1984).

Field trapping studies in several countries and using a wide range of pheromone blends have shown that male *P. operculella* are lured almost equally well to a broad spectrum of ratios of diene to triene of 1 : 9 to 9 : 1 (Persoons et al., 1976; Voerman and Rothschild, 1978; Raman, 1984; Ono and Orita, 1986). In these tests, the blends generally captured more males than did the individual components, but in certain trials, the diene (Raman, 1984) or the triene (Voerman and Rothschild, 1978; Ono and Orita, 1986) alone captured as well as the mixtures. Given the broad range of blends suitable for attraction, a less precise regulation of pheromone component ratios in females of this species might be expected.

To document the variation among individual females in pheromone component ratios, we analyzed the gland content of females from the United States and Japan and found that there is indeed substantial variation in the quality and

quantity of the blends produced. In addition, we also describe how titers of both components vary according to the time of day and age of the females.

METHODS AND MATERIALS

Insects. The U.S. strain of *P. operculella* originated from laboratory stock supplied from Albany, California, and the Japanese colony was derived from insects collected from potato fields in Nagoya. Larvae were reared on potato tubers in plastic containers at 26±2°C and 70–80% relative humidity on a 14 : 10 light–dark photoperiod regime. Pupae were held individually in test tubes, and adult emergence was monitored daily 30 min prior to lights-off. Adults were maintained under the same conditions as larvae with access to water.

Pheromone Extraction and Quantification. Glandular pheromone content of individual females was analyzed by GLC. Virgin females were anesthetized by N_2 or CO_2 gas, and the abdominal tips including the pheromone gland (Adeeson et al., 1969) were excised. The glands were extracted for 1 hr in conical glass tubes containing 50 μl of either CS_2 (California strain) or hexane (Nagoya); 5 ng of (*E*)-11-tetradecenyl acetate or tetradecyl acetate was present as an internal standard in California and Nagoya samples, respectively. Preliminary tests showed that immersion of the glands ($N = 10$) for 1 hr in hexane or CS_2 extracted, respectively, 96 ± 5% ($\bar{X}$ ± SD) and 95 ± 7% of the pheromone present. Samples were stored in vials with Teflon-lined caps at −10°C until analysis.

Prior to analysis, solvent was evaporated from each sample using a gentle stream of N_2 gas until ca. 1 μl of solution remained. This method of sample concentration caused a reduction in the absolute amounts of each component but did not alter their ratio; following concentration and GLC analysis, a 1 : 1 diene–triene solution (5 ng/component in 50 μl hexane) yielded 48.9 ± 2.2% diene and 51.1 ± 1.9% triene (based on 10 samples analyzed on an SP-2340 capillary column).

Analyses were performed on Varian 3700 (California strain) or Shimadzu GC-9A (Nagoya) GLCs, both equipped with flame ionization detectors and splitless injectors. Chromatographs were fitted with SP-2340 fused silica capillary columns (30 m × 0.25 mm ID; 0.25- or 0.20-μm film thickness; Supelco, Inc.); nitrogen carrier gas flow was 2–3 ml/min. For the Varian chromatograph, the column temperature program was 120°C for 4 min, then a 5°C/min increase to a final temperature of 160°C for 10 min. The Shimadzu initial column temperature was 80°C, then programmed to 150°C at 20°C/min with a 10 min final hold. Both temperature profiles provided baseline resolution of the pheromone components and internal standards. Peaks were characterized by retention times, and peak areas were quantified by a Hewlett-Packard 3390A

electronic integrator. The limit of quantification for both systems was ca. 0.1 ng.

Pheromone Titer and Composition Analyses. To describe daily fluctuations in titer, glands of Nagoya females (ca. 30 generations in culture) were excised at 1600 hr (lights-off) of day 1 (one day postemergence) and every 4 hr thereafter for the ensuing four days. In addition, the titer of females 30 min following emergence was determined. Twelve to fifteen insects were analyzed for each time period.

Variation in pheromone composition was determined by analyzing the glands of individual California and Nagoya females on the second day following emergence (from 2 hr before until the onset of scotophase when titers attained maximal levels). At the time this study was conducted, Nagoya females had been in laboratory culture for five generations, whereas California females had been reared for >30 generations.

RESULTS

Daily and Age-Related Changes in Pheromone Titer. As shown in Figure 1, the titers of individual and combined components varied in a regular pattern throughout the diel period. Titers attained maximal levels at lights-off, corresponding to the beginning of the female calling period (Ono, 1977). Pheromone levels then gradually declined during scotophase to their low point centered on the onset of photophase; there was always some pheromone stored, even during periods of minimal titer. Immediately following emergence (<30 min), females also had appreciable levels of pheromone in their glands (total 4.8 ± 1.0 ng; triene 4.0 ± 0.9; diene 0.8 ± 0.6).

A stepwise multiple linear regression analysis (SPSS, 1975) was used to determine whether total pheromone titer varied in a periodic fashion. A 24-hr sine function [sine f(time)] with the 90° peak synchronized to 1600 hr (lights-off) was generated from the sample time variable; the sine function was used in the regression analysis with the sample time variable itself. The analysis revealed that the data conformed very well to this model [sine f(time): slope $\pm$ SEM $= 1.43 \pm 0.14$; $F = 103.6$; $P < 0.001$], confirming that pheromone titer cycled with a period of 24 hr.

Daily means were calculated by combining all titer determinations for a particular day ($N = 82$–88). Figure 2 shows that as females aged, the levels of the diene, triene, and total pheromone declined in a linear fashion so that by day 4 these amounts were roughly halved compared to day 1.

Individual Variation in Pheromone Ratios. Considerable variability in the ratio of the two components was apparent in the previous measurements at different daily times and adult ages (Figure 1). The pheromone composition of individual females ranged from no detectable triene (1 individual) to exclusively triene ($N = 42$).

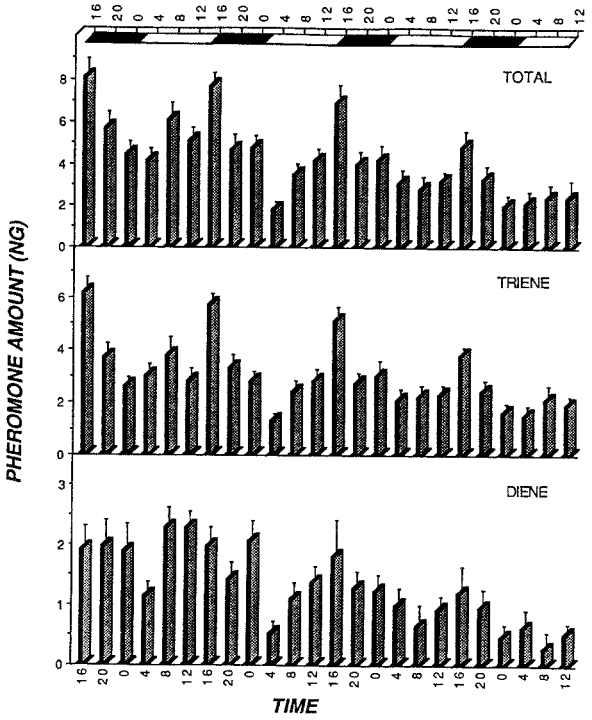

FIG. 1. Daily fluctuations in pheromone titer of 1- to 4-day-old Nagoya females whose glands were extracted at various times during the photoperiod. Each point represents the mean and associated standard error of 12–15 gland extracts. Shaded horizontal bars indicate scotophase.

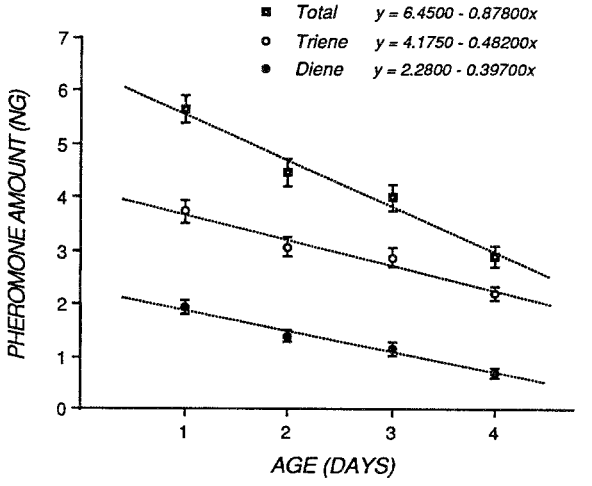

FIG. 2. Pheromone titers of Nagoya females as a function of age; each point represents the average of all titer determinations for a particular day (N = 82, 82, 88, and 84 for days 1, 2, 3, and 4, respectively). Vertical bars denote standard errors of the means.

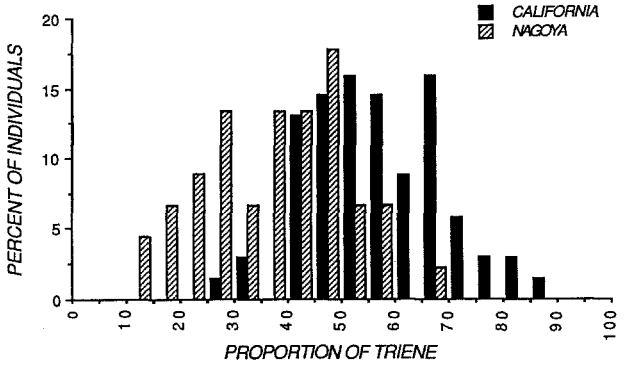

FIG. 3. Frequency distributions of the proportion of triene [triene/(diene + triene)] × 100 in the pheromone of California (N = 69) and Nagoya (N = 44) females. Glands of day 2 females were excised from 2 hr before until the onset of scotophase for both populations.

Individual variation in the composition of pheromone derived from California and Nagoya females extracted 2 to 0 hr before scotophase was also substantial. Figure 3 shows that the frequency distributions of the proportion of triene in the pheromone blends were broad for both populations. The range of triene proportions for the Nagoya females was 16.3–71.3% (equivalent to a diene–triene ratio of 0.4 : 1–5.2 : 1, or a 12.9-fold difference). The range of values was comparable for the California population: 28.2–88.2% (0.2 : 1–2.6 : 1, a 12.8-fold difference). For both populations, the mean ratio of diene to triene was approximately equal (Table 1); in the Nagoya population the diene tended

Diene	58.1(12.9)	22.2	4.8(2.1)	43.7	43.8(13.0)	29.6	1.2(0.7)	58.3
Triene	41.9(12.9)	30.8	3.8(2.3)	60.5	56.2(13.0)	23.1	1.5(0.8)	53.3
Total			8.6(3.9)	45.3			2.7(1.4)	51.9

[a] Derived from capillary GLC analyses of 44 Nagoya and 69 California individual female glands excised 0–2 hr before the onset of scotophase, two days after emergence. CV: coefficient of variation.

to be present in higher amounts [ratio 1.7 : 1 (1.1 SD); CV = 62.9)], whereas, on average, the triene was the more prevalent component in California females [0.9 : 1 (0.5); CV = 52.3]. The mean proportion of triene was ca. 15% higher in California females.

Glands of Nagoya strain females contained substantially more total pheromone, 8.6 ± 3.9 ng ($\bar{X}$ ± SD) than did those of their California counterparts (2.7 ± 1.4). Amounts of total pheromone extracted from Nagoya females ranged from 2.9 to 20.5 ng versus 0.4 to 6.3 ng for California females. Amounts of the individual and combined components also exhibited a high degree of variability in both strains, as is evident from the large associated coefficients of variation (Table 1).

DISCUSSION

The glandular titers of both *P. operculella* pheromone components fluctuated in a periodic fashion during the photoperiod. Peak amounts were present at the onset of scotophase; titers then declined during the dark period, attaining minimal levels soon after lights-on before beginning again to rise. Investigations on several other moth species have also revealed the existence of daily rhythms of pheromone production (e.g., Webster and Cardé, 1982; Raina et al., 1986; Snir et al., 1986; Delisle and McNeil, 1987; Dunkelblum et al., 1987a). Although we did not establish whether the cycling of pheromone titers in *P. operculella* has a circadian basis, circadian control of pheromone titer periodicity has been demonstrated in at least one moth, *Pseudaletia unipuncta* (Delisle and McNeil, 1987). Similar investigations will probably reveal that this is true for many moths.

The reduction in pheromone titer during the course of the scotophase may be attributable to emission of pheromone during calling and the resultant depletion of stored pheromone which is not offset by biosynthesis. Pheromone release in *P. operculella* commences at lights-off and ends at lights-on (Ono, 1977). An analogous pattern, characterized by the peak in titer preceding the peak female calling period, has also been documented for *Platynota stultana* (Webster and Cardé, 1982) and *Conogethes punctiferalis* (Konno, 1986). This type of pattern contrasts with the more widespread situation found in moths wherein peak pheromone titers either are essentially synchronous with maximal calling periods (e.g., Pope et al., 1982; Raina et al., 1986; Delisle and McNeil, 1987) or show little variation over the diel cycle (Sower et al., 1972; Schal et al., 1987).

Both populations exhibited substantial variation in the blend of components produced by the females. Moreover, the amounts of the individual components stored in the glands also were highly variable. The pooled quantities of com-

ponents extracted from both strains approximated a 1:1 ratio, similar to the ratios reported for pooled extracts of pheromone from other *P. operculella* populations (Persoons et al., 1976; Toth et al., 1984). In terms of amounts, Nagoya females produced 4.8 and 3.8 ng of the diene and triene, values similar to the 3.5 ng diene and 3.7 ng triene reported by Toth et al. (1984) for an Australian strain. The California strain produced substantially less pheromone (1.2 ng diene and 1.5 ng triene). Whether the lower titers reflect geographic variation or are the result of laboratory inbreeding depression is not clear. However, in this study, no significant differences were found in amounts of total pheromone from Nagoya females of comparable age that had been in laboratory culture for five generations (8.6 $\pm$ 3.9 ng; $N = 44$) versus ca. 30 generations (data from periodicity study: 7.7 $\pm$ 1.7 ng; $N = 15$).

Whether the ratio of the components in the glands of individual *P. operculella* females is indicative of the blend actually emitted remains to be determined. In other moths that utilize acetates in their pheromone, it has been found (at least in the 12- to 14-carbon-chain range) that the ratio of released components closely approximates their composition in the gland (Bjostad et al., 1984; Dunkelblum et al., 1987b), thus suggesting that the same situation may also apply to *P. operculella*.

The divergence in ratios of diene to triene between the California and Nagoya strains indicates substantial differentiation, but it seems unlikely in *P. operculella* that a ca. 15% difference in composition would impart any barrier to communication and mating, were the two strains to cooccur. Males are attracted to a broad spectrum of ratios (Persoons et al., 1976; Voerman and Rothschild, 1978; Raman, 1984; Ono and Orita, 1986), so that the difference in ratios produced by females from California and Nagoya is unlikely to be of behavioral significance. The Japanese population of *P. operculella* appears to have been introduced from Australia some 30 years ago (Koizumi and Ohshima, 1954), but it is not known if these populations are similar in either titer or component ratio.

Variation in pheromone ratio among individuals has been documented in several moth species. Miller and Roelofs (1980) showed that the mean proportion of (*E*)- and (*Z*)-11-tetradecenyl acetates extracted from the pheromone gland of wild *Argyrotaenia velutinana* females was 9.1 $\pm$ 1.8% SD, with a CV of 9.7%. (The CV is a useful measure for comparing relative variation among populations that differ in the magnitude of their means). Similarly, the mean ratio of (*Z*,*E*)- to (*Z*,*Z*)-7,11-hexadecadienyl acetate extracted from laboratory strain female *Pectinophora gossypiella* was 44.2 $\pm$ 2.3% SD, with a CV of 5.3% (Collins and Cardé, 1985).

In these species, the variation in male response appears moderately well linked to the limited variability in signal production. However, in *A. velutinana*, male attraction to blends about the natural ratio of (*Z*)- to (*E*)-11-tetra-

decenyl acetates is narrower (Baker et al., 1981; Linn and Roelofs, 1983) than *P. gossypiella* attraction to variants about its natural ratio (Flint et al., 1979; Linn and Roelofs, 1985). Such asymmetry in variability between female production and male response could reflect coding for differing strategies for signal selectivity in males and females. In general, males might be expected to be less narrowly tuned in response than females in signal production; this strategy could yield males responsive to all naturally available female ratios.

In *Agrotis segetum* (Löfstedt et al., 1985), variation in the ratio of the three pheromone components is substantial: 14.8 ± 127% CV for (*Z*)-5-decenyl acetate, 55.6 ± 32% CV for (*Z*)-7-dodecenyl acetate, and 29.6 ± 59% CV for (*Z*)-9-tetradecenyl acetate. Male attraction to dispensers loaded with a wide spectrum of blend ratios elicited only a 2.2-fold range of trap catch. In a similar study with *Ephestia cautella*, Barrer et al. (1987) also found a broad distribution of blend components; the individual composition of the two pheromone compounds, (*Z,E*)-9,12-tetradecenyl acetate and (*Z*)-9-tetradecenyl acetate, ranged from 63:27 to 97:3, with an overall mean of 88:12. These broadly tuned systems appear to be analogous to that of *P. operculella*.

Based on the available studies, it is possible to generalize about the relationship between the nature of the pheromone compounds used by moths and variation in blend quality. In general, blends composed of geometrical isomers (comprising either part or all of a particular pheromone) exhibit relatively low signal variance. Conversely, blends consisting of compounds that differ in the number or position of double bonds or that differ in chain length or functional moiety appear to have higher associated variability. The degree of variability associated with a given pheromone communication system may be a reflection of environmental and/or biosynthetic constraints. For example, among the latter systems, precise blend regulation may be unwarranted, because over the range of typical environmental temperatures and windspeeds, the ratio of the blend released can differ, not substantially, but by an amount above the range of variation found in tightly regulated blends (Cardé and Baker, 1984; but see Löfstedt et al., 1985). On the other hand, the variability may simply stem from inherent limitations in the ability of the moths to biosynthesize components in precisely regulated amounts. Roelofs and Bjostad (1984) have proposed that the diene and triene pheromone components of *P. operculella* are biosynthesized from different precursors, namely, linoleic and linolenic acid, respectively. Regulation of precise ratios of components derived from disparate precursors may not be as feasible as is the tight control of *Z* and *E* isomeric blends of acetates, because isomers of a particular acetate arise from the same saturated, long-chain fatty acyl precursor which itself is typically biosynthesized *de novo* (Roelofs and Wolf, 1988).

The extent to which congeners and perhaps unallied species employing similar communication systems cause a restriction of blend specificity will have

to await other evidence, such as would be provided by demonstration of reproductive character displacement in the chemical communication channel (Cardé, 1986). Species possessing a unique pheromone bouquet (as may be the case for the odd-carbon-chain components of *P. operculella*) would be under no selection pressure to maintain a narrowly tuned channel. Furthermore, evolution of a biosynthetic scheme yielding a precise ratio may only occur if there is an advantage, such as creation of an exclusive communication channel that avoids cross-attraction, to emitting a signal with a restricted variance (Löfstedt et al., 1985).

Acknowledgments—We gratefully acknowledge Dr.'s L.K. Etzel and R. Yamaoka for supplying the U.S. strain of *P. operculella* and synthetic chemicals, respectively; Prof. H. Kondo for allowing T. Ono to use his GLC; N. Haver and S. Rosenblum for rearing the U.S. culture; J. Tang for critiquing the manuscript; and S. Woods for providing expert advice on statistical matters.

(Received January 9, 1989; accepted March 13, 1989)

Abstract—Hydroxydanaidal, the corematal courtship pheromone of male *Utetheisa ornatrix*, shows pronounced quantitative variation in natural populations of the moth. Males that, as larvae, fed on seed-bearing rather than immature food plants (*Crotalaria spectabilis* or *C. mucronata*) produce higher levels of hydroxydanaidal. Such males also have higher systemic loads of pyrrolizidine alkaloid, the known metabolic precursor of hydroxydanaidal, which *Utetheisa* sequester from their larval diet and which is concentrated in the seeds of *Crotalaria*. Males raised on seed-bearing plants also achieve higher adult weight. In the context of sexual selection, therefore, female *Utetheisa* could, through assessment of male hydroxydanaidal levels, gauge both the alkaloid content and body weight of their suitors.

Key Words—Courtship pheromone, *Utetheisa ornatrix*, Lepidoptera, Arctiidae, sexual selection, hydroxydanaidal, pyrrolizidine alkaloid, *Crotalaria*.

INTRODUCTION

In this paper we investigate the natural variability in pheromone titer of a male moth and inquire into the possible cause of this variability. The moth in question, *Utetheisa ornatrix* (L.) (family Arctiidae), is one in which the chemistry

0098-0331/90/0200-0543$06.00/0

of courtship is inextricably related to the chemistry of defense (Eisner and Meinwald, 1987).

Utetheisa, as larvae, feed on legumes of the genus *Crotalaria*, plants long known to be poisonous by virtue of the pyrrolizidine alkaloids they contain (Bull et al., 1968; Mattocks, 1986). *Utetheisa* sequester the ingested alkaloids and retain them systemically throughout development, deriving protection against predators as a result (Eisner, 1980; Eisner and Meinwald, 1987; Dussourd et al., 1988). Courtship in *Utetheisa* is initiated at dusk by release of a sex attractant from the female that lures the male. Upon reaching the female, the male flutters about her, while intermittently everting a pair of scent brushes (coremata) from his abdomen. The pheromone associated with the coremata, hydroxydanaidal, is derived by the male from the acquired pyrrolizidine alkaloid and is a key to the male's acceptance by the female. Males raised on a laboratory diet devoid of pyrrolizidine alkaloid fail to produce hydroxydanaidal and are relatively unsuccessful in courtship (Conner et al., 1981). These findings led to the suggestion that females, by favoring males of high hydroxydanaidal titer, could be sexually selecting for partners of high larval alkaloid-sequestering ability, a beneficial trait that could be heritable (Eisner, 1980; Conner et al., 1981). The subsequent discovery that males transfer a substantial fraction of the alkaloid to the female by seminal infusion, and that the female in turn bestows some of the "gift," together with alkaloid of her own, for protective purposes upon the egg, forced modification of the hypothesis. Hydroxydanaidal, it seemed, rather than serving strictly for appraisal of a larval trait, could be used by the female also for assessment of a male's potential alkaloidal offering (Dussourd et al., 1988). Quantitative data obtained with laboratory-reared *Utetheisa* provided some support for these notions. Males bore hydroxydanaidal at levels roughly proportional to their alkaloid load, and the amount of alkaloid they transferred to females at mating was itself proportional to this load (Dussourd, 1986). Missing from the scheme were values pertaining to *Utetheisa* in the field. No information was available on the natural variability of hydroxydanaidal in males and on whether such variability correlates with variation in larval alkaloid intake. The data we present here address these unknowns. Specifically we show that hydroxydanaidal levels vary over a broad range in nature, and that the titers of the pheromone are higher in males that had larval access to the alkaloid-rich parts (seeds) of their food plants. Moreover, hydroxydanaidal levels were found to correlate positively with adult male size.

In North Carolina and Florida where we study *Utetheisa*, the primary food plants of the moth are *Crotalaria spectabilis* and *C. mucronata*. The two plants differ qualitatively and quantitatively in pyrrolizidine alkaloid content. *C. spectabilis* produces primarily monocrotaline (Adams and Rogers, 1939); *C.*

mucronata mainly usaramine (Sawhney et al., 1967). The former produces substantially higher quantities of alkaloid (Williams and Molyneux, 1987). In both species the alkaloid is concentrated in the seeds and is present at substantially lower concentration in the leaves (Sharma et al., 1965; Johnson et al., 1985).

Our study involved analyzing adult males of two types, "wild" and "garden-raised," the former for corematal hydroxydanaidal content, the latter for both hydroxydanaidal content and systemic alkaloid load. Wild males were taken as adults from natural populations of the moth. Garden-raised males were reared outdoors on either mature (seed-bearing) or immature stands of both *C. spectabilis* and *C. mucronata*.

METHODS AND MATERIALS

Wild Males. Individuals were collected at five field sites, three in Moore County, North Carolina, and two in Highlands County, Florida. The sites consisted of disturbed wayside areas dominated by *C. spectabilis* or *C. mucronata*, or both. Individual males were captured by net and taken to the laboratory in plastic vials. Their coremata were then either excised at once (the elongate scent scales were removed with forceps, together with the underlying cuticle and glandular epithelium), or after live shipment to Ithaca, New York, and analyzed for hydroxydanaidal content.

Garden-Raised Males. These individuals were raised on eight stands of *Crotalaria*, planted outdoors in Durham, North Carolina. The stands were arranged in two replicate plots of four (within each plot the arrangement of stands was randomized). Within each plot the stands were as follows: one of 60 mature *C. spectabilis* plants with fully formed seedpods, another of 60 young *C. spectabilis* plants devoid of such pods, a third of 60 mature *C. mucronata* plants, and a fourth of 60 young *C. mucronata* plants. Each stand was "seeded" with 120 first-instar *Utetheisa* larvae, the offspring in each case of five females collected in Moore County, North Carolina. After approximately one month, surviving larvae, now in their fifth instar (ranging in number from 13 to 32 per stand) were retrieved from the stands and allowed to pupate in individual containers in an incubator (27°C; 16 : 8 light–dark photoperiod). Eclosing adults were maintained on 5% sucrose solution for seven days, then weighed and corematectomized. Coremata and bodies were analyzed for hydroxydanaidal and alkaloid content, respectively.

Chemical Analyses. The hydroxydanaidal contents of the coremata of wild males were determined by GC analysis using a Hewlett-Packard 5890 chromatograph equipped with a cool on-column injector, a 7673A autosampler, a flame ionization detector, and a 3392A recorder/integrator. Coremata were

weighed and placed in 1-dram vials to which methylene chloride (0.5 ml) and an internal standard (4 μg of benzophenone in 100 μl of methylene chloride) were added. Coremata were pulverized, further dispersed by sonication, and stirred for 24 hr. After centrifugation, the supernatant was removed; the remaining solids were extracted with two additional aliquots of 250 μl of methylene chloride. The supernatants were combined and their total volume reduced to ca. 200 μl. One microliter of this solution was injected into a wide-bore fused silica capillary column (0.53 mm × 25 m, 1 μM methylsilicone phase, Quadrex Corp.) using hydrogen (3.75 psi, 5 ml/min, 30 cm/sec) as the carrier gas. Column and injector were held at 35°C for 1 min, raised to 115°C at 25°C/min, raised to 145°C at 1.5°C/min, raised to 225°C at 25°C/min, and maintained at 225°C for 10 min. The retention times were 14.5 min and 21.0 min for hydroxydanaidal and benzophenone, respectively.

For the later analysis of the coremata of garden-raised males, the above extraction procedure was shortened to a 1-hr extraction in methylene chloride without reducing yields.

Body alkaloid analyses were carried out by a gradient HPLC technique using the pyrrolizidine alkaloid riddelliine as an internal standard. Samples were pulverized in a mixture of ethanol (2 ml) and mobile phase A (1 ml) containing a known quantity of riddelliine. Mobile phase A was prepared by dissolving 2.7 g of potassium dihydrogen phosphate, 2 ml of triethylamine, and 0.4 ml of trifluoroacetic acid in 4 liters of HPLC grade water. The pH was adjusted to 3.25 with phosphoric acid. The samples were stirred and sonicated for 24 hr. Each sample was then centrifuged and the supernatant drawn off. The residue was reextracted with 2 ml of mobile phase A for 24 hr, and the supernatants were combined. The combined extract was filtered into an autosampler vial.

HPLC separations were performed on a deactivated C-18 column (Supelco LC-18DB, 3 μM, 4.6 × 150 mm) at 35°C in an Eldex CH-150 column oven. An Eldex 9600 pump was used to deliver a mobile phase gradient [98% mobile phase A : 2% mobile phase B for 5 min (mobile phase B was prepared by adding 400 ml of acetonitrile and 10 ml of tetrahydrofuran to 1.6 liters of mobile phase A) changed linearly to 50% A : 50% B at 20 min]. The flow rate was programmed from 0.75 ml/min at injection with a linear increase to 1.25 ml/min at 25 min. Amounts of each alkaloid were determined based on relative responses observed from calibration standards of monocrotaline, monocrotaline *N*-oxide, usaramine, and usaramine *N*-oxide. All four alkaloids including riddelliine were resolved well by a UV detector at 205 nm (retention times: monocrotaline 7.0 min; monocrotaline *N*-oxide 13.5 min; usaramine 22.5 min; usaramine *N*-oxide 24.5 min; riddelliine 18.0 min).

RESULTS

Wild Males. The coremata of the field-collected males showed considerable variation in hydroxydanaidal content at all field sites (Table 1). Values did not differ significantly for the various sites (ANOVA; $P > 0.05$), justifying combination of the data into a single frequency diagram (Figure 1). The distribution is normal with a mean of 15.8 ± 8.2 μg hydroxydanaidal/male corematal pair.

Garden-Raised Males. Host plant age and species had a significant effect on corematal hydroxydanaidal levels (two-way ANOVA) (Figure 2). Males raised on mature, pod-bearing plants had higher hydroxydanaidal levels than males raised on podless plants ($P < 0.01$). Individuals raised on *C. spectabilis* had higher levels of hydroxydanaidal than individuals raised on *C. mucronata* ($P < 0.01$). No significant interactions were detected.

Significant differences were also apparent in the alkaloid content of males of the four categories (two-way ANOVA) (Figure 3). For both plant species, males raised on mature plants had higher alkaloid loads than individuals from podless plants ($P < 0.01$). Individuals raised on *C. spectabilis* had higher overall alkaloid levels than individuals raised on *C. mucronata* ($P < 0.01$). No significant interactions were detected. The particular alkaloid in the moths matched the type found in their food plant: moths raised on *C. spectabilis* contained monocrotaline, while those raised on *C. mucronata* contained usaramine. In all moths the alkaloid was present predominantly in the *N*-oxide form. The free base form accounted for less than 5% of the total alkaloid. The data are presented as sums of *N*-oxide and free base.

The data revealed a further correlate of larval diet. Adult male weight was found to be significantly greater for individuals raised on mature plants than for those raised on immature plants (79.4 ± 26 μg vs. 49.3 ± 1.8 μg; two-way

ANOVA; $P < 0.01$). There was no significant difference in the weights of males raised on the two plant species ($P > 0.05$).

Hydroxydanaidal levels correlated significantly (simple linear regression; $P < 0.05$) with both the total alkaloid content and weight of males, but each

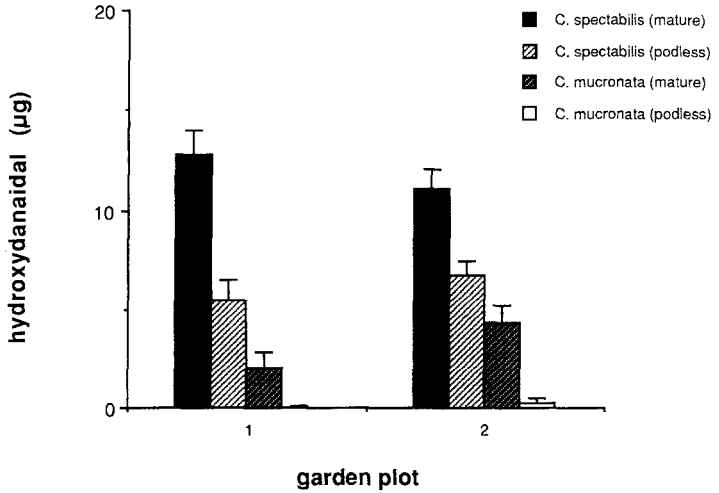

FIG. 2. Hydroxydanaidal titer of coremata of male *Utetheisa* raised on gardens of four types, with replication. Bars indicate standard errors.

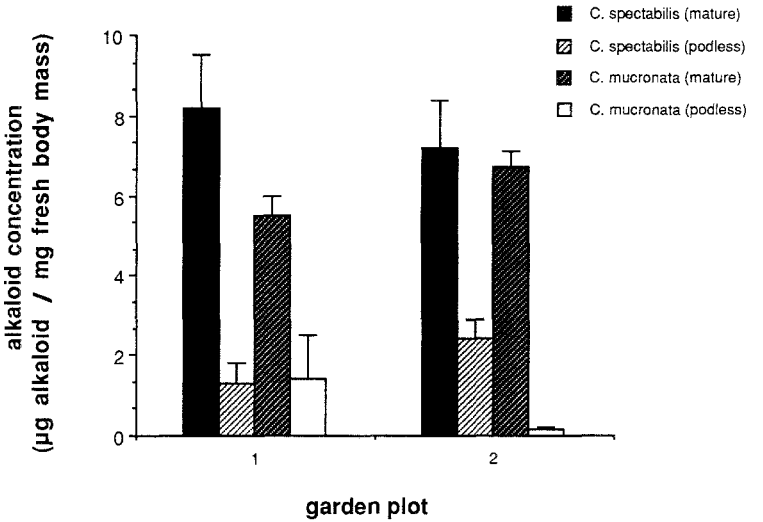

FIG. 3. Pyrrolizidine alkaloid concentration of male *Utetheisa* raised on gardens of four types, with replication. Bars indicate standard errors.

variable accounted for less than 20% of the total hydroxydanaidal variance. The correlations improved when the data from the *C. spectabilis* and *C. mucronata* stands were analyzed separately. For the *C. spectabilis* stands, alkaloid content and weight accounted for 36.1% and 59.0% of the variance, respectively (Figure 4). The corresponding values for the *C. mucronata* plots were 25.1% and 39.7% (Figure 4).

DISCUSSION

It seems established that corematal hydroxydanaidal levels in male *Utetheisa* vary over a broad range in natural populations and that the levels of the pheromone are affected by larval diet. The finding that hydroxydanaidal levels were highest in males with larval access to pod-bearing plants, as opposed to podless plants, makes sense, given that hydroxydanaidal is derived from ingested alkaloid and that the alkaloid is maximally concentrated in the seeds of *Crotalaria*. We know from field observation that *Utetheisa* feed avidly on the seeds of their food plants, and we noted them to do so on our experimental stands. As expected, access to pods also resulted in higher systemic alkaloid loads. In the context of courtship, therefore, by gauging a male's hydroxydanaidal titer, a female could be appraising both her suitor's dietary history and alkaloid load, assessments by which she could exercise mate choice. While it remains to be proved that *Utetheisa* females discriminate behaviorally between incremental

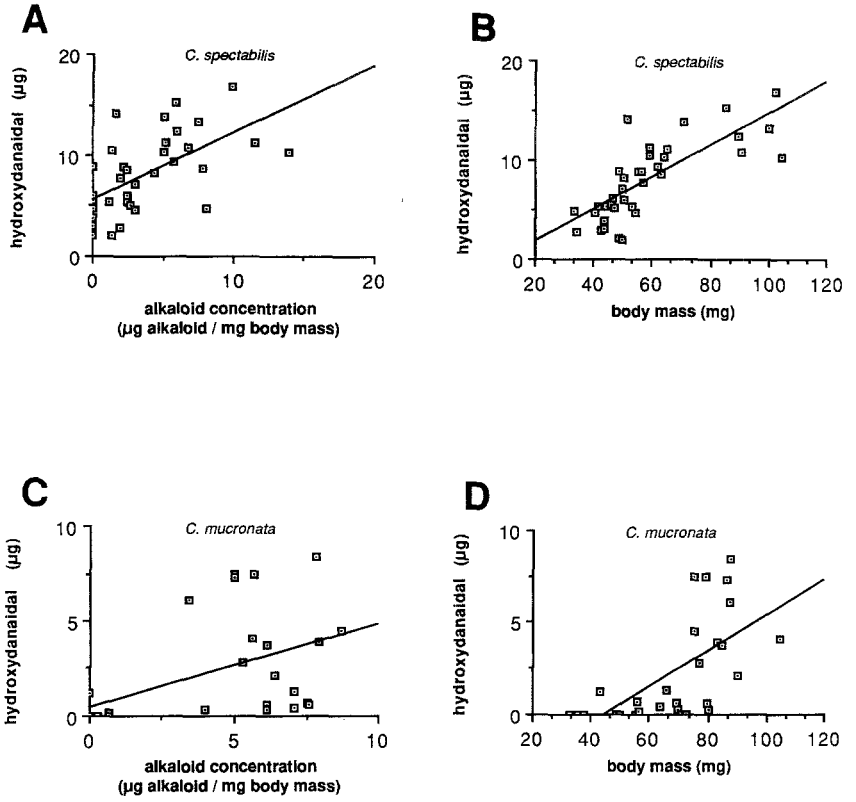

FIG. 4. (A) Correlation between total alkaloid load in male *Utetheisa* raised on *C. spectabilis* and the hydroxydanaidal content of their coremata. (B) Correlation between body mass of males (same individuals as A) and the hydroxydanaidal content of their coremata. (C) Correlation between total alkaloid load in male *Utetheisa* raised on *C. mucronata* and hydroxydanaidal content of their coremata. (D) Relationship between body mass of males (same individuals as C) and the hydroxydanaidal content of their coremata.

levels of hydroxydanaidal and that they select suitors on that basis, it is known that they can differentiate between presence and absence of the pheromone and that they favor males that have the compound (Conner et al., 1981). Electrophysiological data on antennal chemoreceptors do predict that the female should be able to discriminate between even slight concentration differences of hydroxydanaidal (Grant et al., 1989).

The correlation between hydroxydanaidal level and alkaloid load (Figures 4A and C) is far from tight. Nonetheless, within limits, hydroxydanaidal could serve as a predictor of male alkaloid content, and this could well be one role of the pheromone.

Additional complexity is introduced by the finding that hydroxydanaidal titers also correlate with male size. Not surprisingly, males with larval access to the more nutritious seed-bearing plants achieved greater adult weight. Hydroxydanaidal could thus provide the female also with a measure of male size and, indirectly, spermatophore size (do males transmit nutrients in addition to alkaloid with their spermatophores and is the amount transferred a function of male size?). The spermatophores of *Utetheisa* are large, averaging 7.5% of male body weight (Dussourd, 1986) and their size correlates with male body weight in laboratory-raised individuals (David Dussourd, personal communication). A similar relationship between male courtship pheromone levels and male size has been reported for the tobacco moth, *Ephestia elutella* (Phelan and Baker, 1986).

In our view, the finding that hydroxydanaidal levels are widely variable in nature need not indicate solely that the moths had larval access to plants of different maturational age. It also could signify that the moths had a history of competing for seeds on mature plants and that they did so with varying success. Field observations support this notion. We often observed in natural stands of *C. mucronata*, when *Utetheisa* larvae were dense, and especially when another seed-eater, the larva of the pyralid moth *Etiella zinckenella* (Treit.), was also abundant, that virtually the entire seed set of the plants was eaten away. *Utetheisa* males with minimal levels of hydroxydanaidal, such as we now know to occur in nature, could thus represent the losers in such combined intra- and interspecific competition, rather than merely individuals that fed on immature plants.

The hydroxydanaidal values presented here are substantially higher than those we initially reported for *Utetheisa* (Conner et al., 1981). We attribute this to differences in the corematectomy techniques used. By the earlier method we snipped off and extracted the corematal scales only, while for the current extractions we excised the underlying glandular tissue as well.

BIOLOGY OF PHEROMONE RELEASE BY MALE CARIBBEAN FRUIT FLIES, *Anastrepha suspensa* (DIPTERA: TEPHRITIDAE)[1]

JAMES L. NATION

Department of Entomology and Nematology
University of Florida
Gainesville, Florida 32611

(Received January 5, 1989; accepted March 16, 1989)

Abstract—Males of the Caribbean fruit fly, *Anastrepha suspensa* (Loew), typically form leks and attract females by releasing a multicomponent volatile pheromone. Previous reports have identified two nine-carbon alcohols, three lactones, a sesquiterpene, and a monoterpene in the volatiles. The present report is a study of the physiology of male pheromone release and of ecological and social interactions that influence pheromone release by laboratory-reared flies. Volatiles released by males were trapped on Tenax, eluted, separated, and quantitatively measured by gas chromatography. Experiments showed that the volatiles were primarily released from mouth and anus. Sealing the anal opening or the mouth with melted beeswax resulted in up to 40% or greater reduction in most components, and sealing both mouth and anus further reduced release of volatiles, but some volatiles are possibly still released directly from the cuticle. An anal pouch of everted tissue played a major role as a large evaporative surface for release of some of the volatile components. Male flies entrained to a 14 : 10 light-dark cycle showed a peak release of volatiles at 11-12 hr into the photophase, but smaller quantities of the same volatiles were released over a broad period during the daylight hours. Laboratory-reared males peaked in pheromone release at 7-10 days and production and release continued through 35 days of age. Single males released significantly more of all components measured than did groups of males. The reduction by aggregations of males may be related to lekking behavior in this fruit fly. The pheromone probably serves to attract females to a lek site, but additional parameters are likely to enter into the choice of male made by the arriving female.

Key Words—*Anastrepha suspensa*, Diptera, Tephritidae, fruit flies, pheromone, volatiles, lek, circadian rhythm, mating behavior.

INTRODUCTION

Male Caribbean fruit flies, *Anastrepha suspensa*, attract females, at least in part, by release of a volatile pheromone, as shown in both laboratory and field experiments (Nation, 1972; Perdomo et al., 1975, 1976; Dodson, 1982; Burk, 1983; Webb et al., 1983). In field tests, but not in lab tests, males are also attracted to sticky traps baited with live males (Perdomo et al., 1976) and aggregations of males have been observed in the field (Perdomo, 1974; Burk, 1983). Several authors (Dodson, 1982; Burk, 1983; Sivinski, 1984) have considered the behavioral ecology of Caribbean fruit flies to include lekking behavior, a mating system in which males aggregate and attract females to a lek arena for mating (Alexander, 1975; Bradbury 1981). Lek behavior has been recognized in a number of insects (Spieth, 1970; Alexander, 1975; Willis and Birch, 1982), including some other tephritid fruit flies (Tychsen, 1978; Morgante et al., 1983; Prokopy and Hendrichs, 1979; Kuba et al., 1984; Dodson, 1986).

The volatile pheromonal components released by Caribbean fruit fly males have been identified and synthesized, and include (Z)-3-nonenol, (Z,Z)-3,6-nonadienol (Nation, 1983), two chiral lactones, anastrephin and epianastrephin (Battiste et al., 1983), and a nonchiral lactone, suspensolide (Chuman et al., 1988). In addition to these, unpublished data from this laboratory and a verbal report from another laboratory (J. Tumlinson, 1987, "Pheromone chemistry: Getting it right," Annual Meeting, Entomological Society of America, Boston, Massachusetts) have identified the presence of β-bisabolene and β-ocimine in the volatiles, but their behavioral roles are uncertain. While the two nine-carbon alcohols and the two gamma lactones have individual behavioral activity in bioassays with female flies (Nation, 1975, and unpublished data), the behavioral role of the macrolide is not well defined. Laboratory bioassays show that it has some behavioral activity upon females (unpublished data).

A general review of the behavioral and chemical ecology of the Caribbean fruit fly and related fruit flies, as well as preliminary details from collection of the volatiles of the male flies, has been reported (Nation, 1989). In that review, the then incompletely identified suspensolide was referred to as lactone B, bisabolene was identified only as a sesquiterpene, and ocimine as a monoterpene. This paper presents a more detailed report of volatile collections and of environmental and behavioral factors that influence the quantity and blend of pheromone volatiles released by male flies.

METHODS AND MATERIALS

Insects. A. suspensa were obtained from a laboratory colony of flies reared according to the procedures of Greany et al. (1976). The colony has been in continuous culture since about 1966. Adults were maintained on dry yeast

hydrolysate, dry sucrose, and water fed ad libitum. Adult flies were segregated by sex into cloth-covered aluminum-frame cages on the first day after emergence or earlier and held in separate incubators at 26–27°C with a 14 : 10 light–dark cycle.

Collection of Volatiles: Volatiles were collected from male flies as previously reported (Nation, 1989) by utilizing a water pump to draw air over flies in a cylindrical glass vessel. Males were placed into the collection device a few minutes before the experiment was to begin. A cylindrical glass vessel was used to hold males during the course of the collections (Figure 1A). Cylinder 1 was 38 mm ID and 235 mm long. A screen cap at the air inlet end retained the males, while an aluminum foil-covered rubber stopper with a glass tube passing through closed the other end and provided an exit tube for air and volatiles. Cylinder 1 was used to collect all data except data for Figure 4. Collection of Figure 4 data was made with cylinder 2, which measured 34 mm ID and 173 mm long. A screen at one end retained males and admitted air. The opposite end of the cylinder was drawn into a single exit tube 6 mm in diameter. Air flow over male flies in the cylinder was adjusted to 0.8–1 liter/min and was led from the exit tube in each cylinder into two traps in series, each containing 300 mg Tenax GC as the adsorbant (Cross, 1980; Golub and Weatherston, 1984). The column of adsorbent was about 3 cm long and was held in glass tubes (12 mm ID, 18–20 cm long) between plugs of silanized glass wool. After a predetermined time of collection, traps were removed and volatiles were eluted from the Tenax with pentane. Some collections were made with a prefilter of Tenax or charcoal at the air intake (ground glass joint) end of the apparatus (Figure 1B), but in practice the prefilter proved unnecessary most of the time and often it was not used. If contaminants showed on the chromatograms, the prefilter was reinstated (as for example, when the interior of the building was being repainted).

In preliminary tests designed to determine possible breakthrough of volatiles from the first trap, the two traps were eluted separately, each with 10 ml pentane, and subsequent GC analyses conducted on the eluates. After conditions to minimize breakthrough were established, the eluate from trap 2 was allowed to drip into trap 1 and washing of the two traps was continued until 10 ml effluent was collected from trap 1. In some collections from a single male for 1 hr, only one trap of 300 mg Tenax was used. Poropak and coconut charcoal (Fisher Scientific Co., activated coconut charcoal, 50–200 mesh) were also tested as trapping agents.

Preliminary experiments revealed that addition or omission of food and water from males for the usual collection period of 3 hr had no effect upon quantity or composition of volatiles collected. Thus, no food or water was placed in the collection apparatus with males if the experiment was to last only 3 hr. For longer experiments, dry sucrose, dry yeast hydrolysate, and water were placed in the apparatus in separate vial caps. Although yeast hydrolysate released

some volatiles, the quantity was minor, and fortunately none of them interfered with the measurement of the male produced volatile components.

Determination of Release Sites for Volatiles. Volatiles were collected from male flies with either the mouth or anus, or both sealed with melted beeswax. Control males had wax deposited on the thorax. Care was taken to heat the wax just to the melting point in order to avoid injury to flies by wax that was too hot. At the end of a collection period, males were examined by viewing under 10–30× magnification to see if the wax still sealed the mouth or anus. Generally, failure of the wax seal was not a problem, but if males were found that had broken the seal loose, the experiment was discarded.

Determination of Influence of Photoperiod, Age, and Male Density on Release of Volatiles. Collection of volatiles from a group of 25 males was begun at 6 hr into the photophase and the Tenax traps were changed hourly to determine the time and rhythm of volatiles release. The same 25 males were retained in the apparatus for the entire day of collection and they were provided with dry sucrose, dry yeast hydrolysate, and water.

To determine the influence of age of males upon the quantity and composition of volatiles released, collections were made from single males or from 25 males of known age in the collection apparatus for a period of 3 hr that included the 11th through the 13th hours of the photophase. Males taken at random from the same cohort of flies were used on successive days for the age study.

The influence of the number of males in the holding chamber upon volatiles released was determined with two cylinders (type 1) placed side by side on the table top. One apparatus contained a single male, while the second apparatus contained two, three, five, or 10 males. Additional experiments were also conducted in which one apparatus contained three or five males, while the other contained a larger group. All males were from the same cohort of flies and were taken at random from a large cage of males held in the incubator. Volatiles were collected for 3 hr during the 11th through the 13th hours of the photophase. Care was taken to adjust air flow equally in the two systems.

Chromatography and Quantitation of Volatiles. An internal standard containing decanol, tetradecane, and methyl tridecanoate was mixed with the eluted pheromone solution and the volume was reduced to about 0.5 ml by a gentle jet of nitrogen gas. The quantity of each of the three internal standards was adjusted from time to time to produce GC peak areas similar to the peak area of the component(s) to be estimated by that standard. For example, smaller quantities of standards were used in measuring collections of volatiles from a single male than were used in measuring collections from a group of males. Suitability of the three internal standards for quantitation of particular pheromonal components was determined from gas chromatographic analyses and measurement of peak areas produced from weighed samples of pure synthetic components and internal standards.

The mixture of volatile components and internal standards was separated by gas chromatography with a Varian 3700 or Varian 2400 gas chromatograph equipped with a flame ionization detector and interfaced with an HP 3390 A recorder–integrator. The chromatographs contained a 10 m × 0.5 mm ID wide-bore RSL 150 or RSL 160 Non-Pakd column (Alltech Associates) or a 30 m × 0.25 mm ID DB-1 (J&W Scientific, Inc.) capillary column. Injections into the wide-bore columns were on-column and splitless, and splitless into the capillary columns. Injections into the RSL columns were made at 105°C with immediate programming at 1°C/min to 170°C. Helium carrier gas flow was 3 ml/min with no additional makeup gas flow. The injector port was held at 165°C and detector at 185°C. Injections into the DB-1 column were made at 50°C, held for 5 min, then programmed at 2°C/min to 150°C, and held for 45 min. The injector port was held at 180°C and the detector at 250°C. Helium linear flow was 16.1 cm/sec, with makeup gas flow approximately 25 ml/min.

Data Analysis. Comparisons of the quantity of individual volatile components released by male flies were made with a paired Student's *t* test (Stat-Pak software). The 0.05 probability level was chosen for rejection of the null hypothesis that release rates of specified volatile components were equal in the various experimental situations. The relationship between levels of volatile components was also examined by linear regression.

RESULTS

Validation of Internal Standards as Quantitative Estimators of Pheromonal Volatiles. The accuracy and reproducibility of decanol, tetradecane, and methyl tridecanoate as quantitative estimators of the components in the volatiles from male flies are shown in Table 1. Decanol gave excellent estimation of a weighed sample of (Z)-3-nonenol (97.4 ± 3.7%, mean ± SEM), and it was chosen to

TABLE 1. EVALUATION OF INTERNAL STANDARDS FOR ESTIMATION OF PHEROMONAL COMPONENTS IN VOLATILES COLLECTED FROM MALE *A. suspensa*[a]

Synthetic pheromonal component	Internal standard (% of actual found)		
	Decanol	Tetradecane	Methyl tridecanoate
(Z)-3-Nonenol (N = 9)	97.4 ± 3.7	78.3 ± 2.9	90.1 ± 2.5
β-Bisabolene (N = 11)	137.4 ± 3.5	109.1 ± 2.5	127.1 ± 3.2
Epianastrephin (N = 11)	106.2 ± 3.4	82.9 ± 2.3	98.4 ± 3.1

[a] Synthetic pheromonal and internal standards were weighed and dissolved in pentane or isooctane, and chromatographed by GC. Mean percent (± SEM) of weighed quantity found.

estimate the two nine-carbon alcohols, (Z)-3-nonenol and (Z,Z)-3,6-nonadienol, which eluted together and just before decanol on the columns used. Tetradecane, a straight-chain hydrocarbon, slightly overestimated a weighed sample of bisabolene (109.1 ± 2.5%), but it was used as the internal standard for estimating bisabolene without correction. Methyl tridecanoate allowed 98.4 ± 3.1% estimation of a weighed sample of epianastrephin and was used to measure anastrephin, epianastrephin, and suspensolide. The best standard for estimating suspensolide and an evaluation of accuracy cannot be determined because very pure synthetic suspensolide is not available for gravimetric preparation of a standard. All pheromonal components collected (except β-ocimine) were calculated on the basis of a 1 : 1 detector response with the internal standard used. β-Ocimine was not routinely measured because it elutes too rapidly under the chromatographic conditions used for the other components. Some preliminary analyses of ocimine were reported earlier (Nation, 1989), indicating that β-ocimine is a very minor component in the volatiles, and its behavioral status is also uncertain.

Evaluation of Trapping Agent for Pheromonal Volatiles. Preliminary experimentation with the quantity of Tenax to use in the collecting traps, as well as experiments to see if breakthrough of the volatile components occurred, showed that two Tenax traps, each containing 300 mg Tenax GC, would trap all the volatiles from up to 50 males for several hours (Table 2). Some breakthrough of suspensolide and epianastrephin into trap 2 occurred when large collections were made from 50 males over a period of 6 hr. None of the other compounds showed breakthrough. In typical collections of volatiles from a few males for up to 3 hr, only trace amounts of suspensolide broke into trap 2. At

TABLE 2. RECOVERY OF VOLATILE COMPONENTS FROM *A. suspensa* MALES IN TWO TRAPS CONNECTED IN SERIES AND EACH CONTAINING 300 MG TENAX GC[a]

		Total Found (μg)[b]				
		N	S	B	A	E
Trial 1	Trap 1	44.6	72.9	165.7	37.6	158.0
	Trap 2	none	64.4	none	none	6.7
Trial 2	Trap 1	61.0	45.3	185.6	36.3	153.1
	Trap 2	none	67.4	none	none	13.7

[a] Air flow over males and into traps was provided by a water vacuum pump. The air flow rate was adjusted to 0.8–1 liters min. Volatiles were collected continuously from 50 males for 6 hr.
[b] N = (Z)-3-nonenol and (Z,Z)-3,6-nonadienol; S = suspensolide; B = β-bisabolene; A = anastrephin; E = epianastrephin.

the end of the collection period the two Tenax traps were disconnected and trap 2 was clamped above trap 1. Elution of the trapped volatiles was started by adding pentane at the top of trap 2. The eluate from trap 2 dripped into trap 1, and washing of both traps was continued until 10 ml eluate was collected from trap 1. About 5 ml of pentane was sufficient to elute all collected volatiles from the two 300-mg traps, but elution was routinely continued until 10 ml eluate had been collected to ensure quantitative collection. Periodic checks by gas chromatography of a few milliliters eluted after 10 ml was collected showed that elution from the two traps was complete.

Poropak was discarded as a trapping agent after preliminary use because it was difficult to get it as clean as Tenax. Charcoal was tried and discarded because it was more difficult to elute the polar compounds in the volatiles from charcoal traps. Ten milliliters of pentane, which was more than sufficient to quantitatively elute all compounds from the Tenax traps, eluted less than 50% of the adsorbed anastrephin and epianastrephin from two charcoal traps. Those compounds could be eluted with ether.

Quantitative Analysis of Collected Volatiles. A typical chromatographic record obtained from the RSL 160 megabore column is shown in Figure 1. Identities of the peaks in Figure 1 were based on chromatographic comparison with authentic synthetic standards for compounds previously identified from male Caribbean fruit flies and included (*Z*)-3-nonenol and (*Z*,*Z*)-3-6-nonadienol (coeluting), suspensolide, β-bisabolene, anastrephin, and epianastrephin. Since (*Z*)-3-nonenol and (*Z*,*Z*)-3,6-nonadienol eluted together as one peak in the chromatographic systems used, they are henceforth referred to in this report as nonenols. Measurements of components left on the collecting vessel walls showed that 6–8% of the anastrephin and epianastrephin was left on the vessel walls, while residues of other components were not detected.

The data in Table 3 indicate that the pheromonal volatiles were liberated from both mouth and anus. When either the mouth or anal opening, or both, were sealed with melted beeswax, the quantity of all pheromonal volatiles was reduced. There was from 35% to greater than 50% reduction in volatile components when the mouth was sealed. This would prevent the flies from releasing components from the mouth and would also prevent them from swallowing air that might be passed through the gut. Sealing of the anus resulted in nearly as great reductions as when the mouth was sealed. When both mouth and anus were sealed with wax, there was 62–76% reduction in volatiles released. Probably some or most of the pheromone collected with both mouth and anus sealed was already on the body surface.

The anal pouch (Figure 2) that males evert when releasing pheromone is shiny and has occasionally been mistaken for a droplet of liquid at the tip of the abdomen (Burk, 1981; and cited by Prokopy and Roitberg, 1984). The pouch is the everted lining of the posterior portion of the rectum. It undoubtedly con-

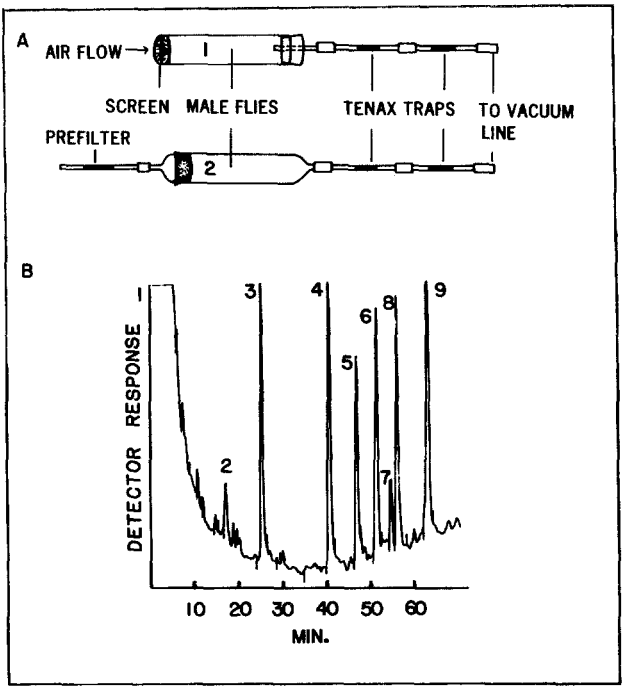

FIG. 1. (A) Diagram of the two types of collection devices used. (B) Gas chromatographic separation of volatiles from a single male *A. suspensa*. The record is from a 10 m RSL 160 Non-Pakd column, 0.5 mm ID. Peak identities are: 1, solvent; 2, combined quantities of (Z)-3-nonenol and (Z,Z)-3,6-nonadienol; 3, decanol (internal standard); 4, tetradecane (internal standard); 5, suspensolide; 6, β-bisabolene; 7, anastrephin; 8, epianastrephin; and 9, methyl tridecanoate (internal standard).

TABLE 3. PERCENT (MEAN ± SD, $N = 13$) REDUCTION IN PHEROMONAL COMPONENTS RELEASED BY MALE *A. suspensa* WHEN MOUTH (MS) OR ANAL OPENING (GS) WAS SEALED WITH BEESWAX, OR BOTH WERE SEALED (MS, GS; MEAN ± SD, $N = 2$)[a]

	Percent Reduction			
	N	S	B	A + E

tains pheromone on its surface. Males repeatedly touch or dab the pouch to the substrate surface when behaviorally displaying (Nation, 1972). Males also repeatedly touch the labellum to the substrate surface, sometimes leaving tiny droplets that can be observed, and it seems very likely that they are depositing pheromone on the substrate by this behavior.

Influence of Photoperiod and Age upon Pheromone Release. A daily rhythm strongly influences quantity and composition of volatiles released (Figure 3). During the early morning hours of the photophase the quantity of all components released is very low, but later rises to reach a broad maximum extending from about 11 through 13 hr into the photophase. Release declines toward the end of the photophase. Males kept in the light, however, beyond the normal 14-hr photophase showed continued declining volatile release for the next 5–6 hr, beyond which collections were not continued (unpublished data). The total quantity of components and ratios of components in the volatiles changed hourly and in unpredictable ways, and neither quantity nor ratios were constant for any particular hour from day to day.

A pattern of changing release rate with a high degree of unpredictability was found also in the influence of age upon volatiles release (Figures 4 and 5). Although nonenols could be collected from 1- and 2-day-old males, the total complement of volatile components could not be detected in collections earlier than about 4 days of age and then only in extremely small quantities. The levels increased rapidly, however, and reached a maximum usually at about 7–9 days in the laboratory-reared strain of flies. Feral flies, which have a much longer

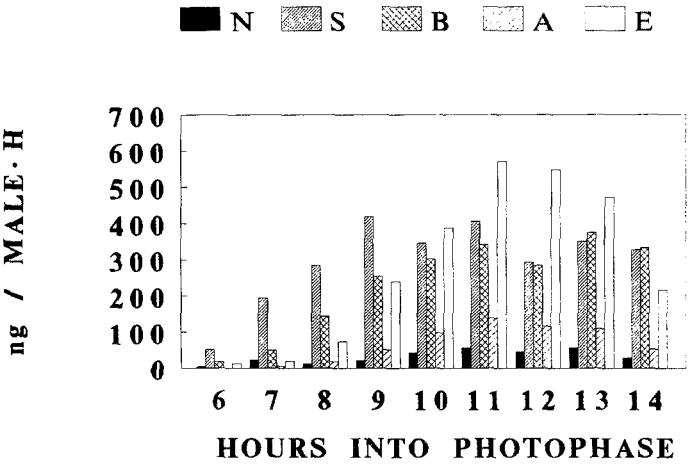

FIG. 3. Volatile components (ng/male/hr) collected from a group of 25 male *A. suspensa*, 12 days old, during successive hours in the photophase. Males were kept on a 14 : 10 light–dark cycle. N, S, B, A, and E refer, respectively, to combined nonenols, suspensolide, bisabolene, anastrephin, and epianastrephin. Each bar represents the mean of two separate collections, made simultaneously from flies of the same cohort.

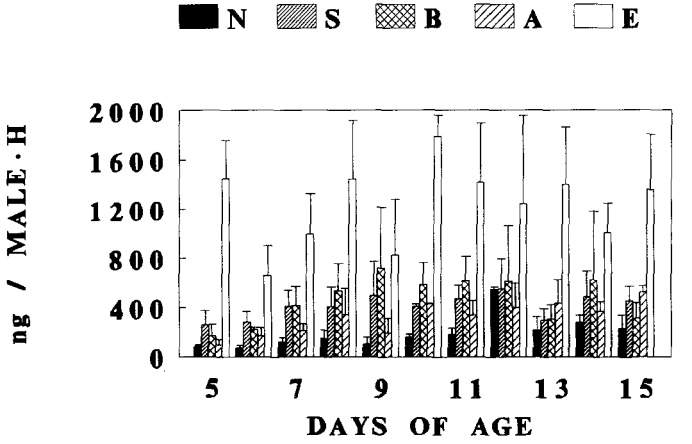

FIG. 4. Quantity (mean ± SD) and blend of volatiles released by a single male as a function of age. Males were taken at random from a large cage of males held in a 14 : 10 light–dark cycle. Collection was made during the 11th through the 13th hour of the photophase to include the hours of maximum release of volatiles. Values for most days represent six to eight collections from different males, with only a few representing as few as two collections. N, S, B, A, and E refer, respectively, to combined nonenols, suspensolide, bisabolene, anastrephin, and epianastrephin.

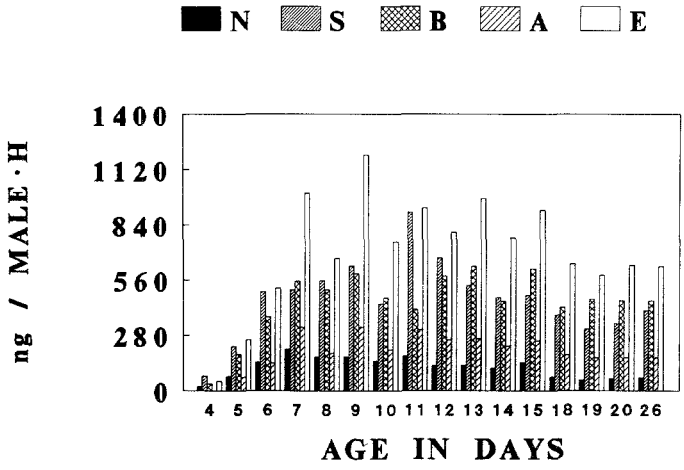

FIG. 5. Quantity (mean of two collections) and blend of volatiles released by a group of 25 males of *A. suspensa*. Males were kept on a 14:10 light-dark cycle. Volatiles were collected continuously for 21 hr at each age. N, S, B, A, and E refer, respectively, to combined nonenols, suspensolide, bisabolene, anastrephin, and epianastrephin.

prereproductive period as adults, started release of volatiles at about 5 days, but did not reach a maximum until they were 12–14 days old (Nation, 1989). Release of volatiles continued in old males; the oldest monitored were 35 days old, and they released (in nanograms per male per hour) nonenols 27, suspensolide 173, bisabolene 192, anastrephin 29, and epianastrephin 203.

Influence of Male Density on Quantity and Composition of Volatiles. The number of males in the group during collection of the volatiles influenced both the quantity and blend of the volatiles released. A single male released more total volatiles and more of each component than the per male average for a group of males (Figure 6, Tables 4 and 5). Differences in component ratios can also be seen in Figures 4 and 5, from single and multiple males, respectively. The reduction in anastrephin, epianastrephin, and nonenols by grouped males (32–37.5%, per male) is about twice as great as the reductions (14–16%) in suspensolide and bisabolene (Table 5). The minimum number needed to demonstrate the reduction in anastrephin or epianastrephin appeared to be about three individuals; a group of two males failed to show significant reduction, whereas three, five, and 10 males did show the reductions (Table 4).

Groups of males not only released less per male of components than a single male, but larger groups released less per male than smaller groups. Ten

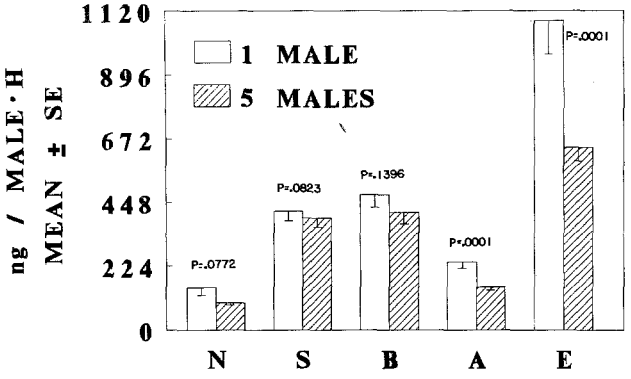

FIG. 6. Comparison of quantity of volatile components released by one male and the average for five males ($N = 25$). Male age varied from 6 to 21 days, but on any given day the single male and five males were the same age and were taken at random from a larger cage of males held on a 14:10 light-dark cycle. Probability values refer to the null hypothesis that the quantitative determination for a given component from the single male equals the value for the same component for the average of five males. N, S, B, A, and E refer, respectively, to combined nonenols, suspensolide, bisabolene, anastrephin, and epianastrephin.

or 15 males released less per male of anastrephin and epianastrephin than five males (Table 4). Apparently the difference between three and five males was not great enough, however, to result in detectable difference, or perhaps the flies did not detect a small difference in group size.

The possibility that a group effect might be demonstrated when females were present with a single male was tested. Collections ($N = 10$) from one male with four females did not result in reduction of any component in the volatiles, but the male was kept from mating by a separating screen because release of volatiles ceased during mating (Nation, 1989).

The relationship between epianastrephin and anastrephin collected from single males ($N = 116$ determinations) is shown in the linear regression data of Figure 7. Although the absolute quantities of anastrephin and epianastrephin released vary a great deal with group size, age, rhythm, cohort of flies, and individual tested, the ratio of epianastrephin to anastrephin was not influenced by any variables tested. In 52 determinations of volatiles collected from a single male the ratio was 4.7 ± 0.3 (mean $\pm$ SEM), while that for greater than one male collections (two, three, five or 10 males) was 4.5 ± 0.2 ($t = 0.54$, $P = 0.5905$).

Epianastrephin	999.2 ± 70.7	624.5 ± 36.3	<0.0001	37.5

[a] Values are mean ± SEM; $N = 52$.

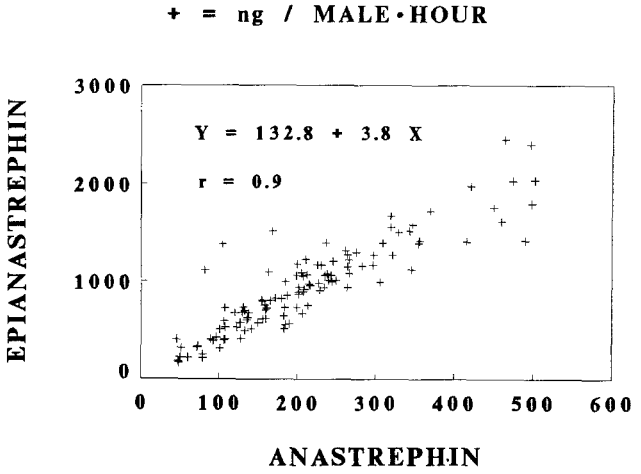

FIG. 7. The regression relationship for epianastrephin as a function of anastrephin in the pheromone blend released by single male flies ($N = 116$). Pheromone was collected during the period of maximum pheromone release (11–13 hr of the photophase) with flies on a 14:10 light–dark cycle. Flies varied in age from 6 to 21 days of age at collection.

DISCUSSION

Site of Release of Male Volatiles. The evidence presented supports the conclusion that volatile components are released from both mouth and anus of the male flies but does not entirely rule out the possibility that some volatiles are released directly through the cuticle. There are two male-specific glandular

tissues in male flies (Nation, 1974, 1981). These glands are the enlarged and highly modified salivary glands and large epidermal cells below the lateral abdominal pouches. Both glands show developmental changes correlated with sexual maturity in males (Nation, 1974). Gas chromatographic analyses of these and other tissues dissected from male flies showed that anastrephin, epianastrephin, and the nonenols were concentrated mainly in the rectal region of the hindgut, while suspensolide and bisabolene were absent or present only in very small quantities (Nation, 1989). Suspensolide, bisabolene, and small quantities of the nonenols and gamma lactones were present in the enlarged salivary glands of males. Suspensolide and bisabolene, but not nonenols and the gamma lactones, were present in pleural glands (enlarged epidermal cells) in males (Nation, 1989). Thus the distribution of pheromonal components in the rectum and in the salivary glands supports a release mechanism through the mouth and from the anus and/or anal pouch. Presumably, pleural gland cells could secrete components into and through the cuticle that lies immediately over the cells on the ventropleural abdomen.

Quantity and Blend Ratio in Volatiles. The total quantity of volatiles released by a single fly in an hour is very remarkable. Inspection of Table 5 shows that more than 2 μg/hr of total volatiles can be released. Only slightly more than 1 μg total was present in whole body extracts (Nation, 1989), so the males must synthesize the components rapidly as needed. This high level of synthetic activity can continue for a number of hours during an afternoon and, together with the physical display of puffing pouches and wing fanning, must be energetically very costly. Perhaps it should not be so surprising that males may, at times, adopt an alternative to the lek strategy (Burk, 1983), or that in groups they should find ways to reduce the quantity of pheromone released.

One constant feature of the collected volatiles was the ratio of epianastrephin to anastrephin (E/A). Anastrephin and epianastrephin are diasteriomers of each other (Battiste et al., 1983), and Chuman et al. (1988) suggested that they were derived from suspensolide or that they and suspensolide were derived from a common precursor. There is no obvious relationship indicated by the data of this report that allows one to choose between these possibilities. Another pattern that emerged was that the quantity of suspensolide and bisabolene in the volatiles was close to 1 : 1, with suspensolide coming out slightly greater than bisabolene in the data of Table 5. In collections on a given day, either might be the greater of the two, but they were always close. Preliminary analyses indicate that about 60% of the measured nonenols was (*Z*,*Z*)-3,6-nonadienol, and 40% was (*Z*)-3-nonenol.

Possible Role of Volatiles in Behavioral Ecology of Flies. Although Burk (1983) found that feral males under natural conditions in Homestead, Florida, actively courted females on fruit during the morning hours, he observed no matings during the morning. Late in the morning and during midday, both males

and females tended to rest underneath the leaves of (mostly) host trees. Male display behavior and territorial defense began to increase at about 1500 hr and peaked at 1700 hr, as did mating activity. The increase in display and mating activity in Burk's study in the field from 1500 to 1700 hr corresponds closely with a rhythm that is 10–12 hr into the photophase in the summer in Homestead and agrees with laboratory data from the present work on time of maximum pheromone release. Burk (1983) proposed, on the basis of his field observations, that males adopted, during the morning hours, an alternative to the lek strategy in which they attempted forced matings with females that were on the fruit and engaged in test borings or ovipositing. Data from this report show that males are releasing very low levels of pheromone during the morning hours and that the pheromone blend is very different early in the day compared to midafternoon and later in the day when most sexual activity and mating take place. Perhaps their courtship displays and the small amount of pheromone released, as well as the different blend, have important implications in the context of forced mating on the fruit during the morning, while the lek strategy requires its own set of parameters with respect to blend and quantity of pheromone released.

Selection of a male from a lek by females is expected to lead to selection for increasingly complex and elaborate courtship and/or display behaviors on the part of highly competitive males and even to establishing a rank order of males within a lek (Alexander, 1975; Emlen and Oring, 1977; Thornhill, 1980; Bradbury, 1981; Thornhill and Alcock, 1983; Burk, 1984). Thus males might be expected to try to outdo each other, and it might be expected that the mean per male pheromone output from a group of males would exceed the output from a single male. An unexpected result from this study was the discovery that groups of males reduce, on a per male basis, the quantity of all pheromonal components released in comparison to those released by single males. Reduction rather than stimulation of pheromone release seems inconsistent with the male competition theory. Perhaps a situation in which only some males might cease or greatly reduce volatiles production while letting others in the lek advertise and attract females to the vicinity is operating (Hendrichs, 1986). A selective advantage might accrue for males that ceased or greatly reduced pheromone production. The reduction in synthesis and release of pheromonal molecules may enable males to save energy, a savings that might enable a male to survive longer, release pheromone longer, release the most attractive blend longer, display longer, or broadcast a song (Webb et al., 1976, 1983, 1984) longer or louder, all of which may lead to increased chances of mating. Each male may be seeking to maximize chances for successfully mating and for survival. Unfortunately, no mechanism has been devised yet to collect volatiles separately from each member in a group in order to determine if only some individuals are reducing output.

It remains to be determined if observation of other sexual display characteristics, such as puffing of the body pouches or wing fanning, correlates closely enough with the actual quantity or blend of volatiles released to be of use in providing insight into pheromone output. McDonald (1987) has stated that there is intragroup stimulation of pheromone release, stimulation by sight of a mirror reflection, stimulation by sight of other males, and lack of stimulation by wingless flies of *Ceratitis capitata*, but in that work pheromone release was not measured chemically. Apparently the assumption was made that the puffing and other display characteristics can be used as indicators of pheromone release. I agree that displaying flies are releasing pheromone, but display behavior may not be indicative of the quantity being released. The display characteristics may serve functions other than, and in addition to, pheromone release, such as the establishment of male dominance within a lek.

It has been theorized that choosy females will benefit by selection of the male best fit to sire her offspring from among an assemblage of males in a lek (Bradbury, 1981, and references therein). The exact mechanism for female choice in Caribbean fruit flies is not known, although several parameters correlated with successful males are large size, display behavior, and sound production (Burk and Webb, 1983; Sivinski, 1984; Hendrichs, 1986). Because the pheromone blend released varies continuously with age and time of day, it seems unlikely that females choose a male based upon either blend or quantity of pheromone released. The role of the pheromone may be to attract females to the lek site, whereupon other close-range mechanisms, possibly involving pheromone as well as sound (Webb et al., 1976, 1984) and vision, play roles. Recent field trapping of flies with sticky traps baited with the total volatiles mixture collected as in this report indicated that both laboratory-reared and released, and feral Caribbean fruit flies were attracted to the volatiles in a trap (data to be published elsewhere). Tests in the field with individual components or combinations have not been conducted.

All data reported in this paper have come from observations on laboratory-reared flies. While it has been shown that wild flies do release the same components and in similar proportions (Nation, 1989), it is now well known that long-established laboratory cultures of insects usually show differences from wild populations. It is important to determine the responses of wild flies, particularly in density-dependent situations that may more nearly mimic a true lek situation than the present glass cylinders do. Males of several tephritid fruit flies release pheromonal volatiles, some with characteristic body and behavioral displays similar to those reported for Caribbean fruit fly males (Feron, 1959; Lhoste and Roche, 1960; Pritchard, 1967; Malavasi et al., 1983; Morgante et al., 1983; Robacker and Hart, 1985a,b), but detailed collections and analyses of the volatiles, or of factors influencing pheromone release, have not been reported.

Acknowledgments—I thank Dr. R.M. Baranowski for providing pupae of laboratory-reared *A. suspensa* to me on a regular basis, and Kathy Milne for technical assistance in the laboratory and for preparing some of the figures. I thank Drs. Tom Phillips, Gary Dodson, James H. Tumlinson, and two anonymous reviewers for helpful and critical reviews of drafts of the manuscript. Partial support for this research was provided by a grant from the Florida Department of Citrus, Citrus Advisory Council, Lakeland, Florida. I thank Dr. M.A. Battiste, Department of Chemistry, University of Florida, for synthesis of the components isolated from the volatiles and for providing gas chromatographic standards of the components in the volatiles.

(Received December 29, 1988; accepted March 20, 1989)

Abstract—The effectiveness of predator fecal odors in modifying feeding selection by sheep and cattle was investigated in two trials. In trial 1, animals could select from feed bins contaminated with coyote, fox, cougar, or bear fecal odor, and oil of wintergreen, or select the control feed. All odors were rejected ($P < 0.01$) by sheep and cattle, except bear odors by sheep. In trial 2, animals could select feed during 10-min periods in an open 11-m × 16-m arena. Fecal odor did not influence approaches to feed bins, or head entries into bins. Only coyote fecal odor reduced ($P < 0.05$) the time spent feeding in the contaminated bin, and increased ($P < 0.05$) consumption from the control bin by both cattle and sheep. Some animals on some test days refused to feed from either feed bin, although cattle and sheep closely inspected bins. Results suggest that fecal odors may not prevent livestock from entering a treated area but may reduce the time spent grazing in such an area.

Key Words—Feeding behavior, predator odors, feces, cattle, sheep.

INTRODUCTION

Chemical signals have been used to modify herbivore feeding behavior, usually to protect crops or tree plantations (Müller-Schwarze, 1983; Melchiors and Leslie, 1984; Campbell and Bullard, 1972; Conover, 1987). Predator odors have modified feeding by black-tailed deer (*Odocoileus hemionus columbianus*) (Müller-Schwarze 1972, 1983; Melchiors and Leslie, 1984; Sullivan et al., 1985a), snowshoe hares (*Lepus americanus*) (Sullivan et al., 1985b), voles (*Microtus* spp.) (Sullivan et al., 1988a), and pocket gophers (*Thomomys talpoides*) (Sullivan et al., 1988b). Müller-Schwarze (1972) suggested that black-tailed deer and possibly other ungulates possess innate negative responses to predator odors.

Olfaction by domestic livestock such as sheep (*Ovis aries*) or cattle (*Bos taurus*) is important in feeding (Arnold, 1966; Arnold and Hill, 1972; Arnold et al., 1980). Livestock may also react negatively to odors (Arnold and Hill, 1972). Engle and Schimmel (1984) noted that steers were marginally displaced from a preferred grazing site because of peripheral application of a deer repellent. Poindron (1974) reported that dog (*Canis familiaris*) feces repelled feeding sheep. Although predator fecal odors have repelled grazing ungulates such as deer, it is uncertain whether livestock would also be repelled either by smell (Arnold et al., 1980) or novelty (Chapple and Lynch, 1986) rather than fear of a potential predator (Sullivan et al., 1985a). Gregarious livestock species probably depend more upon visual and auditory acuity or vigilance (Ydenberg and Dill 1986) than upon olfactory cues for predator defense. For example, Hutson (1982) reported that flight distance in sheep decreased as group size increased.

Our research was designed to determine if food selection by sheep and cattle was affected by predator fecal odors. We are interested in the potential use of repellents for application to large patches of toxic larkspur (*Delphinium barbeyi*) plants (Ralphs et al., 1988). Grazing cattle ingest large amounts of tall larkspur when foraging in larkspur-dominated vegetation areas (Pfister et al., 1988a,b). We compared the responses of cattle and sheep to assess species differences.

METHODS AND MATERIALS

Trial 1. Fecal material was collected from bear (*Ursus americanus*), cougar (*Felis concolor*), fox (*Vulpes vulpes*), and coyote (*Canis latrans*) housed in zoos. Animal diets were a variable mixture of red meat, commercial feeds, and vegetables. Fecal material was collected fresh each morning, and frozen immediately at −20°C. Trials involved five Holstein steers each weighing 255 kg and five Targhee sheep each weighing 60 kg. The steers had no previous expe-

rience with predators, and the sheep may have had prior contact with coyote scat, but probably had no prior contact with the excreta of other predators.

Steers and sheep were individually housed under shelter in 3 × 4-m and 1.5 × 3-m pens, respectively. All animals were fed an ad libitum diet of alfalfa hay pellets in their pens for 14 days before trials began. Two feed bins were attached to the pen wall 3 m and 2 m apart for cattle and sheep, respectively. A preliminary 10-day trial determined whether there was any position bias in feed selection (Elliott and Loudon, 1987).

Feed bins were contaminated with fecal odor by placing fecal material in 20 × 6 × 6-cm aluminum pans fitted with wire-mesh lids, and pans were wired into position 30 cm above the bottom of the feed bin. This did not alter the animals' ability to feed from the bin, but ensured that fecal odors were in close proximity to feed. Fecal material was thawed at room temperature beginning 12 hr before use and mixed with water (4 : 1) in a Waring blender. Approximately 75 ml of the resultant slurry was added to the pans. During odor trials of 72-hr each, feed intake from each bin was monitored at 1, 6, 24, 48, and 72 hr (Arnold et al., 1980), except cattle intake was not monitored at 1 hr. The containers holding the fecal material were recharged and bin position changed at 0, 12, 24, 36, 48, and 60 hr. Control bins were treated similarly but no fecal material was added. Consecutive 72-hr trials were conducted using the fecal material; an additional trial using cotton wool saturated with oil of wintergreen was added as a novel control odor (Arnold et al., 1980). Feed consumption from contaminated feed bins was expressed as a percentage of total feed eaten (contaminated + control bins), following the procedures of Elliott and Loudon (1987).

Trial 2. Trial 2 determined whether cattle and sheep responded to odors when feeding in a open arena. The 16-m × 11-m outdoor arena had a dirt floor, and sides of metal panels covered with heavy canvas. There was a feed bin in each of two corners, 14 m apart. Animals were habituated to the arena by feeding alfalfa pellets from a large feeder for three days. Animals were fed at 2% of body weight (maintenance ration) and could consume their daily ration in about 1 hr. Before their daily feeding for the next eight days, animals were individually fed a limited amount of pellets for 10-min periods each morning from the experimental feeders. The animals learned to quickly move from one feeder to another to maximize pellet consumption.

Fecal material was treated as described above when placed in the pan in the treated bin; an empty pan was wired in the control feeder. Other pans with and without fecal material were placed 1 m apart at ground level in an L-shape around the treated and control bins, respectively, so animals had to pass a pan in order to approach the bin. To avoid a position bias, the fecal and control treatments were alternated daily. After an overnight fast, animals were tested each morning for two consecutive days. The sheep or cattle were individually

monitored for 10-min periods in the area. Measured variables were the number of approaches to the control or treated bin, the number of distinct head entries into the bins, the time spent feeding in each bin, and pellet consumption from each bin.

Statistical Analysis. For trial 1, confidence intervals (99%) were calculated based on consumption during the preliminary trial to correct for position bias. This confidence interval is feed consumed from the contaminated bin expressed as a percentage of total feed eaten from both the control and contaminated bin, and was calculated from results of the 10-day preliminary trial. Consumption of pellets during the trials at levels below the 99% confidence limit indicate rejection due to odor treatment (Elliott and Loudon, 1987). For trial 2, feed consumption from treated and control bins was analyzed by ANOVA techniques, using animals as blocks ($N = 5$) with repeated measurements over days ($N = 6$) (Gill, 1978). Confidence intervals (95%) were used to test differences in approaches, entries, and time spent feeding at each bin.

RESULTS

Trial 1. Cattle and sheep exhibited no significant position bias (Table 1). Both cattle and sheep responded ($P < 0.01$) to fecal odors and to oil of wintergreen (Table 2) by decreasing feed consumption from the treated bin. However, fecal odors were ~4–20× more effective than oil of wintergreen in reducing consumption. Bear feces was not effective with sheep ($P > 0.01$), but was effective with cattle ($P < 0.01$). There was little evidence of adaptation to coyote, cougar, or fox odors over the 72-hr periods (Figure 1). However, both cattle and sheep clearly adapted to bear feces and oil of wintergreen (Figure 1).

Trial 2. Animals did not alter their approaches to the bins because of treatment ($P > 0.05$), nor did the fecal odors affect the number of head entries into the bins ($P > 0.05$) (Table 3). Coyote fecal odor influenced ($P < 0.05$) the

time sheep and cattle ate from the bins (Table 3). Although trends were similar for all fecal odors, there were no other significant differences ($P > 0.05$) because of the high variability.

Consumption was affected by day ($P < 0.05$) for cattle, but not for sheep ($P = 0.15$). There were day × treatment interactions ($P < 0.05$) for both cattle and sheep responses. Only coyote fecal odor decreased ($P < 0.05$) pellet consumption (Table 3, Figure 2); cattle and sheep responses to fox and cougar fecal odors were not consistent over days.

DISCUSSION

Cattle and sheep responded negatively to fecal odors during trial 1. Livestock disliked feeding in close proximity to coyote, fox, and cougar feces. There was less response to bear fecal odors, and sheep and cattle differed in their responses. Sullivan et al. (1985a) reported that coyote, fox and cougar feces suppressed deer feeding, while Melchiors and Leslie (1984) found that cougar but not coyote feces inhibited deer feeding.

Oil of wintergreen was much less effective in deterring feeding than most types of fecal material, which indicates that animal response was not due simply to novel odors. Both oil of wintergreen and fecal odors were novel, but most fecal odors caused greater avoidance. Arnold et al. (1980) found that oil of wintergreen reduced feed consumption by sheep. Unlike the methods of Arnold et al. (1980), oil of wintergreen did not directly contact the feed in our study.

There was no evidence of habituation to those fecal odors that deterred feeding. In contrast, Arnold et al. (1980) found that sheep habituated rapidly

[b] Means in the same column for the same variable and type of fecal material with the same letter are not different ($P > 0.05$).

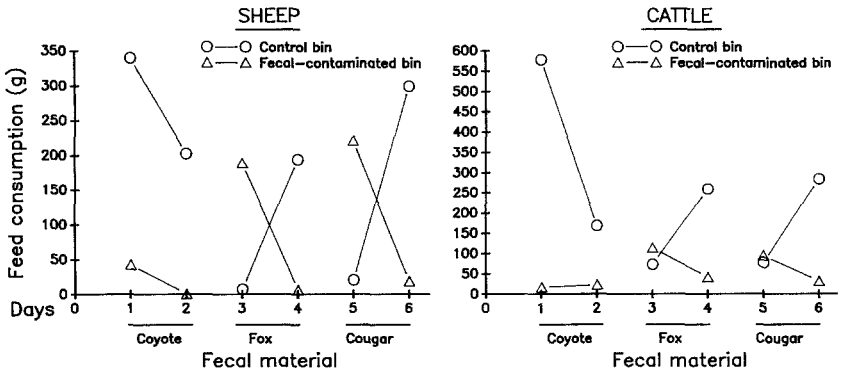

FIG. 2. Mean consumption (g) of alfalfa pellets during 10-min testing periods by cattle and sheep from control and treated feed bins in a large arena.

to chemical odors. In the mornings, most of the sheep bedded down on the opposite side of the pen from the bin contaminated with coyote, cougar, or fox feces, an indication of a severe aversion to the odors.

Sheep and cattle tended to respond similarly over time to coyote, cougar, and fox feces (Figure 1). Peak consumption was reached at 24 hr, with consumption declining over the rest of the period. We are unable to explain this trend.

In both trials, livestock investigated the odors in the bins. During trial 2, animals quickly entered the arena and would stop suddenly and sniff carefully when they approached the pans containing the feces. The animals would then usually approach the feed bin. As Sullivan et al. (1985a) and Müller-Schwarze (1972) noted, deer closely examined predator feces. This behavior may be characteristic of other ungulates.

Coyote feces deterred feeding by both cattle and sheep in the large arena trial. This material was also highly deterrent to both species in the small pen trial. The active compound(s) that elicited this response is unknown. These trials also gave no indication whether the response is innate or if the predator odors are deterrent independent of selective pressures. Coyote predation in sheep flocks in the western United States has a serious detrimental impact on sheep, but predation in cattle herds is probably small (Taylor et al., 1979).

Results of our trials suggest that feces may not deter livestock from entering an area contaminated with fecal material. However, the odor may cause grazing livestock to reduce the amount of feeding time spent in an area because of noxious olfactory stimuli. Engle and Schimmel (1984) reported that cattle use of preferred grazing areas was reduced by application of a commercial deer repellent around the periphery of the areas. Müller-Schwarze (1983) also noted that fecal odors reduced the amount of time that deer foraged in gardens. During trial 2, one sheep and one steer refused to eat from either bin during the last four test days. Even though they were very hungry, they simply wandered around the arena. Two other sheep and steers also exhibited this avoidance behavior for at least two days of the trial. When livestock did eat during trial days 3–6, they often appeared to be confused when they entered the arena and eventually went to a favored position, regardless of treatment. This position bias, absent during the coyote fecal trial (day 1 and 2), surfaced during the last four trial days with cougar and fox feces, producing the trends found in Figure 2.

Research trials in which feces or other repellents are applied under grazing conditions seem warranted. These studies should examine the efficacy of semiochemicals for modulating livestock feeding on toxic, but otherwise palatable plants, and how responses are influenced by environmental variables and time. Research should also determine the efficacy of deterrents in reducing livestock browsing damage in agroforestry situations (Knowles and Tahan, 1979). The

use of synthetic compounds derived from predator feces would greatly enhance research efforts and practical application. Abbott et al. (1989) have developed a synthetic repellent from active compounds in African lion (*Panthero leo*) feces that has been effective in preliminary trials.

Acknowledgments—We thank L. Kitchen for technical assistance, and personnel from Willow Park Zoo, Logan, and Hogle Zoo, Salt Lake City, for cooperation in providing fecal material. We also thank T. P. Sullivan and M. H. Ralphs for helpful comments on an earlier vesion of the manuscript.

(Received November 21, 1988; accepted March 20, 1989)

Abstract—Frass of late-instar larvae of *Tenebrio molitor* L. contained 0.0889 g of butyric acid, 0.0279 g of propionic acid, and 0.0175 g of valeric acid per 100 g. Grouped larvae were strongly repelled by butyric acid at the 10^{-1} M concentration. Lower concentrations of butyric acid were less repellent. Valeric acid was repellent at 10^{-1} M to 10^{-3} M concentrations, below which no tested concentration, including one identical to that occurring in prepared solutions of frass found to be attractive, displayed any effect. Propionic acid was repellent at the concentration in prepared solutions of frass, which were strongly attractive. Concentrations of 10^{-1} M, 10^{-3} M, and 10^{-4} M propionic acid were also found to be repellent. The implications of the repellency of these compounds to groups of mealworm larvae are discussed, with particular reference to the interaction between these frass components and others that have already been studied.

Key Words—Repellency, volatile fatty acids, propionic acid, butyric acid, valeric acid, yellow mealworm, *Tenebrio molitor*, Coleoptera, Tenebrionidae.

INTRODUCTION

Infestations of the yellow mealworm, *Tenebrio molitor* L., are generally found in damp, dark places where cereals may be decaying (Cotton, 1963). These localized regions may contain large amounts of frass from several generations

0098-0331/90/0200-0585$06.00

of *T. molitor*. Experiments have been conducted testing mealworm frass, and lactic and acetic acids, which are frass components, for behavioral effects (Weaver et al., 1989; Weaver and McFarlane, 1989). The frass and lactic acid acted as aggregants, and acetic acid had no behavioral influence (Weaver et al., 1989). However, the chemical analysis of *Tenebrio* frass indicated the presence of volatile fatty acids in significant amounts, as were found in the frass of other omnivorous insects (McFarlane and Alli, 1985). McFarlane (1984) found that frass volatile fatty acids were repellent to *Blattella germanica*. Lactic acid in the frass of *Blattella* was found to be aggregative (McFarlane and Alli, 1986). These results indicated a variety of responses were possible with these chemical stimuli in the frass, with one component being dominant. In addition, propionic acid has been found to aggregate *Acheta domesticus* (McFarlane et al., 1983) and butyric acid has been identified as an aggregant for *Periplaneta americana* (McFarlane and Alli, 1987). The present article deals with the behavioral responses caused by volatile fatty acids in the frass of larval *Tenebrio molitor*. In particular, experiments were conducted using serial dilutions of volatile fatty acids to determine activity at various concentrations. Experiments were also conducted using concentrations of acids identical to those occurring in behaviorally active frass samples. These frass samples, and lactic acid occurring in them, were found to be attractive (Weaver et al., 1989). Bioassay indicated the isolated volatile fatty acids were repellent. A mixture of volatile fatty acids and lactic acid was prepared to determine how the activity of these isolated components of frass was manifested in the natural environment, where they occur concurrently. Volatile fatty acids 10^{-1} M were also evaluated for olfactory responses in an active airflow olfactometer.

METHODS AND MATERIALS

Yellow mealworms, *Tenebrio molitor* L., were raised on a diet of wheat bran, whole wheat four, and brewer's yeast (50:45:5 w/w) at 25 ± 1°C and 55 ± 5% relative humidity and a photoperiodic regime of 14:10 light–dark. The density of all stages per filled 4.55-liter glass culture jar was not allowed to exceed 250 individuals. Collection of frass and diet, determination of volatile fatty acids, and the bioassay arena in both were identical to those used in Weaver et al. (1989).

The test protocol involved a choice test using Whatman No. 1 filter papers treated with 0.68 ml of test chemical in aqueous solution at the appropriate concentration versus a paper treated with 0.68 ml of water (distilled, deionized in both cases). The papers were allowed to dry 1.5 hr prior to testing. Dried papers were fixed in the arena opposing each other, and 20 yellow mealworms (140–160 mg) were introduced simultaneously. The papers were examined at

0.5-hr intervals after the initiation of the trial, and larvae on each paper were counted, if they were actually on the paper or were touching it with their antennae, mouthparts, or legs. Trials were terminated after 5 hr. Reagent grade acids (Anachemia Limited, Montreal, Canada) were used in preparation of all test solutions.

An active airflow olfactometer (as in Weaver and McFarlane, 1989) was used to evaluate the mode of chemoreception for these repellent chemicals. The test stimuli were derived from two shredded filter paper strips treated with 0.68 ml of a 10^{-1} M aqueous volatile fatty acid solution and evaporated 0.5 hr prior to bioassay. Control stimuli were similarly prepared using filter paper strips treated with 0.68 ml distilled water.

Statistical comparisons between the various test stimuli were based on analysis of variance using Tukey's HSD test on mean aggregation indices (AI) calculated by subtracting the number of larvae on the control paper from that on the treated paper and dividing by the total number on the two papers. Index values may range from -1 (complete repellancy) to $+1$ (all responding individuals on the treatment paper). A value of -0.2 corresponds to 50% more insects on the control paper and -0.33 corresponds to twice as many insects on the control as were on the treatment paper (Roth and Cohen, 1973). Indices were based on ten observations per replicate, with 12–20 replicates being conducted per test chemical. Indices were analyzed by *t* test for significant differences from a value of zero (SAS Institute, 1982), which would represent identical numbers on treatment and control papers. Analysis of the responses to the grouped olfactometer bioassay were based on a one-tailed test using Wilcoxon's signed-ranks test for paired observations to determine if the number of insects responding to the chemical stimulus was significantly less than the number responding to the control.

RESULTS

Frass of late instar larvae of *Tenebrio molitor* L. contained 0.0889 g of butyric acid, 0.0279 g of propionic acid, and 0.0175 g of valeric acid per 100 g. These acids were not present in the diet.

The responses of late-instar *T. molitor* to serial dilutions of those acids present in the frass and one not occurring in the frass but chemically similar (isobutyric acid) are shown in Table 1. Valeric acid at 10^{-2} M and 10^{-3} M was most strongly repellent. Two unusual effects were evident as well. The values of 10^{-2} M propionic acid and 10^{-2} M isobutyric acid were both distinct from those for the concentrations surrounding them. Propionic acid at 10^{-2} M had a much higher (though statistically similar) AI value and showed no significant repellency at all. Both 10^{-3} M and 10^{-1} M propionic acid are significantly

repellent. Isobutyric acid was significantly repellent at 10^{-2} M and caused no effect at either 10^{-1} M or 10^{-3} M.

The responses of grouped yellow mealworms to the amounts of isolated frass acids found in 20 mg frass/ml H_2O (13.6 mg frass/paper), as tested in Weaver et al. (1989), are shown in Table 2. Propionic acid was the only repellent chemical (when tested in isolation) found in this solution of frass, which had been found to exhibit overall attractancy (Weaver et al., 1989).

The olfactometer bioassay of 10^{-1} M concentrations of the volatile fatty acids indicated they were significantly repellent to groups of large *Tenebrio* larvae. These results are shown in Table 3.

A mimic solution composed of all acids (volatile fatty acids + lactic and acetic acids) isolated from the frass at the concentration in which they occurred in attractive 20 mg frass/ml H_2O gave an AI value of 0.35 ± 0.04. This showed significant attraction at the $P \leq 0.001$ level (based on 12 replicates).

Figure 1 shows the response of yellow mealworms to repellent 10^{-3} M propionic acid throughout the bioassay. Trial stabilization occurred rapidly and a large decrease in mealworms on the treatment and control papers occurred at 4.5 hr (consistent through 12 replicates).

Figure 2 shows the response of yellow mealworms to 10^{-3} M butyric acid,

a noneffective concentration, throughout the duration of the bioassay. The response occurred much more slowly in this case than it did for a repellent chemical (approximately 2.5 hr to have 75% of the insects responding versus 1.0 hr in Figure 1).

DISCUSSION

The analyses of frass and diet samples indicate that these volatile fatty acids are produced in the larval mealworms, since they are not found in the diet but are present in the frass. These chemicals may therefore be utilized as discriminants of areas that were previously inhabitated by conspecific larvae.

The bioassays conducted suggest that relatively high concentrations of these volatile acids are required to significantly repel yellow mealworms. In fact, only propionic acid is active at the same concentration as in biologically active frass solutions. The effect, is in apparent contradiction with that induced by aqueous extracts of frass containing the same amount of isolated acid, since frass extracts and their lactic acid component have been previously demonstrated to be attractive/arrestant (Weaver et al., 1989). Therefore, a bioassay was conducted using the precise concentration of synthetic volatile fatty acids + lactic and acetic acids that occurred in active frass preparations, with the results indicating strong attraction to this mimic solution. These volatile fatty acids are present in frass samples in 1/3 to 1/10 of the amount (g) that the lactic and acetic acids were

observed in the frass (Weaver et al., 1989). Therefore, it is not surprising that the overall response to a solution of volatile fatty acids + lactic and acetic acids designed to mimic an attractive frass stimulus (equivalent to 20 mg frass/ml H_2O) was aggregative.

However, there are factors other than concentration involved. Earlier experiments have established that lactic acid in the frass of *Tenebrio* does not have an airborne influence on behavior, but is likely to be perceived through contact chemoreceptors (Weaver and McFarlane, 1989). This was probably because lactic acid has very low volatility and probably does not volatilize from dilute aqueous solutions or the surface of fecal pellets. These volatile fatty acids, however, did display repellent effects when tested on groups of larvae in an olfactometer at higher concentrations. It is evident that the larval mealworms must come into contact with the filter paper to aggregate in response to frass extracts or isolated lactic acid (Weaver and McFarlane, 1989), so it is likely that initial exploration is directed towards substrate evaluation, although this might be overcome by repellent airborne messages. It may also be likely that the concentration of airborne molecules from a treated filter paper or fecal pellet may not exceed the behavioral threshold until a larva is extremely close to it. The amount of volatile fatty acid on the paper (or arising from the fecal particles) and that at any given distance from source would decrease by volatilizing and subsequently dissipating with the passage of time. The attractive component is not subject to this reduction in quantity and can remain strongly attractive. Therefore, frass in the environment can exert a pronounced behavioral influence through contact, without the prolonged manifestation of the repellency of these low concentration volatile components. This was similar to the effect noted by McFarlane (1984) when isolated volatile fatty acids in concentrations occurring in the frass were found to be repellent to larvae of the German cockroach, but frass-conditioned papers and certain components of the frass were attractive. It is likely that the attractive chemical (lactic acid in both species) elicited a dominant behavioral response.

Therefore, the preference of the larvae for the control papers in these trials may involve an initial rejection of the substrate (through close range repellency) and then aggregation on the control paper, rather than only responding to a continuous repellent stimulus. Weaver and McFarlane (1989) have demonstrated an innate tendency for mealworms to aggregate on control papers in clusters of higher than expected densities, which means individuals may attract each other. Bioassays determining the orientation of animals that occur in groups naturally should be based on the responses of groups primarily and subsequently on the factors mediating this grouping. The existence of conspecifics in these bioassays in no way invalidates the significance of grouped larvae being repelled from a stimulus in these experiments.

Comparison of Figures 1 and 2 illustrates that trial stabilization required

more time in those cases where the insects showed no orientation to a particular chemical. This was also observed in our earlier experiments with certain non-attractive concentrations of lactic acid (Weaver et al., 1989). This may indicate that both repellent and attractive chemicals serve to orient *T. molitor* larvae more rapidly to suitable locations for cluster formation.

The preceding discussion centers on the nature of the interaction between the components in a given quantity of frass. We feel that this readily supports our hypothesis that frass acts as a chemical marker of safe refugia for these slow-developing insect larvae (Weaver et al., 1989). However, the rapid accumulation of fresh frass from a relatively high density of mature larvae may result in a considerable airborne concentration of volatile fatty acid. The resulting repellency could be of considerable ecological benefit, since large numbers of these relatively large slow-developing larvae might well have exhausted the available foodstuffs in that particular region. This would be the situation where larval dispersion might be the most beneficial. In addition, we have demonstrated that high concentrations of lactic acid are also repellent (Weaver et al., 1989), which might also occur under such conditions. Therefore, the repellent chemical message may be further enhanced by the probable epideictic (Prokopy, 1981) nature of lactic acid. Regardless of the relative role of the individual chemicals, very high concentrations of frass are likely to produce chemical messages that differ from those of more moderate amounts.

Abstract—After 20 days in a high-density culture containing many larvae, female sawtoothed grain beetles, *Oryzaephilus surinamensis* (L.), laid half as many eggs in a 24-hr oviposition bioassay as females held for six days in the same culture, or for six or 20 days in a low-density culture. Oviposition by females held for six days in a high-density culture was reduced to a similar extent when they were exposed in the oviposition bioassay to an oat flake treated with an extract of Porapak Q-captured larval volatiles (equivalent to 5000 larval hours). A retained suppression of oviposition rate after prolonged exposure to larvae or an induced reduction caused by short-term exposure to larval volatiles both could be of adaptive advantage in reducing the risk of oviposition in an already densely populated habitat.

Key Words—*Oryzaephilus surinamensis* (L.), Coleoptera, Cucujidae, population density, culture age, semiochemicals, oviposition, larval volatiles.

INTRODUCTION

Population density has many complex influences on insects that exploit exhaustible food resources. For example, some insects release epideictic (spacing) pheromones that mitigate against excessive population density by promoting

0098-0331/90/0200-0595$06.00/0

intraspecific dispersion (Prokopy, 1981). In other species, fecundity may be reduced at high population densities (Peters and Barbosa, 1977).

The sawtoothed grain beetle, *Oryzaephilus surinamensis* (L.), is a cosmopolitan pest of stored products. Feeding male *O. surinamensis* produce macrolide aggregation pheromones (Pierce et al., 1985, 1987), a class of pheromones given the trivial name cucujolide because of its prevalence in the family Cucujidae (Oehlschlager et al., 1988). Pheromone production rates by young *O. surinamensis*, as well as olfactory responses to pheromones and food volatiles, are sensitive to the density of conspecifics (Pierce et al., 1983, 1989).

Observations of mature, dense laboratory cultures of our strain of *O. surinamensis* revealed the presence of very few larvae per female, suggesting that oviposition may be suppressed by exposure to high-density cultures. We tested this hypothesis by investigating the oviposition response by *O. surinamensis* in relation to culture age, adult density, and the presence of larval volatiles.

METHODS AND MATERIALS

Maintenance and Handling of Experimental Insects. O. surinamensis were maintained on large-flake, rolled oats and brewer's yeast (95/5, w/w) in 3.8-liter glass jars at 28–30°C and 40–60% relative humidity in darkness (Pierce et al., 1981). Adults and larvae were separated from oat flakes with a sieve and collected by aspiration.

Collection of Larval Volatiles. Larval volatiles were obtained by aerating larvae (ca. 10,000) without food in a 2-liter Erlenmeyer flask at 24°C in darkness (Pierce et al., 1981, 1985). Charcoal-filtered, humidified air was drawn by aspiration (1.65 liters/min) over the larvae and then through a glass trap (150 × 14 mm OD) filled with Porapak Q (50–80 mesh, Applied Sciences Division, Milton Roy Laboratory Group, State College, Pennsylvania). An aeration was continued with the same Porapak Q trap for 480 hr, using fresh larvae and a clean chamber for each 24-hr period. Mixed-sex larvae (predominantly last instar) for aerations were harvested 20 days after inoculation of fresh medium with 24,000 adults (mixed age and sex) per kilogram of medium. Volatiles were recovered by extraction of the Porapak Q with purified pentane in a Soxhlet extractor for 24 hr and concentrated by distilling off the pentane through a Dufton column. The amount of volatiles collected was expressed as larval hours (lh) where 1 lh = the volatiles from one larvae in 1 hr.

Oviposition Bioassay. Mixed-sex cultures were set up with 800 or 24,000 adults/kg of medium. To obtain females for bioassay from cultures without larvae and pupae, beetles were removed six days after culturing, just before the first eggs were ready to hatch. For females from cultures with larvae and pupae,

beetles were removed 20 days after culturing, just before the first adults of the next generation were about to emerge.

For each test, beetles (23–40 days posteclosion) were removed from a culture, immediately sexed (Halstead, 1963), and 20 females per treatment (i.e., 20 replicates) were put individually into the bottoms of 20, 1-dram glass vials, each containing one oat flake. Polyethylene vial stoppers (with five small holes punctured for ventilation) were put on, and the vials were placed in darkness at 30°C and 65–75% relative humidity for 24 hr. Fresh oat flakes had been conditioned at 30°C and 65–75% relative humidity for 24 hr prior to bioassay. In tests where the oat flakes were treated, a 10-μl aliquot of either larval volatiles in purified pentane or purified pentane as a control was applied to an oat flake, the solvent allowed to evaporate, and the oat flake and a female immediately placed in the vial as above. After 24 hr the females were removed from the vials, and all eggs were counted under a dissecting microscope.

Experiments. In the first of two experiments, females that had spent six or 20 days in either low-density cultures (800 adults/kg) or high-density cultures (24,000 adults/kg) were tested in the 24-hr, oat-flake, oviposition bioassay. In the second experiment, females were removed from high-density cultures after six or 20 days and tested in the oviposition bioassay for response to one of three treatments: an untreated control oat flake, a pentane-treated (solvent control) oat flake, and an oat flake treated with a pentane extract of 5000 lh of Porapak Q-captured larval volatiles. The data were analyzed by ANOVA followed by the Newman-Keuls test.

RESULTS

In all cases, no larvae or pupae were present in 6-day-old cultures. Conversely, larvae and pupae were always present in 20-day-old cultures (Tables 1 and 2).

After 20 days in a high-density culture, female *O. surinamensis* laid significantly fewer eggs than females removed from the same culture after six days or removed from low-density cultures after six or 20 days (Table 1).

In the second experiment, *O. surinamensis* females from a 6-day-old, high-density culture laid significantly fewer eggs in the presence of an oat flake treated with a pentane extract of Porapak Q-captured larval volatiles than did females exposed to pentane-treated and untreated control oat flakes (Table 2). Females removed from the 20-day-old culture with larvae and pupae laid significantly fewer eggs on untreated or solvent control oat flakes than females removed from the same culture after six days (Table 2), confirming the results of the first experiment. Exposure of these females to an oat flake treated with larval vola-

tiles, however, did not cause a statistically significant decrease in their oviposition rate (Table 2).

DISCUSSION

Different mechanisms may be involved in suppression of oviposition in females removed after 20 days from high-density cultures (Tables 1 and 2) and those removed after six days and exposed to larval volatiles (Table 2).

The induced suppression of oviposition in the latter females by the odor of

larvae is apparently a response to a pheromonal signal indicating a well-populated habitat. Another example of a larval egg-laying deterrent occurs in *Spodoptera littoralis* (Boisduval), for which an aqueous extract of larval feces suppressed oviposition to about the same degree as in our experiments (Hilker, 1985). There are various examples of epideictic (marker) pheromones (Prokopy, 1981) emitted by eggs, larvae, pupae, and adults of other insect species (Prokopy et al., 1984). These pheromones apparently serve an immediate, density-regulating function in habitats (unlike stored grain) that cannot easily support large larval populations. Similarly, the antiaggregation pheromones produced by bark beetles indicate a saturated habitat (Borden, 1985).

Additionally, we have provided evidence indicating retained suppression of oviposition as a consequence of prior residence in a crowded population. In the females exposed to high-density cultures for 20 days, suppression of oviposition was retained for at least the 24-hr period of the bioassay. This suppression might be the result of a physiological feedback mechanism that inhibits vitellogenesis in response to the odor of immatures or some other component of a high-density culture. (Alternatively, it might be a learned habituation caused by prolonged exposure to larval odor.) It could not occur as a result of physiological fatigue following oviposition, because females removed from low-density cultures after 20 days retained the capability for maximal oviposition (Table 1). Like the pheromonal suppression of oviposition, the retained suppression following long-term exposure to immatures could be of adaptive advantage in deterring oviposition in a potentially befouled habitat.

We have been unable to duplicate the results in Table 1 with two strains of the merchant grain beetle, *O. mercator* (Fauvel), although there was an apparent weak, but insignificant, suppression of oviposition by females in one strain held for 26 days in a high-density culture. Thus, our results with *Oryzaephilus* spp. parallel those with *Tribolium* spp. in which net fecundity was only slightly reduced in the confused flour beetle, *T. confusum* du Val, maintained in flour previously occupied by adults, whereas it was reduced to a greater extent in the red flour beetle, *T. castaneum* (Herbst), in previously occupied medium (Prus, 1961). In populations of *T. castaneum*, however, there exists genetic variability for the responsiveness of egg production to the quality of the environment (Lavie et al., 1978), and this genetic character is maintained in natural populations by a balance between the selective advantage of high responders in optimal environments and their selective disadvantage in suboptimal environments (Lavie et al., 1981).

O. surinamensis and *O. mercator* have a taxonomically close relationship (Slow, 1958). Differential habits of resource utilization may contribute to species specificity. Based on a model proposed for *Tribolium* spp. (Ghent, 1963; Ziegler, 1976), we previously have suggested that *O. surinamensis* and *O. mercator* might perform different ecological roles as colonists of temporary habitats

(Pierce et al., 1983, 1987). The more dispersive *O. surinamensis* may be a primary colonist suited to exploit widely distributed, sparsely populated, and very fresh habitats, whereas *O. mercator* may be a secondary colonist better able to invade and persist in partially depleted habitats already occupied by populations of the same or different species.(Pierce et al., 1983). Sensitivity of aggregation pheromone production (Pierce et al., 1989) and perception (Pierce et al., 1983) to overcrowding by conspecifics in *O. surinamensis* supports our model, as does the strong cross-attractiveness of an *O. surinamensis*-produced cucujolide to *O. mercator* (Pierce et al., 1987). The oviposition response demonstrated by *Oryzaephilus* spp. is consistent with this model. Female *O. surinamensis* might restrict the number of eggs laid in depleted habitats already heavily occupied with larvae and adults by either a long-term, retained suppression of oviposition, or through the detection of an epideictic pheromone. Alternatively, our present results and past studies (Pierce et al., 1983, 1987, 1989) suggest there are little or no means by which *O. mercator* can detect and avoid a partially depleted habitat. Since *Oryzaephilus* spp. lay a predetermined number of eggs in a lifetime (Howe, 1956), it could be of definite adaptive benefit for females of a pioneering, colonizing species such as *O. surinamensis* to delay oviposition until a fresh or sparsely inhabited resource is located.

Acknowledgments—We thank S.R. Loschiavo for providing an isolate of *O. mercator*.

Abstract—Experimental groups of juvenile coho salmon (*Oncorhynchus kisutch*) were released to elucidate the relative importance of site-specific ("imprinted") odors and intraspecific odors ("pheromones") in homing. Adult salmon returned to their release site rather than a hatchery containing both adult and juvenile salmon of their population. Furthermore, salmon sharing the same parents returned to different sites, suggesting that local movements are not strongly influenced by siblings or other conspecifics.

Key Words—Coho salmon, *Oncorhynchus kisutch*, homing, imprinting, olfaction.

INTRODUCTION

It is generally accepted that salmonid fishes use olfaction to locate their natal river in the final stages of homing (Wisby and Hasler, 1954). However, it is not clear which odors convey the identity of the river. It has been hypothesized that the fish are guided by chemicals from riverine features such as rocks, soil, and plants, which create a unique combination of odors (Hasler and Scholz, 1983). On the other hand, Nordeng (1971, 1977) propounded the hypothesis that population-specific odors ("pheromones") emanating from both juvenile conspecifics residing in freshwater and those migrating to sea (smolts) guide the homing adults. Studies with artificial odorants (e.g., Scholz et al., 1976) indicated that pheromones were not necessary for homing. However, recent laboratory studies have indicated that salmonids can discriminate between populations based on chemical cues (Groot et al., 1986; Olsen, 1986; Quinn and Tolson, 1986; Stabell, 1987). Moreover, coho salmon (*Oncorhynchus kisutch*)

0098-0331/90/0200-0603$06.00/0

can also distinguish siblings from nonsiblings (Quinn and Busack, 1985; Quinn and Hara, 1986). There is currently no evidence that discrimination of kin- or population-specific odors is involved in homing.

Larkin (1975) expanded upon Nordeng's (1971) hypothesis that odors from juveniles guide returning adults and hypothesized that salmon from a given population might associate with each other while at sea on their homeward migration. Larkin's hypothesis stemmed from the mathematical demonstration that errors in group orientation decrease as school size increases, if the individuals jointly orient to a mean direction (Larkin and Walton, 1969). Thus if salmon schooled with members of their population, migration might be more efficient.

To investigate the relative importance of site-specific odors and odors emanating from conspecifics in homing, coho salmon were reared under experimental conditions, marked, and released. The subsequent patterns of homing by adult salmon from the experimental groups were monitored. The study posed two specific questions: (1) Will adult coho salmon pass a site containing both adults of their population and juveniles directly related to them (full siblings) to reach an upriver site where they had been released? (2) Will the homing behavior of one group of salmon influence that of a genetically related group returning at the same time to a different site within a river system?

METHODS AND MATERIALS

Incubation and Treatment of Juveniles. Between November 18 and 25, 1985, adult coho salmon from the University of Washington population were spawned and the fertilized eggs divided into two groups. No parents were common to both groups or to any other juvenile coho produced that season. All embryos were incubated at the University of Washington (UW) hatchery using dechlorinated Seattle city water, a source not generally used in the hatchery. Previous experiments (Whitman et al., 1982; Quinn et al., 1983) demonstrated that adult salmon can distinguish between city water and hatchery water. Water temperatures averaged 7–9°C and the eggs hatched in early January 1986. Development of hatchlings ("alevins") continued until yolk sac absorption was complete in March.

When the fry were free-swimming, they were moved to the Seward Park hatchery on Lake Washington (Figure 1) (March 8 for group 1 and March 21 for group 2). Both groups remained at this site in circular ponds, rearing in water pumped from the lake directly into the hatchery. Small individuals were culled from group 1, and 9489 fish were marked by excision of the adipose fin and internal coded wire tags on June 16. Group 2 was culled and divided into two subgroups (2A: $N = 10{,}020$ and 2B: $N = 10{,}148$) for fin-clipping and tagging on June 13–14. The salmon began the process of transformation from

freshwater "parr" to marine-adapted "smolts" in late June, judged by silvery appearance and downstream swimming behavior. On July 8, 1986, the tagged members of group 1 were released from the Seward Park hatchery into Lake Washington. Approximately 4000 untagged coho from group 1 were retained at the hatchery. On June 27, the tagged fish from group 2B were released from Seward Park hatchery. On July 1, group 2A fish were trucked from Seward Park to a site on Lake Union about 2.2 km below the UW hatchery (Figure 1) and released. The release site was a boat launching ramp with no suitable spawning area in the vicinity. Table 1 summarizes the treatments which the three groups received.

Collection of Returning Adults. Salmon released as smolts in 1986 were expected to return as adults primarily in fall 1987. This population has relatively few precociously maturing males, known as jacks (Brannon et al., 1982). Jacks could have entered the UW hatchery return pond in fall 1986 and would have been detected in the regular surveys taken three times each week. The trap at

the return facility at Seward Park was not constructed until late summer 1987, however, and returning jacks would not have been collected there in 1986.

Dechlorinated city water, used to incubate the eggs and embryos, was not released from the UW hatchery at any time during the spawning season. The adult coho (and chinook, *O. tshawytscha*) salmon holding in the UW hatchery's pond in the fall presumably produce a high concentration of salmon odors in the effluent. These odors were supplemented by the 4000 immature siblings from group 1, which were transferred from Seward Park to the UW hatchery prior to adult returns.

All salmon returning to the UW and Seward Park hatcheries were inspected for marks. Additionally, three other opportunities for recovering tagged fish were pursued. The U.S. National Marine Fisheries Service (NMFS) has a small hatchery across the ship canal from the UW hatchery. While no NMFS fish were expected to return in 1987, the hatchery's trap was checked for stray experimental salmon. The Washington Department of Fisheries operates a large

hatchery for chinook and coho salmon on Issaquah Creek, a tributary to Lake Samammish above Lake Washington (Figure 1). Coho salmon returning to this facility were checked for coded wire tags. Additionally, a gillnet fishery in the north end of Lake Washington and in Lake Samammish targets Issaquah Creek hatchery salmon. Subsamples from this fishery were taken by the Washington Department of Fisheries and checked for tags.

RESULTS

Thirty-nine salmon from group 1, incubated in dechlorinated city water and reared in Seward Park water, bypassed the UW hatchery containing full-sib relatives and other adults of their population and returned to Seward Park. No members of this group entered the UW hatchery. Similar behavior was shown by group 2B coho with a similar rearing history: all 43 recoveries were at the Seward Park hatchery (Table 1). However, 32 salmon (including one jack in 1986) from group 2A, reared at Seward Park but trucked to Lake Union for release (Figure 1) returned to the UW hatchery and only six adults returned to Seward Park.

Fifteen coho salmon entered NMFS trap but none were from any of the experimental groups. No coho salmon from any of the three groups were recovered from the fishery in Lake Washington or at the Issaquah hatchery.

DISCUSSION

Salmon returning to Seward Park had to swim within about 100 m of the UW hatchery. The UW hatchery contained full-sibling relatives of group 1 as well as 1708 adult coho (and 506 chinook) salmon over the course of the spawning season. In spite of these odors in the hatchery's effluent, salmon from groups 1 and 2B swam past the UW hatchery and approximately 16 km in Lake Washington to Seward Park. The tendency of salmon to return to a site experienced as juveniles rather than to one containing conspecifics' odors is consistent with the attraction of adult coho salmon to hatchery water without coho odors over city water containing juvenile coho in a two-choice apparatus (Brannon et al., 1984). Our result is also consistent with the demonstration by Black and Dempson (1986) that Arctic char were not decoyed into a nonnatal river by the presence of adults.

Laboratory experiments have indicated that coho salmon are capable of population-specific and family-specific chemosensory discrimination (Quinn and Busack, 1985; Quinn and Hara, 1986; Quinn and Tolson, 1986; Courtenay, 1989). Intraspecific discrimination may be related to juvenile social behavior

or mate selection by adults, but it apparently is not crucial to homing as all adults swam past the UW hatchery to Seward Park.

The return of all members of group 2B to Seward Park corroborated the results with group 1: pheromones or other population-specific odors in the UW hatchery did not attract them. Moreover, the fish in group 2B were the full siblings of those in 2A. The return of 2A to the UW hatchery (32 of 38 adults) indicated that homing salmon were not influenced by the behavior of siblings. This particular experiment was motivated by Larkin's (1975) hypothesis that homing salmon might school preferentially with kin at sea and by the idea that the local movements of adult salmon in freshwater are influenced by density of conspecifics (Quinn and Fresh, 1984). While our results provided no evidence for kin-based schooling, the tendency of group 2A to enter the UW hatchery was noteworthy. These fish were never reared in UW hatchery water and were moved to Seward Park prior to the presumptive time of olfactory imprinting (Hasler and Scholz, 1983) on the same schedule as groups 1 and 2B.

The return migration of group 2A might be explained by the following scenario which assumes that smolts imprint on a sequence of odors during emigration (Quinn et al., 1989, in press). The smolts learned the characteristics of Seward Park water and the odors of the release site but were denied the opportunity to experience the waters in between. Upon return to the watershed, they located the release site in Lake Union. However, from that point they could not detect Seward Park effluent odor, and they lacked experience of the homeward path. In this situation the fish were decoyed to the UW hatchery, the site that either most resembled the odors of home or contained familiar salmon odors (Brannon and Quinn, 1989). Some of the group 2A salmon (16%) were apparently more persistent in their search and returned to Seward Park. Thus this study indicates that salmon odors were not used to guide salmon home, although in the absence of primary cues they may facilitate the selection of spawning sites by straying salmon.

Acknowledgments—This research was supported by National Science Foundation grant BNS 8515202. We thank the many people who assisted with the marking and recovery of the salmon, especially Ann Setter, John Konecki, and Chuck Peven. Andrew Dittman provided comments on the manuscript.

RESPONSES TO INTER- AND INTRASPECIFIC SCENT MARKS IN PINE MARTENS (*Martes martes*)

MICHELE de MONTE and JEAN-JACQUES ROEDER

Laboratoire de Psychophysiologie, URA/CNRS 1295
7 rue de l'Université
67000 Strasbourg, France

(Received June 14, 1988; accepted April 6, 1989)

Abstract—In order to analyze intra and interspecific olfactory discrimination, behavioral responses (sniffing and marking) towards various odors were observed in pine martens (*Martes martes*). Two adult males and two adult females were tested for intraspecific discrimination of abdominal gland odors and urine. Both sexes sniffed and marked objects carrying their own scent less than unscented objects. There were no differences in sniffing or marking objects impregnated with odors from known and unknown conspecifics of the opposite sex or objects carrying the odor of an unknown male or female. A second experiment with two adult females gave no evidence for interspecific discrimination: no differences emerged when comparing reactions towards marks of pine martens, stone martens (a closely related species), or genets. The most obvious result of this study is the reduced response of pine martens towards their own mark. It is suggested that scent marking in martens may reflect "autocommunication," the primary effect being to familiarize an animal with its environment.

Key Words—Carnivores, pine martens, scent marking, odor discrimination, *Martes martes*.

INTRODUCTION

Studies on olfactory communication in carnivores (Rasa, 1973; Gorman, 1976; Roeder, 1980; Macdonald, 1985) have shown that scent marking has diverse social functions: scent marks are indicators of individual identity and carry information about sexual and social status as well as physiological state. Pine martens (*Martes martes*) show two types of marking: secretions from the

0098-0331/90/0200-0611$06.00/0

abdominal gland and urine. Based on field observations, Pulliainen (1981a) has stated that "pine martens recognize the smells of other martens individually" and has suggested that "the pine marten also has its distinctive smell, which serves for interspecific recognition" (pp. 1085–1086).

The aim of the present study was to observe martens' reactions towards various odors in order to clarify the possibility of intra- and interspecific scent discrimination and thus analyze the social significance of scent marking in this species, which has been studied only rarely (e.g., Pulliainen 1981a,b; 1982). The first experiment investigates the reactions of martens towards various conspecific scent marks, while the second analyzes responses towards other species' scent marks.

METHODS AND MATERIALS

Experiment 1: Intraspecific Discrimination. In this experiment, the ability of martens to discriminate between their own scent mark and those of known and unknown males and females was tested. The study was carried out on two adult females and two adult males kept separately in outdoor cages (3 × 2.50 × 2.70 m), each containing shelters, tree trunks, and a water bowl. Every day the animals were fed dead chickens, fruits, and cake. Fresh water was available ad libitum.

The reaction of each individual to various conspecific scent marks was observed. The different scent marks were collected on plastic boxes (12 × 10 × 10 cm) that were introduced into the donor's cage the night preceding the test. Concurrent observations (mean of 3 hr/day/animal) on social interactions allowed us to verify that the test boxes were marked by the donors. Each animal was tested in the presence of (1) control boxes (unscented), (2) its own scent marks, (3) an unknown male's marks, (4) an unknown female's marks, (5) a known male's marks for females and a known female's marks for males. A known conspecific is defined as an individual living in visual, auditory, and probably olfactory contact with the subject (i.e., separated by a double wire mesh).

Each test consisted of placing the object in the animal's enclosure and recording the total duration of sniffing the object, the number of times the object was marked and the number of marking acts elsewhere in the cage. This last measure was taken to test whether general scent marking activity was modified by introducing the boxes. Each test lasted 10 min. (Previous observations of 30 min showed that 5 min after the introduction of the box, the animals no longer showed interest in the object.) A series of tests consisted of presenting the five stimuli to one individual in random order. Nine series of tests were completed

for each male, and nine and five, respectively, for each female, the discrepancy being due to different activity levels in the two females. The durations of sniffing and marking frequencies in the different odor conditions were compared with those recorded during control tests using Mann-Whitney U tests.

Experiment 2. Interspecific Discrimination. In this experiment, the ability of two female martens to discriminate between scent marks of their own and other carnivore species was investigated. This study was conducted on two adult females that had been maintained together for three years but separated four weeks prior to the study. They lived in indoor cages (3.20 × 2.50 × 1.90 m). The floor was covered with sawdust. The light cycle of 12 hr light (0700–1900 hr) and 12 hr dark was inverted. The martens were fed mainly on mice but were also given supplements of fruits and eggs.

The two females' responses to the following objects were observed: (1) unscented, (2) animal's own mark, (3) known female conspecific's mark, (4) stone marten's (*Martes foina*) mark, (5) genet's (*Genetta genetta*) mark. Stimuli 4 and 5 were used to compare reactions towards marks of a closely related species (stone marten) and a distantly related species (genet). The different scent marks were collected on bricks (15 × 6 × 3 cm) previously left in the donor's cage for several days. The procedure was the same as in experiment 1, the only difference being that each test lasted 5 min. Ten series of tests were completed for each subject. Statistical analyses were done as in experiment 1.

RESULTS

Experiment 1. The results are shown in Table 1. The typical behavior of martens towards novel objects consisted of sniffing the object and then scent marking on it. The most frequent type observed was abdominal marking; urination accounted for only 14% of all marking acts in females and 22% in males. The most obvious result for all four animals was that the control box was sniffed significantly longer and marked more frequently than the object carrying the test animal's own scent ($P < 0.05$). No statistical differences were observed between control objects and any other condition (known and unfamiliar, male or female), except for males reacting to the scent of known females: the duration of sniffing was longer with the known female's odor ($P < 0.05$), but the rate of marking did not differ.

There were no significant differences in responses to marks of known and unknown conspecifics of the opposite sex, either in males or in females. In females there were no significant differences in responses to the scent marks of an unknown male and an unknown female. Similarly, males did not behavior-

ally differentiate between the scent marks of an unknown female and those of a strange male.

Comparing the various test conditions, no significant change in marking activity elsewhere in the enclosure was noted. Therefore, the reactions observed towards the various scent marks appear to be specific to objects carrying the different scents.

Experiment 2. As in experiment 1, the object carrying the animal's own mark was sniffed and marked significantly less than the unmarked object (Table 2, $P < 0.05$). Female A never marked the object carrying her own scent. No statistical differences appeared either when comparing control objects with other odors or when comparing reactions (sniffing duration and marking activity) towards marks of pine martens, stone martens, or genets.

DISCUSSION

The most clear-cut result of this study concerns reactions of pine martens towards their own marks. In all the tested animals, the scent-marked object was always sniffed and marked less than unscented objects, and there were no differences in reactions to unscented objects and objects carrying scent marks from a conspecific or from other species, except in males. Pulliainen (1982) argued that in pine martens scent marking has a "self-centered primary function" by playing a role in orientation and familiarity with a locality. Both experiments 1 and 2 suggest that pine martens recognize their scent marks as being their own, since the animals respond little to the presence of their own mark (this being particularly significant considering the marking rate of the animals). Another explanation would be that the animals were "blind" to marked objects and simply mark every object that contrasts with the general olfactory background. However, this explanation appears untenable since differences were found when males were confronted with known females' scent marks. Nevertheless, these two interpretations would lead to the same conclusion, namely, that scent marking could play a role in the maintenance of environmental familiarity.

We observed no differential behavioral reactions towards the scents of familiar and strange conspecifics. Using training techniques, Rasa (1973) in the African dwarf mongoose, Kruuk et al. (1984) in the badger, and Clapperton et al. (1988) in the ferret have shown that the animals could discriminate scents from different individuals and groups of individuals. It seems possible that by using such methods, this ability could also be demonstrated in martens. Nevertheless, spontaneous behavioral reactions towards scent marks did not reveal such an ability. It would also be interesting to see whether martens would discriminate between fecal pellets from familiar and strange conspecifics. Along the same lines, chemical analysis of glandular compounds from the abdominal

glands might show individual variations as in anal sac secretions of otters (*Lutra lutra*) (Gorman et al., 1978), anal sac compounds of stoats (*Mustela erminea*) (Erlinge et al., 1982), and subcaudal glands of badgers (*Meles meles*) (Kruuk et al., 1984).

Data on sex recognition in mustelids are scarce (e.g., Crump, 1980; Clapperton et al., 1988, in the ferret). In our study, no significant results were obtained (experiment 1), but these negative findings do not necessarily imply that no information about sex is transmitted by olfactory cues. Seasonal variations in marking activity (De Monte and Roeder, 1990) suggest that olfactory cues are involved in reproduction. It is conceivable that outside the rutting period, scent marks from animals of both sexes could have the same meaning for males and females and simply indicate the presence of a stranger. In mustelids, social organization is generally considered to be based on intrasexual exclusion (Powell, 1979). In martens in particular, spatial distribution is not strictly restricted to such an organization but includes overlapping of home ranges among neighboring males and females (Pulliainen, 1982). This could explain why our animals reacted in the same way to the presence of male and female scent marks. It would be interesting to know how olfactory cues (especially scent marks) act during the rutting period and whether they convey information about the physiological state of females.

In experiment 2, there was no evidence of interspecific discrimination. Reactions towards scent marks of stone martens (a phylogenetically closely related species partly sympatric with the pine marten) and genets did not differ from those towards control objects or the martens' own marks. These results provide no evidence that olfactory cues are involved in interspecific relations between these two sympatric species.

In conclusion, the study of spontaneous responses of martens towards various scent marks gave no evidence for intra- or interspecific recognition. The only condition in which duration of sniffing *and* marking frequency were modified was in the presence of the animal's own scent. These results suggest that scent marking in martens may be a self-oriented behavior and act in "autocommunication" (Roeder, 1985). It remains to be clarified whether other functions ascribed to scent marking (territorial maintenance, individual recognition, pair-bond formation; see Thiessen and Rice, 1976; Gosling, 1982) should be considered as primary functions in this species or as outcomes of scent marking used for familiarization (Kleiman, 1966). Further behavioral studies (e.g., on marking activity during the rutting period and during social encounters) are necessary for clarifying the functions of scent marking in martens.

Acknowledgments—We thank Mr. Wayre for allowing us to study the pine martens at the Norfolk Wildlife Park, and the staff for their kind assistance. We are grateful to Dr. J.R. Anderson for valuable criticisms and correcting the English.

(Received August 16, 1988; accepted April 7, 1989)

Abstract—Soldiers of free-ranging termites of the genus *Lacessititermes* (Isoptera, Nasutitermitinae) secrete from their frontal glands a mixture of monoterpenes, sesquiterpenes, and diterpenes. *Lacessititermes ransoneti*, *L. laborator*, and *L.* species A produce species-specific secretions, the composition being most complex for *L. laborator*. Apart from known mono- and dihydroxytrinervitadienes, the following new diterpenes were isolated and tentatively assigned as trinervita-1(15),8(19)-dien-2β,3α,9α,14α-tetraol 2,3,14-*O*-triacetate, trinervita-1(15),8(19)-dien-2β,3α,9β,14α-tetraol 2,3,14-*O*-triacetate, 2β,3α,9α,14α-tetraacetoxy-1(15),8(19)-trinervitadiene, and 2β,3α,11α,13α-tetraacetoxy-1(15),8(19)-trinervitadiene. Data on intragenus chemical variations were subjected to canonical discriminant analysis and genetic distances among the species were calculated to depict intragenus identities and affinities.

Key Words—Isoptera, Termitidae, defense secretions, interspecific variations, *Lacessititermes*, diterpenes.

INTRODUCTION

Diterpenes, together with monoterpenes and less frequently sesquiterpenes, form the base chemicals of the defense secretion of termite soldiers of the subfamily Nasutitermitinae. This subfamily, of which over 500 species have been reported (Tho, 1982), contributes the largest number of species within a subfamily. The

0098-0331/90/0200-0619$06.00/0

evolution of defense chemicals in the soldier termites has contributed, to a large extent, to successful defense of their colonies against predators. Studies on the chemical constitution of soldier termite secretions in relation to their phylogeny have indicated that the regression of their mandibles occurs concurrently with the development of chemicals (Goh et al., 1984; Prestwich, 1986). In the monophyletic scheme of the evolution of nasute termites, diterpene biogenesis developed somewhere along the evolutionary line close to *Longipeditermes* and *Hirtitermes* (Goh et al., 1984). The secretions of *Longipeditermes longipes* [morphologically identified as a single species (Tho, 1982)] contain diverse diterpene structural types from which the existence of three chemotypes within the species could be deduced. Similarly, based on diterpene chemistry from the relatively more advanced genus *Hospitalitermes*, two chemotypes were discovered from a single species of *Hospitalitermes umbrinus* (Chuah et al., 1983, 1986, 1987; Goh et al., 1988).

The genus *Lacessititermes* is restricted to the Indomalayan region with 15 known species. Although eight species have been recorded from Malaysia (Tho, 1982), only *L. ransoneti* and *L. laborator* are commonly encountered. The termites are characterized by having long antennal segments, long legs with the hind legs much longer than the body length, and highly pigmented body colors. Behaviorally, all species recorded have free-ranging habits; they march out in long columns without covered trails. The columns, starting from arboreal nests built around small branches of trees, often extend to more than 20 m. Food comprises scrapings off the surfaces of decomposing leaf litter, twigs, and bark of trees. They often feed on lichen growths on the tree. The food material is gathered and rolled into a small ball by the worker caste and is then carried all the way back, along the trail, to the nest. The soldiers can be monomorphic and dimorphic, and they protect their foraging columns of workers by positioning themselves along the fringes of the columns. Defense is effected by ejecting chemical secretions at their enemies. Our field observations so far have indicated that these termites, while on the march, are seldom attacked by predators, which would presumably attest to the effectiveness of their defense strategy. Additionally, the relatively long legs of the soldier termites of this genus are well adapted to enable them to move swiftly to converge at the sites of disturbances.

METHODS AND MATERIALS

Termite Material. Soldier termite materials used for the present studies were all collected from within closed canopy dipterocarp forests from the following localities in Peninsular Malaysia (Figure 1): (1) Muka Head Field Station [5°20′N, 100°8′E; 200 m above sea level (ASL)]—a coastal hill dipterocarp

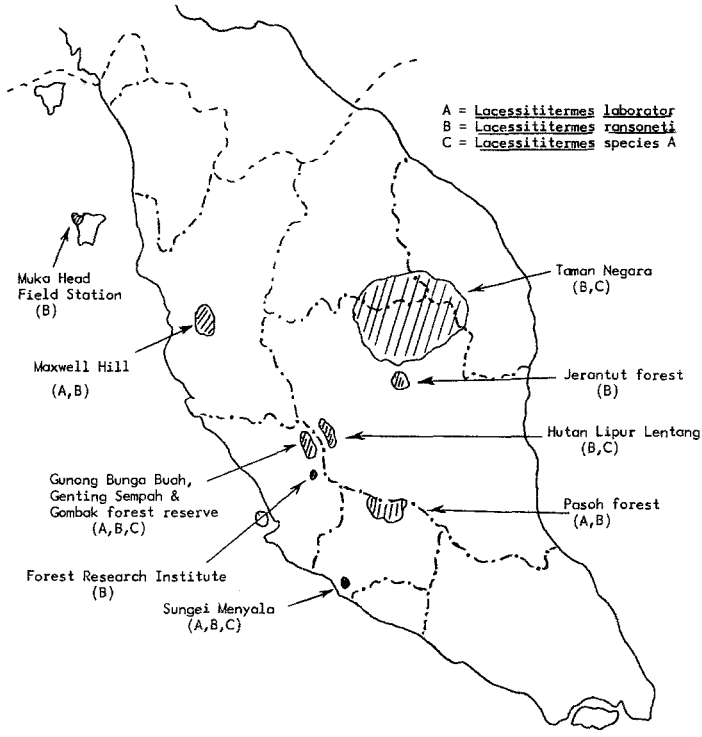

FIG. 1. Distribution of *Lacessititermes* in Peninsular Malaysia.

forest reserve in the state of Penang; (2) Maxwell Hill forest reserve (4°50′N, 100°50′E; 1000 m ASL)—an upper hill dipterocarp forest in the state of Perak; (3) Taman Negara (4°20′N, 102°25′E; 1000 m ASL)—the national park of Peninsular Malaysia in the state of Pahang; (4) Jerantut forest reserve (3°50′N; 102°20′E; 50 m ASL)—a forest reserve area in the state of Pahang; (5) Hutan Lipur Lentang forest reserve (3°30′N, 100°30′E; 300 m ASL)—a hill dipterocarp forest in the state of Pahang; (6A) Gombak forest reserve (3°20′N, 101°46′E; 300 m ASL), (6B) Gunong Bunga Buah forest reserve (3°10′N, 101°46′N; 600 m ASL), and (6C) Genting Sempah forest reserve (3°14′N, 101°46′E; 500 m ASL)—6A–6C are all hill dipterocarp forests in the state of Selangor; (7) Forest Research Institute (3°10′N, 101°30′N; 50 m ASL)—a forest research station at Kepong in the state of Selangor; (8) Pasoh forest reserve (2°58′N, 101°55′E; 100 m ASL)—a lowland dipterocarp forest in the state of Negeri Sembilan; and (9) Sungei Menyala forest reserve (2°29′N, 101°55′E; 100 m ASL)—a lowland dipterocarp forest in the state of Negeri Sembilan.

Analytical Methods. Gas chromatography (GC) and spectral data were recorded as described previously (Chuah et al., 1983, 1986, 1989; Goh et al., 1984, 1988). Monoterpenes (I–XII) and diterpenes (XIII–XXIX) as shown in Figure 2 were characterized by NMR and MS spectral data by comparison to reported data (Braekman et al., 1984, 1986; Dupont et al., 1981; Prestwich, 1979; Valterova et al., 1986; Vrkoč et al., 1978) and by coinjection with identical compounds previously characterized (Chuah et al., 1983, 1986, 1989; Goh et al., 1984, 1988). The secretion of *L. laborator* was fairly complex and repeated HPLC (SiO_2) chromatographic cycles were performed to obtain compounds XXIV–XXIX. The diterpenes isolated by HPLC were checked for purity by GC and TLC on Merck 5 × 10-cm 0.25-mm silica gel 60 plates. Four new diterpenes (XXIV, XXV, XXVI, and XXIX) were identified and tentative structures were assigned based on [^{1}H]NMR and MS data. [^{1}H]NMR data are given in Table 1.

Statistical Analysis. The relative mean proportions of monoterpenes and diterpenes were calculated. Differences between species were estimated by the

lambda, which tests the null hypothesis that species means are equal. (3) Standardized canonical discriminant function coefficients, to identify the most important dependent variables for discriminating among species. All analyses were run on the SPSS/PC$^+$ program (Norusis, 1986).

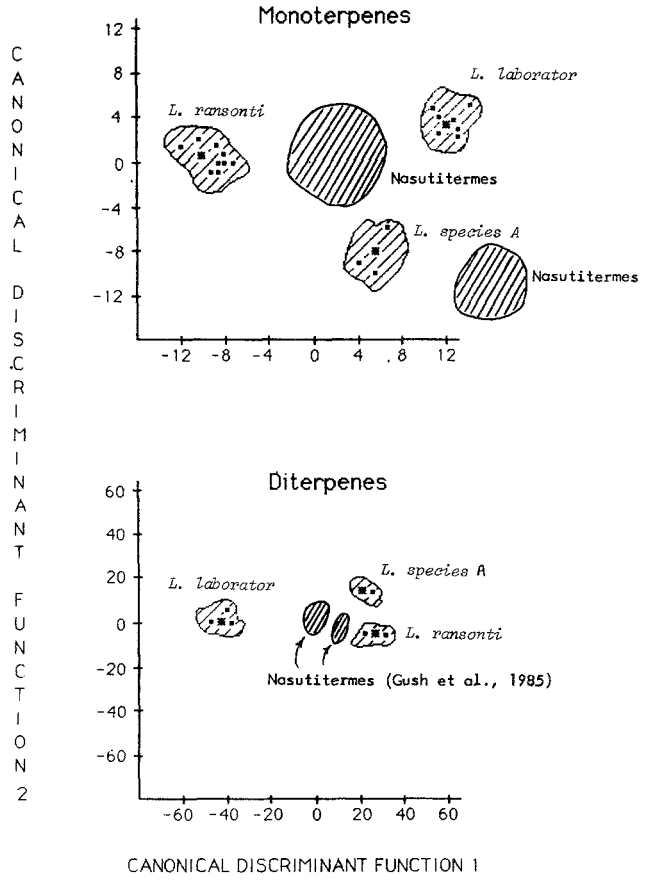

FIG. 3. Canonical discriminant plots for *Lacessititermes*.

The genetic distance between two species was calculated using the mean relative proportions of all the mono- and diterpene compounds following the formula of Nei (1972):

$$D_{XY} = -\ln\left[\frac{\sum X_i Y_i}{\sqrt{\left[\sum X_i^2 \sum Y_i^2\right]}}\right]$$

where X and Y are the mean relative proportion of compound i in species X and Y, respectively. A dendrogram using the unweighted pair-group arithmetic average clustering method was constructed (Figure 4).

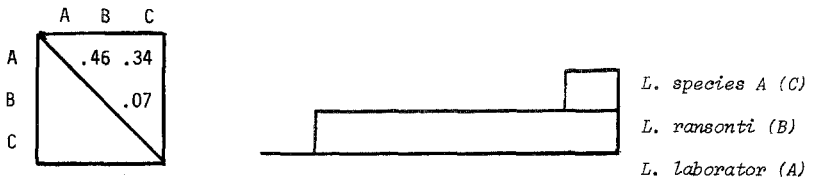

FIG. 4. Matrix and dendograms constructed from genetic distances among *Lacessititermes*.

RESULTS AND DISCUSSION

The genus *Lacessititermes* is closely related to the previously studied *Hospitalitermes* (Chuah et al., 1983, 1986, 1987). The three species of *Lacessititermes* presently studied show the same tricyclic diterpene (trinervitene) skeletal type that is dominant in their diterpene secretions. Based on the chemical compositions, only one chemotype was evident for each of the three species studied from colonies collected over many locations in Malaysia (Figure 1). As with many other genera, the convergence towards the trinervitane tricyclic skeleton may be a feature associated with the more advanced nasute soldier and distinct levels of evolution showing this trend have been represented by a monophyletic regression line (Goh et al., 1984). Variations in chemical composition of the defense secretions in the Nasutitermitinae would have been the result of selective natural forces that impact upon the various species in their adaptation to the environment. This would include predation pressure, behavioral changes as a response to food preferences, and reproductive isolation through a need for interspecific identities. Hence, it has been suggested (Prestwich, 1984) that compositional and structural variations in the defense chemicals may be viewed as an indirect way of measuring the genetic variation within a given taxon and may be used as chemosystematic criteria for identifying species in morphologically ambiguous cases.

Limonene, α-pinene, and β-pinene are noted as the most abundant monoterpenes in the defense secretions of *Lacessititermes* soldiers. These monoterpene hydrocarbons, being natural repellents, are common in the secretions of all the three species. As many as 12 monoterpenes (I–XII) are recorded for *L. ransoneti*, indicating a "broad spectrum" pattern (Table 2) in contrast to a greater preference for selected monoterpenes, as shown by non-free-ranging *Nasutitermes* termites (Chuah et al., 1989). Each soldier termite of *L. ransoneti* provides defense secretion of 1.0–3.3% of its body weight consisting of 4.7–7.2 μg monoterpenes, 0.5–1.5 μg sesquiterpenes, and 7.7–11 μg diterpenes. Similarly each *L. laborator* soldier gives 2.4–3.2% of secretion consisting of 5.3–7.7 μg monoterpenes, 12–21μg sesquiterpenes, and 31–41 μg diterpenes.

For *L.* species A the value is 2.0–2.3% of secretion consisting of 7.2–8.6 μg monoterpenes, 1.5–2.9 μg sesquiterpenes, and 13.6–15.2 μg diterpenes. Thus, only *L. laborator* secretes a relatively large proportion of sesquiterpenes in comparison to the other terpenes. GC-MS spectral data show that the sesquiterpenes are hydrocarbons and alcohols. A few of the larger components are tentatively assigned as β-caryophyllene (55%), longifolene (10%), α-gurjunene (20%), and γ-gurjunene (15%) based on their EI-MS fragmentation spectral data and by coinjection with commercially available standards. Among the species studied, variations in the composition of the monoterpenes, sesquiterpenes, and diterpenes can be used to provide diagnostic patterns that depict intergeneric and interspecific differences.

As shown by the present study, the defense secretions of these free-ranging termite soldiers appear to be characterized by having a relatively wide spectrum of volatile chemical components (Table 2) in comparison to more selective terpenoids found for the covered-trail termite *Nasutitermes* (Chuah et al., 1989). This could be associated with their free-ranging habits and behavioral adaptations; their free-ranging columns extend over considerable distances and are unprotected by any sheltered cover. Thus a wide spectrum of volatile monoterpene components is needed to repel a larger number of arthropods.

The defense secretion of *L. laborator* is especially noteworthy as being relatively complex (Table 2) because as many as 17 diterpene components can be detected by GC and isolated by HPLC. Eleven of the diterpenes (XIII–XXIII), also present in the defense secretions of *L. ransoneti*, are known from previous studies on *Longipeditermes longipes* (Goh et al., 1984), *Hospitalitermes* species (Chuah et al., 1986), and *Nasutitermes* species (Chuah et al., 1989).

Diterpenes XXVI, XXVII, XXVIII, and XXIX all had $M^{+\cdot}$ at 504, compatible with the molecular formula $C_{28}H_{40}O_8$, and characteristic fragment ions of *m/z* 444, 384, 324, and 264 corresponding to the elimination of one to four molecules of acetic acid and strong ions of *m/z* 60 and 43 ($AcOH^{+\cdot}$ and CH_3CO^+, respectively) were recorded. As the MS of diterpenes XXVI and XXIX are almost identical not only to each other but also to those of tetraacetates (XXVII and XXVIII) previously isolated from *Nasutitermes* species (Braekman et al., 1984), they are assigned as 1(15),8(19)-trinervitadiene derivatives bearing four acetoxy groups. The [^{1}H]NMR spectral data are in agreement with this hypothesis since four ^{1}H signals, attributable to protons on carbon-bearing acetoxyl groups, appear in the low field region (see Table 1). The [^{1}H]NMR spectral data of XXVI and XXIX are quite similar to those reported for 2β,3α,9α,13α-tetraacetoxy-1(15),8(19)-trinervitadiene (XXVIII) from *Nasutitermes PNG (F)* and 2β,3α,9α,11α-tetraacetoxy-1(15),8(19)-trinervitadiene (XXVII) from *Nasutitermes gracilirostris* reported by Braekman (1984).

A comparison of the proton chemical shifts of the diterpene XXVI to those of the reported diterpene XXVIII reveals some similarities except that the absorption of δ5.2 (H-14) is a doublet of doublet (6 and 3 Hz) for XXVI instead of δ5.0 (H-13, multiplet) for XXVIII. Thus, the diterpene XXVI is tentatively assigned as 2β,3α,9α,14α-tetraacetoxy-1(15),8(19)-trinervitadiene.

The chemical shifts of XXIX for protons H-2, H-3, H-7, H-13, H-16, H_3-17, H_3-18, H_2-19, H_3-20 and acetyl groups match quite closely with those of the reported diterpene XXVIII. Diterpene XXIX's absorption at δ5.00 (multiplet) is assigned to H-13 due to the similarity of the splitting pattern of this proton to that in the known 2β,3α,9α,13α-tetraacetoxy compound XXVIII. The chemical shift of δ4.8 (multiplet) is assigned for proton H-11 to an acetoxy group, in close agreement to that reported for XXVII by Braekman et al. (1984). Based on this data, the diterpene XXIX is tentatively assigned as 2β,3α,11α,13α-tetraacetoxy-1(15),8(19)-trinervitadiene (XXIX).

The mass spectra of triacetyl tetraols XXIV and XXV, with $M^{+\cdot}$ (462) compatible with the molecular formula $C_{26}H_{38}O_7$ and characteristic fragment ions of *m/z* 402, 342, and 282 corresponding to the elimination of one to three molecules of acetic acid as well as elimination of ketenes, are almost identical not only to each other but also to that of trinervita-1(15),8(19)-dien-2β,3α,14α-triol 2,3,14-*O*-triacetate reported by Braekman et al. (1984). The fragmentation pattern is suggestive of a 1(15),8(19)-trinervitadiene skeleton bearing three acetoxyl groups and a hydroxy group (indicated by the elimination of H_2O). The [^{1}H]NMR (100 MHz) of compound XXIV also provides evidence for the presence of three acetoxy groups (δ = 2.03s, 2.05s, and 2.06s) of which two assume the positions 2β and 3α [doublets at δ = 5.5 (9 Hz) and 5.6 (9 Hz)] and the third at position 14α [δ = 4.8dd (6 and 3 Hz)]. The hydroxyl group is assigned at carbon 9 based on the doublet of doublet at δ4.4 (9 and 2 Hz). Thus the structure is tentatively assigned as trinervita-1(15),8(19)-dien-2β,3α,9α,14α-tetraol 2,3,14-*O*-triacetate (XXIV). Diterpene, XXV, possessing an identical MS spectrum as that of XXIV, is an H-9 positional epimer of XXIV. The proton chemical shift at δ4.5 (doublet-doublet of 9 and 2 Hz) can be assigned to the 9β configuration because the exomethylene protons are shifted to higher field (δ = 4.9 and 4.93 compared to δ5.1 and δ5.2 for XXIV). The diterpene XXV is thus tentatively assigned as trinervita-1(15),8(19)-dien-2β,3α,9β,14α-tetraol, 2,3,14-*O*-triacetate (XXV).

The data obtained from soldier defense secretions of *L. laborator*, *L. ransoneti*, and *L.* species A provide an opportunity for further statistical analysis, particularly canonical discriminant analysis and calculation of genetic distances. The Kruskal-Wallis tests indicate greater variation in diterpenes than in the monoterpene distribution among species (Table 2). Of a total of 12 monoterpenes (I–XII) and 17 diterpenes (XIII–XXIX), four components from monoterpenes (camphene, myrcene, β-phellandrene, and terpinolene) and two

from diterpenes (XV and XXI), respectively, were not significantly different (Kruskal-Wallis test, $P > 0.05$) among the species (Table 2). Apart from the most abundant monoterpenes, α-pinene, β-pinene, and limonene, which were similar for all three species investigated, monoterpene compositional patterns were readily distinguishable. The distribution of diterpenes as described earlier was distinct (Table 2) for *L. laborator* compared to the two other species. Diterpenes (XXIV–XXIX) were found to be present only in *L. laborator*, while diterpenes XVIII and XX were found to be present in relatively small amounts in comparison to the other two species.

Discriminant analysis of the monoterpenes and diterpenes gave significant values for Wilks lamda ($P < 0.001$) for both the first and second discriminant functions, the former accounting for 92.6% and 99.7% of the total variance for monoterpene and diterpene, respectively. Species could then be differentiated by the distribution of these compounds. A comparison of the standardized discriminant function coefficients showed that the three most important compounds for discriminating among species were α-pinene (I), Δ^3-carene (VI), and limonene (VIII) for the monoterpene content and trinervita-1(15),8(19)-dien-2β,3α-diol (XVIII), trinervita-1(15),8(19)-dien-2β,3α,9α,14α-tetraol 2,3,14-*O*-triacetate (XXIV) and 2β,3α,9α,14α-tetraacetoxy-1(15),8(19)-trinervitadiene (XXVI) for the diterpene content. As such, species were correctly classified (100%) according to monoterpene or diterpene compositions for *L. ransoneti*, *L. laborator* and *L.* species A. This is graphically expressed by the scatterplots for the two discriminant function axes (Figure 3). This is in contrast to that reported by Gush et al. (1985) for four species of *Nasutitermes*, in which correct classification was 98.9% and 76.1%, respectively, for monoterpene and diterpene as discriminating variables (also included in Figure 3).

With the assumption that the defense chemicals are genetic in nature, the genetic distances between the species are computed, and the results are as follows: *L.* species A and *L. laborator*: 0.34, *L.* species A and *L. ransoneti*: 0.07, and *L. ransoneti* and *L. laborator*: 0.46. The dendrogram constructed from these values is shown in Figure 4. The results show that *L. laborator* is distinct from *L.* species A and *L. ransoneti* but having a closer affinity with the latter.

Discriminant analysis has shown conclusively that both monoterpenes and diterpenes can be used to distinguish among these species of the genus *Lacessititermes* used in this study (Figure 3). The discriminant functions were significant and very accurate (100%) in assignment ability for both types of terpenoids. Although the present study provided little ambiguity because of the definite chemical patterns of the secretions among the three species, further data on other species and genera may provide more challenging problems for such statistical analysis. Earlier results with monoterpenes and diterpenes as dependent variables reported for the genus *Nasutitermes* by Gush et al. (1985) were also indicative of the usefulness of such analysis.

(Received August 18, 1988; accepted April 7, 1989)

Abstract—The nest of the stingless bee, *Trigona (Tetragonisca) angustula*, is guarded by bees positioned in the nest entrance and others hovering in front of it. Hovering guard bees track returning foragers sideways along the last 10 cm in front of the nest, but intercept and incapacitate nest intruders by clinging with mandibles to wings and legs. When attacked by the cleptobiotic stingless bee *Lestrimelitta limao*, the colony strengthens its aerial defense with hundreds of additional hoverers. To test our hypothesis that this reaction is due to interspecific chemical communication based on kairomone effects, we presented synthetic cephalic volatiles of both species at the nest entrance and counted the number of bees leaving the nest and taking up hovering positions. We conclude that guard bees recognize *L. limao* by the major terpenoids of their volatile cephalic secretions, geranial, neral (=citral) and 6-methyl-5-hepten-2-one; other components may fine-tune this recognition. The effect of chemical stimuli is not significantly enhanced by combination with a dummy of *L. limao*. Guard bees, we hypothesize, respond to this kairomone by secreting a species specific alarm pheromone; a major component of this pheromone, benzaldehyde, recruits additional bees to defend the nest.

Key Words—Cephalic volatiles, kairomone, nest defense, *Lestrimelitta limao*, *Trigona (Tetragonisca) angustula*, stingless bees, Hymenoptera, Meliponini, Apidae.

INTRODUCTION

In species of stingless bees, especially those that have nest entrance tubes with wide openings, disturbances in the periphery of the nest evoke rapid attacks by outflying guard bees, often followed by recruitment of additional defending bees (Wille and Michener, 1973; Michener, 1974). Generally, these mass attacks are triggered by alarm pheromones. Other species of stingless bees, especially those that have small nest entrances with diameters of one or a few bees' heads, rarely react aggressively to disturbances of their nest. Instead, they vacate or close the entrance tube before retreating into the nest. *T. angustula* (formerly *Trigona jati*) responds to general disturbance around the nest by retreating. However, they possess a nest defense that may be unique among stingless bees: Besides guard bees occupying the nest entrance tube, there are additional guards that hover in stable positions on both sides in front of the nest entrance and its close vicinity (Wittmann, 1985; Zeil and Wittmann, 1989). These hovering guards attack flying insect intruders and pull them to the ground by clinging to their wings or legs.

The value of this defensive behavior becomes obvious when attacks of the cleptobiotic stingless bee, *Lestrimelitta limao*, are taken into account. Bees of this genus do not visit flowers, but instead rob nests of other stingless bees of nectar, pollen, and nest construction material. Scout bees, after having detected a host colony, recruit hundreds of nestmates for a raid.

T. angustula workers defend their nests against attacks of *L. limao* by intercepting a scout in front of the nest or by mass recruitment of additional hovering guard bees. We and others (Sakagami et al., 1989) have observed these bees successfully fighting off even full-scale attacks of the robber bees. Earlier experiments on the defensive behavior suggested that the recruitment of additional hovering guards was triggered by a kairomone secreted by *L. limao* workers (Wittmann, 1985).

The major components of mandibular gland secretions in *L. limao* are the monoterpenes neral and geranial (= citral; Blum, 1966). Our recent gas chromatographic and mass spectrometric analysis of cephalic volatiles revealed additional compounds. Here we report on studies that identify the chemical and visual cues involved in the recognition of intruders and in the recruitment of hovering guard bees during raids of *L. limao*.

METHODS AND MATERIALS

Heads of *Lestrimelitta limao* workers that participated in raids were extracted in pentane. Gas chromatographic and mass spectroscopic analyses were carried out on a Varian MAT 311 A coupling system using a 50-m ×

[a] Single compounds tested are marked with an asterisk, compound mixtures tested are indicated with brackets.

0.25-mm-ID fused silica column with FFAP-CB as a stationary phase. Confirmation of the structures of identified compounds is based on comparison of mass spectra of gas chromatographic retention times with pure synthetic reference samples. Pure synthetic samples and mixtures of the identified compounds (Table 1) were tested in a bioassay designed to evaluate their properties in interspecific chemical communication.

From 1984 until 1987 one nest of *L. limao* and two of *T. angustula* were kept under observation in a suburbian area of Porto Alegre, Rio Grande do Sul, in southern Brazil. In front of *T. angustula* nests the flight behavior of hovering guard bees and their response to returning foragers were filmed and reconstructed by single-frame analysis. We simulated approaches of flying insect intruders towards both nests by passing dried collection specimens as well as live and slightly squeezed workers of the robber bees through the group of hovering guards to the entrance tube. Mass attacks by robber bees were simu-

lated by presenting 1 μl (corresponding to 4–100 robber bees) of single volatile components, component mixtures, and a whole synthetic pheromonal bouquet (artificial head) of *L. limao* for 5 min to the guard bees at the nest entrance (Table 1). The volatiles were pipetted on cell bottoms punched from *Apis*-comb foundations and fixed on a 25-cm-long plastic stick slightly underneath the opening of the entrance tube. For each trial a new wax disk and a new stick were used. After testing, the stimulus was completely removed. The substances were presented in random sequence, with five replicates per test at either one of the nests. Furthermore, the same compounds were presented together with a shiny black pin head serving as a dummy of the similarly sized and colored robber bees. The reaction of guard bees during stimulus presentation was quantified by counting the number of bees that left the nest and immediately took up hovering positions at its entrance. As controls, numbers of hovering bees were recorded for 5 min during pentane and during dummy presentation before each test. Trails were separated from each other by at least 30 min, in some cases by more than 3 hr, depending on the time a colony needed to reestablish control conditions.

Voucher specimens are deposited at the Fundação Zoobotânica do Rio Grande do Sul in Porto Alegre, Brazil and at the Zoological Institute of the University of Tübingen, West Germany.

RESULTS

Visual and Olfactory Discrimination of Intruders. Inspection of 16-mm films and video recordings revealed that hovering guard bees track incoming foragers on the final 10 cm of their return to the nest. These tracking episodes are not easy to see, since most of them only last about 100 msec and are difficult to distinguish from spontaneous jittering movements of guard bees (Zeil and Wittmann, 1989). Figure 1 shows two longer sequences with typical tracking movements of guard bees. As guard bees prefer hovering positions close to the nest entrance and the flight corridor, they might be able to recognize foragers visually by their size. At a distance of 2 cm from the flight corridor—as in the sequences in Figure 1—a forager subtends horizontally about 15° and vertically about 6° at the eye of a guard bee. Horizontal and vertical interommatidal angles in the frontal visual field in *T. angustula* workers are 2.5°–4.5° and 1.2° respectively, as determined with the aid of the pseudopupil. At 2 cm, therefore, a forager will be seen by about 25 ommatidia.

Discrimination between returning foragers and intruders must, in addition, involve olfactory cues: We rarely observed attacks by guard bees on dried collection specimens of *L. limao* workers that were moved towards the nest entrance, whereas live robber bees that were fixed to a stick and approached to

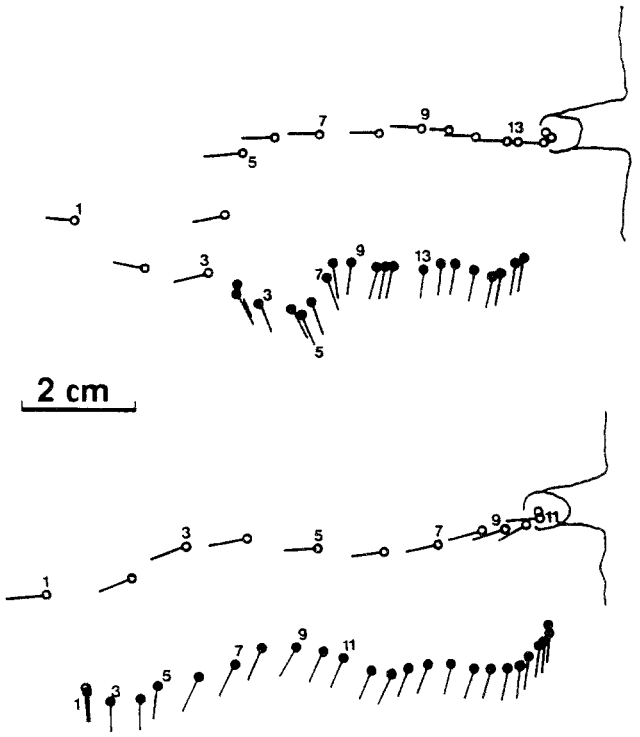

FIG. 1. Two sequences in which a guard bee tracks a returning forager seen from above. Circles mark the position of the head of guard bees (black) and foragers (open) every 20 msec, lines attached to circles represent the body axis orientation, positions are numbered consecutively. The nest entrance tube is shown at the right. Note that guard bees keep their orientation constant during tracking, except for a short turn in the direction of movement of the forager (between position 7 and 9, top sequence; and position 5 and 7 bottom sequence).

the nest were rapidly attacked by the guard bees (Wittmann, 1985). These attacks are fast (about 400 msec) and seem to be triggered whenever a robber bee passes through the frontal visual field of a guard bee (Figure 2). We did not observe guard bees turning towards dead or live robber bees when they were moved towards them from the side. From inspection of films, it is our impression that hovering guard bees tend to point into the wind during mass defense. Although we do not have a record of wind directions in front of the nest, we think that the following observations support the view that guard bees of *T. angustula* approach and attack a target against the wind: (1) consecutive attacks on a stationary live *L. limao* worker tend to occur from one direction only and

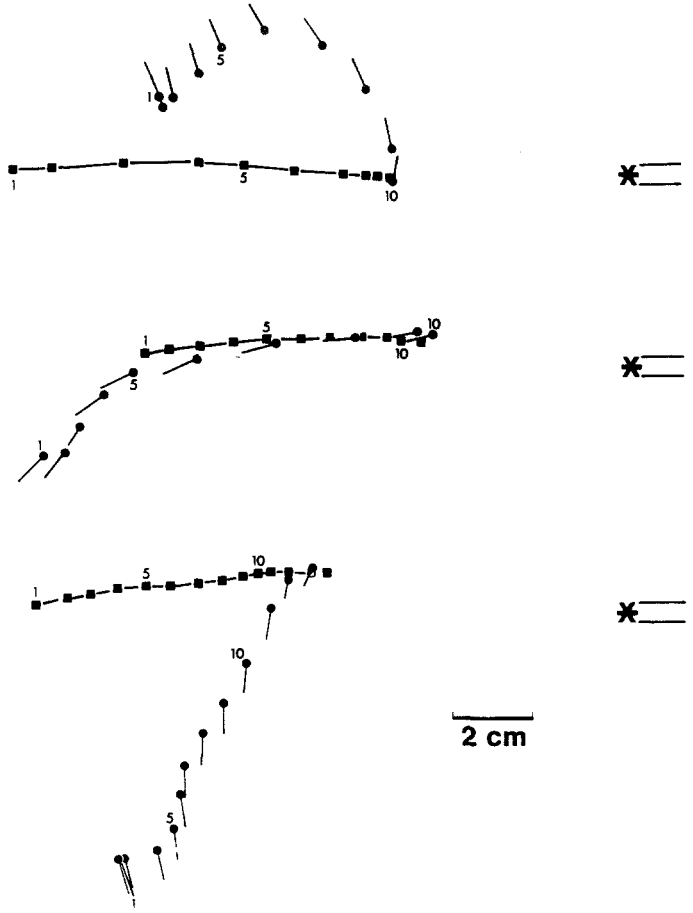

FIG. 2. Three attacks on a moving *L. limao* bee seen from above. Guard bee positions (black circles) and robber bee position (black squares) are shown every 40 msec; consecutive positions are numbered. The nest entrance tube is marked with an asterisk. At the end of each approach the bee has landed on the target. Note that the target is always seen in the frontal visual field of the attacking bee.

(2) the orientation of a bee is rather constant during the approach (Figure 3). We suggest, therefore, that an attack on a robber bee is most likely triggered by the coincidence of an olfactory perception and a target in the frontal visual field. However, since attacks are very fast, the actual execution of an attack must be under visual control.

When we presented cephalic volatiles of the robber bee to guard bees in

FIG. 3. Two approaches (left) and two attacks (right) on a stationary robber bee (square) recorded within 30 sec of each other. Conventions as before.

the nest entrance, slightly more workers were provoked to fly out when those chemical stimuli that had a recruiting effect were combined with a nonmoving black dummy. The effect, however, is not significant (t test, $P = 0.05$; Figure 4).

Interspecific Chemical Communication. Tests of identified compounds and mixtures of the cephalic volatiles of *L. limao* workers revealed that the alcohols, hydrocarbons, and esters did not elicit significant defensive response in *T. angustula* guards. In contrast, 6-methyl-5-hepten-2-one and citral provoked great numbers of *T. angustula* bees to fly out of the nest and take up hovering positions. Other bees fly in loops of about 1 m in diameter around the nest, thus patrolling its vicinity seeking out and attacking robber bees. The mixture of all compounds (artificial head of *L. limao*) elicited the strongest reaction among all synthetic volatiles tested. This response reached about 60% of that provoked

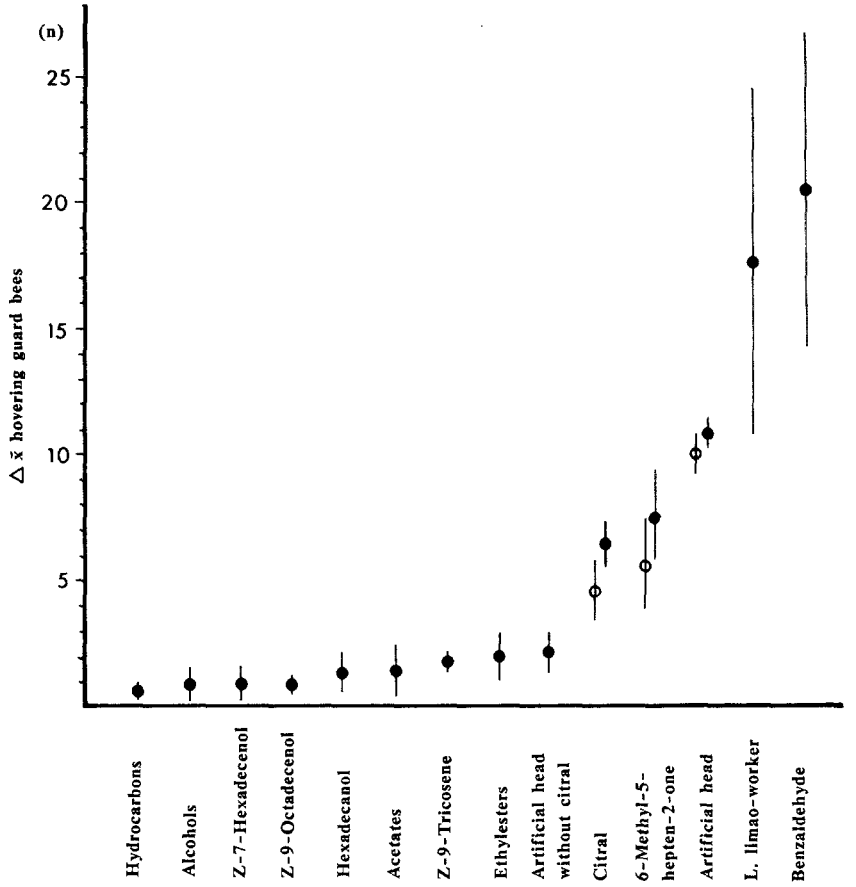

FIG. 4. Defensive reaction of *T. angustula* workers in response to single volatiles and compound mixtures presented 1 cm in front of the nest entrance tube without (circles) or together with a dummy (black dots). In five repetitions of each experiment, bees leaving the nest and taking up hovering positions were counted. Citral and 6-methyl-5-hepten-2-one released by the robber bees operate as the key substances in triggering the defense reaction (kairomone effect). Benzaldehyde is a component of the cephalic volatiles in *T. angustula* and a key substance of their alarm pheromone.

by a live robber bee (Figure 4). In none of the controls the number of hovering guard bees was increased.

These results demonstrate that cephalic volatiles of *L. limao* have a kairomonal effect on *T. angustula* workers, as they trigger their defense behavior. The question arises whether this kairomone operates as a direct releaser of the

massive defense reaction in *T. angustula* or whether its message is transformed by the guard bees into a species specific alarm signal.

Intraspecific Chemical Communication. In this context, it should be noted that *T. angustula* does not recruit additional hovering guard bees in response to general disturbances of the nest, like shaking, hitting, or blowing into the nest entrance. However, when 1 μl of benzaldehyde, one of the compounds of the mandibular gland secretion of *T. angustula* (Schröder and Francke, unpublished) is presented at the nest entrance, numerous bees are recruited to fly out and take up hovering positions. This reaction is as strong as the response to an alive *L. limao* (Figure 4).

DISCUSSION

The response to raids of the robber bees is not consistent within the Meliponinae: In some species of stingless bees, like *T. pectoralis*, *M. mexicana*, and *M. beecheii*, guard bees react aggressively when workers of *L. limao* are presented at the nest entrance (Weaver et al., 1975). On the other hand, colonies of a variety of species appear to be completely disoriented by the presence of citral (Moure et al., 1956), which in this case functions as an allomone (Blum et al., 1970). Guard bees and workers of other species retreat to the interior of the nest where they hide between brood combs, thus avoiding bee losses during pillages of *L. limao* (Nogueira-Neto, 1970).

Of the about 350 species of neotropical stingless bees, apparently only three (*Cephalotrigona capitata*, *T. angustula*, and *L. limao*) have a sympatric distribution that reaches from Mexico to southern Brazil (Camargo et al., 1988). During their long common history and due to high frequencies of aggressive encounters between *L. limao* and *T. angustula* (Schwarz, 1948; Wille, 1961; Nogueira-Neto, 1970; Sakagami et al., 1988) *T. angustula* has obviously adapted its nest guarding behavior and defensive strategy to raids of the robber bees.

The *T. angustula* colonies on which this study was carried out had not suffered any attacks of *L. limao* for more than six months before the experiments. Even if raids had been carried out in the absence of an observer, they could have easily been detected by high amounts of dead robber bees and nest defenders in front of the hives. As worker bees of *T. angustula* have a longevity of a few weeks, associative learning effects are not involved in their reaction to our simulated *L. limao* attacks.

Comparing the reactions of *T. angustula* to citral and 6-methyl-5-hepten-2-one with those to the more or less complete mixture of synthetic volatiles ("artificial head") suggests that those compounds which themselves cause no

or low responses in the guard bees, have a synergistic effect when added to these two volatiles.

The strengthening of the nest defense in *T. angustula* is, therefore, based on the recognition of *L. limao* workers by their pheromonal bouquet. Decisive for this are key volatiles (citral and 6-methyl-5-hepten-2-one), which are absent in the volatile secretions of the receiver (Schröder, 1985). In this basic feature, the interspecific communication of *L. limao* and *T. angustula* differs, for instance, from the reaction of workers of *T. fulviventris* on raids of the robber bees (Johnson, 1987). Here citral (geranial and neral), secreted by *L. limao*, is confused by the attacked bees with components of their own alarm pheromone (geraniol and nerol) and elicits their defense of the nest.

As already suggested by B. Smith (personal communication), benzaldehyde was found to be a major component of the alarm pheromone in *T. angustula*. However, these bees do not make use of their alarm pheromone to recruit additional guards during unspecific disturbances at the nest. Apparently, a necessary stimulus for its secretion is the presence of the kairomone released by *L. limao*.

We conclude that effective defense of the nest in *T. angustula* against pillages of the robber bees is achieved by two successive processes of inter- and intraspecific chemical communication: (1) The recognition of *L. limao* workers by their kairomone. This information, together with a visual stimulus, is sufficient to locally trigger attacks of the hovering guard bees on approaching robber bees. However, to strengthen the nest defense, even before a robber bee has made its way into the nest, the information on the attack has to reach the interior of the colony. (2) Apparently, the message of the kairomone is transformed by guard bees at the entrance into the species-specific alarm pheromone, which can be rapidly transmitted through the long inner entrance tube to recruit hundreds of additional nest mates that leave the nest and seek out targets for their aerial attacks.

Guest Editorial

At the annual meeting of the International Society of Chemical Ecology in Göteborg, Sweden, August 7–11, 1989, the assembled membership unanimously adopted the principles embodied in the following resolution, drafted by a small group of us:

> Natural products constitute a treasury of immense value to humankind. The current alarming rate of species extinction is rapidly depleting this treasury, with potentially disastrous consequences. The International Society of Chemical Ecology urges that conservation measures be mounted worldwide to stem the tide of species extinction, and that vastly increased biorational studies be undertaken aimed at discovering new chemicals of use to medicine, agriculture and industry. These exploratory efforts should be pursued by a partnership of developing and developed nations in such fashion that the financial benefits flow in fair measure to all participants.

In its essence the resolution is self-explanatory. It expresses our concern for the loss of the very substances that are the focus of our professional interest, and it urges remedial action. The vast majority of natural products remains to be discovered. If, over time, we are to have the opportunity to prospect for these riches, biodiversity will need to be conserved. Species are now vanishing faster than they are being scrutinized chemically. To counter this alarming reality, we will need to accelerate the exploratory search for natural products, while at the same time expanding the efforts to conserve nature itself.

The question, of course, is how to proceed. Species loss is most pronounced in the tropics, where biodiversity is greatest, yet the nations are also the poorest and least able to implement conservation programs. What the resolution proposes is that a substantial fraction of the cash flow stemming from the commercialization of new natural products be specifically channeled to Third World nations, where these funds could in turn help foster the conservation effort. Developing nations are the repositories of much of nature's remaining undiscovered chemical wealth. If they are to open this wealth to exploration, it is only fair that they share equitably in the profits derived from the marketing of the wealth. Such has clearly not been the case in the past. Nor has there been

0098-0331/90/0200-0643$06.00/0

an explicit policy of reinvesting a share of the profits derived from useful natural products in the preservation of nature's treasury.[1]

One would hope that as our Society moves into its seventh year, and gains in strength and influence, it would see fit to build upon this resolution. Chemical exploration in developing nations could be promoted by establishing or strengthening in these nations laboratories appropriately suited for such efforts. The initial step in chemical exploration is the discovery of biological activities associated with specific organisms or parts thereof. It would obviously be desirable and feasible to set up laboratories devoted to such chemical screening at or near sites slated for conservation. A network of such laboratories the world over, operating, it is hoped in some sort of coordination, could help enormously in promoting the chemical prospecting venture, while indirectly contributing to the conservation of nature. To move toward such a goal, a vigorous dialog will need to be established involving representatives of pharmaceutical and chemical industries, academic institutions, governments, and foundations. Our Society would do well to catalyze such interactions.

VOLATILE SEED GERMINATION INHIBITORS FROM PLANT RESIDUES[1]

JUDITH M. BRADOW and WILLIAM J. CONNICK, JR.

USDA, ARS, Southern Regional Research Center
P.O. Box 19687
New Orleans, Louisiana 70179

(Received February 28, 1989; accepted April 11, 1989)

Abstract—Volatile emissions from residues of the winter cover legumes, Berseem clover (*Trifolium alexandrinum* L.), hairy vetch [*Vicia hirsuta* (L.) S.F. Gray], and crimson clover (*Trifolium incarnatum* L.), inhibited germination and seedling development of onion, carrot, and tomato. Using GC-MS, 31 C_2–C_{10} hydrocarbons, alcohols, aldehydes, ketones, esters, furans, and monoterpenes were identified in these residue emission mixtures. Mixtures of similar compounds were found in the volatiles released by herbicide-treated aerial and root residues of purple nutsedge (*Cyperus rotundus* L.) and the late-season woody stems and roots of cotton (*Gossypium hirsutum* L.). Vapor-phase onion, carrot, and tomato seed germination bioassays were used to determine the time- and concentration-dependent inhibition potential of 33 compounds that were either identified in the plant residue emissions or were structurally similar to identified compounds. Cumulative results of the bioassays showed that (*E*)-2-hexenal was the most inhibitory volatile tested, followed by nonanal, 3-methylbutanal, and ethyl 2-methylbutyrate. All the volatile mixtures examined contained at least one compound that greatly inhibited seed germination.

Key Words—Allelopathy, allelochemicals, *Allium cepa, Daucus carota, Lycopersicon esculentum*, volatiles, cover crops, conservation tillage, cotton, hydrocarbons, alcohols, ketones, aldehydes, furans, esters.

INTRODUCTION

Allelochemicals released into the soil from decomposing plant residues strongly impact the soil ecosystem, affecting the chemical environment of the entire detritus food web and rhizosphere (Elliott et al., 1978; Putnam, 1985; Hendrix et al., 1986). However, information is extremely limited concerning the chemical composition of plant residue emissions, particularly volatile compounds that affect the ecology of both higher plants (Putnam, 1985; Bradow and Connick, 1987, 1988c; Connick et al., 1987) and fungi (Lindermann and Gilbert, 1975; French, 1985; Gramss, 1985). The bioactive emissions from plant residues are a particularly important factor in conservation tillage practices that leave high levels of decomposing plant residues in the root zone and at the soil surface (Elliott et al., 1978; Phillips et al., 1980; Gebhardt et al., 1985; Putnam, 1985; Hendrix et al., 1986).

Few plant volatile emission profiles that represent plant residues are found in the literature. In insect semiochemical research a variety of host-plant volatile profiles have been determined (Metcalf, 1987) using harsh distillation procedures that produced volatile mixtures unrepresentative of natural plant residue emissions (Flath et al., 1978; Buttery and Kamm, 1980; Flath et al., 1984). By using prompt isolation from fresh plant material and gentler trapping techniques, other researchers obtained profiles more representative of growing plants and, depending on harvest technique, plant residues as well (Buttery et al., 1984, 1985, 1986; Buttery and Ling, 1984, 1985). Many of the compounds identified in these profiles have both insect semiochemical activity (Visser, 1979, 1983; Light et al., 1988), and also affect fungal growth and seed germination (French et al., 1977; French and Leather, 1979).

Germinating seeds are particularly vulnerable to chemicals released by plant residues into the soil atmosphere (Klarich and Weaver, 1973; Lill et al., 1979; Heisey and Delwiche, 1984; Bradow and Connick, 1987; 1988c; Oleszek, 1987). Cover crop residues and other plant debris have been reported to cause significant reductions in seedling survival and growth (Buntley, 1986; Dabney et al., 1986; Menges, 1987), as well as seed cotton yield reductions (Rickerl et al., 1988). Residues of the weed, Palmer amaranth (*Amaranthus palmeri* S. Wats.), release volatiles into the rhizosphere in sufficient quantity to inhibit the germination and seedling development of onion, carrot, and tomato and Palmer amaranth itself (Bradow and Connick, 1987). The volatile emissions profiles of one- and 15-day post harvest dried residues of *A. palmeri* (Connick et al., 1987) and *A. hybridus, A. cruentus, A. spinosus*, and *A. hypocondriacus* (Connick et al., 1989) have been reported, and the relative reductions in seed germination produced by the methyl ketones and related alcohols and aldehydes identified in those profiles have been described (Bradow and Connick, 1988a, b).

To provide further information necessary for the proper management of

crop residues in cover crop and reduced tillage situations, profiles of the volatiles emitted by residues of three winter cover crop legumes, Berseem clover (*Trifolium alexandrinum* L.), hairy vetch [*Vicia hirsuta* (L.) S.F. Gray], and crimson clover (*Trifolium incarnatum* L.), were determined. This paper also presents plant residue emission profiles from herbicide-treated residues of the common cotton-field weed, purple nutsedge (*Cyperus rotundus* L.) and end-of-season, mature woody cotton (*Gossypium hirsutum* L.) stems and roots. Vapor-phase seed germination bioassays of the effects of ethyl butyrate, geraniol, farnesol, and 31 compounds identified in these plant residue emission profiles were conducted.

METHODS AND MATERIALS

Plant Residues. The three winter cover crop legumes, *Trifolium alexandrinum* L. (Berseem clover cv. Bigbee), *Vicia hirsuta* (L.) S.F. Gray (hairy vetch), and *Trifolium incarnatum* L. (crimson clover cv. Tibbee), were inoculated with appropriate *Rhizobium* strains and planted after fall cotton plow-down in mid-December, 1986. The aerial portions were harvested in late March 1987, after flower anthesis and immediately before field preparation for the 1987 cotton crop.

Aerial and root portions of *Cyperus rotundus* L. (purple nutsedge) were harvested from between rows of *Gossypium hirsutum* L. (cotton cv. Stoneville 825) seven days after the application of the herbicide, MSMA (monosodium methane arsonate). Rainfall during the period between herbicide application and harvest was 1.3 cm.

Mature woody main stems and roots of *Gossypium hirsutum* L. (cotton, cv. Stoneville 825) were collected in mid-October 1987. The cotton had been hand-harvested and was not treated with defoliant.

Bioassay Materials. Chemicals used in the bioassays were purchased from Aldrich Chemical Company (Milwaukee, Wisconsin) with the exception of a 4-methyl-2-pentanone and 5-methyl-2-heptanone, which were obtained from Polyscience Corp. (Nile, Illinois). Cover crop legume and assay seeds were purchased from commercial sources.

Volatiles Trapping Procedure. All nonwoody plant materials were cut into 0.5- to 2.5-cm pieces and allowed to air-dry in the laboratory for one or 15 days before analysis. Woody purple nutsedge roots and cotton stems and roots were cut into 1- to 3-cm pieces and pounded with a mallet before air-drying. Volatiles from the separate plant residues were collected as previously described (Connick, et al., 1987). A sample of plant residue (80 g if dried for one day or 20 g if dried for 15 days) was placed in a 1.2-liter glass solvent storage bottle with Teflon inlet and outlet valves. Ultrapurified water (10 ml) was added, the

valves closed, the bottle wrapped in aluminum foil, and the sample incubated for daily cycles of 10 hr at 31°C and 14 hr at 21°C. A glass tube (84 mm long × 9 mm OD × 1 mm wall thickness) packed with 0.1 g Tenax GC (60–80 mesh) and preconditioned at 220°C (24 hr, 15 ml/min He) was attached to the exit valve of the sample bottle and swept through with headspace atmosphere by purified nitrogen (20 min, 100 ml/min). Two Tenax tubes were collected sequentially for each plant residue. Volatile control profiles were collected using only 10 ml water in the sample bottle.

GC-MS Analysis. For separation and identification, plant residue volatiles were thermally desorbed from the Tenax tubes in an external, closed inlet system (Scientific Instrument Service, River Ridge, Louisiana) interfaced with a Perkin-Elmer Sigma 300 GC/Finnigan MAT Ion Trap Detector (ITD) model 700 unit (Connick et al., 1989). The capillary GC column was 50 m × 0.31 mm ID coated with 0.52 μm of 5% phenyl methyl silicone (Hewlett-Packard Ultra-2). Volatiles were desorbed according to the thermal protocol of Connick et al. (1989). Compounds were considered to be positively identified if their retention times and mass spectra matched those obtained using authentic compounds run on the GC-ITD under the same conditions as the residue volatile mixtures.

Time-Dependent Seed Germination Bioassays. The desiccator seed germination assay technique used is the same described previously (Bradow and Connick, 1987, 1988a, b; Connick et al., 1987). Seeds of onion (*Allium cepa* L., cv. Texas Early Grano 502), carrot (*Daucus carota* L., cv. Danvers Half-Long) or tomato (*Lycopersicon esculentum* Mill., cv. Homestead) were spread on double sheets of deionized water-saturated Whatman No. 1 filter paper placed on the porcelain plate of a 2.5-liter glass desiccator. Circles (22 mm diam.) had been removed from the filter paper to facilitate diffusion of volatiles, and the filter paper circles were divided into eight equal segments (replicates) containing 20 seeds each. Each desiccator well contained a 10-ml glass beaker (volatile source) resting on 50 g of pure sand in a crystallizing dish (100 × 50 mm). The sand was moistened with 10 ml of deionized water. The source beaker was left empty in the controls.

In the time-dependent studies, a volume equivalent to 34.4 μM/liter (full volatilization assumed) of the volatile test compound was placed undiluted in the source beaker, and the separate seed species were incubated under the same temperature regimen used in the volatile-trapping procedure for 72 hr before germination evaluation (three-day data). Radicle protrusion was the germination criterion. The source beaker was then either removed (three- + four-day data) or the test volatile was renewed by the addition a second 34.4 μM equivalent (seven-day data). All seeds were then incubated an additional four days before final evaluation. Each assay was performed two times (16 replicates, total), and controls (deionized water) were repeated at three-month intervals throughout

the duration of the experiments. Germination of the controls did not change significantly during the course of the experiment (data not shown).

Concentration-Dependent Seed Germination Bioassays. The source beaker of the desiccator apparatus contained the appropriate volume of a single test compound to give a nominal volatile concentration of 6.9, 20.8, or 34.4 μM/liter, assuming total volatilization and negligible adsorption. The volume of each test volatile was adjusted on the basis of the compound density and added undiluted to the source beaker, using a microliter syringe (Bradow and Connick, 1988a). Seed germination was evaluated after a three-day exposure to a test volatile, the volatile source was removed, and the seeds were incubated for an additional four days. In both types of bioassays, the humidity within the desiccators was maintained by the addition of 10 ml deionized water after the three-day germination evaluation.

Statistical Analyses. After normalization by the transformation $(x + 0.5)^{0.5}$, germination count data from the concentration-dependent bioassays and the seven-day and three- + four-day time-dependent assays were compared separately for each seed species by two-way analyses of variance with 16 replicates. Within the three-day, seven-day, and three- + four-day data, one-way analyses of variance were used to determine significant differences between the mean effects of 34.4 μM/liter of the test compounds and appropriately incubated deionized water controls, using Tukey's Honestly Significant Difference procedure (significance level, $P = 0.01$). The concentration dependence data were examined by regression analysis (Sokal and Rohlf, 1981). To permit comparisons with data from previous papers (Bradow and Connick, 1988a, b), one-way analyses of variance were performed on the data from the time dependence (34.4 μM) bioassays of all volatiles tested for this and the other publications.

RESULTS

Volatile Emissions from Plant Residues. The compounds identified in the emissions from the residues of the three winter legumes, purple nutsedge, and cotton roots and stems are shown in Table 1. Two branched-chain alcohols, 2-methyl-1-propanol and 3-methyl-1-butanol, were the only compounds found in all the volatile mixtures examined. Acetaldehyde appeared to be present in the emissions from all nonwoody residues, but the GC retention time was too short to allow positive identification (Connick et al., 1989). Small, but identifiable, amounts of *n*-pentane, ethanol, methylene chloride, chloroform, and benzene were found in the water controls, indicating that the strong *n*-pentane peaks obtained from residues of the legumes and nutsedge may be a partial artifact. The *Z* and *E* forms of 3-hexen-1-ol and 4-methyl-2-pentene isomers were not separated, but both isomers were bioassayed.

[a] Observed: [+]; major peak: [++]; not observed: [−].
[b] Specific isomer not determined.

The following compounds were found in the volatile profiles from the three cover crop legumes: *n*-pentane, *n*-nonane, 2-methyl-1-propanol, 2-butanol, 3-methyl-1-butanol, 1-hexanol, 3-hexen-1-ol, 2-butanone, 3-pentanone, 2-heptanone, 3-octanone, 2-nonanone, methyl acetate, ethyl propionate, and 2-ethylfuran. The volatile mixtures from the two clovers, but not the vetch, also contained 2-propanol and 2-pentanol. The volatiles emitted by vetch contained 4-methyl-2-pentene, which was not found in the emissions from the legumes but did occur in those from aerial nutsedge.

Aerial purple nutsedge volatile emissions were similar to those of the three winter legumes. Of the compounds listed above as ubiquitous in the legume emissions, only 3-octanone, 2-nonanone, and methyl acetate were not present in the aerial nutsedge mixtures. 4-Methyl-2-pentene, 1-pentanol, nonanal, and *trans*-2-hexenal were unique to aerial nutsedge; and 4-methyl-2-pentene, 2-pentanone, α-pinene, and β-myrcene were emitted by aerial and root parts of nutsedge, but not by the winter legumes. Nutsedge aerial and root portions released more terpenes than did the winter legumes. Drying the plant residues for 15 days altered the volatile profiles quantitatively, but not qualitatively.

The woodier tissues, the purple nutsedge roots, and the cotton roots and stems qualitatively and quantitatively emitted fewer volatiles than did the more succulent green aerial plant parts. Extensive maceration, in contrast to simple chopping, was necessary to release identifiable levels of volatiles from the woodier tissues at the ambient temperatures used in these experiments. Ethyl 2-methylbutyrate was unique to the woody nutsedge roots and cotton. Pentane, 2-heptanone, 2-butanone, and 2-ethylfuran appeared in the every volatile profile examined except that of cotton wood.

Effects of Plant Residue Volatiles on Seed Germination. The generation effects of five methyl ketones (Bradow and Connick, 1988a), three alcohols, acetaldehyde, and 3-pentanone (Bradow and Connick, 1988b), listed in Table 1, have been described previously. The terpenoids, geraniol and farnesol, occur as unstable pyrophosphates in the mevalonate pathway, which is ubiquitous in plants (Goodwin and Mercer, 1983), and were included in the bioassays as examples of monoterpenoid and sesquiterpenoid alcohols, but neither compound was detected in any volatile profile examined. The *Z* and *E* isomers of 3-hexen-1-ol and 4-methyl-2-pentene were assayed separately to permit examination of the effects of hydrocarbon chain isomerization. Ethyl butyrate was not detected in any of the volatile emission mixtures tested, but it was included to allow structure–activity comparisons with ethyl isobutyrate and ethyl 2-methylbutyrate, which were detected in the volatiles from purple nutsedge and cotton.

Onion Seed Germination. After a three-day exposure to 6.9 μM, the vapors of all test compounds except 3-methylbutanal, 4-methyl-2-pentanone, 5-methyl-2-heptanone, and 3-octanone significantly inhibited onion seed germination, compared to the water controls (Table 2). The most inhibitory compound at this

concentration was (*E*)-2-hexenal. Germination was reduced to 50% of that observed in the control by the hydrocarbons *n-pentane, n*-octane, and *n*-nonane; both 4-methyl-2-pentene isomers; the alcohols 1-propanol, 2-propanol, 1-pentanol, and (*Z*)-3-hexen-1-ol; the aldehydes pentanal, 2-methybutanal, (*E*)-2-hexenal, and nonanal; the esters methyl acetate, ethyl propionate, ethyl isobutyrate, ethyl butyrate, and ethyl 2-methybutyrate; by both furans, and by all five terpenoids.

When concentrations of test volatiles were increased to 20.8 μM, only 4-methyl-2-pentanone and 5-methyl-2-heptanone did not significantly inhibit onion germination. Exposure for three days to 34.4 μM of the test volatiles, *n*-octane, *n*-nonane, both 4-methyl-2-pentene isomers, 3-octanone, and all alcohols, aldehydes, esters, furans, and terpenoids from Table 2, reduced onion seed germination to less than 50% of control germination. At the lowest concentration (*E*)-2-hexenal prevented onion germination entirely; and (*Z*)-3-hexen-1-ol, 3-methylbutanal, nonanal, and pentanal were nearly as inhibitory, followed by ethyl butyrate and ethyl isobutyrate.

Regression analysis showed that, when the data for the water control were included, the concentration dependence of the effects of each of the test compounds had a significant linear component. However, flat responses to most of the compounds over the assay concentration range used contributed significant regression deviation from the linear. Simple linear concentration-dependent effects were seen only in onion seeds exposed for three days to n-hexane, (*E*)-3-hexen-1-ol, and ethyl acetate. Increasing concentrations of 4-methyl-2-pentanone and 5-methyl-2-heptanone had no effect on onion germination. There were no significant changes in slope in the three- + four-day concentration-dependent data, which have, therefore, been omitted from this table.

When the volatile source was removed after the three-day exposure and seed germination evaluated under an exhausting safety hood, an additional four-day incubation allowed onion seeds exposed to all test compounds, except 1-propanol, (*Z*)-hexen-1-ol, pentanal, 3-methylbutanal, (*E*)-2-hexenal, nonanal, ethyl acetate, ethyl propionate, ethyl butyrate, and ethyl 2-methylbutyrate, to germinate as fully as the water controls. After this additional incubation in the absence of the test volatile, germination of only those seeds originally exposed to 3-methylbutanal, hexenal, and ethyl butyrate was below 50% of the germination observed in the water controls after a seven-day incubation period. These same three compounds, plus ethyl 2-methylbutyrate, reduced onion seed germination to less than 50% of water control germination after a continuous seven-day exposure. Continuous seven-day exposure to all the hydrocarbons, 2-propanol, 2-butanol, (*Z*)- and (*E*)-3-hexen-1-ol, pentanal, nonanal, 2-ethylfuran, and β-myrcene also significantly inhibited onion germination.

Carrot Seed Germination. Carrot seeds were less sensitive than onion seeds to a three-day exposure to 6.9 μM levels of the volatiles (Table 3). Only *n*-pentane, (*E*)-2-hexenal, nonanal, the three ketones, ethyl butyrate, ethyl 2-

[a] Percentages are the means of 16 replications. Values in columns followed by the same letter and associated with a given exposure time are not significantly different ($P = 0.01$). Standard errors of the means were $< 1.8\%$.

methylbutyrate, and 2-ethylfuran significantly inhibited germination at that concentration. When carrot seeds were exposed to 20.8 μM of the test volatiles, germination was reduced to 50% of the control values by (*E*)-2-hexenal, nonanal, 4-methyl-2-pentanone, 5-methyl-2-heptanone, ethyl propionate, ethyl isobutyrate, ethyl butyrate, and 2-methylfuran. At this concentration *n*-pentane, 2-propanol, (*Z*)-3-hexen-1-ol, 3-octanone, ethyl 2-methylbutyrate, 2-ethylfuran, and geraniol also significantly inhibited carrot seed germination. When the concentrations were increased to 34.4 μM, all volatiles tested except the four saturated alkanes, the two 4-methyl-2-pentene isomers, 2-butanol, methyl acetate, ethyl acetate, 2-ethylfuran, α-pinene, β-myrcene, and farnesol significantly inhibited carrot seed germination. A three-day exposure to 1-pentanol, both 3-hexen-1-ol isomers, pentanal, (*E*)-2-hexenal, 2-methylbutanal, 3-methylbutanal, nonanal, all three ketones, ethyl propionate, ethyl isobutyrate, ethyl butyrate, 2-methylfuran, and limonene reduced carrot seed germination percentages to below 50% of the control values.

Regression analyses showed that the response of carrot seed to increasing volatile concentrations were linear in the case of 2-propanol, 1-pentanol, the three ketones, methyl acetate, ethyl acetate, ethyl isobutyrate, ethyl 2-methylbutyrate, 2-methylfuran, and geraniol. Increasing concentrations of *n*-nonane, (*E*)-4-methyl-2-pentene, and farnesol had no effect, and increasing the concentration of *n-pentane,* (*Z*)-4-methyl-2-pentene, 2-ethylfuran, and α-pinene from 6.9 to 34.4 μM reduced the inhibitory effect of exposure to these compounds and produced nonlinear response curves. The concentration-dependence regressions obtained for all other test compounds in the carrot seed bioassay had both significant linear and nonlinear components.

When the volatiles source was removed and the carrot seeds were incubated an additional four days, the initial three-day exposure to 34.4 μM (*E*)-2-hexenal proved sufficient to completely prevent carrot seed germination. Of the other test compounds, only 3-methylbutanal and nonanal residually inhibited carrot seed germination. There were no residual effects from exposure to lower concentrations of any of the compounds except (*E*)-2-hexenal, 3-methylbutanal, and nonanal, and the slopes of carrot seed responses to those three compounds did not change over the additional four days of incubation (data not shown). Continuous exposure for seven days to the two 4-methyl-2-pentene isomers increased carrot seed germination to levels significantly higher than the germination percentage of the control. The three compounds that had a residual effect on carrot seed germination, plus ethyl propionate, reduced carrot seed germination to less than 50% of the control value after a seven-day continuous exposure. 3-Octanone, ethyl isobutyrate, ethyl butyrate, and ethyl 2-methylbutyrate also significantly inhibited carrot seed after a seven-day exposure.

Tomato Seed Germination. A three-day exposure to 6.9 μM (*E*)-3-hexen-1-ol, 4-methyl-2-pentanone, 5-methyl-2-heptanone, methyl acetate, 2-ethyl-

furan, α-pinene, and geraniol reduced tomato seed germination to less than 50% of the germination observed in the water controls (Table 4). Significant inhibition was also observed in tomato seeds exposed to the same concentration of *n*-pentane, *n*-octane, 2-methylbutanal, nonanal, ethyl propionate, 2-methylfuran, limonene, and β-myrcene. At 20.8 μM, a three-day exposure to all of these compounds plus 2-butanol, (*Z*)-3-hexen-1-ol, pentanal, (*E*)-2-hexenal, 3-methylbutanal, (*E*)-2-hexenal, 3-octanone, ethyl isobutyrate, ethyl butyrate, and ethyl 2-methylbutyrate significantly inhibited the germination of tomato seeds. At 34.4 μM, all the test compounds except *n*-nonane, the two methyl pentene isomers, ethyl acetate, ethyl propionate, 2-ethylfuran, and farnesol inhibited tomato germination significantly. Significant residual inhibition after the removal of the volatile source and an additional four-day incubation was observed in tomato seeds initially exposed for three days to (*E*)-2-hexenal and nonanal. There were no significant residual effects observed in tomato seeds exposed to 6.9, 20.8, or 34.4 μM levels of any of the other compounds, and the slopes of the tomato seed residual responses to the three levels of (*E*)-2-hexenal and nonanal did not differ from those obtained after the initial three-day exposure (data not shown). Continuous seven-day exposure to 3-methyl butanal, (*E*)-2-hexenal, nonanal, 3-octanone, ethyl butyrate, and ethyl 2-methylbutyrate significantly inhibited tomato germination, but only the hexenal and nonanal reduced germination to below 50% of the control.

The only linear responses to increasing volatile concentration were observed when tomato seeds were exposed to *n*-hexane, *n*-octane, 2-methylfuran, and limosene for three days. Null concentration effects were observed in tomato seeds exposed to *n*-nonane, and the two 4-methyl-2-pentene isomers. All other tomato seed concentration response regressions had significant linear components and significant deviations from linearity.

DISCUSSION

The literature offers few direct comparisons with volatile emission profiles obtained for plant residues through passive Tenax trapping techniques. The "green plant" volatiles identified in the leaf odor blends from Solanaceae (Visser et al., 1979; Visser, 1983) and Cruciferae (Wallbank and Wheatley, 1976) contained significant levels of straight chain C_6 saturated and unsaturated alcohols, aldehydes, and the derivative acetates. In plant residue emissions, hexanal was identified in the volatile profile of *Amaranthus palmeri* (Connick et al., 1987). By comparison, 1-hexanol and the 3-hexen-1-ol isomers were found in the profiles obtained from the aerial parts of the three legumes and purple nutsedge, and (*E*)-2-hexenal was identified in the volatiles emitted by the nutsedge aerial parts (Table 1). The only compounds found in the volatiles released by

[a] Percentages are the means of 16 replications. Values in columns followed by the same letter and associated with a given exposure time are not significantly different ($P = 0.01$). Standard errors of the means were $< 1.5\%$.

freshly harvested aerial parts of red clover (*Trifolium pratense* L.) that also occur in the Berseem and crimson clover residue volatiles were 2-heptanone, 1-hexanol, and 3-hexen-1-ol (Buttery et al., 1984).

The C_6 compounds ubiquitous in leaf odors hypothetically arise from the oxidation of plant leaf lipids (Visser and Ave, 1978), probably through the action of endogenous lipoxygenase and alcohol dehydrogenase (Eriksson, 1975). In contrast, the plant residue emission mixtures contained mostly methyl ketones, alcohols with branched chains or chains of more than six carbons, and relatively few aldehydes (Connick et al., 1987, 1989). None of the compounds identified in the emissions of woody cotton residues were found in the "air space" of growing cotton plants (Hedin et al., 1975b). Plant residue profiles also changed when the pretrapping incubation was anaerobic, but the residue emissions did not change qualitatively with time after an initial air-drying for one day (Connick et al., 1987). The volatiles emitted by plant material clearly depend qualitatively on whether the plant is growing, freshly harvested, or decomposing aerobically or anaerobically.

The woodiness of the tissue and the method of collection also greatly influenced the plant volatile profiles obtained. Steam distillation of green cotton bracts produced a volatile mixture that contained, along with a large number of other compounds, α-pinene, β-myrcene, and 3-methyl-1-butanol (Hedin et al., 1975a). These three compounds were also detected in the volatiles passively emitted by cotton wood. Nonanal, 1-pentanol, (*E*)-2-hexenal, 1-hexanol, and (*Z*)-3-hexen-1-ol were detected in steam distillates from fresh cotton buds (Hedin et al., 1975a) but not in the passive emissions from cotton wood. Fewer compounds were detected using passive Tenax trapping than with harsher distillation techniques (Buttery et al., 1982), but Tenax-trapped volatiles are more representative of natural emissions from both green plants and plant residues. As observed with aerial and root nutsedge emissions (Table 1), the root tissue of corn emitted fewer compounds than does aerial tissue (Buttery and Ling, 1984, 1985).

Although the bioassay species differed in sensitivity to the different volatile compounds, the most inhibitory compound tested was (*E*)-2-hexenal, an emission from residues of aerial nutsedge. Hexenal has also been reported as a general "green plant" volatile (Visser et al., 1979) and identified in the steam distillate from *Amaranthus retroflexus* (Flath et al., 1984). Comparison of time- and concentration-dependent data from this and other publications (Bradow and Connick, 1988a, b) show (*E*)-2-hexenal to be significantly more inhibitory than 2-octanone, 2-nonanone, and 2-heptanone, the most inhibitory volatiles from plant residues reported previously.

In general, using the combined data from this and two previous papers (Bradow and Connick, 1988a, b), aldehydes were the most inhibitory of onion and carrot seed germination, and tomato seeds were most sensitive to ketones.

Onion seeds were more affected by the presence of volatile esters, particularly ethyl 2-methylbutyrate and ethyl butyrate, than were carrot and tomato seeds. Tomato seeds were not sensitive to terpenoid vapors than were onion and carrot seeds. The inhibitory activity of a specific volatile compound was related to the nature and position of the functional groups present and the length and degree of unsaturation of the hydrocarbon chain.

Decreases and retardations of seed germination are not the only ecologically significant effects that can be attributed to allelochemicals emitted into the soil atmosphere by plant residues. Some of the inhibitory compounds characterized in this and earlier papers (Bradow and Connick, 1988a, b) also stimulate the germination of competitive weeds (French and Leather, 1979; French et al., 1986) and the spores of pathogenic fungi (French, 1984; French et al., 1986). Volatiles from plant residues can also stimulate sclerotial (King and Coley-Smith, 1968; Linderman and Gilbert; 1969) and mycelial growth (Menzies and Gilbert, 1967). Many of these same compounds that retard seed germination and promote fungal growth are also insect attractants (Visser, 1979; 1983; Visser et al., 1979; Light et al., 1988) and retard seedling root elongation (Bradow and Connick, 1988c). Thus, seeds and seedlings already stressed by the presence of plant residue volatiles in the root zone become more susceptible to attack by fungi and insects.

Our results show that the "green plant" volatiles emitted by very fresh plant residues are extremely inhibitory to seed germination. This indicates that any tillage practice that incorporates large amounts of fresh green cover crop into the seeding zone immediately prior to planting should be avoided. Furthermore, dried plant residues, after rehydration, emitted detectable levels of inhibitory volatiles for more than four months after harvest (Bradow and Connick, 1987). The even-number carbon chain methyl ketones released from plant residues under anaerobic conditions are among the most inhibitory volatile allelochemicals. Volatile emissions from plant residues may have a decisive role in the success of any agricultural practice that involves incorporation of large quantities of plant material into the soil.

(Received November 21, 1988; accepted April 13, 1989)

Abstract—Structure–activity relationships for chain-shortened analogs of (Z)-5-decenyl acetate, a pheromone component of the turnip moth, *Agrotis segetum*, have been studied by electrophysiological single-sensillum technique and interpreted in terms of a previously reported receptor–interaction model. The results indicate that the terminal methyl group, as well as the acetate group, interacts with highly complementary receptor sites. The terminal alkyl chain is suggested to interact with a hydrophobic "pocket" extending over the two methylene groups closest to the terminal methyl group. The amounts of stimulus actually released from the odor source have been studied. The results demonstrate the necessity to take differences of volatility into account in comparisons of electrophysiological data for compounds of different chain lengths. It is shown that relative vapor pressures may to a good approximation be employed to estimate correction factors.

Key Words—Structure–activity, single-cell recordings, receptor interaction, (Z)-5-decenyl acetate, chain-shortened analogs, volatility, vapor pressure, *Agrotis segetum*, Lepidoptera, Noctuidae.

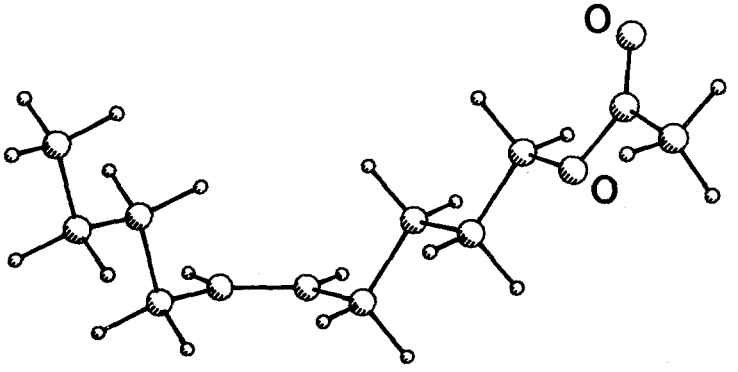
INTRODUCTION

In a series of papers, we have reported the development and applications of a model for the interaction between a monoolefinic pheromone component and its receptor, employing structures and conformational energies calculated by the molecular mechanics method (Liljefors et al., 1984, 1985, 1987; Bengtsson et al., 1987). This model has been successfully used to rationalize the effects of chain elongation (Liljefors et al., 1985, 1987), change of double-bond configuration (Liljefors et al., 1987), and the introduction of an additional (*E*)-double bond at various positions (Bengtsson et al., 1987) on electrophysiological single-cell activities of analogs of (Z)-5-decenyl acetate (**1**), a sex pheromone component of the turnip moth, *Agrotis segetum* (Bestmann et al., 1978; Arn et al., 1980; Löfstedt et al., 1982).

Furthermore, the receptor–interaction model has been employed to predict the biologically active conformation of (Z)-5-decenyl acetate (Bengtsson et al., 1987). The predicted conformation is shown in Scheme 1. This prediction has recently been corroborated by the use of conformationally constrained analogs (Bengtsson, 1988).

The basic idea in our previous structure–activity studies is that, in order to show activity, it is necessary for an analog to mimic the natural pheromone component with respect to the spatial locations of the acetate group, the double-bond, and the terminal methyl group. It is assumed that the receptor cavity contains highly complementary interaction sites for these three molecular parts. All analogs previously studied were chosen for their ability to mimic the natural substrate in this respect through conformational rearrangements. We found that the observed electrophysiological activities for such analogs were determined essentially by the conformational energies required for the analogs to mimic the natural substrate.



SCHEME 1.

Since our receptor–interaction model at the present stage of its development requires mimicking of the acetate group, the double bond, and the terminal methyl group of the natural substrate, it cannot be applied to compounds that are unable to mimic the natural substrate in this respect. Thus, an important class of analogs that presently cannot be treated by our model is chain-shortened analogs. The acetate group, the double bond, and the terminal methyl group in this type of compound cannot simultaneously interact optimally with all three receptor sites of our model.

Chain shortening has consistently been found to lead to a decrease in the activity. However, for analogs one or two methylene units shorter than the natural component, a significant amount of the activity seems to be retained (Priesner et al., 1975; Priesner, 1979a,b, 1983; Struble and Byers, 1987).

Most of the previous studies on chain-shortened analogs have been performed with the EAG technique or by field-trapping experiments. Since chain-shortened analogs may be structurally very close to more than one of the components in the pheromone blend of the studied species, they may interact with more than one receptor type. Thus, the results of such studies are not suitable to be directly interpreted in terms of interactions with a single receptor type. In this respect, only single-cell recordings can provide unambiguous experimental data.

In order to further develop our receptor-interaction model, we have in the present paper studied a series of chain-shortened analogs, compounds **2–7**, of (*Z*)-5-decenyl acetate **1** (Figure 1). We report the synthesis of and electrophysiological single-cell measurements on them. The implications of the experimental data on the shape and other properties of the receptor cavity are discussed.

To corroborate the results, the accuracy of the stimulation system was investigated with respect to differences in volatility between test compounds and different amounts loaded onto the odor source.

METHODS AND MATERIALS

Chemicals. Final products were purified by flash chromatography (Taber, 1982a,b) on TLC-Silica gel 60 H supplied by Merck, and by argentation chromatography (Houx et al., 1974). All products were at least 98.5% pure and at least 99.7% pure with respect to geometric isomers as determined by capillary GLC on a Supelcowax 30-m or DB-Wax 30-m column.

Saturated acetates used for the methodological studies were from different sources, with the overall chemical purity always more than 95%.

Mass spectra were recorded on a Finnigan 4021 mass spectrometer, ^{1}H and ^{13}C NMR spectra on a Varian XL-300, a Nicolet 360 WB, or a Jeol FX-

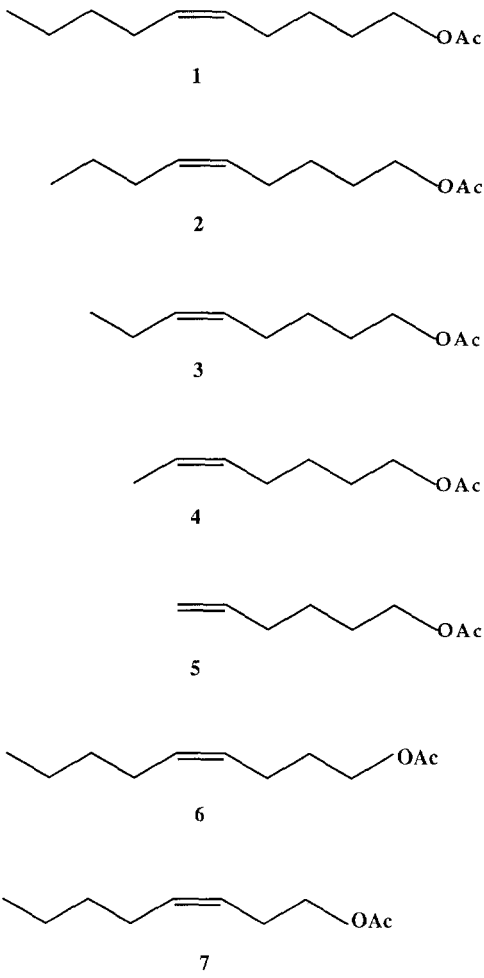


FIG. 1. Compounds studied.

60 spectrometer. NMR spectra were recorded on $CDCl_3$ solutions with Me_4Si as internal reference. For some of the products, the ^{13}C signal for the carbonyl carbon was of too low an intensity to be unambiguously identified.

DMPU was purchased from Fluka AB. Immediately before use, it was distilled over CaH_2 at reduced pressure and kept over 4 Å molecular sieves under an argon atmosphere.

(Z)-5-Decenyl Acetate (1). This was prepared as previously described (Olsson et al., 1983).

(Z)-5-Nonenyl Acetate (2). Ethyl 4-bromobutyrate was reduced with lith-

ium aluminium hydride, and the resulting bromoalcohol was protected with dihydropyran, according to standard procedures, affording 4-(2-tetrahydropyranyloxy)-1-bromobutane that was distilled at reduced pressure in base-washed glassware, bp 66–73°C/0.2 mm Hg. To a solution of liquid ammonia (100 ml) and dry ether (10 ml) at −78°C under a nitrogen atmosphere, lithium amide (0.92 g, 0.04 mol) was added in portions. The mixture was stirred for 20 min, and 1-pentyne (2.11 g, 0.03 mol) was added, according to a method described for similar systems by Berger and Canderday (1968). After stirring for an additional 45 min, 4-(2-tetrahydropyranyloxy)-1-bromobutane (5.00 g, 0.02 mol) dissolved in dry ether (25 ml) was slowly added. The resulting mixture was stirred for 2 hr at −78°C and then allowed to slowly warm up to room temperature while the ammonia evaporated. Water (50 ml) was added, and the resulting solution was extracted three times with hexane. The combined organic layers were washed with saturated NaCl solution and dried over $MgSO_4$. Removal of the solvent gave the crude product (4.04 g, 89%). Reduction with Lindlar catalyst (Lindlar, 1952; Maurer and Grieder, 1977; Leznoff et al., 1977; Marvell and Li, 1973; Wong et al., 1984), followed by acetylation (Schwartz and Waters, 1972) of the tetrahydropyranyl ether gave **2.** δ_H (300 MHz) 0.90 (t, 3H, Me), 1.31–1.46 (m, 4H, CH_2CH_2), 1.59–1.69 (m, 2H, $CH_2{-}C{-}O$), 1.96–2.10 (m, 4H, $CH_2C{=}$), 2.04 (s, 3H, Me−COO), 4.06 (t, 2H, $CH_2{-}OCO$), 5.34–5.40 (m, 2H, J_{AB} = 10.5 Hz, CH=CH). δ_C (75.4 MHz) 13.8, 20.9, 22.8, 26.0, 26.7, 28.2, 29.1, 64.5, 129.2, 130.3, 171.2. *m/z*: 124 (M^+-60; 7%), 109(1), 96(24), 81(35), 67(37), 61(2), 54(45), 43(100).

(Z)-5-Octenyl Acetate (3). 4-(2-Tetrahydropyranyloxy)-1-bromobutane (17.6 g, 0.074 mol) was reacted with lithium acetylide, ethylenediamine, complex, affording 14.4 g (62%) of 1-(2-tetrahydropyranyloxy)-5-hexyne (Smith and Beumel, 1974; Rossi et al., 1980; Jäger, 1977). Butyllithium (6 ml of a 1.44 M solution in hexane) was slowly added to 1-(2-tetrahydropyranyloxy)-5-hexyne (1.5 g, 8.2 mmol), dissolved in dry THF (8 ml). The solution was stirred at room temperature for 2 hr. Ethyl iodide (2.0 g, 0.013 mol) dissolved in DMPU (14 ml, freshly distilled from CaH_2) was added at such a rate that the temperature did not exceed 25°C (Bengtsson and Liljefors, 1988). The solution was stirred for 3 hr, then poured into ice water (50 ml) and extracted with hexane. The combined hexane layers were washed with saturated NaCl solution and dried over $MgSO_4$. After removal of the solvent, 1.69 g (92%) of crude 1-(2-tetrahydropyranyloxy)-5-octyne was obtained. After hydrogenation with Lindlar catalyst and acetylation, **3** was obtained. δ_H (300 MHz) 0.95 (t, 3H, Me), 1.38–1.46 (m, 2H, CH_2CH_2), 1.59–1.68 (m, 2H, $CH_2{-}C{-}O$), 2.01–2.10 (m, 4H, $CH_2C{=}$), 2.04 (s, 3H, Me−COO), 4.06 (t, 2H, $CH_2{-}OCO$), 5.28–5.41 (m, 2H, J_{AB} = 10.7 Hz, CH=CH). δ_C (75.4 MHz) 14.3, 20.5, 21.0, 26.0, 26.6, 28.1, 64.4, 128.4, 132.1, 171.2 *m/z*: 110 (M^+-60; 9%), 95(6), 82(40), 67(52), 61(2), 55(19), 43(100).

(Z)-5-Heptenyl Acetate (4) was prepared from 1-(2-tetrahydropyranyloxy)-5-hexyne and methyl iodide, according to the same procedure as described above for **3.** δ_H (300 MHz) 1.36–1.47 (m, 2H, CH_2CH_2), 1.58–1.69 (m, 5H, MeC=, CH_2—C—O), 2.03–2.11 (m, 2H, CH_2C=), 2.05 (s, 3H, Me—COO), 4.06 (t, 2H, CH_2—OCO), 5.32–5.52 (m, 2H, J_{AB} = 10.6 Hz, CH=CH). δ_C (75.4 MHz) 12.7, 21.0, 25.8, 26.3, 28.1, 64.5, 124.3, 130.0, 171.3. *m/z*: 96 (M^+-60; 11%), 81(20), 68(64), 61(3), 55(27), 43(100).

5-Hexenyl Acetate (5). 1-(2-Tetrahydropyranyloxy)-5-hexyne was reduced with disiamyl borane (Brown and Zweifel, 1961) and acetylated. δ_H (300 MHz) 1.37–1.48 (m, 2H, CH_2CH_2), 1.56–1.66 (m, 2H, CH_2—C—O), 2.00–2.09 (m, 2H, CH_2C=), 2.01 (s, 3H, Me—COO), 4.03 (t, 2H, CH_2—OCO), 4.91–5.02 (m, 2H, C=CH_2), 5.70–5.83 (m, 1H, CH=C). δ_C (75.4 MHz) 20.9, 25.1, 28.0, 33.2, 64.4, 114.8, 138.3, 171.2. *m/z*: 82 (M^+-60; 13%), 73(2), 67(29), 61(2), 54(35), 43(100). $C_8H_{14}O_2$ calc. C 67.6, H 9.9; found C 67.3, H 9.9.

(Z)-4-Nonenyl Acetate (6). 3-(2-Tetradropyranyloxy)-1-brompropane (prepared from 1-bromo-3-propanol and dihydropyran) was coupled with hexyne in liquid ammonia–ether as described for **2.** δ_H (300 MHz) 0.90 (t, 3H, Me), 1.28–1.35 (m, 4H, CH_2CH_2), 1.63–1.73 (m, 2H, CH_2—C—O), 1.99–2.15 (m, 4H, CH_2C=), 2.05 (s, 3H, Me—COO), 4.06 (t, 2H, CH_2—OCO), 5.31–5.43 (m, 2H, J_{AB} = 11.2 Hz, CH=CH). *m/z*: 124 (M^+-60; 9%), 109(1), 95(15), 81(38), 68(49), 61(1), 54(40), 43(100).

(Z)-3-Octenyl Acetate (7). 2-(2-Tetrahydropyranyloxy)-1-bromoethane (prepared from 1-bromoethanol and dihydropyran) was coupled with hexyne in liquid ammonia/ether as described for **2.** δ_H (300 MHz) 0.90 (t, 3H, Me), 1.30–1.36 (m, 4H, CH_2CH_2), 2.01–2.06 (m, 2H, CH_2C=), 2.04 (s, 3H, Me—CO), 2.36–2.41 (m, 2H, O—C—CH_2—C=), 4.06 (t, 2H, CH_2—OCO), 5.32–5.38 (m, 1H, J_{AB} = 11.2 Hz, CH=C). 5.46–5.52 (m, 1H, J_{AB} = 11.2 Hz, CH=C). *m/z*: 110 (M^+-60; 8%), 95(3), 81(17), 73(2), 68(20), 54(46), 43(100).

Electrophysiology. The biological activities of the pheromone component and of the analogs were investigated by the single sensillum technique (Kaissling, 1974), in which action potentials generated in olfactory sensilla on the male moth antenna were recorded. The method used was modified according to van der Pers and Den Otter (1978). Two days after emergence of the male moth, one of the antennae was excised and mounted in a grounded pipet electrode filled with Beadle-Ephrussi Ringer solution. To establish electrical contact with the olfactory neurons, the tip of a pheromone-sensitive sensillum was cut off. The Ringer-filled recording electrode was placed over the cut surface and connected to a high-impedance amplifier by an Ag–AgCl wire. The responses were stored on a Racal four-channel tape recorder and visualized on a storage oscilloscope.

The stimulus was applied to a piece of filter paper and put into a 5-ml plastic disposable syringe. Two milliliters of the syringe atmosphere was

injected by a hydraulic injection device (Murphy Developments, Hilversum, The Netherlands) into a purified and moistened air stream flushing over the preparation at a speed of 0.5 m/sec. For each stimulus concentration, 10 replicates were recorded.

Olfactory receptor cells specifically tuned to (*Z*)-5-decenyl acetate (**1**) are present in antennal sensilla type SW1 of *Agrotis segetum* and are readily accessible for single-cell recording (Hallberg, 1981; Löfstedt et al., 1982; van der Pers and Löfstedt, 1983). The receptor cell selective for (*Z*)-5-decenyl acetate could unambiguously be distinguished from the other receptor cells present in the sensillum by the amplitude of its action potential (Löfstedt et al., 1982). The responses of this receptor cell were recorded for all analogs.

The receptor cell response was defined by the number of action potentials generated during 1 sec from the onset of the stimulation. Dose–response curves were constructed using five different stimulus concentrations. For the pheromone component, **1**, the stimulus concentration ranged from 10^{-4} μg to 1 μg in decadic steps. For the analogs, the stimulus concentration ranged from 10^{-3} μg to 100 μg in decadic steps. The relative activity of each compound was expressed as the reciprocal of the relative quantities required to elicit the same response from the receptor cell, as the actual pheromone component elicited.

Stimulus Amounts Released from Odor Sources. The quantitative release of stimulus from the syringes used as odor sources (see above) was investigated by capillary gas chromatography on a Hewlett Packard 5830 GC equipped with a flame ionisation detector. Disposable syringes were loaded with stimulus applied to the filter paper in 100 μl of hexane. The syringe was fitted to an injection needle and 2 ml of the 5-ml syringe atmosphere was injected slowly (during approximately 1 min because of the limited flow capacity of the capillary column) splitless into the gas chromatograph. The initial temperature (60°C) was maintained for 2 min following the beginning of the injection. Then the split valve was opened, and the oven temperature was programmed at 5°C/min to 200°C. A 30-m × 0.25-mm-ID fused silica DB-1 column (J&W Scientific, Folsom, California 95630) was used for the separations. Hydrogen was supplied as carrier gas at 40 cm/sec linear velocity.

Six syringes containing a constant amount of the internal standard (*Z*)-5-decenyl acetate (500 μg) and different amounts of decyl acetate (30, 50, 100, 300, 500, and 1000 μg) were prepared to investigate the release of stimulus from odor sources loaded with different amounts of stimulus compound. The amount of decyl acetate relative to the internal standard was estimated in five consecutive injections for each dose. Absolute amounts released were estimated by comparison of peak areas with those obtained when known amounts of decyl acetate were injected split–splitless in 1–3 μl of hexane. In this experiment, the syringe atmosphere was allowed to equilibrate during the time of the preceding analysis (1 hr or more).

A mixture of six saturated acetates (hexyl, heptyl, octyl, nonyl, decyl, and undecyl) and the internal standard **1** was prepared to investigate the relation between volatility and relative amounts released from the odor sources. One hundred micrograms of each saturated acetate and 500 μg of the internal standard in 100 μl of hexane were applied to the odor source filter paper. In one experiment, the relative amounts released in five consecutive injections from the same syringe were investigated as described above. In a second experiment, the amounts released from five different, freshly prepared syringes were quantified. In this experiment, the hexane was allowed to evaporate, the syringe atmosphere were replaced once, and was then allowed to equilibrate during 2 min, before injection of the 2 ml on the GC.

RESULTS AND DISCUSSION

Dose–response curves in insect electrophysiology are usually based on amounts of stimuls applied to the odor source rather than the amount of stimulus to which the insect preparation is actually exposed. Quantification of the stimulus amounts released from the syringes used as odor sources in this and in our previous studies corroborated our assumption that the amounts released are proportional to the amounts applied to the filter paper (Figure 2) within the concentration range usually used in our experiments.

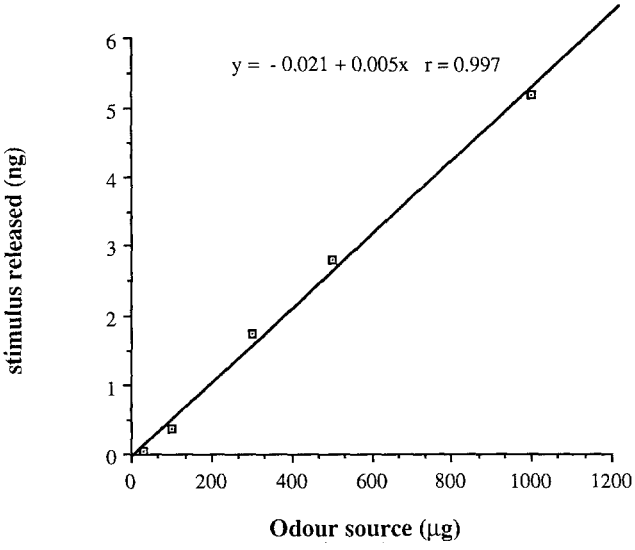

FIG. 2. Amounts of stimulus released from odor sources loaded with different amounts of decyl acetate on filter paper (N = 5).

The amount of a saturated acetate in 2 ml of syringe atmosphere was found to be proportional to the chain length of the acetate (Figure 3). The results of the two different experimental procedures shown in Figure 3A and B are essentially identical. The addition of one methylene unit on the average reduced the released amount by a factor of 3.9 [the average of exp (1.389) and exp (1.349)]. This factor is similar to the factor by which the saturated vapor pressures of straight-chain alkyl derivatives are reduced on the addition of a methylene group on the alkyl chain. Accurate vapor pressures for the entire series of alkyl acetates studied here are not available, but for lower homologs up to pentyl acetate,

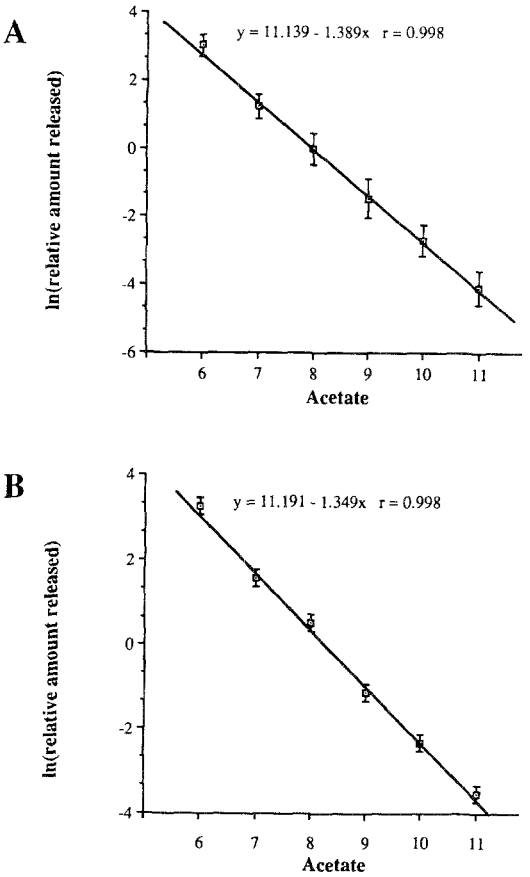

FIG. 3. Natural logarithm of relative amounts released of a homologous series of straight chain acetates (hexyl to undecyl acetate). The data points represent the average of injections from five consecutive injections from the same syringe (A) and five different freshly prepared syringes (B). (See text for further explanation.)

this factor is 2.8 (Jordan, 1954). The relative vapor pressures of decyl acetate (Olsson et al., 1983) and pentyl acetate correspond to a factor of 2.9 for each methylene group added to pentyl acetate. Thus, the relative amounts released from the odor source correspond to a reasonably good approximation to the relative saturated vapor pressures. The relative vapor pressures on chain shortening–chain elongation are similar for different classes of straight-chain alkyl derivatives. For a homologous series of alkanes (6–16 carbons), the corresponding factor is 3.2 (Stein, 1981). For straight-chain aldehydes (8–12 carbons) it is 3.7, and for 1-alkenes (10–13 carbons) it is 3.4 (Dykyj and Rep'as, 1979). Olsson et al. (1983) reported an average factor of 2.6 in the relative vapor pressures of monoenic acetates differing by one methylene unit. This indicates that relative standard vapor pressures may be used to estimate the relative amounts of compounds, differing in volatility, actually released from an odor source.

Our results demonstrate the necessity of corrections for differences in volatility when the electrophysiological activity of compounds with different chain lengths and/or vapor pressures are compared. For instance, with equal amounts of hexyl and decyl acetate at the odor source, approximately 231 times more hexyl acetate will stimulate the antenna if a chain length constant of 3.9 is used. Regardless of the exact value of the constant, corrected stimulus amounts are much more accurate than uncorrected ones.

The electrophysiological single-cell activities for compounds **1–7,** including corrections for volatility differences, are shown in Figure 4. All the chain-shortened analogs show a decrease of the biological activity compared to the natural pheromone component **1.** For the analogs shortened in the n-chain (Scheme 2), a loss of activity is found for each additional CH_2 group removed (compounds **2–5**). The loss of activity is about a factor of 16 for the removal of the first methylene group (compound **2**), and a factor of 6 for the removal of the second one (compound **3**). With further shortening of the *n* chain, the electrophysiological activity decreases drastically, finally giving the essentially inactive compound **5.**

These results are in line with those obtained by Priesner (1979a,b) in EAG screenings of several species of Noctuidae and Tortricidae. For five species, analogs chain shortened by one methylene unit showed activities 5.6–18 times less than those for the natural pheromone component. The analogs chain shortened by two and three methylene units were found to be 18–180 and 180–560 times less active, respectively. On stimulation of a male receptor cell of the

SCHEME 2.

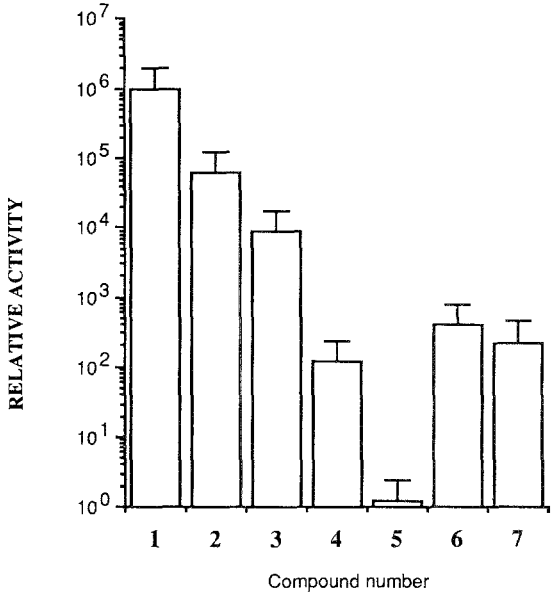

FIG. 4. Experimental single-cell activities for compounds **1–7.** The data are corrected for differences in vapor pressure. Error bars show maximal errors.

tortricid moth, *Adoxophyes orana*, selective for (Z)-9-tetradecenyl acetate, with (Z)-9-dodecenyl acetate, Priesner (1983) observed an activity loss of a factor of 30. Similarly, (Z)-7-decenyl acetate is about 25 times less active than the natural substrate on the (Z)-7-dodecenyl acetate receptor of *Agrotis segetum* (Liljefors et al., 1984). It should be noted that these data from the literature do not take differences in volatility into account.

The results shown in Figure 4 indicate that although the chain length of the natural component **1** is the optimal one, compounds one and two methylene units shorter can interact with and activate the receptor to a significant degree. For instance, compound **3** which is chain shortened by two methylene units, is 10 times as active as the corresponding compound chain elongated by two methylene units (Liljefors et al., 1987). The quite high activities of compounds **2** and **3** indicate that not only the terminal methyl group but also at least the next two methylene groups in the chain may efficiently interact with a hydrophobic region of the assumed receptor cavity, a region which is complementary to the van der Waals surface of the substrate molecule. Thus, the shape of the part of the receptor cavity interacting with the *n* chain may be a deep "groove" or "pocket," at least partly circumscribing the aliphatic chain. Figure 5 shows a clipped dot-surface representation of the van der Waals surface of part of the *n*

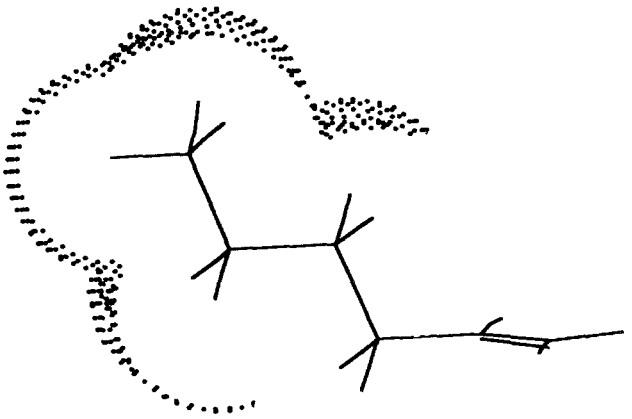

FIG. 5. A cross-section of the van der Waals surface of part of the terminal alkyl chain in compound **1**, indicating the size and shape of the complementary receptor cavity area interacting with this part of the molecule.

chain indicating a possible shape of this region of the receptor cavity. The lower part of the surface in Figure 5 is left undefined. It should correspond to a cavity large enough to accommodate the chain loops formed by chain-elongated analogs according to our receptor–interaction model (Liljefors et al., 1987).

From binding experiments on various enzymes, a maximum binding energy of 3.2 kcal/mol has been evaluated for a methyl group interacting with a site with "perfect" complementarity (Fersht, 1985). This value for hydrophobic binding of a methyl group is somewhat larger than that obtained from free energies of transfer of hydrocarbons from aqueous solution to pure liquid hydrocarbon, 2.1 kcal/mol (Tanford, 1980). Since the cavity in the enzyme is preformed, while the cavity in solution must be created to accommodate the solute, this is to be expected.

In order to make comparisons with binding energies possible, conformational entropies must be taken into account. The chain-shortened analogs **2–5** have one single bond less for each methylene group removed compared to the parent compound **1.** If we assume, as in previous studies (Liljefors et al., 1985, 1987; Bengtsson et al., 1987), that the molecule is rigidly bound to the receptor, the loss of conformational entropy on binding to the receptor is smaller for a chain-shortened analog of **1** than for **1.** Assuming an entropy loss of ca. 4 cal/mol K for "freezing" an internal rotation (Winnik, 1981; Liljefors et al., 1985), this difference may be estimated to be ca. 1 kcal/mol for each methylene unit removed. The maximum binding energy ("perfect" complementarity) for the terminal methyl of compound **1** then becomes $3.2 - 1.0 = 2.2$ kcal/mol.

Previously we found that an increase of the interaction energy of 1.6 kcal/

mol corresponds to an activity decrease by a factor of 10 (Liljefors et al., 1987; Bengtsson et al., 1987). As the activity drops by a factor of 16 on going from compound **1** to compound **2** (Figure 4), this corresponds, according to our model, to a loss of 1.9 kcal/mol of interaction energy. Note that relative activities reflect differences in total interaction energies. The total interaction energy is a sum of intermolecular interaction energies due to hydrophobic interaction, hydrogen bonding, and so on, subtracted by the conformational energy needed for the substrate molecule to acquire the "correct" conformation. In our previous work on compounds that have the ability to mimic the natural pheromone component, differences in total interaction energies only depend on the conformational energy term (Liljefors et al., 1987; Bengtsson et al., 1987). However, for chain-shortened analogs, differences in total interaction energies also depend on the intermolecular interaction energy term.

Shortening of compound **1** by one methylene group removes the methyl group from its interaction site (see Figure 5). Since the calculated energy loss is close to the value for maximum binding energy of a methyl group as derived above, this strongly indicates that the terminal methyl group is interacting with a very high degree of complementarity with its receptor site in the receptor cavity. This supports our model, in which the terminal methyl group of the natural pheromone component **1** is assumed to interact with a very well-defined receptor site (Liljefors et al., 1987).

In our receptor–interaction model, the double bond is also assumed to interact with a well-defined receptor site. This implies that the terminal methyl group in compound **2** cannot interact with the methyl group site in the receptor cavity—the *n* chain is too short. Providing that the "pocket" that binds the *n* chain extends to the methylene unit in the 8-position, shortening of the *n* chain in **2** by one methylene group to give compound **3** should result in a somewhat smaller activity loss than for the corresponding shortening of compound **1.** The decrease in activity should correspond to the loss of hydrophobic interactions of one methylene group, which in energy terms is about one third of the hydrophobic binding energy for a methyl group (Tanford, 1980). The experimental data support this conclusion: the activity drops by only a factor of 6 on going from compound **2** to compound **3** (Figure 4). On further shortening of the *n* chain (compounds **4** and **5**), the observed low activities (Figure 4) indicate that the alkyl groups have no interactions, or only very weak interactions, with the receptor.

When chain-shortening is done in the *m* chain (compounds **6** and **7,** Figure 4), the loss of electrophysiological activity is more dramatic. The removal of one or two CH_2 groups from the *m* chain results in a decrease of the biological activity by a factor of about 3000. From extensive EAG investigations of noctuid moths, Bestmann and Vostrowsky (1982) concluded that structural variations of the alkyl parts of a pheromone component of the investigated species

produce a more drastic loss of activity if the *n* chain is varied than when the equivalent changes are made in the *m* chain. This "structure–activity rule" is not in agreement with the results in Figure 4, and we have previously found that this "rule" is also not in agreement with experimental data for dienic analogs of (Z)-5-decenyl acetate (Bengtsson et al., 1987).

Interestingly, the experimental single-cell data (Figure 4) show that essentially the same loss of activity is obtained with the removal of one or two CH_2 units from the *m* chain. This was also observed by Priesner (1979a,b) in the EAG screening relative to above. Similar observations were done in a single-cell study on pheromone components of some saturniid species (Bestmann et al., 1987). In the single-cell study of *Adoxyphyes orana* mentioned above, Priesner (1983) found that a shortening of the *m* chain of (Z)-9- and (Z)-11-tetradecenyl acetate by two methylene units resulted in an activity decrease by factors of 100 and 30, respectively. When these values are corrected for differences in volatility, the first one is similar to the results we obtain for the corresponding compound **7.**

In our study on modifications of the acetate group and the corresponding effects on the electrophysiological activity (Liljefors et al., 1984), we found very strict requirements on the shape as well as on the electron distribution of the polar functional group for a productive interaction with the receptor. The results in Figure 4 are consistent with this conclusion. If the receptor cavity is highly complementary to the acetate group in **1,** as illustrated in Figure 6, a shortening of the *m* chain in this compound with one methylene group essentially destroys all interactions between the acetate group and the receptor. As shown in Figure 7, the orientation of the acetate group is very different in the

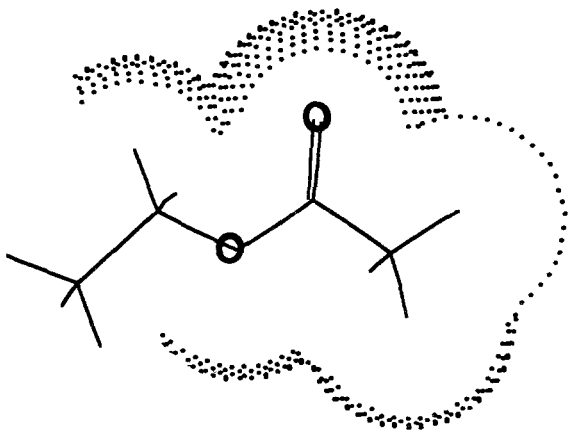

FIG. 6. A cross section of the van der Waals surface of part of the acetate group.

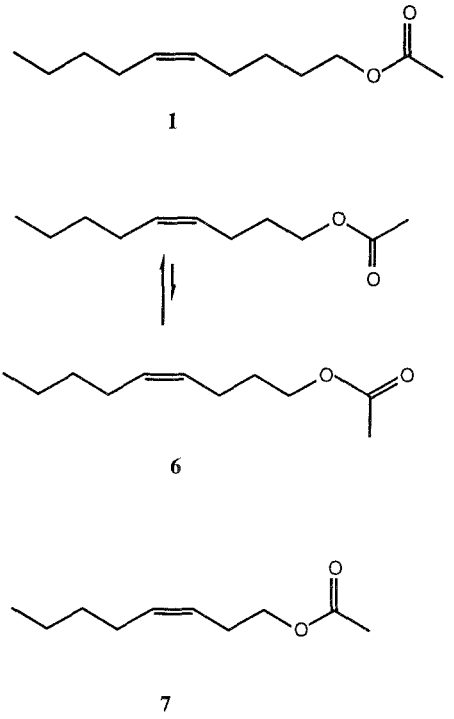

FIG. 7. Orientations of the acetate group in compounds **1**, **6**, and **7**.

thermodynamically preferred conformers of compounds **1** and **6**. We have found previously that the direction of the dipole moment of the polar functional group is of decisive importance for a productive receptor interaction (Liljefors et al., 1984). The direction of the dipole moment of the acetate group is approximately parallel to the carbonyl group. Thus, these dipole moment directions are antiparallel in **1** and **6**, which is incompatible with a productive receptor interaction for **6**. Rotation about the C—O bond in **6** (Figure 7) changes the dipole moment direction of its acetate group, but it is still far away from the optimal direction. Furthermore, such a conformational rearrangement is of prohibitively high energy, 8.5 ± 1.0 kcal/mol (Blom and Günthard, 1981).

Since the type of interaction between the acetate group in **1** and the receptor is not known, it is not possible to calculate the loss of interaction energy on going from compound **1** to **6**. However, as all parts of the acetate group seem to contribute to this interaction energy (Liljefors et al., 1984), this loss should be greater than the loss of interaction energy on removal of a methyl group from its site as discussed above.

In compound **7** the direction of the dipole moment of the acetate group is

the same as in **1** (Figure 7). However, an optimal interaction with the receptor sites by this group removes the double bond and the terminal methyl group from their sites. It is more likely that these interactions are as in **1** and that the acetate group only very weakly interacts with the receptor sites occupied by the acetate group in compound **1.** The experimental data in Figure 4 support this conclusion. Shortening the *m* chain in **6** to give compound **7** should, in this case, only reduce the activity by a factor corresponding to, at most, the loss of the hydrophobic interactions of one methylene group. As discussed above, for the *n* chain this corresponds to an activity drop by about a factor of 6. The observed activity for **7** is lower by a factor of about two compared to that for **6** (Figure 4), which is in reasonably good agreement with this prediction.

CONCLUSIONS

The terminal methyl group as well as the acetate group in the natural pheromone component **1** are concluded to interact with highly complementary sites in the receptor cavity. Thus, the dimensions of the receptor cavity in this respect correspond very closely to the length of the natural substrate. Our analysis of the experimental single-cell data indicates that the *n* chain binds to a hydrophobic "pocket" that extends over the two methylene groups closest to the terminal methyl group. Thus, compounds that are chain shortened by one or two methylene units have sufficiently strong interactions with the hydrophobic "pocket" to activate the receptor to a significant degree.

Chain shortening of one methylene unit in the *m* chain leads to a large drop in activity, probably due to the more or less complete removal of the strong interaction between the acetate group and its receptor sites. Further shortening of the *m* chain leads to a much lower activity loss due to loss of only hydrophobic interactions.

(Received December 15, 1988; accepted April 13, 1989)

Abstract—The defense secretions of the soldiers of the Malaysian rhinotermitid, *Parrhinotermes aequalis* (Havilandi) and *P. pygmaeus* (John), *Termitogeton planus* (Havilandi) and *Schedorhinotermes malaccensis* (Holmgren) consist mainly of vinyl ketones, whereas that of *Prorhinotermes flavus* (Bugnion & Popoff) gives (*E*)-1-nitropentadecene. The chemistry of the defense secretions of *Parrhinotermes* and *Termitogeton* is documented and based on their chemical relationships; *Termitogeton* shows a closer affinity to the Rhinotermitinae than Heterotermitinae.

Key Words—Isoptera, Rhinotermitidae, defense secretions, *Termitogeton*, *Parrhinotermes*, *Prorhinotermes*, *Schedorhinotermes*.

INTRODUCTION

The family Rhinotermitidae in Peninsular Malaysia is represented by six genera belonging to five subfamilies. The soldiers of all these genera have prominent and well-developed mandibles, which they use effectively for the defense of their colonies. In addition, copious amounts of chemicals are produced in their frontal glands that are used for defense. These chemicals are ejected via an opening (fontanelle) on the top of the head capsule during defensive action. The dimorphic soldiers of *Schedorhinotermes* and monomorphic soldiers of *Parrhinotermes* (Rhinotermitinae) have developed large tonguelike labra with a frill of short hairs at the distal end. These are used like brushes to spread the chem-

0098-0331/90/0300-0685$06.00/0

ical secretions as they flow out from the fontanelle. None of the other genera exhibit this morphological adaptation. In *Prorhinotermes* (Prorhinotermitinae), a prominent groove leads away from the fontanelle. *Termitogeton* (Termitogetoninae) and *Heterotermes* (Heterotermitinae) have very small frontal gland openings. In contrast, *Coptotermes* (Coptotermitinae) has large and conspicuous fontanelles, and the frontal gland is prominent and well developed, extending well into the abdominal cavity of the soldier termites.

The chemical secretions of *Schedorhinotermes* and *Prorhinotermes* have been reported to consist mainly of a lipophilic mixture of electrophilic compounds such as vinyl ketones (*Schedorhinotermes*) and nitroolefins (*Prorhinotermes*), which act as contact poisons (Prestwich, 1979b). The daubing-brush method of application of the chemicals as practiced by *Parrhinotermes* and *Schedorhinotermes* must have undergone considerable morphological adaptions over time in order to arrive at its current efficacy (Prestwich, 1979a,b, Prestwich and Collins, 1982).

In this paper we report our investigations on the defense chemicals from Malaysian rhinotermitid species belonging to five genera and their chemical affinities.

Genus *Parrhinotermes* are small termites that feed on woody litter and are mostly found under the bark of trees forming distinct tracks and galleries in the wood they infest. They do not import soil into their feeding sites. The soldiers are monomorphic and are generally smaller than the worker caste. Chemical secretions are released through the frontal glands. Two species, *P. aequalis* (Havilandi) and *P. pygmaeus* (John), were investigated in this study.

Genus *Termitogeton* termites are found in logs of wood infested by wet and brown rot lying on the forest. The monomorphic soliders are flattened dorsoventrally, with legs displaced to the sides of the body. Defense secretions are released through the small frontal opening on the top of the head. Nests are generally found in proximity to the feeding sites. *Termitogeton planus* (Havilandi) is the only species found in Peninsular Malaysia.

Only one species of genus *Prorhinotermes*, *Prorhinotermes flavus* (Bugnion & Popoff), is so far known in Malaysia. This species is commonly found in mangrove swamps. Nests are built inside the stems of dead trees or in the tree stumps on the landward side of the mangrove. Their nests consist of many galleries in the wood. Defense secretions are released through the unmodified frontal gland pore of the monomorphic soldiers.

The genus *Schedorhinotermes* is found generally in closed canopy forests. The soldiers are dimorphic and have very well-developed labra. They nest in dead tree stumps and within hollowed trees. The species *Schedorhinotermes malaccensis* (Holmgren) feed primarily on wood undergoing initial rot. The major soldier is almost twice the size of the minor. Minor soldiers are in turn smaller than the workers. These termites forage under covered trails.

In the genus *Coptotermes* six species are reported in Malaysia. *Coptotermes curvignathus* is by far the most common species and can be found in natural forest, agricultural, and urban areas. The species is a recognized pest of forest and agricultural crops as well as timber and houses. The soldiers are monomorphic and can inflict a vicious bite when agitated. At the same time they release copious amount of a sticky white fluid. The genus is found mainly in tropical regions.

METHODS AND MATERIALS

Collection and Isolation. Part colonies of *Parrhinotermes aequalis*, *P. pygmaeus*, *Schedorhinotermes malaccensis*, *Termitogeton planus*, and *Coptotermes curvignathus* were obtained from Pasoh Forest Reserve in the state of Negri Sembilan; *Prorhinotermes flavus* was collected from Kuala Selangor forest reserve. The soldiers were removed from the colonies and stored in the freezer at −10°C overnight. Extractions of defense secretions from the crushed soldier heads (ca. 10) were carried out using hexane. The crude extracts were then filtered, and the solvent was partially removed in vacuo before analysis.

Analytical Method. Gas chromatography (GC) was performed on a HP 5790a instrument fitted with a flame ionization detector using a 2.1-m × 3-mm 3% OV-101 on 120–140 Gas Chrom Q column. Gas chromatography–mass spectrometry (GC-MS) was performed on a Pye 104 gas chromatograph fitted with the above column interfaced to a double-beam Kratos MS30 mass spectrometer by a membrane separator. Mass spectra were obtained at 70 eV with the MS source at 150°C and membrane interface temperature at 230°C. Mass spectral data were accumulated by a Kratos DS55 data system. The data on the vinyl ketones (Figure 1, **I–IX**) were characterized by GC, GC-MS, and coinjection with frozen and sealed extracts from *Schedorhinotermes lamanianus* Sjöstedt previously supplied by Prestwich for the identification of compounds **I–III** and **V–VII** (Prestwich et al., 1975). Compound **X** with molecular ions at *m/z* 255 was identified based on similar MS data reported for *Prorhinotermes simplex* by Vrkoc and Ubik (1974). The results (Table 1) indicate that the secretion from *Prorhinotermes flavus* is almost exclusively 1-nitropentadecene (**X**).

Three compounds not previously reported were identified as 1,14-pentadecadien-3-one (**IV**) from *Schedorhinotermes malaccensis* and 1,16-heptadecadien-3-one (**IX**) from *Termitogeton planus*, both being homologs of compounds **III** and **VII**. 1-Heptadecen-3-one (**VIII**) from *Parrhinotermes pygmaeus* was identified as a homolog of vinyl ketones **II** and **VI**. These three compounds, **IV**, **VIII**, and **IX**, are assigned 1,14-pentadecadien-3-one, 1-heptadecen-3-one, and 1,16-heptadecadien-3-one, respectively, based mainly on GC retention times and GC-MS spectral characteristics of expected homologs. The mass spectra of **IV**, **VIII**, and **IX** exhibit molecular ions at *m/z* 222, 252,

RESULTS AND DISCUSSION

The family Rhinotermitidae from the Malaysian region is represented by five subfamilies: Termitogetoninae (Holmgren), Coptotermitinae (Holmgren), Prorhinotermitinae (Quennedey & Deligne), Heterotermitinae (Froggart), and Rhinotermitinae (Froggart). Psammotermitinae and Stylotermitinae are absent in this region (Roonwal, 1970). Previous work on Rhinotermitidae has shown that soldier termites from the subfamily Coptotermitinae, which includes the genus *Coptotermes*, produce mainly hydrocarbons and mucopolysaccharides of glucosamine (Moore, 1968: Prestwich, 1979a). The soldiers of *Coptotermes curvignathus* found in the Malaysian region are capable of releasing large droplets of similar white latexlike fluid through the large frontal openings on the head. This fluid is well suited to immobilizing small assailants because it dries quickly and entangles them. Current chemical analysis has shown that it is a suspension of saturated *n*-alkanes (C_{22}–C_{27}) in an aqueous solution of mucopolysaccharides of glucosamine and glucose units. Apart from chemical secretion, this termite also employs small, slender, incurved mandibles that are well adapted for piercing action.

The soldier of *Termitogeton planus* of the subfamily Termitogetoninae have a characteristic flat, heart-shaped, and hairy head from which they secrete mainly vinyl ketones (Table 1). These soldiers have well-developed slender, inwardly curved mandibles adapted for biting or piercing action with the simultaneous ejection of vinyl ketones into the wound of the predator.

The genus *Prorhinotermes* of the subfamily Prorhinotermitinae is represented by *P. flavus* in Malaysia. The soldier frontal gland of *Prorhinotermes* has a hypertrophied reservior cavity and is well adapted for ejection of defense secretions, especially against its predators such as ants. The genus *Prorhinotermes* was elevated to the current monogeneric subfamily Prophinotermitinae within the Rhinotermitidae because of different morphological features (Quennedy and Deligne, 1975). The secretion chemistry of the Malaysian *P. flavus*, in which nitroalkene **X** is produced, is also different from the usual vinyl ketones of Rhinotermitinae. The long-chain nitroalkene **X** has also been reported previously for *Prorhinotermes simplex* (Hagen) from Cuba (Vrkoc and Ubik, 1974). Nitroalkenes would therefore appear to be a taxonomic feature for soldiers of *Prorhinotermes*.

The frontal glands of major and minor soldiers of *Schedorhinotermes* are well adapted for daubing-brush chemical defense. Several *Schedorhinotermes* species have been reported to release odorous repellents consisting of vinyl

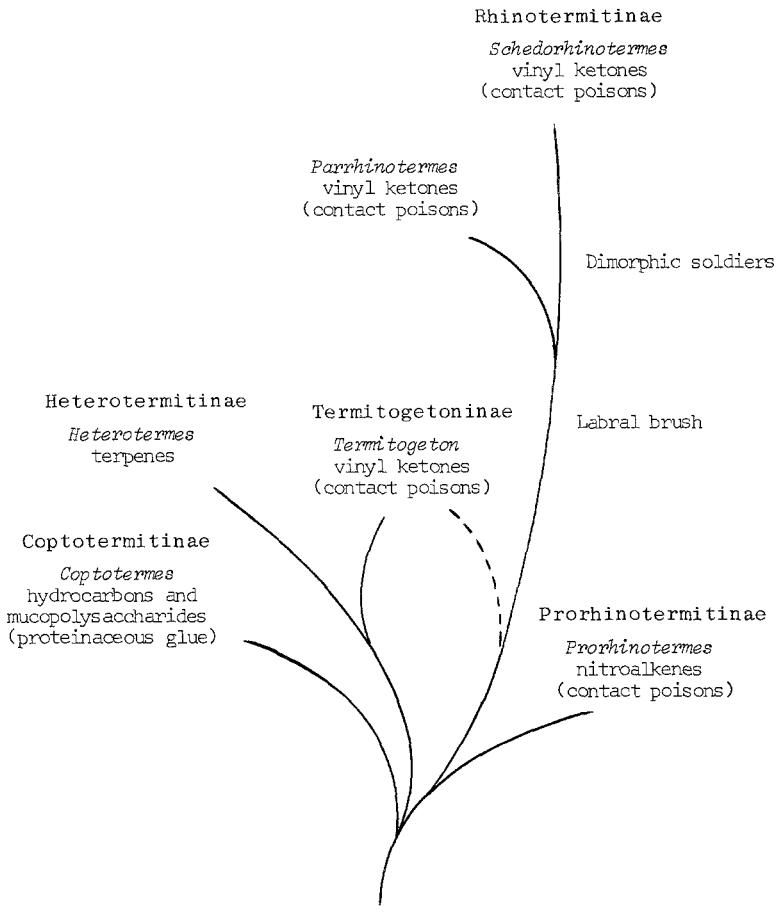

FIG. 2. Phylogeny of Rhinotermitidae—redrawn from Quennedey and Deligne (1975) with modification based on present study.

ketones. Several alkanones, alkenones, and alkadienones have been identified and are known to have a toxic effect on ants (Quennedey et al., 1973; Prestwich et al., 1975). The Malaysian *Schedorhinotermes* and *Parrhinotermes* of the subfamily Rhinotermitinae are now shown to produce mainly vinyl ketones (Table 1). *Parrhinotermes* is of interest since it has been considered the most primitive genus of Rhinotermitinae family (Quennedey and Deligne, 1975). Morphological comparisons of the soldiers of *Schedorhinotermes* and *Parrhinotermes* (both have well-developed labra with "brushes" on the distal ends) would already suggest the defense chemicals of the two genera would not be

too different from each other. Indeed, the chemicals secreted by *P. pygmeaus* and *P. aequalis* consist of a mixture of vinyl ketones, the dominant one being 1-hexadecen-3-one (**VI**) as shown in Table 1. Thus, the similarity of the chemistry of their defense secretions supports their close phylogenetic position as already evident based on their morphology (Prestwich, 1983).

It should be noted that defensive secretions from other *Schedorhinotermes* spp. from different parts of the world (Moore, 1968; Prestwich et al., 1975; Prestwich and Collins, 1982; Quennedey et al., 1973) also consistently have been determined to consist of vinyl ketones. Based on their studies, Quenneday and Deligne (1975) had proposed the phylogenetic relationships for the various genera and subfamilies in the Rhinotermitidae (Figure 2). In their interpretation of the phylogenetic tree, they have placed the subfamily Termitogetoninae together with Heterotermitinae on a line distinctly separate from the Rhinotermitinae and *Prorhinotermitinae*. However, as evident from this study, the soldier defense secretions of *Termitogeton* have been shown to consist of mainly vinyl ketones, as occur in *Parrhinotermes* and *Schedorhinotermes*. This would suggest that the subfamily Termitogetoninae could be much more closely related to the Rhinotermitinae than Heterotermitinae. Hence it should be more appropriate to place it on the same phylogenetic line (this is indicated in Figure 2 by broken lines).

It has also become quite evident from current knowledge of the chemistry of the defense secretions of the family Rhinotermitidae that they are all derivatives of polyketide/fatty acid biosynthesis, therefore providing a common link and possibly common ancestral stock. Hence, for this family, the secretion chemistry provides useful and vital information for the taxonomic and phylogenetic positions of the various genera and subfamilies.

Acknowledgments—We thank G.D. Prestwich for specimens of *Schedorhinotermes lamanianus* and confirming the GC-MS of (*E*)-1-nitro-pentadecene. We thank University of Malaya and Forest Research Institute Malaysia for financial support.

DERMATITIS-INDUCING FURANOCOUMARINS ON LEAF SURFACES OF EIGHT SPECIES OF RUTACEOUS AND UMBELLIFEROUS PLANTS[1]

ALICJA M. ZOBEL and STEWART A. BROWN

Department of Chemistry
Trent University
Peterborough, Ontario, Canada K9J 7B8

(Received January 3, 1989; accepted April 13, 1989)

Abstract—Eight species of Rutaceae or Umbelliferae, known to cause or suspected of causing photophytodermatitis, had the linear furanocoumarins psoralen, bergapten, and xanthotoxin on their leaf surfaces, in concentrations varying from 0.014 to 1800 μg/g fresh weight, equivalent to 0.17–56% of the total leaf concentration. The higher percentage generally observed for spring leaves compared to autumn leaves suggests a higher rate of transfer of these furanocoumarins to the surface in the younger leaves. Among the plants studied, *Ruta graveolens* had the highest surface concentrations of all three furanocoumarins. The relatively high effectiveness in causing dermatitis of some species with low surface concentrations may be explained by a more effective mechanism of transfer of the furanocoumarins to the skin. A role in the defense of the plant is suggested by their accumulation on the plant surface.

Key Words—Furanocoumarins, plant surface, dermatitis, Rutaceae, Umbelliferae.

INTRODUCTION

Although the existence of furanocoumarins in many species of the Rutaceae and Umbelliferae is well documented (Gray and Waterman, 1978; Murray et al., 1982; Matern et al., 1988), attempts to localize them in these plants have been

[1] A paper based on the work reported here was presented at the Groupe Polyphénols conference, Brock University, St. Catharines, Ontario, Canada, August 16–19, 1988.

0098-0331/90/0300-0693$06.00/0

confined to entire organs, with very little attention to specific tissues (Andon and Denisova, 1974; Capalletti et al., 1984). In this laboratory, *Ruta graveolens* L. recently has been the subject of more detailed study in this context (Zobel and Brown, 1988, 1989). This species has long been notorious for inducing contact dermatitis (photophytodermatitis), which arises from the reaction of its linear furanocoumarins (psoralens, **1**) with skin DNA in the presence of UV radiation (Mitchell and Rook, 1979). High surface concentrations of these physiologically active coumarins (Zobel and Brown, 1989) can account for the marked propensity of *R. graveolens* to induce photophytodermatitis.

In the work reported here we have examined other species of the Rutaceae and Umbelliferae known to cause dermatitis (Mitchell and Rook, 1979) or suspected from anecdotal evidence of doing so, with the object of determining to what extent a substantial surface concentration of the three principal dermatitis-inducing psoralens is a general phenomenon in these families.

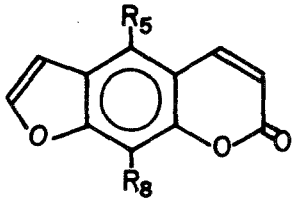
METHODS AND MATERIALS

R. graveolens was cultivated in a garden or greenhouse at Trent University, and *Heracleum lanatum* was collected from the wild state on the campus. The remaining species studied were obtained from the collection of the Royal Botanical Gardens, Hamilton, Ontario.

The procedure for removal of surface deposits by a single brief dipping of the leaves into almost boiling water (ca. 96°C, 100 ml) has recently been described (Zobel and Brown, 1988). In each case duplicate samples of ca. 10 leaves were used. Preliminary examination of the extracts was done by thin-layer chromatography on silica chromatoplates (Macherey Nagel, 0.25 mm thick) developed in ethyl acetate–isooctane, 1:3. This was followed by quantitative analysis of psoralens by high-performance liquid chromatography (Thompson and Brown, 1984; Zobel and Brown, 1989) on a 7.5-cm reversed-phase, 4-μm C_{18} column (Waters Nova-Pak) developed with 25% aqueous acetonitrile. Quantitation was by measurement of peak areas and reference to standard curves prepared from reference samples in our collection.

RESULTS

The three linear furanocoumarins predominating in these two families—psoralen (Scheme 1, **a**), bergapten (**b**) and xanthotoxin (**c**)—were detected on the surfaces of all five species of the Rutaceae and all three of the Umbelliferae examined in the present study (Table 1, values for duplicate samples shown in



1

a $R_5 = R_8 = H$

b $R_5 = OMe$, $R_8 = H$

c $R_5 = H$, $R_8 = OMe$

SCHEME 1.

each case). However, there was a great variation in the total surface concentrations, amounting to a range of five orders of magnitude, among the different species. They were highest on young spring leaves of *R. graveolens* (ca. 1800 μg/g fresh weight) and lowest on old, autumn leaves of *Evodia danielli* (0.014). In these two plants, as well as in *Orixa japonica* and *Peucedanum officinale*, the total concentrations of the three coumarins were higher on young leaves than on old, but the converse was the case in *Phellodendron chinensis*. Owing to unavailability of material at one or the other season, we could not compare the concentrations in the spring and autumn leaves of three species. The sum of the surface concentrations on spring leaves ranged from 6.7 to 56% of the total in the leaf, and on autumn leaves from 0.17 to 37%.

The three furanocoumarins in the species investigated were found in varying amounts on the leaf surface, with xanthotoxin predominant in many cases (Table 2). The concentration of this coumarin was highest on spring leaves of *R. graveolens* (ca. 880 μg/g fresh weight), with the next highest, *O. japonica*, having ca. 100, followed by *H. lanatum* with only ca. 0.5, differences of >1000-fold. Differences of an even greater order, >10,000-fold, were observed for psoralen, with respective values of 690, 1.6, and 0.06. Bergapten was again found in the highest concentrations on *R. graveolens* (220 μg/g fresh weight), followed by *O. japonica* with 22 and *Peucedanum officinale* with 0.56, a difference of ca. 400-fold.

In only one case (Table 3) were equivalent concentrations of the three

[a]P, psoralen; X, xanthotoxin; B, bergapten.

coumarins observed, i.e., young *E. danielli* leaves. This table shows the proportions of the three, with that of bergapten taken as unity. Bergapten in the spring leaves appeared to be present in low concentrations, but in old leaves it can even predominate, as seen in *Peucedanum officinale* and *Phellodendron chinensis*.

Table 2 shows, as well as the concentration in micrograms per gram fresh weight, the concentration of each surface furanocoumarin as the percentage of its total concentration in the entire leaf. The higher percentage values were observed with spring leaves except for *Phellodendron chinensis*, where the xanthotoxin values for spring and autumn leaves were similar; *E. danielli*, where on autumn leaves the xanthotoxin values were higher; and in *Peucedanum officinale*, where the percentage of psoralen on autumn leaves was, if anything, higher than on the spring leaves. Data from Table 2 permit the inference that even the small concentrations of each coumarin on the surface are a substantial part of the total in the plant. The values in the upper part of the observed range of 0.13–56% indicate that a large part of the furanocoumarins produced within the cells is sent to the surface.

DISCUSSION

Furanocoumarins have long been known to exist in leaves of the species of Rutaceae and Umbelliferae examined here (Murray et al., 1982), but their localization had not been previously studied. In this work we have located psoralen, xanthotoxin, and bergapten on the surface of the leaves, to a substantial degree in many cases, and not only inside.

In the case of waxes, leaves can be washed with organic solvents for 10–

45 sec (Tulloch 1987; Tulloch and Hoffman, 1982) without concern about leakage, as these substances are known to exist on the surface only. However, for removal of furanocoumarins from *R. graveolens* leaves, we found organic solvents unsuitable (Zobel and Brown, 1989); methanol, for example, which is used for washing out flavonoids (Proksch et al., 1986), is well known as a tissue fixer that rapidly penetrates and denatures proteins, "fixing" the membranes. Concerned about such drastic action of methanol and acetone, we compared their ability to remove furanocoumarins with that of a very short extraction into almost boiling water. Amounts released into this last solvent were of the order of hundreds of times as high, or in some cases even higher, without leakage from the epidermal cells (Zobel and Brown, 1988), and corresponded in the present experiments to surface concentrations ranging from 0.17 to 56% of the total concentrations in the leaf. These values may still represent only minima—the smallest amounts obtainable after a single brief dipping into hot water, which at least partially removes an overcuticular layer. Further experiments are in progress to determine whether a longer dipping time will remove yet more material without leakage from the epidermal cells.

The total furanocoumarin concentration (psoralen + xanthotoxin + bergapten) differs in different species. *R. graveolens* has a remarkably high furanocoumarin concentration on the surface, even compared to the 28% of the total flavonoid concentration on the leaf surface of *Flourensia resinosa* (Wollenweber, 1986). As no mechanism for the synthesis of coumarins can exist on the surface, concentrations of all three furanocoumarins ranging between 700 and 1800 μg/g fresh weight on the surface indicate that this plant must export large amounts from the interior. The sum of the surface concentrations in *R. graveolens* was higher than that in the whole leaf of *Orixa*, which contains the next highest concentrations. Those of the three individual furanocoumarins are not equal (Table 3): xanthotoxin predominates in many cases, except for *Phellodendron* and *Peucedanum* (autumn leaves), where there is more bergapten, and in *Phellodendron* and *Orixa* (spring leaves), where the psoralen concentration is highest. The variation of proportions in autumn and spring leaves suggests developmental changes, and these variations are now being investigated in *R. graveolens*, *R. chalepensis*, and *H. lanatum* over more extended periods.

A point of importance is that even the small concentrations of furanocoumarins on the leaf surface, both individually and in total, constitute a significant percentage of the whole concentration of the plant leaf. This suggests active transport of these substances to the surface, where, as we have already discussed for *R. graveolens* (Zobel and Brown, 1989), they could play a defense role, forming a coating over the cuticular layer (see also the discussion below). Xanthotoxin is recognized as a plant toxicant (Berenbaum and Neal, 1985).

A further question of interest is why plants causing dermatitis do not contain approximately the same concentrations of furanocoumarins on the surface.

When two of the plants causing photophytodermatitis, *R. graveolens* and *H. mangazzanianum*, are compared, we note that the surface concentrations of furanocoumarins are drastically different: 1800 and 3.6 μg/g, respectively. The phenomenon could be at least partially explained by postulating different mechanisms of transferring these toxins to the skin. *R. graveolens*, having a smooth, hairless surface, could induce dermatitis when the grayish waxy cover is removed by touching. In contrast, *H. mangazzianianum* possesses erect trichomes with a very thick, strong cell wall and sharp tips that could mechanically penetrate the upper layer of the skin and carry their furanocoumarins beneath the surface. In this way smaller amounts on the surface of the plant could produce comparable levels of irritation.

Dictamnus albus seem to be more of a threat after the leaves have been crushed or when there are breaks in the skin. More studies are needed to determine if *D. albus* can induce contact dermatitis and if, at the concentration there (0.025 μg/g), it has an antibiotic function. In our laboratory, furanocoumarins in concentrations found on *R. graveolens* leaves (and even lower by a factor of 10) have been shown to play an antibacterial role, and they decreased mitoses in root tips of *Allium cepa* (A.M. Zobel and K. Mwiraria, unpublished).

In our experiment, substances other than the three furanocoumarins, exhibiting a blue-green fluorescence, were also extracted into water. As demonstrated by Cesca et al. (1986) in the case of *Daucus carota*, such a complex of various surface substances, including a furananocoumarin, can act as an insect attractant. We consider it possible that such complexes of surface compounds could serve as a defense barrier for the plant, not only at the actual surface but comparable on a microscale to the atmosphere around the surface of the Earth. For example, as furanocoumarins are readily sublimable, slow continuous sublimation under natural conditions could give such an atmosphere adjacent to the plant surface that is toxic to approaching bacteria or fungal spores. In this context we hope that workers elsewhere will be interested in identification of other compounds extracted from plant surfaces by our procedure.

Acknowledgments—The research described here was supported from operating grant A2487 of the Natural Sciences and Engineering Research Council of Canada. We are also very grateful to the director and staff of the Royal Botanical Gardens, Hamilton, Ontario, and in particular to Dr. James Pringle, for their repeated willing assistance in obtaining specimens for us from their collection.

SUNFLOWER AROMA DETECTION BY THE HONEYBEE
Study by Coupling Gas Chromatography and Electroantennography

(Received August 15, 1988; accepted April 14, 1989)

Abstract—Combined electrophysiological recordings (EAG) and gas chromatographic separation were performed in order to investigate which volatile chemical components of a sunflower extract could be detected by honeybee workers and thus are likely to trigger the foraging behavior. A direct coupling device allowed for the stimulation of the antennal receptors with individual constituents of a polar fraction of the flower aroma shown to be attractive to bees. More than 100 compounds were separated from the extract. Twenty-four compounds elicited clear EAG responses. These compounds were identified by mass spectrometry (electronic impact and chemical ionisation). Both short- and long-chain aliphatic alcohols, one short-chain aliphatic aldehyde, one acid, two esters, and terpenic compounds were found to stimulate the antennal receptors. Six compounds identified in previous behavioral experiments were found to exhibit EAG activity. The chemicals screened by this method may be used for recognition of the plant odor and the selective behavior of honeybees.

Key Words—Insect–plant relationships, olfaction, honeybee, Hymenoptera, Apidae, sunflower, allelochemicals, coupling GC-EAG.

INTRODUCTION

Chemical analyses of plant volatile extracts of various species showed a large diversity among different chemical classes. More than 50 compounds were found in artichokes (MacLeod et al., 1982), cotton (Hedin, 1976), Ranunculaceae (Pellmyr et al., 1984), maize (Buttery et al., 1978), about 150 in orchid flowers (Borg-Karlson and Tengo, 1986), and between 80 and 250 in different genotypes of sunflower (Etiévant et al., 1984; Pham Delègue et al., 1988). Moreover, these complex blends can fluctuate in quality and quantity according to plant phenology (Maarse and Kepner, 1970; Thompson et al., 1971; Hedin, 1976; Pham Delègue et al., 1988, Hamilton-Kemp et al., 1988), and also in response to climatic factors and soil characteristics (Robacker et al., 1982). One question arising is how phytophagous insects process the chemical information available and adapt their behavior to such complexity and variation of plant aromas (Masson, 1983).

In natural conditions, honeybee foragers are attracted to sunflower crops and are able to distinguish between different genotypes (Parker, 1981; Pham-Delègue et al., 1985). In a previous work, Pham-Delègue et al. (1986) conditioned bees to a sunflower extract and offered them a choice between the conditioning scent and different fractions of this extract. This work established the attractiveness of a fraction of the sunflower extract containing mainly the polar constituents and led to the identification of a limited number of molecules possibly involved in the recognition of the total aroma by bees. Electroantennogram responses (EAG) at the outlet of a gas chromatograph (GC) were recorded in order to determine which compounds of the polar fraction are detected by the olfactory receptor cells and hence are likely to be used as chemical cues to elicit the orientation of bees.

Most of the GC-EAG methods described in the literature for screening the olfactory activity of chemical substances are based on a trapping of these products at the outlet of the GC and a subsequent flushing of the trapped material onto the biological preparation (Moorhouse, 1969; Wallbank and Wheatley, 1979; Löfstedt et al., 1983). Such a technique is not practical when large numbers of constituents from plant extracts have to be tested for EAG activity. We therefore used a direct coupling of EAG and GC based on the same principles as those developed by Arn et al. (1975) and Wadhams (1982) for pheromones or by Guerin and Stadler (1984) for plant odors.

METHODS AND MATERIALS

Plant Extract. Ten sunflower heads were extracted in a Soxhlet apparatus with dichloromethane. Volatile constituents were removed from the resultant concentration by a high-vacuum cold-finger distillation. Volatile materials con-

tained in the cold traps and condensed on the cold finger were taken up in dichloromethane and concentrated. The extract was then separated into polar and apolar fractions by column chromatography on silica gel. The column was eluted with purified pentane (apolar fraction) and purified ether (polar fraction). The polar fraction was stored under nitrogen in sealed glass tubes at −20°C. The entire procedure was described elsewhere (Etiévant et al., 1984).

Insect Material. Worker honeybees (*Apis mellifera ligustica*, L.) emerging in June were kept in an incubator at 33°C and were fed with a piece of candy sugar and water. Electrophysiological recordings were performed when the bees were 8 days old (number of bees: 10).

Direct Coupling between Gas Chromatography and Electroantennographic Apparatus. Gas chromatography (GC) was performed on a Girdel 3000 gas chromatograph equipped with a J&W retrofit on-column injector (Jennings and Takeoka, 1984). A 30-m long fused silica megabore column (0.53 mm ID, J&W DB5, thickness 1.5 μm) was used for the separations. A deactivated fused silica column (5m) was connected to the megabore column as a retention gap (Grob et al., 1985). Helium was used as carrier gas with a velocity of 28 cm/sec. Samples of 0.4 μl were injected at room temperature into the precolumn, which was then pushed inside the oven. After 3 min at 40°C, the temperature was linearly raised at 3°C/min up to 250°C. At the exit of the column, the effluent was split into two parts: one directed onto the insect antenna (2/3), the other sent to the flame ionization detector (1/3). The splitter was a Y-shaped vitreous silica outlet splitter (SGE Ltd.) without gas makeup added. To avoid variations of the split ratio with temperature, the splitter and the two silica lines were maintained at a constant temperature of 250°C.

The molecules eluted from the column were blown onto the antenna in a humidified stream of purified air (speed 20 cm/sec, internal diameter of the glass tubing = 0.8 cm). The distance between the outlet of the silica line and the outlet of the tubing was set at 3 cm (ca. 4 cm from the antenna).

The relative concentration of each stimulating compound was expressed as a percentage of the sum of all the peaks after subtraction of the solvent peak area.

Electroantennograms (EAGs) were recorded by an electrode covering the cut tip of the left antenna of each bee. The indifferent electrode was gently inserted at the base of the same antenna. The bees were maintained inside a Perspex block adjusted to the bee. Glass electrodes were filled with a physiological saline solution (NaCl, 6.5 g/liter; KCl, 0.25 g/liter; $CaCl_2$, 0.3 g/liter; Na_2CO_3, 0.2 g/liter). An Ag–AgCl wire inserted into each electrode connected the antenna with the recording device: input probe, preamplifier (Carrack PB 181-11), and differential oscilloscope (Tektronix 5A22N). EAG amplitudes were measured on the oscilloscope screen and expressed in millivolts. The impedance of the preparations used was lower than 2×10^6 Ω. Changes in the sensitivity of the preparation were checked regularly with a

standard stimulus (1 ml of air flushed into the air stream through a pipet containing a filter paper soaked with 20 μl of hexanol in paraffin oil, dilution 1% v/v). Olfactory stimulations by the standard were delivered at least four times during each GC run. Compounds eliciting responses in more than eight of 10 preparations were considered as effective stimuli, others were ignored. Since the physiological significance of hyperpolarizing EAGs is questionable, the mean value of EAGs was calculated on the basis of depolarizations exclusively; confidence intervals (CI) are calculated as follows: $t \times (SD)/\sqrt{n}$ where SD is the standard deviation and t is the value of the t test at $P < 0.05$.

Chemical identifications of peaks eliciting significant EAG responses were performed using a coupled GC-MS device (GC Girdel 300, R 10/10 Nermag). Identifications were based on electron-impact ionization (EI) (70 eV). Chemical ionization (CI-NH_3^+) was used to confirm the molecular weights. The mass spectra were confirmed by injection of standard compounds when available. Confidence in identifications is given in Table 1.

RESULTS

More than 100 compounds were detected in the polar fraction of the sunflower extract. The separation of all the compounds was obtained within 90 min. As an example, in Figure 1 are shown EAG recordings superimposed on the FID signal during a 13-min period of chromatography. The response to the standard stimuli was rather constant (mean = -1.7 mV, CI = -0.15 mV). The decrease of the EAG amplitude to the standard stimuli during the period of chromatography was small (less than 20%). Therefore, no correction was applied to the observed values of the EAGs.

From the 10 individuals for which complete recordings were obtained, a total number of 529 responses were observed during the chromatography: 95% of them were depolarizations (varying from -0.2 mV to -1.9 mV), and 5% were hyperpolarizations (varying from $+0.2$ mV to $+2$ mV). The responses to the different constituents were found throughout the chromatogram (Figure 2), except at the end when nonvolatile products were eluted (Figure 3). A larger number of responses occurred in the middle part of the chromatogram (retention times between 30 and 70 min) when compared to the remaining periods (Figure 2). Hyperpolarizations occurred throughout the period of analysis and were not related to particular peaks. The hyperpolarizations are evenly distributed along the chromatogram (χ^2, $P < 0.02$), and 85% of these hyperpolarizations occurred for only four individuals. The number of hyperpolarizations recorded from each bee could not be correlated with the sensitivity of each bee (mean value of the depolarizations recorded in each antenna) ($r^2 = 0.20$).

[a] Relative intensities of the eight major ions of unidentified peaks: 9: 43(100), 41(72), 55(65), 83(44), 39(38), 67(36), 95(35), 99(34); 12: 41(100), 93(85), 39(84), 53(58), 105(53), 121(50), 91(46), 120(38); 13: 108(100), 41(54), 93(47), 95(37), 43(29), 39(27), 109(26), 55(23); 22: 123(100), 43(90), 41(12), 124(11), 55(6), 39(4), 77(4), 79(3).

[b] Letters in parentheses indicate the reliability of identification: (a) EI mass spectrum identical with literature spectra, MW confirmed by $CI-NH_3^+$ and identity confirmed by injection of standard compounds; (b) EI mass spectrum identical with literature spectra, MW confirmed by $CI-NH_3$; (c) EI mass spectrum in agreement with literature spectra based on eight major peaks, MW confirmed by $CI-NH_3$; (d) EI mass spectrum in agreement with literature spectra based on eight major peaks. The molecular weight is the result of the chemical ionization (reported when available).

[c] The frequency of responses is calculated from the number of antenna responding to the same stimulation: * = 80%, ** > 80%, *** = 100%.

[d] Mean calculated from depolarizations, CI is the confidence interval = standard error. $t = 0.05$).

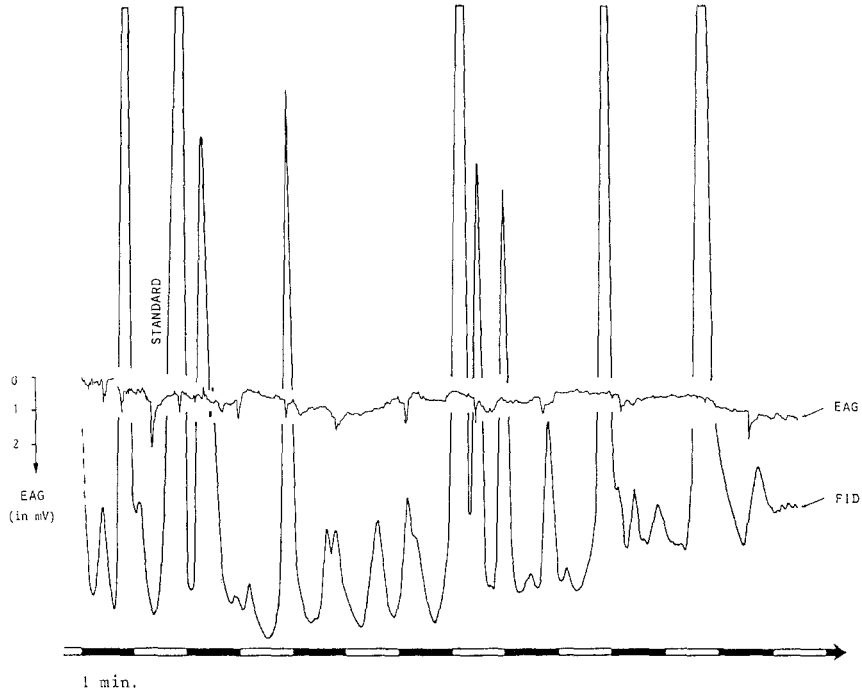

FIG. 1. Thirteen-minute sequence of the coupled signal synchronously recorded from the flame ionization detector (FID) and from a honeybee antenna (EAG). Standard is 1 ml of air odorized with hexanol 10:2 (v/v) in paraffin oil.

Twenty-four chemicals were found to stimulate the antennae for more than eight individuals. Amplitudes of the depolarizations recorded with these 24 compounds are plotted Figure 3. The total amount of these products account for 17% of the volatile constituents of the extract. The relative concentrations of these products range from 0.01% (thujenol cis) to 3.9% (sesquiterpenic alcohol, peak 20). Four compounds were commonly detected by all bees [*trans*-2-hexanal, peak 12 (unknown), peak 20 (sesquiterpenic alcohol), peak 22 (unknown); Figure 3, Table 1]. The variability of the amplitude of the recorded responses did not seem to be related to the retention time of the products: the higher variability observed (CI higher than 0.4 mV) occurred both at the beginning and the end of the experiment with 1-pentene-3-ol, 3-methyl-1-butanol, 1,8-cineole, and β-elemene.

The chemical identification of the 24 compounds found to be active in this experiment is given in Table 1. As expected, most of the stimulating compounds are oxygenated compounds belonging to different chemical classes. Fourteen of these identifications were confirmed by comparison with standard

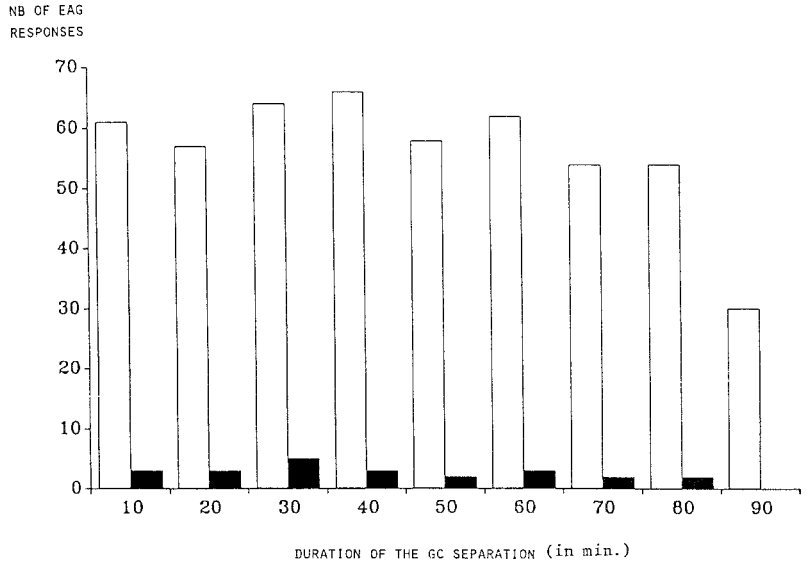

FIG. 2. Distribution of the EAG(s) recorded during the gas chromatographic separation of the polar fraction from a sunflower extract. White bars = depolarizations; black bars = hyperpolarizations.

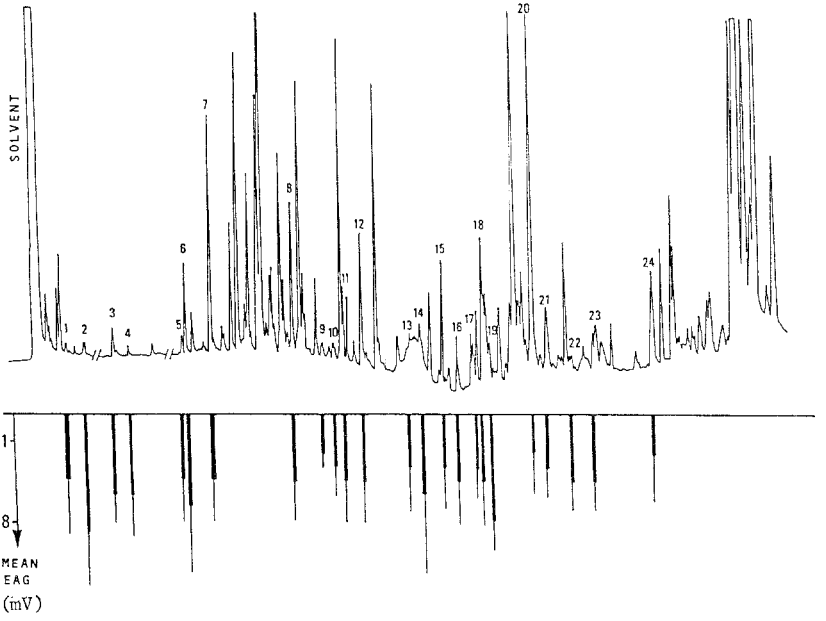

FIG. 3. Mean EAG responses of the honeybee antennae to compounds constitutive of a sunflower polar fraction. Numbers correspond to peak releasing responses in more than 80% of the recorded antennae. Thick bars represent the mean EAG, thin bars represent confidence intervals. Identification of chemicals is given in Table 1.

compounds; four of them were identified by comparison to published mass spectra; six compounds could not be identified precisely, although there is evidence that peaks 16 and 20 are a branched C_{10} methyl ester and a sesquiterpenic alcohol, respectively. The mass spectra of the four remaining products are listed in Table 1.

DISCUSSION

In a previous comparative study between the Soxhlet extraction technique and headspace sampling methods, Etiévant et al. (1984) stressed the validity of both methods for sunflower odor analysis. The Soxhlet extraction procedure has been preferred according to the higher concentration of chemicals collected as compared to air sampling. In the present work, more than 100 compounds have been separated from a polar fraction of sunflower solvent extract. From the same extract, Etiévant et al. (1984) separated a polar fraction of 47 compounds from a total of 84 products occurring; 31 polar compounds were identified. These differences may result from several reasons: our polar–apolar fractioning procedure could have been performed in slightly different conditions, degradation compounds may have appeared even if the initial extract was sealed in glass tube under nitrogen. The performance of our GC separation was higher, since we used a different bonded phase and an "on-column injector" that avoid thermal degradations and favors high-boiling compounds when compared to split–splitless injectors (Jennings, 1984; Jennings and Mehran, 1986).

In honeybees, detection of odors is thought to be achieved by olfactory receptor cells with broad overlapping quality spectra (Lacher, 1964; Vareschi, 1971). Since the EAG is believed to represent a summation of the receptor potentials of the responding cells (Kaissling, 1971), the exposure of antennal receptor cells to repeated stimuli may provoke an adaptation and a subsequent decrease of the EAG amplitude. Therefore the EAG activity needs to be interpreted with care. However, the slight decrease in response observed to the standard during the experiments suggests that the adaptation of receptors was limited, which may ensure the validity of such a screening.

In the present work, we used 8-days-old bees, which were grown in similar olfactory environment. Foraging bees (usually older than 8 days) may present differences in olfactory sensitivity because of age and also previous experience (Arnold and Masson, 1980; Masson and Arnold, 1984). Thus the spectrum of responses to the constituents of the sunflower odor might be different according to the age.

The EAGs recorded from the components of the polar fraction of the sunflower extract presented at a single concentration demonstrate that as many as 24 products were detected by the antennal receptor cells. The first four com-

pounds that release significant responses are only minor constituents of the extract (ranging from 0.06% to 0.2% of the extract). These are a short-chain aldehydes and alcohols (1-penten-3-ol, 3-methyl-1-butanol, 2-hexenal (*trans*), and 1-hexanol), which are common plant compounds also found in alfalfa flowers (Buttery et al., 1982), red clover flowers (Buttery et al., 1984), and ophrys flowers (Borg-Karlason and Tengo, 1986). Two of these compounds (3-methyl-1-butanol and 1-hexanol) are present in the alarm pheromone of honeybees and are highly effective in releasing alarm behavior (Collins and Blum, 1983). Tetradecanol is also mentioned as a volatile component of orchids flowers (Bergström, 1978). Ten of the 24 compounds detected by bees are terpenes and sesquiterpenes. Volatile terpenic compounds seem to occur frequently in flower aromas of the compositae (Etiévant et al., 1984; Flath et al., 1985; Buttery et al., 1986). These chemicals may be partly involved in flower recognition by bees (Waller et al., 1974; Pham Delègue et al., 1986). Caryophyllene oxide is probably a degradation product that may have appeared in the stored extract. It is nevertheless striking that bees are particularly sensitive to this product. This compound, identified in cotton plant extracts (Hedin, 1976), was also reported as releasing weak EAG responses in the boll weevil (Dickens, 1984). Some high-boiling-point compounds (e.g., linoleic acid) also elicited EAG responses in the bees. Their occurrence as olfactory stimulants may be due to the heating of these compounds in the gas chromatograph. Since they have very low volatility in natural conditions, it is doubtful whether they are important in olfactory communication and plant odor recognition.

The results presented here show a pattern of compound detection different from that found using foraging behavior experiments (Pham-Delègue et al., 1986). The 24 chemicals that elicited reproducible responses in our experiment are probably good candidates to be involved in the recognition of sunflower aroma by bees. Of these 24 compounds, more attention should be paid to the six compounds identified in the behavioral experiments mentioned above; namely, bornyl acetate, vanillin, propiovanillone, the products corresponding to peaks 9 and 10, and the branched methyl ester (peak 16), previously misidentified as methyl caprate.

In conclusion, coupling GC and EAG recordings allowed for rapid screening for components of the complex volatile mixtures in order to determine which of them might be used in olfactory recognition. However, the present results should be followed by behavioral tests to stress the role of the active components in blends. This approach can be useful for the tentative identification of a reduced chemical blend used by the bees for complex odor recognition. A better understanding of the role played by some component chemicals of the sunflower odor in the olfactory process could lead to their use in plant breeding programs in order to enhance the attractiveness of the plant and thus ensure pollination.

(Received January 23, 1989; accepted April 18, 1989)

Abstract—Tridecane, not previously reported in infested bin-stored grain, was associated with three mite species, *Acarus siro* (L.), *Aeroglyphus robustus* Banks, and *Lepidoglyphus destructor* (Schrank), which were introduced into 15.2% moisture content wheat stored in two unheated experimental bins in Manitoba during 1986–1987. The mites and volatiles were sampled at weekly to bimonthly intervals throughout the year. The mites produced tridecane all year, although they overwintered at low numbers. Ventilation of one bin at an airflow rate of 1 liter/sec/m^3 did not appear to affect mite survival and volatile production. Citral, an alarm pheromone for mites, was detected in mite-infested bin-stored grain. In laboratory studies all three mite species produced tridecane in wheat incubated at 20°C and 70% relative humidity for two weeks. *Acarus siro* and *Aeroglyphus robustus* reared at 25°C and 90% relative humidity for four weeks on wheat and fungus-inoculated wheat also produced tridecane. Production of tridecane by *A. robustus* and *L. destructor* is being reported for the first time.

Key Words—Odor volatiles, mites, stored wheat, *Acarus siro, Aeroglyphus robustus, Lepidoglyphus destructor*, Acarina, fungi, ventilation, tridecane, citral.

INTRODUCTION

Stored grain can be subjected to the deteriorative effects of various biotic agents including microflora, insects, mites, and rodents (Sinha, 1979). Mite-infested grain can be downgraded due to odor and taint, resulting in financial losses to

0098-0331/90/0300-0713$06.00/0

producers and elevator companies. Prevention of such degradation is especially important to grain-exporting countries such as Canada and the United States if they wish to maintain their export markets and reputation as producers of high-quality grain.

Because of their minute size, compared to stored-grain insects, the presence of mite pests in a grain mass often remains undetected. Consequently, control measures are rarely applied until unacceptably high levels of infestation occur. Thus any chemical that is specifically produced only by mites and that could be detectable during early stages of mite development may provide an indication of infestation before serious damage to stored grain occurs.

A mite-specific volatile, tridecane, has been detected in large quantities from the headspace of laboratory cultures of stored-product mites (Curtis et al., 1981; Baker and Krantz, 1984). The collection method involved the adsorption of volatiles on a porous polymer over several days using large mite populations. This time-consuming method makes detection of tridecane in mite-infested grain difficult, particularly when levels of infestation are low. Another volatile, the alarm pheromone citral, was also detected in disturbed cultures of several stored-product mites (Baker and Krantz, 1984; Kuwahara et al., 1980). Neither of these volatiles was ever reported in unheated bins with mite-infested grain on a seasonal basis.

Ventilation of stored cereals with near-ambient air prevents spoilage of grain through drying and cooling and has become a common practice in Canada and elsewhere (Fraser and Muir, 1981; Metzger and Muir, 1983). Ventilation, however, can increase the number of some mite species in stored grain (Muir et al., 1977). The purging effect of airflow on the detection of mite volatiles in ventilated grain has not been studied.

The objective of this study was to monitor quantitatively odor volatiles characteristically produced by mite populations in nonventilated and ventilated grain bins containing mite-infested wheat and to determine in the laboratory whether there is a cause–effect relationship between mite species and the main mite volatile, tridecane.

METHODS AND MATERIALS

Stored-Grain Ecosystem: Bins, Wheat, Ventilation

The experimental bins, constructed inside an unheated machine shed, consisted of internally wax-coated cardboard cylinders 3.66 m high and 0.61 m diameter. The bins, sampling ports, and ventilation plenum have been previously described (Sinha et al., 1988).

Locally harvested Canada western hard red spring wheat [*Triticum aestivum* L., cv. Katepwa, 1985 crop, 20 and 25% moisture content (mc)] had been

ventilated and dried in 1986. The wheat was at 15.2% mc when placed in the experimental bins on July 21, 1986. The bin tops were covered with fine mesh and sealed with silicone to prevent escape of mites and infestation from external sources. Ventilation of grain with ambient air started on August 26, 1986, at a rate of 1 liter/sec/m^3 in one bin and continued for 16 weeks until December 18, 1986. Ventilation was resumed on June 12, 1987, for another six weeks until the end of experiment on July 31, 1987. The control bin was not ventilated.

Equal volumes of food media containing three species of stored-product mite pests, *Acarus siro* (L.) (Acarina; Acaridae), *Aeroglyphus robustus* Banks (Acarina; Glycyphagidae), and *Lepidoglyphus destructor* (Schrank) (Acarina, Glycyphagidae) (Hughes, 1976) were introduced into the grain in the control and ventilated bins. Mites were reared on yeast–wheat germ media (3:1, v/v) at 25 ± 1°C and 75 ± 2% relative humidity as part of the stock cultures maintained by the Agriculture Canada Research Station, Winnipeg. The estimated numbers of live mites introduced per bin location were: 443,000 for *A. siro*, 30,900 for *A. robustus*, and 97,350 for *L. destructor*. Mites were placed 15 cm below the grain surface at two points mid-way between the sides and center of the bin.

Samples for all analyses were taken through the bin port closest to the grain surface, using a metal probe. Samples for estimation of mite numbers were taken weekly, the frequency of sampling decreased to biweekly in November and to monthly in January 1987. Samples for volatiles analysis were taken monthly until November and bimonthly thereafter.

Mite Count. Mobile stages of adult and nymphal mites from grain samples were collected using Berlese funnels filled with 350 ml of grain and placed under 30-W lamps for 17 hr (Sinha, 1964). Heat from the lamps drove mobile mites from the grain into jars filled with 70% ethanol. A stereomicroscope was used to count the numbers of mites per sample and reported as mite number per 500 g of grain.

Grain Moisture Content and Temperature Measurement. Moisture content was determined on a wet-mass basis by oven-drying duplicate samples (15 ± 1 g) from each bin (American Society of Agricultural Engineers, 1983). Temperature was monitored using a Hewlett-Packard 3497A data acquisition unit (Hewlett-Packard, Avondale, Pennsylvania) and copper–constantan thermocouples located along the centerline of the bin.

Seed Germination and Microfloral Assessment. The rate of seed germination and microfloral infection were determined by filter-paper method using seeds surface-sterilized with 0.6% aqueous sodium hypochlorite solution (Wallace and Sinha, 1962; Mills et al., 1978). Plates were incubated in plastic bags at 22 ± 1°C for seven days. To break seed dormancy, seeds plated for germination were kept at 10°C for seven days before incubation. Infection levels were calculated as percentages of seeds on which microflora grew.

Determination and Analysis of Odor Volatiles

Samples of 500 g of wheat were flushed for 17 hr with N_2 at 60 ml/min flow and volatiles were preconcentrated on Chromosorb 105 adsorbent (Sinha et al., 1988). Volatiles were then desorbed into 100 μl acetone, and 1-μl aliquots were injected onto a Carbowax 20 M fused silica capillary column (50 m $\times$ 0.32 mm) in the splitless mode. The injector and flame ionization detector in the gas chromatograph were maintained at 200 and 250°C, respectively. Helium was used as carrier gas at a flow velocity of 45 cm/sec. Oven temperature remained at 37°C for 0.5 min, then increased to 77°C at a rate of 20°C/min, was held at this temperature for 5 min, and then increased to 150°C at a rate of 2°C/min.

Acetone solution of known volatiles (40 ng/μl) was injected daily and retention times were used for identification of peaks in new samples. Identities of peaks in samples were confirmed by cochromatography with known chemicals. The unknown volatiles were identified using electron-impact ionization and confirmed using methane positive-ion chemical ionization on a Hewlett-Packard 5985B quadruple gas chromatography-mass spectrometry system.

Diacetone alcohol (4-hydroxy-4-methyl-2-pentanone), present in the acetone used as a solvent, served as a convenient internal standard for quantifying the results. The peak area of each volatile was compared with the peak area of the diacetone alcohol for relative percent calculations. The mean relative percent of the volatile was calculated from two or three chromatographic runs.

Laboratory Experiments

Mite Volatiles on Wheat. Number 1 hard red spring wheat (*Triticum aestivum* L., cv. Katepwa, 1988 crop, 12% mc) was moisturized to 14% mc at ambient temperature and two weeks later stored at −10°C until used. A total of 400 adult mites were placed in round-bottom 0.5-liter flasks filled with 200 g of wheat. The flasks were closed with a cotton plug, covered with filter paper, then sealed with parafilm and incubated at 20 $\pm$ 1°C and 70 $\pm$ 2% relative humidity for two weeks. Two flasks per species and two control flasks containing only wheat were analyzed for mite volatiles in one to three chromatographic runs. These analyses were repeated, thus totaling four replicates for each treatment; standard errors were calculated from a maximum of 12 measurements.

Mite Volatiles on Fungus-Inoculated Wheat. Number 1 hard red spring wheat (*Triticum aestivum* L., cv. Katepwa, 1986 crop, 15% mc) was moisturized to 20% by adding sterile water in a mixer for 30 min and equilibrated for 24 hr at 10°C. Round-bottom 1-liter flasks were filled with 500 g of moisturized wheat, plugged with nonabsorbant cotton, and covered with aluminum foil. All flasks with moisturized wheat were autoclaved immediately at 121°C for 20 min, then stored at −15°C until required.

Fungal species *Alternaria alternata* (Fr.) Keissler, *Arthrobotrys* spp., *Eurotium herbariorum* (Wiggers)Link:Fr. (the perfect state of *Aspergillus repens*), *A. flavus* Link ex Fries, *A. versicolor* (Vuill.) Tiraboschi, *Penicillium cyclopium* Westling, *P. chrysogenum* Thom, *Fusarium moniliforme* Sheldon, and *Fusarium semitectum* (Cook) Sacc. were isolated on synthetic media from grain in a previous study (Tuma, 1988). A 1-ml suspension containing 10^6 spores (cells) was added into 1-liter flasks containing moisturized wheat. Duplicates of each treatment were incubated at 25°C and 90% relative humidity for one week, after which they were analyzed for microfloral volatiles (Tuma, 1988) and reused for mite incubation.

Mite Rearing. Large populations of two mite species, *Acarus siro* (L.) and *Aeroglyphus robustus* Banks were reared on a yeast-wheat germ media (3:1, v/v) at 20 ± 1°C and 70 ± 2% relative humidity for six weeks. A lot of 1000 adult mites was counted and placed, using a sable-hair brush, into each flask containing fungus-inoculated wheat. Flasks were incubated at 25 ± 1°C and 90 ± 2% relative humidity for four weeks. The standard error values presented in Table 1 were calculated from a maximum of six chromatographic measurements of volatiles collected from two flasks with 500 g of wheat.

TABLE 1. MEAN TRIDECANE COLLECTED FROM HEADSPACE OF TWO FLASKS CONTAINING MITE-INFESTED WHEAT WITH OR WITHOUT FUNGAL INOCULATION AFTER INCUBATION AT 25°C AND 90% RELATIVE HUMIDITY FOR 4 WEEKS

Mite species	Fungal species	Tridecane (%) (X ± SE)
Acarus siro (noninoculated)		404.7 ± 35.2
Acarus siro 7-day wheat (OA)[a]		476.8 ± 63.1
Acarus siro	*Aspergillus repens*	380.5 ± 15.1
Acarus siro	*Aspergillus repens* (OA)	423.9 ± 25.3
Aeroglyphus robustus	*Aspergillus repens*	56.9 ± 5.5
Acarus siro	*Penicillium cyclopium*	n.d.[b]
Acarus siro	*Penicillium cyclopium* (OA)	n.d.
Aeroglyphus robustus	*Penicillium cyclopium*	8.4 ± 1.4[c]
Acarus siro	*Penicillium chrysogenum* (OA)	n.d.
Acarus siro	*Aspergillus versicolor* (OA)	n.d.
Acarus siro	*Aspergillus flavus* (OA)	n.d.
Acarus siro	*Fusarium moniliforme* (OA)	334.9 ± 4.3
Acarus siro	*Fusarium semitectum* (OA)	1030.5 ± 5.9
Acarus siro	*Arthrobotrys* spp. (OA)	221.2 ± 11.2
Acarus siro	*Alternaria alternata* (OA)	489.9 ± 88.0

[a] OA, previously analyzed for odor volatiles
[b] n.d., not detected
[c] Tridecane detected and calculated from one flask only.

One-Way Analysis of Variance. The data from the laboratory study on mite volatiles in fungus-inoculated wheat were statistically analyzed with one-way analysis of variance (ANOVA) using Scheffe's and Student-Newman-Keuls' (SNK) multiple comparison methods (Statistical Analysis System, 1985).

RESULTS

Bin-Stored Wheat Ecosystem

Physical Conditions. The initial grain temperature of 26°C decreased to 18°C by the end of August. Grain temperatures in the ventilated bin were usually a few degrees lower than those in the nonventilated control bin, presumably because of the movement of cold outdoor air. Temperatures in both bins generally followed the decreasing ambient temperature to 12–14°C in September, 6–8°C in October, and −10°C in November, at which level the grain temperature remained unchanged during the winter months. Grain temperatures then increased with ambient temperature to 3°C in March 1987, 11°C in April, 16°C in May, 22–25°C in June, and finally to 26°C when the experiment was terminated on July 31, 1987. Grain moisture content in control and ventilated bins fluctuated between 14.1 and 15.5% during the storage period.

Mite Populations and Odor Volatiles. Three mite-specific volatiles were detected in both nonventilated control and ventilated bin-stored wheat ecosystems. These were tridecane, neral, and geranial; the last two volatiles are components of the pheromone citral and occurred in lower quantities than tridecane. Occurrence of three mite species *Acarus siro, Aeroglyphus robustus*, and *Lepidoglyphus destructor* coincided with the incidence of tridecane, which was detected during the entire storage period. Although the number of *Acarus siro* introduced was 14 times higher than that of *Aeroglyphus robustus*, the ratio of population sizes between the two species reversed as time proceeded. During the winter months when grain temperature reached −10°C, *Aeroglyphus robustus* had the highest survival of the three introduced mite species.

Acarus siro was the most abundant mite species in the control bin during August–October 1986 (Figure 1A). This mite was not detected during the winter months, and its numbers remained relatively low during the rest of the experiment. Two other introduced mite species, *Lepidoglyphus destructor* and *Aeroglyphus robustus* fluctuated within their original population levels during August–October. In November 1986 the numbers of *Aeroglyphus robustus* (560 per sample) far exceeded those of the other two mite species. *A. robustus* remained as the only active species during the winter. In the spring and summer, *A. robustus* was the most common and abundant mite species, increasing sharply in numbers once in March and then again in April 1987; it had the highest survival rate.

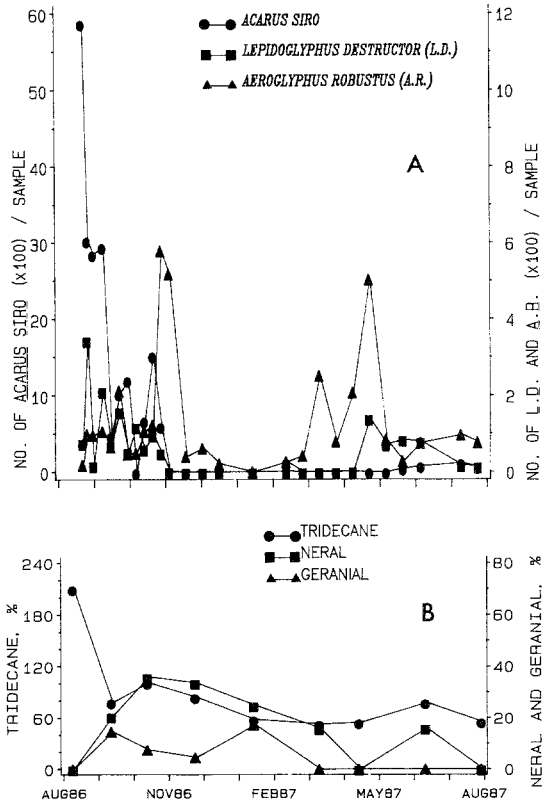

FIG. 1. Seasonal fluctuations of mite populations and mite volatile levels in 500-g samples from nonventilated control bin containing 15.2% mc wheat in Winnipeg, Manitoba, during 1986–1987. (A) Three species of stored-grain mites; (B) mite volatiles expressed as relative percent of diacetone alcohol internal standard.

Tridecane, initially recorded at 210% in August 1986, occurred within a 50–110% range during September 1986–July 1987 in the control bin (Figure 1B). Neral and geranial were detected during September 1986–January 1987. Only neral was detected twice at the 15% level during March–July 1987.

In the ventilated bin, *Acarus siro* was the most abundant mite species during August–October 1986 (Figure 2A). This mite species was not detected during the winter and spring, but it reappeared at low levels in the summer. In November 1986 the numbers of *Aeroglyphus robustus* (1080 per sample) far exceeded those of the other two species; it remained as the only active species during winter. *L. destructor* increased to its highest level in April 1987. Of the three introduced mite species, *A. robustus* had again the highest survival rate.

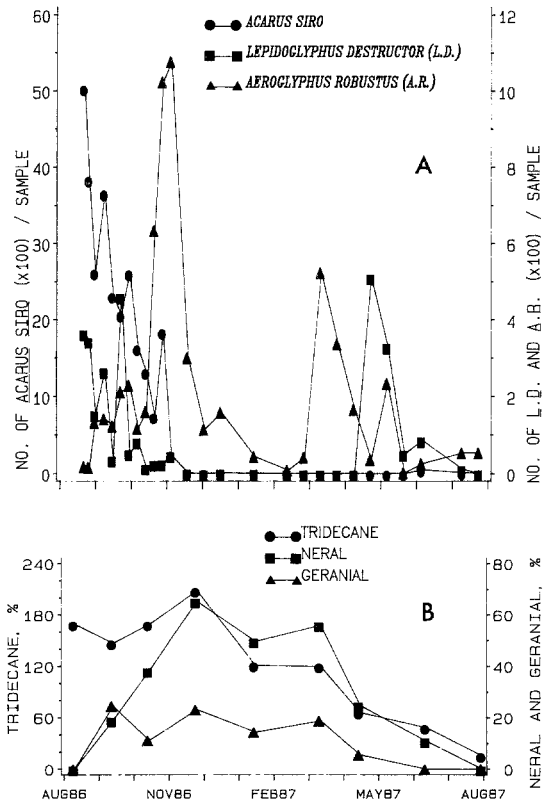

FIG. 2. Seasonal fluctuations of mite populations and mite volatile levels in 500-g samples from ventilated bin containing 15.2% mc wheat in Winnipeg, Manitoba, during 1986–1987. (A) Three species of stored-grain mites; (B) mite volatiles expressed as relative percent of diacetone alcohol internal standard.

In the ventilated bin, tridecane increased to 210% in November 1986; henceforth, the level declined steadily to 20% in summer (Figure 2B). Neral and geranial also peaked in November and then decreased to undetectable levels in July 1987.

Seed Germination and Microflora. There were no substantial differences in seed germination and internal infections between control and ventilated bins. Seed germination fluctuated between 48 and 88%. The level of infection by storage fungi was between 48 and 84% for *Aspergillus glaucus* gr. and between 20 and 56% for *Penicillium* spp. The level of infection by a field fungus *Alternaria alternata* was between 0 and 32% and that by bacteria between 8 and 72%.

Laboratory Experiments on Mite Odor Volatiles

Mite Volatiles on Wheat. Tridecane was detected at 14.6–29.1% in all three mite species after two weeks of incubation at 20°C and 70% relative humidity. The mean percent of tridecane level with standard errors for *Acarus siro* was 20.6 ± 1.8, for *Lepidoglyphus destructor* 14.6 ± 2.0 and for *Aeroglyphus robustus* 29.1 ± 4.1.

Mite Volatiles on Fungus-Inoculated Wheat. Tridecane was not detected in flasks containing fungi-inoculated wheat (Table 1) (Tuma, 1988) except in one containing *A. repens*-inoculated wheat; this flask, showing 78.4% tridecane, was infested by a contaminant stored-product mite, *Tyrophagus putrescentiae* (Schrank). When *Acarus siro* was introduced separately into flasks with noninoculated wheat, the mites contaminated the wheat with *Aspergillus repens* and sporadically with *Penicillium* spp.

In wheat with *Aspergillus repens* and *Acarus siro*, the tridecane level (380.5%) was seven times as high as that in wheat with *A. repens* and *Aeroglyphus robustus* (56.9%). In wheat inoculated with *Aspergillus repens, Aeroglyphus robustus* had a lower reproduction than *Acarus siro*. In wheat inoculated with *Penicillium* spp. and *Acarus siro* or *Aeroglyphus robustus*, no tridecane occurred except in one flask, which had an 8.4% tridecane level; the mite populations in all these flasks were declining and in poor condition. Condensation in the flasks containing wheat inoculated with *P. cyclopium* and *P. chrysogenum* could have negatively affected the survival of both mite species.

In wheat with *Fusarium semitectum* and *Acarus siro*, tridecane occurred at a 1030.5% level; this level was significantly different (ANOVA, $P < 0.05$) from those in all other treatments. Fungal spores were eaten by mites in all flasks in which high levels of tridecane were recorded. Based on tridecane levels, fungal substrates that provide the best dietary source for *Acarus siro* include: *Fusarium semitectum, Alternaria alternata, Aspergillus repens, Fusarium moniliforme*, and *Arthrobotrys* spp. Another mite-specific volatile, perillen, was detected in most flasks that produced tridecane. The perillen levels, ranging from 23 to 191%, were always lower than those of tridecane in all flasks.

DISCUSSION

Tridecane was detected in bin-stored wheat only when it was infested with the stored-product mites, *Acarus siro, Aeroglyphus robustus*, and *Lepidoglyphus destructor*. The laboratory study demonstrated that tridecane could be produced by all three mite species. The production of citral components and perillen by mites was always less frequent and in lower quantities than the production of tridecane.

The highest levels of tridecane occurred during the first four months of the

12-month storage period when the mite counts from grain samples were also high. *Acarus siro*, which was most abundant during the first three months of storage, was replaced by *Aeroglyphus robustus* during subsequent months. The high survival rate of the active stages of *Aeroglyphus robustus* could have accounted for most of the tridecane detected during winter. Because both *Acarus siro* and *L. destructor* overwinter in the cold-tolerant nonfeeding hypopus stage; mites in this stage are inadequately extracted by the Berlese method used in this study (Sinha, 1964). Thus, the numerical dominance of *Aeroglyphus robustus* over the two other mite species could be misleading. Neral and geranial, detected in mite-infested grain, probably resulted from disturbing the mites during handling in the laboratory, as mites do not yield large quantities of these volatiles unless alarmed (Baker and Krantz, 1984; Kuwahara et al., 1980).

Laboratory-incubated *Acarus siro* produced tridecane at a 20.6% level after two weeks and at 404.7 and 476.8% levels after four weeks. This substantial difference could have resulted, at least in part, from differences in incubation time, moisture content of wheat, and initial population size. Contamination of media with *Aspergillus repens* could be another factor responsible for higher tridecane levels in 19% mc wheat, after a four-week incubation. This wheat was more susceptible to fungal contamination than a similar but contaminant-free 14% mc wheat, after a two-week incubation. This contamination could have provided an additional dietary source for the mites, thereby enhancing reproduction and subsequent tridecane production.

Both laboratory-incubated mite species, *Acarus siro* and *Aeroglyphus robustus*, reared on wheat and wheat inoculated with fungal species produced tridecane. Curtis et al. (1981) also observed this phenomenon for *Acarus siro*. The production of tridecane by *Aeroglyphus robustus*, however, has not been previously reported. *Aeroglyphus robustus* is a well established mite pest of stored grain in Canada (Sinha, 1966) and a native of North America (Banks, 1906); its volatile production has not been previously studied. Tridecane was also produced in *Tyrophagus putrescentiae*-contaminated wheat, but it was not detected in bin-stored wheat naturally infested with *Tarsonemus granarius* Lindquist. This natural infestation occurred in all bins, but the numbers were not reported because it was presumed that the presence of *T. granarius* did not affect the tridecane production. Further research is needed to assess the tridecane production capabilities of other species of stored-grain mites reared under laboratory conditions.

Abundance of tridecane produced by mites differed substantially when mites were reared on wheat infected with fungi. The ranking of fungal diets for *Acarus siro*, according to tridecane production levels, was: *Fusarium semitectum, F. moniliforme, Aspergillus repens*, and *Arthrobotrys* spp. No neral or geranial was detected from mites in our laboratory experiments; absence of

these volatiles could have resulted from not disturbing the flask contents and mites prior to analysis (Baker and Krantz, 1984; Kuwahara et al., 1980). In our studies lesser quantities of perillen than tridecane were detected in the headspace of flasks containing media with *Acarus siro*; this finding is in agreement with that of Curtis et al. (1981).

Little is known about the biological effects of these volatiles on various species of fungi and mites. There is some evidence, however, that citral and citral-containing mite extracts inhibit fungal proliferation (Cole and Blum, 1975; Matsumoto et al., 1979) and function as alarm pheromones against mites (Kuwahara et al., 1980).

Further studies on the specificity and temperature dependency of tridecane are necessary before tridecane can be tested as a possible bioindicator of early infestations in stored grain. Stored grain is a dynamic ecosystem and must be monitored in a sophisticated manner if sound strategies to prevent degradation of grain quality are to be formulated.

Acknowledgments—We thank Dr. E.D. Murray, Food Science Department, University of Manitoba, Winnipeg for supporting this work, and we are also grateful to Mr. B. Sanderson for preparation of storage bins and wheat. This study was supported by a Natural Sciences and Engineering Research Council of Canada strategic grant awarded to W.E. Muir and R.N. Sinha.

Abstract—Porcupine quills possess antibiotic properties. The antibiotic activity is associated with free fatty acids (but not neutral lipids) coating the quills. Extracts of quill fatty acids strongly inhibited the growth of six gram-positive bacterial strains. No growth inhibition was observed against four gram-negative strains. Free fatty acids made up 18.6% of total quill lipids in samples collected in the summer, and 5.5% of total lipid in samples collected in the winter. The fatty acids were separated and identified (as the methyl esters) by gas–liquid chromatography and mass spectroscopy. Major components of a complex mixture included 14-methylpentadecanoic, 9-hexadecenoic, hexadecanoic, and 9-octadecenoic acids. It is suggested that porcupines benefit from the quill fatty acids: evidence from healed fractures of major skeletal components (35.1% incidence in 37 skeletons examined) suggests that porcupines fall relatively frequently from trees. Quill antibiotics may limit self-injury suffered in such falls.

Key Words—*Erethizon dorsatum*, porcupine, fatty acids, antibiotics, healed fractures.

INTRODUCTION

Wounds produced by quills of the North American porcupine (*Erethizon dorsatum*) rarely become infected (Shadle, 1955; Maser et al., 1981; Strickland et al., 1982; Maser and Rohweder, 1983; Roze, 1985). In contrast, spine penetration from other spine-defended animals such as echinothurid and diademid sea urchins (Echinodermata: Echinoidea) frequently produces secondary infections (Earle, 1940, 1941). Because porcupine quill wounds typically remain uninfected, a quill antibiotic factor was suspected. Porcupine quills are covered

0098-0331/90/0300-0725$06.00/0

with a greasy coating; the search for an antibiotic factor focused on this lipid material.

Quilled or spine-covered animals would be expected to evolve defenses that inflict maximal damage to predators. To understand the apparent limitation placed on quill defense in the porcupine, the hypothesis was examined that the animals may suffer self-quilling as a result of accidents while foraging in the small outer branches of food trees.

METHODS AND MATERIALS

Lipid Composition. Porcupines were live-trapped in a hardwood–hemlock (*Tsuga canadensis*) forest in Greene County, New York, and anesthetized with ketamine HCl. Approximately 50–100 quills, weighing ca. 1.5 g, were removed with forceps from the lower backs and tails of each animal and stored at −20°C until used. Quills of individual animals were extracted with *n*-hexane (10 ml/g quills) at room temperature, and the extract clarified by centrifugation. The hexane extract was evaporated to dryness under a stream of nitrogen, weighed, redissolved in hexane, and separated into a free fatty acid fraction and a neutral lipid fraction.

The free fatty acid fraction was obtained by shaking 15 ml of hexane extract with 13 ml of 0.2 N aqueous KOH. The organic phase contained neutral lipids. The aqueous phase was acidified with 0.3 ml conc. HCl and extracted with 10 ml *n*-hexane. The hexane reextract containing free fatty acids was removed and concentrated under a stream of N_2. For gas chromatographic analysis, heptadecanoic acid (Sigma Chemical Co.) was added as an internal standard, and the fatty acids methylated with BF_3/MeOH (Supelco methylation kit 3-3020).

The esterified fatty acid content of the neutral lipid fraction was measured by transesterifying 1 ml of neutral lipid fraction with 1 ml 0.2 N (*m*-trifluoromethylphenyl) trimethylammonium hydroxide in MeOH (Meth-Prep II, Alltech 18007) plus 1 ml CH_3Cl, and treating for 20–30 min at room temperature. Trimyristin (Sigma Chemical Co.) was used as the internal standard. Under these conditions, esters of fatty acids were transesterified to fatty acid methyl esters (FAMEs). Complete separation of the free fatty acid and neutral lipid fractions was indicated by the absence of myristyl FAME in free fatty acid fraction, and C-17 FAME in neutral lipid fraction.

FAME analyses were carried out with a Hewlett-Packard 5988A gas chromatograph–quadrupole mass spectrometer (GC-MS) with a Hewlett-Packard 1000 data system. A 30-m × 0.25-mm-ID fused silica capillary column with a DB-5 bonded methyl silicone stationary phase (J&W Scientific) was used with helium carrier gas and splitless injection. Initial column temperature was held

at 35°C for 1 min, then programmed at 20°C/min to 150°C, where it was held for 2 min, and then programmed at 2.5°C/min to 225°C, with a final hold of 15 min. GC-MS results were confirmed using a 50-m × 0.32-mm Hewlett-Packard cross-linked Carbowax 20 M column. Compound identification was based on cochromatography of sample components with standards, comparison of mass spectra of sample components with those of standards, or the NBS-Wiley spectral library (installed in the Hewlett-Packard 1000 system), and mass spectral interpretation based on Odham and Stenhagen (1972) and Ryhage and Stenhagen (1960). FAME standards were obtained from Supelco (4-7028), Sigma (189-1, 189-4, 189-6, and C-17), and Regis Chemical (Qualmixes BR2 and BR4).

The triglyceride content of the neutral lipid fraction was measured by coupled enzymatic assay of glycerol generated by saponification of the neutral lipids by KOH–EtOH (Sigma triglyceride kit 320-A). In addition, the neutral lipid fraction was separated qualitatively by thin-layer chromatography (TLC) on silica gel G, using three solvent systems (1, hexane–ethyl ether–HAc 70 : 30 : 1; 2, toluene; 3, $CHCl_3$–EtOH 100 : 1).

Antimicrobial Effects. Bacteriostatic properties of the neutral lipid and fatty acid fractions were tested at a concentration of 50 μg/ml, after removal of hexane under a stream of N_2. Nonclostridial bacterial cultures were grown aerobically in nutrient broth at 37°C in a rotary water-bath shaker. Growth was followed for 4–6 hr by absorption at 600 nm, as measured by a Bausch and Lomb Spectronic 20 spectrophotometer. Clostridial species (American Type Culture Collection) were grown in capped vials containing 0.05% thioglycollate in fluid broth (Difco Laboratories). Growth was followed for 48 hr and measured as above.

Healed Fractures. To estimate the incidence of serious injuries in porcupines, 37 available skeletons were examined for evidence of healed fractures. Porcupine skeletons were examined from the collections of four museums (American Museum of Natural History, New York, New York = AMNH; Field Museum, Chicago, Illinois = FM; University of Wisconsin Zoological Museum, Madison, Wisconsin = UWZM; and U.S. National Museum of Natural History, Washington, DC = USNM) and the Queens College (QC) collection. Only complete, non-zoo skeletons were examined. Porcupines with deciduous premolars (Pls) were classified as subadults (SA), and those with permanent Pls as adults (A) (Earle and Kramm, 1980; Sutton, 1972).

Because rib and phalangeal injuries are difficult to classify (Bulstrode et al., 1986), they were excluded from the analysis. For comparison, 45 skeletons of the woodchuck (*Marmota monax*) and 39 skeletons of the raccoon (*Procyon lotor*) were examined. Results are presented as means ± SD. Statistical procedures follow Sokal and Rohlf (1981).

RESULTS

Lipid Composition. Hexane-extractable quill lipids averaged 8.0 ± 5.7% w/w of quill weight. Table 1 lists average concentrations of principal components (>2% w/w) present in the free and esterified fatty acid fractions of seven different animals. The amounts are normalized to 100% for comparison. Minor components (<2% each) included tridecanoic (13:0), 12-methyltridecanoic (iso-14:0), tetradecanoic (14:0), 14-methylhexadecanoic (iso-17:0), octadecanoic (18:0), and 16-methylheptadecanoic (iso-18:0) acid, as well as six unidentified components. The close similarity between the transmethylated and free fatty acid fractions suggests that the latter arise from hydrolysis of fatty acid esters. A straight-chain saturated fatty acid (16:0) appears to be released preferentially.

The free fatty acid content of quill grease varied inversely with esterified fatty acid content ($r = -0.915$, $P < 0.05$). Quill grease from animals sampled in August averaged 18.6 ± 5.1% free fatty acid; January–February samples averaged 5.5% ± 1.5% free fatty acid ($t = 4.98$, $P < 0.01$) (Figure 1). Triglyceride content was proportional to neutral lipid content and averaged 5.6 ± 0.4% w/w of neutral lipid in both summer and winter samples (expressed as triolein equivalent). TLC showed presence of triglycerides plus at least nine additional components in the neutral lipid fraction.

Bacteriostatic Properties of Quill Lipids. The neutral lipid fraction proved inactive against all microorganisms tested. The free fatty acid fraction, on the other hand, showed strong growth inhibition of six of 10 bacterial strains tested (Table 2). All sensitive strains were gram-positive. The minimal inhibitory concentration, measured against *S. aureus*, was 6.2 μg/ml.

Healed Fractures. Of 37 porcupine skeletons examined (28 adults, 9 subadults), 13 (35.1%) showed healed fractures of bones other than ribs or phalanges. Healed injuries included the following: tibia and fibula (QC); femur, scapula, and dislocated rib 6 (AMNH 120842); ischium (AMNH 128710);

TABLE 1. MAJOR FREE AND ESTERIFIED FATTY ACIDS (FAS) IN PORCUPINE QUILL LIPIDS

192546). All but one of the healed fractures (USNM 88619) were found in adult porcupines.

The following porcupine specimens were examined and found free of healed fractures: AMNH 63759, SA; AMNH 97646, A; AMNH 97647, SA; AMNH 121197, A; AMNH 126094, A; AMNH 146825, SA; AMNH 147530, SA; AMNH 185327, A; FM 20343, A; FM 43299, A; FM 58811, SA; FM 124114, A; UWZM 20223, A; UWZM 21657, A; UWZM 24049, A; USNM 676, A; USNM 822, A; USNM 21159, A; USNM 21516, A; USNM 88617, SA; USNM 90475, A; USNM 90477, SA; USNM 192541, A; USNM 249955, SA.

Of 45 woodchuck skeletons examined, three (6.7%) showed evidence of healed fractures: radius, accompanied by arthritic disease of same (UWZM 22705); ilium, tibia, and sacrum (USNM 20765); and tibia (USNM 514747). The following woodchuck skeletons were examined and found free of healed fractures: UWZM 4059; UWZM 13950; UWZM 18563; UWZM 20400; UWZM 20459; UWZM 20620; UWZM 22222; UWZM 22704; UWZM 22707; AMNH 35615; AMNH 38873; AMNH 67882; AMNH 70014; AMNH 97386; AMNH 98963; AMNH 126079; AMNH 179937; AMNH 180314; AMNH 207022; AMNH 235277; AMNH 235648; FM 41087; FM 53201; FM 121211; USNM 604; USNM 88618; USNM 191374; USNM 191376; USNM 258735; USNM 260385; USNM 291554; USNM 293895; USNM 347666; USNM 349705; USNM 349710; USNM 349711; USNM 396282; USNM 397378; USNM 397379; USNM 397400; USNM 506225; USNM 514748.

Of 39 raccoon skeletons examined, all from the AMNH collection, four (10.2%) showed healed fractures: femur, 208968; radius, 245491; scapula, 253188; tibia and fibula, AMNH unnumbered September 15, 1928. The following skeletons were examined and found free of fractures: 93145; 121198; 123880; 145143; 173897; 173898; 173899; 183363; 187080; 235185; 235189; 235209; 236135; 236137; 237438; 237439; 238270; 238271; 238272; 238273; 238274; 238275; 238276; 238278; 238458; 238565; 238603; 243100; 245493; 245494; 245495; 245498; 245629; 245645; 255651.

The incidence of healed fractures in porcupines is significantly higher than in woodchucks or raccoons ($\chi^2 = 11.66$, $df = 2$, $P < 0.005$).

DISCUSSION

The antibiotic activity of fatty acids has long been recognized (Glassman, 1948; Wyss et al., 1945). Fatty acids kill gram-positive bacteria and many fungi, but are not active against gram-negative bacteria (Wyss et al., 1945). The mode of action is thought to involve an attack on the bacterial cell membrane (Esplin, 1970). Presumably gram-negative microorganisms escape attack

because of their lipid-rich outer envelopes (Stanier et al., 1976). In humans, free fatty acids are released by enzymatic attack on triglycerides and wax esters by normal flora such as *Propionibacterium acnes* (Sherris, 1984a; Marples et al., 1970). On human skin, the bacterial lipases preferentially release straight-chain saturated fatty acids (Bore et al., 1982).

The higher free fatty acid content of summer quill grease samples is consistent with a temperature-dependent enzymatic hydrolysis release. Likewise, an enzymatic hydrolysis release mechanism is supported by the observed inverse relationship between free fatty acid and esterified fatty acid contents of quill grease (Figure 1).

The composition of porcupine quill lipids differs significantly from the typical mammalian pattern. Skin lipids of most mammals contain only minute amounts of free fatty acids or triglycerides. The notable exception is human skin, where fatty acids make up about 30% of total lipids (Lindholm et al., 1981; Nicolaides, 1974). In most mammals, major components of skin surface lipids include mono- and diester waxes, internal lactones, sterol esters, and free sterols. Suggested functions of skin surface fatty acids in humans include reduction of bacterial and fungal infections of the skin (Sauer, 1980; Sherris and Ray, 1984).

The greasy coating of porcupine quills may serve multiple functions such as keeping quills stiff and water-resistant and aiding in individual recognition. For the fatty acid component of the quill grease, we here suggest an additional function: limitation of self-injury following impalement on the animal's own quills. Evidence presented from healed fractures suggests that porcupines suffer injuries more often than nonarboreal (woodchuck) or arboreal (raccoon) animals of comparable body weight.

Others have also noted that porcupines may suffer injuries in the wild. Dodge (1967) found healed fractures in legs, hips, and ribs, as well as broken incisors, injured eyes and ears, hernias, and miscellaneous soft-tissue injuries. Most such injuries are consistent with falling from trees. Curtis and Kozicky (1944) observed a full-grown porcupine falling from a poplar tree. Marshall (1951) found a porcupine dead in a double-stemmed tamarack tree. The animal had apparently slipped while climbing and had wedged itself sideways, just behind the forelimbs, in the V of the trunks. It had been unable to extricate itself from this position.

During seven years of following radiotelemetered porcupines in the Catskills in New York, additional circumstantial evidence has suggested that porcupines can fall from trees: broken branches in feeding trees, quill masses under feeding trees, and external as well as internal injuries suggestive of falling (U. Roze, unpublished observations).

The incidence of healed fractures reported here for porcupines is comparable to figures reported for other arboreal and semiarboreal species. Schultz

(1956) found that in wild *Hylobates*, *Pongo*, *Pan*, and *Gorilla*, the frequency of adult specimens with at least one healed fracture was 33%, 34%, 18%, and 21%, respectively. The figures include phalangeal and rib fractures. Kano (1984) interprets the Schultz data as suggesting that degree of arboreality in apes is correlated with frequency of accidents.

Clarke and Glander (1984) offer more direct evidence for a correlation between arboreality and accidents, by the observation that Costa Rican howler monkeys (*Alouatta palliata*) can fall from trees, sometimes with fatal results. They speculate that the much higher infant mortality among howler males (59%) compared to females (11%) results from more vigorous play in trees and an earlier age of independence.

This suggests that accidents result not from arboreal behavior per se but from risk-taking behavior in trees. The lower incidence of healed fractures observed in raccoons may reflect the fact that raccoons use trees primarily for rest and denning, and therefore confine their use to the trunk and large branches (Lotze and Anderson, 1979; Stuewer, 1943; Urban, 1970).

During summer in a deciduous forest habitat, porcupines may be in trees almost continuously, using them for diurnal rest and nocturnal feeding in the thin outer leaf-bearing branches of the trees. Tree use declines in winter as animals spend the bulk of their time in dens, emerging only for nightly feeding bouts. These are focused on the inner bark of trunks and larger branches (Dodge, 1967; Roze, 1987). Hence the animals encounter higher risks in summer. Data presented in Figure 1 show that porcupine quills carry higher fatty acid concentrations during this time.

It is postulated that a significant fraction of porcupines who fall would impale themselves on their own quills, with consequent risk of infection. Self-quilling has been observed in many cases of attempted capture, because of the flailing of the animal (U. Roze, unpublished observations).

In such cases of self-impalement on quills, how effective an antibacterial defense might the quill fatty acids be expected to offer? Much of the quill damage would be self-limited, since porcupines are skilled in removing embedded foreign quills (Dodge, 1967). However, quill tips may break off and travel beyond reach through internal tissues (Shadle, 1947; Vincent and Owers, 1986). Under such conditions, the bacteria associated with the quill tip would be in position to start an infection.

In humans, *Staphylococcus aureus* (Table 2) is the most common pathogen associated with contaminated puncture wounds, although the major threats are tetanus and gas gangrene, caused by the gram-positive *Clostridium tetani* and *C. perfringens*, respectively (Isenberg and D'Amato, 1985; Sherris, 1984b). These organisms are associated with foreign bodies such as splinters, soil particles, and fecal material. The den environment of the porcupine typically contains accumulations of fecal material. Clostridia may multiply under the

anaerobic conditions of deep puncture wounds. Mixed infections, frequently derived from the normal flora, and consisting of an anaerobic gram-negative or gram-positive organism plus a facultative anaerobe such as the gram-positive *S. aureus*, may also represent a threat. Under puncture-wound conditions, growth of the anaerobes is favored because of local oxygen depletion by the aerobe (Sherris, 1984b; Gorbach, 1974). Quill fatty acids, by inhibiting the gram-positive members of such an association, could contribute substantially to reducing quill infectivity. The quills of the North American porcupine remain formidable defense weapons, but their efficacy rests on physical factors, not microbiological ones.

BRANCH-CUTTING BEHAVIOR BY THE VOLE (*Microtus pennsylvanicus*) A Mechanism to Decrease Toxicity of Secondary Metabolites in Conifers

JACQUELINE ROY and JEAN-MARIE BERGERON

(Received November 1, 1988; accepted April 19, 1989)

Abstract—While investigating the preferences of meadow voles (*Microtus pennsylvanicus*) toward various coniferous species, we noted they often cut the branches of young trees, and then left them lying on the snow for two days or more before eating them completely. We tested whether this "behavioral manipulation" of a potential food resource resulted in a decrease in the level of secondary metabolites in branches. We found that after being cut for more than three days, the branches of young conifers had significantly less phenolics and condensed tannins. These postmanipulation levels of secondary metabolites were similar to those found in preferred summer food resources. Voles were thus capable of transforming a low-quality resource into one that was more compatible with their feeding patterns and detoxification mechanisms.

Key Words—Meadow vole, *Microtus pennsylvanicus*, plant–animal interaction, conifers, phenolics, tannins.

INTRODUCTION

Herbivores have developed different means to reduce the toxicity of secondary metabolites commonly found in plants (Levin, 1976). Freeland and Janzen (1974) have suggested that mammals could transform terpenes into vitamin A, E, and K precursors, but the most striking adaptations reside in the food manipulation behaviors that many species have developed. African ungulates are known to prefer tree species that are low in tannins (Cooper and Owen-Smith, 1985) while Colobus monkeys (*Colobus quereza*) prefer the foliage of trees that

0098-0331/90/0300-0735$06.00/0

have low levels of procyanidin tannins (Oates et al., 1977). Mountain hares (*Lepus timidus*) and snowshoe hares (*Lepus americanus*) are so sensitive to triterpenes or phenolic glycosides that they select very carefully individual trees or parts of trees having the lowest concentration (Reichardt et al., 1984; Tahvanainen et al., 1985). Large herbivores, like smaller ones, are thus well equipped to evaluate the palatability of potential foods on the basis of phenolic compounds (Beart et al., 1985; Swain, 1979). While doing cafeteria tests with meadow voles (*Microtus pennsylvanicus*) to establish their ranking preferences toward various coniferous species, we observed that they routinely manipulated the conifers in a peculiar way. After cutting the branches from the trunk and stripping the needles from the branches, they left the branches on the snow for two or three days before eating them completely. We set up an experiment mimicking this behavior to find out whether it had an effect on the levels of secondary metabolites in branch tissues. The target metabolites were phenolics and tannins, because they are already known to affect food selection, growth, and survival in the vole (Lindroth et al., 1986; Bergeron and Jodoin, 1987).

METHODS AND MATERIALS

The following procedure was adopted to mimic exactly the branch-cutting behavior that voles showed in cafeteria tests during winter. On day 1, all branches of 30 young conifers were cut off and left exposed outdoors to early winter conditions. The enclosure was adjacent to the animal house and roofed to protect the experimental animals from rain, sleet, and snow. Ambient temperature ranged from -5 to $0°C$ at the time of study. The branches of 10 more trees per species were cut, stripped of their needles, and brought to the laboratory to be divided into three subsamples for immediate analysis. The first subsample consisted of the whole branch; the others were comprised of bark and cambium and of secondary xylem only. These samples were ground to 1 mm in a Brinkmann mill and processed immediately. On day 3, needles of the 30 trees left outside were removed from the branches, and a sample involving 10 of these trees was brought to the laboratory to be divided into another three subsamples to be processed as previously described. On day 5, all branches of the remaining 20 trees were dissected to separate bark and cambium from the secondary xylem, and a sample of 10 of these trees was brought to the laboratory for immediate analysis. The remaining material from the last 10 trees was analyzed on day 7 to complete the time gradient observed from voles.

Manipulations of young trees ($3\frac{1}{2}$ years; height 30–45 cm) were all performed under winter conditions, and the samples were ground and analyzed the same day to circumvent the rapid chemical changes in the laboratory that characterize phenolics and tannins in biological material (Lindroth and Pajutee, 1987). Total phenolics were estimated from the colorimetric method of Single-

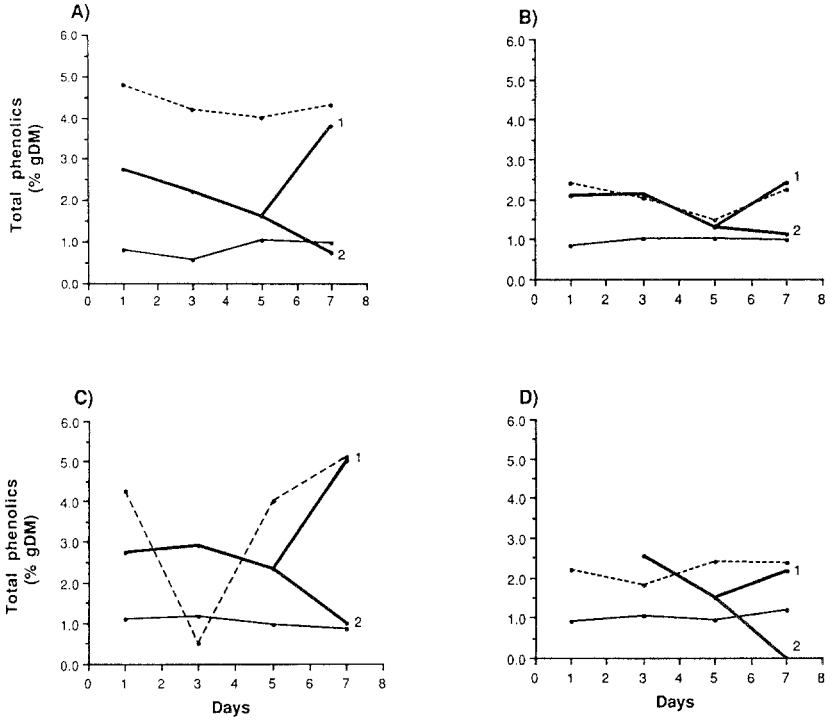

FIG. 1. Estimation of total phenolics in branch tissues of various coniferous species: ———— whole branch, ---------- bark/cambium layer, ———— xylem. ton and Rossi (1966) using gallic acid as a standard (readings at 765 nm). Condensed tannins were quantified following the colorimetric procedure of Burns (1971) as modified by Price et al. (1978) using a 1 : 1 mixture of catechin and epicatechin as standards (readings at 500 nm). Experiments were performed on duplicate samples of four coniferous species: Norway spruce (*Picea abies*), white spruce (*Picea glauca*), Norway pine (*Pinus resinosa*) and white pine (*Pinus strobus*). Differences in phenolic or tannin levels between day 1 and day 5 were drawn from one-way ANOVAs (SAS Institute, 1985).

RESULTS

Phenolic contents in whole branches tested decreased dramatically from day 1 to day 5 for three of the four coniferous species (Figure 1). In white spruce, phenolics dropped from 2.8%/g DM (Dry Matter) to 1.5% on day 5

(Figure 1A), which represents a significant loss ($Fs = 122.09$, $P < 0.05$) of 72%. Branches of Norway pine (Figure 1B) showed a loss of 64% ($Fs = 63.73$, $P < 0.05$), while those of Norway spruce (Figure 1C) yielded the lowest, albeit significant, results with a 22% decline ($Fs = 18.08$, $P < 0.05$). Dosages in branches of white pine (Figure 1D) could not be established on day 1 because of a handling error, but a closer examination of phenolics found in the bark–cambium and xylem tissues suggests that similar phenomena could also exist for the species. Total phenols increase slightly in three of the four coniferous species between day 5 and 7 to dosages that become almost equal to those of day 1.

The reduction of condensed tannins in branches follow exactly the patterns showed by phenolics (Figure 2). In white spruce (Figure 2A), doses varied from 0.29%/g DM at day 1 to 0.18%/g DM at day 5, representing a loss of 68% ($Fs = \infty$, $P < 0.05$). Branches of Norway pine (Figure 2B) lost 60% of their

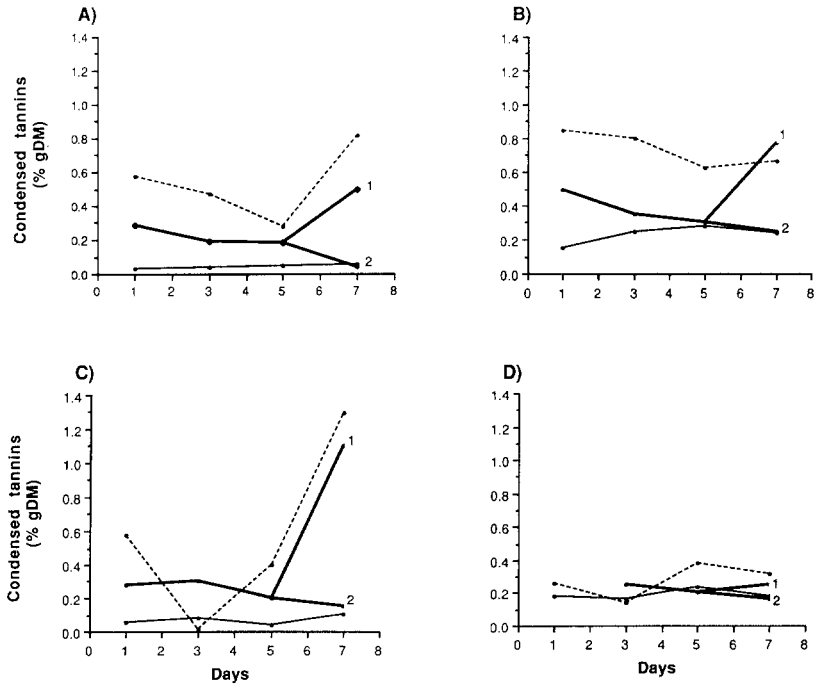

FIG. 2. Estimation of condensed tannins in branch tissues of various coniferous species: ——— whole branch, ---------- bark/cambium layer, ——— xylem. contents in tannins during the same period ($Fs = 70.0$, $P < 0.05$), while that of Norway spruce (Figure 2C) decreased by 43% ($Fs = 16.0$, $P < 0.07$). Branches of white pine (Figure 2D) would probably have followed the same pattern because tannin levels in bark–cambium and xylem subsamples vary in the same way as the other species (Figure 2).

DISCUSSION

Voles are well known to cause debarking damage to deciduous and coniferous trees in winter (Sartz, 1970; Byers, 1974; Wysolmerski et al., 1980). Reports in the literature cite that they gnaw partly or entirely the base of trunks (Jokela and Lorenz, 1959), and more rarely the branches, although Hansson (1985) reported this type of feeding behavior. However, voles cannot cut the branches off trees very easily unless thay are young trees or trees exposed above the snow cover.

We had the opportunity in the spring of 1988, after a peak year of vole numbers, to observe more than 10 million young coniferous trees destroyed in a government nursery using the branch-cutting method that we have just explored in this experiment. Herbivores are known to prefer high-nutrient food resources with low levels of secondary metabolites such as polyphenolics (Bryant, 1981; Bryant and Kuropat, 1981; Sinclair et al., 1982; Palo, 1984; Tahvanainen et al., 1985). Hares seem to be able to detect camphor dosages in conifers, notably in white spruce, and adjust their browsing behavior accordingly (Sinclair et al., 1988). Furthermore, food preferences of meadow voles are positively associated with low phenolic contents in plants (Bergeron and Jodoin, 1987). We have shown elsewhere (Bergeron and Jodoin, 1987) that unpreferred herbaceous species contained about twice as much phenolic (± 3.0 to 5.0%/g DM) compared with preferred species (± 1.3 to 2.5%/g DM). Moreover, it is known that voles grow poorly and have poor body condition when fed diets with phenolic additives (Lindroth et al., 1986). Condensed tannins have also been associated with low reproductive success (Berger et al., 1977) and reduced food intake (Lindroth and Batzli, 1984) in many vole species. In spite of the fact that most of the phenolics tested were different in structure, we can very easily see the reasons why voles can readily detect them in plants.

This experiment showed that phenolics from fresh-cut branches of most conifers were as high as those found in avoided plant resources of a vole habitat. We argue here that voles do not have to use detoxification mechanisms to transform a low-quality food into a potentially good food resource. By cutting the branches and letting them stand under normal early winter conditions, voles reduced by half the doses and transformed on a short-term basis (within five days) the twigs into usable food. Disappearance of phenols may be explained

in terms of polymerization or oxidation processes that have not been followed in this experiment. Isoprenoids are volatile compounds that could have disappeared easily after handling by voles. The sudden increase of phenols after the initial five-day period is unexplainable at the present time but suggests that voles must use quickly such food resources to maximize nutrient intake. Samples of cut twigs yielded protein contents as high as 12% in winter (Bergeron, unpublished data). If this is coupled with low amounts of phenolics (1.5%/g DM), this material can be regarded as a high-quality food supply. Triggering mechanisms leading voles to switch from their normal winter diet in terms of stems, roots, fruits, and seeds of herbaceous species (Batzli, 1985) to young deciduous or coniferous trees are not understood at present time, but whatever the cause, these animals have developed a remarkable adaptation that may increase tremendously the overall food supply in a harsh season.

Acknowledgments—This study was supported by a Quebec FCAR scholarship to Jacqueline Roy, by grants from the Strategic Program of the Natural Sciences and Engineering Research Council of Canada, and from la Fondation FCAR to Jean-Marie Bergeron. Technical assistance of J.D. Bucyanayandi and B. Mercier was greatly appreciated. We thank L. Jodoin, B. Talbot, D. Thomas, and two anonymous reviewers for their helpful comments on earlier drafts of this manuscript. A NEW SARPEDOBILIN-CONTAINING BUTTERFLY *Papilio graphium stresemani stresemani* and Its Bioecological Situation Within the Species

MICHEL BARBIER

Institut de Chimie des Substances Naturelles
CNRS, 91198 Gif sur Yvette Cedex, France

(Received January 17, 1989; accepted April 20, 1989)

Abstract—The doubly cyclized bile pigment sarpedobilin (**3**) represents a unique case in nature. In spite of being present in trace amounts in many butterfly and moth species containing pterobilin (**1**) or phorcabilin (**2**) as the main bilin, this substance occurs as the main pigment in a restricted number of species geographically limited to Southeast Asia. We have isolated and identified sarpedobilin **3** (as the dimethyl ester) as the main bile pigment from *Papilio graphium stresemani stresemani* (from Ceram island, Indonesia) in the amount of ca. 0.1 mg per individual, double that found in *Papilio sarpedon* or *P. weiskei*. We conclude that *P. sarpedon* (and subspecies) *P. weiskei,* and *P. stresemani* represent, in terms of evolution (see article), a group of closely related species. By comparison of colored wing patterns and resistance of the chromoproteins to hydrolysis by MeOH–H_2SO_4, *P. stresemani* is near *P. weiskei*. The bioecological relationships of the three sarpedobilin-containing species is discussed.

Key Words—Sarpedobilin, bile pigment, butterfly, *Papilio graphium stresemani stresemani, P. sarpedon, P. weiskei,* Lepidoptera, Papilionidae, bioecological relationships.

INTRODUCTION

We have shown, over the past 25 years (Barbier, 1981) that the linear bile pigment pterobilin (biliverdin IX γ, **1**, Figure 1) is widely distributed among both larvae and adults of butterfly and moth species. This screening of the Lepidoptera was extended to some 250 species and led to the isolation of two other blue–green bilins, phorcabilin (**2**) and sarpedobilin (**3**), pigments which were first extracted from *Papilio phorcas* (males) and *Papilio sarpedon* (Vuillaume and Barbier, 1969; Choussy and Barbier, 1975; Bois-Choussy and Barbier,

FIG. 1. Butterfly and moth bile pigments: (**1**) pterobilin, (**2**) phorcabilin, (**3**) sarpedobilin. P = $-CH_2CH_2COOH$ or $-CH_2CH_2COOCH_3$ in the methyl esters.

1977, 1978). Pterobilin **1** is formed from the ring opening of protoporphyrin IX at the γ bridge position. Phorcabilin **2** and sarpedobilin **3** can be obtained in vitro by irradiation with visible light (Choussy and Barbier, 1976; Bois-Choussy and Barbier, 1978). These substances occur in the hemolymph or in the cuticle and wing membranes, and are bound to proteins that protect them from irradiation. Chromoproteins of **1** and **2** cannot be photocyclized as shown by an in vitro experiment (Bois-Choussy, 1977; Barbier, 1981). Many species contain trace amounts of phorcabilin and sarpedobilin as secondary bile pigments (Barbier, 1981). Species containing sarpedobilin **3** as the main pigment are very rare and, until now, where limited to *P. graphium sarpedon* (all investigated subspecies to date) and to *Papilio weiskei* (Choussy and Barbier, 1975). *P. sarpedon* is widely distributed in the southeast of Asia, while *P. weiskei* is more abundant in Papua and New Guinea. *P. weiskei* shows an extraordinary patchwork of colors on its wings with superimposition of zones containing sarpedobilin (blue-green) with pink areas from which ommin was isolated (Barbier, 1983). Recently, the screening among species was extended to butterflies and moths from South America, but we were unable to discover any other sarpedobilin-containing species. This observation pointed out the scarcity of Lepidoptera containing this pigment. Due to its polycyclized structure, sarpedobilin **3** is more reminiscent of an alkaloid than of a bile pigment, and it was shown to give stable adducts with polyanions. Thus, dicarboxylic acids of the Krebs cycle (Barbier, 1985), ATP, and DNA, react with sarpedobilin (as the dimethyl ester), and this reactivity explains the moderate growth-inhibiting properties (Vuillaume et al., 1986) that were noted in vitro.

Recently we noted a rare butterfly species, *Papilio graphium stresemani stresemani*, presenting blue-green spots on the wings with a pattern that resembles *P. weiskei* but with no apparent pink areas, and we decided to extract and study this pigment. We present the isolation, identification, and spectrophotometric determination of sarpedobilin in this species and discuss the bioecological relationships involved.

METHODS AND MATERIALS

Wings of *Papilio graphium stresemani stresemani* from Ceram Island, Moluccas Archipelago, Indonesia, were cut into small pieces and submerged in a mixture of absolute methanol–sulfuric acid 15% (ca. 4 ml/animal). The suspension was stirred vigorously with a magnetic stirrer to a paste and then kept 30 hr at room temperature. After filtration through a small cotton plug and washing the filter by ca. 2 vol of methylene chloride (8 ml/animal), twice the volume of water was added. After shaking, the organic CH_2Cl_2 phase contained all the pigment dimethyl ester. The organic phase was washed twice with an equal volume of water, dried over Na_2SO_4, and concentrated to a small volume prior to chromatography.

TLC was carried out on Schleicher-Schüll SiO_2 films, developed with a mixture of CCl_4–CH_2Cl_2–MeOH 5 : 1 : 1 (R_f of sarpedobilin dimethyl ester, 0.35), and compared with a standard. Authentic samples of pterobilin, phorcabilin, and sarpedobilin dimethyl esters for comparison were prepared according to Bois-Choussy and Barbier (1983) or extracted from butterflies (*Pieris brassicae, P. phorcas*, and *P. sarpedon*). Spectrophotometric determination of the pigment dimethyl ester was carried out on a Perkin-Elmer lambda-5 automatic recorder. Microdegradation of the pigment dimethyl ester was obtained by the action of chromic acid according to Rüdiger et al., 1968, and the fragmentation pattern was compared with an authentic sample of sarpedobilin dimethyl ester (TLC, development with CCl_4–cyclohexane–ethyl acetate 5 : 1 : 3), visualization of imides by treatment with Cl_2, and spraying with a benzidine solution.

RESULTS AND DISCUSSION

Papilio graphium stresemani stresemani presents on its wings a series of green and deep blue spots in a patchwork similar to that of *P. weiskei*, except for the pink areas due to accumulation of ommin. *P. graphium stresemani stresemani* is a rare butterfly occurring in Ceram Island, Indonesia, that is, in a very delimited geographical zone. Extraction of the bile pigment as the dimethyl ester was accomplished by treatment of the butterfly wings with methanol–sulfuric acid according to Choussy and Barbier (1975). Identity with sarpedobilin dimethyl ester was demonstrated by direct comparison with an authentic sample isolated from *P. sarpedon* by using the same method (cochromatography on SiO_2 layer with CCl_4–CH_2Cl_2–MeOH 5 : 1 : 1, R_f = 0.35), VIS spectra in methanol (single maximum at 600 nm), shift of the maximum of absorption to 660 nm by adding malonic acid (Barbier, 1985) (formation of an adduct, a specific property of sarpedobilin), and chromic acid oxidation to imides as reported (Choussy and Barbier, 1975).

The spectrophotometric determination of the pigment after isolation indicated ca. 0.1 mg/animal, that is to say approximately double the amount of sarpedobilin dimethyl ester previously isolated from *P. sarpedon* or *P. weiskei* obtained from Malaya and New Guinea.

Biosynthesis of the bilins in butterflies and moths appears to be under genetic control, resulting in specificity in the structure of the final main pigment. Due to its insularity, *P. stresemani* has very likely undergone genetic changes from a common ancestor with *P. weiskei*, both species remaining near neighbors of *P. sarpedon*, which had a wider distribution. These three sarpedobilin-containing species thus form a bioecological group of closely related butterflies that have followed different paths of evolution.

Several attempts to establish the role of irradiation in the transformation of pterobilin into sarpedobilin in vivo led to contradictory results. *P. sarpedon* larvae were reared in absence of light (except for cleaning and feeding), and sarpedobilin dimethyl ester was spectrophotometrically determined. As could be expected from such experiments, mortality among the larvae reared under such conditions from L_1 to L_5 was very high, and results were not reproducible in four different assays. In these experiments, the amount of sarpedobilin in the surviving pupae was 65% more in the first series, but 30, 48, 60% less in three further assays, by reference to rearing in normal condition of light. For example, in the fourth experiment, of 60 larvae that were reared in absence of light from L_2 to L_5, only eight survived to pupation and contained ca. 10–12 μg each of sarpedobilin, while standard pupae contained 18–22 μg of pigment. It is, of course, impossible to draw conclusions from these experiments carried out under difficult biological conditions. It thus remains to be learned if the cyclization of pterobilin **1** into phorcabilin **2** and sarpedobilin **3** is due to the action of light on the integuments or if these cyclized bile pigments arise from an enzymatic process. A relay should be taken by biologists to demonstrate if, by means of cellular extracts, the cyclized bilins **2** and **3** could be formed from pterobilin in the absence of light.

When the extraction of sarpedobilin is carried out on the wings of butterflies that were simply cut into pieces, not mashed with a magnetic stirrer, great differences are noted between the species. *P. sarpedon* gives most of the pigment extracted into the methanol–sulfuric mixture after 30 hr, while *P. weiskei* only furnishes a small amount. In the case of *P. stresemani*, nearly all the pigment remains unextracted from the wing membrane. This last case seems to indicate a similarity with *P. weiskei*, which is susceptible to a biogenetic interpretation. It has been shown previously that these pigments are bound as chromoproteins within the wing membranes. [They can be extracted as such by a phosphate buffer, pH 7.2, and purified by repeated precipitations with 25, 20, 15% ammonium sulfate solutions, according to Bois-Choussy (1977).] The biosynthesis of these associated proteins and their binding to the wing membranes are, of course, under genetic controls. Due to the small number of animals so far available, such chromoproteins from *P. stresemani* could not be extracted and chromatographically compared.

BEHAVIORAL RESPONSE OF MALE WHITE PEACH SCALE TO THE SEX PHEROMONE, (*R*,*Z*)-3,9,-DIMETHYL-6-ISOPROPENYL-3,9-DECADIEN-1-OL PROPIONATE AND CORRESPONDING ALCOHOL[1]

J.R. McLAUGHLIN

Insect Attractants, Behavior and Basic Biology Research Laboratory, Agricultural Research Service, U.S. Department of Agriculture Gainesville, Florida 32604

(Received December 12, 1988; accepted April 17, 1989)

Abstract—Males of the white peach scale, *Pseudaulacaspis pentagona* (Targioni-Tozzetti), in Florida differ from this scale in France in their responses to putative pheromonal chemicals presented in a laboratory bioassay. Males from Florida were attracted to, and exhibited sexual (copulatory) behaviors at, the locus of evaporation of (*R*,*Z*)-3,9-dimethyl-6-isopropenyl-3,9-decadien-1-ol propionate (P) (previously identified from effluvia of Florida females). Addition of the corresponding primary alcohol (A) to the propionate did not alter the attraction of Florida males to the synthetic P and did not alter their sexual responses from those exhibited by males exposed to P alone. In contrast, the effluvia from French scales has been reported to contain P and A, and the alcohol has been reported in laboratory studies to be required to release sexual behavior in French males. This suggests that the conspecific status of the scale in Florida and France should be reexamined. Field trap baits with 2.5 μg of a 1 : 1 mixture of P and A captured significantly fewer Florida males than traps baited with 1.25 μg of P alone, but traps similarly baited with 0.125 μg of each material captured the same number of insects as traps baited with 0.125 μg of P alone.

Key Words—Pheromonal races, white peach sale, *Pseudaulacaspis pentagona*, Homoptera, Coccoidea.

INTRODUCTION

A volatile chemical, (*R*,*Z*)-3,9-dimethyl-6-isopropenyl-3,9-decadien-1-ol propionate, was identified by Heath et al. (1979) as a female sex pheromone of the white peach scale, *Pseudaulacaspis pentagona* (Targioni-Tozzetti) in Florida, U.S.A. Sex pheromones are commonly blends of chemicals, and Einhorn et al. (1983) reported the presence of the above propionate and the corresponding alcohol in volatile material emanating from female white peach scales in France. They described laboratory behavioral assays (Einhorn et al., 1983) in which the propionate attracted males while the alcohol did not; however, very few of the males exposed to only the propionate exhibited sexual behavior. When males were exposed to mixtures of the alcohol and propionate, many of them were attracted and displayed sexual behavior. Conversely, Heath et al. (1979) (assays conducted by J.R.M.) had reported that U.S. males responding in a similar assay to the biosynthesized propionate obtained from extracts of female volatiles or to laboratory-synthesized propionate exhibited sexual behavior that appeared the same as that of males exposed to pheromone-releasing females.

This study examines the response of U.S. males to these putative pheromonal chemicals (synthetic) and to the natural propionate and alcohol isolated and purified from extracts from French females.

METHODS AND MATERIALS

The chemicals were synthesized and analyzed according to the methods described in Heath et al. (1979, 1980) ($\geq 99\%$ *R* and $\geq 98\%$ *Z*).

Volatiles from French scale were provided by J. Einhorn, CNRS Laboratoire des Médiateurs Chimiques, Domain de Brouessy, Magny-les-Hameaux, 78470 Saint-Rémy-lés-Chevreuse, France. French scale was collected from peach and mulberry and reared on white (Irish) potato. The volatiles were collected as described by Einhorn et al. (1983) and were dissolved in pentane. The propionate and alcohol within these volatile extracts were isolated on a silica column and by gas–liquid chromatographic methods described in Heath et al. (1979, 1980) and analyzed in the manner described by Heath et al. (1979, 1980) using capillary column chromatography (Dexsil 300 GC, 60 m × 0.76 mm ID; OV-101, 35 m × 0.25 mm ID; SP-1000, 45 cm × 0.25 mm ID), and GC-MS (Nermag R-10-10 C in EI and CI modes). The isolated materials were at least 99% pure. The naturally derived alcohol and propionate were recombined in pentane in a ratio of 1 : 1. This ratio was chosen because it is in the mid-range of the ratios tested by Einhorn et al. (1983).

The insects used in the laboratory bioassay were newly emerged from pupae on infested peach wood obtained at Quincy, Florida. The assays were con-

ducted during the afternoon hours of peak male emergence (1–4 PM) (McLaughlin and Ashley, 1977). The procedure was that described in Heath et al. (1979). Groups of males were aspirated into small clear glass bottles. A test sample in 5 μl of pentane was then placed on an 8 × 12-mm stainless-steel planchet at the center of a 90-mm-diam. arena (inverted plastic Petri dish lid lined with filter paper). After the solvent evaporated, males (mean = 11.4, range 6–16) were introduced ca. 25–30 mm from the treated end of the planchet by sharply striking the lip of the open bottle mouth against the floor of the arena. The cover (dish bottom) was placed on the arena and the males were observed for 2 min. (The arena covers were wiped with a 10% solution of ethylene glycol in water to reduce the static charge, which would interfere with the mobility of the males.) The number of males on or touching the planchet, the number exhibiting copulatory movements, and the total number of males in the arena were recorded at the end of the 2-min observation period. An arena was used only once in a day. The filter paper liner was discarded, and the Petri dish was washed in a water–detergent solution and stacked open to dry and air out for three days before being used again. The planchets were washed with pentane and held overnight in a 100°C oven. Each treatment was tested concurrently in three different arenas each day (replicate). Tests were conducted on 10 different days at doses of 10 pg, 1 pg, and 0.1 pg of synthetic propionate alone and of synthetic alcohol to propionate ratios of 6 : 1, 1 : 1, and 0.1 : 1, in which the dose of propionate was 10 pg, 1 pg, and 0.1 pg. A test also was conducted with the natural propionate and alcohol obtained from the French scale extract (1 : 1 ratio) at the same three doses and number of replications.

Field assays were conducted in a peach orchard (13 ha) near Hawthorne, Florida. Each field trap consisted of a 22 × 14-cm panel constructed from the cardboard top of a Pherocon 1C-type trap (Trece, Inc., Salinas, California) covered on both faces with an insect trapping material (Stickem Special, Michel & Pelton, Co., Emeryville, California) mixed with about 10% (volume) of mineral oil. A bait was treated with the candidate attractant and suspended within a 2 × 2-cm opening cut at the center of each sticky panel. The baits were prepared from cylindrical 8-mm × 3-mm-diam. needle seal rubber septa (Chemical Research Supplies, Inc., Addison, Illinois) which were cut lengthwise into quarters. Each material or mixture was dissolved in 10 μl of pentane and pipetted onto a cut septum. The treated septa were held in a laboratory hood at about 23°C for two days prior to being placed in traps.

The traps were suspended 1.5 m from the ground and 30 cm apart in a line. Each trap line was about 3 m from the nearest scale-infested tree. For each experiment, each treatment was assigned a random location within a trap line (block) and then systematically moved to the adjacent position each time the traps were inspected. Two blocks of traps, separated by 50–80 m, were employed in each experiment. The first experiment compared the capture of

males on traps baited with 1.25 μg of synthetic propionate, 2.5 μg of the 1 : 1 mixture of female-synthesized P and A, and pentane controls. These traps were inspected on eight consecutive days. The bait was transferred each day to a clean panel and moved to the next trapping position. The panels were brought into the laboratory and the male captures determined and recorded. In the second experiment, the traps were baited with two doses (1.25 or 0.125 μg) of synthetic propionate alone, synthetic alcohol alone, a 1 : 1 mixture of synthetic alcohol–propionate, or a pentane control. The second test was conducted for six days.

RESULTS

Males responded to pheromone in the bioassay by rapidly walking directly to or in an arc toward the treated planchet. Males never walked or flew onto untreated steel planchets placed in assay dishes. I have observed several hundred males of white peach scale interacting with colonies of sexually mature females on potato or collected peach wood and on peach trees. Males that fly to a female or colony of females land adjacent (millimeters to 1–2 cm) to a female and walk to her. Typically, a male mounts the cover of the female, turns to orient to her (head toward the center of the cover and genital stylet aligned with the pygidium of the female), and exhibits a very characteristic probing behavior under the lip of the cover with his aedeagus. These same behaviors are released in the presence of female sex pheromones in the laboratory assay: The male walks to the locus of the evaporating pheromone, mounts the planchet and then rocks back and forth while thrusting at the surface between its metathoracic legs with its aedeagus, often turning as if attempting to become properly oriented to a female.

Behaviors that resulted in males arriving upon the planchet are termed attraction, and behaviors involving thrusts with the aedeagus are termed copulatory behavior in the ensuing discussion. These behaviors were performed by the Florida males in the presence of the synthetic propionate alone, and the addition of the alcohol did not alter this response of U.S. males.

Table 1 summarizes the attraction and copulatory behavior measured in the laboratory bioassays. The attraction responses are in very close agreement with the data of Heath et al. (1979). Copulatory behavior was noted with all doses of propionate alone, and neither attraction nor copulatory behavior appeared to be altered by the presence of the alcohol in mixtures with the propionate, i.e., mean percentages for males attracted (or exhibiting copulatory behavior) at each dose are not statistically different across propionate–alcohol mixtures (Table 1). Neither attraction nor copulatory behavior was exhibited in tests with the alcohol alone. Both behaviors were reduced in the 6 : 1 (A/P) treatments, which may reflect a reduction in the evaporation rate of the propionate but does not

appear to indicate any strong inhibitory effects due to the alcohol. Responses to the 1:1 mixture of natural alcohol and propionate were equivalent to those of the synthetic materials at all doses.

The results of the field-trapping experiments are summarized in Tables 2 and 3. The 1:1 mixture of natural propionate–alcohol captured only 49% of the number of males captured by the bait containing only the synthetic propionate (Table 2). When the synthetic alcohol was added (1:1) to 1.25 μg of the synthetic propionate, male captures were reduced by 71% (Table 3). However,

when the dose of the propionate and alcohol was reduced 10-fold, the propionate and the 1 : 1 (P/A) mixture captured like numbers of males (Table 3). Male captures with the alcohol alone were not statistically different from captures in the unbaited control traps.

DISCUSSION

The alcohol at the higher dosage reduced the number of males captured in field traps, but it did not reduce the response of males to a locus of evaporating propionate in the laboratory bioassay. This may have been due to the presumably higher evaporation rate of the alcohol from the trap bait (1.25 μg) than from the assay planchet. Certainly, the laboratory assay and field trap data in which the lesser dose of alcohol was presented (0.125 μg) suggest that the alcohol is not highly inhibitory to male attraction.

Heath et al. (1979) found no evidence for the presence of behaviorally active chemicals other than the propionate in Florida scale and did not analyze fractions of the effluvia that may have contained the alcohol. Their identification was based upon the laboratory assay described here, which, in the case of the Florida scale, is not influenced by the alcohol within the dosages tested. Thus, the presence of the alcohol in the volatile emissions of sexually mature Florida scales is not precluded.

Einhorn et al. (1983 and personal communication) reported that the volatile emissions of the French female white peach scales contained 15–40% of the propionate and 60–85% of the alcohol. A mixture of 1 : 1 alcohol to propionate

would evaporate the two compounds at a ratio (alcohol–propionate) of about 80:20 [estimated from gas chromatography data using the method of Heath et al. (1986)]. Einhorn et al. (1983) tested dose ratios (amount applied to the evaporative substrate) of 500:85, 50:8.5, and 85:85 (ng of alcohol–ng of propionate) in their laboratory assay, which was similar to the assay I described in Heath et al. (1979) and in this study. These are much greater amounts than were applied in assays with Florida scales; however, the French assays were conducted using filter paper (Whatman No. 3) as the evaporative substrate (Einhorn et al., 1983) while the Florida assays utilized a metal surface. Experiments (McLaughlin, unpublished) leading to the development of the assay described in Heath et al. (1979) determined that the amounts of female extracts placed on filter paper that elicited a given level of male response were greater than the amounts required when the steel surface was used (these preliminary tests indicated at least a 10- to 100-fold difference). This difference in bioassay method prevents any definitive conclusion regarding the relative sensitivity of French and U.S. males to pheromone in laboratory bioassay; however, when taken together, the results of this paper and of the experiment of Einhorn et al. (1983) strongly indicate that U.S. males from Florida and French males respond differently to the propionate in the absence of the alcohol.

These results suggest that the taxonomic status of this species should be reexamined. White peach scale occurs worldwide and has a very great host range. The suggestion that there are different races or forms of *P. pentagona* has been put forward in several reports of differences in egg coloration (Tremblay, 1958; see also Bennett and Brown, 1958) and variation in host relationships and parasites (for some examples see Hughes, 1960; Clausen, 1978; Cock, 1983). One taxonomic revision in the United States resulted in the recognition of an additional cryptic species, *P. prunicola* (Maskell) (Davidson et al., 1983) whose sex pheromone has not been examined.

Acknowledgments—I thank J. Einhorn for the extract of volatiles from French scale and R.R. Heath of this laboratory for preparation of the propionate and alcohol and quantification of the chemicals used. Drs. F.D. Bennett, Department of Entomology University of Florida; D.S. Moreno, Subtropical Fruits Insect Research, USDA/ARS, Weslaco, Texas; and J.A. Coffelt, USDA/ARS, Gainesville, Florida, provided very useful reviews of the manuscript.

(Received March 13, 1989; accepted April 24, 1989)

Abstract—Several cotton *Gossypium* spp. race stocks have been identified that possess resistance to the boll weevil *Anthonomus grandis* Boh. because oviposition is decreased. In this work, a number of known cotton constituents that influence stimulation of feeding and attractancy for this insect were found to have little or no influence on oviposition. These include gossypol, β-bisabolol, caryophyllene, some fatty acids and their methyl esters, some wax esters, flavonoids, condensed tannins, and chrysanthemin. Analysis of cotton bud surfaces showed that the content of volatile terpenoids was generally higher in resistant lines, but bioassays did not show decreased oviposition in the presence of the terpenoids. The sugars (glucose, fructose, and sucrose) found in anthers, uniformly stimulated oviposition in the bioassay, and their content was higher in susceptible lines. These results suggest that a major basis of resistance to boll weevils as related to oviposition may be the decreased content of sugars in resistant lines. The analysis of free sugars in the anthers, and perhaps also the analysis of bud surface terpenoids, may provide a basis for selection or genetic production of cotton lines resistant to the boll weevil.

Key Words—Cotton, *Gossypium* spp., boll weevil, *Anthonomus grandis*, Coleoptera, Curculionidae, oviposition, plant–insect interaction, terpenoids, sugars.

INTRODUCTION

The identification of constituents in cotton *Gossypium* spp., plants that affect boll weevil *Anthonomus grandis* Boh. (Coleoptera: Curculonidae) feeding and oviposition behavior has been pursued over the past 30 years since the report of Keller et al. (1962) that feeding stimulants were present in cotton flower

buds. Reports on the constituents of flower buds were made by Chan et al. (1978); Hanny (1980); Hedin et al. (1967, 1977); Struck et al. (1968a,b); Waiss et al. (1981). McKibben et al. (1985) recently identified some cotton plant wax esters with feeding stimulant activity. Since the 1960's, there also has been an active interest in cotton volatiles that affect boll weevil behavior, particularly attractancy. However, factors affecting boll weevil oviposition behavior have not been similarly addressed, although it was observed that certain primitive (wild) race stocks suppressed oviposition. Jenkins et al. (1978) reported that oviposition was decreased to 30% and 36% of normal in field tests with two selected entries, T-326 and T-1180. In later no-choice laboratory tests, McCarty et al. (1987) showed that while feeding punctures were 24% higher in flower buds of these two primitive race stock entries, presumably because of changes in searching and probing behavior, oviposition was reduced to 54% and 57% of the control. In a subsequent field test, damaged squares were reduced to 59% and 65% of the control and adult emergence was decreased to 47% and 50% of the control (McCarty et al., 1987). These studies indicate selection for host-plant resistance to the boll weevil may be possible, and the resistance may have a chemical basis.

The adult female moves to the flower bud after alighting on the plant and then proceeds to construct an oviposition hole in which the egg is placed and the hole sealed. It is not understood how chemicals and/or other factors may affect the normal behavior of the female in making a decision to oviposit. Bud surface chemicals may modulate initial behavioral responses. Chemicals in the carpel and anthers that are encountered in the excavation of the hole may also affect the oviposition sequence. In this present study, we report efforts to establish laboratory bioassays that will reliably evaluate the constituents that the female encounters both on the bud surface and in the anther that affect the oviposition process and to identify active constituents.

METHODS AND MATERIALS

Cultivars, Race Stocks, and Agronomic Practices. Day-neutral BC_2F_4 lines of T-326 and T-1180; a commercial cultivar, Stoneville 213 (ST213); and a breeding line, Stoneville 213 glandless (ST213 gl), were grown in field plots to produce flower buds for the various chemical analyses. These four plus nine other lines were analyzed for bud surface chemicals. The day-neutral lines, T-326 DN and T-1180 DN, hereafter referred to without DN, previously were reported to carry resistance to boll weevil oviposition (McCarty et al., 1987). Stoneville 213 and Stoneville 213 glandless served as susceptible controls. Standard cultural practices were followed during the growing season. All plant material was collected from cotton plants of similar maturity.

Laboratory Bioassays, Coated Buds, Oviposition Plugs, and Handling of

Insects. Boll weevils used in the bioassays were obtained from a small colony maintained on standard artificial diet at the Boll Weevil Research Laboratory. Wild males are introduced into this colony yearly to maintain the genetic diversity of the colony. Boll weevils were removed from the colony five to seven days after emergence, and sex was determined.

Coated-Bud Bioassay. Freshly collected cotton buds (8 mm diameter) from ST213 gl with bracts removed were coated with 250 μl ethyl ether or ethanol containing 250 μg of test material. The coated bud was placed in a plastic cage (2.54 cm^3) with one female weevil. The female was allowed to feed and oviposit on the test bud, in a no-choice situation, for 4 hr after which it was removed. The bud was then examined for feeding and oviposition punctures using a binocular microscope, dissected, and the number of eggs was recorded (a feeding puncture is an open puncture, while an oviposition puncture is sealed and contains an egg). The tests were run at a temperature of 29 $\pm$ 1°C, a relative humidity of 70 $\pm$ 5%, and under normal laboratory light conditions.

Oviposition Bioassay. The test chemical or isolate was incorporated in a 2% agar cylindrical plug (8 mm diameter, 12 mm length = 0.603 cc^3) that was coated with a mixture of 40% beeswax and 60% paraffin (see tables, below, for concentrations). Twenty diet plugs were produced for each test chemical. Each agar plug was placed in a plastic cage (2.54 cm^3) with one female boll weevil. The female was allowed to feed and oviposit for 4 hr. The agar plug was then examined using a binocular microscope and the number of eggs was recorded. A control consisting of a 2% agar diet plug was used with each bioassay. The laboratory conditions were the same as for the coated bud bioassay.

Chemical Analyses of Flower Bud Nutrients. Association of Official Analytical Chemists (AOAC) methods (Horwitz, 1975) were used for the following analyses: total solids (moisture), 14.083; crude fat, 14.019; crude fiber, 14.118; ash, 14.114; total protein, 2.049 (percent nitrogen $\times$ 6.25); nitrogen-free extract (NFE), by difference from 100%. Total sugars were determined by the colorimetric anthrone procedure. Protein was also determined colorimetrically by the Coomassie blue test.

Analysis of Allelochemicals. Analyses for gossypol and related terpenoid aldehydes were performed on cyclohexane–ethyl acetate–acetic acid (500:500:1; CHEA) extracts of plant (whole bud and anther) tissue by the phloroglucinol reaction [2% in absolute EtOH–concentrated HCl (1:1); stand 1 hr] with subsequent spectrometric analysis at 550 nm. The concentration was determined by comparison with data obtained from authentic gossypol and is expressed as gossypol equivalents. Condensed tannin analyses were performed on 70% aqueous methanol (MW) extracts of tissue. The anthocyanidin chromophore was developed from the tannin by boiling 1 hr with 1-butanol–HCl (95:5) (Hedin et al., 1982). The concentration was determined by comparison with the color obtained at 550 nm from a purified cotton condensed tannin sam-

ple, the structure of which was elucidated by Collum et al. (1981). The anthocyanin content was determined by measuring the absorbancy at 540 nm of an extract of freeze-dried tissue extracted with methanol–water–HCl (79:19:3), using the molar extinction coefficient (E) of cyanidin 3-β-glucoside (Hedin et al., 1967). Flavonoids were determined after extraction of freeze-dehydrated tissue with 70% aqueous acetone. Diphenylboric acid–ethanolamine complex (Natural Product Reagent A. Aldrich Chemical Co., 1%) in methanol was added, and the chromophore absorptivity at 440 nm was determined and compared to that obtained from a purified sample of isoquercitrin, the most prevalent flavonoid in cotton.

Isolation of Wax Esters. Anthers (3 g) were ground in chloroform–methanol–water (2:1:1). The nonpolar phase was concentrated and chromatographed on a 2 × 18-cm Biosil A column (Biorad Laboratories, Richmond, California) with chloroform, which eluted the wax esters as a yellow band. CI-MS (methane) via solid probe revealed the presence of a mixture of wax esters based on comparison of the fragmentation patterns with those of a number of synthetic esters. IR provided additional confirmation for the presence of the esters.

Synthetic Wax Esters. The esters were prepared via reaction of the acid with an excess of thionyl chloride in benzene at reflux temperature according to the procedure of McKibben et al. (1985). After removal of solvent and excess thionyl chloride, the acid chloride was redissolved in dry benzene and added to a molar equivalent of the alcohol and pyridine in dry benzene. The reaction mixture was heated overnight at 60°C, then solvent was removed under vacuum and the dry residue was triturated with hexane. The hexane-soluble material was chromatographed over Biosil A with the esters generally being eluted with methylene chloride. The fractions were analyzed by TLC and synthesis was confirmed by CI-MS. All chemicals were purchased from Sigma Chemical Co. (St. Louis, Missouri) except geranyl-geraniol, which was a gift from Dr. Malcolm Thompson, USDA, Beltsville, Maryland. In some cases, the ester or the acid chloride were commercially available from Sigma, obviating part or all of the synthetic work.

Isolation of Anther Water-Soluble Protein, Amino Acids, and Sugars. Water extracts of homogenized anthers (5 g in 100 ml H_2O, repeat and combine) were freeze-dried and then redissolved in water and chromatographed on a 5 × 70-cm Sephadex G-50-150 column with water as the eluant. Eight to ten 250-ml fractions were collected with the proteins eluting in the first 750 ml, and the amino acids and sugars eluting together from 1200 to 1600 ml. The amino acid–sugar fraction was freeze-dried and reconstituted in water prior to chromatography on a 2 × 6-cm Dowex 50 column that was prepared by equilibration with HCl followed by washing with water. When the sample was applied to the column, the sugars were eluted with water until reaction of aliquots with

anthrone demonstrated no further presence of sugars. The amino acids were subsequently eluted with 10% NH_4OH until reaction of aliquots with ninhydrin demonstrated that all of the amino acids had been eluted. The sample fractions were again freeze-dried prior to analysis.

GLC-MS Analysis of Cotton Bud Surface Chemicals. Approximately 30 g of cotton buds (13 lines for this only) were stirred in 200 ml of ethyl ether for 5 min. The ether was decanted, and the process was repeated with a second 200-ml portion of ethyl ether. The combined washings were concentrated to 10 ml under reduced pressure. Then 0.5–1.0 μl was analyzed by GLC–EI–MS on a DB-1 fused silica column (15 m $\times$ 0.322 mm) that was interfaced to a Hewlett Packard 5985-B quadrupole mass spectrometer through an open-split interface. The GLC was programmed from 70 to 250°C at 10°/min. An approximation of concentrations of components was obtained by comparing the MS data system total abundance count of the ion chromatograms with that of standards.

HPLC Analyses of Terpenoid Aldehydes, Amino Acids, and Sugars. HPLC analysis of the gossypol-type terpenoid aldehydes was performed on a reverse-phase C_{18} column according to the procedure of Stipanovic et al. (1988), who also kindly provided samples of hemigossypolone, and heliocides H_1 and H_2 for column calibration. Amino acids were determined by HPLC analysis after hydrolysis of anther tissue, employing their phenylthiocarbamyl derivatives (Cohen et al., 1986). Individual sugars were determined by HPLC analysis, employing a Waters μBondapak NH_4 column and acetonitrile–water (80:20).

Procurement of Chemicals. All commercially available chemicals were obtained from Sigma Chemical Co. St. Louis, Missouri. Gossypol was a gift from the Southern Regional Research Center, USDA, New Orleans, Louisiana.

RESULTS AND DISCUSSION

Bud Surface Terpenoids. The terpenoids present on the bud surface were stripped with ethyl ether and subsequently analyzed by GLC-MS. It is shown in Table 1 that β-caryophyllene was the most prevalent terpenoid in all susceptible (S) and resistant (R) lines. The total terpene content was generally higher in R lines than S lines. The glandless line, ST213 gl, possesses almost no terpenes, in confirmation of the report of Elzen et al. (1985) and Chang et al. (1988). After the terpenoids were chromatographed to yield hydrocarbon and alcohol fractions, it was determined that the hydrocarbons had no effect on oviposition. Although not statistically significant, the alcohol fraction appeared to decrease oviposition (Table 2).

Effects of Anthers and Anther Extracts on Oviposition. In the first test (Table 3), isolates from a two-phase extraction carried out with chloroform : methanol : water (2 : 1 : 1) were coated onto bud surfaces of ST213 gl. The

nonpolar fraction of the R line T-326 significantly decreased oviposition, and T-1180 also appeared to depress oviposition relative to the S lines ST213 and ST213 gl. The oviposition depression caused by the nonpolar phase of ST213 relative to that of ST213 gl probably can be attributed to gossypol in the former, although this may be of limited importance because high gossypol lines do not

strongly deter boll weevil oviposition in the field (Lambert et al., 1980; McCarty, unpublished data).

Effects of Anther and Synthetic Wax Esters on Oviposition. To determine whether the wax esters in cotton buds reported by McKibben et al. (1985) to the boll weevil feeding stimulants also affected oviposition, the following tests were carried out. Anthers were preextracted with ethyl ether to remove the wax esters. Ground, ether-extracted and nonextracted anthers were incorporated into feeding plugs. It is shown in Table 4 that oviposition punctures appeared to be

lower on the R anther lines, although this was not statistically significant. The same trend, although also not significant, was observed when ether-extracted anthers were bioassayed. All of the isolated waxes were slightly stimulatory.

Fragmentation patterns obtained by solid probe CI-MS, IR, and TLC showed that several wax esters were present in the ethyl ether extract of anthers, particularly in the R lines T-326 and T-1180. ST213 and ST213 gl contained only about 20% of that in T-326 and T-1180. By comparison with the CI-MS obtained for 17 synthetic esters, the presence of oleyl oleate, oleyl phytol, palmityl cholesterol, and palmityl and oleyl sitosterol could be presumptively detected in the ether extracts. These compounds and others had been found previously in cotton anthers by McKibben et al. (1985) and Lusby et al. (1987).

The ovipositional activity of the synthetic wax esters was bioassayed at one or more concentrations using feeding plugs. According to the results shown in Table 5, most appeared to be mildly stimulatory, and three (two of which were sterol esters) appeared to be mildly suppressant, although none of the results were significantly significant. Behenyl geranylgeraniol and lauryl phytol, compounds found by McKibben et al. (1985) to be the most feeding stimulatory of the compounds they tested, tended to stimulate oviposition mildly. The results obtained with these synthetic feeding stimulatory wax esters indicated that their potency did not appear to extend to either inhibition or enhancement of oviposition, hence further purification work on our wax esters isolates did not seem warranted.

Effects of Cotton Allelochemicals on Oviposition. The whole buds and their excised anthers were analyzed for the major allelochemicals in cotton. Gossypol was significantly higher in the anthers of ST213 than in the two R lines (Table 6) and also appeared to be slightly higher in the whole bud. ST213 gl was very low, as expected. The gossypol content of anthers was several-fold higher than in the whole buds within lines. When glands were removed by dissection from the anthers, and the glands extracted with cyclohexane–ethyl acetate–acetic acid (500:500:1) (CHEA), gossypol was found in ST213 glands, but the glands were nearly devoid of gossypol in the two R lines. Previous work by us (Belcher et al., 1983) had shown ST213 anther glands contained 43% gossypol. Bell and Stipanovic (1977) reported even higher gland gossypol (about 80%). Flavonoids appeared to be slightly lower in buds of the two R lines. Tannins and anthocyanins were much higher in buds of all lines than in anthers. The only major difference in allelochemicals between S and R lines was the lower gossypol in anthers of the two R lines.

Because gossypol is known to coexist in the plant with a number of related terpenoid aldehydes, the gossypol fraction was investigated by HPLC. Of the six major terpenoid aldehyde components, four of which were identified, all are present in ST213 and the two R lines, and there are no major differences in their distribution that could likely account for differences in oviposition by the boll weevil on these lines (Table 7).

[a] Differences from the control were not significant according to a least significant difference test at the 0.05 level.
[b] Found in wax ester isolate from T-326 and T-1180.

Finally, gossypol and several other cotton constituents were tested for their effects on oviposition in the feeding plug bioassay (Table 8). The levels tested were those present in anthers. Gossypol, a known feeding stimulant (Hedin et al., 1968), appeared to be an oviposition depressant, although not significantly so, but as previously mentioned, moderately high gossypol lines are not resistant to the boll weevil (Lambert et al., 1980; McCarty, unpublished data). Scopoletin, reported to be present in cotton plants by Wakelyn et al. (1984), was significantly depressant at the higher level. Scopoletin was not found by us in these lines, although we did obtain MS evidence for a trace of scoparone, which

had been found in cotton by Chan and Wilson (1988), and appeared to be mildly stimulatory (Table 8).

Palmitic acid appeared to be a mild oviposition stimulant while methyl linolenate was not active. Methyl linolenate was identified as an important feeding deterrent for the boll weevil in rose-of-Sharon, *Hibiscus syriacus* (L.), calyx, while palmitic acid, also present in *H. syriacus* calyx, was stimulatory (Bird et al., 1987).

The most active boll weevil plant attractant, β-bisabolol (Minyard et al.,

	0.25	36
β-Caryophyllene	0.25	98

[a] Constituents dissolved in 0.2–0.5 ml ethanol and added to 0.4 g agar and 20 ml water. The mixture was boiled, poured into the 8-mm-diameter holes of a 20-hole, 12-mm-thick aluminum plate, dipped into a melted beeswax–paraffin mixture to yield 20 agar plugs.
[b] Significantly different from the control according to a least significant difference test at the 0.05 level.

1969) appeared to be oviposition depressant at the 0.25-mg level (although not statistically so) while β-caryophyllene, also found to be attractive to the boll weevil, was not active. Overall, gossypol and β-bisabolol may contribute to suppression of oviposition, but by themselves do not appear to account for the total activity if consideration is given to the results of Tables 3 and 4, which indicate other classes of compounds also contribute to suppression of oviposition.

Effects of Anther Amino Acids, Protein, and Sugars on Oviposition. When anthers were analyzed for these nutrients (Table 9), protein was not different in the S and R lines, but the free amino acids were lower in ST213 and ST213 gl than in the two R lines. Nitrogen-free-extract (essentially total carbohydrates)

was not different in the S and R lines, but free sugars were at least 30% higher in ST213 than in the two R lines and the glandless line. In a second test, the free sugar content of ST213 was again higher than those of T-326 and T-1180.

The results of HPLC analysis of the total water-extractable solids of anthers are presented in Table 10. Comparable yields (39.9–46.8%) of solids were extractable from the four lines. The sugars fructose, glucose, sucrose, and maltose were recovered from each of the lines. Other maxima were present for which assignments could not be made, 42–65% of the solids being accounted for by these sugars. Notably, fructose was lower in the two R lines.

Free amino acid and protein isolates from anthers and, for comparison,

glycine and an amino acid mixture, were incorporated into feeding plugs for boll weevil oviposition tests (Table 11). Although none of the results was statistically significant, protein isolates of the two R lines and ST213 gl appeared to mildly depress oviposition, while the amino acid isolates tended to stimulate (up to 67%) oviposition. Glycine alone did not appear to have an effect, but a mixture of amino acids based on analysis for casein appeared to be mildly stimulatory.

Sugar isolates from anthers and several commercially procured sugars were likewise incorporated into feeding plugs at levels of 1.7–16.7% (compare with free sugars in anthers: 6.5–12.3%, Table 9) for boll weevil oviposition tests (Table 12). The sugar isolates from all lines, although not statistically significant, appeared to stimulate oviposition. The authentic sugars were all moder-

ately to strongly stimulatory except for inositol, giving responses of 19–145% above that of the control at levels equal to or below those in anthers (Table 12).

SUMMARY

Laboratory evidence was obtained that some factors present in cotton lines resistant to the boll weevil may contribute to deterrence of oviposition. The surface chemicals of cotton buds were isolated and analyzed by GLC-MS. The R lines were found to possess a higher concentration of volatile terpenoids, especially the sesquiterpenes, than the S lines. However, bioassays did not show that the terpenoid extracts, or standard terpenoids, suppressed oviposition. Nevertheless, there may be a correlation between surface terpenoids and oviposition resistance, and perhaps, some other bioassay could demonstrate a causative basis.

The wax esters may be important boll weevil feeding stimulants, but we were not able to demonstrate that they possessed any substantial effect on oviposition.

Total gossypol was higher in anthers of the susceptible ST213 line than in the two R lines. Paradoxically, gossypol appeared to depress oviposition in laboratory tests even though it previously was shown in other laboratory tests to be a feeding stimulant (Hedin et al., 1968). Because high gossypol lines have not been shown to be boll weevil resistant, the role of gossypol in oviposition does not appear to have been established.

Free sugars stimulated oviposition more consistently and to a greater degree than any other class of constituents. The free sugar content in the R lines was lower than in ST213. If this trend can be confirmed with a number of R lines, it may be established that a major basis of resistance to boll weevils (as related to oviposition) is the decreased content of free sugars in the R lines and, therefore, nutritional. Carbohydrate metabolism in these lines may favor conversion of sugars to bound carbohydrates. There is precedence for the importance of sugars in the report of Dean and Chapman (1973) which indicates that percent sucrose and total sugars contributed to the oviposition of apple maggot, *Rhagoletis pomenella* (Walsh).

The significance of these findings, if further supported, is that the analysis of free sugars in the anther, and perhaps also the analyses of bud surface terpenoids, may provide a basis for selection or genetic production of cotton lines resistant to the boll weevil.

MALE EUROPEAN CORN BORER, *Ostrinia nubilalis* (HÜBNER), ANTENNAL RESPONSES TO ANALOGS OF ITS SEX PHEROMONE

Strain, Electroantennogram, and Behavior Relationships

HOWARD W. FESCEMYER[1] and FRANK E. HANSON

University of Maryland Baltimore County
Department of Biological Sciences
Catonsville, Maryland 21228

(Received July 28, 1988; accepted May 1, 1989)

Abstract—Experiments were conducted to (1) determine whether the electroantennogram (EAG) can detect differences among the responses of antennae from males derived from the three strains of *Ostrinia nubilalis* (Hübner), and (2) characterize the EAG responses of each strain to isomeric forms of the natural pheromone, (*E*)- and (*Z*)-11-tetradecen-1-ol acetate (TDA), and analogs possessing differences in the terminal alkyl group, cyclopropyl (CPA), or *tert*-butyl (TBA).

EAG responses differed among the strains in two ways: (1) Antennae from *ZZ* males always produced an EAG to (*Z*)-TDA with an extended duration of response. This "signature" EAG response was found to be unique to the antennal response of *ZZ* males to (*Z*)-TDA, thus providing a relatively easy method of distinguishing live *ZZ* males from *EE* or *ZE* males. Correlated with this longer EAG response was a longer disadaptation time, i.e., the EAG response of *ZZ* antennae disadapted more slowly (ca. 10 min) than the response of *EE* antennae. (2) Strain differences in the relative EAG amplitudes to isomers and analogs were observed at the stimulus amounts eliciting the peak EAG amplitude as follows: TDA $\geq$ CPA $>$ TBA for *ZZ* males and both isomers; TDA $>$ CPA $\geq$ TBA and CPA $\geq$ TDA $>$ TBA for *EE* males and the *E* and *Z* isomers, respectively; CPA $>$ TBA $\geq$ TDA for *ZE* males and both isomers. Dose–response relationships were seen for all compounds if amplitude ("peak height") of the EAG was used as a measure of response. However, if width of the EAG at half the peak height ("peak width") was used, then only the *ZZ* antennal response to (*Z*)-TDA resulted in a meaningful

[1] Current address: United States Department of Agriculture, Agricultural Research Service, Insect Reproduction Laboratory, Building 306, Room 323, BARC-EAST, Beltsville, Maryland 20705.

dose–response relationship. For all strains, the EAG amplitudes elicited by the *Z* isomers of any of the tested compounds were greater than those elicited by the corresponding *E* isomers. Therefore, correlations between the relative EAG and upwind flight responses were observed in the *ZZ* ($r = 0.86$) and *ZE* ($r = 0.80$) strains but were not correlated in the *EE* strain ($r = 0.18$). Temporal studies showed that adaptation, not postexcision deterioration, was responsible for the observed decreases in the EAG amplitude after repetitive stimulation or after stimulation with amounts in a descending order. Disadaptation required at least 20 min for a moderate dose (10 μg for 1 sec). Developmental studies showed that antennae from 2-day-old adults had the greatest EAG response.

Key Words—Adaptation, chemoreception, electroantennogram, European corn borer, Lepidoptera, *Ostrinia nubilalis*, Pyralidae, sex pheromone, genetic strains, 11-tetradecen-1-ol acetate.

INTRODUCTION

Sexual behavior in the adult European corn borer, *Ostrinia nubilalis* (Hübner) (Lepidoptera: Pyralidae), is elicited by two geometric isomers of 11-tetradecen-1-ol acetate (TDA) (Klun et al., 1973; Kochansky et al., 1975). Three genetic strains (*ZZ*, *EE*, and *ZE*) of *O. nubilalis* adults can be distinguished by the ratios of (*E*)- and (*Z*)-TDA emitted by the female (Klun and Maini, 1979). Males respond preferentially to the pheromone blend emitted by females of their own strain (Klun and Maini, 1979). Differences between the electroantennogram (EAG) responses of the three strains of *O. nubilalis* males were observed by Nagai et al. (1977). Schwarz et al. (1989) observed strain differences in the behavioral responses of *O. nubilalis* males to analogs of TDA, which they hypothesized to be due to strain differences in the structure of the antennal receptors.

Therefore, the following study was undertaken to determine if the EAG technique will detect strain differences in the male *O. nubilalis* antennal response, not only to the natural pheromone as shown by Nagai et al. (1977), but also to the pheromone analogs tested by Schwarz et al. (1989). The EAG as an empirical tool has correlated well with the behavioral responses of many insects (Kaissling, 1971; Roelofs, 1977). For example, male pheromone morphs of the larch bud moth, *Zeiraphera diniana* (Guenée), could be distinguished by their EAG responses to the pheromone composition of sibling females (Priesner, 1979).

The EAG is hypothesized to be the summation of receptor potentials from all the excited and inhibited sensory receptor neurons in the antenna (Schneider, 1962; Kaissling, 1971; Mayer et al., 1984). Although it is the action potential(s) that encodes information about the chemical stimulus (Kaissling, 1971;

Kaissling and Thorson, 1980), the EAG is a convenient indicator of the summed neural activity being sent to the brain (Mayer et al., 1984). Transduction of an olfactory stimulus into neural activity requires several molecular steps with different chemical specificities (Kaissling, 1976). Since the EAG provides a measure of the overall transduction process occurring throughout the antenna, this technique seems to be an appropriate way to investigate the ability of male *O. nubilalis* olfactory receptors to distinguish the natural pheromone from pheromone analogs.

The three most important parts of a pheromone molecule necessary for specific interaction with receptors on olfactory neurons are the double bond, polar functional group, and terminal alkyl group (Bestmann and Vostrowsky, 1982; Liljefors et al., 1984, 1987). EAGs have been useful in determining the position and configuration of unsaturation and the functional groups to which the antennae of many moth species are the most sensitive (Roelofs, 1977). Responses observed in both EAG (Nagai et al., 1977) and single sensillum studies (Nagai, 1983; Hansson et al., 1987) to (*E*)- or (*Z*)-TDA indicate that the antennae of male *O. nubilalis* can perceive differences in the configuration of unsaturation about carbons 12 and 13. Behavioral studies of *O. nubilalis* corroborate the findings of the EAG studies in demonstrating the importance of the position of unsaturation (Klun et al., 1973, 1979) and the acetate functional group (Klun and Robinson, 1972). However, the sensitivity of the *O. nubilalis* antenna to changes in the terminal alkyl group has not been determined.

Behavioral (Chapman et al., 1978a,b) and EAG (Bestmann et al., 1980) responses of male *O. nubilalis* to chiral analogs of TDA suggested that the receptor for TDA is chiral and that the manner in which the last four carbons of TDA coil within the receptor is important for binding. Bestmann et al. (1980) also found that EAG responses were greater for open-chain (pentadecenyl) analogs than ring structures. They speculated that this is related to the greater flexibility of the open-chain analogs and the ability of the acceptor to adapt to a less rigid structure. Schwarz et al. (1989) found that only acetate analogs with 13 or 14 carbon chain lengths, in which branching at carbon 13 was limited to one methyl group or a cyclopropyl group, elicited upwind flight from *O. nubilalis* males in a flight tunnel. They also observed that upwind flight responses elicited by isomers of the cyclopropyl analogs vary with strain. This was interpreted by Schwarz et al. (1989) to indicate intrinsic receptor differences in the three pheromonal strains.

Although the above behavioral data suggest that differences exist in receptor specificity among strains, they are not conclusive. It is difficult to determine why certain analogs do not elicit behavior: Is this because the antenna (1) does not detect the compound, or (2) detects the compound, but this detection does not result in a behavioral response? As a first step in attempting to answer this question, the EAG was used to determine the ability of the male *O. nubilalis*

antenna to detect (respond to) analogs of (*E*)- or (*Z*)-TDA in which structural modifications were made at carbon 13. As a second step, we compared relationships between chemical structure and antennal response for the three pheromonal strains, and correlated these with the behavioral results of Schwarz et al. (1989). During the course of this investigation, we determined how EAG responses were affected by adaptation, length of time after antennnal excision, and adult age.

METHODS AND MATERIALS

Insects. O. nubilalis males were obtained from cultures homozygous for *ZZ* or *EE* female sex pheromone production genes, or hybrids (*ZE*) obtained by crossing the *ZZ* and *EE* genotypes (Klun and Huetell, 1988). Designation of male strain was based on the ratio of (*E*)- and (*Z*)-tetradecen-1-ol acetate emitted by sibling females (*ZZ* = 3:97; *EE* = 97:3; *ZE* = 66:35; *E*:*Z*). Cultures were maintained at the Insect Chemical Ecology Laboratory, USDA, Beltsville, Maryland. Moths were reared (Reed et al., 1972) at 80% relative humidity and 16:8 light–dark and 26:19°C temperature regime (lights off at 0800 hr). Water was provided for adults emerging from the pupae. Two-day-old males in the hours 2–6 of scotophase were used in all experiments except for those testing for the effect of adult age. Unmated males were used in all experiments. Synchronously developing adults were obtained by collecting males at the end of each scotophase (ca. 87% of the adults emerge during the scotophase). Preexposure of males to pheromone was prevented by removing newly emerged females from the incubator daily.

Recordings. EAGs were obtained from excised antennal flagella using glass capillary electrodes (ca. 100 μm openings) filled with hemolymph Ringers (Kaissling and Thorson, 1980) and held in metal holders possessing Ag–AgCl bridges in contact with the Ringers solution. To facilitate antennal excision, the insects were immobilized with CO_2 for 30 sec. (No differences in the EAG response were observed among antennae obtained from insects immobolized at 5°C or with CO_2.) The antennal flagellum was cut with microscissors and placed in contact with the reference electrode; after removal of the distal 1–2 segments, the distal (cut) end of the antenna was placed in contact with the active electrode. Surface tension and hydrophilic attraction between the antennal tissue and the Ringers solution at the tip of the electrodes maintained electrical contact and supported the antenna. The ventral scale-free side was positioned horizontally to face a constant air flow delivered from the stimulus jet. Not more than 5 min was required to mount an antenna on the electrodes. Usually the baseline stabilized within the next 5 min; preparations that continued to "drift" were discarded.

Short coaxial cables connected the electrode holders to a chopper-stabilized DC amplifier with a gain of 150 (George Johnson Electronics, Baltimore, Maryland). Built into the amplifier was a 1-mV calibration pulse applied via the reference side of the amplifier and a circuit which rezeroed the baseline at the touch of a button. The EAG signal was displayed and quantified by a recorder–integrator (Hewlett Packard 3392A). The integrator determined the peak height and area and width at half the peak height. The height of the calibration signal was used to determine the EAG peak amplitude in mV.

Stimulation. Compounds tested in this study were geometrical isomers of 11-tetradecen-1-ol acetate (TDA), 13,13-dimethyl-11-tetradecen-1-ol acetate (TBA), and 12-cyclopropyl-11-dodecen-1-ol acetate (CPA) (Schwarz et al., 1986, 1989). Capillary gas chromatographic analysis (Carbowax 20 M and DB-1) showed the compounds to be ca. 98% pure with no cross-contamination between isomers.

We assumed that the stimulus release rate, concentration, and rate of adsorption onto the antennal receptor sites were proportional to the amount of compound placed on a strip of filter paper (4 × 0.8 cm; Whatman No. 1). Since TDA is 1.8× and 2× more volatile than TBA and CPA, respectively, correspondingly greater amounts of TBA and CPA were used. For each cohort of five insects tested, new sets of papers containing stimulus were prepared and stored in sealed amber vials at 4°C between experiments. Only one antenna was tested per individual. The duration of stimulation (1 sec), air flow rates, physical factors (filter paper, cartridge and jet sizes and positions, etc.) and protocol for replicates were constant in all experiments.

The odor delivery system was a modification of a system designed by R. W. Mankin and A. J. Grant (personal communication) and figured in Frazier and Hanson (1986). Compressed breathing air, filtered through ×13 molecular sieve, was split into a dry stimulus air flow (150 ml/min) and a humidified (ca. 80% relative humidity at the antenna) carrier air flow (2000 ml/min), which passed continuously through a glass mixing chamber and then over the antennal preparation. Papers containing stimulus were placed in glass cartridges inserted in the stimulus air flow between Teflon stoppers. The air flowed continuously through the cartridge, resulting in a constant release of stimulus from the paper, but a vacuum air flow (160 ml/min) normally prevented this stimulus from mixing in the glass chamber with air flowing over the antenna. To stimulate the antenna, this vacuum line was closed for 1 sec, thereby diverting the stimulus air flow into the mixing chamber to combine with the carrier air flow. The oval-shaped mixing chamber outlet (2 × 0.5 cm) was positioned 2 mm from the antennal preparation. An exhaust line (10 cm diameter), positioned 5 cm behind the antenna, evacuated air flowing over the antenna to a fume hood.

Experimental Design and Methods for Evaluation of Results. Four types of experiments were performed: (1) The responses and antennae from *ZZ*, *ZE*,

and *EE* males to isomers of TDA, TBA, and CPA were compared by exposing antennae of each strain to ascending doses of each compound. (2) Adaptation was studied by sequentially presenting descending doses of (Z)-TDA to *ZZ* male antennae. (3) Recovery (disadaptation) of the EAG after stimulation of individual antennae with 10 μg of (Z)-TDA was examined in *EE* or *ZZ* males by varying the time between stimulus presentation (intertrial interval) from 5 to 60 min. Each antenna was stimulated only three times and each stimulation was separated by a given interval, i.e., only one interval was tested per antenna. (4) The effect of adult age on the EAG response was examined by stimulating antennae from *ZZ* males of various ages with 10 or 40 μg of (Z)-TDA.

Application of a control stimulus also resulted in an EAG response. This EAG appeared to be produced by the stimulation of antennal mechanoreceptors that are sensitive to the small changes in air flow that occur when the stimulus air flow mixes with the constant air flow. The EAG response to a heptane-treated paper dried for 4 min in a fume hood (control stimulus) was the same as a paper which had no heptane applied to it. In all experiments conducted, the mean control response was calculated from the response elicited by three control stimuli (30 sec between each repetition) that preceded each set of chemical stimuli.

For experiments 1, 2, and 4, delivery of a chemical stimulus to each antenna was replicated three times at 30-sec intervals (amounts 10 μg or lower) or at 1-min intervals (amounts above 10 μg) between each repetition. Each set of three chemical stimuli were followed by 3 min of clean air. The mean response elicited by each set of three replicates was calculated, and the mean control response was subtracted from the mean response to the compound. For each time tested in experiment 3, the mean control response was subtracted from the response to a single delivery of a chemical stimulus.

A factorial design was used to determine the effects of strain, compound, and isomer on the EAG responses calculated for experiment one. Since the treatments were not presented in a random order, the factorial was analyzed by amount of compound. For experiment 2, Student's t test was used to compare mean EAG responses for differences (H_0: $\mu_1 = \mu_2$). A factorial design was used to examine the effects of intertrial interval time and stimulus number (replicate) on disadaptation of the EAG response (experiment 3). A completely randomized design was used to determine the effect of adult age (experiment 4) on the EAG response. Relationships among the EAG amplitude, peak area, and peak width at half the peak height were tested using regression analysis and Pearson product–moment correlations (Steel and Torrie, 1980). The latter were also used to examine the relationship between the EAG and upwind flight activity. Means were separated by Tukey's w procedure (Steel and Torrie, 1980; Jones, 1984). Values in the results section are means plus or minus the standard error. Probability (P) values in the results section are for the independent effects type III sums of squares F test. Student's t test was used to determine if means were

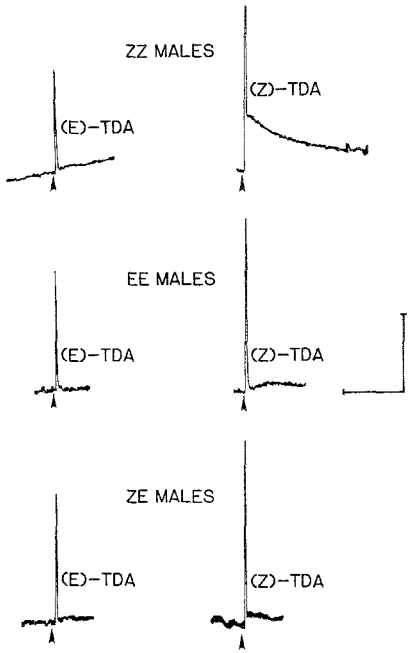

FIG. 1. Typical recordings of the EAGs elicited by 40 μg of (*E*)- or (*Z*)-tetradecen-1-ol acetate (TDA) from the antennae of male *O. nubilalis*. Responses within a strain were obtained from the same preparation. Arrows indicate when the stimulus solenoid was activated. Calibration: 1 mV, 1 min.

different from zero (H_0: $\mu = 0$). SAS was used to perform all statistical analyses and graphs (SAS Institute, 1985, 1987).

RESULTS

Description of EAG. A 1-sec pulse of pheromone elicited an EAG from *O. nubilalis* antennae that was recorded as an initially rapid negative-going change in the background potential to a sharp peak followed by a slightly slower decay phase (Figure 1). The entire response duration was ca. 4–5 sec. The only exception encountered was the response of *ZZ* male antennae to (*Z*)-TDA (10–400 μg). In this case, a slow decay phase was always observed after an initial sharp peak (Figure 1).

The standard measure of the EAG has traditionally been the amplitude (mV) of the peak, which is the primary measure used in this study. Other measures are also plausible: for example, a correlation between amplitude and peak area was observed ($P > |r| < 0.0001$; $r^2 = 0.9$; $N = 2058$). Regression analysis indicated that this correlation was linear [$P < 0.0001$; $r^2 = 0.83$;

N = 2058; peak area = (−9872) + amplitude (678989)], i.e., amplitude and peak area increased together. In contrast, width of the peak at half the peak height was not a good indicator of differences in the EAG. This measure was usually not different from the blank response ($P > |t| > 0.5$). The one exception was the response of *ZZ* male antennae to ascending doses of (*Z*)-TDA, which increased from a width of 0.07 min at 1 μg to a maximum width of 0.97 min at 40 μg and then decreased to a width of 0.55 min at 400 μg.

Experiment 1: Ascending Dose–Response Relationships. As stimuli above 0.1 μg for TDA, 0.2 μg for CPA, and 0.18 μg for TBA were presented to the antennae in ascending order, the EAG amplitudes increased to a peak and then decreased (Figures 2 and 3). Shapes of the ascending dose–response curves for

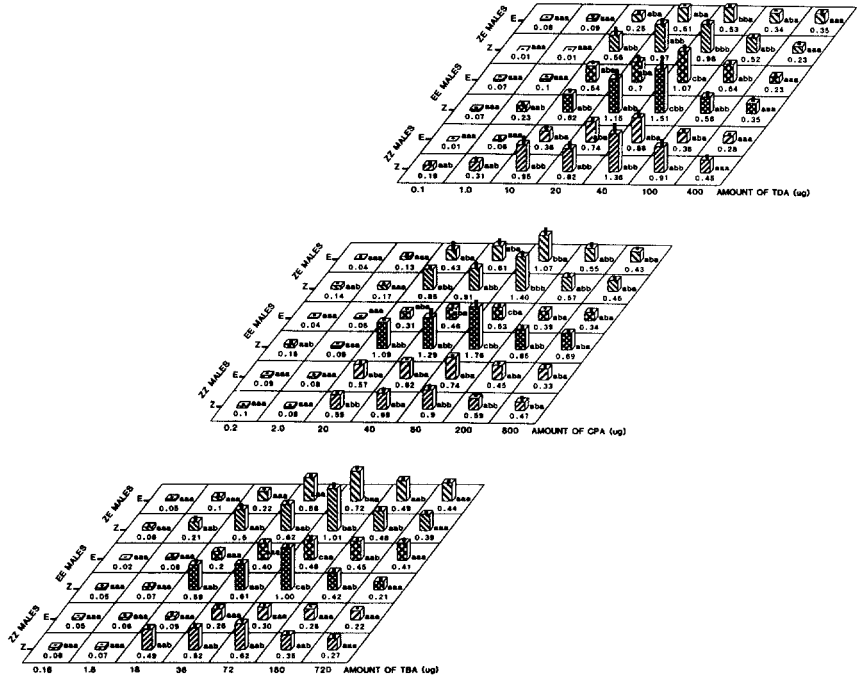

FIG. 2. Ascending dose–response relationships for the amplitude (mV) of the EAGs from male *O. nubilalis* antennae (N = 10–17 per strain, compound, and isomer combination). Vertical bars represent the mean values printed at the base of each bar. The standard error is represented by the smaller solid bar at the top of each mean vertical bar. Means of EAGs elicited by the same amount of compound are not significantly different if followed by the same letter group (α = 0.05; Tukey's w procedure). The first letter in the group denotes significant differences among strains, the second letter denotes significant differences among compounds within a strain, and the third letter denotes significant differences between isomers within a strain and compound.

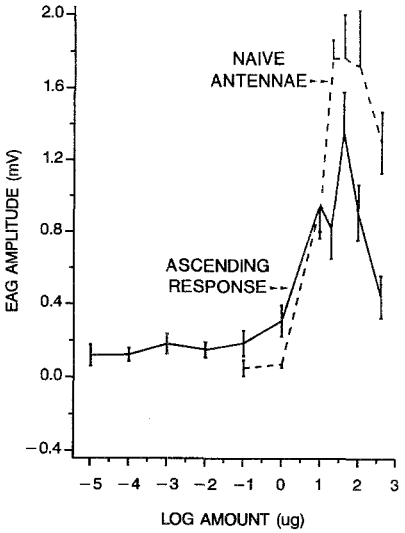

FIG. 3. Comparison of ascending and descending dose–responses for the amplitude of the EAGs from *ZZ* male *O. nubilalis* antennae stimulated with (*Z*)-tetradecen-1-ol acetate. The solid line is the response curve for an ascending series of amounts ($N = 17$). The dashed line is the reconstructed response curve obtained from the first response of the naive antennae used in Table 1 ($N = 10$ for each point). Points represent means ± standard error.

EAG amplitude were similar for each combination of strain, compound, and isomer tested (Figure 2). The maximum amplitude was observed at 40 μg TDA, 80 μg for CPA, and 72 μg for TBA, irrespective of the strain and isomer. EAGs produced by low stimulus amounts (<0.1 μg for TDA, <2.0 μg for CPA, and <0.18 μg for TBA) were not different from zero ($P > |t| > 0.1$).

Interactions among the treatment groups strain, compound and isomer were observed for the EAG amplitudes elicited by doses >1.0 μg ($P < 0.04$). These interactions are reported in Figure 2 and summarized as follows:

1. Responses of the three strains were generally similar. Differences ($P < 0.001$) among strains were only observed at one dose (40 μg of TDA, 80 μg of CPA, and 72 μg of TBA); for example, the *ZE* strain had the lowest response to TDA but usually had the highest responses to CPA and TBA (Figure 2).

2. Differences ($P < 0.03$) in responses among compounds within strains were observed when doses exceeded 1.0 μg of TDA, 2.0 μg of CPA, or 1.8 μg of TBA. Amplitudes of the EAGs elicited by TDA were similar to those elicited by CPA and usually greater than those elicited by TBA (Figure 2).

3. All strains elicited greater responses to the *Z* isomer than to the *E* iso-

mer for doses of all compounds exceeding 1.0 μg ($P < 0.03$), except for the highest doses ($P > 0.15$). The largest differences between EAG responses to isomers were observed when *EE* antennae were stimulated by the isomers of CPA (Figure 2).

Experiment 2: Descending Dose–Response Relationships. Stimulation of antennae using a descending series of amounts of (*Z*)-TDA results in a reduced or eliminated EAG at lower amounts of stimulus (Table 1). This demonstrates that the antenna adapts readily and suggests that even the ascending dose–response curve may be partially depressed at the higher stimulus intensities (>40 μg). This can be shown by reconstructing a dose–response curve (dashed line in Figure 3) using naive antennae for each stimulus dose. At higher doses (>10 μg of TDA), the EAGs in the actual ascending curve are smaller ($P > |t| < 0.005$) than when naive antennae are stimulated with the corresponding amount (i.e., the first value in each line in Table 1). This difference between the two curves in Figure 3 indicates that in the ascending series, the antenna was still partially adapted to the previous stimulation. The largest amount of stimulus that did not result in adaptation was 10 μg of (*Z*)-TDA.

Experiment 3: Disadaptation of EAG Response. The duration of the intertrial interval affected EAG responses of *ZZ* males differently than *EE* males ($P < 0.0047$) (Figure 4). A 15- to 20-min interval between stimulations with 10 μg of (*Z*)-TDA was sufficient to enable antennae from *EE* males to disadapt, whereas *ZZ* males required 20–30 min. The EAG response decreased with increasing stimulus number ($P < 0.048$) or decreasing interval duration ($P < 0.0001$) for intertrial intervals ≤ 15 min (*EE*) or ≤ 20 min (*ZZ*) (Figure 4). When intertrial intervals ≥ 20 (*EE*) min or ≥ 30 min (*ZZ*) were tested, responses to the second and third stimuli were usually greater than responses to the first stimulus ($P < 0.009$) (Figure 4).

These results suggest that antennae disadapt in 15–30 min and suffer no postexcision deterioration with time up to 120 min, which is the total duration of the 60-min intertrial interval experiment (Figure 4). To further distinguish among adaptation and postexcision deterioration, another experiment was conducted in which *ZZ* antennae were excised, mounted on the electrodes, but not stimulated until 105 min after excision; these EAG amplitudes (2.7 ± 0.2 mV) were similar ($P < 0.8$) to the amplitudes (2.61 ± 0.15 mV) recorded at time zero in other experiments (e.g., at stimulus 1 in Figure 4). This similarlity in response shows that the preparations had not deteriorated during the 105-min waiting period between excision and first stimulation.

Experiment 4: Effect of Adult Age on EAG Response. After increasing ($P < 0.0001$) to a peak on the second day after emergence, EAG responses decreased with increasing age to a level that was not different ($P > 0.15$) from 0.5- or 1-day-old adults (Figure 5).

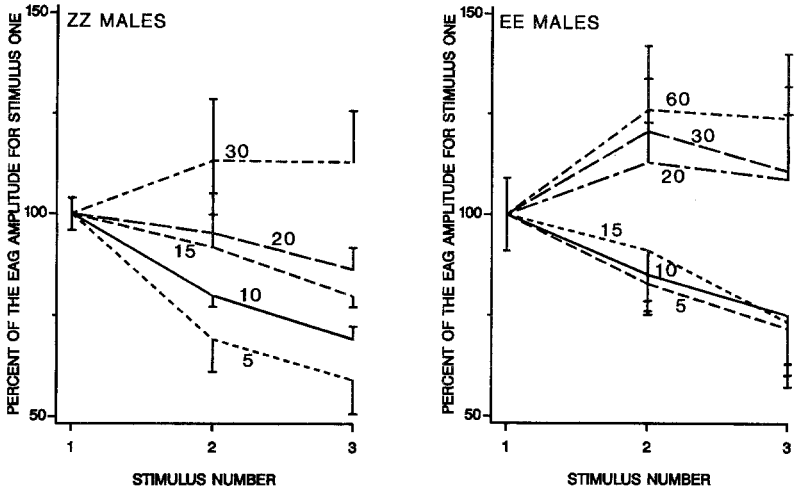

FIG. 4. Disadaptation of the EAG response or the effect of varying intertrial interval time on the amplitude of the EAG response to 10 μg of (*Z*)-tetradecen-1-ol acetate. The intertrial interval (in minutes) is indicated beside each adaptation curve. The mean EAG amplitude to the first stimulus in each series was 2.61 $\pm$ 0.15 and 1.57 $\pm$ 0.12 mV for *ZZ* and *EE* antennae, respectively. Points represent means $\pm$ standard error (N = 8–10 per curve).

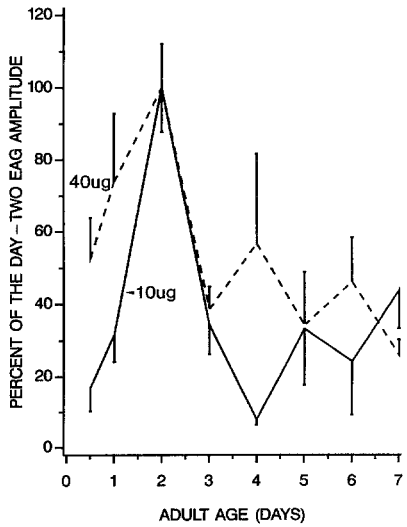

FIG. 5. Effect of adult age on the amplitude of the EAG response. The solid line is the relative EAG response to 10 μg (*Z*)-tetradecen-1-ol acetate and the dashed line is the relative response to 40 μg. Points represent means $\pm$ standard error (N = 5–10 per point).

DISCUSSION

EAG amplitudes elicited by the *Z* isomer were always greater than those elicited by the *E* isomer for all compounds and strains tested. Nagai et al. (1977) and Nagai (1983) also found that (*Z*)-TDA elicited higher EAG and single sensillum DC responses than the *E* isomer in the *ZZ* strain of *O. nubilalis*. However, Nagai et al. (1977) reported that the responses to the two isomers were similar in the *EE* and *ZE* strains, while we found (*Z*)-TDA to elicit a greater EAG response than the *E* isomer in all strains tested. Our EAG results for *O. nubilalis* are consistent with those for noctuid and tortricid species (reviewed in Priesner et al., 1975; Priesner, 1979) that also use straight chain, (*Z*)-monoolefinic acetates as part of the pheromonal complement. In these species, both EAG (Priesner et al., 1975) and single olfactory sensilla (Priesner, 1979) responses from male antennae have shown that the *Z* isomer elicits a significantly greater response than the *E* isomer. This difference in response has been correlated with conformational properties of the entire molecule, i.e., the conformational energy for the *Z* isomer is lower than the *E* isomer (Liljefors et al., 1987). Hansson et al. (1987) showed that for all strains of *O. nubilalis*, a greater single sensillum DC potential is elicited by (*Z*)-TDA than by (*E*)-TDA. This relationship is similar to our data for the EAG amplitude. The results summarized above suggest that, irrespective of strain, the ability of male *O. nubilalis* antennae to detect differences in the stereochemistry of the double bond between carbons 11 and 12 is not affected by the modifications made at carbon 13.

Schwartz et al. (1989) hypothesized that the dissimilarity they observed in behavioral responses of *ZZ* and *EE* males to (*Z*)- and (*E*)-CPA indicated that strain differences existed in the structures of the antennal receptors. In our experiments, strain differences in EAG amplitude were observed, but only at stimulus amounts that elicited the peak EAG response. These differences were: TDA $\geq$ CPA $>$ TBA for *ZZ* males and both isomers; TDA $>$ CPA $\geq$ TBA and CPA $\geq$ TDA $>$ TBA for the *EE* males and *E* and *Z* isomers, respectively; and CPA $>$ TBA $\geq$ TDA for *ZE* males and both isomers. Since the differences observed in the EAGs elicited by the isomeric forms of TDA, CPA, and TBA were consistent across strain and mirrored the single sensillum DC potentials elicited by the the isomeric forms of TDA (Hansson et al., 1987), our EAG results indicate the existence of strain differences in detecting modifications in the terminal alkyl group. Although these EAG data are indicative, single sensillum recordings accompanied by cross-adaptation studies are needed for confirmation.

Since sexual behavior in *ZZ* and *ZE* males is elicited preferentially by a pheromone blend with a higher content of (*Z*)-TDA than (*E*)-TDA and the reverse is true for *EE* males (Klun and Maini, 1979), one might expect a similar relationship among the EAG responses if EAG amplitude accurately reflects

behavior (Kaissling, 1971; Roelofs, 1977). A good correlation between our EAG amplitude data and the upwind flight data of Schwartz et al. (1989) was observed for *ZZ* and *ZE* males, but not for *EE* males (Figure 6). This correlation was 0.86 for *ZZ* males ($P > |r| < 0.05$; $N = 6$) and 0.8 for *ZE* males ($P > |r| < 0.04$; $N = 4$); i.e., the upwind flight and EAG responses elicited from *ZZ* and *ZE* males by *Z* isomers were greater ($P < 0.01$) than the responses elicited by the *E* isomers (Figure 6). In contrast, for *EE* males the *Z* isomer

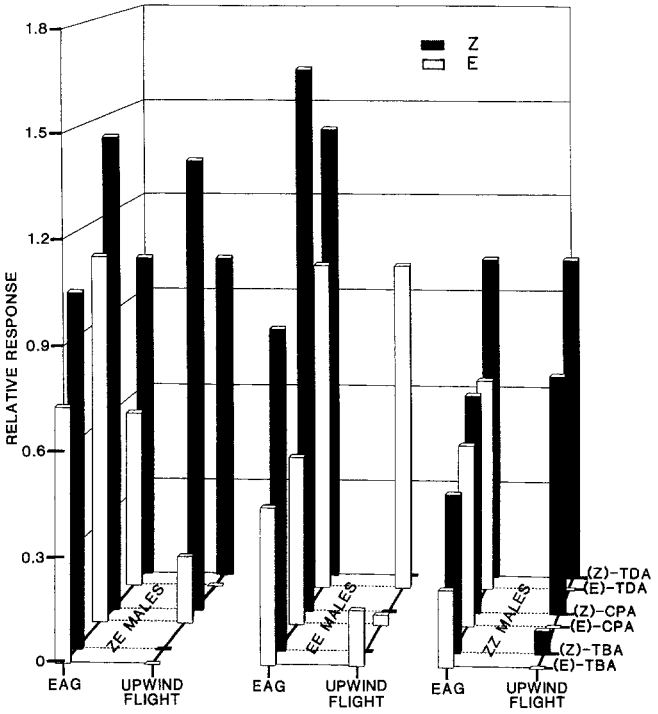

FIG. 6. Relative upwind flight and EAG responses of male *O. nubilalis* to the female sex pheromone and analogs. Within a strain, bars represent values relative to the responses produced by (*E*)-TDA for *EE* males and (*Z*)-TDA for *ZZ* and *ZE* males, separately. The relative within-strain upwind responses to the natural pheromone blend were 1.00, 1.10, and 1.44 for *ZZ* (3:97), *EE* (97:3), and *ZE* (65:35; *E*:*Z*), respectively. The flight tunnel data are from Schwarz et al. (1987) or J.A. Klun (personal communication). Amount of compound used in all behavioral experiments shown was 100 ng. The EAG response compared was elicited by amounts (40 μg for TDA, 80 μg for CPA, and 72 μg for TBA) which produced the maximum amplitude (Figure 2), although similar trends were observed for other amounts on linear portions of the ascending dose–response curves (10–40 μg for TDA, 20–80 μg for CPA, and 18–72 μg for TBA; Figure 2).

elicited a greater EAG amplitude than those elicited by the *E* isomer, which was not correlated with upwind flight (Figure 6). A general trend observed for all strains was the ability of the antennae to detect or elicit EAG responses even when little or no upwind flight was observed (Figure 6).

The inconsistent correlation between EAG amplitude and behavioral response could be the result of one or more of the following: (1) the analogs bind to the same receptors as TDA, but with a lower affinity; (2) the analogs bind to receptors of nonpheromonal olfactory neurons, which provide an EAG response but no behavior; (3) the analogs bind to the same receptors as TDA, but indiscriminantly on the *Z* and *E* neurons (Hansson et al., 1987), thereby providing the wrong action potential code for behavior; or (4) the central nervous system may be different in each strain such that the sensory pattern that evokes behavior in one strain does not do so in another.

The time for repolarization of the EAG is longer for (*Z*)-TDA than for (*E*)-TDA. This was first observed by Nagai et al. (1977); our results confirm their finding and demonstrate that this relatively long repolarization time is unique to the EAGs elicited in *ZZ* male antennae by (*Z*)-TDA. Although the amplitude of the EAG could not be used to distinguish among male strains, the duration of the repolarization time (e.g., width of the peak at half the peak height) could be used to distinguish live *ZZ* males from the other two strains. Since the EAG technique requires less specialized equipment and is easier to perform than the single sensillum techniques, it could be useful in assessing the relative composition of *ZZ* males in populations.

Stimulation of a *ZZ* male antenna with a particular amount of (*Z*)-TDA resulted in a reduction or elimination of the EAGs elicited by amounts lower than that used in initial stimulus, indicating that adaptation of receptors had occurred. Nagai et al. (1977) also observed adaptation of the EAG response from *ZZ* antennae after repetitive stimulation with (*E*)- or (*Z*)-TDA and found the EAG recovered in ca. 20 min. In our study, the EAG response of *EE* antennae recovered in ca. 20 min, which was ca. 10 min faster than the EAG response of *ZZ* antennae. By comparison, *Bombyx mori* (L.) required hours to completely disadapt from a strong stimulus (Kaissling, 1977; Mayer and Mankin, 1985). In *Epiphysas postvittana* (Walker), Rumbo (1988) found most of the adaptation was brought about by a single exposure to a compound [e.g., 10 μg (*E*)-TDA]. We also observed most of the change from the nonadapted state to the adapted state to occur on the first exposure to (*Z*)-TDA (Table 1, Figure 4). Our results indicate that antennal adaptation is strain specific and correlated with the ability of the antenna to repolarize after each stimulus. Repolarization time courses for the EAG response from *B. mori* antennae were observed to be similar to those of the receptor potentials of individual olfactory receptor neurons (Kaissling, 1974). The physiological basis for EAG adaptation is currently hypothesized to be the adaptation of the receptor potential of individual olfactory receptor neu-

rons (Mayer and Mankin, 1985). Thus, the strain-specific differences we observed in the repolarization and disadaptation of the EAG response from *O. nubilalis* antennae could have as its cause: (1) lowered affinity of the receptor for the pheromone molecule, (2) decreased rate of receptor neuron activation, (3) decreased rate of pheromone molecule degradation, and (4) reduction of conductance in the receptor neuron membrane (Kaissling, 1977).

Studies of the effect of adult age on the EAG response showed that peak response occurred during the second day after eclosion. Maximum upwind flight response also occurs on the second day after eclosion (J.A. Klun, personal communication), indicating that the maturation of behavioral responses is linked to that of the sensory cells in *O. nubilalis*. The decline in the EAG response after day 2 implies that the olfactory cells on the antennae are not physiologically stable and may be senescing. Maturation and senescence of the EAG response after emergence was also reported for male and female *Pseudaletia unipuncta* (Haworth) (Seabrook et al., 1979). However, the EAG response of male *Trichoplusia ni* (Hübner) (Payne et al., 1970) and *Argyrotaenia velutinana* (Walker) (Roelofs and Comeau, 1971) showed no change with adult age after emergence. In *Manduca sexta* (L.), maturation of the EAG response and complete development of olfactory sensilla, neurons, and synapses occurs before adult eclosion (Schweitzer et al., 1976; Tolbert et al., 1983). This variation among species in the maturation and senescence of the EAG response suggests comparable differences in the developmental rates of the sensory cells in olfactory systems.

Acknowledgments—We thank H.-C. Chen, D. Flaim, P. Ho, J. Jackson, O. Paul, and B. Todd for technical assistance. We thank Drs. J.A. Klun and M. Schwarz for the chemicals, collaboration, and comments; and E. Uebel for rearing the corn borer. Financial support was provided by a cooperative agreement (58-32U4-4-770) with the Insect Chemical Ecology Laboratory of the USDA/ARS, Beltsville, Maryland.

ANTIFOULING AGENTS FROM MARINE SPONGE *Lissodendoryx isodictyalis* Carter

MARGARET A. SEARS, DONALD J. GERHART, and DAN RITTSCHOF

Duke University Marine Laboratory
Pivers Island
Beaufort, North Carolina 28516

(Received September 12, 1988; accepted May 1, 1989)

Abstract—The sponge *Lissodendoryx isodictyalis* is an odorous, encrusting, blue-gray sponge found on subtidal flats in North Carolina waters. The strong odor of *L. isodictyalis*, coupled with the observation that it is rarely overgrown by fouling organisms, suggested that this sponge may produce metabolites with potent antifouling activity. Ethyl acetate extracts of *L. isodictyalis* inhibit larval settlement of the barnacle *Balanus amphitrite* in laboratory assays at 10 ng/ml. Barnacle settlement bioassays of isolated preparative TLC fractions show that *L. isodictyalis* produces at least two pungently scented, antifouling agents with EC_{50} values of less than 85 μg/ml and less than 250 μg/ml, respectively. The most potent agent inhibits settlement at or below a concentration of 400 ng/ml and kills approximately 25% of settlement-stage barnacle larvae at 400 μg/ml. The other agent causes 100% mortality of larvae at concentrations greater than 400 μg/ml and inhibits settlement at approximately 40 μg/ml. These metabolites of *L. isodictyalis* may inhibit overgrowth of the sponge in nature.

Key Words—*Lissodendoryx isodictyalis*, *Balanus amphtrite*, fouling, antifouling agents, marine sponge.

INTRODUCTION

The marine fouling community is composed of a variety of sessile marine organisms including tunicates, hydroids, bivalves, bryozoans, barnacles, polychaete worms, and sponges that live attached to hard subtidal and intertidal surfaces (Sutherland, 1984). Spatial competition, not predation, is the major factor in

0098-0331/90/0300-0791$06.00/0

determining structure of the fouling community in North Carolina waters (Sutherland and Karlson, 1977). Invertebrate larvae and algae may settle on and overgrow other organisms. Such overgrowth provides a potential source of mortality; furthermore, fouling organisms may obstruct feeding, compete with their host for food, and increase sedimentation (Stoecker, 1978; Ware, 1984; Rittschof et al., 1985; Gerhart et al., 1988).

A variety of sessile marine invertebrates, especially octocorals, tunicates, and sponges, are rarely fouled by other organisms. These species frequently contain high concentrations of secondary metabolites (Tursch et al., 1978; Goad, 1978; Faulkner, 1977, 1984; Fenical, 1978, 1982). Some of these metabolites possess potent antifoulant activity, and may play an important role in the inhibition of fouling in nature (Stoecker, 1978; Standing et al., 1982; Targett et al., 1983; Ware, 1984; Rittschof et al., 1985, 1986; Keifer et al., 1986; Bakus et al., 1986; Gerhart et al., 1988).

Lissodendoryx isodictyalis Carter (Order Poesilosclerida) is a blue-gray, encrusting sponge commonly encountered in eel grass (*Zostera marina*) beds in Core Sound, North Carolina. The species is found along the coast of the southeastern United States, the West Indies, and Pacific Mexico, with members of the genus distributed throughout the world (Wiedenmayer, 1977; Laubenfels, 1947). Because of its strong, pungent odor, *L. isodictyalis* is commonly known as the garlic sponge.

Lissodendoryx isodictyalis is rarely overgrown by fouling organisms. This observation, coupled with the strong, garlicky terpenoid odor of the sponge, suggests that *L. isodictyalis* could produce metabolites that prevent fouling. Terpenoids have been shown to prevent fouling in laboratory and field situations (Targett et al., 1983; Rittschof et al., 1985, 1986; Gerhart et al., 1988).

Secondary metabolites from sessile marine invertebrates are rarely tested for their ability to inhibit settlement of sympatric fouling organisms. The acorn barnacle, *Balanus amphitrite* Darwin, can comprise a major component of the fouling community in areas where *L. isodictyalis* is found. The objectives of this study were to determine whether *L. isodictyalis* contains metabolites that inhibit the settlement of *B. amphitrite*, to perform bioassay-directed isolation, and to determine the chromatographic mobility and potency of these biologically active compounds.

METHODS AND MATERIALS

Collection. Lissodendoryx isodictyalis was collected from Core Sound near Straits, North Carolina, at depths less than 1 m below mean low tide. Colonies were collected on September 16, 1987. Sponge tissue was cleaned by removing

and discarding material that the sponge had overgrown. Cleaned sponge tissue was either extracted immediately or frozen for later use.

Extraction. Fresh or frozen tissue of *L. isodictyalis* were soaked overnight in four volumes (w/v) of HPLC-grade ethyl acetate at room temperature. The extract was decanted and the sponge reextracted with four volumes of fresh solvent. The extracts were combined and the cloudy solution filtered through Whatman No. 1 filter paper. The filtrate was concentrated to a viscous oil by rotary evaporation. The extract was partitioned between HPLC-grade methylene chloride and deionized water to remove salts. Solvent was removed from the organic layer using a rotary vacuum evaporator, yielding 0.22 g of dark green, viscous oil. The crude extract was stored in the dark at 4°C in methylene chloride at a concentration of 50 mg/ml. For bioassays, aliquots of this solution were removed, the methylene chloride evaporated, and the residue resuspended in aged seawater filtered to remove particles with size greater than 100 kDa.

Isolation of Antifouling Compounds. Preparative TLC was performed using Whatman PK6F plates (20 × 20 cm). Each plate received 25 mg of extract dissolved in 0.5 ml of methylene chloride. Plates were developed in 1:9 acetonitrile–methylene chloride, and visualized with visible light, long-wave UV light, short-wave UV light, and a vanillin/sulfuric acid spray. TLC plates were divided into six zones, designated 0 through 5, which covered the area from origin to solvent front. Each zone was scraped from the plate, and the compounds were eluted from the silica with HPLC-grade methylene chloride. These solutions were then filtered through Whatman No. 1 filter paper and evaporated to dryness. The resultant residues were tested in bioassays for barnacle-settlement inhibition. Zones that were highly active were further purified by preparative TLC as described above and bioassayed a second time. In initial bioassays (Figure 2 below), fractions were tested at concentrations of 10^{-4} g/ml in seawater. Inhibitory zones of the TLC plate were tested at concentrations ranging from 4×10^{-3} g/ml to 4×10^{-8} g/ml, in steps of 10-fold dilution.

Settlement Inhibition Bioassays. Adult individuals of the acorn barnacle *Balanus amphitrite* Darwin were collected from the Duke University Marine Laboratory seawall in Beaufort, North Carolina. Collected specimens were crushed, and the nauplius-stage larvae they released were cultured to cyprid (settling) stage according to the methods of Rittschof et al. (1984). Settlement assays were performed as previously described by Rittschof et al. (1985). Briefly, 3-day-old cyprid larvae were added to Falcon 50 × 9-mm polystyrene Petri dishes containing either 5 ml of 100-kDa-filtered seawater (approximately 35 ppt salinity) or seawater containing sponge extract. The dishes were incubated at 28°C on a 15:9 light–dark cycle for 22–24 hr. After incubation, the dishes were observed under a dissecting microscope to determine whether the larvae were alive. The larvae were then killed by adding several drops of 10%

formalin. Attached and unattached larvae were counted, and settlement was calculated as the percentage of total larvae that were attached. Differences in the rate of settlement in treatments versus controls were tested for significance using a G test for independence (Sokal and Rohlf, 1981). The number of replicates used in each assay ranged from two to four, depending on the availability of cyprid larvae. The number of replicates was taken into account in statistical analyses of results.

RESULTS

Extraction Yield. Sixty milligrams of crude extract was obtained from 100 g of wet sponge material. The concentration of crude extract within the wet sponge tissue was thus 600 μg/g. The crude extract was dark greenish brown in color and gave off a strong, minty odor. Normal-phase TLC separated the crude extract into 13 distinct bands.

Zone 0 extended from the sample origin to $R_f = 0.10$. Zone 1 extended from $R_f = 0.10$ to 0.20. Zone 2 extended from $R_f = 0.20$ to 0.37. Zone 3 extended from $R_f = 0.37$ to 0.78. Zone 4 extended from $R_f = 0.78$ to 0.90. Zone 5 extended from $R_f = 0.90$ to the solvent front. Compounds from zones 4 and 5 comprised approximately 5% of the total weight of crude extract and were characterized by a greenish color and pungent odor.

Settlement Inhibition by Crude Extracts. Crude extracts significantly inhibited barnacle settlement (Williams adjusted $G = 611$, $P < 0.01$) at concentrations of 10 ng/ml or greater (Figure 1). All larvae were killed at concentrations greater than 400 μg/ml. The EC_{50} for settlement inhibition, estimated graphically, was approximately 100 μg/ml.

Settlement Inhibition by Partially Purified Fractions. Of the six zones generated by preparative TLC, zones 4 and 5 produced the strongest inhibition of barnacle settlement. Zone 2 was moderately active in the settlement inhibition assay, while zones 0 and 1 facilitated settlement (Figure 2). Zone 4 was composed of a green band and an adjacent band that appeared purple under short-wave UV light. Zone 4 possessed an EC_{50} for settlement inhibition that was less than 85 μg/ml (Figure 3). Approximately 25% of the larvae were killed after 24-hr exposure to this compound at concentrations greater than 400 μg/ml. Unkilled larvae appeared less mobile than larvae kept in seawater without additions. The second active component, zone 5, was composed of a yellow band and an adjacent band that also appeared purple under short-wave UV light. This component possessed a settlement inhibition EC_{50} of less than 250 μg/ml (Figure 4). All larvae were killed by zone 5 at concentrations greater than 400 μg/ml.

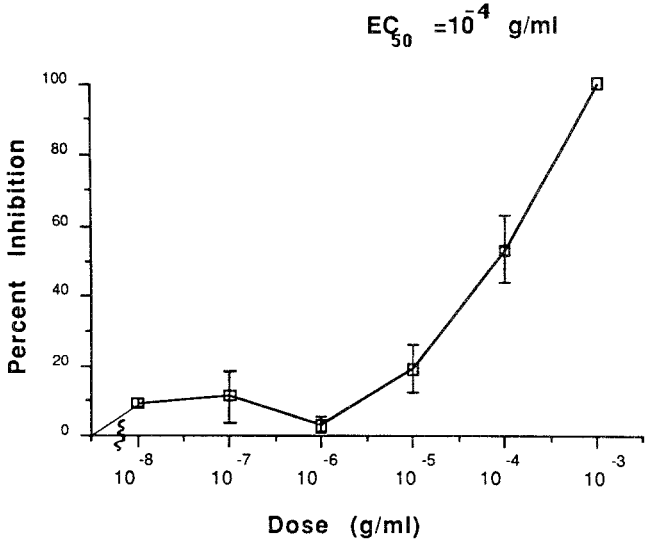

FIG. 1. Inhibition of *Balanus amphitrite* settlement on polystyrene dishes by a crude extract of *Lissodendoryx isodictyalis*. Each rectangle represents the sum of four replicate assays; error bars represent standard errors. Concentrations of 10^{-8} g/ml and higher produced statistically significant inhibition of larval settlement.

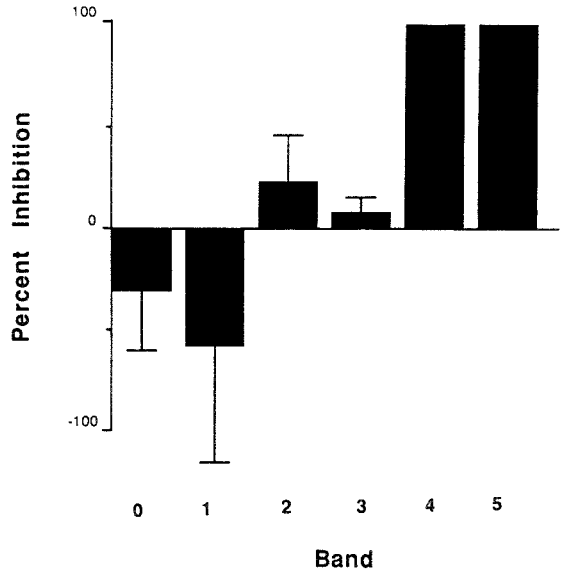

FIG. 2. Inhibition of *Balanus amphitrite* settlement on polystyrene dishes by fractions of *Lissodendoryx isodictyalis* extract at concentrations of 10^{-4} g/ml. Each bar represents the mean of two replicate assays; error bars represent standard errors. Material from zones 0, 1, 4, and 5 produced rates of settlement that differed significantly from control values.

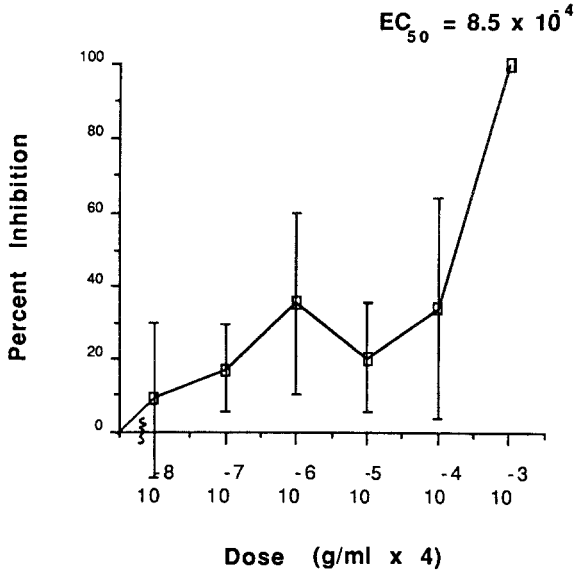

FIG. 3. Inhibition of *Balanus amphitrite* settlement on polystyrene dishes by zone 4 of the *Lissodendoryx isodictyalis* extract. Each rectangle represents the mean of three replicate assays; error bars represent standard errors. Concentrations equal to or greater than 4×10^{-7} g/ml produced statistically significant inhibition of larval settlement.

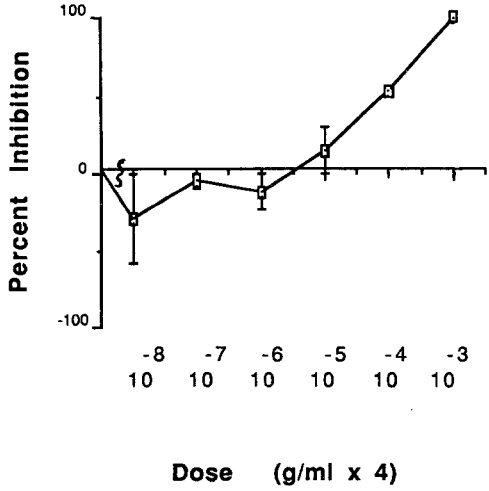

FIG. 4. Inhibition of *Balanus amphitrite* settlement of polystyrene dishes by zone 5 of the *Lissodendoryx isodictyalis* extract. Each rectangle represents the mean of three replicate assays; error bars represent standard errors. Concentrations equal to or greater than 4×10^{-5} g/ml caused statistically significant inhibition of larval settlement.

DISCUSSION

Crude extracts of *L. isodictyalis* significantly inhibit barnacle settlement in the laboratory at concentrations as low as 10 ng/ml. These extracts are similar in potency to the active concentration reported for *Bugula neritina* settlement inhibitors from the sponge *Xestospongia halichondroides* (Ware, 1984). There are at least two antifouling agents in *L. isodictyalis*. Material from zone 4 appears to inhibit settlement by partially anesthetizing the larvae and being somewhat toxic, while fraction 5 appears to prevent settlement by killing larvae. The anesthetizing effect of fraction 4 is similar to that noted for *X. halichondroides* extracts (Ware, 1984). Additional research is needed to determine whether the anesthetizing effect is the result of slowed metabolism, inhibited sensory or motor processes, or other mechanisms.

The antifoulant fractions from *Lissodendoryx isodictyalis* are less potent than purified settlement inhibitors from the octocorals *Leptogorgia virgulata* (Gerhart et al., 1988) and *Renilla reniformis* (Keifer et al., 1986; Rittschof et al., 1986). The R_f values for the antifoulants from *L. isodictyalis* are much higher than those reported for the settlement inhibitors from octocorals (Rittschof et al., 1985; Keifer et al., 1986). In addition, both active fractions are toxic to barnacle larvae, while those from octocorals are not (Rittschof et al., 1985; Keifer et al., 1986). Both characteristics indicate that the compounds from the sponge are different than those previously reported from the octocorals. Further research is in progress to determine the structural identity of these active agents.

The distinctive, minty odor of the inhibitors suggests that the active agents may be terpenoids. Since the pungent aroma of the settlement inhibitors is reminiscent of the odor of the undisturbed sponge in nature, these antifouling agents may be released into the environment by *Lissodendoryx isodictyalis*.

The antifouling activity of *L. isodictyalis* extracts may explain why this sponge is rarely overgrown by fouling organisms in nature. The crude extract comprised 600 μg/g of wet sponge tissue and possessed significantly inhibitory activity at this level. Significant inhibition of barnacle settlement is produced by the most active component of *L. isodictyalis* extracts at levels that are lower than or approximately equal to the tissue concentration (>30 μg/g) of this agent.

The potency of the crude extract may reflect the additive effects of compounds from zone 4. Although the sponge extract possesses components that both inhibit and facilitate settlement of cyprids, the net effect of the sponge crude extract is to inhibit settlement. Similar effects have been noted for extracts of octocorals (Standing et al., 1982). Furthermore, larval settlement occurs only on the surface of the sponge, and surface concentrations of antifouling metabolites may be higher than their concentration as a percentage of the entire col-

ony. Thus, while the EC_{50} values determined in the present study are high compared to those for other antifouling terpenoids, such as pukalide and the renillafoulins (Keifer et al., 1986; Gerhart et al., 1988), the settlement inhibitors from *L. isodictyalis* are still potent enough, relative to natural concentrations within the sponge, to be considered a likely antifouling mechanism. These metabolites may also play multiple roles, acting simultaneously as agents of chemical defense against predators, pathogens, or competitors.

Regardless of their role in nature, the settlement inhibitors from *L. isodictyalis* potentially may provide useful insight into the mechanisms controlling larval settlement and metamorphosis. In addition, nontoxic settlement inhibitors, such as those found in zone 4, are of potential value to marine technology as alternatives to the ecologically damaging toxic chemicals currently incorporated into paints to prevent the fouling of ships.

Acknowledgments—A. Schmidt cultured all cyprids used in the biological assays. W. Kroen, R. Forward, and F. Nijout reviewed early versions of this manuscript. Helen Nearing provided invaluable secretarial support. Supported in part by ONR Contract N00014-86-K-0261.

(Received November 21, 1988; accepted May 1, 1889)

Abstract—Preferences of meadow voles (*Microtus pennsylvanicus*) toward various coniferous species were tested under winter conditions. Cafeteria tests showed preferences for Norway spruce (*Picea abies*) and Norway pine (*Pinus resinosa*) and rejection of white pine (*Pinus strobus*) and white spruce (*Picea glauca*). When phenolic extracts of these species were prepared and added to a low 8% protein diet, food intake of voles and preferences by rank followed the same patterns. Determination of the concentration of phenolics in branch samples using the Singleton and Rossi procedure showed that Norway pines contained the smallest amount (2.15%/g dry matter) while spruces yielded the most (2.76%/g dry matter). These experiments lead us to expect high losses of Norway pine and Norway spruce in habitats harboring high vole densities.

Key Words—Voles, *Microtus pennsylvanicus*, phenolics, conifers, *Picea*, *Pinus*, deterrents, food choice, preference by rank.

INTRODUCTION

The province of Quebec for several years has sponsored a massive reforestation program aimed at planting 250 million seedlings yearly. Most of this effort is oriented toward conifers because they are easier to handle and they benefit from well-known and standardized growing methods in the nursery. By the time the seedlings are well established in their new habitat, they face various mortality factors, among which meadow voles (*Microtus pennsylvanicus*) are certainly not the least. These small secretive creatures gnaw the base of trunks (Hansson,

0098-0331/90/0300-0801$06.00/0

1985) and inflict severe debarking damage when population density is high (Green, 1978). This causes serious disruption in cropping schedules and biomass increment (Sullivan and Vyse, 1987) as well as long-term effects of wounds on tree mortality (Harper and Harestad, 1986).

Small animals like voles and hares are known to be quite selective and usually prefer food items that are low in secondary metabolites (Bryant and Kuropat, 1981; Palo, 1984; Tahvanainen et al., 1985; Bergeron and Jodoin, 1987). This is particularly true of meadow voles because phenolics and tannins are known to reduce food intake (Lindroth and Batzli, 1984), growth, and survivorship when added as supplements to laboratory diets (Lindroth et al., 1986). We have also shown (Bergeron and Jodoin, 1987) negative correlations between food preference indices and levels of total phenolics in herbaceous species. This suggested that their feeding strategy is partly driven by the contents of such secondary metabolites in potential food resources. The bark of trunk and twigs of deciduous trees and conifers contains phenolics and tannins (Bryant, 1981; Sinclair et al., 1982; Tahvanainen et al., 1985), and, since several species of conifers are currently used in reforestation programs, we need to know if the debarking behavior of voles is related to levels of phenolics in young trees and to what extent this can form the basis of their preferences toward particular species under field conditions.

METHODS AND MATERIALS

Wild and laboratory-reared meadow voles were acclimatized to fall and winter conditions in individual polypropylene cages. The mean daily temperature in the first experiment (January 8–14) was $-7.7°C$ and for the replicate (January 21–27), $-0.3°C$. We did not find any significant differences between the two sets of temperature because of the high daily variation that occurred during this period. The enclosure was adjacent to the animal house and roofed to protect the experimental animals from rain, sleet, and snow. They were fed a high-protein (16%) Purina Rabbit Chow, bedded with cotton, and watered ad libitum. Experimental cages measuring $30 \times 60 \times 60$ cm were built with thick plywood (2.0 cm). A layer of 15 cm of potting soil was used to plant seedlings of four conifer species used in this experiment (Norway spruce, *Picea abies*; Norway pine, *Pinus resinosa*; white spruce, *Picea glauca*; white pine, *Pinus strobus*). Roots were protected from gnawing by a floor made of galvanized mesh wire (7-mm mesh size). All conifers used in the cafeteria tests were even-aged ($3\frac{1}{2}$ years) and came from the same public nursery to reduce the biases due to soil type and growing conditions. Prior to each test, one tree per species was planted in each cage and left outside for a week before introducing the animal to its experimental conditions. A ration of 8 g/day of a low 8% protein diet

(ICN diet 904667) and ample bedding and ice cubes were given to voles during the seven-day trial period. The low-protein diet was used to mimic as closely as possible the minimum requirements that voles need to maintain body mass (Lindroth and Batzli, 1984). Cafeteria tests were done on 20 voles but, because of severe winter conditions, a small number of animals died during the tests (five for the first experiment and two during the second). Replicates were performed on all surviving animals, and these were completed by using either wild or laboratory-reared and acclimatized animals to increase sample size.

Daily temperatures and damage level to trees were recorded. Damage indices on individual trees were modified from those of Byers (1974) and Wysolmerski et al. (1980) to meet our experimental procedure. The criteria are summarized as follows: 0 for undamaged trees, 1 for trees with $\frac{1}{3}$ or less of the branches cut, 2 for trees with $\frac{1}{3}$ to $\frac{2}{3}$ of the branches cut, 3 for trees with $\frac{2}{3}$ or more of the branches cut, and 4 when the trunk itself was cut into pieces. These indices were used to rank the species by order of preference. Skewness of data distribution in favor of high-ranking indices forbade the use of parametric tests. Ranks were compared by Kruskal-Wallis tests and ordered by a posteriori multiple comparison tests. Weather data between replicates were compared with Student's t test.

Cafeteria tests were carried a step further using phenolic extracts from conifer seedlings mixed with a low 8% protein diet. Winterized seedlings (without roots and needles) were cut and ground to 1 mm in a Brinkmann mill to prepare phenolic extracts (Singleton and Rossi, 1966). Samples of 66 g of the winterized seedling powder were used for the extractions, which were afterwards mixed in 200 g of the low-protein diet. The mixtures were dried at room temperature for 48 hr, and samples of these were reprocessed through the phenolic extraction method to quantify the real daily dosage given in the rations. The extraction consisted of boiling at 70°C a mixture of ethanol 50% and the powder for 30 min, followed by centrifugation to eliminate the powder. A quantification of total phenolics was done using Folin-Ciocalteu reagent and compared with a standard of gallic acid. Cafeteria tests were conducted under a laboratory standard environment (20°C, 16:8 light–dark regime, 50% relative humidity). They consisted of giving voles a choice between five diets in five different feeding trays: a control diet made of the 8% protein chow and the four experimental ones made of their respective conifer extracts. A ration of 9 g (equivalent to plant extracts from one tree) per experimental tray was given to 10 adult males and 10 adult females to verify daily food intake, which was transformed afterwards into ranks of preferences. Pretest trials on animals fed the control diet for 11 days indicated that the position of feeding trays did not influence food intake.

Student's t test was used to verify body mass differences of experimental animals at the start. Ranks (based on food intake) were analyzed by Kruskal-

Wallis and classified a posteriori by multiple comparison range tests. A Friedman test (K sample test for location-matched data) between data sets of males and females was made to pool the data when necessary. All data sets were processed through the Statistical Analysis System (SAS, 1985).

RESULTS

Since weather conditions can influence food intake in small animals such as voles, we compared the means of daily temperatures between replicates. Both data sets were found to be normally distributed and did not differ significantly (Student's t test = 1.64). It became evident very early in the feeding trials that two coniferous species ranked high as preferred food items, while two others were left almost untouched. Norway pine and Norway spruce were always heavily damaged while white pine and white spruce seemed to be rejected by voles or attacked at a much later date in the experiment. Data sets of the former two species then were compared to those of the last two species using a Kruskal–Wallis test on ranks (Table 1). Both data sets were highly different ($P < 0.05$) with Norway pine and Norway spruce showing the lowest ranks, which means the highest preferences. We then extracted phenolics from branch samples of three of these species to compare the contents between preferred and rejected categories (Table 2). Dosages varied from 2.15%/g dry matter in Norway pine to 2.76%/g dry matter in white spruce. Thus, preferred species had significantly less total phenolics than rejected ones.

We designed a second series of cafeteria tests under more standardized indoor conditions to associate the types of phenolic extracts to preferences (by ranks) among voles. Phenolic additives in diets were also standardized by using an equal quantity of plant powder for each species and incorporating them into

TABLE 1. PREFERENCES OF MEADOW VOLES TOWARD FOUR CONIFEROUS SPECIES AS SHOWN BY KRUSKAL–WALLIS TESTS ON AVERAGE RANK

Experimental features		Rank of preferred species: Norway pine Norway spruce	Rank of rejected species: white pine white spruce
First experiment	Mean rank	14.08[a]	20.96
	N	19	14
Replicate	Mean rank	18.56[a]	31.35
	N	27	20

[a] Found to be significantly different by Kruskal-Wallis tests at $P < 0.05$.

TABLE 2. PHENOLIC CONTENTS OF WHOLE BRANCH AND DIET SAMPLES GIVEN TO VOLES IN CAFETERIA TESTS

Coniferous species	Dosages in whole branch samples from winterized seedlings (mean ± SD)	Dosages in diet samples after laboratory procedures (mean ± SD)
Norway pine	2.15 ± 0.03	0.47 ± 0.03
Norway spruce	2.48 ± 0.04	0.67 ± 0.03
White spruce	2.76 ± 0.08	0.62 ± 0.02
White pine		0.38 ± 0.002

200 g of a low 8% protein diet. Dosages of phenolics from such diets varied from 0.38% per g dry matter in white pine-based diets to 0.67% per g dry matter in Norway spruce based diets (Table 2). This represented only a fraction of the dosages found in branches and shows the impact of laboratory dilution procedures on such compounds.

Mean body mass of experimental males (59.1 g) was not statistically different from that of females (51.0 g: Student's t test = 1.62, $P > 0.05$). Food preferences based on intake data according to time were transformed into a ranking order before being submitted to a Kruskal–Wallis test followed by a posteriori multiple range test. Both males and females rank the experimental diets in a similar manner (Table 3). They preferred, equally well, the control diet and the rations containing Norway pine additives, while they showed a low preference toward white pine and white spruce based diets. A Friedman test between the preferences of males and females was not statistically significant and permitted us to pool the data sets from both sexes and analyze them as one

TABLE 3. CLASSIFICATION OF PREFERENCES BY RANK OF MEADOW VOLES FED DIETS WITH PHENOLIC ADDITIVES[a]

Diet category	Mean rank of males	Mean rank of females	Mean rank from pooled data
Control	5.0	4.5	9.0
Norway pine	18.8	13.5	31.7
Norway spruce	19.1	21.6	40.2
White pine	35.0	30.4	64.8
White spruce	37.1	32.5	69.3

[a] Values connected by vertical bars are not statistically different ($\alpha = 0.05$) (Kruskal–Wallis).

sample (Table 3, right hand side). The control diet that contained no secondary metabolite additives was most preferred, followed by the two diets supplemented with Norway pine and Norway spruce phenolic extracts. Diets with white pine and white spruce extracts had the lowest rank (highest order in the test).

DISCUSSION

Food preferences of wild voles are influenced by the phenolics of herbaceous species (Bergeron and Jodoin, 1987). Moreover, reduction in food intake, growth, and survival (Lindroth and Batzli, 1984; Lindroth et al., 1986) have also been associated with the presence of phenolic additives in diets of laboratory-reared animals. When given the choice between various coniferous species or diets supplemented with plant extracts from conifers, voles showed consistent preferences toward low-phenolic diets. The seedlings of Norway spruce and Norway pine contain less total phenolics than white pine and white spruce. This may explain why Norway spruce and Norway pine registered higher damage levels in cafeteria tests than the other two species. We may hypothesize that the repulsive action is done by only one phenolic compound and that its concentration is proportional to the total phenolic concentration in the conifer. This was confirmed by the second series of cafeteria tests using phenolic extracts from seedlings. Diets supplemented with extracts of the same two species were preferred over those with white pine and white spruce additives. Phenolics are generally considered as deterring substances against herbivores because of their complex association with proteins (Whittaker and Feeny, 1971), and voles seem to take advantage of this by preferring food resources with low phenolic contents.

Our study shows the existence of two conifer categories: one with a low and one with a high predation risk by meadow voles. Norway pines are at high risk but are not extensively used in eastern Canadian reforestation programs. However, Norway spruce is also a high-risk species and is being planted, and has been planted in the past, in the hundreds of millions, mostly in the form of seedlings. These seedlings must withstand four or fives vole cycles in the first 15 years after planting in lands reclaimed from agriculture or in rejuvenated woodlots. Seedlings of Norway spruce are also highly preferred as winter forage by snowshoe hares, *Lepus americanus* (Bergeron and Tardif, 1988), so that high losses are to be expected in years of high population densities of either one or both of these species. Norway pine and Norway spruce probably represent easier growing stocks in public and private nurseries, but they also mean heavier losses for private landowners during times of peak densities of small herbivores.

However, white pine and white spruce seem better able to resist the branch cutting or debarking behavior that voles and hares express in winter. These latter species should be the preferred plantation species over Norway pine and Norway spruce in habitats where high population density of both voles and hares are expected.

Acknowledgments—This study was supported by a scholarship from le Fonds pour la Formation de Chercheurs et l'Aide à la Recherche (FCAR) of the Quebec Province to Jacqueline Roy and by grants from the Stragegic Program of the Natural Sciences and Engineering Research Council of Canada and from le Fonds FCAR to Jean-Marie Bergeron. (Received November 30, 1988; accepted May 2, 1989)

Abstract—Rice plant volatiles extracted as steam distillates significantly affected the behavior of the brown planthopper *Nilaparvata lugens* (Stal). In a choice test, significantly more females settled and fed on tillers of a susceptible rice variety, Taichung Native 1 (TN 1), sprayed with acetone or untreated TN 1 plants than on TN 1 tillers sprayed with the extracts of resistant wild rice *Oryza officinalis*. *O. officinalis* steam distillate was highly toxic to first-instar nymphs of *N. lugens*. Ingestion and assimilation of food by females was significantly reduced on TN 1 plants sprayed with *O. officinalis* distillate compared to TN 1 plants sprayed with acetone. Application of *O. officinalis* distillate on TN 1 plants adversely affected hatchability of eggs of *N. lugens*.

Key Words—Brown planthopper, *Nilaparvata lugens*, Homoptera Delphacidae, *Oryza officinalis*, plant volatiles, wild rice, plant–insect interaction.

INTRODUCTION

The brown planthopper (BPH) *Nilaparvata lugens* (Stal) causes severe damage to susceptible rice varieties by excessive feeding and transmission of virus diseases. It fails to feed, grow, survive, and reproduce adequately on resistant varieties (Pathak et al., 1969). Reduced feeding on resistant varieties was attrib-

0098-0331/90/0300-0809$06.00/0

uted, therefore, to either lack of phagostimulants or to the presence of antifeedants.

Sogawa and Pathak (1970) postulated that the resistance of the rice variety Mudgo was possibly due to existence of smaller quantities of asparagine, which stimulates BPH feeding. Transaconitic acid in the nonhost barnyard grass *Echinochloa crus galli* L. acted as a BPH antifeedant (Kim et al., 1976). Soluble silicic acid and oxalic acid isolated from leaf sheaths of rice plants acted as brown planthopper sucking inhibitors (Yoshihara et al., 1979, 1980). This assumption was abandoned when it was found that silicic acid was a general inhibitor occurring in both resistant and susceptible rice varieties (Saxena, 1986). Kawabe et al. (1980) collected pure phloem sap from rice plants by severing the stylets of planthoppers and leafhoppers feeding on rice plants with a laser beam, and the analysis of the exuded sap indicated that sucrose was the main translocate in the phloem.

Saxena and Okech (1985) discussed the role of rice plant volatiles in the resistance of rice varieties to BPH. According to them, rice plant volatiles extracted as steam distillate were not likely to be found within phloem tissue. The odoriferous and volatile nature of volatiles strongly influenced the internal and external environment of the rice plant and the volatiles were thus ecologically significant in BPH resistance. Khan and Saxena (1985) demonstrated that steam distillate extract of a resistant cultivar, when applied to a susceptible cultivar, disrupted the normal feeding behavior of green leafhopper *Nephotettix virescens*. In the present study we investigated the effect of plant volatiles obtained as steam distillate extract from resistant wild rice *Oryza officinalis* on the behavior of BPH.

METHODS AND MATERIALS

Steam distillate of 50-day-old plants of highly resistant wild rice *O. officinalis* (Heinrichs et al., 1985; Velusamy, 1987) were bioassayed against greenhouse-reared *N. lugens*.

Steam Distillation and Extraction of Rice Plant Volatiles. Leaf sheaths of 50-day-old plants of the resistant wild rice *Oryza officinalis* (IRRI accession number 100179) grown in an insect-proof screenhouse were harvested and ground with an electric grinder. Steam distillation and extraction were done according to the method of Saxena and Okech (1985). A 200-g ground sample was steam distilled for 3 hr, during which time approximately 900 ml of distillate were collected. The distillate was extracted with diethyl ether (300 ml distillate; 100 ml diethyl ether) by thoroughly shaking a mixture of the two together in a separating funnel for 5 min. Diethyl ether extracted the essential oils and

other volatiles, and the ether mixture settled above the water layer in the funnel. If emulsion was formed while mixing, a few crystals of sodium sulfate were added to break the emulsion. The water layer was discarded while the ether extract was pooled in a 500-ml beaker, to which 50 g of anhydrous sodium sulfate was added. The resultant mixture was kept inside a fume hood to evaporate excess ether until the remaining volume was approximately 25 ml. The beaker then was covered with aluminum foil and held overnight to allow sodium sulfate to absorb traces of water from the extract. The extract was evaporated further to 10 ml and decanted into a weighed glass vial, which was then covered with perforated aluminum foil and placed inside a desiccator. Ether was evaporated under vacuum, leaving behind a yellow oily residue. The vial was reweighed, sealed with nitrogen, and kept at $-10°C$. The yellow oily residue was diluted in acetone–water (4 : 1) and tested at levels of 1000, 2000, 3000, and 4000 ppm.

Influence of Wild Rice Plant Volatiles on BPH Settling Responses. The settling responses of BPH were tested by the method described by Saxena and Okech (1985). Thirty minutes before exposure to the BPH, single tillers of 30-day-old TN 1 plants grown in 6-cm-diameter pots were sprayed with 1 ml of acetone–water solutions of extracts of resistant wild rice at a rate of 1000, 2000, 3000, or 4000 ppm using a quick spray atomizer. Control plants were untreated or treated with acetone. The pots with treated and control plants were arranged 7 cm apart in a circle in a plastic container (30 cm diameter, 16 cm deep) partly filled with water. The tillers of test plants were inserted through 1.5-cm-diameter holes bored equidistantly near the periphery of the lid covering the container. Fifty newly emerged, CO_2-anesthetized, brachypterous females were released at the center of the lid and covered with a snug-fitting cylindrical Mylar cage (55 cm height, 30.2 cm diameter). The females moved to the plants upon revival. Individuals that settled on each plant were counted at 4, 8, 24, and 48 hr after release. The experiment was replicated five times in a randomized complete block design.

Toxicity of Steam Distillate Extracts to First-Instar Nymphs. Toxicity of steam distillate extracts to first instars was tested following the method of Khan and Saxena (1985). Ten-day-old TN 1 seedlings were dipped separately in 1000, 2000, 3000, or 4000 ppm solutions of extracts of resistant wild rice and placed individually in test tubes (15×1.5 cm). Control seedlings were untreated or treated with acetone. After the acetone had evaporated, 10 first instars were released on each of the treated or control seedlings. The test tubes were capped and arranged in a randomized complete block design in an incubator. Nymphal mortality was recorded after 24 hr. Each treatment, including the control, was replicated five times.

Ingestion and Assimilation of Food on Extract-Treated Plants. Leaf sheath

portions of intact tillers of potted 40-day-old TN 1 rice plants were painted using a camel-hair brush with 0.25 ml of acetone–water solutions of extracts of resistant wild rice at a rate of 1000, 2000, 3000, or 4000 ppm per tiller. Control plants were untreated or treated with acetone. One hour after treatment, newly emerged females (starved for 2 hr but water satiated) were weighed individually on a microbalance and enclosed singly in air-tight parafilm sachets (5 × 5 cm) through which the leaf sheath of treated or control plants passed. The weight of each female and its excreta were recorded separately after 24 hr. A control insect was maintained to assess the loss in insect body tissue as a result of catabolism, and the insect was given access to a moist cotton swab to prevent desiccation. The amount of food ingested and assimilated was calculated as follows (Khan and Saxena, 1986):

$$\text{Food assimilated} = W_1\left(\frac{(C_1 - C_2)}{C_1}\right) + (W_2 - W_1)$$

where W_1 is the initial weight of insect; W_2 is the final weight of insect; C_1 is the initial weight of control insect; C_2 is the final weight of control insect; and food ingested is the food assimilated + weight of excreta. The experiment was replicated 10 times.

Hatchability of Eggs on Treated Plants. Thirty-day-old single tillers of potted TN 1 plants were infested with five gravid brachypterous females and allowed to oviposit for 24 hr after, which the plants were removed and painted with 0.25 ml acetone solutions at a rate of 1000, 2000, 3000, or 4000 ppm extract per tiller. Control plants were untreated or treated with acetone. The number of nymphs that emerged was recorded, and at the end of emergence of nymphs, unhatched eggs were counted by dissecting leaf sheaths under a 20× binocular microscope.

RESULTS

Influence of Steam Distillate Extract on Settling Responses. In the choice test, BPH adults settled uniformly on TN 1 plants sprayed with extract of resistant *O. officinalis* or with acetone 1 and 4 hr after release. However, 8 hr after release, there were significantly fewer females on TN 1 plants sprayed with *O. officinalis* extract than on acetone treated plants (Table 1). Fewer females were also recorded on TN 1 plants sprayed with the extracts of resistant wild rice *O. officinalis* than on control plants even 24 and 48 hr after release.

Toxicity of Steam Distillate Extracts to First-Instar Nymphs. The extracts of *O. officinalis* were highly toxic to first-instar nymphs (Table 2). There were significant differences in toxicity among extracts of different concentrations, and extracts at 3000 and 4000 ppm caused significantly higher mortality of

TABLE 1. SETTLING RESPONSE OF *N. lugens* FEMALES ON TN 1 PLANTS SPRAYED WITH STEAM DISTILLATE EXTRACTS OF RESISTANT WILD RICE *O. officinalis* AT 4, 8, 24, AND 48 hr AFTER RELEASE IN FREE-CHOICE TEST

Cultivar	Treatment	Individuals settled (%) on plants at given hr after release[a]			
		4	8	24	48
TN 1	None	10.4a	22.4a	28.6a	27.2a

nymphs on extract-treated TN 1 plants than lower concentrations. Even at 1000 and 2000 ppm, more nymphs died on TN 1 susceptible plants treated with extracts of resistant wild rice than on acetone-treated and control plants. The nymphs rejected the treated plants and settled on Mylar cages.

Ingestion and Assimilation of Food on Treated Plants. The quantity of food ingested and assimilated by BPH was significantly less on extract-treated TN 1 plants than on acetone treated or control TN 1 plants (Table 3). Distinct differences in quantity of food ingested were recorded among different concentrations of extracts, and ingestion was significantly lowest on TN 1 plants

TABLE 2. TOXICITY OF STEAM DISTILLATE EXTRACTS OF RESISTANT WILD RICE *O. officinalis* TO FIRST-INSTAR NYMPHS OF *N. lugens*

Cultivar	Treatment	Nymphal mortality (%)[a]
TN 1	None	0d
TN 1	Acetone	2.0d
TN 1	1000 ppm *O. officinalis* extract	70.0c
TN 1	2000 ppm *O. officinalis* extract	88.0b

DISCUSSION

Plant chemicals are very important in insect–plant relationships and even subtle differences in the physical and chemical attributes of plants can affect their suitability as hosts. Recently, several authors have demonstrated the role of plant chemical factors in determining susceptibility of rice cultivars to insect pests (Pathak and Saxena, 1980; Khan and Saxena, 1985; Saxena and Okech, 1985; Saxena, 1986). The present study elucidated the role of rice plant volatiles as allelochemics (Whittaker and Feeny, 1971) involved in BPH–rice plant interactions. The low settling response of BPH females on TN 1 plants treated with steam distillate extracts of highly resistant *O. officinalis* plants showed that the treatment conferred resistance at least temporarily. Similarly, nymphs caged on treated TN 1 plants were unable to settle on them and suffered high mortality. The restlessness of BPH nymphs and adults on treated susceptible TN 1 plants can be attributed to the volatile compounds present in the distillate, which are deleterious to the insect (Saxena and Okech, 1985).

Food intake and assimilation also decreased significantly in susceptible TN 1 plants treated with extract of *O. officinalis*. TN 1 plants treated with *O. officinalis* extract at 4000 ppm conferred a high level of resistance against insect feeding. Khan and Saxena (1986) also demonstrated that ingestion and assimilation of food by *Sogatella furcifera* females were reduced more on TN 1 plants treated with extracts of resistant varieties than on plants treated with acetone or TN 1 extracts. According to them, the volatile repellents present around resistant plants would discourage prolonged staying and sustained feeding of insects on them and therefore could have a multitude of subtle, yet distinct effects on pest behavior and could limit pest establishment.

Reduced egg hatchability on TN 1 plants treated with extract *O. officinalis* compared with acetone-treated or control TN 1 plants suggests that the extract of *O. officinalis* has an allelochemical (or allelochemicals) that affects egg hatching. Previous studies have shown that topical application of steam-distillate extract of resistant TKM 6 on eggs of striped stem borer, *Chilo suppressalis*, adversely affected embryonic development and reduced egg hatchability. Saxena and Puma (1979) also demonstrated that hatchability of BPH eggs was greatly reduced when incubated for three days in 0.5% transaconitic acid, an allelochemic factor present in *Echinochloa crusgalli* L.

The allelochemicals in the resistant and susceptible rice cultivars have not been identified but a large group of low-molecular-weight compounds, such as essential oils, terpenoids, alcohols, aldehydes, fatty acids, esters, and waxes have been obtained (Gunther, 1952; Bianchi et al., 1979). A mixture of 14 esters, seven carbonyl compounds, five alcohols, and isocyanurate in the volatile fraction of BPH-susceptible rice cultivar has been identified (Obata et al.,

1985). Saxena and Okech (1985) detected 34 different peaks in the steam distillate extracts of different rice cultivars. Most of these compounds are insoluble in water and are not likely to be translocated in the vascular bundles.

Sogawa (1982) suggested the occurrence of sucking inhibitory chemicals in the phloem sap of resistant varieties. However, our studies have demonstrated that application of steam-distillate extract of resistant varieties to susceptible plants can confer resistance against BPH without altering the chemistry of phloem sap in susceptible plants. It has also been demonstrated for another rice green leafhopper, *N. virescens* (Khan and Saxena, 1985), that resistance of susceptibility to feeding was governed by the sum of allomones or kairomones present in rice plant volatiles. Thus, our findings support Fraenkel's (1959, 1969) view that allelochemics play an important role in insect–plant interactions.

Acknowledgments—The authors express their thanks to Dr. T.T. Chang, Principal Geneticist and Head, International Rice Germplasm Centre, IRRI, Philippines, for supplying seeds of *Oryza officinalis*.

(Received June 7, 1988; accepted May 4, 1989)

Abstract—(*Z*,*Z*)-3,13-Octadecadien-1-ol **1a** is identified as the sex pheromone from the poplar pole clearwing moth, *Sphecia siningensis* Hsu, by GC-MS analysis, synthesis, EAG, and field bioassay. Species isolation among Sesiidae by pheromone is also discussed.

Key Words—Poplar pole clearwing moth, *Sphecia siningensis* Hsu, sex pheromone, Lepidoptera, Sesiidae, (*Z*,*Z*)-3,13-octadecadien-1-ol, geometric isomers.

INTRODUCTION

The poplar pole clearwing moth, *Sphecia siningensis* Hsu was once named poplar large hornet moth *Aegeria apiformis* Clerk (Hsu, 1981). This pest is distributed over Shanxi, Gansu, Qinghai, Ningxia, Shanxi, Inner Mongolia, and other provinces in China (Zhong, 1983; Lin, 1984), which are high elevation, dry, cold areas, covering an area of 26,700 ha. It damages trees over 8

years old by boring into the base or bole and sometimes even into branches. Under severe attack, the xylem and pith are extensively damaged and are easily snapped by a strong wind.

The poplar pole clearwing moth has one generation every two years (Zhong, 1983; Hsu, 1984). Larvae develop in the tunnel of the tree for 23 months; adults, eggs, and larvae live outside the tree pole for a few days. Therefore, it is very difficult to control. Since it mates only once, mass trapping using the sex pheromone could be used for control. As we previously reported (Zhang et al., 1986), in the field tests, one of the synthetic isomers **1a**-(*Z*, *Z*), although inactive toward *Paranthrene tabaniformis* Rott, the poplar twig clearwing moth, was highly attractive to *Sphecia siningensis* Hsu. Both of them belong to Sesiidae. We report here the structure determination, synthesis, and pheromone response by the poplar pole clearwing moth *S. siningensis* Hsu, as well as species isolation among Sesiidae.

METHODS AND MATERIALS

Pheromone Collection. Moths were collected from the countryside of Yuci City, Shanxi Province, and 2-day-old unmated male moths were used for EAG tests. The ovipositor areas of 1- to 2-day-old unmated females (80 FE) were dipped and extracted with CH_2Cl_2. The extract was filtered over glass wool, and the filtrate was concentrated under dry N_2 flow to 20 μl for analysis.

Instruments. For the natural product, MS spectra were obtained on a Shimadzu QP-1000 GC-MS instrument equipped with 3% OV-1 column (2 m $\times$ 2 mm). The temperature was programmed from 150°C (1 min) to 250°C at 5°C/min. For the synthesized compounds, [^{1}H]NMR spectra were recorded in $CDCl_3$ solution with TMS as an internal standard on Varian XL-200 and EM 360L spectrometers. Capillary gas chromatographic analyses were performed on HP 5880A-type instrument equipped with a DEGS column (40 m $\times$ 0.28 mm) at a column temperature of 180°C with a split ratio of 40:1. MS spectra were obtained with Finnigan 4021 model spectrometer with an EI source.

Bioassay. EAG equipment was constructed according to Roelofs and Comeau (1971). The chemicals were diluted with CH_2Cl_2 to 1 mg/ml and transferred (10 μg) onto a piece of filter paper in a 1-cm^2 area with a microsyringe. Every sample was tested no more than three times on each antenna in random order; all tests were performed in a well-ventilated laboratory.

Field tests were conducted in the forest belt (trees 10–12 years old) in Taigu County of Shanxi Province and Dingxi and Ninxia regions of Gansu Province during the adult flight seasons from 1983 to 1987. Delta-type adhesive traps were used and hung on trees about 1.5 m above the ground. Traps were charged with various amount of synthetic lure using red rubber specta as dispensers.

RESULTS AND DISCUSSION

Synthesis.

1a, *Z,Z* R = H

1b, *E,Z* R = H

1c, *Z,E* R = H

2b, *E,Z* R = Ac

2c, *Z,E* R = Ac

2d, *E,E* R = Ac

(*Z,Z*)-3,13-Octadecadien-1-ol **(1a)**, its geometric isomers **(1b–d)**, and the corresponding acetate **(2a)** were prepared as previously reported by Zhang et al. (1986) according to the following scheme. The geometric purities of **1a–d** and **2a** were all more than 95% and these were employed in EAG and field tests.

The procedure chosen to prepare **1a** is outlined in Scheme 1. The preparation of compounds **3–10** was done according to our previous report (Zhang et al., 1986). Treatment of **10** (84 g) with TsOH—CH_3OH followed by P-2 Ni

$$HC{\equiv}CCH_2OH \xrightarrow[80\%]{a} C_7H_{15}C{\equiv}CCH_2OH \xrightarrow[83\%]{b} HC{\equiv}C(CH_2)_8OH \xrightarrow[83.6\%]{c,d}$$

3 **4** **5**

$$C_4H_9C{\equiv}C(CH_2)_8OTHP \xrightarrow{e} C_4H_9\overset{H}{C}{=}\overset{H}{C}(CH_2)_8X \xrightarrow[94\%]{h}$$

6

f, g: **7** X = OTHP; **8** X = OH; **9** X = Br

$$C_4G_9C{\equiv}C(CH_2)_8\overset{H}{C}{=}\overset{H}{C}(CH_2)_2OTHP \xrightarrow[90\%]{f,e} C_4H_9\overset{H}{C}{=}\overset{H}{C}(CH_2)_8\overset{H}{C}{=}\overset{H}{C}(CH_2)_2OH$$

10 **1a**

SCHEME 1. (a) Li-Liq.NH_3, *n*-$C_7H_{15}Br$; (b) NaH-1,2-PDA or 1,2-EDA; (c) DHP, HCl; (d) *n*-BuLi/*n*-BuBr; (e) P-2 Ni/H_2; (f) TsOH—CH_3OH; (g) Py-TsCl LiBr-acetone; (h) LiC≡CCH_2OTHP-HMPT.

(Brown and Ahuja, 1973) gave **1a** (75.6 g) in 90% yield. The overall yield of **1a** from **3** was 43%. Calcd. for $C_{18}H_{34}O$: C, 81.13, H, 12.86. Found: C, 81.00, H, 13.18. IR, ν_{max}: 3300 (OH), 3010 and 730 (*cis*-CH=CH) cm^{-1}. NMR, δ_H: 0.83 (3H, t = 7, CH_3), 1.26 [16H, br, (CH_2)n], 1.47–2.3 (8H, m, CH_2C=), 3.60 (2H, t, J = 7, $C\underline{H}_2OH$), 5.24–5.6 (4H, m, CH=CH) ppm. MS, *m/z*: 266 (M^+, 1.6%), 248 ($M-H_2O$, 0.5%), 55 (base). GC (DEGS) analysis showed that **1a** contained *Z,Z*, 95.2%; *Z,E*, 2.7%; *E,Z*, 1.0%; and *E,E*, 1.1%, with R_t of 27.68, 26.36, 25.25, and 24.12 min, respectively.

The other three isomers **(1b–d)** were synthesized in a similar manner to **1a** (Zhang et al., 1986) and were fully characterized by IR, NMR, and MS spectrometry. **1b:** *E,Z*, 95.1%; *E,E*, 2.9%; *Z,Z*, 1.1%; *Z,E*, 0.9%; **1c:** *Z,E*, 95.2%; *E,E*, 3.5%; *Z,Z*, 1.3%; **1d:** *E,E*, 95%; *Z,Z*, 3%; *Z,E*, 1%; *E,Z*, 1%.

Structural Determination. The pheromone extract (2 μl) was injected into a GC-MS for mass fragmentography using *m/z* 266 (M^+) and 248 (M-18). There was a peak on GC (Figure 1) with R_t 16.1 min, which was the same as that of synthetic **1a** under the same conditions and could be detected at both *m/z* 266 (M^+) and 248 (M-18). The MS spectra obtained from this peak was shown to be identical to that of **1a** (Figure 2).

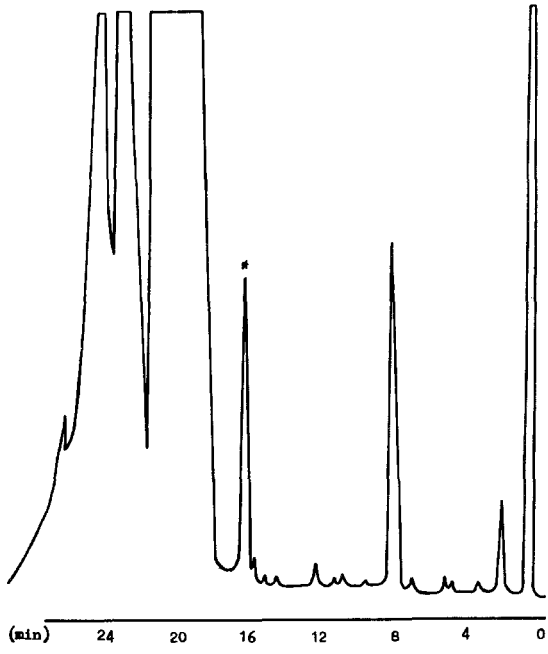

FIG. 1. Gas chromatogram of the pheromone gland washings from *Sphecia Siningensis* Hsu. GC condition: column 3% OV-1, column temperature programmed from 150°C to 250°C at a rate of 5°C/min.

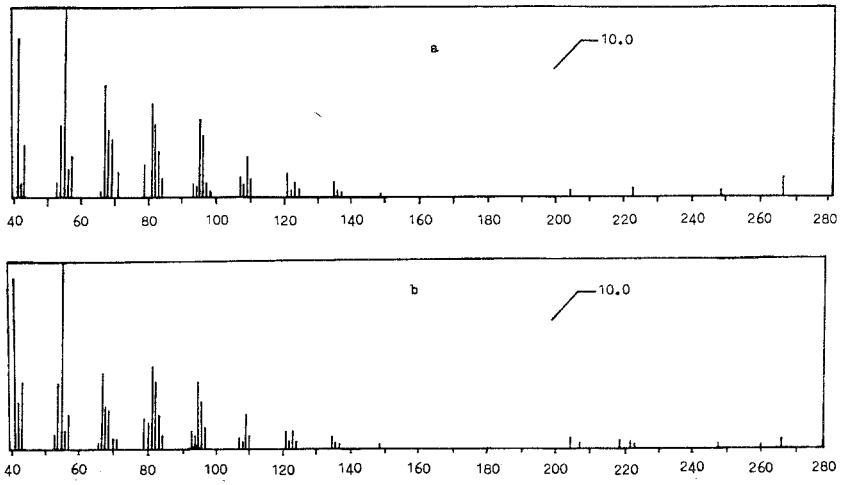

FIG. 2. MS spectra of natural pheromone of *Sphecia siningensis* Hsu (b) and the synthetic compound **1** (a).

Further evidence was obtained by bioassays. Among eight compounds tested, (*E*,*E*)-OH[5] **(1d)** elicited the highest response to male moth antenna, (*Z*,*Z*)-OH **(1a)** is the second highest. The other two isomers **(1b, 1c)** and all the corresponding acetates **(2a–d)** have no effect in the EAG bioassay (Table 1). The average response for **1a** was 1.25 mV (75.76%, in comparison with that of **1d** as 100%), and for **1d** it was 1.65 mV. The average responses for **1b** and **1c** were 0.15 mV and 0.20 mV, which might be due to contamination. The related acetates **2a–d**-OAc and the control test has no detectable signal on EAG. Besides, in each EAG test **1d** always got the highest response, **1a** the second highest.

However, in the field tests only **1a** was attractive to male moth. Although (*E*,*E*)-OH **(1d)** had the strongest EAG reaction by the poplar pole clearwing moth, it acted as an inhibitor in field trials; therefore it seems that there are two kinds of chemoreceptors in antennae. Compound **1d** stimulates the inhibitional chemoreceptor in antennae and produces an EAG reaction. Compound **1a** stimulates the sex pheromone receptor and is responsible for sex behavior.

The same effect was observed in the case of the EAG response test of the male poplar twig clearwing moth. *P. tabaniformis* Rott where both **1a** and **1b** gave strong EAG responses; the other two isomers, **1c** and **1d**, gave rather weak responses. However, in the field bioassays, only **1b** proved to be the natural pheromone. Thus **1a** was established as the sex pheromone of the poplar pole clearwing moth.

[5](*E*,*E*)-OH stands for (*E*,*E*)-3,13-octadecadienol; similar abbreviations were used for the other compounds.

TABLE 1. EAG RESPONSE OF POPLAR POLE CLEARWING MOTH TO DIFFERENT CHEMICALS

Chemical samples	Amplitude of reaction of EAG (mv)					EAG (%)
	I	II	III	IV	$\bar{X}$	
1a, *Z,Z*-OH	2.0	1.8	0.8	0.4	1.25	75.76
1b, *E,Z*-OH	0.4	0.2	0	0	0.15	9.20
1c, *Z,E*-OH	0.4	0.2	0.2	0	0.20	12.27
1d, *E,E*-OH	3.0	2.3	1.0	0.2	1.65	100
2a–d-OAc	0	0	0	0	0	0
CK	0	0	0	0	0	0

Field Evaluation. In an observation spot, the dose of each trap was 200 μg and the test was repeated twice. During the peak period of adult emergence, a number of male moths flew toward the trap baited with (*Z,Z*)-OH at 8 PM. Males circled the traps for 1–2 min, then entered it. Trap capture averaged 50 males per day. The other geometric isomers were ineffective in attracting males.

To compare the trapping efficiency of different dose of Z,Z-OH **(1a)** to male moths, four separate experiments were done in three different locations in 1986–1987. Table 2 shows that among the doses of 200, 400, and 800 μg, those with dose of 800 μg caught the most males. For example, in Taigu, 16 traps with a dosage of 800 μg caught 623 male moths during August 15 to September 30 with an average 39 moths per trap, while those with dosages of 200 μg and 400 μg caught an average of 20.5 and 23.4 moths per trap.

In Table 3, six traps of different doses were used, and the number of captured males was recorded each day. The trap with a dosage of 800 μg caught

Percentage of total	1.29	4.5	72.0	12.54	9.6	0	0	100

the largest number of male moths, which was 72% of the total number of captured male moths.

The trap baited with 800 μg synthetic pheromone was five to seven times more attractive than that of the trap with dose of 1200 μg of the total number of the captured male moths. When the dose used was over 1600 μg, no moths were caught; the male moths only flew near the trap instead of entering it. For convenience, traps at dosages of 600–800 μg were used in the field to get optimum catches.

Species Isolation among Sesiidae. In order to understand the species isolation by pheromone, two more species of clearwing moths in China were examined by screening test in the field. Male *Paradoxecs prelli lien*, a mulberry tree borer, gave strong response only to **2b,** an acetate of (*E*,*Z*)-3,13-Octadecadien-1-ol (Tan, unpublished), and the related vine tree borer *Paranthrene regalis B* was captured by **1b** (Guo et al., unpublished). Therefore, two kinds of clearwing moth use the same *E*,*Z*-OH **(1b)** as the major pheromone component. There must be either a minor component in the pheromone of one of the species or other reasons for the species isolation. This is now under investigation.

CONCLUSION

The structural determination in combination with EAG and field bioassays gave strong evidence that (*Z*,*Z*)-3,13-Octadecadien-1-ol **(1a)** is a sex pheromone of the poplar pole clearwing moth *Sphecia siningensis* Hsu. Other geo-

metric isomers **(1c–d)** and the corresponding acetates **(2a–d)** were inactive. Compound **1a** demonstrated a high level of attractancy to the poplar pole clearwing moth, which could be useful for mass trapping the male moths or for monitoring adult emergence in pest control programs.

(Received November 15, 1988; accepted May 7, 1989)

Abstract—The Dufour gland of *Manica rubida* contains a simple mixture of (*Z*, *E*)-α-farnesene and (*Z*, *E*)-α-homofarnesene with tiny amounts of other farnesene, homofarnesene, and bishomofarnesene isomers. The gland also contains a mixture of very volatile compounds, chiefly acetone, with smaller amounts of acetaldehyde, ethanol, propanol, isobutyraldehyde, butenone, and butanone. The workers of *M. rubida* are not attracted to these highly volatile compounds as are workers of *Myrmica* species, but *M. rubida* workers show a strong increase of linear speed when stimulated by a freshly isolated gland. This response of increased speed of both *M. rubida* and *M. rubra* to their own or each other's Dufour gland secretion is consistent with the presence of the farnesenes in them both.

Key Words—Ant, *Manica rubida*, Hymenoptera, Formicidae, Dufour gland, farnesene, homofarnesene, acetone.

INTRODUCTION

Manica rubida (Latreille) is the only Eurasian member of the genus *Manica* Jurine. It is generally described as a primitive myrmicine ant on the basis of its

[3]Present address: Department of Chemistry, Cornell University, Ithaca, New York.

0098-0331/90/0300-0827$06.00/0

colony foundation system and some of its morphological characters. Moreover, it does not recruit nestmates to collecting food. Goetsch (1934) has already shown that *Manica rubida* workers lay odor trails. We have observed that foragers lay down trails on their way back to the nest, then again to the food, and follow these trails singly (M.C. Cammaerts and Cammaerts, 1985; R. Cammaerts and Cammaerts, 1985). The trail pheromone is a minor component of the venom contained in the poison gland and was identified as 3-ethyl-2,5-dimethylpyrazine, which is also used by *Myrmica* species (Attygalle et al., 1985, 1986). There is, on average, 7 ng of the substance in the poison reservoir of each worker (Attygalle et al., 1986). The contents of *Manica rubida* mandibular glands have also been chemically studied (Bestmann et al., 1987), and the ethological activities of the most abundant compounds determined (M.C. Cammaerts et al., 1988). The major substance, manicone, (4*E*)-4,6-dimethyl-4-octen-3-one, is attractive and a locostimulant. It is also the principal constituent of the mandibular glands of *M. mutica* and *M. bradleyi* (Fales et al., 1972), two species of the Neartic regions (Wheeler and Wheeler, 1970). This substance is not present in the mandibular glands of *Myrmica* species.

Manica rubida generally forms large colonies. Behavioral studies, performed essentially in the field, verified the absence of any recruitment in the species, and provided information about nest topology, nestmate recognition, territorial marking and homing (R. Cammaerts and Cammaerts, 1987).

In order to understand how *M. rubida* can survive or be dominant in its appropriate biotope, and in order to extend our pheromonal knowledge of the species, we have now studied its Dufour gland contents both chemically and ethologically. We have compared the Dufour gland contents with that of *Myrmica rubra*, and observed cross-reactions of these two species towards the substances from each other's glands.

METHODS AND MATERIALS

Collection of Ants. Fragments of five nests of *M. rubida* were collected in France, at St André-en-Vivarais (Ardèche, September 1985), and at the Pas de Peyrol, near the Puy Mary (Cantal, August 1986 and September 1987). Nests of *M. rubra* were collected in Belgium. All these colonies were maintained in artificial nests made from plastic boxes partly filled with regularly humidified plaster of Paris and provided with an exit hole for the ants (see R. Cammaerts and Cammaerts, 1987, Figure 4). The artificial nests were placed in polyethylene basins (59 × 38 × 5 cm or 68 × 38 × 7 cm) serving as foraging areas, on which food (dead cockroaches, sugared water) was provided twice a week. Stimuli (sources of pheromones) could be presented to workers on their artificial foraging area.

Another sample of *Manica rubida* from Ochotnica Górna, in the Gorce mountains of Poland was provided dead in dichloromethane and was used only for confirmation of chemical studies.

Chemical Methods. The Dufour glands were dissected under water from freshly killed workers and sealed individually in glass capillary tubes and by that means injected onto the gas chromatograph by the method of Morgan and Wadhams (1972a) without the intervention of solvent. The tubes were kept in the injection port for 2 min at various temperatures from 130°C to 160°C before crushing them. Analysis was carried out on a fused silica capillary column (25 m × 0.32 mm) coated with OV-1 silicone of 0.4 μm film thickness in a Hewlett Packard 5890 gas chromatograph. The carrier gas was helium at 4 psi column head pressure (a flow rate of approx. 1 ml/min). The oven temperature was initially 30°C for 2 min and then increased at a rate of 4°C/min to 270°C. The column effluent was passed straight into the mass spectrometer, a Hewlett Packard 5970B Mass Selective Detector with HP59970C ChemStation data processor. The Mass Selective Detector was set to monitor m/z 35–350, giving a rate of 1.5 scans/sec using 70 eV ionization.

Samples of the dichloromethane extract of the Polish ants were injected (1 μl) onto the same system, using the same conditions, but using a microliter syringe and an inlet splitter with split ratio of 1 : 30 (column–waste).

The very volatile components of the Dufour gland were separated and analyzed by gas chromatography using a Chrompack PLOT fused silica capillary column (10 m × 0.32 mm, Chrompack Ltd., London) coated with PoraPLOT Q (10 μm) in a Carlo Erba (Milan) Fractovap 4160 series gas chromatograph with FID and a Shimadzu Chromatopac C-R3A data processor (Dyson Instruments, Hetton, U.K.). Individually sealed Dufour glands were injected as above. The oven temperature was initially 50°C, then increased at 20°C/min to 150°C. Retention times and peak areas were determined using aqueous solutions of pure compounds of concentrations 5–10 ng/μl.

Ethological Methods. Dufour glands of *M. rubida* or *M. rubra* were dissected in tap water under a binocular microscope and placed on pieces of filter paper (Whatman No. 1, 1 cm^2). Each gland was then presented to the ants, on the piece of paper, in the foraging areas.

Three measures of ethological responses were observed and quantified: the workers' orientation towards the stimulus, their linear speed, and their angular speed in its vicinity. The procedure used is detailed in M.C. Cammaerts et al. (1988). A total of 20 individual workers were observed to calculate the values for the linear and angular speed and 30 individuals for the orientation in each experiment. This furnished a distribution of 20 or 30 experimental values. Each distribution was characterized by its median (and quartiles), and was compared, by means of nonparametric χ^2 tests, with results from other tests or those from control experiments obtained by using untreated pieces of paper.

RESULTS

Chemical Analysis. The amount of very volatile components of the Dufour gland secretion, analyzed on the PoraPLOT Q column, varied in quantity from sample to sample, but the pattern of substances was similar in different individuals. An example of a gland rich in these low-mass, volatile substances is shown in Fig. 1. Peaks corresponding to acetaldehyde (ethanal), ethanol, acetone, 1-propanol, isobutyraldehyde (methylpropanal), butenone, butanone, and 2-butanol are clearly seen. The acetaldehyde and ethanol peaks each represent 4 ng, the acetone peak, 70 ng, but the average amount of acetone was 20 ng. These substances were all identified by comparison of their retention times with authentic specimens. Analysis of *Myrmica* glands on the same column gave a mixture of the same substances but with acetaldehyde or acetone the major component.

Samples of Dufour glands from *M. rubida* workers collected in 1985 and 1987 as well as the preserved sample from Poland all gave similar results for the less volatile components on gas chromatography–mass spectrometry. A typical result for a single gland is given in Figure 2. (*Z*, *E*)-α-Homofarnesene

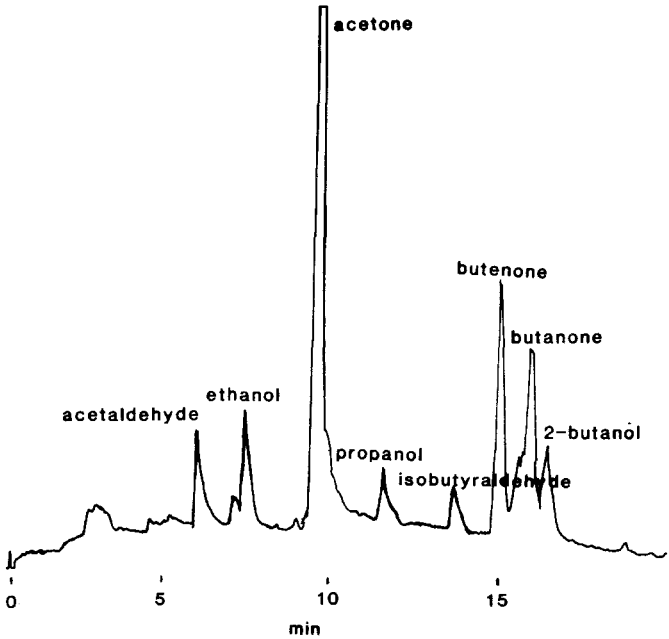

FIG. 1. Gas chromatogram of a single Dufour gland of a worker of *M. rubida*, rich in the volatile components, chromatographed on a PoraPLOT Q column. The small, incompletely resolved peak at 15.7 min is due to butanal or a butenol.

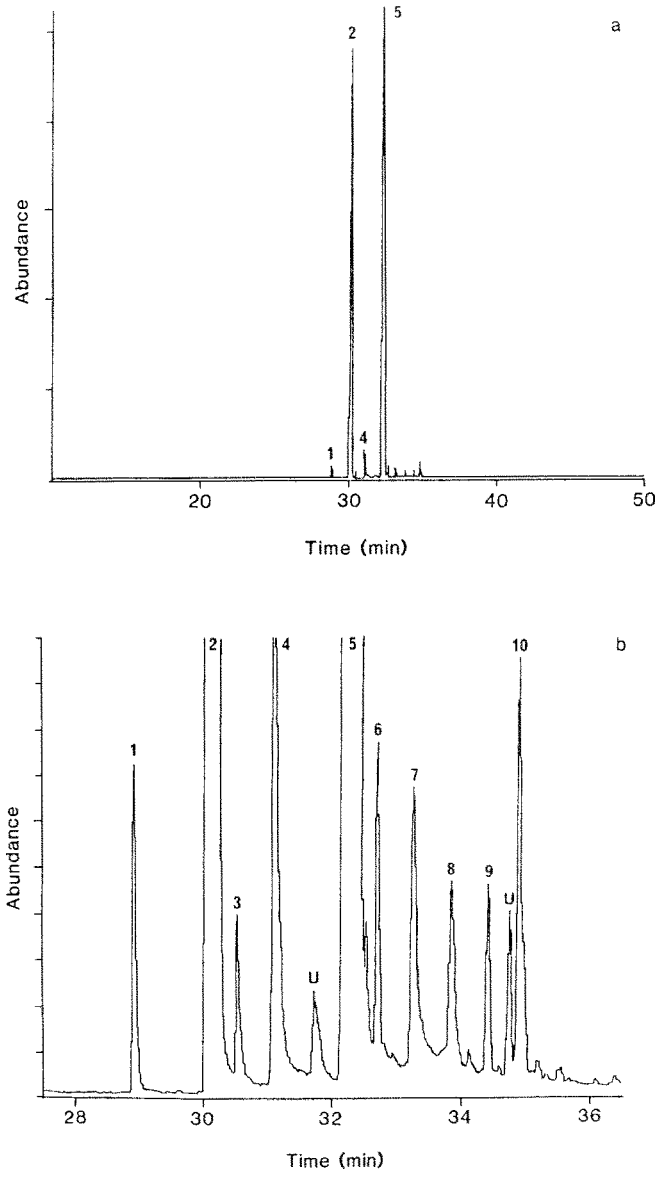

FIG. 2. Gas chromatogram of the contents of the Dufour gland of one worker of *M. rubida*, (a) showing the two main components, (*Z*, *E*)-α-farnesene and (*Z*, *E*)-α-homofarnesene, and absence of other major components. (b) Expansion of the region 28–36 min, to show the minor components. The numbers correspond to those in Table 1. U indicates unidentified substances. This gland was selected as one richer in the minor components. The sum of the masses in all the peaks is approximately 1 μg.

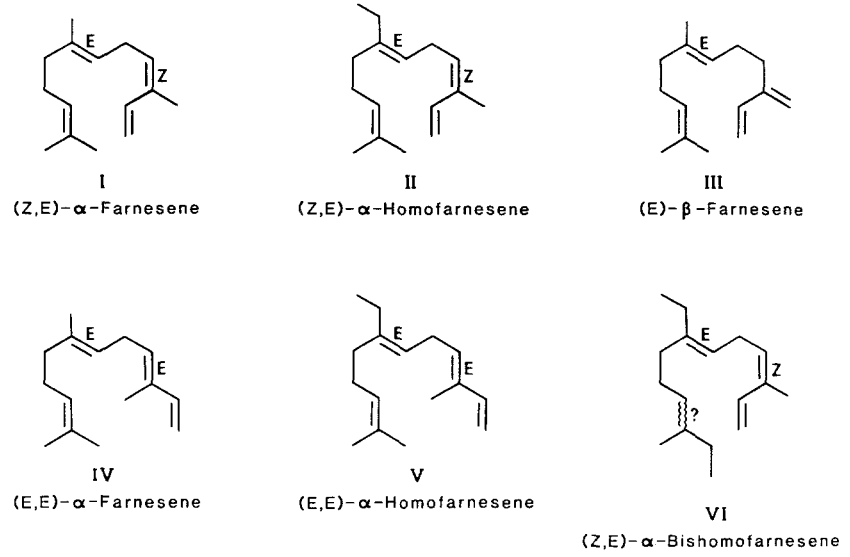

FIG. 3. Structures of farnesene isomers and homologs identified in *Manica rubida* Dufour glands.

(structure II, Figure 3) was in each case the major substance found, with (*Z*, *E*)-α-farnesene (I) next. The ratio of these compounds in individual workers varied from 4:1 to almost equal quantities. In the pooled sample of approximately 100 workers collected in Poland, the ratio was 3:2, which represents an approximate average value for the French sample collected in 1987.

Identification of these two substances was made from their mass spectra and confirmed by comparison of spectra and retention times with the same substances found in *Myrmica* Dufour glands (Attygalle and Morgan, 1984) that have been fully characterized by degradation (Attygalle and Morgan, 1982) and synthesis (Morgan and Thompson, 1985). Much smaller amounts of other farnesene isomers and homologs were also found. These are seen in Figure 2b and listed in Table 1, together with the more diagnostic ions in their mass spectra. (*E*)-β-Farnesene (III) and (*E*, *E*)-α-farnesene (IV) are well characterized (Anet, 1970) and synthetic samples, prepared by dehydration of nerolidol (Morgan et al., 1979) were available for comparison. (*E*, *E*)-α-Homofarnesene (V) was identified by its retention time relative to (*Z*, *E*)-α-homofarnesene and because its mass spectrum closely resembled that of (*E*, *E*)-α-farnesene with the higher mass ions displaced by +14 mass units. (*Z*, *E*)-α-Bishomofarnesene (VI) is the same as the *Myrmica* substance (Morgan and Wadhams, 1972b) confirmed by degradation (Attygalle and Morgan, 1982). Another still smaller peak, identi-

[a] Refers to Figure 2.

fied in only some samples, was the bishomofarnesene found in *Formica lemani* (Ali et al., 1987). The (*E*)-β-homofarnesene found here is not the same as that identified in *Harpagoxenus sublaevis* (Ollett et al., 1987). The latter has a quite different mass spectrum with a strong ion at *m/z* 133 (compare with Table 1). The *Manica* substance is therefore called (*E*)-β-homofarnesene-2 until these structures are solved in full. Small quantities of two further bishomofarnesenes were identifiable in some samples (less than 0.5% of the total in the gland).

Behavioral Studies. Freshly isolated Dufour glands of *M. rubida* and of *M. rubra* were presented to workers of *M. rubida*. For comparative purpose, Dufour glands of *M. rubida* were also presented to workers of *M. rubra*. In each case, the locomotion reactions of workers were observed and quantified. The numerical results obtained are reported in Table 2.

They show that *M. rubida* workers do not orient themselves either towards their own or towards *M. rubra* Dufour glands. However, *M. rubra* workers are attracted towards *M. rubida* Dufour gland contents. We know *M. rubra* workers are attracted to their own Dufour gland contents because of a few extremely volatile compounds, chiefly acetaldehyde (Cammaerts-Tricot et al., 1976).

TABLE 2. LOCOMOTION REACTIONS OF *Manica rubida* AND *Myrmica rubra* WORKERS STMULATED BY ANTS' DUFOUR GLANDS[a]

Tested species and presented stimuli	O (ang. deg.)	*P*	V (mm/sec)	*P*	S (ang. deg./cm)	*P*
Manica rubida						
Control	92 (57–105)		18.0 (15.1–21.4)		85 (60–108)	
M. rubida Dufour gland	92 (78–106)	NS	38.0 (32.0–45.6)	$P < 0.001$	92 (80–105)	NS
M. rubra Dufour gland	87 (70–99)	NS	33.0 (27.0–36.0)	$P < 0.001$	116 (102–140)	$P < 0.01$
Myrmica rubra						
Control	105 (70–119)		11.0 (10.0–12.0)		142 (120–158)	
M. rubida Dufour gland	55 (45–67)	$P < 0.001$	30.8 (26.8–34.4)	$P < 0.001$	110 (97–120)	$P < 0.01$

[a]Each time the ant's orientations (=O), linear speed (=V) and angular speed (=S) were quantified, as detailed in Cammaerts-Tricot et al. (1976), by 20 or 30 individual values. The table gives the median (and the quartiles) of the distributions obtained as well as results of non-parametric χ^2 tests between control and experiments. P = level of probability; NS = non significant difference for $P = 0.05$.

These very volatile substances also occur in *M. rubida* Dufour glands, but the workers of that species do not respond to them.

Myrmica rubra workers seem to react positively to *M. rubida* Dufour glands only during the first 1–2 min following the isolation of the gland. This time is somewhat shorter than that found when presenting *M. rubra* Dufour glands to workers of this species. This can be explained by the relatively small amount of acetaldehyde produced by *M. rubida* Dufour glands.

From Table 2 it appears that *M. rubida* workers exhibit a very large increase of linear speed, and almost no change of angular speed in the presence of their own Dufour gland contents. When stimulated by *M. rubra* Dufour gland contents, workers of *M. rubida* exhibit a similar large increase of linear speed and a small increase of angular speed. The reactions to the two glands are thus similar, but not identical.

When perceiving *M. rubida* Dufour gland contents, workers of *M. rubra* present a very large increase of linear speed, and a small decrease of angular speed (Table 2). We know from earlier studies on *M. rubra* Dufour glands that its own gland contents induce a rather large increase of linear speed and an increase of angular speed (Table 3). Therefore, the locomotion reactions produced in *M. rubra* workers, by *M. rubra* and *M. rubida* Dufour glands, are once again similar but not identical.

In short (Table 3), a Dufour gland of *M. rubida* releases a larger positive orthokinesis (and consequently a smaller positive klinokinesis) than a Dufour gland of *M. rubra*, and this is independent of the different locomotion characteristics of the two species studied. It was also noted during observation of the ants, although no quantitative data are given, that an *M. rubida* Dufour gland remained ethologically active for a shorter time than an *M. rubra* Dufour gland.

TABLE 3. CROSS-ACTIVITY OF *Manica rubida* AND *Myrmica rubra* DUFOUR GLANDS

	Glands from					
	M. rubida		*M. rubra*		Means for each species	
Tested species	V	S	V	S		
M. rubida	38	92	33	116	35.5	105
M. rubra	31	110	20	180	25.5	145
Means for each gland	34.5	101	26.5	148		

[a] The ethological activities recorded are the ant's linear (=V, mm/sec) and angular (=S, ang.deg./cm) speed. The values given here are the medians of distributions of 20 experimental values, obtained in the present study (see Table 2) and in previous ones (e.g., Morgan et al., 1977).

DISCUSSION

Chemical Results. Wadhams (1972) has shown from electroantennographic studies that *Myrmica rubra* workers could detect some very volatile components in their Dufour gland. Cammaerts-Tricot et al. (1976) showed that this very volatile and, therefore, short-acting component, elicited characteristic behavioral movements from workers. The mixture contained a number of alcohols, aldehydes and ketones of one to four carbon atoms, with acetaldehyde and acetone most abundant. The cross-activity studies of behavior in the present work indicated that we should look for such volatile components in *M. rubida*. We have done this using gas chromatography, but for the first time with a capillary column coated with a 10-μm layer of a copolymer of styrene and divinylbenzene, which is the same as the porous polymer (Porapak Q) used in the packed columns in the earlier work (Morgan and Tyler, 1977). A similar mixture of volatile substances was found, with acetone the most abundant (Figure 1).

The less volatile component of the Dufour gland secretion is one of the simplest patterns of Dufour gland substances we have encountered, with two components making up 98% of the total secretion. However, seven other substances, all sesquiterpene hydrocarbons, comprise the further 2%. Another three substances, representing together less than 0.1% of the total, are also sesquiterpenes but are of unknown structure. No linear alkanes or alkenes were detected. It was surprising to find (*E*, *E*)-α- and (*E*)-β- isomers present. These are the most stable isomers, and it was suspected that they might have been formed by isomerization, which occurs readily above 140°C (Anet, 1970). Therefore, a series of injections of single glands was made varying the injection temperature from 130 to 160°C, but there was no decrease in the amounts of these isomers at the lower temperature, and so it is concluded they are true components in the gland. Using a temperature of 140°C for other species containing (*Z*, *E*)-α-farnesene, we have found no trace of *E*, *E* isomers. Such a rich mixture of sesquiterpene hydrocarbons has not been encountered before in ant Dufour glands.

Manica is regarded as a close relative of the genus *Myrmica*, indeed *M. rubida* was once included in *Myrmica* (Weber, 1947). It is interesting, therefore, in assessing these experiments to make comparison with our earlier work on *Myrmica*.

In a chemical sense, the substances present in the Dufour gland are superficially similar. Of some 13 species of *Myrmica* ants so far studied (Attygalle et al., 1983; Jackson et al., 1989), all have some farnesene, homofarnesene, and bishomofarnesene in them; in some, these are the major components, but we almost always find them mixed with some linear hydrocarbons in *Myrmica*, and we do not usually find the (*E*)-β- and (*E*, *E*)-α- isomers and corresponding homologs.

Furthermore the mixture of undiluted farnesenes and homologs, as found in *M. rubida*, is much less stable than when diluted with alkanes (Morgan et al., 1989) as they are in *Myrmica*. The undiluted mixture reacts with atmospheric oxygen more rapidly, giving a complex mixture of oxidized and polymerized products (cf. Murray, 1969; Sal'kova et al., 1975). Any pheromone message contained in the *Manica* substances will be shorter-acting than in other species.

Behavioral Observations. From our ethological observations, we first deduced that very volatile substances were likely to be present in *M. rubida* Dufour glands, and this was confirmed by our chemical analysis. The lack of attractancy of the Dufour gland for *M. rubida* workers is consistent with the absence of "group recruitment" in this species (M.C. Cammaerts and Cammaerts, 1985; R. Cammaerts and Cammaerts, 1985), in contrast to the behavior in *Myrmica rubra*, for example.

Second, we observed, in the present work, that the displacement of *Manica rubida* workers near isolated Dufour glands is very similar to that seen on marked areas in natural and in experimental environments (R. Cammaerts and Cammaerts, 1987). Our earlier experiments have demonstrated that this secretion is used for marking territories around nest entrances (R. Cammaerts and Cammaerts, 1987). In *Myrmica rubra* also, the less volatile part of the Dufour gland secretion is used for marking territories (M.C. Cammaerts et al., 1977).

Third, *Manica rubida* and *Myrmica rubra* both react, but somewhat differently, to the less volatile portion of their own and each other's Dufour glands. Both species contain quantities of (*Z*, *E*)-α-farnesene and (*Z*, *E*)-α-homofarnesene, but each contains other components that are not common to both species. We have shown elsewhere (M.C. Cammaerts and Morgan, 1989) that the odor detected by the ants diffuses slowly from the gland.

Fourth, we observed that *M. rubida* Dufour glands remained ethologically active for a shorter time than those of *M. rubra*. This may be because the mixture of pure farnesenes in *M. rubida* will decompose more rapidly when exposed to the oxygen of the air than will the same substances diluted with linear hydrocarbons in *M. rubra* secretion (Morgan et al., 1989).

It may be that *Manica rubida* is able to form large and vigorous colonies, although recruiting no nestmates, because it is highly polygynous, because workers continually forage, marking the territory all around the nest entrances and so discouraging the intrusion of other ant species, and because collecting ants appear to be responding to some stimulus (need for food, liquid, nest material) by returning to the same nest entrance from which they last emerged (R. Cammaerts and Cammaerts, 1987). We believe this interesting species will repay further behavioral studies.

Acknowledgments—We thank Dr. W. Czechowski, Polish Academy of Science, Warsaw, for collecting the sample of *M. rubida* and Professor M.S. Blum for making them available. B.D.J. thanks the SERC for a research studentship and E.D.M. thanks the Royal Society and the SERC

for grants for the purchase of equipment. We thank Dr. D. Grant and Chrompack UK Ltd., for the loan of a Chrompack PoraPLOT Q chromatography column.

(Received January 23, 1989; accepted May 7, 1989)

Abstract—Quantitative laboratory biosassays measuring short-range attraction of worker honeybees to pheromone-treated pipets or glass pseudo-queens are described. Each replicate involves only 15 workers, allowing a single colony to provide sufficient individuals for a complete study as well as for between-colony comparisons. The more sensitive pseudo-queen bioassay provides a measurable response at levels of queen mandibular extract of 10^{-7} than that of an average individual mated queen. Formation and maintenance of the pseudo-queen's retinue, as well as more detailed behavior, can be evaluated by following the actions of individual workers replayed on video tape. Using this sensitive bioassay, the response of workers to queen mandibular pheromone has been shown to be sensitive to daily variation and colony source of the workers, but independent of worker age.

Key Words—*Apis mellifera* L., honeybee queen mandibular pheromone, retinue behavior, attraction bioassays, Hymenoptera, Apidae, honeybee pheromone, (*E*)-9-keto-2-decenoic acid, (*R*,*E*)-9-hydroxy-2-decenoic acid.

INTRODUCTION

Many activities of worker honeybees, *Apis mellifera* L., are regulated by a complex of semiochemicals, the full chemical identities and behavioral effects of which are, in most instances, unknown (Free, 1987; Winston, 1987; Gary, 1974). Identification of pheromones requires a simple, but discriminating, quantitative bioassay that highlights the behavior being investigated. One such behavior is the formation of a retinue or royal court around the reproductive

0098-0331/90/0300-0841$06.00/0

queen honeybee (Velthius, 1985). Workers form a dynamic circle around her, touching her with their antennae and licking her. Many experiments have indicated that the behavior is initiated and maintained by chemicals from the mandibular glands in the queen's head (Gary, 1961). Although many compounds have been identified from this source, no single component was capable of reproducing retinue behavior.

Several worker retinue bioassays have been described that can be carried out both in the colony (Simpson, 1979) and in the laboratory (Pain, 1966; Pham et al., 1982, Velthuis, 1972). Simpson's (1979) study was of special interest as he initiated chemical fractionation studies and assayed the fractions within the colony. Replication necessitated frequent manipulation of several colonies with differing characteristics. Laboratory bioassays circumvented these problems by utilizing workers from a single colony tested under controlled conditions. However, the low sensitivity of these bioassays demanded large initial quantities of queen extract and made fractionation and reconstitution of stimuli without loss of potential volatile constituents cumbersome.

We describe two quantitive laboratory bioassays that utilize workers from a single colony and are readily replicated. Their utility has been established in the determination of the composition of the mandibular pheromone of the mated queen honeybee (Slessor et al., 1988). We also describe the application of the bioassays in determining the response of worker honeybees of differing ages and origins to retinue pheromone.

METHODS AND MATERIALS

Preparation of Bioassay Cages and Chemical Stimuli. Worker bees were removed at random from the upper recesses of a 2-Langstroth deep-super colony between 10:00 and 10:30 AM, lightly narcotized with carbon dioxide, apportioned in groups of 15 into bioassay cages or arenas, and held at room temperature for 3–5 hr with access to 50% aqueous sugar syrup. Stimuli were presented at known concentrations, 1 Qeq representing the average content of the mandibular glands of one honeybee queen. This pheromone composition was established by analysis of a mandibular gland extract obtained from several mated queens (Slessor et al., 1988), and comprised, on average, 150 μg of (*E*)-9-keto-2-decenoic acid, 55 μg of 67% (*R*,*E*)-(−)-9-hydroxy-2-decenoic acid, 13 μg of methyl *p*-hydroxybenzoate, and 1.5 μg of 4-hydroxy-3-methoxyphenylethanol per queen. Fresh stimuli were prepared daily in advance, coded so that the observer did not know the order or identity of the stimuli, and placed randomly on drying racks. Each group of workers was used only once, killed by freezing, and the containers washed in hot water and air dried. Replicates consisted of fresh treatments of identical stimuli to untested bees on the same or

subsequent bioassay days. Both laboratory bioassays were readily performed through the year.

Micropipet Bioassay. The wooden cages used for micropipet bioassays measured 10 × 10 × 6.5 cm, with the back large side covered with screening and the front with a sliding Plexiglas door. The stimuli consisted of two micropipets, one containing a solvent control and the other an extract, fraction, or synthetic compound placed against the screen at the bottom of the cage. A single stimulus presented within a cage of worker honeybees previously was used for an attraction bioassay (Pham et al., 1982). Stimuli were prepared by drawing a pheromone solution in methanol into the micropipet and allowing the solvent to evaporate while the pipets were maintained at an angle with the aperture directed downward, thereby depositing any residuals at the tip.

A response was recorded when any worker contacted either pipet by reaching through the screen with either its antennae, mouth parts, or tarsi during the 5-min observation period. Responses were summed as a measure of the activity for each assay.

Pseudo-Queen Biosassay. Bioassay arenas were prepared from disposable plastic Petri dishes (15 × 2 cm). One circular hole (1.5 cm diam.) was cut into the top and covered with screening, through which the bees were fed. Another hole (1 cm diam.) was cut in the side for introducing a glass pseudo-queen. Pseudo-queens are prepared from a 7-cm length of a 1-ml Pasteur pipet (2 cm of the top and 5 cm of the narrowed bottom), cut and sealed at both ends. A small indentation suitable for receiving 10 μl of test solution was formed in the larger "head" end. On evaporation of the solvent, the pseudo-queens were stored for 2–3 hr in a refrigerator until 2–3 min before a bioassay.

Upon introduction of the pseudo-queen stimulus, activity within the dish was recorded on video tape for 5 min. At 30-sec intervals the number of workers contacting the stimulus area of the pseudo-queen and those within an "active ellipse," i.e., within 1 worker length (1.5 cm) of it, were recorded. The contact and ellipse counts were summed separately for each replicate.

Persistence. Early observations using the micropipet technique had shown that some worker honeybees that found the lure would not vacate their position and allow others to contact it. Such activity prevented the positive response of other workers and illuminated the persistent behavior of individual workers to remain in contact with the stimulus. With the more accessible pseudo-queen lure, a measure of this persistence was established by review of the video tapes. The time spent by each bee that had entered the ellipse within the first 2 min of the trial was measured to a maximum of 3 min.

Age Study. Frames containing emerging brood were removed from a single colony and placed in an incubator at 33°C and 70% relative humidity. Workers that emerged overnight were marked with an enamel paint dot on the thorax

and returned to the parent colony. This procedure was repeated every second day for 30 days (July 20–August 19, 1987), using a different color paint, and resulted in marked bees comprising 15 age groups between 1 and 29 days old.

Pseudo-queen bioassays were then conducted as previously described, but with workers of known ages. Test bees were chosen so that one member of each age group was in each arena, i.e., 15 workers per arena. Fifteen stimulus replicates and one blank were tested on each of the two test days. In this way, 30 individuals from each age class were tested. Glass pseudo-queen stimulus containing 10^{-3} Qeq of synthetic retinue pheromone were used. Workers that remained within the ellipse for >1 min were scored and their age recorded.

Colony Variation. The responses of workers from 12 colonies of *A. mellifera ligustica*, eight headed by domestic queens (Southern Interior Apiaries, Keremeos, B.C.) and four headed by imported queens (Haines Bee Breeders, Kaitaia, New Zealand) were compared in the pseudo-queen bioassay with 10^{-2} Qeq stimuli of synthetic retinue pheromone. A replicate consisted of one group from each of the 12 colonies. There were two groups of 10 replicates tested on February 2–24 and May 10–June 1, 1988. At the conclusion of the May experiment, the best- and worst-responding colonies were chosen for a 16-replicate experiment to evaluate their response at doses of 10^{-1}, 10^{-3}, 10^{-5}, and 10^{-7} Qeq.

RESULTS AND DISCUSSION

The response of workers to honeybee queen mandibular synthetic pheromone was dose dependent (Figure 1). In the micropipet bioassay, the response to stimuli of 10^{-1} and 10^{-2} Qeq was significantly different from the response to solvent control (Tukey's multiple-range test, $P < 0.05$), a slightly more sensitive response than in the cage bioassay described by Pham et al. (1982). The exclusive position established by persistent workers at the pipet and the relatively small size of the lure in relation to the cage volume, which frequently resulted in the workers not coming near the stimulus, reduced the sensitivity of the bioassay. Nevertheless, the pipet bioassay was used to establish the involvement of several relatively polar molecules that are components of the queen mandibular pheromone that elicits retinue behavior (Slessor et al., 1988). The recognition volume of this pheromone signal must be quite small compared to many other insect pheromones, e.g., lepidopteran sex pheromones, since the full blend is necessary for complete perception and several of the components have very low volatilities. The direct contact of the workers with the pheromonal source observed in both bioassays implies a physical transfer of semiochemical rather than perception of an airborne signal. Queen presence studies, as measured by the behavior of workers kept at noncontact distances, support this concept (Free, 1987; Winston, 1987).

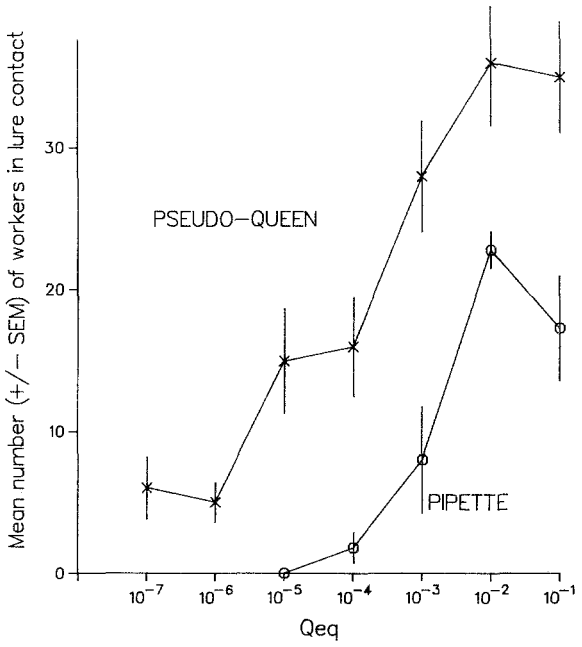

FIG. 1. Responses of worker honeybees to stimuli containing various quantities of synthetic mandibular pheromone in the two types of bioassay.

The pseudo-queen bioassay was considerably more sensitive to worker response than the micropipet technique. Workers oriented head-first to the glass pseudo-queen, touching it with their antennae and/or tongue and tarsi. Positive responses were obtained at 10^{-7} Qeq of synthetic pheromone, demonstrating the sensitivity of worker honeybees to extremely small quantities of queen mandibular pheromone that signals the presence of a queen within a strong and vigorous colony. There was no greater sensitivity in contact data over ellipse data at a given extract concentration.

Bimodal behavior patterns were observed in the persistence of individual workers to both queen mandibular extract and synthetic queen mandibular substances (Figure 2). Typical retinue behavior was exhibited by 25–30% of the bees, including prolonged antennation and licking of the lure, occasional turning away to groom their mouth parts or to antennate with other bees, but no movement from the active ellipse. Longer visits (>2.5 min) were clearly a response to chemical stimuli while short visits (<30 sec) appeared to be random or exploratory. Natural and synthetic queen mandibular retinue pheromones were different from solvent (Kolmogrov-Smirnov, two-tailed test, Kleinbaum and Kupper, 1978; Zar, 1984, $P < 0.001$) but not significantly different from each other ($P > 0.10$). The percentage of worker bees responding and their

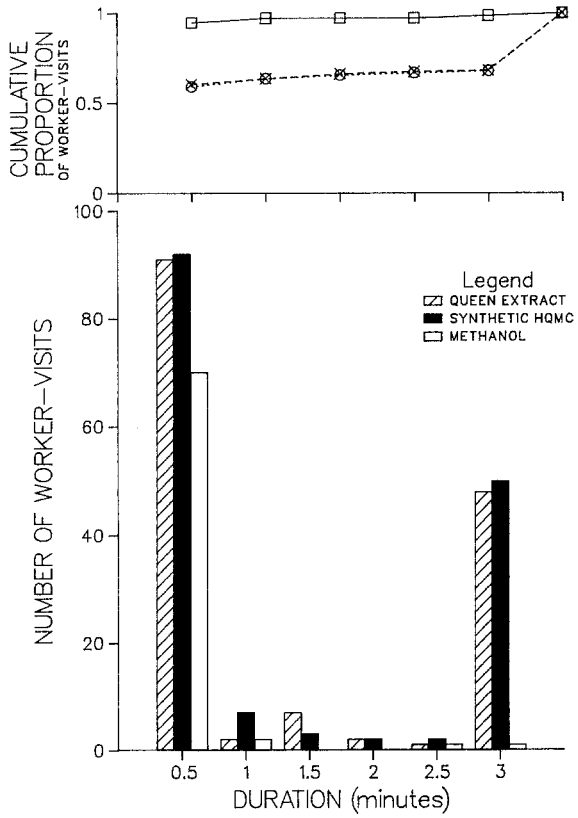

FIG. 2. Persistence of worker honeybees in the pseudo-queen bioassay to natural and synthetic mandibular pheromone, as well as methanol solvent. Persistence is defined as the time spent in any visit by a worker bee entering the active ellipse during the first 2 min of a bioassay. Run at 10^{-3} Qeq ($N = 9$). Symbols for cumulative response curves are: X = queen, ○ = synthetic mandibular extract, and □ = methanol solvent.

persistence were greater than those of the messenger bees described by Seeley (1979); however, our experimental bees were queen- and task-deprived and had been treated with CO_2, any one of which might have caused an enhanced response to the queen's semiochemicals.

No age dependence was observed in response of worker bees to pseudo-queens treated with retinue pheromone (Figure 3). Of the 450 bees tested, 42 remained within the ellipse >1 min. The mean age of the responders was 14.0 days, within the range found for queen attendants in observation hives [5.5 days (Seeley, 1979), 10.7 days (Allen, 1960), and 17.1 days (Winston and Punnett, 1982)]. In the attraction bioassay (Pham et al., 1982), a greater response was

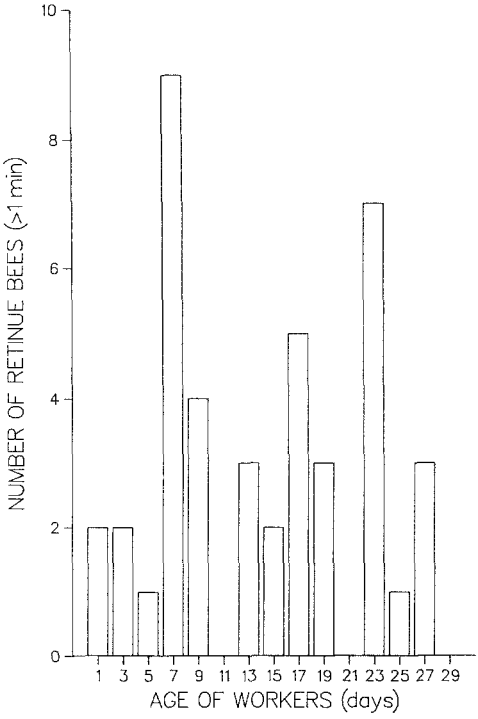

FIG. 3. Ages of worker bees remaining >1 min in the active ellipse during a 5-min pseudo-queen bioassay. Run at 10^{-3} Qeq of synthetic mandibular pheromone, (N = 30).

observed with very young 3-day-old workers, suggesting a different behavioral response. The workers observed in the present study were raised in late summer, and, consequently, their development and behavior may not fully match workers raised earlier in the year where life-spans would be greatly reduced. Nevertheless, the lack of age dependence facilitates the use of the pseudo-queen bioassay, since marked age cohorts are not necessary to produce repeatable results.

Significant variation in contact response to 10^{-2} Qeq stimuli of retinue pheromone existed between colonies measured in February and May (Table 1). Workers from colonies headed by queens from New Zealand were less responsive than bees derived from British Columbia queens at both dates. Daily variation in response to stimuli was large and did not appear to be directly correlated with weather conditions, including pressure changes. Workers from the highest and lowest responding colonies exhibited significant differences in response to stimulus concentrations 10^{-5} Qeq and above (t test, $P < 0.05$) (Figure 4).

TABLE 1. MEAN NUMBER OF CONTACTS IN PSEUDO-QUEEN BIOASSAY RELATIVE TO QUEEN ORIGIN AND TIME OF YEAR

Queen origin	*N*	February[a]	May[a]	Differences between dates
British Columbia	8	13.5 ± 1.4a	18.2 ± 1.4a	<0.025
New Zealand	4	2.7 ± 0.5b	8.4 ± 1.7b	<0.001
Mean	12	9.9 ± 1.1	15.2 ± 2.0	

[a]Means within a column followed by the same letter are not significantly different ($P < 0.05$).

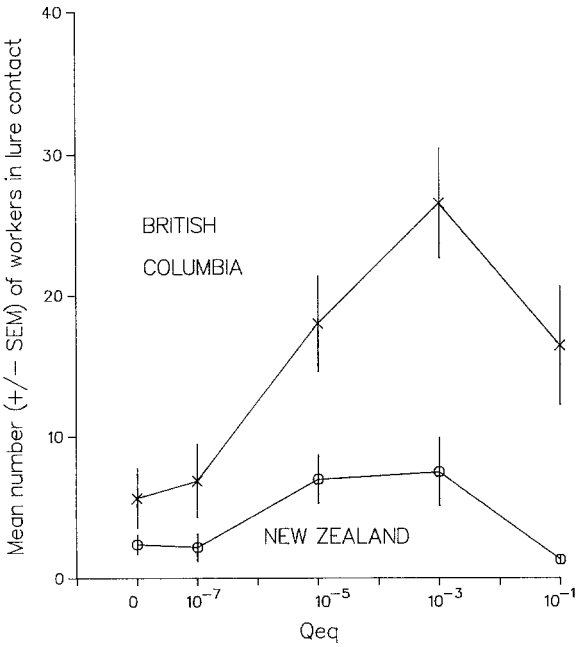

FIG. 4. Contact responses to various stimulus concentrations by worker honeybees from two colonies selected on the basis of the strongest (headed by a queen from British Columbia) and weakest (headed by a queen from New Zealand) response in the pseudo-queen bioassay during June 1988. All concentrations were run with both sets of bees each day for eight days ($N = 16$).

Subsequent analysis of these two queens for their mandibular components, both within the individual glands and over the remainder of the body, showed no significant difference or correlation with the contact response observed for that colony. A weak, but significant correlation of response to the size of the colony population was found ($R^2 = 0.68$, $P < 0.05$), but no significant correlation with the size of the brood area was observed ($P > 0.05$). The correlation of response with colony population may result from a decreased ability of workers in large colonies to distribute queen pheromone. Between-colony variation has implications for the breeding and selection of queens if queen pheromone is correlated with productivity or other queen traits. The lower response to stimuli at 10^{-1} compared to 10^{-3} Qeq indicates that response is diminished when high amounts of synthetic queen mandibular pheromone are presented, at least in the bioassay situation.

CONCLUSIONS

Our facile laboratory bioassays quantitatively evaluate the presence and retinue effect of queen mandibular pheromone on worker honeybees. The simpler pipet bioassay has the advantages of minimal equipment investment and greater probability of detection of more volatile worker attractants. The more complex pseudo-queen bioassay provides a substrate more accessible to worker honey-bees for the presentation of queen pheromones. These bioassays have already proven to be of value in the isolation and identification of the components of the mandibular retinue pheromone of queen honeybees (Slessor et al., 1988). The quantitative aspects of the pseudo-queen bioassay add to its utility. In this study, it was employed to demonstrate the persistent behavior of some workers in the presence of queen retinue pheromone, to demonstrate that there is little or no age variation in the bioassay response of worker honeybees to the mandibular retinue pheromone, and to demonstrate that variations in response occur within a colony on a day-to-day and seasonal basis, and between colonies on the same day.

(Received January 23, 1989; accepted May 7, 1989)

Abstract—The ontogeny of the five queen mandibular gland semiochemicals that initiate and maintain the retinue behavior of worker honeybees was investigated by quantitative splitless capillary gas chromatography. No detectable pheromone is present at the time of eclosion, but decenoic acid levels build up rapidly during the first week of the queen's life. Two aromatic components attain detectable levels later, with the more plentiful methyl *p*-hydroxybenzoate preceding the 4-hydroxy-3-methoxyphenylethanol. Pheromone levels are maximal in mature, mated, laying queens. The ratio of (*R*,*E*)-(−)-9-hydroxy-2-decenoic acid to the (*S*,*E*)-(+) enantiomer increases with the age of the queen. Pheromone levels in queen mandibular glands are largely unaffected by queen banking, restraint with workers in mailing cages, and limited storage on dry ice. All major body parts of typical queens, especially the head and legs, have sufficient mandibular exudate to be highly attractive to worker bees.

Key Words—Hymenoptera, Apidae, *Apis mellifera* L., honeybee queen mandibular semiochemicals, retinue pheromone, splitless capillary gas chromatography, (*E*)-9-keto-2-decenoic acid, methyl *p*-hydroxybenzoate, 4-hydroxy-3-methoxyphenylethanol. (*R*,*E*)-(−)- and (*S*,*E*)-(+)-9-hydroxy-2-decenoic acid.

INTRODUCTION

The importance of semiochemicals for queen recognition and caste maintenance within honeybee colonies, *Apis mellifera* L., has been well documented (Free, 1987; Winston, 1987). The five substances that are secreted from the mandib-

0098-0331/90/0300-0851$06.00/0

ular gland of the queen that initiate and maintain retinue behavior are: (*E*)-9-keto-2-decenoic acid (9ODA), (*R*,*E*)-(−)- and (*S*,*E*)-(+)-9-hydroxy-2-decenoic acid (9HDA), methyl *p*-hydroxybenzoate (HOB), and 4-hydroxy-3-methoxyphenylethanol (HVA) (Slessor et al., 1988). The first recognized queen pheromone, 9ODA (Callow and Johnston, 1960; Barbier and Lederer, 1960), is also attractive to mating drones (Gary, 1962). Only when the complete pheromone complement is present are worker bees attracted and full retinue behavior exhibited. Inside the colony, the queen mandibular pheromone suppresses the formation of emergency queen cells, and, outside the colony, it provides a focal point for swarm clustering (Winston et al., 1989). Thus, the chemical composition of the mandibular glands throughout the life of queen honeybees is crucial to the normal response of workers within that colony to the presence and absence of their queen.

Analysis of 9ODA, as the methyl ester, in queen mandibular glands has demonstrated a fluctuation with time of day and year (Pain and Roger, 1978; Pain et al., 1974). Quantitative analysis of polar organic compounds, such as the components of the queen retinue pheromone, is readily accomplished by their conversion into trimethylsilylated derivatives by bistrimethylsilyltrifluoroacetamide (BSTFA) (Gehrke and Leimer, 1971). Gas chromatography of these derivatives on packed columns provided evidence for the compositional changes that take place in the mandibular glands of false queens (Crewe and Velthuis, 1980). Splitless capillary gas chromatography (SCGC) provided increased resolution and sensitivity for investigations of queen mandibular extracts (Crewe, 1982). SCGC coupled with mass spectroscopy (SCGC-MS) provides a means of establishing the homogeneity of a given peak and consequently its purity. Determination of the chirality of alcohols present in single insects has shown that mandibular 9HDA varies in enantiomeric composition between queens (Slessor et al., 1985).

We describe the chemical composition of the five components of the honeybee queen mandibular pheromone, as measured by SCGC of mandibular gland extracts, during the life of queens of different ages, colony exposure, and backgrounds.

METHODS AND MATERIALS

Sources of Queens. Queens less than 6 months of age were raised in our apiary in May 1987 from California stock (Vaca Valley Apiaries, Vacaville, California, with the exception of unmated, 12-day-old queens (obtained from Southern Interior Apiaries, Keremeos, B.C. in May, 1988). Older queens were originally 1985 California stock that had headed Simon Fraser University colonies for two years and became available due to requeening.

Analyses of Mandibular Gland Components. To a portion of a methanol extract (2–20 μl), prepared from both glands of individual queen bees as described by Slessor et al. (1988), an internal standard containing 0.66 μg of decanoic acid in methanol (2 μl) was added and the sample subjected to reduced pressure until the solvent was just removed. Standards of the components of interest showed no diminution when subjected to this treatment. Trimethylsilylation was accomplished through addition of BSTFA (5 μl) (Sigma Chemical Co., St. Louis, Missouri). The solution was agitated and left at room temperature for 40 min. Redistilled, reagent-grade hexane (100 μl) was added, the solution mixed, and a portion (2–3 μl) injected in splitless mode onto a 30-m DB-1 (J & W Scientific, Inc., Rancho Cordova, California) column on a Hewlett-Packard 5880 gas chromatograph (90°C for 5 min 10°C/min to 200°C, isothermal for 5 min). Integration responses were measured on a flame ionization detector calibrated with known standards for each mandibular component. Determination of the chirality of the 9HDA was done on a portion (5 μl) of the methanol mandibular gland extract (Slessor et al., 1985).

The final unknown component of queen mandibular pheromone was isolated by acetylation and microcolumn silica gel chromatography. The structure was assigned by SCGC-MS and high-resolution ^{1}H nuclear magnetic resonance (NMR) of the resulting diacetate.

Labile and Volatile Constituents. Several studies have suggested that volatile or labile components are involved in retinue response (Butler, 1961; Pain, 1961). To test this hypothesis, a freshly prepared queen mandibular extract was fractionated by high-performance liquid chromatography on a reverse-phase column under conditions separating the primary components into four fractions, including the late-eluting nonpolar constituents. The individual fractions were tested in combination with the five-component synthetic pheromone and together as a reconstituted extract in comparison to unfractionated extract in the pseudo-queen bioassay (Kaminski et al., 1990)

Synthetic Pheromones. The decenoic acids were synthesized according to the methods of Lombardo and Taylor (1978) for 9ODA and Kandil and Slessor (1983) for (*S*)-(+), (*R*)-(−), and (±)-9HDA. HOB and HVA, the latter recrystallized from ethyl acetate: 30–60°C petroleum ether (mp 60–61°C), were obtained from Sigma Chemical Co., St. Louis, Missouri. A queen equivalent (1 Qeq) is arbitrarily defined as 150 μg of 9ODA, 55 μg of 71% (*R*)-(−)-9HDA, 13 μg of HOB, and 1.5 μg of HVA.

Mandibular Gland Compositional Response to Banking and Extreme Cold. To examine the effect of type and duration of queen banking on quantities of queen mandibular pheromone, 2-year-old mated laying queens were restrained in individual queen cages and placed in the top of a two super colony (banking). A portion of the queens was removed after 10 days; some queens were placed

in mailing cages with five workers and sugar candy and kept at room temperature for five days, others were frozen with Dry Ice and kept at −78°C on Dry Ice for seven days, and still others were given both treatments (mailing cages, then Dry Ice). The remaining queens were removed from the colony after 30 days and half were kept on Dry Ice for a further seven days. At the end of each of these treatments, mandibular glands were removed and analyzed for their pheromone composition.

Mandibular Components Present on Queen Body Parts. The amounts of retinue pheromone components present on the body segments of queens that had been kept with five workers in mailing cages for several days were evaluated through analysis of the amounts of 9ODA present in methanol washes of these parts. Seven pooled samples comprising 37 queens were analyzed.

RESULTS AND DISCUSSION

Structural Assignment of HVA. The structural assignment of HVA, a compound new to honeybees, is described for the first time. The isolated diacetate (2–3 μg) provided a SCGC-MS spectrum with a dominant base peak at m/z = 150; as well as 135, 20%; 137, 18%; 210, 8%; 192, 4%, and 252, 2%, reminiscent of the material found by Crewe and Velthuis (1980) in *A. mellifera* queens, and thought to be 4-hydroxy-2-methoxyphenylethanol. When this material was synthesized,[3] it was neither active in bioassays nor did it cochromatograph with the insect-derived material (Slessor et al., unpublished data). The diacetate isolated from five mated, laying queens yielded a proton NMR in CD_2Cl_2 at 400 MHz for 114 hr (97,456 scans), δ = 2.01 (3H, singlet, acetoxy methyl); δ = 2.26 (3H, singlet, aryl acetoxy methyl); δ = 2.92 (2H, triplet, J = 7 Hz, benzylic methylene); δ = 3.08 (3H, singlet, aryl OCH_3); δ = 4.26 (2H, triplet, J = 7 Hz, CH_2O); δ = 6.80 (1H, quartet, J = 2 Hz, 8 Hz, H_6aryl); δ = 6.85 (1H, doublet, J = 2 Hz, H_2aryl); δ = 6.94 (1H, doublet, J = 8 Hz, H_5aryl). A 10,000-scan decoupling of the δ = 2.92 signal eliminated the ~0.5-Hz coupling to the δ = 6.80 and δ = 6.85 aryl hydrogen, confirming these hydrogens as ortho to the ethanol side chain. The chemical shifts of the aryl Hs indicated the substitution as 3-methoxy and 4-hydroxy. Recrystallized HVA was active in the bioassays when incorporated at the appropriate concentration. When silylated, it cochromatographed with insect-derived material on the splitless capillary system; when acetylated, it gave identical retention characteristics and mass spectral fragmentation as the isolated substance.

[3] The reported structural assignments in the synthesis of 4-hydroxy-2-methoxyphenylethanol (Howard et al., 1981) are reversed. See Kaufman and Russey (1965) for the correct structural precursors.

Tests for Volatile or Labile Queen Mandibular Components. Reconstitution of the four fractions of fresh mandibular extract provided an identical worker response to the original extract and synthetic retinue pheromone in the pseudo-queen bioassay at 10^{-3} Qeq (Table 1). Thus, no labile or volatile retinue semiochemical component had been lost in storage or in the fractionation procedure.

Individual Queen Mandibular Glands. Extracts from the mandibular glands of individual queens that had eclosed within the previous 24 hr showed little, if any, semiochemical. Increased levels of 9ODA and 9HDA, and very little HOB, were found in virgin queens six and 12 days after eclosion (Table 2). The presence of significant levels of 9HDA in queens capable of mating and the demonstration of the presence of other active substances involved in the mating process (Gary, 1961) indicate that the 9HDA enantiomers should be further investigated in the attraction of drones and the mating of honey bee queens. Orientation of swarms to a virgin queen is often less effective than to a mated queen. Workers occasionally fail to locate virgins, often forming their main cluster close to but not on a virgin queen. They take longer to find virgin than mated queens and are so frequently restless that swarm clusters may break. The absence of the aromatic mandibular components essential for the full retinue response may underline the observed differences between attraction of workers to virgin and laying queens during swarming (Winston et al., 1989).

Mandibular gland extract from mature laying queens contained significantly enhanced levels of the aromatic constituents (HOB and HVA), compared

[a] Means within columns followed by the same letter are not significantly different at $P < 0.05$ in Tukey's studentized range test for the components and an arcsine transformation Waller-Duncan test, K ratio = 100, for the chirality of 9HDA.

to that in virgin queens. This trend is in keeping with the necessity of fully functioning queens to initiate and maintain retinue behavior. The low levels or absence of aromatic compounds in virgin and newly mated queens, in contrast to laying queens, may explain in part why younger queens are accepted relatively easily by a queenless colony.

Variations in Chirality of 9HDA. The percentage of (*R*)-(−)-9HDA increased significantly when queens were mated and increased further when they had been laying for five or more weeks. Both enantiomers of 9HDA are required for optimal formation and maintenance of the retinue response (Slessor et al., 1988); the (*R*)-(−) enantiomer is most effective in the maintenance of the swarm cluster (Winston et al., 1982). Further implications of the importance of the chirality of 9HDA must await a better understanding of the biosynthetic and metabolic interconversions of the two 9HDA enantiomers and 9ODA.

Although considerable variation in the amounts of pheromone components from individual mature laying queens is observed, a pattern of two- to threefold excess 9ODA to 9HDA, with 1/10 as much HOB and 1/100 as much HVA is common (Figure 1).

For 2-year-old queens, there were no significant differences ($P < 0.05$) in

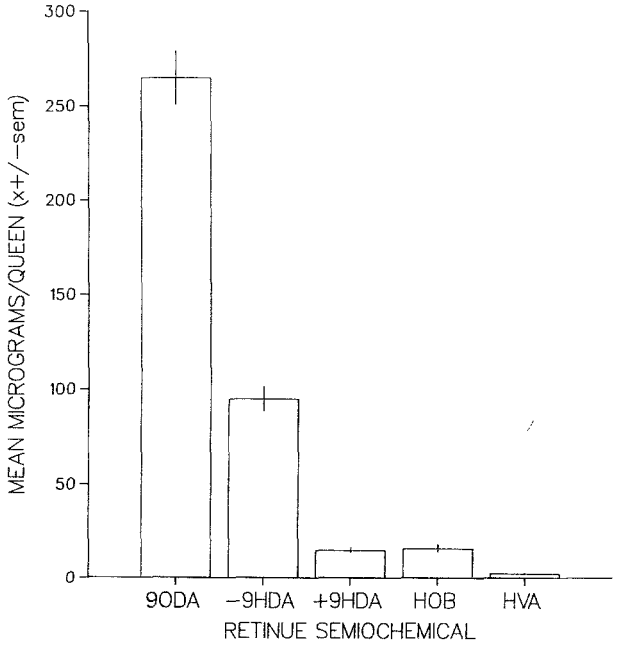

FIG. 1. Average composition of retinue pheromone components in mature, mated laying queens ($N = 55$).

the amounts of the five mandibular pheromone components between mated, laying queens that had been banked ($N = 39$) and control ($N = 16$) queens that had not received banking treatments. Moreover, control queens and those caged with workers and sugar candy in typical queen mailing cages for five days to simulate shipping ($N = 13$) contained similar quantities of the pheromone components. Therefore, all data on 2-year-old queens were pooled (Table 2). We conclude that common treatments of queens in commercial shipping procedures would probably not diminish their capacity to control pheromone-mediated behavior in worker bees. However, the rate of pheromone production could be temporarily altered by banking or similar treatments, and such changes would not be observed by quantitative analysis of stored pheromone in the mandibular glands. Storage of queens ($N = 19$) on Dry Ice (ca. $-78°C$) for seven days resulted in no discernible changes in pheromone amounts or composition.

Determination of queen mandibular pheromone components, other than 9ODA, on queen body segments were often lower than detection limits but, when observed, showed ratios corresponding to their mandibular gland origin. The levels of retinue pheromone found on the head and legs of queens caged with workers for five days were those found to be most attractive to workers in the laboratory pseudo-queen bioassay. Much less ODA was found on the thorax and abdomen of queens caged for five days with workers (Figure 2). The biologically attractive levels of retinue pheromone present on the legs of queens (ca. 10^{-3} Qeq) is of considerable interest in light of the attractiveness of queen "foot-print substance" (Juska, 1978).

CONCLUSIONS

Newly eclosed virgin queens have low or negligible levels of all five mandibular components, but by 6 days of age they contain levels of the decenoic acids that are about half those found in laying queens. HOB appears in virgin queens within 1 week after eclosion, with HVA levels appearing only after queens have mated. The enantiomeric composition of 9HDA strongly favored the *R* enantiomer, especially in mated queens. The amounts of the mandibular pheromone components were unaffected by confinement, either in banks or mailing cages. Storage of queens on Dry Ice caused no change in amounts of pheromone components, offering an alternative method of shipping queen mandibular glands for analysis.

In addition to recognition of queen presence, this blend (or selected combinations of components) is involved in worker orientation during swarming and inhibition of queen rearing (Winston et al., 1989) and may be involved in a myriad of other queen-controlled activities that maintain social cohesiveness in the colony. All of these functions must be reexamined in light of this chemical knowledge. With the identification of queen-produced semiochemicals, a

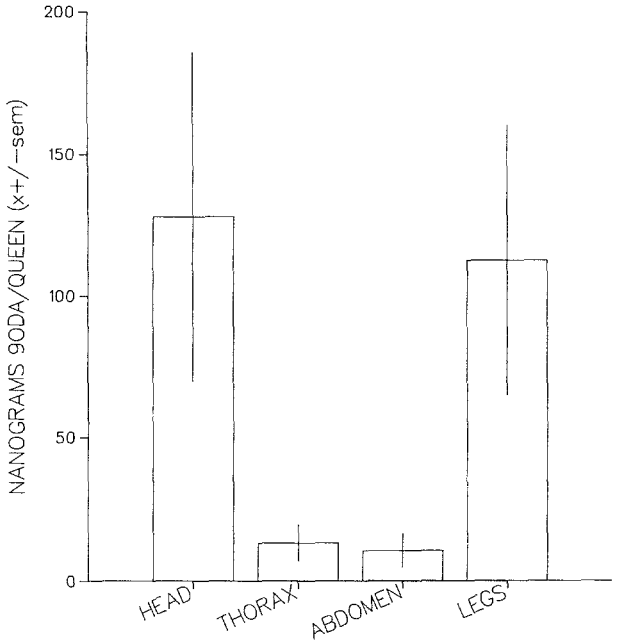

FIG. 2. Mean amounts of ODA found on the body parts of mated queens confined in a mailing cage with five workers for several days (N = 37).

fuller understanding of honeybee society is possible, with considerable potential economic benefits to be derived from an improved ability to manage and control this most complex of social insects.

(Received January 27, 1989; accepted May 8, 1989)

Abstract—Capillary gas chromatography with columns of different polarity and two-dimensional fractionation of effluents were used with novel subtractive-combination bioassays to rigorously isolate host- and insect-produced pheromone synergists of the bark beetle *Pityogenes chalcographus* (Coleoptera: Scolytidae). Methyl (*E,Z*)-2,4-decadienoate (*E,Z*-MD) and the previously identified chalcogran were found to be synergistically attractive to both sexes. *E,Z*-MD was produced sex-specifically in males, and only when they had fed on host-plant tissue. A Norway spruce monoterpene fraction (including α-pinene, β-pinene, and camphene) increased the attractive response to the pheromone components. Dose-response curves for *E,Z*-MD and chalcogran in the laboratory bioassay indicated the two components are highly synergistic. The isolation methods are important for further progress in identifying certain semiochemical synergists found in trace amounts in complex chemical mixtures, such as when insects must feed in host plants in order to produce pheromone.

Key Words—Pheromone, bark beetle, Coleoptera, Scolytidae, *Pityogenes chalcographus*, methyl (*E,Z*)-2,4-decadienoate, chalcogran, *Picea abies*, synergist, subtractive-combination bioassay, two-dimensional fractionation.

INTRODUCTION

In Europe, *Pityogenes chalcographus* (Kupferstecher) is a serious pest of Norway spruce, *Picea abies* (L.) Karst., and is especially damaging to young trees. These tiny bark beetles (2 mm long) aggregate on certain host trees in response to a male-produced pheromone (Francke et al., 1977). Francke et al. (1977) isolated a unique spiroketal, chalcogran (2-ethyl-1,6-dioxaspiro[4.4]nonane), from *P. chalcographus*, which, when released in the forest at 15 mg/hr, attracted conspecifics. They used a differential diagnosis method (Vité and Renwick, 1970) whereby the gas chromatographic elution patterns and mass spectra of chemicals are compared between the sexes for unique differences. About 100,000 beetles of both sexes were treated with juvenile hormone analog (ethyl-3,7,11-trimethyl-2-dodecenoate), but only the male was induced to produce chalcogran. However, since the natural release rates of chalcogran were not known and combinatorial bioassays of fractions in order to detect synergists were not performed, Francke et al. (1977) were not certain whether "a second component may be necessary for maximum response." Chalcogran also was not tested alone, but only with spruce bark (which is unattractive alone), so it was not known whether host volatiles play a role in the orientation response. Thus, we wanted to determine whether host-plant and/or other pheromone components participate with chalcogran in eliciting the attraction response of the beetle.

The problem with isolation of semiochemicals is that solvent extracts of insects or their volatile effluents may contain hundreds of compounds along with the few bioactive components of interest (Millar et al., 1985; Burger et al., 1985; Jackson et al., 1984; Birgersson et al., 1984; Byers et al., 1985) (Figure 1 below). In addition, many insects release trace amounts of pheromones and other semiochemicals only when feeding on host plants, which makes these isolations more difficult because of the complexity of the odors. Thus, in many isolation studies workers have chromatographically fractionated extracts of complex chemical mixtures into successively smaller portions until an active fraction in bioassay contains just a few compounds (Doss and Shanks, 1984; Jackson et al., 1984; Silk et al., 1985; Heath et al., 1986; Burger et al., 1985; Chuman et al., 1985; B.H. Smith et al., 1985; Löfstedt and Van Der Pers, 1985; Teal et al., 1985). These chemicals are usually identified by spectrometric methods, and then the corresponding synthetic compounds are bioassayed to confirm their behavioral role. However, these methods are inadequate for isolating synergistic components, where several in different fractions may be required together for biological activity, the usual case for the multicomponent insect pheromones (Silverstein and Young, 1976; Silverstein 1981).

With this synergistic problem in mind, the additive-combination bioassay of fractions was developed in the 1960s for the isolation of pheromone syner-

gists. Unfortunately, relatively few studies have used this methodology (Silverstein et al., 1966, 1967, 1968; Pearce et al., 1975; Millar et al., 1985) because it is laborious to test all combinations of many fractions for any number of possible synergists. L.E. Browne, while at the University of California, Berkeley, proposed a subtractive method for isolation of synergists (personal communication c. 1976). We have developed this novel idea into a subtractive-combination bioassay of gas chromatographic (GC) fractions, which is as rigorous as the additive method but requires far fewer tests. Our objective was to use this methodology to isolate from a complex, but natural, mixture of plant and insect volatiles all the pheromone synergists that are attractive to the six-spined spruce bark beetle *Pityogenes chalcographus*. If one or more additional pheromone components were discovered, we wanted to elucidate their synergistic properties with chalcogran.

METHODS AND MATERIALS

P. chalcographus beetles were reared in a laboratory culture originating from Lardal, Norway, on freshly cut Norway spruce logs at 27°C. At emergence, adults were collected and maintained at 4°C for several days until used in experiments (Anderbrant et al., 1990).

To determine whether host and/or other pheromone components may participate with chalcogran in eliciting the attraction response, we collected odors from air passed over appropriate host logs or beetle-infested host logs inside glass containers (Byers et al., 1985). Odor collections from logs infested with 40 males were made on 11 occasions as well as twice from uninfested host logs (from December 1982 to May 1985) to obtain enough material for bioassays and identification. Volatiles were collected from headspace air by passage through Porapak Q traps (300 mg, 80–100 mesh) at rates of 100–250 ml/min for two to five days, beginning one day after releasing males onto the logs. The absorbent was subsequently extracted with 2 ml diethyl ether to remove the trapped volatiles.

Each extract from a collection period was concentrated by allowing the diethyl ether to evaporate at room temperature from a tapered glass vial (W. Francke, University of Hamburg, personal communication) before further analysis or bioassay. The attractiveness of extracts and of various ratios of pheromone components were determined in a laboratory bioassay that tested the proportion of walking females in an olfactometer for their upwind responses to odor sources (Byers et al., 1985; Lanne et al., 1987). Beetles that did not respond the first time were given a second chance to reach the source. The light intensity in the bioassay arena was 180 lumens/m^2.

The subtractive-combination method of bioassay compares activity of the

whole blend of recombined fractions to the activities of all such blends, each with a different fraction missing or subtracted. If synergists occur, then one or more blends with a fraction removed will be found to have significantly less bioassay activity than does the whole blend. Thus, each of the removed fractions from these less active blends must contain at least one synergist. Further fractionation and subtractive-combination bioassays are then performed only with these "active" fractions (the fractions that were removed causing the loss in activity).

The concentrated extracts were analyzed on a Hewlett-Packard gas chromatograph (GC) model 5830 using a polar column (No. 1, Table 1) in order to formulate a sequence plan for fractionation by preparative GC. Fractionation was performed on a Carlo Erba model 4160 GC outfitted with a revolving microfraction collector (Wassgren and Bergström, 1984). The sequence GC fractionation of the whole extract is shown in Figure 1. A fused silica capillary

TABLE 1. GAS CHROMATOGRAPHIC COLUMNS[a] USED IN ANALYTICAL AND PREPARATIVE GC AND IN COUPLED GAS CHROMATOGRAPHY–MASS SPECTROMETRY

Analytical GC: Instrument: Hewlett-Packard, model 5830.
Polar GC column 1: Fused silica; length = 46 m, ID = 0.35 mm; OV-351, df = 0.59 μm.
Temperature program: 50°C for 5 min, 5°C/min to 200°C, then isothermal for 20 min.
Mobile phase: N_2 at 20 cm/sec.

Preparative GC: Instrument: Carlo Erba, model 4160.
Polar GC column 2: Fused silica; length = 24 m, ID = 0.35 mm; OV-351, df = 0.5 μm.
Temperature program: 50°C for 2 min, 5°C/min to 220°C, then isothermal for 20 min.
Mobile phase: N_2 at 30 cm/sec.
Nonpolar GC column 3: Fused silica; length = 26 m, ID = 0.32 mm; SE-33 cross-linked, df = 1.0 μm.
Temperature program: 80°C for 2 min, 5°C/min to 220°C, then isothermal for 20 min.
Mobile phase: N_2 at 30 cm/sec.

Analytical GC-MS: Instrument: Finnigan, model 4021.
Polar GC column 4: Fused silica; length = 23 m, ID = 0.20 mm; OV-351, df = 0.5 μm.
Temperature program: 50°C for 4 min, 8°C/min to 200°C, then isothermal for 10 min.
Mobile phase: He at 20 cm/sec.
Nonpolar GC column 5: Fused silica; length = 12.5 m, ID = 0.20 mm; SE-54 cross-linked.
Temperature program: 80°C for 3 min, 8°C/min to 220°C, then isothermal for 10 min.
Mobile phase: He at 20 cm/sec.

Quantitative GC-MS: Instrument: Finnigan, model 4021.
Polar GC column 6: Fused silica; length = 25 m, ID = 0.15 mm; Superox FA, df = 0.3 μm.
Temperature program: 50°C for 4 min, 8°C/min to 200°C, then isothermal for 10 min.
Mobile phase: He at 20 cm/sec.

[a]GC column 5, Hewlett-Packard, other GC columns prepared at Department of Chemical Ecology, Göteborg University.

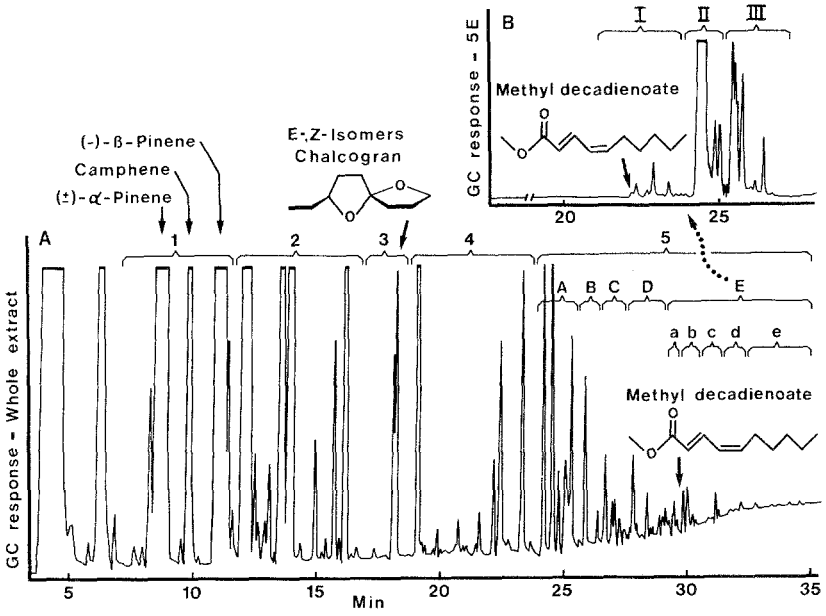

FIG. 1. Gas chromatograms (FID) of volatiles from a 40-male-infested Norway spruce log (25 × 8 cm diam.). Numbers and letters above peaks indicate the effluent collection periods for the respective fractions. Methyl (*E*,*Z*)-2,4-decadienoate cannot be discriminated visually in chromatogram A on a polar GC phase (column 1, Table 1) but was located by EICP-GC-MS and can be seen in chromatogram B as a small side peak (nonpolar GC phase, column 3).

column (No. 2, Table 1) coated with a polar stationary phase was used to obtain fractions 1–5, 5A–5E, and $5E_a$–$5E_e$ (Figure 1A). A second nonpolar GC column (No. 3, Table 1) was used to chromatograph fraction 5E, which contained the synergistic activity with chalcogran (Figure 1B). The identities of the indicated semiochemicals (Figure 1) were confirmed by matching their retention time and mass spectra with authentic standards using GC-mass spectrometry (GC-MS, columns 4–5, Table 1). Further details concerning the GC fractionation (Figure 1) and behavioral bioassays (Tables 2 and 3) used during the isolation of the synergists will be given with the results.

RESULTS AND DISCUSSION

The attractive activity of an extract of odor collection from a log infested with 40 males was compared to a similar extract of an uninfested log and to synthetic chalcogran in the bioassay. Volatiles from the infested and uninfested

logs were released in the olfactometer at the natural collection rates of 40 males/log/min and 1 log/min, respectively. The synthetic chalcogran (from W. Francke, University of Hamburg, West Germany), consisting of a racemic mixture of 46% (*E*)-(2*S*,5*R*- and 2*R*,5*S*-) and 54% (*Z*)-chalcogran (2*S*,5*S*- and 2*R*,5*R*-) stereoisomers, was released at 2 ng/min. The uninfested log extract or synthetic chalcogran alone were not appreciably attractive (both $< 10\%$ female response, $N = 30$–60 each) compared to the extract of volatiles from the male-infested log (73.3% response, $N = 30$, significantly different $P < 0.01$, χ^2). Natural chalcogran amounts were quantified in the extract and estimated to be released from the infested log in amounts up to 10 ng/min in the bioassay or by feeding males at up to 360 ng/beetle/day. A 0.1 rate of release (1 ng/min) from the infested logs of natural chalcogran (two stereoisomers, of which 0.46 ng was the active 2*S*,5*R*-isomer; Byers et al., 1989) still elicited a high female response (56.7%, $N = 30$) compared to the low response ($< 10\%$) to 2 ng synthetic chalcogran/min (four stereoisomers, of which 0.46 ng was the active 2*S*,5*R*-isomer. These results indicated that one or more synergists, in addition to chalcogran, elicit the attraction of the beetle. It was also possible that the 2*R*,5*S*- and 2*R*,5*R*-isomers of chalcogran were blocking response since the beetle does not produce these isomers (Schurig and Weber, 1984), and it has been shown that unnatural enantiomers can inhibit response in some species (Borden et al., 1976). However, in subsequent experiments (Byers et al., 1989), we have not found evidence of either synergistic or inhibitory interactions among the stereoisomers of chalcogran.

Using the subtractive-combination method of fractionation and bioassay (Figure 1A), we confirmed that natural chalcogran is an essential pheromone component of *P. chalcographus*. The combination of all fractions (1–5) released at 8 male/0.2 log/min attracted 65% ($N = 40$ females) but when fraction 3, containing chalcogran, was subtracted from the blend released at the same rate, the response dropped to 0% (Table 2). However, fraction 3 alone was not appreciably attractive (13.3%, $N = 30$). This is in agreement with the relatively low response to synthetic chalcogran reported above. Furthermore, the 65% response to the whole blend was reduced to 12.5% (Table 2) when fraction 5 was subtracted, indicating that this fraction contained one or more additional synergists. Only one other major fraction (No. 1) contributed to the attraction of the whole blend, as indicated by a slight decrease in response when subtracted (37.5% compared to 65% response, Table 2). This fraction contained the host-tree monoterpenes, α-pinene, camphene, and β-pinene (Figure 1A). These monoterpenes were shown later to play a role in host recognition by the beetle (Byers et al., 1988).

Thus, the subtractive bioassay required $1 + 5 = 6$ tests to isolate the synergistic activity in the major fractions (1–5). This is compared to the additive-combination method which would have required $1 + C_1^5 + C_2^5 + C_3^5 =$

TABLE 2. ATTRACTION OF FEMALE *Pityogenes chalcographus* IN THE LABORATORY BIOASSAY TO MIXTURES OF GAS CHROMATOGRAPHIC FRACTIONS (POLAR GC COLUMN 2, TABLE 1) OF AIRBORNE VOLATILE EXTRACTS FROM MALES BORING IN NORWAY SPRUCE LOGS

Stimulus[a]	Females (%) responding[b] (N = 30–40)	95% CI[c]
Fractions tested March 15, 1983 (cf. Figure 1A)		
1 + 2 + 3 + 4 + 5 = total blend	65.0a	49.5–77.9
Total blend − 1	37.5b	24.2–53.0
Total blend − 2	60.0a	44.6–73.7
Total blend − 3	0.0d	0.0–12.8
Total blend − 4	63.3a	45.5–78.1
Total blend − 5	12.5c	5.5–26.1
3 (natural chalcogran)	13.3c	5.3–29.7
Fractions tested April 23, 1983 (cf. Figure 1A)		
1 + CH[d] + 5A + 5B + 5C + 5D + 5E = blend		
Blend − 5A	63.3a	45.5–78.1
Blend − 5B	60.0a	42.3–75.4
Blend − 5C	50.0a	33.2–66.8
Blend − 5D	46.7a	30.2–63.9
Blend − 5E	10.0b	3.5–25.6
CH[d] + 5E	46.7a	30.2–63.9
Fractions tested May 10, 1983 (cf. Figure 1A)		
CH[d] + $5E_a$ + $5E_b$ + $5E_c$ + $5E_d$ + $5E_e$ = blend	50.0a	33.2–66.9
Blend − $5E_a$	50.0a	33.2–66.9
Blend − $5E_b$	46.7a	30.2–63.9
Blend − $5E_c$	46.7a	30.2–63.9
Blend − $5E_d$	50.0a	33.2–66.9
Blend − $5E_e$	40.0a	24.6–57.7
Fractions tested May 22, 1983 (cf. Figure 1A)		
CH[d] + $5E_a$	56.7a	39.2–72.6
CH[d] + $5E_b$	70.0a	52.1–83.3
CH[d] + $5E_c$	3.3b	0.6–16.7
CH[d] + $5E_d$	6.7b	1.8–21.3
CH[d] + $5E_e$	10.0b	3.5–25.6

[a] Release rate was 8 males/0.2 bolt/min.
[b] Values followed by the same letter within a test period were not significantly different ($\alpha = 0.05$, χ^2).
[c] Confidence interval for proportions.
[d] Synthetic chalcogran (46% E:54% Z) released at 2 ng/min.

26 tests to obtain the same information, assuming only three synergistically active fractions (1, 3, and 5 as shown here). However, if there had been 10 initial fractions and three synergists, then the subtractive method would have required 11 tests while the additive method would need 171 tests for the same level of isolation efficiency. However, even more tests than 171 would be needed if there were more synergists, in order to be assured of locating all the fractions with synergists.
