Water Utilization: Experiment 1. Regression analyses using data summarized in Table 3 indicated that FA inhibited tomato mean relative rates of water utilization (RRWU) at all concentrations. As FA concentrations increased, concurrent decreases (linear or quadratic) in RRWU were observed 24 and 48 hr after each treatment (Figure 3). Following the first and second treatments, tomato responses were linear; 48 hr after the third treatment, the response was curvilinear. RRWU of *flacca* 24 hr after the first and second treatments decreased in a concave curvilinear manner, and linearly after the third treatment. RRWU of *flacca* decreased linearly 48 hr after the first and third treatments, and curvilinearly 48 hr after the second treatment.

The initial effect of FA was greater on *flacca* than wild-type tomato at 0.2 and 0.4 mM. RRWU were reduced 24% and 43% for wild type and 52% and 87% for *flacca* at 0.2 and 0.4 mM FA, respectively (Table 3). On subsequent days, relationships of RRWU for wild type and *flacca* were inconsistent. RRWU for both tomato taxa was essentially eliminated at 0.8 mM, except on day 28 when wild-type RRWU was reduced 64%.

[a] Leaves were measured at 11–12 AM. Water measurements were recorded between 12 and 1 PM daily. Cucumber seedlings were treated between 1 and 2 PM on 12, 14, and 16 days from seed. $N = 6$. Values in parentheses are standard errors.
[b] ARLAE = mean absolute rates of leaf area expansion.
[c] RRLAE = mean relative rates of leaf area expansion.
[d] RRWU = mean relative rates of water utilization.

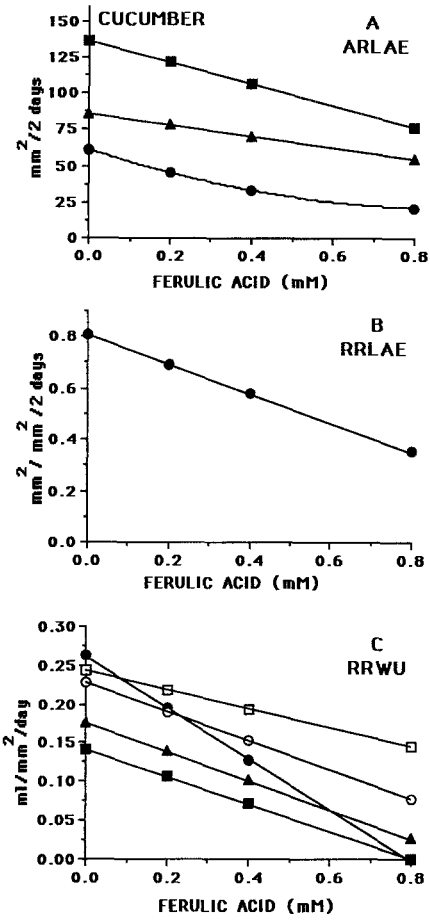

FIG. 2. Effects of ferulic acid concentrations (0.0, 0.2, 0.4, and 0.8 mM) supplied in nutrient solution (pH 5.5) on mean absolute rates of leaf area expansion (ARLAE: A), mean relative rates of leaf area expansion (RRLAE: B), and mean relative rates of water utilization (RRWU: C) of cucumber seedlings. Each ARLAE or RRLAE line was generated from a model for a specific two-day growth period: (●) 12–14, (▲) 14–16, and (■) 16–18. Each RRWU line was generated from a model for a specific day following treatment. The closed symbols represent measurements taken 24 hr after treatment; the open symbols represent measurements taken 48 hr after treatment. Water utilization 48 hr after treatment 2 was not significant and, thus, not shown. The three points above each ferulic acid concentration represent the predicted mean rate of absolute leaf area expansion (ARLAE: A), the predicted mean rates of relative leaf area expansion (RRLAE: B), or the mean relative rate of water utilization (RRWU: C) of the same six plants at the three different growth periods. Seedlings were treated on days 12, 14, and 16. For RRWU symbols are (●) day 13, (○) day 14, (▲) day 15, (■) day 17, (□) day 18. Cucumber r^2 values ranged from 48% to 86% for ARLAE, was 83% for RRLAE of the first growth period, and ranged from 32% to 64% for RRWU, respectively. For all regression equations, $P \leq 0.004$, most $P \leq 0.0009$.

[a] Water measurements were recorded between 12 and 2 PM daily. Tomato seedlings were treated at 2 PM at 22, 24, and 26 days from seed. $N = 6$. Values in parentheses are standard errors.
[b] RRWU = mean relative rates of water utilization (ml/mm/day).

Water Utilization: Experiment 2. Regression analyses using data summarized in Table 2 indicated that FA inhibited cucumber RRWU at all concentrations of FA for all growth periods, except growth period 15–16. A steeper slope was observed for RRWU 24 hr after the first treatment (days 12–13) than for subsequent growth periods (Figure 2). No significant inhibition in RRWU was detected in bean.

Levels of ABA: Experiments 1 and 2. Results from regression analyses using data summarized in Table 4 for ABA levels in tomato and cucumber are presented in Figure 4. For wild-type tomato, leaf tissue ABA levels increased linearly with increasing concentrations of FA (Figure 4). No significant difference was detected between old and young leaves. ABA levels of *flacca* increased curvilinearly in young leaf tissue and linearly in old leaf tissue. No values at 0.8 mM FA were shown for *flacca* since leaf tissue was necrotic.

ABA levels in wild-type tomato leaves, compared to those of control leaves, increased 0–24%, 26–42%, and 75–101% for 0.2, 0.4, and 0.8 mM FA, respectively. ABA levels of young *flacca* leaves were increased 28% and

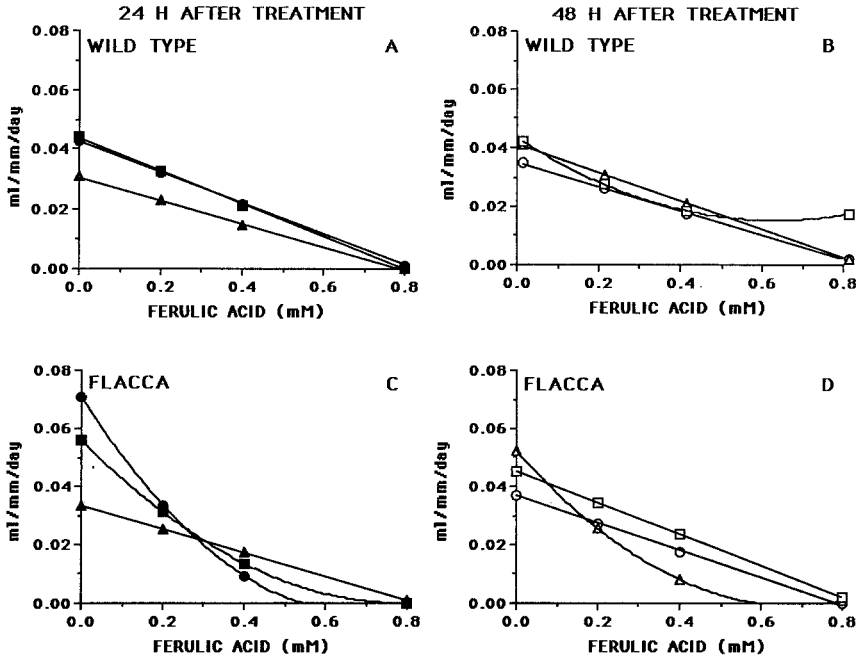

FIG. 3. Effects of increasing ferulic acid concentrations (0.0, 0.2, 0.4, 0.8 mM) supplied in nutrient solution (pH 5.5) on mean relative rates of water utilization (RRWU) of wild-type tomato plants (A, B) and *flacca* tomato plants (C, D). Each line was generated from a model for a specific day following treatment. The three points above each ferulic acid concentration represent the predicted means of relative rate of water utilization (ml/mm/day) of the same six plants treated at three different growth periods. Seedlings were treated on days 22, 24, and 26. For RRWU symbols are (●) day 23, (○) day 24, (▲) day 25, (△) day 26, (■) day 27, and (□) day 28. RRWU r^2 values ranged from 45% to 83% and from 44% to 83% for wild type and *flacca*, respectively. For all regression equations, $P \leq 0.0004$.

162%, while old leaves increased 37% and 93% for 0.2 and 0.4, respectively. *Flacca* contained 31–65% of the ABA levels of wild type.

In cucumber, ABA levels increased linearly in young leaf tissue, but curvilinearly in old leaf tissue. Compared to control leaves, ABA levels of young leaves increased 9%, 7%, and 139%, while old leaves increased 18.5%, 27%, and 383% for 0.2, 0.4, and 0.8 mM, respectively.

Levels of ABA Over Time: Experiment 3. Growth and water-utilization data for wild-type plants in the third experiment were consistent with that of the first experiment and thus are not presented.

ABA levels of wild-type tomato were modified by FA. Within each time

TABLE 4. MEAN ABSCISIC ACID LEVELS OF OLD AND YOUNG LEAVES FOR WILD-TYPE AND *Flacca* TOMATO SEEDLINGS AND CUCUMBER SEEDLINGS TREATED WITH FERULIC ACID SUPPLIED IN NUTRIENT SOLUTION.[a]

Ferulic acid (mM)	Wild type (ng)		*Flacca* (ng)		Cucumber (pg)	
	Old	Young	Old	Young	Old	Young
0.0	1.60	2.06	0.54	0.65	24.05	22.26
	(0.16)	(0.23)	(0.04)	(0.08)	(3.67)	(5.57)
0.2	2.11	2.05	0.74	0.83	28.51	24.35
	(0.20)	(0.22)	(0.03)	(0.10)	(4.37)	(6.95)
0.4	2.27	2.60	1.04	1.70	30.23	23.75
	(0.44)	(0.40)	(0.14)	(0.14)	(3.43)	(4.19)
0.8	3.22	3.60	[b]	[b]	116.10	53.29
	(0.26)	(0.28)	[b]	[b]	(25.94)	(6.50)

[a] $N = 5$. Values in parentheses are standard errors. Tomato leaflets were excised from 28-day old seedlings. Cucumber leaf disks were excised from 18-day-old seedlings. For additional details describing leaf tissue processing, see Methods and Materials.
[b] No values were determined.

interval, significant linear or convex curvilinear (at 24 hr) relationships were observed between FA concentrations and endogenous ABA levels (Figure 5). As FA concentrations were increased, concurrent increases in ABA levels occurred. ABA levels in control plants increased throughout the experiment. Compared to control levels in the respective time periods, ABA levels in plants treated with 0.4 mM FA were 1.5-, 2.6-, 2.7-, 1.6-, and 1.0-fold higher; those treated with 0.8 mM FA were 2.2-, 13.7-, 8.4-, 3.1-, and 1.9-fold higher at 8, 24, 48, 72, and 96 hr after the initial treatment, respectively.

ABA in plants treated with FA reached maximum levels 24 hr after the initial treatment, although ABA levels in plants treated with 0.8 mM FA were five times higher than those treated with 0.4 mM FA. ABA levels did not appear to be affected by the second FA treatment.

DISCUSSION

Leaf Growth and Water Utilization. Increasing concentrations of FA inhibited leaf growth and water utilization rates of three of the four taxa examined. Both leaf elongation and water utilization rates of two tomato taxa were severely affected by FA. The observed inhibition by FA of leaf area expansion and water utilization of cucumber were consistent with earlier studies (Blum and Dalton, 1985; Blum et al., 1985a,b). Bean leaf area expansion rates and water utilization rates were not inhibited by FA.

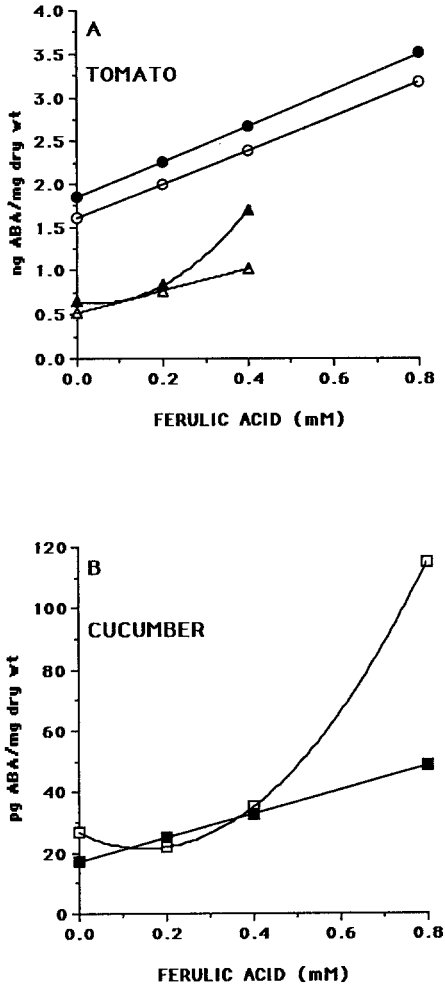

FIG. 4. Effects of ferulic acid concentrations (0.0, 0.2, 0.4, and 0.8 mM) supplied in nutrient solution (pH 5.5) on the mean level of endogenous abscisic acid in leaf tissue of wild-type tomato plants [A; (○) old, (●) young], *flacca* tomato plants [A; (△) old, (▲) young], and cucumber plants [B; (□) old, (■) young]. Regression analyses were based on ABA/mg dry weight leaf tissue. r^2 values ranged from 43% to 49% for wild type, 61% to 78% for *flacca*, and from 44% to 66% for cucumber. $P \leq 0.0001$, except for young cucumber were $P \leq 0.0015$.

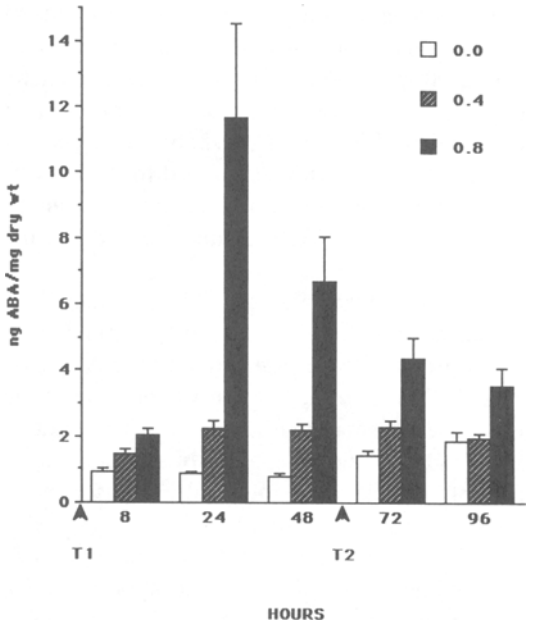

FIG. 5. Effects of ferulic acid concentrations (0.0, 0.4, and 0.8 mM) supplied in nutrient solution (pH 5.5) on the actual mean level of endogenous abscisic acid in leaf tissue on wild-type tomato plants at time intervals after the first treatment. Arrows indicate when treatments were given (T1 = treatment 1; T2 = treatment 2). No distinction between old and young leaves were made. Each column represents the actual mean with standard error of ABA levels for five plants. Regression analyses, based on ng ABA/mg dry weight leaf tissue, revealed significant linear, except for 24 hr where it was concave curvilinear, trends for ferulic acid treatments within time intervals. r^2 values ranged from 64% to 68% for all hours after treatment 1, except 96 hr when $r^2 = 42\%$. $P \leq 0.0003$ for 8, 48, and 72 hr. $P \leq 0.0012$ for 24 hr. $P \leq 0.0089$ for 96 hr.

Differential sensitivities of the taxa to FA were evident. For example, following the first FA treatment (growth period 1), at 0.4 mM FA, leaf growth of wild-type tomato was inhibited 44–49%, *flacca* 82–85%, and cucumber 30–45%; bean was unchanged. The magnitude of the FA-induced water stress was greatest in *flacca*. The mutants wilted at all concentrations of FA following each treatment. In addition, *flacca* treated with 0.8 mM FA became necrotic after the initial exposure. Wild-type tomato wilted only at 0.8 mM, following each of the first two treatments; cucumber wilted only following the first treatment. No water stress-related responses were detected in bean seedlings; they were considered FA-tolerant.

The responses of leaf growth rates of tomato and cucumber to FA changed

over time. Based on the changes in percent inhibitions and shifts in regression equations over time, tomato and cucumber were less affected by subsequent treatments. The reduced inhibitions of growth rates of tomato in this study by FA treatments after the first FA treatment was similar to what has been observed previously with cucumber (Blum et al., 1985b; Klein and Blum, 1990). This suggested that cucumber and tomato acclimated to the presence of FA. Acclimation was not apparent, however, when cucumber in an earlier study were pretreated with 0.1 and 0.2 mM FA, and later exposed to 1 mM FA (Blum and Dalton, 1985).

When considering acclimation as a possible explanation for the suppression of the FA-induced inhibition, one should be reminded that measurements of dry weight or leaf growth are only sensitive for actively growing portions of the plant (Waters and Blum, 1987). Leaf area expansion of the entire seedling, as used in this investigation, may partially or completely obscure responses or recoveries. Even though significant changes may not be detected using these types of measurements, specific physiological processes, not directly involved in leaf expansion, may be significantly altered.

Levels of ABA. Wild-type tomato contained the highest ABA levels of the four taxa. *Flacca* contained 31–65% of the wild-type ABA levels. *Flacca* have been reported to contain between 17% and 26% of the wild-type levels (Tal and Nevo, 1973; Neill and Horgan, 1985). These mutants are still capable of limited biosynthesis (Neill and Horgan, 1985). The level present depends on the conditions under which the tomatoes are grown (Taylor, 1987). Tal and Imber (1970) identified an ABA-like compound that increased with age in both *flacca* and wild-type genotypes of the Rheinland Rhum tomato cultivar. Levels of ABA from control cucumber and bean were 69- to 88-fold less than those from wild-type tomato controls.

FA-induced stress increased ABA levels in three of the four taxa. Leaf ABA levels were increased roughly 0–24%, 26–42%, and 75–101% in wild-type tomato and 9–18.5%, 7–27%, and 139–383% in cucumber, for 0.2, 0.4, and 0.8 mM FA, respectively. Leaf ABA levels were increased roughly 28–37% and 93–162% in *flacca* for 0.2 and 0.4 mM FA, respectively. The lack of change observed in bean leaf ABA levels was expected, since stress-related responses were not detected at any time during the experiment. The elevated ABA levels observed in the other three taxa may have resulted from an FA-induced water stress. The unexpected rise in endogenous ABA levels in *flacca*, although consistently below those of wild type, suggested that mutants were capable of responding to FA-induced stress.

The objective of the third experiment was to establish more definitively when ABA levels rise after FA treatment and whether these levels fluctuate or are maintained over time. In wild-type tomato utilized for this experiment,

induction of ABA biosynthesis occurred within 8 hr after treatment. Maximum levels of ABA were observed 24 hr after the initial treatment. At that time, ABA levels in plants treated with 0.4 or 0.8 mM FA were 2.6 and 13.7 times higher, respectively, than control levels. Tomato appeared to have adjusted physiologically (i.e., acclimated) to the FA in their root environment because ABA levels were apparently not affected by a second FA treatment. At 96 hr after the initial treatment, ABA levels of plants treated twice with 0.4 mM FA approach control levels; ABA levels of those treated twice with 0.8 mM FA were at 1.9 times higher than those of control levels.

Acclimation. A possible explanation for the reduced effect of subsequent FA treatments may be stomatal closure associated with increased ABA levels resulting from the initial FA treatment. In addition to induction of ABA biosynthesis, plants may adjust physiologically in other ways. Shann and Blum (1987b) observed an increase in soluble cell wall peroxidases and in protein level of bound enzyme in cucumber tissue harvested 24 hr after FA treatment at 0.5 and 1.0 mM. Radiotracer also was found in the residues of lignin isolated from seedling tissue treated with [U-ring-^{14}C] FA (Shann and Blum, 1987b). The initial FA treatment may have stimulated the detoxification of FA by its incorporation into bound forms, which are not active (Balke et al., 1987). Upon subsequent treatment, such FA detoxification mechanisms, once induced, could quickly bind or incorporate FA, and thus reduce the effects of subsequent FA treatments. Root uptake of FA also may decline as additional FA treatments are given (Shann and Blum, 1987b). All or various combinations of these mechanisms may be operating to produce the decline in response to multiple FA treatments. Some of these mechanisms also may help to explain the differential sensitivities of the four taxa to FA.

Final Comments. Under field conditions, plants are exposed continually to allelopathic compounds. The low estimates (<0.1 mM) of individual phenolic acids in soil solutions (Whitehead et al., 1982) are not representative of what may interact with roots. Turnover rates of phenolic acid pools in soils can be substantial. Thus, plant roots very likely come in contact with higher concentrations. At present, no information is available on actual uptake of phenolic acids by plants from natural soil environments. Consequently, unequivocal statements of how FA may affect plant growth and ABA levels in field environments cannot be made (Williamson and Weidenhamer, 1990). What should be evident from this study, however, is that (1) plant sensitivity and capacity for subsequent acclimation to phenolic acids, such as FA, are taxon dependent; (2) FA-sensitive taxa under mild water stress and growing in the presence of phenolic acids such as FA, may be more severely impacted than FA-tolerant taxa; and (3) severe drought stress or any other stress that closes stomata and reduces water loss may be antagonistic to FA-induced water stress.

Acknowledgments—We would like to thank Drs. R.S. Boston, E.L. Fiscus, and M.K. Walker-Simmons for their critical reviews of the manuscript. We would also like to thank K. Klein and Dr. S.W. Lyu for their help in data collection, Dr. S.W. Chilton for use of his Speed Vac concentrator, and Dr. J.F. Roberts for use of his monoclonal antibody facilities.

(Received November 12, 1990; accepted January 17, 1991)

Abstract—The radial diffusion assay was applied to estimate the amount of total tannins in extracts from walnut plant materials. We found that the protein-precipitating activity of the tannin extracts were increased by 30–75% when antioxidants (ascorbic acid or sodium metabisulfite, 5.5 mM) were added in extraction solvents (50% aqueous methanol). The extracts obtained with $Na_2S_2O_5$ were much less brown than control. Moreover, two-dimensional thin-layer chromatography revealed some additional polyphenolic compounds in the extracts made with $Na_2S_2O_5$. These results suggest that the amount of tannins and/or their protein-precipitating property may be strongly affected by oxidation events during extraction procedure. The addition of antioxidants in the extraction solvents is useful to limit this problem.

Key Words—Tannins, antioxidants, extraction, protein precipitation, walnut.

INTRODUCTION

Tannins are complex polyphenolic compounds found widely in higher plants. There are two types of tannins chemically different as hydrolyzable and condensed tannins (Swain, 1965; Haslam, 1979). Hydrolyzable tannins are mainly polyesters of gallic or hexahydroxydiphenic acid with glucose or other polyols. Condensed tannins (proanthocyanindins) are flavonoid polymers, with carbon–carbon bonds joining the individual flavonoid monomers. The most outstanding common characteristic of tannins is their ability to bind and/or precipitate proteins (McManus et al., 1985). At present, the characterization of new tannin

*To whom correspondence should be addressed.

molecules and the physiological and ecological significance of these secondary metabolites are widely studied (Beart et al., 1985; Okuda et al., 1989). For example, a high content of tannins decreases the nutrient value of food and feed products (Deshpande et al., 1986). Some evidence indicates that tannins may be important in plant defense (Robbins et al., 1987) and responsible for the great durability of some woods (Hart and Hillis, 1972).

Tannins can be estimated by different chemical assays (Scalbert et al., 1989). Alternatively, some methods based on the protein-precipitating property of tannins have been developed (for review, see Hagerman and Butler, 1989). The radial diffusion assay (Hagerman, 1987) is highly reproducible and suitable for testing a great number of samples. According to this method, tannin extracts are injected in wells in an agarose gel containing bovine serum albumin (BSA). Tannins diffuse in the gel and interact with BSA, marked by a visible ring of tannin–BSA precipitation. However, there are few examples of its application in tannin studies (Hagerman, 1988).

The walnut tree is a woody plant producing wood of high quality and edible fruit. Biochemical analyses showed an abundance of polyphenols in the tissues (Gupta et al., 1972; Muller and Leistner, 1976; Feucht and Schmid, 1983; Jay-Allemand et al., 1988). For example, numerous naphthoquinoids such as juglone and its derivatives and flavonoids such as sakuranetine and myricetine have been identified in walnut pericarp, fruit, and bark (Binder et al., 1989). Furthermore, two ellagitannins (corilagin and its isomer, juglanin) have been isolated from walnut pellicle (Jurd, 1958). By coloration tests, Scalbert et al. (1989) found ellagitannins and condensed tannins in walnut wood. The present paper is devoted primarily to the effect of antioxidants added in the extraction solvents on the BSA-precipitating activity of the tannin extracts in order to improve this quantitative method and adapt it to walnut tissues.

METHODS AND MATERIALS

Plant Material. Seedlings, stump sprouts, annual shoots from adult trees and in vitro shoots in micropropagation (Cornu and Jay-Allemand, 1989) of different species of *Juglans* were collected during growth period. After defoliation, the samples were put in liquid nitrogen and lyophilized before extraction. Leaves freshly sampled from annual shoots and from shoots grown in vitro were either immediately extracted or extracted after lyophilization.

Extraction. Plant material (50 mg dry wt) was extracted by 50% aqueous methanol (1.5 ml × 1 hr × 2 times). In order to study the effect of antioxidants on tannin extraction, ascorbic acid (5.5 mM, Merck) or diethyldithiocarbamic acid (DIECA, 5.5 mM, Sigma), or sodium metabisulfite ($Na_2S_2O_5$, Merck), all at different concentrations, were added to the solvents. In some experiments,

juglone (Aldrich) also was added at different concentrations to the solvents. Extractions were performed in test tubes at 4°C with ultrasound. The homogenates were centrifuged (5000 *g*) at 0°C for 15 min. The supernatants obtained were immediately analyzed.

Radial Diffusion Assay of Total Tannins. The radial diffusion assay was performed according to Hagerman (1987). Agarose gels were prepared with an acetic acid buffer (50 mM, pH 5) containing no antioxidant, or 60 μM antioxidant (ascorbic acid, DIECA, or sodium metabisulfite). The data were expressed as square centimeters of BSA precipitation (the area of the visible ring subtracted by the area of the well) per gram of tissues (dry wt). The BSA-precipitation activity of a commercial tannin mixture (tannic acid, from Extrasynthèse) also was tested. Each value is the mean of nine determinations (three extracts, triplicate for each extract).

TLC Analysis. Two-dimensional thin-layer chromatography (TLC) analysis was performed with Merck DC-Alufolien cellulose plates (20 × 20 × 0.1 mm); first dimension: upper phase of the mixture methyl isobutylketone–formic acid–H_2O (3:1:2; v/v/v); second dimension: formic acid–H_2O (6:94, v/v). Polyphenolic compounds separated on the plates were visualized under UV light in the presence of liquid nitrogen and after fuming with ammonia.

RESULTS

Effect of Antioxidants Added in Agarose Gel. Agarose gels were prepared with or without different antioxidants for the determination of the BSA-precipitation area of the same tannin extracts. Defoliated shoots from an adult walnut tree were extracted by 50% aqueous methanol. As compared to control (gel without antioxidant), the addition of ascorbic acid or $Na_2S_2O_5$ had no effect (Figure 1A). However, the gel containing DIECA showed a precipitation area 20% larger than the control.

Effect of Antioxidants Added in Extraction Solvents. Shoots from an adult walnut tree were extracted by 50% aqueous methanol, 50% aqueous methanol with ascorbic acid, $Na_2S_2O_5$, or DIECA at 5.5 mM. The radial diffusion assay was conducted in the DIECA-containing gel (Figure 1B). The presence of DIECA in 50% methanol did not affect the BSA-precipitating activity of the extracts. On the other hand, ascorbic acid and $Na_2S_2O_5$ addition increased the BSA-precipitation activity by 30% and 75%, respectively. Similar results were obtained when the radial diffusion assay was performed in the gels containing no antioxidant (data not shown).

In the experiments illustrated by Figure 2, $Na_2S_2O_5$ was added to 50% aqueous methanol at different concentrations (1.4–55.0 mM). The BSA-precip-

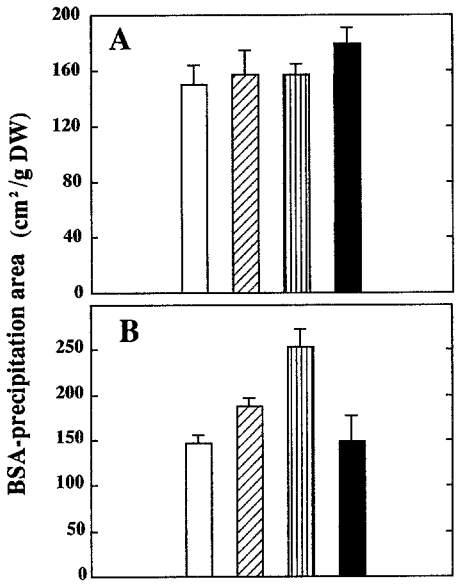

FIG. 1. Effect of antioxidants on BSA precipitation of walnut tannin extracts. Defoliated shoots from walnut trees (*J. nigra* × *J. regia*) were extracted by 50% aqueous methanol with and without antioxidants (5.5 mM). Aliquots of 36-μl extracts were injected in wells in agarose gels with or without antioxidants (60 μM). No addition (control, □), ascorbic acid (▨), sodium metabisulfite (▥), DIECA (■). Each value is the mean (± SD) of nine determinations. (A) Antioxidants in agarose gels for BSA-precipitation assay of the extracts made without antioxidant; (B) antioxidants in extraction solvents, BSA-precipitation assay conducted in gel containing no antioxidant.

itation area of the extracts increased as the concentration of sodium metabisulfite in extraction solvent increased from 0 to 5.5 mM, which is the best condition. No positive effect was observed when the concentration was higher than 27.5 mM. In addition, we noticed that the extracts made without $Na_2S_2O_5$ were dark brown. The extracts became less and less colored with the increasing concentration of sodium metabisulfite in the extraction solvent. Furthermore, our experiments also showed that NaCl (11.0 mM) could not replace $Na_2S_2O_5$ in the extraction solvents (data not shown).

A series of different walnut plant materials were extracted with or without $Na_2S_2O_5$ in 50% aqueous methanol (Table 1). In all the cases, the presence of $Na_2S_2O_5$ in the extraction solvents resulted in a higher BSA-precipiting activity, although the amplitude of the increase varied from 16% to 146% according to plant materials (genotype, plant age, and storage method). The most important effect was found with leaves extracted when fresh.

In order to get information about qualitative changes, walnut leaf extracts

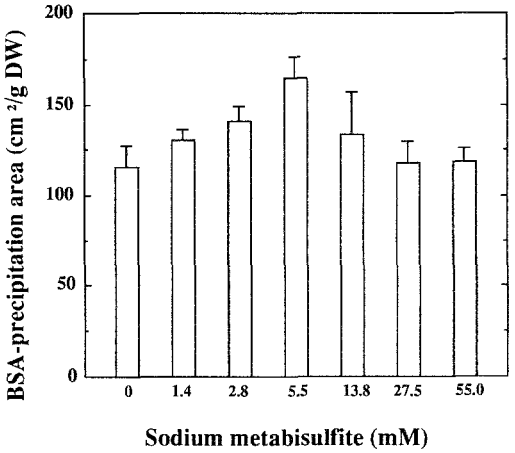

FIG. 2. Effect of $Na_2S_2O_5$ concentrations on tannin extraction. Defoliated shoots from walnut trees (*J. nigra* × *J. regia*) were extracted by 50% aqueous methanol containing $Na_2S_2O_5$ at different concentrations. The BSA-precipitation area (cm^2) was determined in an agarose gel containing 60 μM DIECA. Each value is the mean (± SD) of six determinations.

TABLE 1. EFFECT OF SODIUM METABISULFITE ON TANNIN EXTRACTION[a]

	Juglans species	Tannins (cm^2/g dry wt)		Increase in tannin amount (%)
		Control	Sodium metabisulfite	
Stems				
Seedlings	*J. nigra*	95 ± 1	179 ± 3	88
	J. nigra × *J. rigia*	113 ± 1	134 ± 12	19
Stump sprouts	*J. nigra* × *J. regia*	207 ± 7	354 ± 51	71
Annual shoots	*J. nigra*	248 ± 3	296 ± 12	19
	J. nigra × *J. regia*	150 ± 6	300 ± 6	100
In vitro shoots	*J. major* × *J. regia*	135 ± 3	201 ± 20	49
Leaves				
Annual leaves	*J. major* × *J. regia*	50 ± 5	77 ± 5	54
In vitro leaves	*J. major* × *J. regia* (A)	180 ± 8	240 ± 8	33
	J. major × *J. regia* (B)	151 ± 6	371 ± 22	146

[a] Freshly sampled walnut leaves (A) and lyophilized leaves (B) and stems were extracted by 50% aqueous methanol without (control) or with 5.5 mM sodium metabisulfite. The amount of tannins was determined by the radial diffusion assay in an agarose gel containing 60 mM DIECA. Each value is the mean ±SD of nine determinations.

made in the presence or absence of sodium metabisulfite were compared by two-dimensional TLC analysis. The extracts made with antioxidant showed four marked spots that were not detectable in the control (Figure 3). The compound, corresponding to spot d, has been identified as hydrojuglone glucoside (Jay-allemand et al., 1990).

Effect of Juglone on BSA-Precipitation Activity of Tannins. Stems from stump sprouts of an adult tree were used in these studies. Preliminary experiments showed that the addition of juglone to plant extracts did not change their BSA-precipitation activity (data not shown). Alternatively, juglone was added at two concentrations (0.1 and 1 mM) in 50% aqueous methanol before extracting plant material. The BSA-precipitation activity of the extracts was not affected by the coextraction with juglone (data not shown). However, the positive effect of $Na_2S_2O_5$ added in the extraction solvents was observed in all cases.

Effect of Antioxidants on Commercial Tannins. A commercial tannin mixture (tannic acids, Extrasynthèse) was dissolved in 50% aqueous methanol. Its BSA-precipitation activity in the agarose gel was proportional to the injected tannin amount at the range of 0–0.5 μg/well. No effect of antioxidant addition in 50% aqueous methanol or in agarose gel was observed with commercial tannins (data not shown).

DISCUSSION

Tannins are commonly extracted from plant materials by different solvents such as boiling aqueous methanol, aqueous acetone, or acidic methanol (Deshpande et al., 1986; Hagerman, 1988). Little work has been done to combine the extraction solvents with antioxidants. However, some phenols tend to oxi-

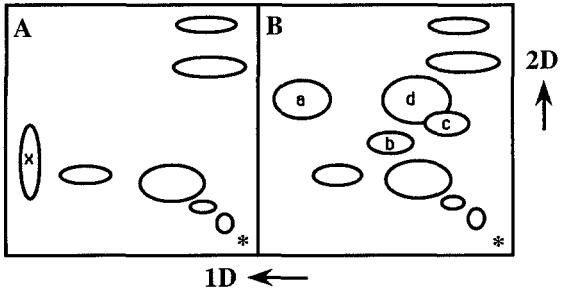

FIG. 3. Two-dimensional TLC analysis of walnut leaf extracts. Leaves from in vitro grown walnut shoots (*J. major* × *J. regia*) were extracted when fresh by 50% aqueous methanol without (A) or with 5.5 mM $Na_2S_2O_5$ (B). Only the most marked spots observed under UV light in the presence of liquid N_2 are drawn. The letter x indicates a spot noticed only for extract A; the letters a, b, c, and d indicate those for extract B.

dize easily during sample preparation and extraction (Deshpande et al., 1986). By the radial diffusion assay, we found that the protein-precipitation activity of walnut tannin extracts is strongly increased when antioxidants are included in the extraction solvents (Table 1).

In enzyme and metabolite extraction, and in cell and tissue cultures, browning often occurs and brings about some detrimental effects. One of the main causes for browning may be polyphenol oxidation (Loomis and Bataille, 1966; Christiansen and Fonnesbech, 1975; Rouet-Mayer et al., 1990). In some cases, the detrimental effects can be limited by addition of antioxidants, such as bisulfite, ascorbic acid (Golan-Goldhirsh and Whitaker, 1984), and cysteine (Dudley and Hotchkiss, 1989), or polyvinylpyrrolidone, which binds polyphenols by hydrogen bonding and prevents their interaction with proteins (Christiansen and Fonnesbech, 1975). According to Hagerman (1987), ascorbic acid is incorporated in the agarose gel for radial diffusion assay of tannins, but in our experiments, the presence of ascorbic acid and bisulfite in the gel did not affect BSA precipitation although the gel containing DIECA showed a slightly larger area of BSA precipitation than the control. On the contrary, when ascorbic acid or bisulfite (5.5 mM) was added to the extraction solvents, the BSA-precipitation activity of tannin extracts was strongly increased. Walnut extracts obtained with 50% aqueous methanol are dark brown. The color is much weaker when $Na_2S_2O_5$ is added to the extraction solvent, suggesting a limited polyphenol oxidation. Alternatively, bisulfite may react directly, like sulfhydryl compounds, with quinones to form colorless adducts (Sanada et al., 1972). These adducts may or may not have the capacity to precipitate proteins. However, ascorbic acid also shows a positive effect on tannin extraction. So the effect of bisulfite on tannin extraction may be due mainly to antioxidation, although we do not know the reasons for the ineffectiveness of DIECA addition in extraction solvents and the reduction of bisulfite effect when its concentration is higher than 5.5 mM. The mechanism involved in the oxidation of tannins and other polyphenols in 50% methanol has not been well understood. The oxidation of polyphenols is catalyzed in higher plants by polyphenoloxidase, which is responsible for the oxidation of *o*-diphenols to *o*-quinones (Vaughn and Duke, 1984; Rouet-Mayer et al., 1990) and which may be partially active in the extraction solvents. Spontaneous polyphenol oxidation may also take place in the solvents.

To form soluble or insoluble complexes under mild conditions, the interaction between tannins and proteins is based on hydrogen bonds, for example, the hydrogen bonds between the phenolic hydroxyl groups of tannins and carbonyl groups of the protein peptide bonds. This interaction may increase with the number of phenolic groups (Calderon et al., 1968; Haslam, 1979; McManus et al., 1985). We suppose that the effect of antioxidants on the BSA-precipitation activity of tannins extracts may be attributed mainly to the prevention of

oxidation of phenolic function. In addition, two-dimensional TLC analysis shows that the walnut extracts obtained with $Na_2S_2O_5$ contain some polyphenolic compounds such as hydrojuglone glucoside, which may have been destroyed during extraction without antioxidant addition (Figure 3). The possibility that similar changes occurred for tannins could not be dismissed. Further studies also are required to determine if some of the spots observed in the presence of bisulfite correspond to the colorless adducts formed between bisulfite and quinones (Sanada et al., 1972).

Hagerman (1987) reported that the presence of nontannin phenolics such as flavonoids, benzoic acids, or hydroxycinnamic acids do not interfere with the radial diffusion assay of tannins. This conclusion has been confirmed further with juglone addition to walnut tannin extracts. In addition, plant materials were extracted with added juglone in order to know if eventual reduction or oxidation of simple phenolic compounds in the presence or absence of sodium metabisulfite brings about interference with the assay. There is no observable interference caused by juglone addition for the BSA-precipitation activity.

The results presented here suggest that the amount of tannins and/or their BSA-precipitating activity may be affected strongly by oxidation events during extraction procedure. When we compare the tannin amounts extracted with or without antioxidant, the difference varies considerably, from 19% to 146%, according to plant material (genotype, plant age, tissue, and storage method). The addition of antioxidants in extraction solvents may allow more accurate determination and comparison of the tanning amounts in different plant materials and will be useful in experiments evaluating the relationship between the tannin amount and a physiological or ecological parameter. It also may allow isolation and characterization of labile tannins and other phenolic compounds (Jay-Allemand et al., 1990), which may be destroyed or modified by oxidation in commonly used extraction solvents containing no antioxidants.

Acknowledgments—The authors wish to express their sincere gratitude to Dr. M.-D. Deng for helpful advices, to Dr. A. Scalbert for critical reading of the manuscript, and to Miss P. Capelli for in vitro culture.

(Received August 29, 1990; accepted January 22, 1991)

Abstract—A unique sex attractant pheromone was isolated and identified from extracts of ovipositor tips from the female browntail moth (Lepidoptera: Lymantriidae). The pheromone compound, (*Z,Z,Z,Z*)-7,13,16,19-docosatetraen-1-ol isobutyrate, $CH_3CH_2CH{=}CHCH_2CH{=}CHCH_2CH{=}CH(CH_2)_4CH{=}CH(CH_2)_6O_2CCH(CH_3)_2$, was identified by a combination of gas chromatography, mass spectrometry, and microreactions and was confirmed by synthesis. Traps baited with 5–50 μg of the synthetic pheromone, dispensed from rubber septa treated with an antioxidant and a UV stabilizer, gave male moth captures that were comparable to traps baited with three virgin females. Higher (250 μg) and lower (0.04–2.5 μg) quantities of the synthetic pheromone on septa captured somewhat fewer males. Captures were the same for similar quantities of the natural and synthetic pheromone. Minor, inactive components in the tip extract were identified as a mixture of 7- and 8-pentacosanone.

INTRODUCTION

The browntail moth, *Euproctis chrysorrhoea* (L.), is native to Eurasia, where periodic outbreaks result in defoliation of forest, shade, and ornamental trees. Accidently introduced into the United States in the late 1890s, the insect had spread into Long Island, New York, most of New England, and southeastern Canada by the early 1900s. Although the infested area in North America expanded rapidly, populations began to decline after 1915 (Burgess and Baker, 1938). At present, known U.S. infestations are limited to coastal islands and neighboring coast in Casco Bay, Maine and coastal dunes on Cape Cod, Massachusetts (Schaefer, 1974; Leonard, 1988) where the larvae feed primarily on beach plum (*Prunus maritima*) and black cherry (*Prunus serotina*). In addition to the damage caused by defoliation, human contact with larval setae can result in severe dermatitis.

The presence of a female-produced attractant was first demonstrated by Komarek and Pfeffer (1939) and traps baited with females have been used for monitoring moth populations (Jacobson, 1972; Schaefer, 1974). The synthetic sex attractant pheromone would facilitate moth detection. This paper describes the isolation and identification of the browntail moth female sex attractant pheromone, the bioassay of the natural and synthetic compounds, and the design of an effective dispenser for use in traps to monitor populations.

METHODS AND MATERIALS

Insects. In late June 1986, last-instar larvae were collected from beach plum at the Cape Cod National Seashore, North Truro, Massachusetts. Larvae were transferred to freshly cut apple foliage to complete their development under conditions of 16 hr:8 hr light–dark photoperiod at 21 ± 1°C. In 1987–1989, field-collected pupae, extricated from their webs, were sexed, held in separate containers, and checked daily for eclosion.

Isolation. Ovipositor tips, excised from 2-day-old females 2–5 hr into scotophase, were extracted with hexane for 10 min (5 tips/100 μl hexane). Whole female bodies were similarly extracted but with 250 μl hexane per insect. All solvents were HPLC grade (Baker Analyzed).

The tip extracts (10–50 female equivalents) were added to 1.2 g Florisil (60–200 mesh, precleaned with hexane in a Soxhlet extractor for 6 hr and dried at 80°C) held in a Pasteur pipet with a small plug of glass wool at the bottom and topped with a thin layer of dry sodium sulfate. Components were eluted

successively with 1 ml hexane, 1 ml 5% ether in hexane, and 4 ml 10% ether in hexane. Fractions of about 0.2 ml were collected and used for electroantennographic (EAG) measurement, flight-tunnel bioassay, and gas chromatographic (GC) analysis and peak collection.

Bioassay. EAG measurements were conducted using excised antennae from 2-day-old males (Roelofs, 1984). Aliquots (about one female equivalent) of the whole tip extract and the Florisil fractions were evaporated in Pasteur pipets. A 4-cc pulse of air through the pipets was used to introduce the stimulus into the continuous airstream, 4 cm upstream from the antenna. Two successive responses (in mV) were recorded for each sample or blank (5 μl hexane). The process was repeated using a new aliquot of each treatment, giving a total of four readings. The EAG activities of the GC-collected fractions also were measured.

Flight-tunnel (1.4 × 0.8 × 2.8 m, w × h × l) bioassays (Cardé and Hagaman, 1979) were used to verify that EAG-active fractions elicited upwind-oriented flight by males. An inactive (fraction 6) and two active (fractions 8 and 9) fractions were selected as being representative of the Florisil fractions for wind-tunnel bioassay. Aliquots (2 μl containing 0.3 female equivalents) were evaporated on filter paper disks (8 mm diam.) which were mounted at the upwind end of the tunnel. Air flow and temperature in the tunnel were 0.5 m/min and 21 $\pm$ 2°C, respectively. Individual males were placed under 30-ml clear plastic cups on small screens in the tunnel to acclimate for at least 1 hr before testing. The behaviors recorded were: activation (wing fanning, flight initiation), zigzag upwind flight, and contact with source.

Field tests were conducted at the Cape Cod National Seashore in mid-July using sticky, wing-type traps (Pherocon 1C). Traps were suspended 1.4 m above the ground from steel stakes. The tests were carried out in a randomized complete block with the traps checked and rerandomized daily. Reference traps were baited with three live, virgin females held in small wire cages (32 mesh, 4 cm high × 7 cm diam.). Aliquots of tip extracts or synthetic compounds were applied to filter paper disks (22 mm diam.) or slices of cotton dental roll (6 mm × 13 mm diam.) for the 1987 and 1988 field tests. Gray synthetic elastomer septa (No. 1888 West Co.) were used for the 1989 and 1990 tests and were extracted for 2 hr with 1 : 1 hexane–acetone and dried at room temperature prior to use. The septa were modified by removing all but 1 mm of the cup end. Each septum was treated with 20 μl of 5 μg/μl hexane solutions (i.e., 100 μg) each of butylated hydroxytoluene (BHT), an antioxidant, and Tinuvin 328 (Ciba-Geigy), a UV stabilizer, prior to sample addition. The quantities of synthetic compound per dispenser ranged from 0.04 to 250 μg. Male capture data were analyzed using analysis of variance (ANOVA) and means were separated using Duncan's (1955) multiple-range test.

Identification. Extracts of female ovipositor tips and fractions from Florisil

chromatography were initially analyzed by gas chromatography (GC) on a Hewlett-Packard model 5890 chromatograph fitted with an SP-2340 (75% cyanopropyl) fused silica capillary column (0.32 mm ID × 30 m; Supelco, Inc.). The column temperature was set at 80°C for 4 min and then programmed at 10°C/min to 210°C, where it was held for 10 min. The injection port and detector temperatures were 180° and 220°C, respectively. The same column (in a Varian 3700 chromatograph) was used to collect fractions in glass capillary tubes connected to the extinguished flame jet with temperature-resistant Teflon tubing. Collection times were 30 sec. The collection tubes were rinsed with 25 μl of hexane, which was concentrated to ca. 10 μl for GC and EAG analysis. Gas chromatographic–mass spectrometric (GC-MS) analyses were conducted on a Finnigan 4500 spectrometer fitted with a DB-1 (methyl silicone) fused silica capillary column (0.25 mm ID × 60 m; J & W Scientific). The column temperature was set at 120°C for 0.6 min and then programmed at 25.5°C/min to 280°C, where it was held. The injection port was set at 200°C. Electron-impact (EI) spectra were recorded at 2-sec intervals at 70 eV. Chemical ionization (CI) spectra were obtained using isobutane reagent gas. Retention indices were measured on an SP-2340 column (0.25 mm ID × 15 m; Supelco) set at 120°C for 6 min and then programmed at 2°/min to 225°C, where it was held.

Tip extracts (about 10 female equivalents) were subjected to microchemical reactions for structural identification. The extract was hydrogenated in hexane in the presence of Adams catalyst at room temperature for 1 hr. Other portions were ozonized for 20 sec (Beroza and Bierl, 1967) in carbon disulfide and in *n*-hexadecane. These treated extracts were subjected to GC-MS analyses with the DB-1 column. The column conditions were modified for the extracts ozonized in carbon disulfide (90°C for 2 min, then programmed at 25.5°/min to 280°C where it was held) and in *n*-hexadecane (70°C for 4 min, then 10°/min to 280°C).

Synthesis. The identified pheromone, (*Z*,*Z*,*Z*,*Z*)-7,13,16,19-docosatetraen-1-ol isobutyrate [(*Z*,*Z*,*Z*,*Z*)-7,13,16,19-22:OiBu] was synthesized (Schwarz et al., in preparation). The synthetic compound was first purified by liquid chromatography on a silica gel (activated at 120°C) column (1.5 cm ID × 60 cm) using hexane, 5% and 15% ether in hexane, and ether as eluents. The fraction containing the compound of interest was further purified by high-pressure liquid chromatography (HPLC) on a Millipore Waters Assoc. Delta Prep 3000 instrument using two passes through a 5-μm Hypersil (YNC Co.) column (2.0 cm ID × 25 cm). A Millipore Waters Lambda-max model 481 LC spectrophotometer was used for UV absorbance detection at 214 nm and an ISCO model 2150 peak separator plus an ISCO Foxy fraction collector were used to collect fractions. The mobile phase was 0.5% diethyl ether in hexane (UV grade, American Burdick & Jackson). The target compound eluted between 28 and 31 min. The final preparation for field examination was >90% pure as

determined by GC on a CP Wax 52 (polyethylene glycol) fused silica capillary column (0.25 mm ID × 10 m; Chrompack) set at 100°C for 2 min and then programmed at 10°C/min to 200°C, where it was held. The retention time of the (Z,Z,Z,Z)-7,13,16,19-22 : OiBu was 29.38 min.

Other synthetic compounds were prepared by conventional methods or procedures to be reported later. These included: (*E*,Z,Z,Z)-7,13,16,19-22 : OiBu, (Z,Z,Z,Z)-6,13,16,19-22 : OiBu, (Z,Z,Z,Z)-8,13,16,19-22 : OiBu, *n*-docosan-1-ol isobutyrate (22 : OiBu), (Z)-7-dodecen-1-ol isobutyrate, (Z,Z,Z,Z)-7,13,16,19-docosatetraen-1-ol [(Z,Z,Z,Z)-7,13,16,19-22:ol], 7-pentacosanone (7-25 : one) and 8-pentacosanone (8-25 : one).

RESULTS AND DISCUSSION

Identification. The chromatographic separation of tip extracts on Florisil resulted in eight fractions (5-10% ether in hexane) that showed an EAG response of 0.3 mV or greater (Figure 1). All other fractions gave a response of <0.3 mV. The flight tunnel bioassay showed that fractions that gave high EAG signals also caused activation, upwind zigzag flight, and source contact by most or all of the male moths (Table 1).

GC analyses (SP-2340) of the Florisil fractions showed the presence of six peaks that were present in all fractions showing high EAG response. The areas of only two of these peaks gave positive correlation ($P = 0.05$) with EAG responses: the peak at 20.25 min, which later was identified as the pheromone, and a minor peak at 18.91 min, which was not isolated for bioassay. The 20.25 min peak, when collected from the GC, gave a similar EAG response (1.20 ±

0.20 mV) as did the crude Florisil fraction 10 (1.63 ± 0.28 mV). The quantity of the 20.25 min peak in the tip extracts was estimated to be about 30–60 ng/female and that of the minor peak (18.91 min) about 3–10 ng/female. Kovats (1964) retention indices of the pheromone peak on SP-2340 and DB-1 capillary GC columns were 3007 and 2695, respectively. On the same columns, the minor peak had indices of 2900 and 2680. These differences in retention indices for polar vs. nonpolar columns were consistent with a single, oxygen-containing functional group in each component.

The mass spectrum of the unidentified major component (Figure 2A) showed that the molecular weight (M^+) was *m/z* 388 (2.8%). This was confirmed by CI-MS with the ion abundances as: $M^+ + 1$ (*m/z* 389) 100%, $M^+ + 2$ (*m/z* 390) 25%, and $M^+ - 1$ (*m/z* 387) 4%. Assuming one oxygenated functional group, the pheromone was thus either $C_{26}H_{44}O_2$ or $C_{27}H_{48}O$ with three to five or three to four double bonds and/or rings, respectively.

GC-MS analysis showed that the minor peak was a mixture of two compounds, each with M^+ of *m/z* 366. Although these compounds did not separate on polar or nonpolar columns, the DB-1 column provided sufficient resolution for the mass spectra, taken on the leading (19.73 min) and tailing (19.76) edges of the peak, to show that the two components were 8–25 : one and 7–25 : one, respectively (Figure 3A–D). A 1 : 1 mixture of the synthesized ketones gave the same retention time and approximately the same relative abundances of the ions that are characteristic of each ketone.

Hydrogenation of the tip extract eliminated the major peak and produced a later-eluting compound with a GC retention index of 2760 on the DB-1 column. The difference in retention index (2760 − 2695 = 65) is consistent with saturation of methylene-interrupted and/or isolated double bonds. The mass

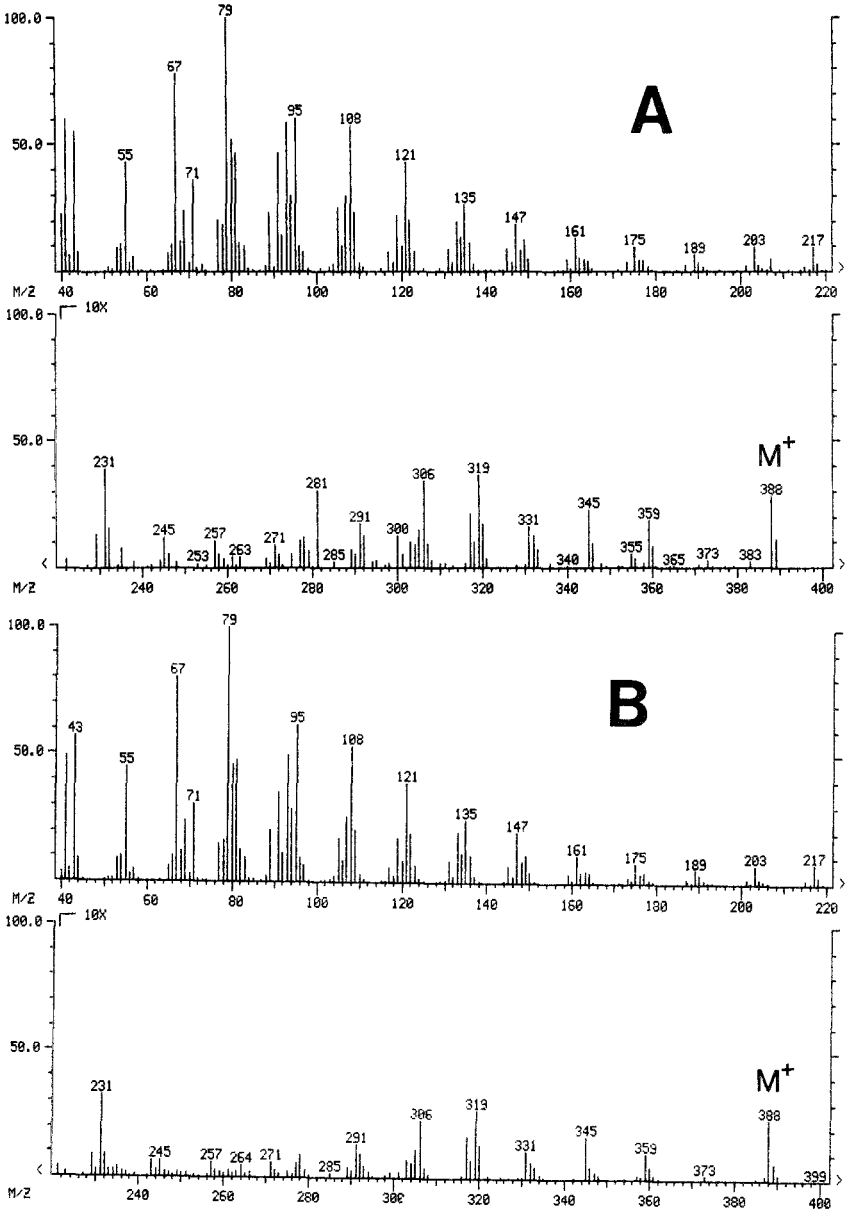

FIG. 2. Mass spectra (EI; 70 eV) of the natural (A) and synthetic (B) pheromone; abundances of ions higher than m/z 220 shown magnified 10×.

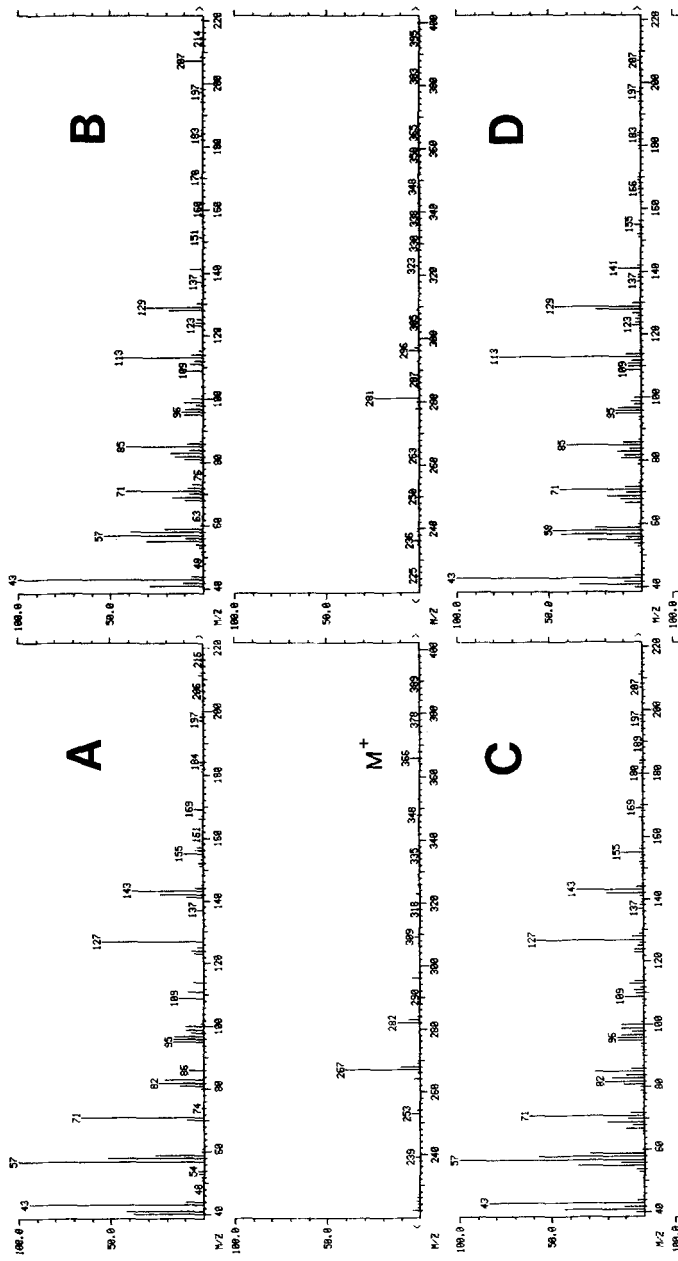

FIG. 3. Mass spectra (EI; 70 eV) of the leading (A) and trailing (B) edges of the minor peak in the female extract and of synthetic 8–25 : one (C) and 7–25 : one (D).

spectrum of the hydrogenation product showed M^+ at *m/z* 396 (31%) and fragment ions at *m/z* 353 (67%), 308 (10%), and 89 (100%), which correspond to $M^+-C_3H_7$, $M^+-C_3H_7CO_2H$, and $C_3H_7CO_2H_2^+$, respectively. The increase in molecular weight established that the pheromone had four double bonds and the *m/z* 89 ion confirmed that the pheromone was an ester of a $C_3H_7CO_2H$. Indeed, the mass spectrum and retention times of the hydrogenation product on polar and nonpolar columns matched those of synthetic 22:OiBu. Coinjection of the hydrogenated extract and the authentic 22:OiBu resulted in a single peak at 21.0 min (DB-1 column). Under the same conditions, *n*-docosan-1-ol *n*-butyrate has a retention time of 22.0 min. Thus, the major peak was an *n*-docosatetraen-1-ol isobutyrate ($C_{26}H_{44}O_2$). The minor peak was present in the hydrogenated extract, although it is not known whether a portion of it had been reduced.

The positions of the four double bonds in the alcohol portion of the major compound were identified by the *m/z* 108 ion in its mass spectrum and by ozonolysis. The *m/z* 108 ion (58%) has been shown to be characteristic of $[CH_3CH_2(CH{=}CH)_3H]^+$ produced by a 3,6,9-triene, counting from the methyl end of the chain (Connor et al., 1980; Underhill et al., 1983). In a docosatetraene isobutyrate, this corresponds to double bonds in the 13,16,19-positions. Ozonolysis of the major compound in carbon disulfide produced a peak at 9.26 min, which showed prominent ions at *m/z* 172 (1%), 157 (13%), 95 (15%), 94 (14%), 89 (53%), 84 (11%), 79 (7%), 71 (64%), 55 (22%), and 43 (100%). Ozonolysis of authentic (Z)-7-dodecen-1-ol isobutyrate produced the same product, i.e., $(CH_3)_2CHCO_2(CH_2)_6CHO$. Ozonolysis of the extract in *n*-hexadecane produced a peak whose retention time (3.2 min) and mass spectrum matched that of *n*-propanal, confirming the placement of the last double bond in the 19 position. These results indicated that the pheromone was 7,13,16,19-docosatetraen-1-ol isobutyrate, $CH_3CH_2CH{=}CHCH_2CH{=}CHCH_2CH{=}CH(CH_2)_4CH{=}CH(CH_2)_6O_2CCH(CH_3)_2$. The minor peak remained unchanged on ozonolysis.

Coinjection of synthetic (Z,Z,Z,Z)-7,13,16,19–22:OiBu and the tip extract gave a single peak by GC analysis on polar and nonpolar columns. The mass spectrum of synthetic (Z,Z,Z,Z)-7,13,16,19–22:OiBu (Figure 2B) was the same as that of the natural compound. On the DB-1 column, the retention time of (E,Z,Z,Z)-7,13,16,19–22:OiBu was 6 sec longer (20.15 min) than that of the all-*cis* compound (20.05 min), and coinjection produced two peaks. Therefore, the unsaturation in the isolated compound was identified as all *cis*, i.e., (Z,Z,Z,Z)-7,13,16,19–22:OiBu. Coinjection of (Z,Z,Z,Z)-7,13,16,19–22:OiBu with (Z,Z,Z,Z)-8,13,16,19–22:OiBu also produced two peaks; the compound with the 7,13,16,19 double bonds eluted 4 sec later than the structure with the 8,13,16,19 double bonds. Coinjection of (Z,Z,Z,Z)-7,13,16,19–22:OiBu and (Z,Z,Z,Z)-6,13,16,19–22:OiBu produced a single but broad peak.

The mass spectra of the three synthetic isobutyrates with the first double bond in the 6, 7, and 8 position are very similar. However, differences in ion abundances were observed for the two C_nH_{2n-7} fragments which were characteristic of the first double-bond position of each compound. The pattern of ion abundances for the series of C_nH_{2n-7} fragments (Figure 4) showed elevated abundances for the two ions that include one and both, respectively, of the two carbons carrying the inner double bond. Both the natural and synthetic (Z,Z,Z,Z)-7,13,16,19-22:OiBu showed increases in intensity at *m/z* 203 ($C_{15}H_{23}^+$) and *m/z* 217 ($C_{16}H_{25}^+$) corresponding to $[CH_3(CH_2CH{=}CH)_3C_3H_8]^+$ and $[CH_3(CH_2CH{=}CH)_3C_4H_{10}]^+$, respectively. The spectrum of (Z,Z,Z,Z)-6,13,16,19-22:OiBu showed enhanced intensity at *m/z* 217 ($C_{16}H_{25}^+$) and *m/z* 231 ($C_{17}H_{27}^+$) and the spectrum of (Z,Z,Z,Z)-8,13,16,19-22:OiBu showed high abundances at *m/z* 189 ($C_{14}H_{21}^+$) and *m/z* 203 ($C_{15}H_{23}^+$) (Figure 4). Thus, these spectral data provide additional support the assignment of the isolated double bond at the 7 position.

Field Studies. Initial trapping tests in 1987–1988 with tip extracts and the synthetic compound gave poor and inconsistent results. Traps baited with the synthetic compound or extracts deposited on filter paper disks or cotton wicks captured some males during the first night. This number increased if the baits were prepared and the traps deployed just before sunset. However, trap captures

[c]Mean number of male moths captured per trap per reading; two replicates and two readings were used in the July 13–17 test, four replicates and six readings in the July 17–27 test, and four replicates and three readings in the July 18–21 test.
[d]μg of the pheromone compound.

in subsequent nights were very low in comparison to those in female-baited traps.

Laboratory tests revealed that the reason for these low trap captures was decomposition of pheromone on filter disks or cotton wicks. When the synthetic pheromone (15 μg) was applied to filter paper disks or cotton wicks, very little of the compound was recovered by extraction following 24 hr of exposure at room temperature. However, similar recovery experiments with 22:OiBu showed that most of this compound remained on the filter paper or cotton wicks. Therefore, evaporation of the pheromone was not occurring and decomposition must have caused the disappearance of the pheromone. However, similar quantities of (Z,Z,Z,Z)-7,13,16,19-22:OiBu and the 22:OiBu, when applied to septa, were recovered by extraction after 24 hr of exposure, suggesting that the septa protected the pheromone from decomposition. BHT and Tinuvin 328 UV

stabilizer were added to all subsequently used septa to help further stabilize the pheromone.

Outdoor exposure of septa treated with 50 μg of synthetic (Z,Z,Z,Z)-7,13,16,19-22 : OiBu or 22 : OiBu resulted in similar recoveries of the two compounds after one, two, and five days of exposure. A longer study measured the residual quantity of (Z,Z,Z,Z)-7,13,16,19-22 : OiBu in septa exposed outdoors in Maryland during late July and early August 1989. The septa were protected from rain but not sun or wind. GC analyses showed that about 60% of the isobutyrate remained after 21 days of exposure.

Dose–response field tests showed (Table 2) that male moth captures in traps baited with 5–50 μg of synthetic (Z,Z,Z,Z)-7,13,16,19-22 : OiBu per septum were equivalent to those baited with three caged virgin females. Higher (250 μg) and lower (0.04–2.5 μg) quantities of the isobutyrate resulted in somewhat diminished moth captures.

No significant differences in male moth captures were detected in comparisons of similar (0.4–1.0 μg) amounts of the synthetic (Z,Z,Z,Z)-7,13,16,19-22 : OiBu and of the natural compound as present in extracts of female ovipositor tips or whole bodies (Table 2). In a 1990 test, male moth captures showed that 7-25 : one and 8-25 : one, alone or in 1 : 1 combination, were not attractive. Addition (0.5, 2.5, and 12.5 μg) of a 1 : 1 blend of these ketones with 25 μg of the synthetic pheromone had no significant effect on attraction (Table 3).

(Z,Z,Z,Z)-7,13,16,19-22 : OiBu is a novel structure and has not been reported previously as an insect pheromone. It has the highest molecular weight (*m/z* 388) thus far recorded for a sex attractant pheromone. However, aliphatic

unsaturated hydrocarbons with similar 3,6,9-unsaturation and their monoepoxides have been reported as attractants for a large number of Lepidoptera, including noctuids, geometrids, lymantriids, and arctiids (Arn et al., 1986). The browntail moth pheromone is exceptional in that it has an additional isolated double bond further towards the ester end of the chain and is terminated by an alcohol functionality esterified by isobutyric acid, heretofore not encountered in pheromone chemistry. The only other sex pheromone identified in the genus *Euproctis* is that of *E. similis xanthocampa*, which is a four-component mixture of valerate and isovalerate esters of four octadecen-1-ols (Tan et al., 1984). However, the biological activity of these compounds has not been described.

In summary, the sex attractant pheromone was isolated from the female browntail moth and identified as (*Z*,*Z*,*Z*,*Z*)-7,13,16,19-docosatetraen-1-ol isobutyrate. This structure has not been reported previously and is dissimilar to other lepidopteran sex attractants because of its high molecular weight and its degree of unsaturation. In the field, the synthetic compound, when properly formulated with an antioxidant and a UV stabilizer, is as attractive as live females to conspecific males.

Abstract—Enantiomerically enriched forms of (*Z*)-6-*cis*-9,10-epoxymonoenes and (*Z*)-9-*cis*-6,7-epoxymonoenes of chain lengths C_{17-21} were synthesized by Sharpless asymmetric epoxidation of allylic alcohol intermediates, followed by tosylation or halogenation and chain extension. The resulting monounsaturated epoxides were field tested as sex attractants for lepidopteran species. *Euchlaena madusaria* Walker males were attracted to blends of the enantiomers of (*Z*)-6-*cis*-9,10-epoxynonadecene {6*Z*-*cis*-9,10-epoxy-19:H; IUPAC name [2α,3α(*Z*)]-2-pentyl-3-(2-dodecenyl)oxirane} in combination with 6*Z*,9*Z*-19:H. The response was antagonized by 9*Z*-*cis*-6,7-epoxy-19:H. 6*Z*,9*Z*-19:H was tentatively identified in pheromone gland extracts. *Xanthotype sospeta* Drury male moths were attracted to lures containing 6*Z*-9*S*,10*R*-epoxy-19:H; the response was antagonized by the opposite enantiomer. *Palthis angulalis* Hübner males were attracted to 9*Z*-6*S*,7*R*-epoxy-19:H; the opposite enantiomer was antagonistic. 6*Z*,9*Z*-19:H and 9*Z*-*cis*-6,7-epoxy-19:H and 9*Z*-*cis*-6,7-epoxy-19:H were tentatively identified in pheromone gland extracts from *Anacamptodes humaria* Guenée females. In field trails, 9*Z*-6*R*,7*S*-epoxy-19:H proved to be the attractive enantiomer, and the response was potentiated by 6*Z*,9*Z*-19:H. Mechanisms by which unique chemical communication channels are maintained by each species are discussed.

lalis, *Anacamptodes humaria*, (Z,Z)-6,9-nonadecadiene, (Z)-6-*cis*-9,10-epoxynonadecene, (Z)-9-*cis*-6,7-epoxynonadecene.

INTRODUCTION

There have been a number of reports of (Z,Z,Z)-3,6,9-trienes and the related *cis*-3,4-,6,7-, or 9,10-monoepoxydienes as lepidopteran sex attractants and sex pheromone components (compilation to 1986, Arn et al., 1986; Millar et al., 1990a–d, and references therein). There also have been several reports of (Z,Z)-6,9-diunsaturated hydrocarbons as sex attractants and pheromones. For example, (Z,Z)-6,9-nonadecadiene (6Z,9Z-19:H; subsequent abbreviations will follow the same pattern) has been reported as a sex attractant for the geometrid species *Bupalus piniaria* L. (Bestmann and Vostrowsky, 1982), *Boarmia repandata* L. (Bogenschütz et al., 1985), and *Alsophila quadripunctata* Esp. (Szöcs et al., 1984), and as a sex pheromone component for *Sabulodes caberata* Gn. (McDonough et al., 1986). 6Z,9Z-21:H has been identified in extracts of the pheromone glands of the arctiid moths *Utetheisa ornatrix* L. (Jain et al., 1983) and *Phragmatobia fuliginosa* L. (Descoins and Frérot, 1984), and the noctuid *Mocis latipes* Gn. (Descoins et al., 1986). To our knowledge, however, there has been only a single report of a monoepoxide analog of these dienes as a sex attractant or pheromone component; Descoins and Frérot (1984) reported 6*Z*-9*S*,10*R*-epoxy-21:H as a component of the sex pheromone of the ruby tiger moth, *Phragmatobia fuliginosa* L. (Lepidoptera: Arctiidae).

As an extension of our field screening of (Z,Z,Z)-3,6,9-trienes and the related monoepoxydienes, we have synthesized and field screened racemic and enantiomerically enriched forms of (Z)-6-*cis*-9,10- and (Z)-9-*cis*-6,7-epoxymonoenes with carbon chain lengths C_{17}–C_{21}. We report here: (1) the identification and optimization of sex attractants containing chiral or racemic monoene monoepoxides for four species of noctuid and geometrid moths; (2) the tentative identification by coupled gas chromatography–mass spectrometry with selected ion monitoring of 6Z,9Z-19:H and *cis*-monoepoxynonadecenes from insect pheromone gland extracts; and (3) the identification of behavioral antagonists which suppress attraction to otherwise attractive lures.

METHODS AND MATERIALS

Insects and Electroantennography

Female moths were field collected with sweep nets or in black-light traps. Male moths were collected as described above or in sticky wing traps (Pherotech Inc., Vancouver, British Columbia) containing attractant lures. Field tests

were carried out in a mixed forest area approx. 100 km north of Saskatoon, Saskatchewan. Sticky wing traps, similar in design to Pherocon 1CP traps (Scentry Inc., Buckeye, Arizona) were used throughout. Traps were hung at heights of approx. 1.5 m, in randomized block design, with traps spaced at least 10 m apart. Survey traps were replicated twice, while specific experiments for a given insect were replicated three or four times.

Trap lures consisted of red rubber septa (#1780J07, Thomas Scientific, Philadelphia, Pennsylvania) loaded with hexane solutions of test compounds, followed by a few drops of a 10% acetone solution of the antioxidant butylated hydroxytoluene. Lure dosages are listed with the appropriate tables.

Summed trap captures were transformed $[(X + 1/2)^{1/2}]$ and subjected to analysis of variance. Treatments with zero trap captures overall were not included in the ANOVA, as the lack of variance within the treatment captures would violate an assumption of the ANOVA. The variances of the transformed data were tested for homogeneity with Bartlett's test (Sokal and Rohlf, 1981). Significantly different means were separated by Duncan's (1955) multiple range test.

Extracts of sex pheromone glands were made by immersion of excised female ovipositor tips in methylene chloride for 20 min. The resulting extracts were concentrated under a stream of N_2, and internal standards (heptadecane and tetracosane) were added. The extracts then were analyzed by coupled gas chromatography–electroantennogram detection (GC-EAD) as previously described (Millar et al., 1987) using a DB-1701 capillary column (30 m × 0.32 mm ID, J&W Scientific, Folsom California; temperature program: initial temperature 40°C, heat ballistically to 90°C, then 4°C/min to 240°C, He carrier gas) or gas chromatography–mass spectrometry. GC-MS analyses were carried out with a Finnigan 4000-E instrument interfaced to an Incos 2300 data system, in electron impact (70 eV) or chemical ionization (isobutane) modes. An Ultra-2 capillary column (50 m × 0.32 mm ID, Hewlett-Packard, Avondale, Pennsylvania) was used with helium carrier gas, programming from 40 to 150°C ballistically, then 4°C/min to 275°C, in on-column injection mode.

Synthetic Chemicals

The syntheses of the (*Z*,*Z*)-6,9-dienes (Underhill et al., 1983) and the geometric isomers of 6*Z*,9*Z*–19:H (Miller et al., 1990d) have been described previously. Samples of 3*Z*,9*Z*–19:H and 3*Z*,6*Z*–19:H were prepared by partial hydroboration of 3*Z*,6*Z*,9*Z*–19:H with 9-borabicyclononane (9-BBN) in refluxing THF, followed by protonolysis with propionic acid in diglyme at 160°C for 3 hr (Brown, 1975). The resulting mixture was separated cleanly into fractions containing monoenes, dienes, and unreacted triene by flash chromatography on 15% $AgNO_3$ on silica gel, eluting with 10% ether in hexane.

Glassware was oven-dried at 120°C and cooled under N_2. All reactions were run under a positive pressure of N_2. THF was distilled from sodium benzophenone ketyl, methylene chloride was distilled from CaH_2, and hexamethylphosphoric triamide (HMPA) was distilled from BaO under reduced pressure. Flash chromatography was performed with 230–400 mesh silica gel (Terochem Laboratories, Edmonton, Alberta). Proton NMR spectra were obtained with a Bruker WM-360 wide-bore instrument, operating at 360 MHz. Infrared spectra were recorded with a Perkin-Elmer 237-B instrument, using neat films on NaCl plates. Mass spectra (EI, 70 eV) were obtained as described above and are reported as *m/z* (relative intensity). Optical rotations were measured with a Perkin-Elmer 141 polarimeter, in a 1-d, 1 ml cell.

Synthesis of (Z)-6-cis-9,10-Monoene Epoxides

2,5-Undecadiyn-1-ol (3). To a solution of 2-octyn-1-ol **1** (6.3 g, 50 mmol) and tosyl chloride (10.1 g, 53 mmol) in dry ether (150 ml) at −10°C was added in portions over 15 min powdered KOH (250 mmol) (Brandsma, 1971). The resulting slurry was stirred 30 min at 0°C, then poured into ice-water (200 ml). The layers were separated, and the aqueous layer was extracted with ether (2 × 50 ml). The combined ether layers were washed with brine, dried (Na_2SO_4), concentrated, and pumped under vacuum (0.1 torr) to remove traces of solvent. The crude tosylate **2** (13.2 g, 94%) was used without further purification.

Ethylmagnesium bromide (approx. 300 mmol) was prepared from Mg turnings (7.3 g, 300 mmol) and ethyl bromide (34 g, 312 mmol) in THF (250 ml). 2-Propyn-1-ol (8.4 g, 150 mmol) was added dropwise over 1 hr, maintaining the temperature <30°C. The resulting slurry was stirred at 20°C for 2.5 hr, then cooled to 0°C, and CuI (380 mg, 2 mmol) was added. Tosylate **2** (13.2 g, 47 mmol) in THF (20 ml) was added dropwise, and the mixture was allowed to warm to 20°C, then heated at 60°C for 24 hr. The mixture was cooled and poured into 10% aqueous NH_4Cl (300 ml), and extracted with ether (1 × 200 ml, 2 × 100 ml). The combined ether layers were washed with brine, dried (Na_2SO_4), concentrated, and distilled, giving diynol **3** (6.53 g, 84%), bp 96–101°C (0.16 torr), lit, bp 100°C (0.09 torr) (Eiter et al., 1978), as a colorless oil, which yellowed on contact with air. Spectral data matched those previously reported (Eiter et al., 1978).

(Z,Z)-2,5-Undecadien-1-ol (4). A solution of P-2 nickel catalyst (Brown and Ahuja, 1973) was prepared by addition of 7.2 ml of a 1 M solution of $NaBH_4$ in EtOH to a solution of $Ni(OAc)_2 \cdot 4H_2O$ (1.79 g, 7.2 mmol) in 95% EtOH (100 ml), while flushing the reaction flask with N_2. When the effervescence subsided, the flash was flushed with H_2, and ethylene diamine (0.96 ml,

14.4 mmol) was added. The mixture was stirred 10 min, then diynol **3** (5.93 g, 36 mmol) was added, and the flask was maintained under a slight positive pressure of H_2 until the reduction was complete ($\simeq$6 hr.) The mixture then was filtered through a 1-cm pad of activated charcoal, rinsing the charcoal well with ethanol, and the filtrate was concentrated. The concentrate was taken up in ether (100 ml), washed with 1 M HCl (50 ml) and brine, dried (Na_2SO_4), and concentrated again. The crude dienol was flash chromatographed on silica, eluting with 20% EtOAc in hexane, giving the pure dienol **4** (4.5 g, 74%). The dienol has been previously described only in communications (Gleason et al., 1980; Mills and North, 1983) with no spectral details reported. [^{1}H]NMR ($CDCl_3$): δ 5.60 (dtt, 1H, J = 10.8, 6.6,1.5 Hz, H-2), 5.51 (dtt, 1H, J = 10.8, 7.2, 1.3 Hz, H-3), 5.40 (dtt, 1H, J = 10.7, 7.2, 1.5 Hz, H-5), 5.30 (dtt, 1H, J = 10.7, 7.2, 1.5 Hz, H-6), 4.21 (br. dd, 2H, J = 5, 5 Hz, H-1), 2.81 (m, 2H, H-4), 2.03 (m, 2H, H-7), 1.4–1.2 (m, 6H, H-8 to H-10), 0.87 (t, 3H, J = 6.8 Hz, H-11). IR (neat) λ_{max}: 3600–3100 (br. s), 3020 (m), 2965 (s), 2940 (s), 2865 (s), 1020 (br. s) cm^{-1}. MS: 168 (M^+, trace), 150 (9.8), 121 (2.2), 107 (4.1), 95 (9.9), 93 (28.6), 91 (16.4), 83 (17.5), 81 (24.3), 80 (83.6), 79 (100), 77 (26.2), 70 (46.4), 67 (55.9), 57 (28.7), 55 (71.8), 54 (35.3), 43 (31.9).

(Z)-cis-*2,3-Epoxy-undec-5-en-l-ols (5).* To 30 ml of CH_2Cl_2 (dried over CaH_2) at $-$ 25°C was added sequentially at 20-min intervals with vigorous stirring titanium isopropoxide (3.0 ml, 10 mmol), (−)-diisopropyl tartrate (2.6 ml, 12 mmol), dienol **4** (1.73 g, 10.3 mmol), and *t*-butyl hydroperoxide (4.16 M solution in CH_2Cl_2; 5 ml, 20.8 mmol). The solution was sealed and stirred at −25°C for one week. The mixture then was worked up by addition of 10% aqueous tartaric acid (25 ml) dropwise over 2 hr, maintaining the temperature at −23°C in a CCl_4/Dry Ice slush bath. The mixture was warmed to 20°C, and stirred until the aqueous layer was clear. The layers were separated, and the aqueous layer was extracted with CH_2Cl_2 (2 × 20 ml). The combined CH_2Cl_2 layers were cooled to 0°C, 10% aqueous Na_2SO_3 (25 ml) was added dropwise, and the mixture was warmed to 20°C and stirred overnight, to decompose excess *t*-butyl hydroperoxide. The layers were separated, the aqueous phase was extracted again with CH_2Cl_2 (2 × 20 ml), and the combined organic extracts were concentrated. The concentrate was taken up in ether (100 ml), cooled to 0°C, 2 N NaOH (150 ml) was added, and the mixture was stirred until all the diisopropyl tartrate had been hydrolyzed ($\simeq$1 hr). The layers were separated, the aqueous phase was extracted with ether (2 × 25 ml), and the combined ethereal extracts were washed with brine, dried (Na_2SO_4), concentrated, and flash chromatographed on silica (4 cm ID × 20 cm), eluting with 30% EtOAc in hexane. (2*R*,3*S*)-Epoxy alcohol **5** was obtained as a clear oil (1.71 g, 90%), $[\alpha]_D^{24}$ = +10.6° (c = 6.32, CH_2Cl_2), lit. $[\alpha]_D^{20}$ = +11° (c = 2.60, CCl_4)

(Rollin and Pougny, 1986). Spectral data were entirely analogous to those previously reported (Rollin and Pougny, 1986).

(2*S*,2*R*)-**5** was obtained in 76% yield by the same procedure, except that (+)-diisopropyl tartrate was used in the formation of the chiral catalyst; $[\alpha]_D^{24} = -10.9°$ (c = 9.72, CH_2Cl_2), lit. $[\alpha]_D^{25} = -10.2°$ (c 1.5, $CHCl_3$) (Mills and North, 1983).

The enantiomeric excesses of the two enantiomers of **5** were checked by formation of diastereomeric derivatives (Slessor et al., 1985). Thus, (*S*)-2-acetoxypropionyl chloride (20 μl) was added to a solution of epoxy alcohol **5** (10 μl) and pyridine (50 μl) in ether (1 ml), and the mixture was stirred 1 hr. The supernatant was pipetted off, washed with water, and dried (Na_2SO_4). The resulting derivatives were gas chromatographed isothermally on a DB-210 capillary column (30 m × 0.25 mm) at 180°C. Baseline separation of the diastereomers was obtained. (2*R*,3*S*)-**5**: ee = 85.7%; (2*S*,3*R*)-**5**: ee = 88.1%.

(Z)-1-Iodo-2,3-epoxy-undec-5-enes (6). Iodine (2.16 g, 8.5 mmol) was added to a ice-bath-cooled solution of triphenylphosphine (2.23 g, 8.5 mmol) and imidazole (0.58 g, 8.5 mmol) in ether–CH_3CN, 3 : 1 (30 ml), and the resulting slurry was stirred briskly until it was a uniform bright yellow color. (2*R*,3*S*)-epoxy alcohol **5** (1.53 g, 8.3 mmol) was added in one portion, and the mixture was stirred 1 hr, allowing the mixture to warm to 20°C. Pentane (125 ml) then was added, and the mixture was stirred a further 10 min. The top layer was decanted off, and the gummy bottom layer was triturated with pentane (2 × 25 ml). The combined pentane extracts were washed with 1 M $Na_2S_2O_3$, dried (Na_2SO_4), concentrated, and flash chromatographed on silica (4 cm ID × 20 cm), eluting with 6% ether in pentane. The (2*S*,3*S*) iodide **6** (2.43 g, 83%) was obtained as a pale yellow oil, $[\alpha]_D^{22} = -32.9°$ (c = 15.35, CH_2Cl_2). [^{1}H]NMR ($CDCl_3$): δ 5.54 (dtt, 1H, J = 10.7, 7.2, 1.4 Hz, H-6), 5.44 (dtt, 1H, J = 10.7, 7.2, 1.4 Hz, H-5), 3.32 (m, 2H, H-1), 3.05 (m, 2H, H-2 and H-3), 2.29 (m, 2H, H-4), 2.04 (dt, 2H, J = 7.2, 7.0 Hz, H-7), 1.5–1.2 (m, 6H, H-8 to H-10), 0.88 (t, 3H, J = 6.8 Hz, H-11). IR (neat): λ_{max} 3020 (m), 2965 (s), 2935 (s), 2865, (s), 1450 (s), 1265 (m), 1160 (m) cm^{-1}. MS (CI, isobutane): m/z 295 (M + 1). MS (EI): 223 (M-71, 0.6), 183 (4.5), 155 (5.4), 127 (2.3), 123 (3.7), 111 (9.7), 99 (7.6), 95 (8.2), 93 (7.2), 83 (15.7), 81 (35.4), 79 (16.0), 69 (47.1), 67 (62.5), 57 (55.2), 55 (100), 43 (32.2).

(2*R*,3*R*)-**6** was obtained in 80% yield by the same procedure, $[\alpha]_D^{22} = +31.9°$ (c = 4.45, CH_2Cl_2), from 2*S*,3*R*-**5**.

(Z)-cis-9,10-Epoxyalk-6-enes (7) {IUPAC Names, [2α(Z),3α]-2-(2-Octenyl)-3-alkyloxiranes}. The following procedure describes the synthesis of (9*S*,10*R*)-**7a** from (2*S*,3*S*)-**6**. The syntheses of (9*S*,10*R*)-**7b–e** were performed under identical conditions, using the appropriate dialkyl lithium cuprate reagents. The syntheses of the (9*R*,10*S*)-**7a–e** series were carried out in similar fashion, using (2*R*,3*R*)-**6**.

A solution of hexylmagnesium bromide ($\simeq$ 1.5 mmol), prepared from hexyl

bromide (248 mg, 1.5 mmol) and Mg turnings (49 mg, 2 mmol) in THF (2.5 ml), was added dropwise by syringe to a mixture of (2*S*,3*S*)-**6** (200 mg, 0.68 mmol) and CuI (20 mg, 0.11 mmol) in THF–HMPA (3:1, 2.4 ml) maintained at −23°C in a CCl_4–Dry Ice slush bath. The reaction was stirred 20 min, then quenched by addition of sat. aq. NH_4Cl (1 ml). The mixture was poured into water (10 ml) and extracted with ether (3 × 5 ml). The combined ether extracts were backwashed with water and brine, dried (Na_2SO_4), concentrated, and flash chromatographed on silica gel impregnated with $AgNO_3$ (7.5%; 1 cm ID × 20 cm), eluting with 3% ether in pentane. Final purification was achieved by Kugelrohr distillation (0.1 torr, oven temp. ≃ 150°C) to remove traces of solvent and chromatographic packing material, yielding (9*S*,10*R*)-**7a** as a clear oil (96 mg, 56%), $[\alpha]_D^{21} = +3.2°$ (c = 2.29, CH_2Cl_2).

The [^{1}H]NMR spectrum of (9*S*,10*R*)-**7a** was entirely comparable to those of the previously reported analogs, (6*Z*,9*S*,10*R*)-epoxyheneicosene and (6*Z*,9*S*,10*R*)-epoxypentadecene (Rollin and Pougny, 1986). The IR spectrum also matched those reported for the analogs; in addition to the previously reported IR absorbtions, we also noted a sharp, medium intensity band at 3020 cm^{-1} (olefinic C-H stretch). MS: 252 (M+, trace), 243 (0.1), 223 (0.1), 209 (0.3), 195 (0.6), 181 (1.9), 167 (1.3), 153 (2.10, 141 (2.0), 139 (1.8), 127 (3.6), 124 (5.0), 113 (9.2), 110 (14.5), 97 (17.6), 96 (13.9), 95 (27.0), 83 (39.8), 82 (33.8), 81 (57.0), 69 (83.0), 68 (62.0), 67 (76.5), 57 (75.30, 55 (100), 54 (88.1), 43 (62.2).

The mass spectra of the higher homologs **7b–e** were characterized by very low intensity molecular ions, a weak M-18 ion, and a series of ions of *m/z* M-29, M-43, ... , M-99. The mass spectra in the mass range *m/z* 43–130 were virtually identical to that of **7a**. There were diagnostic fragments at *m/z* 110 $(C_4H_9CH{=}CH{-}CH{=}CH_2)^+$ and 124 $(C_5H_{11}CH{=}CH{-}CH{=}CH_2)^+$ from cleavage and rearrangement of the epoxide, and at *m/z* 153, from simple cleavage α to the epoxide.

Optical rotations of (9*S*,10*R*) series: **7b** $[\alpha]_D^{21} = +2.7°$ (c = 1.97, CH_2Cl_2); **7c** $[\alpha]_D^{21} = +2.6°$ (c = 0.86, CH_2Cl_2); **7d**, $[\alpha]_D^{21} = +2.6°$ (c = 2.22, CH_2Cl_2); **7e** $[\alpha]_D^{21} = +2.5°$ (c = 1.32, CH_2Cl_2).

(9*R*,10*S*) series: **7a**, $[\alpha]_D^{21} = -1.1°$ (c = 0.44, CH_2Cl_2); **7b**, $[\alpha]_D^{21} = -2.7°$ (c = 2.08, CH_2Cl_2); **7c**, $[\alpha]_D^{21} = -2.7°$ (c = 2.52, CH_2Cl_2); **7d**, $[\alpha]_D^{21} = -2.2°$ (c = 2.35, CH_2Cl_2); **7e**, $[\alpha]_D^{21} = -2.3°$ (c = 2.15, CH_2Cl_2).

Synthesis of (Z)*-cis-6,7-mon-9-ene epoxides (14)* {*IUPAC Names, [2α,3α(Z)]-2-pentyl-3-(2-alkenyl)oxiranes*}

(Z)*-2-octen-1-ol (8).* 2-Octyn-1-ol **2** was reduced with 2.5 mmol of P-2 nickel catalyst, prepared as described above in the synthesis of **4**. The crude product was distilled, giving (Z)-2-octen-1-ol **8** (5.02 g, 78%), bp 89–91°C (12 torr); lit bp 98–102°C (10–15 torr) (Osbond, 1961).

*cis-2,3-Epoxy-octan-1-ols (**9**).* The recently reported modification of the Sharpless asymmetric epoxidation method,[1] using molecular sieves, was attempted. Thus powdered 4 Å molecular sieves (5 g, freshly activated) were added to CH_2Cl_2 (40 ml) at −23°C (CCl_4–Dry Ice slush bath). To this mixture was added sequentially at 20-min intervals titanium isopropoxide (0.6 ml, 2.0 mmol), (+)-diisopropyl tartrate (0.54 ml, 2.5 mmol), alcohol **8** (2.45 g, 19.4 mmol), and *t*-butyl hydroperoxide (4.75 M in CH_2Cl_2; 8.5 ml, 40 mmol). The mixture was stirred at −25°C for 40 hr. The reaction was worked up by addition of aq. tartaric acid (10%, 10 ml) over 1 hr, while stirring vigorously and maintaining the temperature at −23°C. Stirring at this temperature was continued for 1 hr, then the mixture was allowed to warm to 20°C, and stirred another 2 hr. The mixture then was filtered with suction through a bed of Celite (4 cm). The layers were separated and the aqueous phase was reextracted with CH_2Cl_2 (2 × 10 ml). The combined CH_2Cl_2 extracts were cooled to 0°C, and aq. Na_2SO_3 (1.3 g in 10 ml H_2O) was added dropwise over 30 min. The resulting mixture was warmed to 20°C and stirred overnight. The layers were separated, and the aq. phase was extracted again with CH_2Cl_2 (2 × 10 ml). The combined organic extracts were washed with brine, dried (Na_2SO_4), concentrated, and flash chromatographed on silica gel (4 cm ID × 20 cm), eluting with 30% EtOAc in hexane, yielding (2*S*,3*R*)-**9** (1.73 g, 62%), $[\alpha]_D^{21} = -5.42°$ (c = 9.08, CH_2Cl_2). [^{1}H]NMR ($CDCl_3$): δ 3.83 (ddd, 1H, *J* = 12.0, 7.3, 4.1 Hz, H-1), 3.66 (ddd, 1H, *J* = 12.0, 6.8, 4.8 Hz, H-1′), 3.13 (dt, 1H, *J* = 6.8, 4.2 Hz, H-3), 3.01 (m, 1H, H-20, 1.67 (dd, 1H, *J* = 7.3, 4.8 Hz, OH), 1.67–1.25 (m, 8H, H-4 to H-7), 0.88 (br. t, 3H, *J* ≃ 7 Hz, H-8). IR (neat): 3600–3100 (br. s), 2965 (s), 2940 (s), 2965 (s), 1460 (m), 1380 (w), 1040 (s) cm^{-1}. MS: 113 (0.2, M-31), 95 (0.8), 84 (2.5), 83 (37.7), 71 (3.6), 69 (5.2), 67 (3.1), 61 (4.2), 57 (28.2), 56 (18.0), 55 (100), 45 (17.2), 43 (73.8).

The enantiomeric excess was determined by formation of diastereomeric derivatives of the alcohol with (*S*)-2-acetoxypropionyl chloride (Slessor et al., 1985), as described above for compounds **6**. Baseline separation of the derivatives was obtained on a DB-210 capillary column (30 m × 0.25 mm) operated isothermally at 150°C. Ee of (2*S*,3*R*)-**9**: 74.6%.

The (2*R*,3*S*) enantiomer was prepared concurrently in similar fashion in 75% yield, using (−)-diisopropyl tartrate in the asymmetric epoxidation step; $[\alpha]_D^{21} = +5.61°$ (c = 9.65, CH_2Cl_2), ee 76.1%. Mass, NMR, and IR spectra were satisfactory. The (2*R*,3*S*) enantiomer has been previously reported in a communication (Nicolau and Webber, 1985).

*1-Iodo-cis-2,3-epoxy-octanes **10**.* The iodides **10** were prepared exactly as described above for the iodides **6**. The purified products were also vacuum

[1] Referred to in an Aldrich Chemical Co. advertisement on the back cover of *J. Org. Chem. 50*(25), 1985; R.M. Hanson, S.Y. Ko, J.M. Chang, and K.B. Sharpless, unpublished results.

distilled, Kugelrohr over temperature 75°C (0.1 torr), yielding, for example (2*R*,3*R*)-**10** (2.38 g, 88%), $[\alpha]_D^{21}$ = +35.3° (c = 9.41, CH_2Cl_2). [^{1}H]NMR($CDCl_3$): δ 3.29 (m, 2H, H-1), 3.05 (m, 1H, H-3), 2.98 (m, 1H, H-2) 1.6–1.4 (m, 4H, H-4 and H-5), 1.38-1.27 (m, 4H, H-6 and H-7), 0.89 (t, 3H, *J* = 7.0 Hz, H-8). IR (neat): 2965 cm (s), 2935 (s), 2870(s), 1460 (s), 1380 (m), 1265 (m), 1165 (s) cm^{-1}. MS: 254 (0.2), 183 (1.0), 171 (1.5), 155 (4.3), 141 (2.4), 127 (56.7), 83 (73.3), 57 (100), 55 (96.5), 43 (75.2). Isobutane CI-MS: *m/z* 255 (M + 1).

The (2*S*,3*S*) enantiomer was prepared in identical fashion in 92% yield, $[\alpha]_D^{21}$ = −36.5 (c = 6.26, CH_2Cl_2). Mass, NMR, and IR spectra were satisfactory.

(Z)-cis-*6,7-epoxyalk-9-enes 14.* The alkenyl bromides **12a–e** were prepared from 1-alkynes **11**, exactly as previously described (Millar and Underhill, 1986).

The following procedure describes the synthesis of (6*R*,7*S*)-**14a** from (2*R*,3*R*)-epoxyiodide **10**. The syntheses of (6*R*,7*S*)-**14b–e** were performed under identical conditions, using the appropriate alkenyl Grignard reagents **13b–e**. The syntheses of the (6*S*,7*R*)-**14a–e** series were carried out in similar fashion, using (2*S*,3*S*)-**10**.

Grignard reagent **13a** was prepared by slow addition of (*Z*)-1-bromonon-1-ene **12a** (620 mg, 3.0 mmol) to Mg turnings (120 mg, 5 mmol) in THF (6 ml) at 20°C, and stirring for 2 hr. The Grignard solution was added dropwise over 10 min to a stirred solution of (2*S*,3*S*)-**10** (381 mg, 1.5 mmol), CuI (29 mg, 0.15 mmol), and HMPA (1.4 ml, 6 mmol) in THF (2 ml) at −23°C (CCl_4–Dry Ice slush bath). The resulting mixture was stirred for 30 min at −23°C, then poured into 10% aq. NH_4Cl (25 ml), and extracted with hexane (1 × 25, 2 × 10 ml). The combined hexane extracts were washed with water and brine, dried (Na_2SO_4), and filtered with suction through a plug of silica gel (4 cm), rising the silica well with ether. The filtrate was concentrated and flash chromatographed on $AgNO_3$-impregnated silica gel (7.5%; 2 cm ID × 20 cm), eluting with 2.5% ether in hexane. The purified compound was then freed from traces of column packing by vacuum distillation, Kugelrohr oven temperature 140°C (0.05 Torr), yielding (6*R*,7*S*)-**14a** (228 mg, 60%), $[\alpha]_D^{24}$ = +2.86° (c = 1.99, CH_2Cl_2). [^{1}H]NMR($CDCl_3$): δ 5.51 (dtt, 1H, *J* = 10.8, 7.8, 1.2 Hz, H-10), 5.40 (dtt, 1H, *J* = 10.8, 7,2, 1.2 Hz, H-9), 2.91 (m, 2H, H-6 and H-7), 2.45 (m, 1H, H-8), 2.36 (m, 1H, H-8′), 2.02 (br. dt, 2H, *J* = 6.8, 6.8 Hz, H-11), 1.5–1.2 (m, 10H, H-12 to H-16), 0.88 (m, 6H, H-1 and H-17). IR (neat): 3920 (m), 2970 (s), 2935 (s), 2865 (m), 1460 (m), 1380 (m) cm^{-1}. MS: 252 (0.2, M^+), 234 (0.4), 209 (0.4), 196 (0.3), 195 (0.2), 181 (1.4), 167 (1.3), 153 (2.1), 141 (2.9), 138 (3.2), 123 (2.4), 113 (6.50, 110 (8.0), 99 (15.40, 97 (14.6), 96 (15.10, 95 (16.10, 83 (32.6), 81 (33.1), 71 (19.60, 69 (38.7), 68 (36.8), 67 (52.2), 57 (40.50, 55 (92.2), 54 (50.9), 43 (100).

The mass spectra of **14b–e** were characterized by small but distinct ions at M^+, M-18, M-43, M-56, M-111, M-142, and *m/z* 113. The mass spectra were otherwise very similar to that of **14a**. NMR and IR spectra were all satisfactory.

Optical rotations of 6*R*,7*S* series. **14b**, $[\alpha]_D^{24} = +2.51°$ (c = 1.95, CH_2Cl_2); **14c** $[\alpha]_D^{24} = +2.34°$ (c = 1.97, CH_2Cl_2); **14d**, $[\alpha]_D^{24} = +2.32°$ (c = 1.99, CH_2Cl_2); **14e**, $[\alpha]_D^{24} = +1.78°$ (c = 2.08, CH_2Cl_2). (6*S*,7*R*) series: **14a**, $[\alpha]_D^{24} = -2.83°$ (c = 0.92, CH_2Cl_2); **14b**, $[\alpha]_D^{24} = +2.45°$ (c = 1.68, CH_2Cl_2); **14c**, $[\alpha]_D^{24} = +2.35°$ (c = 2.04, CH_2Cl_2); **14d**, $[\alpha]_D^{24} = +1.92°$ (c = 1.98, CH_2Cl_2); **14e** $[\alpha]_D^{24} = +2.12°$ (c = 2.03, CH_2Cl_2).

RESULTS

Euchlaena madusaria Walker. Male *E. madusaria* moths were first caught in 1985. Traps baited with 6*Z-cis*-9,10-epoxy-19:H (replicated three times, 500 μg dosage) caught 89 specimens, while the corresponding traps baited with 9*Z-cis*-6,7-epoxy-19:H, the combined monoepoxide mixture from nonspecific monoepoxidation of 6*Z*,9*Z*–19:H or 6*Z*, 9*Z*-19:H caught no moths. This experiment conclusively demonstrated that 6*Z-cis*-9,10-epoxy-19:H was an attractant for this species, and that the 9*Z-cis*-6,7 regioisomer was antagonistic, as the mixture of monoepoxides caught no moths.

Pheromone gland extracts (one, two, and three female equivalents) from field-collected female moths were analyzed by coupled gas chromatography–electroantennogram detection (GC-EAD) using a DB-1701 column. Male antennae consistently responded to a compound at the retention time of 6*Z-cis*-9,10-epoxy-19:H with a weaker response to a compound at the retention time of 6*Z*,9*Z*–19:H. On this column, 6*Z-cis*-9,10-epoxy-19:H was separated cleanly from the 9*Z-cis*-6,7-epoxy-19:H regioisomer, and a standard sample composed of 3*Z*,6*Z*–19:H, 3*Z*,9*Z*–19:H, and 6*Z*,9*Z*–19:H gave three clearly resolved peaks (relative retention times versus heptadecane: 6*Z*,9*Z*–19:H, 1.226; other two isomers, 1.236 and 1.251) providing additional proof of the position of the double bond. It had been demonstrated previously that all the geometric isomers of 6,9-nonadecadiene also were resolved cleanly under the standard GC-EAD conditions (Millar et al., 1990d).

A pheromone gland extract from two females was analyzed by coupled gas chromatography–mass spectrometry (GC-MS) using an Ultra-2 capillary column, in selected ion mode, with isobutane chemical ionization (CI). A perfect retention time match, and a good ion ratios fit with three ions was obtained for 6*Z*,9*Z*–19:H vs. a 400 pg standard [standard, *m/z* (rel. abundance): 264 (100 M^+), 263 (87, M-1), 155 (11); unknown from insect extract: *m/z* 264 (100), 263 (96), 155 (13)]. The corresponding monoepoxide was not detected.

A field test in 1986 (replicated three times) indicated that *E. madusaria* males were not attracted to either enantiomer of 6*Z*-*cis*-9,10-epoxy-19:H (one moth caught in traps with 9*R*,10*S* enantiomer; 0 moths with 9*S*,10*R* enantiomer), while the racemate was highly attractive (136 moths caught).

Further field tests demonstrated that *E. madusaria* males were optimally attracted to mixtures of the enantiomers of 6*Z*-*cis*-9,10-epoxy-19:H (Table 1), with the most attractive lures containing a 1:1 or 4:1 blend of the (9*S*,10*R*) and (9*R*,10*S*) enantiomers, respectively.

Finally, in an experiment run late in the flight season of this moth, traps (replicated three times) baited with a 4:1 blend of 6*Z*-*cis*-9,10-epoxy-19:H–6*Z*,9*Z*-19:H caught significantly more moths (23 specimens) than traps baited with 6*Z*-*cis*-9,10-epoxy-19:H alone (five specimens), suggesting that 6*Z*,9*Z*-19:H may potentiate the response to the epoxide.

Xanthotype sospeta Drury. This species is sympatric with and has approximately the same flight season as *E. madusaria*. A preliminary field test indicated that the *X. sospeta* males were selectively attracted by 6*Z*-9*S*,10*R*-epoxy-19:H, as traps (replicated three times) containing this compound caught 17 specimens, while the corresponding traps containing the opposite enantiomer or the racemate caught none. This selectivity was confirmed in further field tests (Table 1), wherein only traps containing a high proportion of the 9*S*,10*R* enantiomer caught moths. Thus, the data suggest that 6*Z*-9*S*,10*R*-epoxy-19:H is a powerful attractant for this species, and that the (9*R*,10*S*) enantiomer antagonizes the attractive response.

Palthis angulalis Hübner. Males of this species were first captured in 1984

[a] Enantiomeric excess of 6*Z*-9*R*,10*S*-epoxy-19:H, 88.1%, 6*Z*-9*S*,10*R*-epoxy-19:H, ee 85.7%.
[b] Traps replicated three times. Traps were set out from June 26 to July 16, 1986. Trap captures followed by the same letter are not significantly different ($P > 0.05$).

in several traps containing the combined monoepoxides mixture from nonspecific oxidation of 6*Z*,9*Z*–19 : H as the major component (up to 22 moths caught/lure). A 1985 field experiment (replicated three times) indicated that the 9*Z*-*cis*-6,7-regioisomer was the attractive component, as traps containing this compound (250 μg) caught 16 specimens, while traps containing the 6*Z*-*cis*-9,10-regioisomer (250 μg) caught none. In addition, traps containing the combined monoepoxides mixture (500 μg) caught 16 specimens, indicating that the 9*Z*-*cis*-6,7-19 : H regioisomer was not antagonistic.

An experiment in 1986 demonstrated that 9*Z*-6*S*,7*R*-epoxy-19 : H was the more attractive enantiomer, as traps (N = 3) containing this compound (250 μg) caught 39 specimens, while the corresponding traps containing 9*Z*-6*Z*,7*S*-epoxy-19 : H (250 μg) caught one specimen.

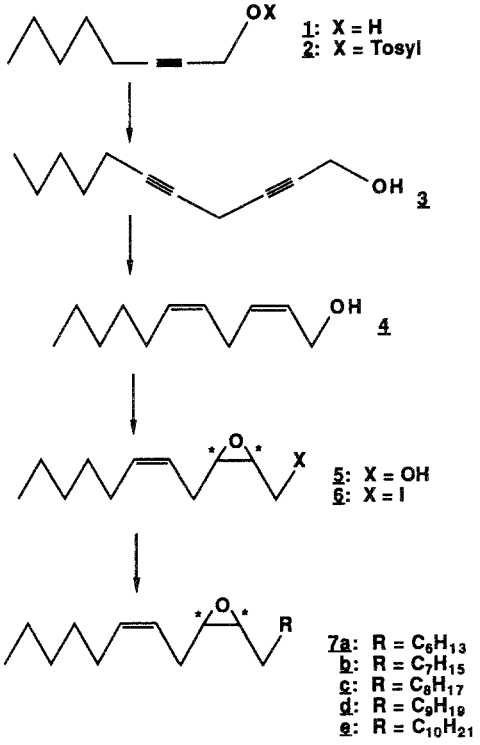
Anacamptodes humaria Guenée. A number of specimens of *A. humaria* (37) were caught in 1986 field survey traps (replicated twice) containing a 1 : 1 blend of 9*Z*-6*R*,7*S*-epoxy-19 : H (250 μg) with 6*Z*,9*Z*–19 : H (250 μg). The corresponding traps containing the opposite enantiomer (6*S*,7*R*) in combination with 6*Z*,9*Z*–19 : H caught no moths. When present as a single component, 9*Z*-6*R*,7*S*-epoxy-19 : H caught 10 specimens, while the corresponding traps containing either 9*Z*-6*S*,7*R*-epoxy-19 : H, 6*Z*,9*Z*–19 : H, or 9*Z*-*cis*-6,7-epoxy-19 : H as single components caught no moths.

6*Z*,9*Z*–19 : H and 9*Z*-*cis*-6,7-epoxy-19 : H were tentatively identified by selected ion monitoring (SIM) GC-MS analysis of the pheromone gland extract from three field-collected female moths on an Ultra-2-capillary column. Perfect retention time and good ion ratios matches were made for 6*Z*,9*Z*–19 : H [400 pg standard, *m*/*z* 264 (89, M^+), 263 (100, M-1), 155 (14); unknown from insect extract: 264 (100), 263 (95), 155 (14)] and 9*Z*-*cis*-6,7-epoxy-19 : H [standard, *m*/*z* 281 (100, M + 1), 279 (4, M-1), 263 (22, M + 1-18), 155 (1); unknown from insect extract: 281 (100), 279 (4), 263 (22), 155 (0)]. The lack of a sizable ion at *m*/*z* 155 was significant, as the 6*Z*-*cis*-9,10-epoxy-19 : H regioisomer, which has a retention time very similar to that of 9*Z*-*cis*-6,7-epoxy-19 : H, has a strong diagnostic ion at *m*/*z* 155 (40% of the *m*/*z* 281 base peak). Thus, the field data and the analyses of pheromone gland extracts both implicate 9*Z*-6*R*,7*S*-epoxy-19 : H and 6*Z*,9*Z*–19 : H as sex pheromone components of this species.

Synthesis. The (*Z*)-*cis*-9,10-epoxymono-6-enes were prepared by the route outlined in Scheme 1. This route was similar to those which had been used to synthesize the enantiomerically enriched forms of the analogous (*Z*,*Z*)-3-6-*cis*-9,10-epoxydienes (Mori and Ebata, 1981, 1986; Wong et al., 1985). The stoichiometric version of the Sharpless asymmetric epoxidation was used (Katsuki and Sharpless, 1980), resulting in enantiomeric excesses of approximately 88%. The enantiomeric excesses of the resulting epoxy alcohols **5** were determined by esterification of the alcohols with (2*S*)-2-acetoxypropionyl chloride (Slessor et al., 1985), and separation of the resulting diastereomeric derivatives by cap-

illary GC on a DB-210 column. The epoxyalcohols **5** were converted to iodides **6** (Garegg and Samuelsson, 1980; Corey et al., 1983), and the syntheses were completed by the dropwise addition of a THF solution of the appropriate alkylmagnesium bromide (2 equiv) to a cooled (−23°C) slurry of iodide (1 equiv), CuI (0.1 equiv), and HMPA (4 equiv) (Millar and Underhill, 1986; Nicolaou et al., 1984). The epoxides **7** were obtained in approx. 25% overall yield from 2-octyn-1-ol **1**. The reaction was sensitive to conditions (Nicolaou et al., 1984), as attempted alkylation of the iodides in ether by addition of dialkyllithium cuprates, as had been reported for 1-tosyloxy-2,3-epoxyalkenes (Mori and Ebata, 1981, 1986; Wong et al., 1985) gave almost exclusively the rearrangement product (*Z*)-1,5-undecadien-3-ol.

The synthetic route to the enantiomerically enriched forms of the (*Z*)-*cis*-6,7-epoxymono-9-enes was similar to that which we had used in the synthesis of the analogous (*Z*,*Z*)-3,9-*cis*-6.7-epoxydienes (Millar and Underhill, 1986), as shown in Scheme 2. However, the catalytic modification of the key Sharpless asymmetric epoxidation step using powdered molecular sieve (Hanson and



SCHEME 1

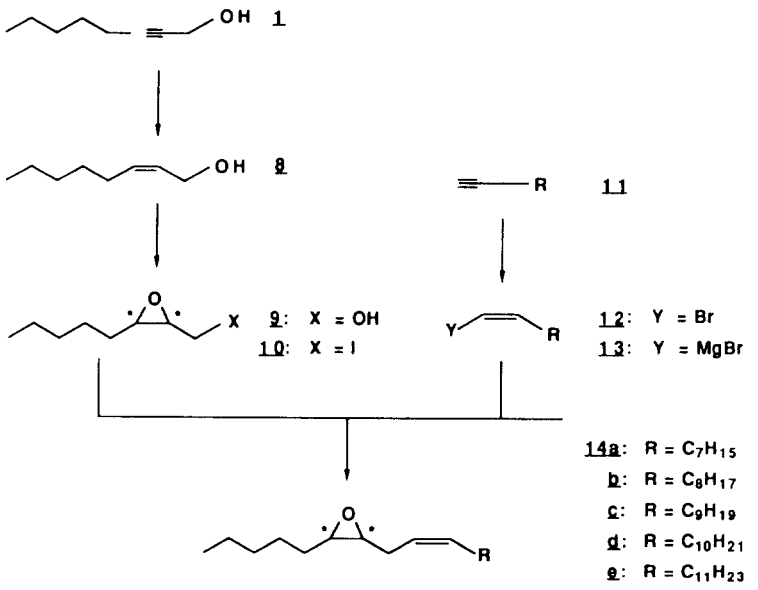
Sharpless, 1986), the details of which were at the time unpublished (see footnote 1, p. 917) was tried, resulting in a much faster reaction but with a somewhat lower enantiomeric excess (approx. 75% ee).

The epoxy alcohols were subsequently converted to the (Z)-*cis*-6,7-epoxymono-9-enes according to the previously reported methods used in synthesizing the epoxydiene analogs (Millar and Underhill, 1986). Overall yields were approximately 25%.

DISCUSSION

In parallel with the increasing number of identifications of pheromones and sex attractants that are derived from epoxidation of (Z,Z,Z)-3,6,9-trienes, it was reasonable to expect that there may be analogous sets of monounsaturated monoepoxides with sex attractant activity. The work reported here confirms this expectation.

The identification of 9Z-6*S*,7*R*-epoxy-19:H as a sex attractant for the noctuid species *P. angulalis* is the first report of a (Z)-*cis*-6,7-epoxymono-9-ene as an insect sex attractant. It was to be expected that compounds such as these would be identified eventually as sex attractants and pheromones, as the cor-



SCHEME 2

responding (*Z*,*Z*)-6,9-dienes and analogous diene monoepoxides had been reported from a number of lepidopteran species (references in Introduction).

To our knowledge, this is the second report of (*Z*)-*cis*-9,10-epoxymono-6-enes as sex attractants and possible sex pheromone components for geometrid moth species; 6*Z*-*cis*-9,10-epoxy-21:H has been reported as an attractant for the geometrid *Caustoloma flavicaria* L. (Kovalev and Nikolaeva, 1986). The same compound has been identified as a sex pheromone component for the arctiid moth *Phragmatobia fuliginosa* L. (Descoins and Frérot, 1984), and the chirality of the epoxide was presumed to be 9*S*,10*R* based on electroantennographic responses to the analogous 3*Z*,6*Z*-9*S*,10*R*-epoxy-21:H (Rollin and Pougny, 1986).

The biologically active compounds described here were discovered by field screening of potential attractants and optimized using information from GC-EAD analyses of standard mixtures and of pheromone gland extracts. There are several clear indications of the intricate balance of attraction and behavioral antagonism, with the chirality of the epoxide components playing a crucial role, as was found with the diene monoepoxide analogs (Millar et al., 1990a–d, 1991a). The results are summarized in Table 2. Distinct communication channels may be maintained by a combination of synergism between components, blend ratio, and antagonism in the cases of blends sharing common components.

For example, *E. madusaria* males were attracted only by blends of the enantiomers of 6*Z*-*cis*-9,10-epoxy-19:H. This represents one of several known examples of enantiomeric synergism in the lepidoptera (Wong et al., 1985; Millar et al., 1991a).

TABLE 2. BIOLOGICAL ACTIVITIES OF COMPOUNDS TESTED AGAINST FOUR LEPIDOPTERAN SPECIES

	Compounds[a]				
Species	6*Z*,9*Z*–19:H	6*Z*-9*R*,10*S*-epoxy-19:H	6*Z*-9*S*,10*R*-epoxy-19:H	9*Z*-6*R*,7*S*-epoxy-19:H	9*Z*-6*S*,7*R*-epoxy-19:H
E. madusaria	P	A	A	I	I
X. sospeta		I	A		
P. angulalis				I(?)	A
A. humaria	P			P	

[a]P = component tentatively identified from pheromone gland extracts; A = sex attractant; I = compound inhibiting attraction.

The sympatric species, *X. sospeta*, was attracted to only one of the enantiomers, with the opposite enantiomer being a strong antagonist (Table 2). Thus, these two species were not attracted to the same lures.

In similar fashion, *P. angulalis* was attracted to lures containing the single component 9*Z*-6*S*,7*R*-epoxy-19:H, while *A. humaria* was attracted by blends of the opposite enantiomer in combination with 6*Z*,9*Z*–19:H (Table 2).

There is considerable but not conclusive evidence to support the tentative identification of 6*Z*,9*Z*–19:H and 6*Z*-*cis*-9,10-epoxy-19:H as sex pheromone components for *E. madusaria*. For 6*Z*,9*Z*–19:H, this evidence consists of exact retention time matches on two capillary GC columns versus a synthetic standard, a good SIM ion ratios match versus a standard, and biological activity in terms of electroantennographic responses and attractant activity in the field. Furthermore, it has been shown that the other geometric isomers of this compound have retention times different from that of 6*Z*,9*Z*–19:H under the GC conditions used (Millar et al., 1990d), and we have shown here that the 3*Z*,6*Z*–19:H and 3*Z*,9*Z*–19:H positional isomers, which might also be potential pheromone candidates, also have retention times different from 6*Z*,9*Z*–19:H under the GC-EAD conditions used. In addition 6*Z*,9*Z*–19:H is a logical biosynthetic precursor to the attractive 6*Z*-*cis*-9,10-epoxy-19:H. However, on the basis of the available data, we cannot absolutely rule out the slim possibility that the insect-produced compound is actually a positional isomer of 6*Z*,9*Z*–19:H.

The evidence for 6*Z*-*cis*-9,10-epoxy-19:H is more tenuous. A compound in the female pheromone gland extract that gave strong electroantennogram activity exactly matched the retention time of a synthetic standard. The biological activity in the field, coupled with the demonstrated behavioral antagonism of the 9*Z*-*cis*-6,7-epoxy-19:H regioisomer, also provided circumstantial evidence for this compound being a pheromone component for *E. madusaria*.

There was reasonably conclusive evidence that 6*Z*,9*Z*–19:H and 9*Z*-6*S*,7*R*-epoxy-19:H are female-produced pheromone components of the species *Anacamptodes humaria*. Both compounds were identified in pheromone gland extracts by a combination of GC retention time matches, and by matches of SIM chemical ionization mass spectra with those of standards. In light of the retention time match with a standard, the possibility of the diene insect-produced compound being an isomer other than 6*Z*,9*Z*–19:H is small, as described above for *E. madusaria*.

Synthesis

Three syntheses of a component of the sex pheromone blend of the ruby tiger moth, 6*Z*-*cis*-9,10-epoxy-21:H, or its enantiomers have been reported. In the first, Rollin and Pougny (1986) synthesized the 9*S*,10*R* enantiomer in 10

steps from D-xylose, providing material of high chiral purity. However, the last step delivered a 9:1 mixture of the 6*Z*:6*E* geometric isomers. In addition, the synthesis was only amenable to the production of the 9*S*,10*R* enantiomer or series of homologous enantiomers.

Ebata and Mori (1989) described a synthesis of both of the enantiomers of 6*Z*-*cis*-9,10-epoxy-21:H, using Sharpless asymmetric epoxidation of the achiral intermediate (*Z*)-tetradecen-2-ol as a key step. Repeated recrystallization of crystalline derivatives of the intermediate epoxy alcohols was used to increase the chiral purities to high levels. However, this synthetic route could only be used to produce the C_{11} compounds, that is, it could not be used to efficiently and convergently synthesize homologs.

It also must be mentioned that the optical rotations reported for the tiger moth pheromone component 6*Z*-9*S*,10*R*-epoxy-21:H by both Rollin and Pougny (1986) ($[\alpha]_D^{20} = +5.5°$) and Ebata and Mori (1989) ($[\alpha]_D^{23} = +9.4°$) are considerably different from each other, and from our result ($[\alpha]_D^{21} = +2.5°$). Rollin and Pougny indicated that their product was contaminated with 10% of the 6*E* isomer, and this or other impurities may have contributed to a possibly erroneous optical rotation. Possible impurities in the pheromone prepared by Ebata and Mori (1989) may have had a similar effect.

Bell and Ciaccio (1988) published a short synthesis of racemic 6*Z*-*cis*-9,10-epoxy-21:H based on an ingenious alkylative rearrangement of an epoxytosylate intermediate. With several minor modifications, this synthesis could be adapted to the production of either enantiomer of this compound or to the production of homologs.

Our synthetic strategies were designed to satisfy two criteria. First, we wanted facile access to both enantiomers of each monoene epoxide. This was expeditiously accomplished by use of the Sharpless asymmetric epoxidation sequence on appropriate readily available allylic alcohol precursors. Although this procedure gives enantiomeric excesses of approximately 90% at best (i.e., a 19:1 ratio of enantiomers) for 1,2-disubstituted allylic alcohol subtrates (Katsuki and Sharpless, 1980), our previous experiences with the analogous diene monoepoxides had demonstrated that compounds of this enantiomeric purity were in many cases sufficient to demonstrate that biological activity, either as an attractant or a behavioral antagonist, could be attributed to one of the two enantiomers.

Our second requirement was for a synthetic route that would be amenable to the efficient production of homologous series of compounds, that is, for syntheses that used a common intermediate to which a chain of variable length could be attached in the penultimate step. The chiral epoxy alcohols obtained by the Sharpless epoxidations, when converted to epoxy iodides, fulfilled this requirement.

(Received September 24, 1990; accepted January 24, 1991)

Abstract—Selected isothiocyanates (mustard oils) were tested as attractants for adult *Nysius niger* Baker, a pest of mustard crops in the Canadian prairies. Individuals of both sexes, but predominantly females, were caught in yellow boll-weevil traps baited with certain mustard oils. Initial testing was done with compounds loaded on rubber septa, a procedure that resulted in a great disparity in release rates between compounds due to differences in volatility. In subsequent experiments, glass tubes of varying dimensions were used so that release rates of each compound could be controlled and maintained at a constant rate. Of mustard oils tested, ethyl 4-isothiocyanatobutyrate, the corresponding methyl ester of which is found in seeds in the cruciferous genus *Erysimum*, was the most attractive. However, the methyl ester itself was either less attractive or not attractive at all. Allyl and *n*-propyl isothiocyanates were less attractive than ethyl 4-isothiocyanatobutyrate, and 2-phenylethyl isothiocyanate was not attractive. Insects were caught in traps almost exclusively when traps were in proximity to canola and mustard fields in bloom.

Key Words—Isothiocyanate, attractant, Cruciferae, host-plant location, Brassicaceae, ethyl 4-isothiocyanatobutyrate, *Nysius niger*, Heteroptera, Lygaeidae.

INTRODUCTION

The northern false chinch bug, *Nysius niger* Baker, formerly known as the false chinch bug, *N. ericae* (Schilling) (Ashlock, 1977), is a minor pest of a wide variety of crops throughout Canada with a preference for crucifers (Beirne, 1972; L. Burgess, personal communication). This pattern of host-plant preference is similar to that of the congeneric U.S. pest, *N. raphanus* Howard (Barnes, 1970). *N. niger* is a vector of the yeast, *Nematospora sinecauda* Holley, formerly known as *N. coryli* Peglion (Holley et al., 1984), which infects mustard crops, *Brassica juncea* (L.) Czern. and *Sinapis alba* L., in the Canadian prairie provinces (Burgess et al., 1983). In Saskatchewan, *N. niger* has two to three generations per year and overwinters in the egg stage (L. Burgess, personal communication). In a July 1985 insect trapping survey using isothiocyanates loaded on rubber septa as baits, appreciable numbers of *N. niger* were collected with two of the baits tested: a mixture (1 : 1) of ethyl and methyl 4-isothiocyanatobutyrate (ethyl–methyl ICB) and, to a lesser extent, 3-methylthiopropyl isothiocyanate (IC). Many insects also were found feeding on the vegetation near the trap baited with ethyl–methyl ICB. All other mustard oils tested, including allyl IC, *n*-butyl IC, ethyl IC, *p*-methoxybenzyl IC, 2-phenylethyl IC and phenyl IC, caught one or no insects (unpublished). Isothiocyanates, or mustard oils, are among the major volatile hydrolysis products of glucosinolates, a group of nonvolatile anions that are found predominantly in five dicotyledonous families including all cruciferous species (family Brassicaceae) Fenwick et al., 1983). Isothiocyanates are released when plant tissue is damaged (Underhill, 1980), and are known to be attractive to a number of crucifer-feeding insect species (Feeny et al., 1970; Matsumoto, 1970; Eckenrode and Arn, 1972; Free and Williams, 1978; Hawkes and Coaker, 1979; Finch and Skinner, 1982). In light of the potential usefulness of an attractant for *N. niger*, we decided to investigate this chemical attraction further.

METHODS AND MATERIALS

Trapping. In 1987, a trapping experiment was carried out using yellow boll-weevil traps (Pest Management Specialists, Inc., Starkville, Mississippi) as described by Burgess and Wiens (1980). The experiment was designed to distinguish between the response of *N. niger* to ethyl and methyl ICB and was arranged in a randomized complete block design with three replicates. Traps were placed in a line, 10 m apart alongside blooming mustard, *B. juncea*, or canola, *B. napus* L. and *B. campestris* L., plots, as this is where all insects were trapped in 1985. Traps were in place from June 16 to July 16 near Saskatoon and all insects caught were sexed. The treatments were baits containing 20 mg of: (1) ethyl ICB; (2) ethyl–methyl ICB mixture; (3) methyl ICB; and

(4) a solvent blank. Each compound was loaded on a rubber septum (No. 1780J07, Arthur H. Thomas Scientific, Philadelphia, Pennsylvania) and washed into the rubber with two drops of solvent (dichloromethane) and one drop of antioxidant (10% butylated hydroxytoluene in acetone). Two of the trap replicates were moved to new flowering *Brassica* plots on June 22 because the plots used initially had finished blooming.

To determine if differences in rates of release of compounds from rubber septa might have been the cause of the large differences in trap captures in response to different mustard oils in 1985, the following experiment was carried out. Release rates of allyl IC and ethyl ICB, loaded on rubber septa, were compared in the laboratory. Twenty milligrams of each compound were loaded on separate rubber septa ($n = 4$ replicates) and these were weighed daily for a week, then twice weekly for a month. Weight losses of less than 10 μg per week could not be detected, and, therefore, once release rates fell below this level, loss of compounds was measured by gas chromatography: septa contents dissolved in dichloromethane were compared to known quantities of standard. Release rates of the compounds were determined from the log-log linear regression. Simple decay curves were not obtained, probably because release rates were functions of both evaporation of the compounds and the physical interaction between the compounds and the rubber septa. All release rate measurements were calculated in terms of weight loss (micrograms per day).

In 1989, an additional trapping experiment was carried out using yellow boll-weevil traps to examine the specificity of response of *N. niger* to mustard oils. Traps were placed in a canola field near Saskatoon in a randomized complete block design, replicated four times. All insects caught were sexed. Traps were in place from July 10 to August 8 and were emptied weekly; baits were changed after two weeks. The treatments were: allyl IC, *n*-propyl IC, ethyl ICB, and 2-phenylethyl IC, at release rates of 400 μg/day and 4000 μg/day, and, for allyl IC only, 40,000 μg/day. Ethyl ICB was chosen for its demonstrated attractiveness, allyl and 2-phenylethyl IC for their widespread occurrence in crucifers, and *n*-propyl IC for its structural similarity to allyl IC. To produce the 40,000 μg/day release of allyl IC, the release device was a serum bottle with a pipe cleaner wick and a rubber septum top as described by Burgess and Wiens (1980). For other release rates, glass tubes, sealed at one end, were used. The tubes were filled with the desired compound so that a specified length of air column extended above the compound. The release rate for any given compound varied directly with the diameter of the tube and inversely with the air column length. The appropriate dimensions for each compound were arrived at by application of the mathematical model of Weatherston et al. (1985) and subsequent empirical testing. Over the course of the experiment, the release rates in the glass tubes did not change appreciably. The inside diameter and air column lengths for each bait releasing at 4000 μg/day were, respectively, 3.7

and 40 mm for allyl IC, 5.0 and 18 for ethyl ICB, and 6.5 and 6 for 2-phenylethyl IC. At 400 μg/day, they were 1.3 and 60 mm, 2.5 and 45, and 2.5 and 9, respectively. Glass tube dimensions for *n*-propyl IC were the same as for allyl IC, as their boiling points are almost identical: 153°C for *n*-propyl IC vs. 152°C for allyl IC. The length of the column of air above the compound in each tube was measured before and after the experiment to determine the actual rate of release. The capillary tubes were taped to stand upright inside the bases of the traps. Square-root transformed trap capture data were analyzed with a two-way ANOVA followed by a protected LSD test.

Compounds. 3-Methylthiopropyl IC and a 1 : 1 mixture of methyl ICB and ethyl ICB were previously synthesized in this laboratory (NRC) according to published methods (Kjaer et al., 1955; Kjaer and Gmelin, 1957). The mixture was intended to be a synthesis of methyl ICB, but GC-MS analysis revealed the presence of ethyl ICB. The individual syntheses of methyl ICB and ethyl ICB are described below. All other compounds were obtained from commercial sources.

Methyl ICB and ethyl ICB were individually synthesized by a modification of the methods of Kjaer and Gmelin (1957) and Kim and Yi (1986). [^{1}H]NMR spectra were taken on a Brucker Am-360-WB instrument at 360 MHz, in $CDCl_3$. Infrared spectra were recorded on a Perkin-Elmer 237B instrument, using films of neat material on NaCl plates. Mass spectra (EI, 70 eV) were recorded with a Finnigan 4000E GC-MS instrument, with an INCOS 2300 data system.

Ethyl 4-aminobutyrate hydrochloride was obtained from Aldrich Chemical Co. Methyl 4-aminobutyrate was synthesized as follows. HCl gas was bubbled into a water-bath cooled slurry of 4-aminobutyric acid (2.0 g, 19.4 mmol) in MeOH (25 ml). When all the solid had dissolved, the solution was cooled in an ice bath, and saturated with HCl gas. The resulting solution was warmed to 20°C, and stirred overnight. The solvent was evaporated, followed by sequential addition and evaporation of aliquots of MeOH and ether (25 ml) to remove traces of HCl. The residue was dissolved in warm MeOH (5 ml), and the product was precipitated as white crystals by slow addition of ether (25 ml). The crystals were filtered off, rinsed with ether, and air dried, giving a quantitative yield of methyl 4-aminobutyrate (3.0 g as the hydrochloride salt).

To prepare ethyl 4-isothiocyanatobutyrate, 1,1′-thiocarbonyldiimidazole (1.98 g, 90% pure, 20 mmol; Aldrich Chemical Co.) was added to a solution of ethyl 4-aminobutyrate hydrochloride (1.68 g, 20 mmol) in 20 ml CH_3CN at 0°C. The mixture was warmed to room temperature while stirring, giving a yellow solution, which subsequently precipitated imidazole by-products. The mixture was stirred at room temperature for 3 hr, water was added (5 ml), and stirring was continued for 30 min. The mixture then was concentrated on a rotary evaporator, and the residue partitioned between water and ether. The ether layer was washed with water and brine, dried (anhydrous Na_2SO_4), and

Kugelrohr distilled, bp ~80°C (0.05 mm Hg), giving 1.61 g (93%) of the isothiocyanate as an oil, 98% pure by capillary GC (DB-5, 20 m × .32 mm ID). NMR: δ 4.14 (quartet, 2H, J = 7.1 Hz; $CH_3C\underline{H_2}O$), 3.60 (t, 2H, J = 6.5 Hz; CH_2-N) 2.43 (t, 2H, J = 7.1 Hz; CH_2COOR), 1.99 (quintet, 2H, J ~ 6.8 Hz; $CH_2C\underline{H_2}CH_2$), 1.25 (t, 3H, J = 7.1 Hz; CH_3). IR: 2990 (m), 2945 (m), 2190 (s), 2105 (s), 1730 (s), 1180 (s), 1030 (m) cm^{-1}. MS m/z (relative abundance): 175 (2; M + 2), 173 (37: M^+), 129 (64), 128 (61), 127 (54), 100 (51), 88 (93), 85 (33), 70 (46), 61 (64), 60 (100), 45 (46).

The analogous methyl 4-isothiocyanatobutyrate was synthesized in similar fashion from methyl 4-aminobutyrate. The NMR and IR spectra were satisfactory. MS m/z: 161 (2; M + 2), 159 (43; M^+), 128 (23), 127 (35), 100 (25), 74 (100), 72 (65), 59 (68), 43 (85).

RESULTS

The results from the trapping experiment in 1987 indicated that the major attractive compound in the ethyl–methyl ICB mixture was ethyl ICB (Table 1).

Release rates of the two mustard oils, allyl IC and ethyl ICB, from rubber septa were very different (Table 2), as a result of differences in their volatility (see Table 3) and differential absorption by the rubber septa. The majority of allyl IC actually evaporated in the 24 hr between loading and the start of the test. On the other hand, 24 hr was required for 20 mg ethyl ICB to be absorbed into the rubber, during which time very little evaporated. At 24 hr after loading, only 5% of allyl IC remained on the septa, compared to 98.5% of the ethyl ICB. Following absorption into the rubber septa, ethyl ICB began to evaporate rapidly, presumably because of the much greater surface area available. How-

TABLE 1. MEAN NUMBER OF *Nysius niger* ADULTS CAUGHT IN YELLOW BOLL-WEEVIL TRAPS BAITED WITH MUSTARD OILS IN CANOLA PLOTS NEAR SASKATOON, JUNE 16–JULY 16, 1987

Compound (20 mg/rubber septum)[a]	Number of insects caught ($\bar{X}$ ± SE; N = 3)[b]	Females (%)
Ethyl ICB	64.3 ± 49.9a	86
Ethyl/methyl ICB	21.0 ± 14.8ab	79
Methyl ICB	2.3 ± 0.7b	100
Control	3.0 ± 2.0b	89

[a]ICB = 4-isothiocyanatobutyrate. More than 90% of insects were caught when release rates of both ethyl and methyl ICB were estimated at between 80 μg/day (day 15) and 15 μg/day (day 30).

[b]Means in columns followed by different letters are significantly different at P = 0.05.

TABLE 2. CALCULATED RELEASE RATES OF ISOTHIOCYANATES FROM RUBBER SEPTA

Day[a]	Release rates (μg/day)	
	Allyl isothiocyanate	Ethyl 4-isothiocyanatobutyrate
1	1250	7,500
8	2.0	250
15	.20	80
22	.05	30
29	.02	15

[a] Day 1 is considered the day after loading septa as it took 24 hr for ethyl ICB to soak into septa. During this initial 24 hr, only 1.5% of ethyl 4-isothiocyanatobutyrate evaporated. During the same period, 95% of allyl isothiocyanate evaporated.

ever, allyl IC still evaporated proportionately more rapidly for the next few days. The results were counterintuitive in that less (in absolute terms) of the more volatile compound (allyl IC) was released over the entire test (which did not include the 24 hr after loading). After one week, only about 9 μg of allyl IC remained.

The 1989 trapping experiment showed that ethyl ICB was the most attractive mustard oil tested based on trap catch (sexes pooled) (Table 3). In addition, this experiment demonstrated that at least some other mustard oils are also attractive at appropriate release rates. When allyl IC was released at 40,000 μg/day, its attractiveness was similar to that of ethyl ICB at between one tenth and one hundredth the rate. *N*-Propyl IC, which is similar in structure to allyl IC except for the lack of a double bond, was similar to allyl IC in attractiveness. 2-Phenylethyl IC was not attractive.

The trap catch increased initially in 1989 and remained at a plateau for the last two weeks of the trapping period while the proportion of females increased (Table 4).

DISCUSSION

N. niger is attracted to mustard oils with specific side-chain structures. Of the mustard oils tested, it is attracted to some strongly, to some weakly, and to others not at all. This was unexpected because *N. niger* is not a crucifer specialist, although a number of crucifer species are preferred food sources (Beirne, 1972; L. Burgess, personal communication). This study is the first to demonstrate mustard oil side-chain specificity in an insect species, although many insects are known to be attracted to mustard oils. Only three previous studies have compared attraction of insects to different mustard oils (Matsumoto, 1970;

Period	Total number caught	Females (%)
July 10–17	25	76
July 17–24	439	86
July 24–31	2129	96.5
July 31–August 8	1955	97.1

Finch and Skinner, 1982; Tuttle et al., 1988): the first in the vegetable weevil *Listroderes obliquus* (Klug), and the latter two in cabbage root flies, *Delia* spp. In these studies no clear preference patterns were demonstrated, and in none of them was the release rate well controlled, possibly resulting in problems similar to those encountered in our 1985 experiment (described in introduction).

The lack of attraction to 2-phenylethyl IC may be related to the feeding habits of *N. niger* as it feeds primarily on flower buds, flowers, seeds and seedlings. We infer these feeding preferences based on the prevalence of *N. niger* on flixweed *Descurainia sophia* (L.) in June in Saskatchewan when this plant is in flower and producing seed (L. Burgess, personal communication), the diet upon which they thrive in captivity (Burgess and Weegar, 1986), and by the fact that we could trap *N. niger* in mustard and canola plots and fields only when these had begun to bloom. In crucifers, these plant parts rarely produce much 2-phenylethyl IC, which is mainly found in roots and leaves (Kjaer, 1960; Sang et al., 1984).

The strong response to ethyl ICB and lack of response to the corresponding methyl ester is intriguing. Methyl ICB is present in seeds of three species of the cruciferous genus *Erysimum* (Kjaer and Gmelin, 1957), but ethyl ICB is not known to occur naturally. Comparisons of release rates of the two mustard oils from glass tubing (unpublished) do not indicate differences in evaporation rates that could explain the differences in capture of *N. niger* using the two mustard oils released from rubber septa. Ethyl ICB or a related compound may be found in a host plant or produced by *N. niger* itself, and this may explain its specific response. Alternatively, the compound may have no biological significance but has, by chance, a high affinity for certain *N. niger* chemoreceptors. This would be analogous to male lures for tephritid fruit flies (Cunningham et al., 1990). Our results do not indicate that methyl ICB is not attractive to *N. niger*; the insect may simply require higher release rates. The estimated rates of release during this experiment were low enough (see footnote in Table 1) that no mustard oil tested, other than ethyl ICB, would likely have elicited a response. The intermediate attraction to other mustard oils including allyl IC, *n*-propyl IC, and 3-methylthiopropyl IC is possibly an indication of the general preferences of *N. niger* for plants in the family Brassicaceae where these or closely related compounds are found (Fenwick et al., 1983).

N. niger was not caught in mustard-oil baited traps at all times. For example, in a trapping experiment in July 1985, five traps baited with five doses of ethyl–methyl ICB were placed beside plots of canola, wheat, and weeds. A total of 145 *N. niger* were caught in traps beside the canola plot while none were caught beside the other plots (unpublished). From June 22 to July 6, 1989, four traps, which released 40,000 μg/day of allyl IC, were placed alongside an alfalfa field that contained high densities of both flixweed and *N. niger* adults, yet none were caught. Two weeks later, in a nearby canola field, large numbers

of adults were attracted to the same kind of traps as this field came into bloom. Large numbers of adults continued to be caught in these traps for the next three weeks (Table 4). Other trapping experiments were also successful only when nearby canola or mustard was in bloom. The most likely explanation is that *N. niger* responded to the mustard oil baits only when they were actively host- or mate-seeking and in the vicinity of the traps. *N. niger* probably does not respond to mustard oils from very far away. The crucifer flea beetle, *Phyllotreta cruciferae* (Goeze), responds to 40,000 μg/day of allyl IC from less than 2 m (Pivnick, unpublished). *N. niger* probably move into canola fields once flowering begins, perhaps responding to the bright yellow flower color, the pungent floral odor, or both. Lygus bugs, *Lygus* spp., are also known to move into canola fields at this time (Butts, 1989) as they, like *N. niger* feed primarily on flowers, fruits, and seeds. This movement is likely also induced by the development of a new generation of *N. niger* adults in July (Pivnick, personal observation) at the time that the early season host plant, flixweed, is maturing and is no longer desirable. Dingle (1972) has summarized a wealth of data indicating that insects tend to increase flight activity early in adult life. Other lygaeid species are known to fly more under unfavorable local conditions particularly under food or mate deprivation (Dingle, 1966, 1968; Solbreck and Pehrson, 1979). Females but not males of the congeneric, *Nysius vinitor* Bergroth, have an increased tendency for sustained flight when starved as adults, particularly for the first few days after emergence (Kehat and Wyndham, 1974).

N. niger does form dense aggregations. We observed large numbers feeding on plants around the ethyl–methyl ICB trap in 1985. This aggregative behavior has been observed before in *N. niger* (Burgess et al., 1983) and in *N. raphanus* (Byers, 1973). We propose that the response to mustard oils is one method by which *N. niger* adults find new food sources, as high levels of mustard oils are released when plant tissue is damaged (Benn, 1977), which occurs when insects are feeding. Moreover, the relatively high specificity of response to mustard oils may allow *N. niger* to find preferentially the plant species and the phenological stages it prefers. Mustard oil response also may be important in producing the aggregations seen in this species, a behavior that likely contributes to its status as a disease vector. Whether the response to mustard oils is related to mating activity is not known, although clearly females were the primary respondents in our tests. The low incidence of males in trap catches may indicate a shorter adult life for males than females under field conditions. It also may reflect a mate location strategy, higher female vagility, or greater use of plants by females. The last possibility is supported by the finding that adult *N. groenlandicus* (Zett.) sampled on host plants are predominantly females even when the sex ratio of individuals found on the ground nearby is approximately equal (Böcher, 1972). In any case, our results indicate that *N. niger*, even though it is polyphagous, does make use of mustard oils in a discriminat-

ing manner that may help it to exploit specific food plants in the family Brassicaceae. Its response to mustard oils also makes possible the investigation of this insect by field trapping.

Acknowledgments—We thank the late Peter Ashlock, formerly of the Department of Entomology, University of Kansas, Lawrence, Kansas, for insect identification, and B.J. Jarvis, H. H. Weegar, and B. Pittendrigh for assistance with trapping. C.F. Hinks and J.J. Soroka reviewed an earlier version of this manuscript.

ISOLATION OF SUBSTANCE FROM SWEET POTATO (*Ipomoea batatas*) PERIDERM TISSUE THAT INHIBITS SEED GERMINATION

JOSEPH K. PETERSON* and HOWARD F. HARRISON, JR.

U.S.D.A., Agricultural Research Service
U.S. Vegetable Laboratory

Charleston, South Carolina, 29414

(Received November 21, 1990; accepted January 28, 1991)

Abstract—Chromatographic procedures were used to isolate inhibitors of seed germination from sweet potato root periderm tissue. The inhibitory activity of all fractions was monitored using a proso millet seed germination bioassay. A single HPLC peak, representing approximately 1.2% of the periderm dry weight, accounted for most of the inhibitory activity. The active fraction was labile in methanolic solution. Further fractionation of this peak by HPLC methods was not successful. In vitro seed germination dose–response relationships were established for the peak. The various seed species exhibited an extremely wide range of sensitivity. The I_{50} values were 0.16, 0.013 and 0.011 mg/ml for redroot pigweed, velvetleaf, and proso millet, respectively. Tall morning glory was not inhibited by any concentration tested.

Key Words—Allelopathy, seed germination, inhibition, sweet potato, *Ipomoea batatas*, proso millet, *Panicum milliaceum*, velvetleaf, *Abutilon theophrasti*, tall morning glory, *Ipomoea purpurea*, redroot pigweed, *Amaranthus retroflexis*.

INTRODUCTION

Interest in allelopathy has kept pace with increasing public pressure against the use of environmentally damaging agrochemicals. In particular, potential weed suppression by crop plants deserves attention. A multitude of studies indicate that some degree of weed suppression can be expected from various crops or

*To whom correspondence should be addressed.

0098-0331/91/0500-0943$06.50/0

their residues. Among the cereals are corn (*Zea mays* L.; Guenzi and McCalla, 1966), oats (*Avena sativa* L.; Fay and Duke, 1977), rye (*Secale cereale* L.; Barnes and Putnam; 1983, 1986), and sorghum [*Sorghum bicolor* (L.) Moench; Alsaadawi et. al., 1986]. Dicotyledonous crops with allelopathic properties include cucumbers (*Cucumis sativus* L.; Putnam and Duke, 1974; Lockerman and Putnam, 1979, 1981), sunflower (*Helianthus annuus* L.; Leather, 1983; Hall et al., 1983) and soybean [*Glycine max* (L.) Merr.; Maun, 1977; Huber and Abney, 1986].

Sweet potatoes are known to contain allelopathic compounds. Taylorson (1967) reported the occurrence of a compound that inhibited the growth of cucumber hypocotyls. Growth of yellow nutsedge (*Cyperus esculentus* L.) and alfalfa (*Medicago sativa* L.) was significantly reduced when plants were grown in field soil that had supported sweet potatoes previously (Harrison and Peterson, 1986). Decaying sweet potato plant residues incorporated into the soil caused significant inhibition of growth of sweet potato vine cuttings and cowpea plants, and nodulation in cowpea was negligible (Walker and Jenkins, 1986). The uptake of Ca, Mg, and S was impaired under these conditions (Walker et al., 1989).

The related species, *Ipomoea aquatica* and *I. tricolor* have been shown to have allelopathic properties. *I. aquatica* contains terpenoid compounds that were inhibitory to pearl millet (*Pennisetum typhoideum* Rich.) seedling growth (Singhvi and Sharma, 1984). Anaya et al. (1990) isolated a jalapinolic acid (11-hydroxyhexadecanoic acid) glycosidic complex that is the most inhibitory chemical component of *I. tricolor* in seed germination and seedling growth bioassays.

Crude polar extracts of sweet potato periderm tissue, tested on nine weed species, inhibited germination differentially. I_{50} values (estimated concentrations at which 50% inhibition occurs) ranged from 0.1 mg periderm eq/ml for velvetleaf to 8.0 mg periderm eq/ml for pigweed (Peterson and Harrison, 1991). These observations led to attempts to isolate inhibitory substances from sweet potato periderm tissue.

METHODS AND MATERIALS

Sample Tissue. Sweet potatoes, cv. Regal, were harvested in the fall of 1989. Within a few days the roots were gently scrubbed under flowing water and the periderm tissue was carefully scraped off with a scalpel. This tissue easily separates from the rest of the storage root (Schalk et al., 1986). Only healthy, nondamaged roots were used to avoid interference by phytoalexins (Hyodo et al., 1969). The periderm tissue was dried at 50°C and subsequently frozen at −20°C until use.

Extractions. Sequential extractions were carried out on a shaker in the dark at ambient laboratory temperature. After the solvents were added (15 ml solvent per gram of dry tissue), they were degassed and blanketed with nitrogen. Each individual extraction lasted 24 hr. The extraction sequence was as follows: hexane (dry, four repetitions), methanol (dry, redistilled, four repetitions), 50% aqueous methanol (2 repetitions), and finally water (two repetitions). Extracts with the same solvents were combined and condensed under vacuum at 40°C.

Low-Pressure Column Chromatography. The methanol (100%) extract was applied to three borosilicate microfibrous filters at a rate of 1.0 g equivalent (extract obtained from 1.0 g periderm tissue). After drying, three filters were placed on top of a Sephadex LH-20 column[1] (4.5 × 14 cm in ethyl acetate) and 1 cm of the stationary phase was placed on top of the sample. A step-gradient elution was performed with mixtures of methanol–ethylacetate, 1:20 (625 ml, 25 ml/min, peak 1), 1:20 (450 ml, 25 ml/min, peak 2), 1:2 (475 ml, 20 ml/min, peak 3), 1:2 (750 ml, 20 ml/min, peak 4), 100% methanol (1500 ml, 20 ml/min, peak 5), and distilled water (1000 ml, 20 ml/min, peak 6). Elution was monitored at 280 nm. The six collected fractions were condensed under vacuum at 40°C and bioassayed (see Figure 2 below).

High-Pressure Liquid Chromatography. Fraction 3 from Sephadex LH-20 chromatography was condensed to dryness, redissolved in methanol, centrifuged, and resolved by HPLC. Column: Waters μ Bondapak 25 mm × 8 cm, C_{18}, 125 Å, 10 μm. Injection: 500 mg eq in 150 μl methanol. Detection: absorption at 230 nm. Solvents: water (solvent A) and methanol–acetonitrile, 50:50 (solvent B). Elution program: (1) 100% A → 56% A, 4 ml/min → 6 ml/min, 8 min. (2) isocratic, 12 min. (3) 56% A → 14% A, 6 ml/min, 4 min. (4) 14% A → 10% A, 6 ml/min, 6 min. (5) 10% A → 100% B, 6 ml/min → 8 ml/min, 8 min. (6) isocratic, 8 ml/min. Solvent and flow gradients were linear in all cases.

UV Absorption. Freshly isolated peak 3 from the HPLC was condensed to dryness, redissolved in redistilled methanol and its UV absorption spectrum determined against methanol with a Shimadzu UV-160 spectrometer.

Seed Sources. Proso millet, tall morning glory, and velvetleaf seeds were obtained from Valley Seed Service (Fresno, California) and redroot pigweed seeds were collected locally.

Bioassays. The crude extracts (hexane, methanol, 50% methanol and water, six fractions from the Sephadex LH-20 column, and three fractions from the HPLC) were tested for inhibition of proso millet germination. Fraction 3 from the HPLC was tested for dose–response based on its actual weight, using

proso millet, redroot pigweed, tall morning glory, and velvetleaf seed germination bioassays.

Seeds were germinated in Petri dishes with two Whatman No. 1 filter papers on the bottom. The filter papers were washed with methanol to remove inhibitory residues. Dilute extracts or chromatography fractions in the original solvents were added to Petri dishes, then the solvents were evaporated. All solvents used were pretested for residue effects; the methanol was redistilled. After adding water and seeds, Petri dishes were sealed in plastic and incubated. Controls were incubated in distilled, deionized water. A seed was considered to have germinated when the protruding radicle had achieved the length of the longest dimension of the seed. Seeds that required scarification were submerged in concentrated sulfuric acid. Subsequently the seeds were submerged in 2% $NaHCO_3$, then rinsed in tap water for 15 min and quickly blotted dry. The germination protocol is listed in Table 1.

Incubation periods were chosen so that nontreated seeds were approximately 50% germinated. All seeds were germinated at 35°C in the dark except proso-millet (30°C). These data were used to calculate the relative percent germination of all treatments. This approach allows detection of stimulatory effects as evidenced in the crude water extract. In order to determine the quality of the seeds, maximum germination (germinability) was also determined (Table 1).

Statistical Analyses. The bioassays were conducted with five replicates for each treatment, including the controls, and were arranged in a completely random design within the incubator. Each bioassay was repeated using fractions from separate extractions or chromatography fractions, and data from two repetitions of the experiments were combined for statistical analyses. Data from the various bioassays were converted to percent control germination, and treatment means and standard errors of the means were calculated. The extract concentration required to cause 50% inhibition of seed germination (I_{50}) was estimated using log-probit analyses after the method of Finney (1971).

TABLE 1. SEED GERMINATION PROTOCOLS[a] AND GERMINABILITY[b]

Species	Petri dish diameter (cm)	Water (ml)	Seeds per dish	Scarification (min)	Incub. period (hr)	Germinability (%)
Proso millet	10	5.0	100		28.5	89
Redroot pigweed	5	1.5	100		24.0	71
Tall morning glory	10	5.0	50	5	22.0	82
Velvetleaf	10	5.0	100	15	32.0	76

[a] Dishes were rotated throughout the incubator twice daily to ensure equal temperature exposure.

RESULTS AND DISCUSSION

Two notations are used to express concentrations, i.e., milligram equivalent per milliliter (mg eq/ml) and milligram per milliliter (mg/ml). The former indicates the amount of periderm extracted, the solute of which is dissolved in 1 ml solvent, and the latter represents the actual weight of extractable material per milliliter of solvent.

Of the four sequentially obtained extracts, the methanol extract (I_{50} = 0.3 mg eq/ml) and the aqueous methanol extract (I_{50} = 4.1 mg eq/ml) showed significant inhibition of germination (Figure 1). Since this study was designed to isolate and purify the major inhibitors of sweet potato, only the methanol fraction was further explored. Preliminary research (unpublished data) showed a large number of UV-absorbing compounds on TLC plates; however, most of the activity was lost during this process. A typical separation profile of the methanol fraction on a Sephadex LH-20 column using gradient elution with organic solvents is shown in Figure 2. Six fractions were collected and bioassayed. At their highest concentration (16 mg eq/ml), fractions 1 and 6 caused 42% and 20% inhibition, respectively, but their I_{50}s could not be calculated due to lack of dose-response. Fractions 2, 3, 4, and 5 produced I_{50} values of 32, 0.4, 9.5, and 14.7 mg eq/ml, respectively. The I_{50} for all fractions recombined

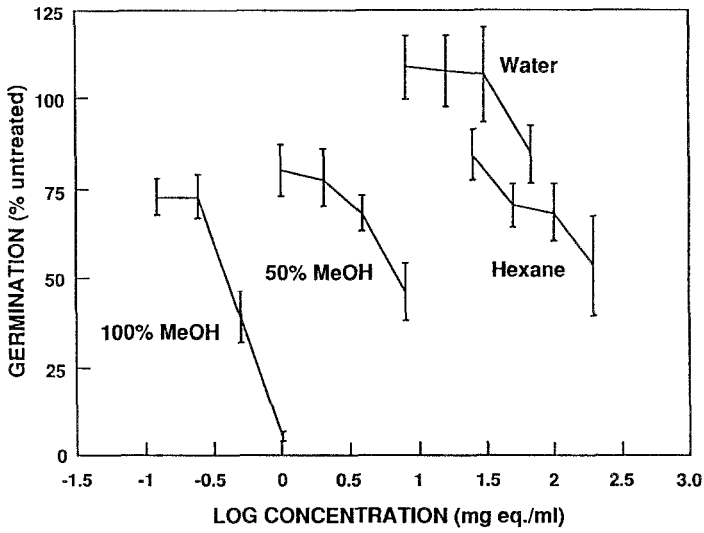

FIG. 1. Proso millet germination bioassays of crude extracts of sweet potato periderm tissue. The I_{50} values are 254, 0.3, and 4.1 mg eq/ml for the hexane, 100% methanol, and 50% methanol extracts, respectively. The I_{50} for the water extract could not be calculated due to the lack of dose-response.

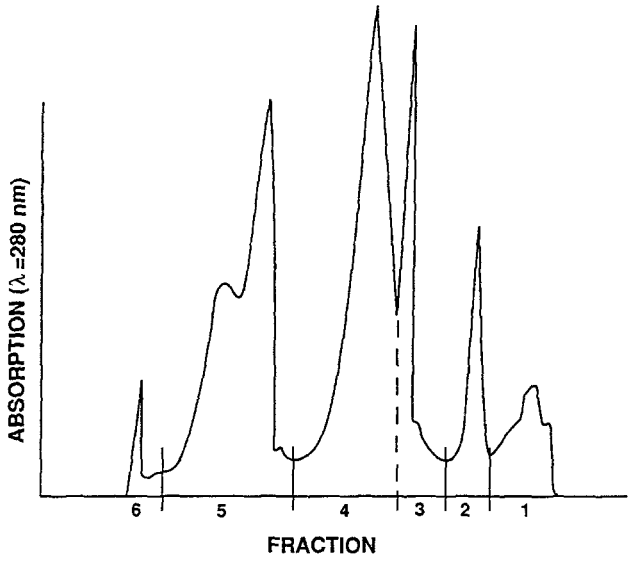

FIG. 2. Low-pressure column chromatography (Sephadex LH-20) of a crude 100% methanol extract.

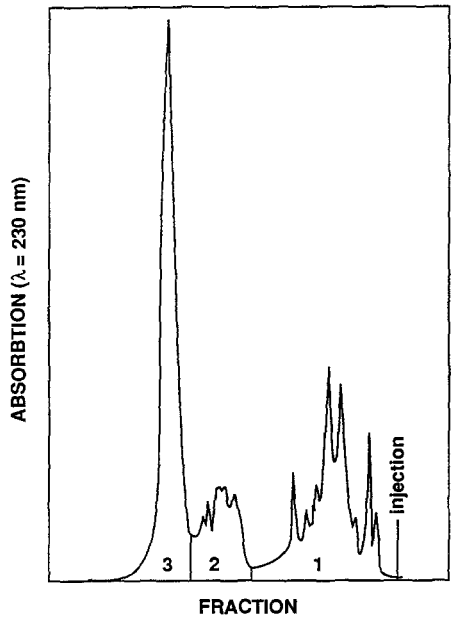

FIG. 3. HPLC record of gradient elution of Sephadex LH-20 column fraction 3, indicating the three collected fractions. Column: Waters μBondapak 25 mm × 10 cm, C_{18}, 125 Å, 10 μm. Injections: 500 mg eq in 150 μl methanol. Detection: absorption at 230 nm. Gradient: linear, H_2O-(MeOH–ACN, 50:50), 100% H_2O → 100% MeOH–ACN.

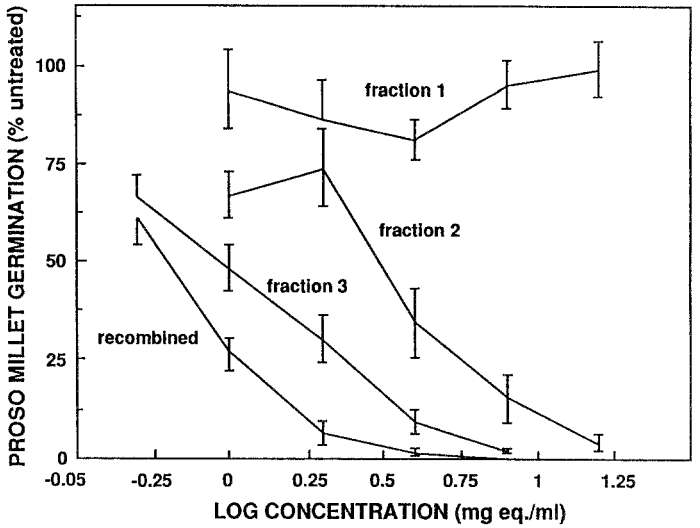

FIG. 4. Proso millet germination bioassays of the HPLC fractions and recombined fractions. The I_{50} values are 2.5, 0.9, and 0.6 mg eq/ml for fractions 2 and 3 and the recombined fractions, respectively. The I_{50} value for fraction 1 could not be calculated due to lack of dose–response.

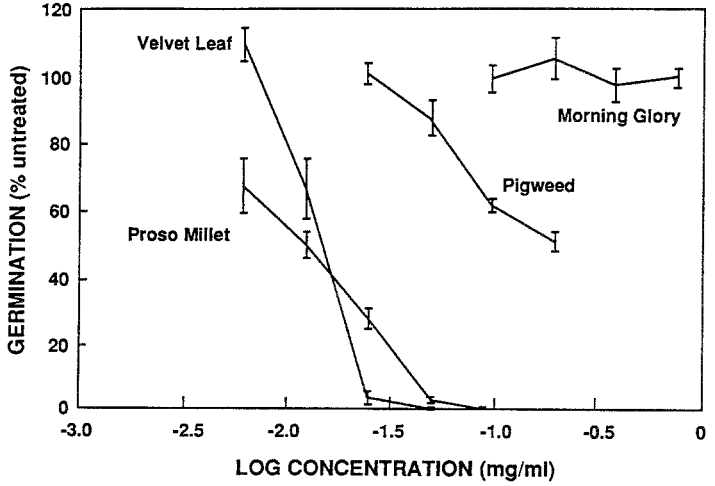

FIG. 5. Seed germination bioassays. The concentrations represent actual weights of HPLC fraction 3. The I_{50} values are 0.16, 0.013, and 0.011 mg/ml for redroot pigweed, velvetleaf, and proso millet, respectively. The I_{50} value for tall morning glory could not be calculated due to lack to dose–response.

was 0.3 mg eq/ml, similar to the 100% methanol extract, indicating that no significant losses had occurred.

Since fraction 3 from the Sephadex chromatography accounted for almost all of the inhibitory activity it was further separated into three fractions by HPLC (Figure 3). Most of the inhibitory activity was found in fraction 3 (Figure 4), which eluted as a single peak (Figure 3). Further attempts to resolve fraction 3 by HPLC or TLC were unsuccessful. The peak was monitored at two wavelengths, the absorption ratios (230/280) were almost constant across the peak. This indicates that the peak may be a pure compound or a mixture of isomers containing the same chromophores. The UV absorption spectrum showed a single maximum at 216 nm. HPLC peak 3, due to its high activity, was tested for dose–response relationships using seeds of four weed species (Figure 5). In this case, the actual weight of material present was used. The total recovery in this peak represented 1.2% of the periderm dry weight. The results of these bioassays showed large differences in sensitivity to the inhibitor(s) between species. Such large differences have been demonstrated previously with crude methanolic extracts (Peterson and Harrison, 1991). The I_{50} were 0.011, 0.013, and 0.16 mg/ml for proso millet, velvetleaf, and redroot pigweed, respectively; tall morning glory showed no response to the fraction. The strong weed-suppressing properties of the sweet potato clone, Regal, as previously observed in field and greenhouse (Harrison and Peterson, 1986, 1991) may be explained by the presence in the periderm of a single compound or a mixture of closely related isomers. The active principle was highly selective with respect to germination inhibition of various seeds and may have potential as a natural herbicide.

Acknowledgments—The authors wish to thank Ms. Naomi Kelly for her excellent technical assistance.

Heliothis virescens: RESPONSE CHARACTERISTICS OF RECEPTOR NEURONS IN SENSILLA TRICHODEA TYPE 1 AND TYPE 2

TOR J. ALMAAS and HANNA MUSTAPARTA*

Department of Zoology
University of Trondheim
AVH, 7055 Dragvoll, Norway

(Received August 17, 1990, accepted January 28, 1991)

Abstract—Partial electroantennograms (EAGs) and single cell recordings from *Heliothis virescens* males have demonstrated the presence of pheromones receptor neurons in sensilla trichodea type 2 as well as in type 1. This is supported by cobalt tracing experiments, showing that primary axons from the distal flagellum, containing only s. trichodea type 2, project into the macroglomerulus complex in the male antennal lobes. Four types of finely tuned pheromone receptor neurons were found in males, whereas in females the corresponding neurons responded mainly to host odors. In males the majority (75 and 18%, respectively) were tuned to the major *Heliothis virescens* pheromone components (Z)-11-hexadecenal (Z11-16:Al) and (Z)-9-tetradecenal (Z9-14:Al). The others (5 and 2%, respectively) responded specifically to (Z)-11-hexadecen-1-ol (Z11-16:OH) and (Z)-11-hexadecen-1-ol acetate (Z11-16:Ac). No neurons responding selectively to the minor pheromone components were found. The Z11-16:Al neurons of both sensilla types possessed similar specificity. However, the sensitivity decreased toward the medial and distal part of the flagellum, where s. trichodea type 2 are located. This suggests that the pheromone concentrations can be detected peripherally by a spatial as well as a temporal mechanism. Differences in temporal response patterns (pronounced phasic vs. tonic component) were found within the same type of neurons, suggesting different ability to encode intermittency of the pheromone plume as well as to mediate maintenance of flight.

INTRODUCTION

Pheromone reception in the tobacco budworm moth *Heliothis virescens* (Lepidoptera: Noctuidae) has been studied previously by electrophysiological recordings from single cells of the male specific sensilla trichodea type 1 (Almaas and Mustaparta, 1990). It was found that the majority of receptor neurons of these sensilla are finely tuned to either one of the two major pheromone components: (Z)-11-hexadecenal (Z11–16:Al) (58%) and (Z)-9-tetradecenal (Z9–14:Al) (27%). In the natural ratio 16:1, these compounds are necessary and sufficient to elicit behavioral responses in males (Roelofs et al., 1974; Tumlinson et al., 1975). In addition to the receptor neurons tuned to the two major components, another type of receptor neuron was found that was tuned to the *Heliothis*-produced compound (Z)-11-hexadecen-1-ol (Z11–16:OH). Whether this alcohol has an intra- or interspecific function remains controversial, since it is present in the *H. virescens* female gland, but is not emitted (Teal et al., 1986). Furthermore, in wind-tunnel experiments it does not influence close-range precopulatory male behavior (Teal et al., 1986), but increases trap catches when added to a three-component blend of pheromone aldehydes (Ramaswamy et al., 1985). However, it is possible that Z11–16:OH disrupts orientation of *H. virescens* males, as in other species of *Heliothis* (cf. Heath et al., 1990).

Receptor neurons tuned to the minor components (Z)-9-hexadecenal (Z9–16:Al), (Z)-7-hexadecenal (Z7–16:Al), hexadecenal (16:Al), and tetradecenal (14:Al) (shown by Teal et al., 1986, to influence the close-range male behavior) were not identified in the male-specific s. trichodea type 1 (Almaas and Mustaparta, 1990). Furthermore, tests with mixtures did not reveal any influence by the minor components on the responses of receptor neurons tuned to the major compounds. However, the fact that minor components elicited some electroantennogram (EAG) response suggests that there might exist some receptor neurons responsive to minor components, perhaps in other sensilla. Therefore, the present study was undertaken to investigate the specificity of receptor neurons in s. trichodea type 2, which are located along the whole antenna of both males and females.

The aims of the present study were primarily (1) to find out whether the receptor neurons of the s. trichodea type 2 are involved in pheromone reception in males and, if they differ from those of females, (2) to determine the response characteristics of the neurons with respect to specificity, sensitivity, and temporal response patterns, and (3) to compare these characteristics with those of receptor neurons in s. trichodea type 1.

METHODS AND MATERIALS

Animals. Pupae of the tobacco budworm moth *Heliothis virescens* from a laboratory culture were kindly provided by Dr. Max Angst, Ciba-Geigy, Basel, Switzerland. The pupae were sex determined, and the sexes were kept separate in closed containers. After eclosion at room temperature, the moths were placed in containers marked with date of eclosion and fed a sucrose solution ad libitum. Most animals were used within four days posteclosion while some were not used until 6 days of age.

Morphology. A standard procedure for in vivo diffusion of cobalt chloride via cut axons was used (Altman and Tyrer, 1980; Obermayer and Strausfeld, 1980). A 5% cobalt chloride (Sigma) solution (aq.) was applied at the top of the cut end of the flagellum, allowing cobalt to migrate at room temperature (22°C) inside the cut axons along the antennal nerve to the glomeruli in the antennal lobe (Figure 1A). For comparison, the flagellum in three specimens was cut proximally (segment 35–45) and in four distally (segment 65–75). After two and three days, respectively, the brain was removed and transferred to a saline solution saturated with hydrogen disulfide for precipitation of cobalt sulfide. After 10 min, the tissue was rinsed in saline (10 min) and fixed (2 hr) in alcoholic Bouin fixative. The silver intensification method of Bacon and Altman (1977) for cobalt-filled neurons in whole-mount preparations was employed. After dehydration in ethanol, the brains were embedded in Durcupan (Fluka) and sectioned (20 μm) for light microscopy of cobalt sulfide precipitation in the antennal lobe. For control, the same procedure was applied to intact antennae.

Electrophysiological Recordings. The experimental procedure and the recording technique were previously described (Almaas and Mustaparta, 1990). The insect body and antenna were fixed in position using a Plexiglas holder and pieces of tape and wax. Tungsten wire hooks were used to prevent any movement of the antennae that could distort the electrodes positioned on the flagellum.

A standard technique was employed for recording the summated receptor potential of the electroantennogram (EAG) (Schneider, 1957; Kaissling, 1971). In males, partial EAG responses also were recorded from the proximal part, containing both s. trichodea type 1 and type 2 (flagellar segments 1–45), and from the distal part, containing s. trichodea type 2 but no type 1 (flagellar segments 46–81). This was carried out by covering the distal and proximal parts, respectively, with a domed sheet of wax, in a manner not touching the sensilla. The edge of the wax cover was gently pressed toward the wax platform, making a seal to prevent odors from reaching the covered sensilla. After recording responses from the proximal part, the wax was removed distally and repositioned proximally. In all experiments the partial EAG recordings were preceded by EAG recordings from the whole antenna. The EAG responses were mea-

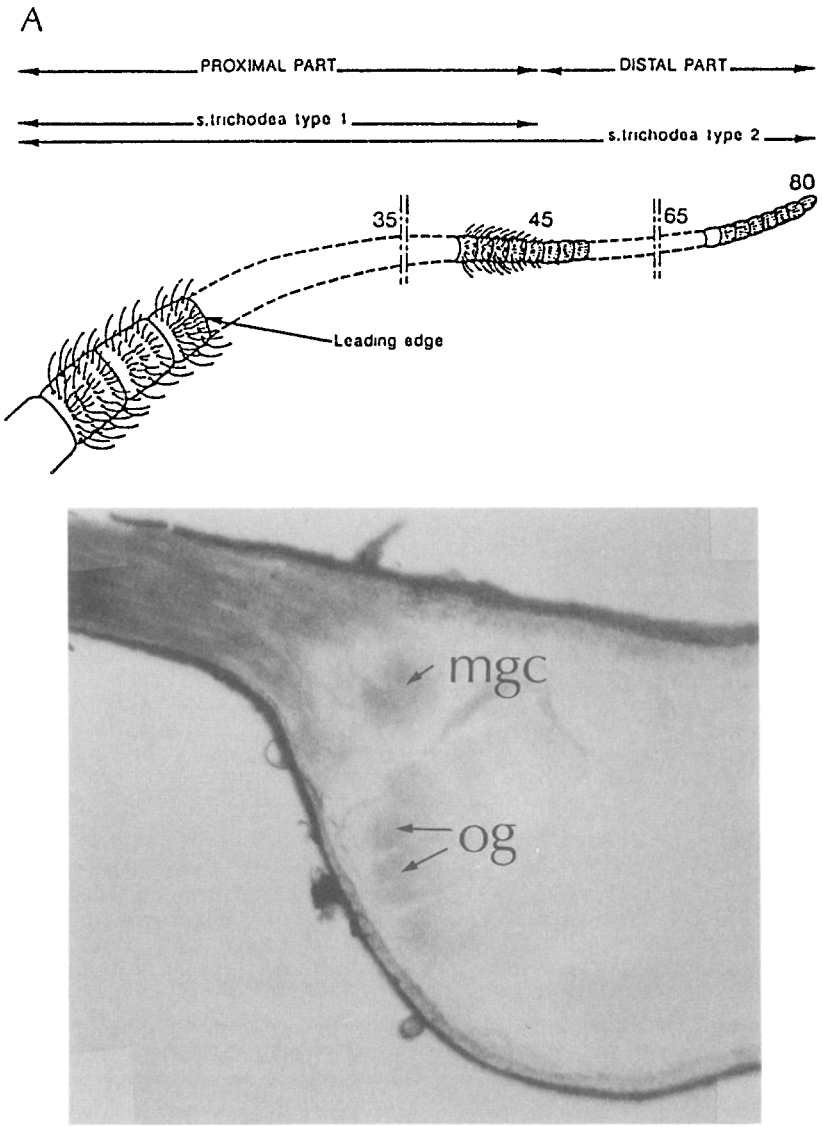

FIG. 1. (A) Schematic drawing of the flagellum in a *H. virescens* male, indicating the position of the s. trichodea type 1 on the proximal part and the s. trichodea type 2 on the distal part. The antenna was cut proximally (segment 35–45) and distally (segments 65–75), and the cut end was placed inside a vaseline cup allowing the cobalt to migrate inside the cut axons towards the antennal lobe. (B) Light microscopy micrograph showing silver-stained cobalt sulfide deposits in the antennal lobe of a *H. virescens* male. The flagellum was cut distally (segment 65). The deposits are restricted to the antennal nerve, the macroglomerulus complex (mgc), and a few ordinary glomeruli (og) close to the entrance of the antennal nerve. Magnification 170×.

sured as peak amplitude (mV) to each odor stimulus from which the response (ca. 1 mV) to the control stimulus was subtracted. All responses (both in males and females) are presented as percentage of the average response (3.2 mV) of male antennae to 100 μg of Z9–14 : Al.

For single cell recordings, tungsten microelectrodes were used (Boeckh, 1962; Mustaparta et al., 1979). Recordings were primarily made from s. trichodea type 2 on the medial side (the leading edge) of the proximal part, and from the medial and lateral sides of the distal part. Some recordings also were made from the longest sexually dimorphic s. trichodea type 1 in order to compare the responses from the two sensilla types when using the same stimulation cartridges. In the females, most recordings originated from the medial side.

The spontaneous activity was 0–10 impulses/0.5 sec and the spike amplitude varied from 30 to 200 μV. The spontaneous activity was not subtracted from the response values. The recordings often displayed impulse activity from more than one neuron. Only cells that were unambiguously identifiable from their spike characteristics were used for further analysis.

Stimuli. The synthetic pheromone compounds Z11–16:Al, Z9–14:Al, Z9–16 : Al, Z7–16 : Al, 16 : Al, and Z11–16 : OH were kindly provided by Dr. Peter Beevor, Natural Research Institute, Kent, England. The purity (in excess of 99%) was rechecked before use by gas–liquid chromatography (GLC) (cf., Almaas and Mustaparta, 1990). Other compounds used were the acetate analogs (Z)-11-hexadecen-1-ol acetate (Z11–16 : Ac), (Z)-9-hexadecen-1-ol acetate (Z9–16 : Ac), and (Z)-7-hexadecen-1-ol acetate (Z7–16 : Ac) (Shin-Etsu Chemical Co., Japan), which are pheromone components in *H. subflexa*. Several synthetic compounds known to be common in plants were also tested: (Z)-3-hexen-1-ol, (Z)-3-hexenyl acetate (Sigma), (E)-2-hexen-1-ol, (E)-2-hexenal, 1-hexanol (Aldrich Chem. Co.), and benzaldehyde (Merck). Other "green odor" stimuli employed were hexane extracts and fresh materials of various host plants (leaves from cotton, tobacco, and corn) and of various fruits of nonhost plants (orange, apple, and banana), as well as fresh material from pot plants. As "green odor" stimuli in the EAG recordings, only fresh materials of nonhost plants were used. Furthermore, these recordings also included two mixtures, where the minor pheromone components were added to Z11–16 : Al and Z9–14 : Al, respectively. For details regarding preparation of stimuli, see Almaas and Mustaparta (1990). The compounds (50 mg) were solved in hexane (1 ml) and diluted in decade steps. The concentrations were checked by GLC, and 200 μl of each dilution was applied on pieces of filter paper, each placed inside a glass cartridge. Four or two series of each compound were made independently in order to check recording conditions and stimulus concentration. In addition to these test series, separate cartridges were used initially for screening the sensitivity of the receptor neurons to the various compounds. The cartridges were stored at $-20°C$ and used within three months. To prevent adaptation, a low concen-

tration (0.1–1.0 μg) was employed for screening. Host odors were used only for qualitative tests.

Stimulation. The stimuli were applied with a "syringe-olfactometer" (Kafka, 1970; Mustaparta et al., 1980). For details of the stimulus apparatus and stimulation procedure, see Almaas and Mustaparta (1990). The cartridges were fastened to the outlet of a clean 20-ml syringe that served to deliver the airflow (7 ml/0.5 sec) through the cartridge. The interstimulation intervals were 1 min for low stimulation intensities (below 1 μg amount in the cartridge) and 1–4 min at higher intensities. Application of air from control cartridges (hexane on filter paper) was regularly carried out during the experiments.

RESULTS

Morphology. In preparations where the flagellum was cut proximally, massive precipitation of cobalt sulfide was observed both in the antennal lobe macroglomerulus complex (MGC) (male-specific glomerulus particularly transmitting pheromone information; Christensen and Hildebrand, 1987; Christensen et al., 1989) and in the ordinary glomeruli (probably dealing with plant odor information; Masson and Mustaparta, 1990). Sections of the antennal lobe in a preparation for which the flagellum were cut distally at segment 65 showed definite cobalt sulfide precipitation in the MGC (Figure 1B), but less pronounced than in the preparations with a proximally cut flagellum. Furthermore, here the precipitate was much more restricted, i.e., confined to the MGC and a few ordinary glomeruli close to the entrance of the antennal nerve. No cobalt was found to migrate into the antennal lobe when using the same procedure with an intact antenna.

Electroantennograms. The summated receptor responses (EAGs) from the whole antenna, its proximal and distal parts respectively, were recorded in eight males of *H. virescens*. Responses to the five pheromone aldehydes and the alcohol analog were compared. Z11–16:Al and Z9–14:Al (major components) elicited considerably higher responses than Z9–16:Al (minor component) and Z11–16:OH (minor component or interspecific inhibitor), whereas Z7–16:Al and 16:Al (minor components) had the lowest effects. This range of effects, measured for the whole antenna, was the same also in the proximal and distal parts. The responses from the proximal part were in general higher than those from the distal part (Figure 2A–C).

The dose–response relationships for Z11–16:Al, Z9–14:Al, and Z11–16:OH are plotted in Figure 2A–C. The diagrams show augmented responses with increased concentrations for both the proximal and distal parts of the antenna. In general, the sum of responses from the two parts matched the responses recorded from the whole antenna. For Z11–16:Al (Figure 2A), the

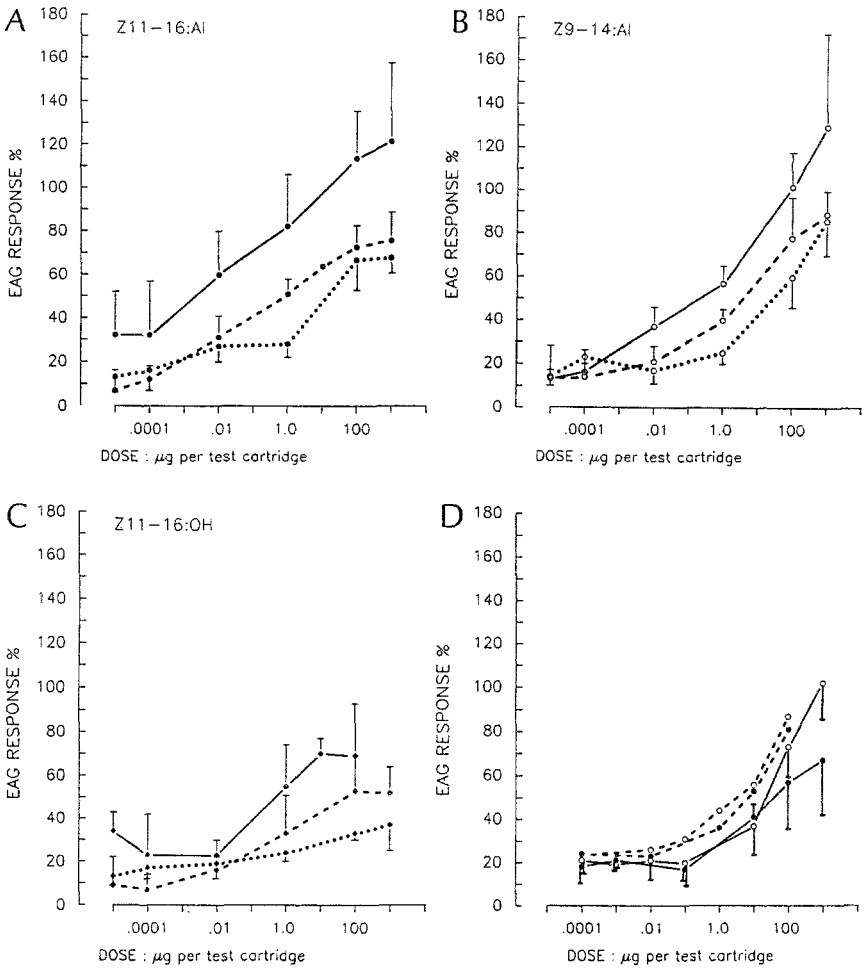

FIG. 2. Electroantennogram dose–response curves from six males (A–C) and seven females (D) of *H. virescens*. In males, the curves are shown for Z11–16:Al (A), Z9–14:Al (B), and Z11–16:OH (C), and recorded from the whole antenna (solid line), proximal part (broken line), and distal part (dotted line). In females (D) the curves are shown for Z11–16:Al (•), Z9–14:Al (○)and the mixtures with minor components (broken lines), recorded from the whole antenna. The data are presented as the mean values calculated as percentage of the average response of male antennae to 100 μg of Z9–14:Al. Standard deviation is indicated by vertical bars.

dose–response curve for the proximal part parallelled roughly (with a shift of 2–3 log units to the right) that of the whole antenna, whereas the curve of the distal part showed a steeper slope starting at a higher concentration (1.0–10 μg). For Z9–14 : Al (Figure 2B), the dose–response curves for the proximal and distal parts were shifted 1–2 and 2–3 log units, respectively. Similar dose–response relationships of the different parts were obtained for Z9–16 : Al and Z11–16 : OH. For the alcohol (Figure 2C), as for Z9–16 : Al, all responses were lower and the dose–response curves less steep.

EAG responses to the pheromones and fresh plant materials were recorded from seven female antennae. Here, responses only from the whole antenna were compared, since s. trichodea type 1 is not present in females. As shown in Figure 2D, the dose–response curves for the major pheromone Z11–16 : Al and Z9–14 : Al were shifted about 4 and 2 log units, respectively, to the right compared to those of the male antennae. When adding minor components, the responses showed a slight increase.

Among the odors from plant material tested qualitatively only, that of orange peel elicited the strongest responses both in males and females; these were even higher than the maximum male response recorded for pheromones. In males, the orange peel response was higher in the distal part than in the proximal part. The mean values for orange peel were 150% in the whole male antenna and 130% in the female antenna (calculated as percentage of the male response to 100 μg Z9–14 : Al). The proximal and distal flagellar responses in males were 77% and 102%, respectively.

Single-Cell Recordings. A total of 96 neurons from *H. virescens* males were investigated, of which 77 were characterized as olfactory receptor neurons. The other 19 neurons did not respond to any of the test odors or to air puffs. The olfactory neurons were divided into five groups, each specifically responsive to one of the following pheromone compounds: Z11-16:Al, Z9-14:Al, Z11–16 : OH, Z11–16 : Ac, or to "green odors." The number and distribution of these receptor neurons are shown in Table 1. The responses to 1.0 μg of *Heliothis* pheromone components from neurons tuned to Z11–16 : Al, Z9–14 : Al, Z11–16 : OH on the medial side of the proximal flagellum are demonstrated in Figure 3A–C, respectively. No receptor neurons selectively activated by the minor aldehydes of the conspecific pheromone blend were found in s. trichodea type 2.

In female *H. virescens* a total of 31 cells were studied, of which 17 could be classified as olfactory receptor neurons. These recordings originated mainly from the medial side of the proximal and distal flagellum. Thirteen of the neurons were classified as host odor cells whereas four responded better to a pheromone compound than to "green odor" stimuli.

Receptor Neurons Tuned to Z11–16 : Al. Twenty-seven male receptor neurons of s. trichodea type 2 were finely tuned to Z11–16 : Al (Table 1). In accord-

ance with type 1 receptor neurons recorded in the present and a previous study (Almaas and Mustaparta, 1990), responses to other pheromone components appeared only at higher concentrations (Figure 4A). Some of them (both type 1 and 2) responded to the extract of orange peel, eliciting a response corresponding to 0.1–1.0 μg Z11–16:Al. As in type 1, the type 2 receptor neurons responded second best to Z9–14:Al, which was only 1/100 as effective as Z11–16:Al (Figure 4B–D). However, different sensitivities between type 1 and 2 receptor neurons were observed. Both in the proximal and distal parts, the cells of s. trichodea type 2 showed lower sensitivities. Furthermore, their sensitivity decreased from proximal to more distal annuli as well as from the lateral to the medial side of the distal part (Figure 4 and 5). On the proximal part, it was only recorded from medially located s. trichodea type 2. The dose–response relationships of single receptor neurons are shown in Figure 4, where the dose–response curves of receptor neurons from s. trichodea type 2 (Figure 4B–D) are compared with that of one cell from s. trichodea type 1 (Figure 4A). The dose–response curves show a shift to the right from the lateral (Figure 4A) to the medial (Figure 4B) side of the proximal part, from the lateral (Figure 4C) to the medial side (Figure 4D) of the distal part, as well as from proximal to distal annuli. The average dose–response relationships of receptor neurons in these areas are shown in Figure 5, demonstrating the different sensitivities.

Variations of temporal response characteristics were found for receptor neurons of both s. trichodea type 1 and 2. Some neuron responses showed a pronounced phasic component with a fast decay, whereas others showed a more tonic component with slow decay and responses far outlasting the stimulation period. This is exemplified in Figure 6, showing temporal response characteristics for neurons of each response type from s. trichodea type 2 located at the

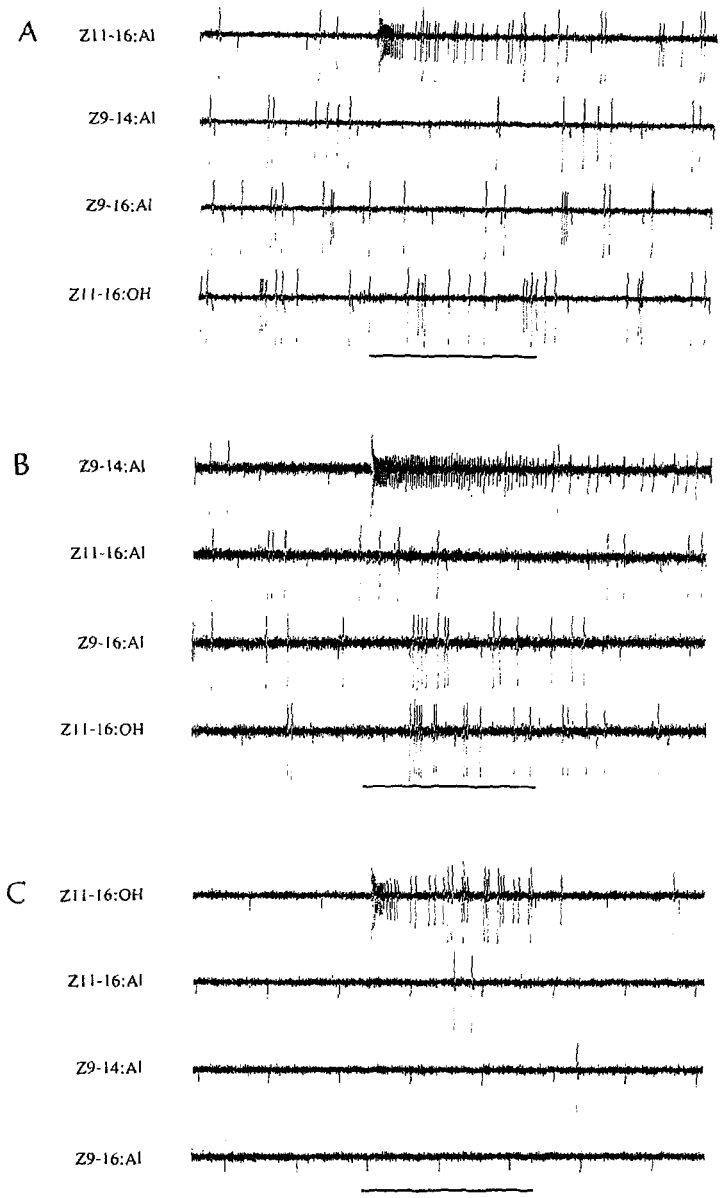

FIG. 3. Electrophysiological recordings of spike activity from single olfactory receptor cells tuned to Z11-16:Al (A), Z9-14:Al (B) and Z11-16:OH (C) in *H. virescens* males. All stimulations were carried out at the same concentration (1.0 μg). The stimulation period of 500 msec is indicated by horizontal bar below. Regular deflections in recordings are time markers.

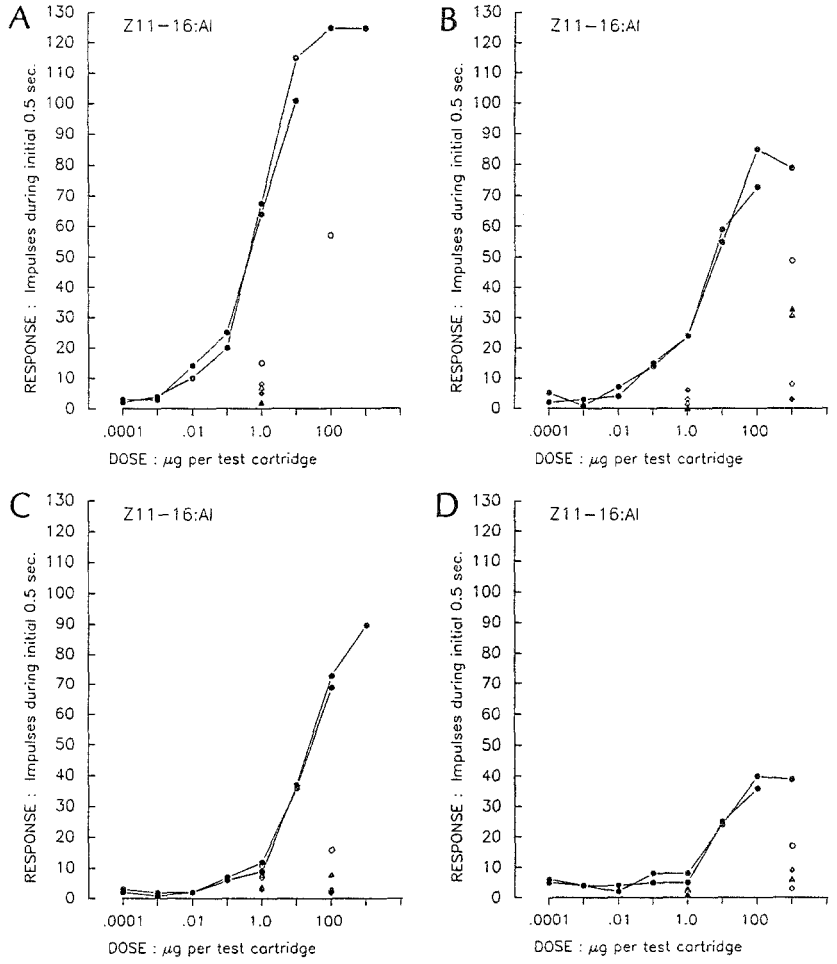

FIG. 4. Dose–response curves obtained for four receptor cells in male *H. virescens*, all tuned to the major pheromone compound Z11-16:Al. The duplicated curves represent independently performed test series of the key compound. The receptor neurons were positioned on the lateral and medial sides of the proximal part (A, B) and distal part (C, D) of the flagellum, respectively. Responses to the other test compounds are indicated by: ○ Z9-14:Al, ▲ Z9.16:Al, △ Z7-16:Al, ◇ 16:Al, ◆ Z11-16:OH. (B is the same neuron as demonstrated in Figure 3A).

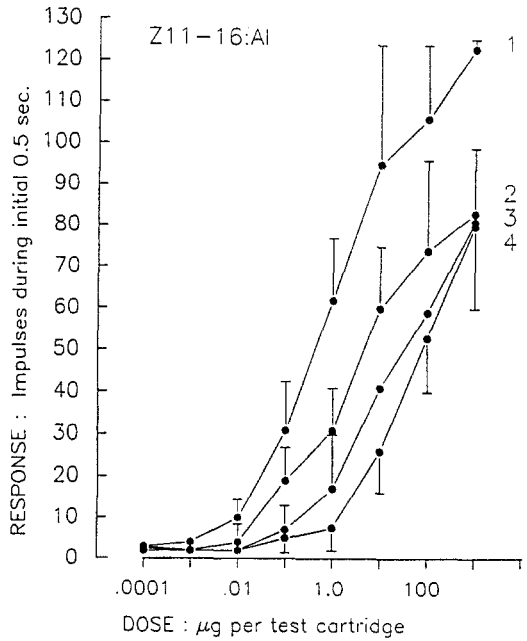

FIG. 5. Average dose-response curves for olfactory receptor neurons in *H. virescens* males, tuned to the major pheromone component Z11-16: Al. The curves represent neurons located laterally (line 1, $N = 7$) and medially (line 2, $N = 14$) on the proximal part; the laterally (line 3, $N = 5$) and medially (line 4, $N = 5$), on the distal part of the flagellum. Standard deviation is indicated by vertical bars, but omitted at the lowest concentrations for clarity.

medial side of the proximal part (A: phasic, B: tonic) and from s. trichodea type 1 located at the lateral side of the proximal part (C: phasic, D: tonic). The type of response patterns (phasic vs. tonic) was consistent at both low and high concentrations, as demonstrated in Figure 6A vs. B. Some neurons showed intermediate types of temporal response patterns.

The variability of temporal response characteristics did not correlate with sensitivity of the receptor neurons, i.e., neurons showing phasic responses did not necessarily show highest sensitivity. However, on the proximal part, more neurons of the phasic type were obtained from the lateral trichodea type 1 (10 of 14) than from the medial s. trichodea type 2 (six of 16) (Table 1). On the distal part, four of five neurons laterally and three of five medially (one not determined) were phasic.

Receptor Neurons Tuned to Z9-14:Al. Ten of the receptor neurons were finely tuned to Z9-14: Al (Table 1). Of these, three were located on the lateral (s. trichodea type 1) and seven on the medial side (s. trichodea type 2) of the

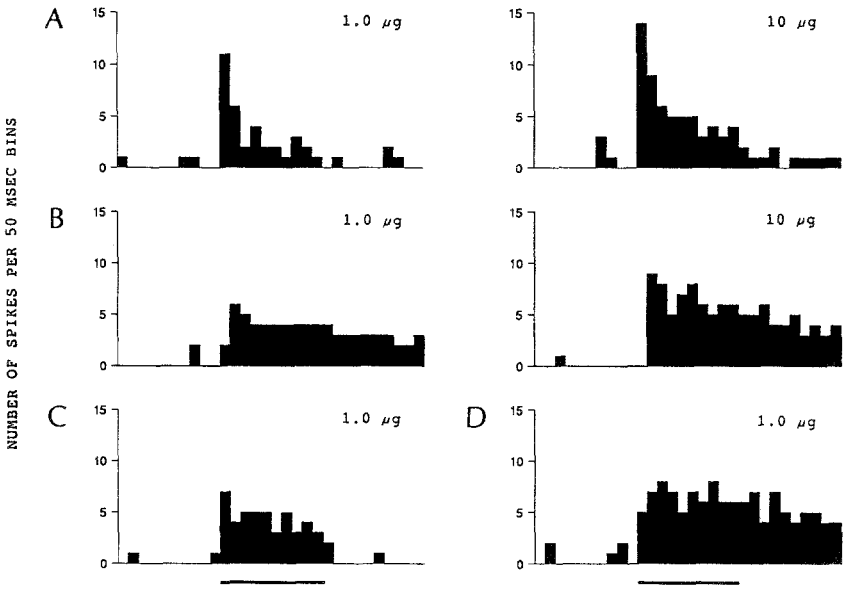

FIG. 6. Temporal response patterns of olfactory receptor neurons tuned to Z11–16:Al on the proximal part of the flagellum in *H. virescens* males. The figures demonstrate response patterns of a more pronounced phasic vs. tonic type, from receptor neurons on the medial side (A vs. B; s. trichodea type 2) and on the lateral side (C vs. D; s. trichodea type 1) . Stimulation period of 500 msec is indicated by horizontal bar below. Note the prolonged tail of discharge at the end of stimulus in the tonic type (B, D). Neurons in A and C are the same as in Figure 4B and A, respectively.

proximal part. Like the type 1 Z9–14:Al neurons previously studied (Almaas and Mustaparta, 1990), these cells had a low response to the other pheromone components at high concentrations (Figure 7) and to the extract of orange peel. In all neurons activated by this "green odor," the responses were approximately the same as for 0.1–1.0 μg of Z9–14:Al. Z9–16:Al was the second best stimulant, being 1/1000 to 1/10000 as effective as Z9–14:Al (Figure 3 and 7), which might either be an analog effect or due to impurities of Z9–14:Al.

The average dose–response relationships for four medially located Z9–14:Al receptor neurons (for which the full dose–response curve was recorded) are shown in Figure 7. The sensitivity of these neurons was not significantly different from that of the laterally located s. trichodea type 1 receptor neurons previously studied (Almaas and Mustaparta, 1990), as indicated by the dotted line in Figure 7. In the present study two of the laterally recorded Z9–14:Al neurons showed a markedly lower sensitivity. No receptor cells selective for Z9–14:Al were detected in the distal part.

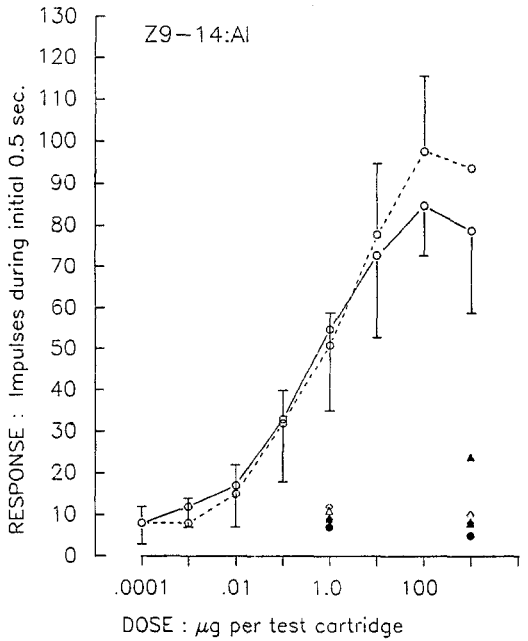

FIG. 7. Average dose–response curves from olfactory receptor neurons in *H. virescens* males, tuned to the major pheromone compound Z9–14 : Al. The recordings were obtained from s. trichodea type 2 on the medial side ($N = 4$, solid line) and from s. trichodea type 1 on the lateral side ($N = 4$, broken line) of the proximal part of the flagellum. Standard deviation is indicated by vertical bars. The average responses to other test compounds are indicated: • Z11-16:Al, ▲ Z9-16:Al, △ Z7-16:Al, ◇ 16:Al, ◆ Z11-16:OH.

The receptor neurons both of s. trichodea type 2 and 1 showed variations regarding phasic and tonic characteristics. This is demonstrated in Figure 8, showing the temporal characteristics of each type in medially and laterally located receptor neurons. The phasic component with a rapid decay and a fast resumption of spontaneous activity was observed for neurons of both sensilla types (Figure 8A and C). More pronounced tonic characteristics with slow decay and responses that far outlasted the stimulation period are demonstrated in Figure 8B and D. Figure 8A and B show that the type of response pattern (phasic or tonic) is consistent at both low and high concentrations.

Due to the relatively low number of Z9–14 : Al receptor neurons, no correlation could be made between temporal response pattern, sensitivity, and location.

Other Pheromone Components. Of the 77 olfactory receptor neurons identified in the present study, only four responded specifically to other pheromone

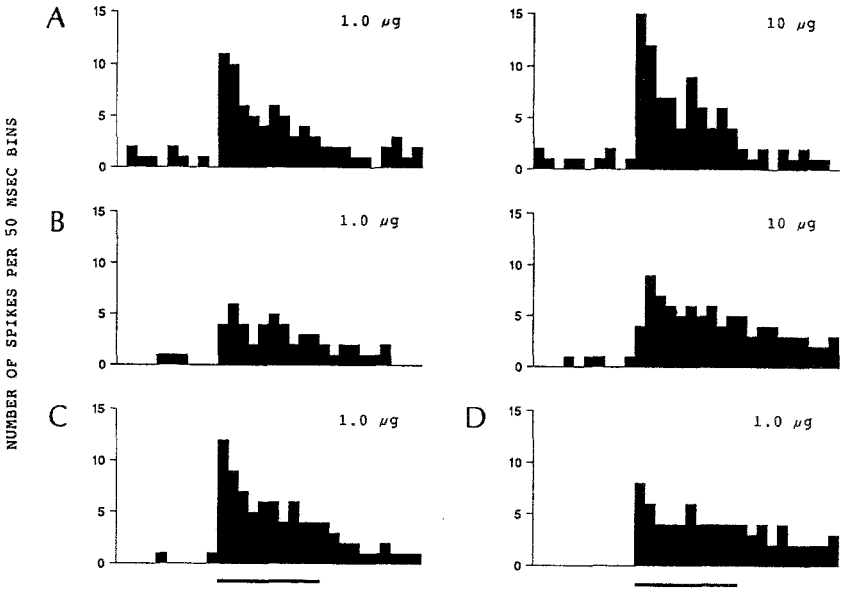

FIG. 8. Temporal response patterns of olfactory receptor neurons from the proximal part of the flagellum tuned to Z9-14:Al in *H. virescens* males. The figure demonstrates response patterns of a more pronounced phasic vs. tonic type, from receptor neurons on the medial side (A vs. B; s. trichodea type 2) and on the lateral side (C vs. D; s. trichodea type 1). Stimulation period of 500 msec is indicated by horizontal bar below. Note the prolonged tail of discharge at end of stimulation in the tonic type (B, D).

components (three to Z11-16:OH and one to Z11-16:Ac) of the genus *Heliothis* (Table 1). The Z11-16:OH neurons had a similar type of specificity and sensitivity. The dose-response relationships of an alcohol and an acetate receptor neuron are shown in Figure 9A and B. The sensitivity of these neurons was similar to the Z11-16:Al receptor neurons located in corresponding areas; i.e., medially on the proximal part (Figure 9A; Figure 5, line 2) and laterally on the distal part (Figure 9B; Figure 5, line 3). The acetate receptor neuron exhibited a pronounced tonic response with a very slow decay.

Host Odors. Twenty-two of the olfactory receptor neurons in males (Table 1) could be classified as "host odor detectors," i.e., they showed strongest response to various plant odors and no response to *Heliothis* pheromones.

In general, these units fired below 60 impulses per 0.5 sec when exposed to several of the "green odor" stimuli. Certain response groups could be distinguished: (1) Three neurons reacted to fresh materials of cotton, and two of these also responded to the cotton extract. (2) Five neurons were activated by the odors of tobacco and/or corn, but also responded to other "green odor"

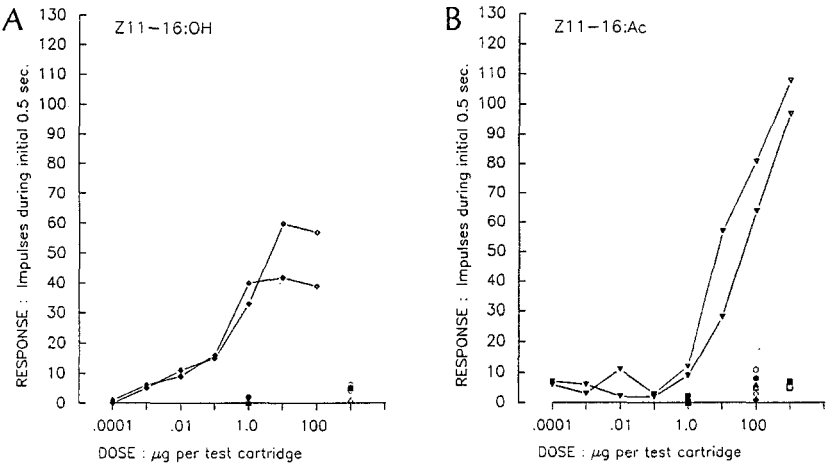

FIG. 9. Dose-response curves of two olfactory receptor neurons in male *H. virescens*, tuned to Z11-16:OH (A, same neuron as in Figure 3C) and Z11-16:Ac (B). The duplicated curves represent independently performed test series with the key compound. Responses to the other test compounds are indicated: • Z11-16:Al, ○ Z9-14:Al, ▲Z9-16:Al, △ Z7-16:Al, ◇16:Al, ◆ Z11-16:OH, ■ Z9-16:Ac, □ Z7-16:Ac.

stimuli. (3) One neuron was activated selectively by the synthetic alcohols. (4) Thirteen units responded best to extracts of fruit (primarily orange peel extract). Four of them also reacted to the synthetic plant volatiles, either the alcohols or the acetate. The synthetic compounds consistently elicited phasic responses, whereas the bouquet of natural plant odors elicited firing patterns that varied with the response strength and predominantly were tonic at high responses.

Receptor Neurons in H. virescens *Females.* In females, 13 of the 17 olfactory neurons studied responded to the "green odor" stimuli with minimal or no reaction to the pheromone components tested. The other four neurons, however, responded better to high concentrations (100 μg) of pheromone components than to any of the "green odor" stimuli. Compared to male pheromone receptor neurons in corresponding areas, their sensitivity was much lower. Furthermore, the specificity differed from that of the units in males by being less selective for one particular compound. Thus, two neurons responded to Z9-14:Al (50 and 52 impulses per 0.5 sec), Z11-16:Al (38 and 42 impulses), Z9-16:Al (30 and 36 impulses) and Z7-16:Al (21 and 19 impulses). The other two were activated by the acetates, one of them somewhat better to Z7-16:Ac (62 impulses, dose-response curve shifted 1 log unit to the left) than to Z11-16:Ac (30 impulses) and Z9-16:Ac (26 impulses). The 13 "green odor" units were divided between the same response groups as found in males (see above), and the response strength of these neurons was similar to that recorded in males.

One neuron was specific for fresh cotton leaves and cotton leaf extracts. Also in the female, the synthetic compounds elicited a phasic response pattern, whereas the responses to the bouquet of "green odors" predominantly were of the tonic type.

DISCUSSION

The observed specific responses of receptor neurons in s. trichodea type 2 indicate that these neurons are involved in pheromone reception. This is supported by the results of cobalt tracing, showing that primary axons from the distal flagellum project into the MGC of the male antennal lobes (Figure 1B). Furthermore, specificities of these receptor neurons were different in males and females. While finely tuned to one pheromone compound in males, they generally did not respond to *Heliothis* pheromone components in females. However, the finding of four units in *H. virescens* females responding to these compounds suggests that females might possess a few receptor neurons detecting *Heliothis* pheromones.

The similar specificity of the pheromone receptor neurons in male s. trichodea types 1 and 2 (Figure 4) suggests that these neurons posses functionally similar membrane receptor types. It is interesting to note that the type 2 receptor neurons tuned to Z11–16:Al exhibited a lower sensitivity than those of s. trichodea type 1. A further decrease of sensitivity occurred medially and distally (Figures 4 and 5). The variation in sensitivities between neurons may be due to several reasons, e.g., differences in filtering capacities of the sensilla, numbers of membrane receptors, or amplification in the transduction (features discussed by Kaissling, 1986). The specificity and sensitivity of the Z11–16:Al receptor neurons are reflected by the EAG responses of the proximal and the distal parts, since no other olfactory receptor neurons contribute by significant analog responses to Z11–16:Al. The stronger EAG response by the proximal part, which parallels the responses of the whole antenna (Figure 2A), can be explained by both a larger number and a higher sensitivity of the receptor neurons in this part of the antenna. The lower sensitivity of the Z11–16:Al receptor neurons on the distal part (Figures 4 and 5) is in accordance with the EAG dose–response curve (Figure 2A). Lower sensitivities of receptor neurons in shorter than in longer s. trichodea also have been observed in two *Antheraea* species (Meng et al., 1989). In the noctuid species *Trichoplusia ni*, however, a higher sensitivity was found for neurons in the shortest s. trichodea, which are located laterally and possess a higher number of pores (O Connell et al., 1983).

The large proportion of receptor neurons (Table 1) tuned to Z11–16:Al indicates that this compound might be detected at lower concentrations and thus

have a long-distance effect, whereas Z9–14 : Al, detected by fewer neurons, mediates the species-specific signal at a closer range. Furthermore, the presence of receptor neurons tuned to the same compound (Z11–16 : Al), but with a different sensitivity, suggests that the concentration (and thus the distance from the odor source) can be determined peripherally by a temporal as well as a spatial mechanism, i.e., by increased firing rates of equally sensitive neurons and by activation of additional neurons contributing to the antennal lobe information when the male approaches the pheromone source.

The present results do not reveal any different sensitivities for the Z9–14 : Al receptor neurons located laterally and medially on the proximal part of the flagellum. Only two lateral (present study) and three medial neurons (Almaas and Mustaparta, 1990) exhibited a lower sensitivity. It seems, therefore, that these neurons contribute less to the spatial mechanism of concentration detection. In the present and a previous study (Almaas and Mustaparta, 1990) a total of 24 Z9–14 : Al neurons and 71 Z11–16 : Al neurons were identified in *H. virescens* males (i.e., ratio of 1 : 3). This is consistent with the observed lower average EAG response to Z9–14 : Al than to Z11–16 : Al (Figure 2A and B). However, in EAG responses, the analog effect of Z9–14 : Al on Z11–16 : Al receptor neurons should not be neglected, since it would increase the EAG response to Z9–14 : Al.

In addition to the Z11–16 : Al and Z9–14 : Al receptor neurons, 10 Z11–16 : OH neurons (including seven units from Almaas and Mustaparta, 1990) and one Z11–16 : Ac neuron were found. It is possible that the two latter types mediate important interspecific messages. It is surprising that, of 106 receptor neurons identified, no neuron tuned to any minor pheromone compound was found. Furthermore, no host odor receptor neuron responded to either major or minor components. Since the minor components, added to the major pheromones did not influence any responses of the Z11–16 : Al and Z9–14 : Al receptor neurons (Almaas and Mustaparta, 1990), it is difficult to explain how the minor components are detected. Still they might exist in a very low number or in sensilla types not examined. It might be that the minor components are important only for some individuals of the population or that there are differences between lab-reared and wild *H. virescens* (Raina et al., 1989).

The temporal response patterns observed in *H. virescens* male receptor neurons are generally in accordance with previous results obtained in *H. virescens* males (Almaas et al., 1990). Both as regards the Z11–16 : Al and Z9–14 : Al neurons, phasic as well as tonic temporal response patterns were observed. As for *H. zea*, these differences probably can be correlated with the ability to follow pulsed stimuli; i.e., a phasic neuron follows the pulsed stimuli better than a tonic neuron and may, therefore, more easily encode the intermittency of the pheromone plume. While phasic and tonic responses for neurons tuned to the same compound were found in *H. virescens* and *H. zea* (Almaas

et al., 1990), these characteristics could be correlated to the specificity of the receptor neurons in *Antheraea* (Meng et al., 1989; Rumbo and Kaissling, 1989).

Responses to "green odors" were revealed in males and females both as results of the single cell and EAG recordings. Because of the markedly higher number of olfactory sensilla in females than in males (Almaas and Mustaparta, 1990) a higher female EAG response to "green odors" would be expected. However, an explanation for the similar responses seen here in the two sexes is that "green odors," e.g., orange peel (perhaps containing pheromone analog), also activate the numerous pheromone receptor neurons in males. The higher distal EAG response to the orange peel in males indicates that the largest numbers of host odor neurons are distally located in this sex.

In conclusion, the peripheral olfactory system in *H. virescens* males possesses receptor neurons that distinguish pheromone blends of conspecifics and other species by finely tuned receptor neurons located in two morphological types of s. trichodea. Concentrations of the blend can apparently be detected by a temporal as well as by a spatial mechanism. Furthermore, the *H. virescens* males have receptor neurons with a high ability to encode intermittency of the pheromone plume as well as neurons that might be of importance for long-term maintenance of flight.

IMPACT OF UV RADIATION ON ACTIVITY OF LINEAR FURANOCOUMARINS AND *Bacillus thuringiensis* var. *kurstaki* AGAINST *Spodoptera exigua*:[1] IMPLICATIONS FOR TRITROPHIC INTERACTIONS

J.T. TRUMBLE,* W.J. MOAR,[2] M.J. BREWER and W.G. CARSON

(Received October 25, 1990; accepted January 28, 1991)

Abstract—Acidic fogs with a pH of 2.0 and duration of 2 hr did not reduce the efficacy of *Bacillus thuringiensis* var. *kurstaki* (Berliner). Therefore, the impact of UV radiation was investigated on the interactions between (1) levels of the antibacterial linear furanocoumarins psoralen, bergapten, and xanthotoxin in *Apium graveolens* (L.) occurring following a 2.0 pH acidic fog episode, (2) the noctuid *Spodoptera exigua* (Hübner), and (3) a sublethal dosage of the microbial pathogen *B. thuringiensis* var. *kurstaki*. Mean time to pupation in the absence of UV radiation (survival was too low to conduct this analysis for insects exposed to UV) was significantly extended by the addition of either psoralens or *B. thuringiensis*. Larvae developing on diets containing *B. thuringiensis* plus psoralens required nearly 40% longer to pupate than controls, but their effects were additive as the interaction was not significant. Although the mean times to adult emergence were significantly different, time spent in the pupal stage did not vary significantly between treatments, indicating that increases in larval developmental time were responsible for the observed decrease in developmental rate. Mean time to mortality, a weighted average time of death, was not significantly affected by any of the treatments. In a $2 \times 2 \times 2$ factorial analysis, all main effects (linear furanocoumarins. *B. thuringiensis*, UV radiation) reduced survival significantly, as did the three-way interaction. Thus, antagonistic interactions with psoralens that would reduce the effectiveness of *B. thuringiensis* in the field were not observed. When pairs of main effects were nested within the two levels (presence and absence) of the third factor, several two-way inter-

actions were found. Interestingly, the activity of *B. thuringiensis* and the psoralens, individually or in combination, was enhanced by exposure to UV radiation. Implications of this research are discussed for both natural and agricultural ecosystems.

Key Words—Linear furanocoumarins, *Spodoptera exigua*, Lepidoptera, Noctuidae, UV light, tritrophic interactions, *Bacillus thuringiensis*.

INTRODUCTION

Few reports are available on the in vivo impact of plant dietary constituents on the susceptibility of insects to pathogens (Felton and Dahlman, 1984; Krischik et al., 1988). Some plants, such as *Apium graveolens* (L.) (celery), are known to contain the phototoxic linear furanocoumarins psoralen, bergapten, and xanthotoxin (hereafter referred to collectively as psoralens) (Trumble et al., 1990). These compounds generally exhibit increased toxicity in the presence of UV radiation (Igali et al., 1970; Berenbaum, 1978). In addition, the insecticidal activity of *B. thuringiensis* is rapidly degraded in the presence of UV radiation (Dunkle and Shasha, 1988), presumably due to trytophan destruction (Pozgay et al., 1987). To our knowledge, no reports document investigation of such tritrophic interactions in the presence of UV radiation.

Antibacterial substances from plants have been implicated in the reduced insecticidal activity of *B. thuringiensis* (Kushner and Harvey, 1962; Maksymiuk, 1970; Smirnoff, 1972). A primary mode of action of the psoralens is to alkylate DNA (Scott et al., 1976), producing profound mutagenic, carcinogenic, and sometimes lethal effects on bacterial cells (Fowlks et al., 1958; Ashwood-Smith et al., 1986). A second reported activity is as an insect antifeedant (Yajima and Munakata, 1979; Muckenstrum et al., 1981). Thus, the psoralens could theoretically degrade or inhibit (through feeding reduction) the insecticidal activity of microbial pathogens such as *Bacillus thuringiensis* (Berliner), which are under consideration for control of *Spodoptera exigua* (Hübner) (Lepidoptera: Noctuidae) in commercial celery production (Trumble, 1990).

Increased production of psoralens in *A. graveolens* can be induced by a variety of environmental stresses (Berenbaum, 1981). Beier and Oertli (1983) demonstrated that his phytoalexin response could be initiated by general elicitors including copper sulfate, UV light, and cold temperatures. Mechanical damage occurring during harvesting and storage also have been shown to increase concentrations from about 2 μg/g to 95 μg/g (Chaudhary et al., 1985). In addition, Berenbaum (1981) and Zangerl and Berenbaum (1987) demonstrated that distribution of psoralens in wild parsnip was significantly correlated with increasing nitrogen content. Not surprisingly, the high-nitrogen acidic fogs of the type and duration occurring in the Los Angeles Basin are known to gen-

erate exceptionally high levels of linear furanocoumarins in celery (Dercks et al., 1989).

Therefore, a multifactor experiment testing several hypotheses was designed to elucidate the various potential interactions. Initially, we wanted to determine if acidic fogs would directly affect the activity of *B. thuringiensis* against *S. exigua*. A second objective was to test the hypothesis that the enhanced levels of psoralens resulting from acidic fog-induced stress on *A. graveolens* would have an impact on the susceptibility of *S. exigua* to *B. thuringiensis*. A third objective was to investigate these interactions in the presence and absence of UV radiation. In addition, the effects of UV radiation on larval developmental rates and survival were documented.

METHODS AND MATERIALS

Simulated Acidic Fogs. Simulated acidic fogs were prepared by adjusting distilled water to pH 2.0 with reagent grade nitric and sulfuric acid mixed at a 2.5:1 (v/v) ratio. This acid ratio is typical of fogs in California (Waldman et al., 1982). The pH levels also are consistent with fogs occurring coastally near Los Angeles (Hoffman, 1984) in areas where the annual value of field-grown celery exceeds $5 million dollars (U.S.) (Ivey and Johnson, 1986). Additional ionic components known to occur in such fogs were also added (R.T. Musselman, U.C. Statewide Airpollution Resource Center, U.C. Riverside, Riverside, California 92521; personal communication). Control fogs consisted of distilled water and background ions adjusted to pH 6.2–6.3. Fogs were created within a 1-m^3 chamber using a fogging apparatus designed by Musselman et al. (1985), which operated at 7.03 kg/cm^2 and produced droplets averaging 20 μm in diameter. Temperature during treatment averaged 22–26°C. Shade cloth was used to reproduce incident radiation levels consistent with coastal fogs of no more than 300 $\mu E/m^2/sec^{-1}$.

Experiment I—Effects of Acidic Fogs on B. thuringiensis *Activity.* Commercially available *B. thuringiensis* (Dipel 2X, Abbott Labs, Chicago, Illinois, containing the HD-1 isolate of *B. thuringiensis* susbsp. *kurstaki*) was spread evenly at 1-mm thickness in standard, uncovered Petri dishes and exposed to acidic or control fogs for 3 hr. Following treatment, the *B. thuringiensis* was dried by pulling air over the Petri dishes with a vacuum for approximately 12 hr. The resulting material then was incorporated into artificial diets using procedures reported previously (Moar and Trumble, 1987).

Larvae used in all tests were obtained from a laboratory colony established in 1982 from insects collected in Orange County, California, and maintained on artificial diet (Patana, 1969) at 27 ± 1°C with a light–dark period of 16:8 hr. New genetic material was added annually.

Bioassays consisted of eight concentrations of *B. thuringiensis* plus a control for each fog treatment. Concentrations tested were as follows: 25, 50, 100, 200, 300, 400, and 800 μg/ml diet. Thirty neonate larvae were tested at each concentration, and the entire test was repeated twice. Larvae were held on diets in an environmental chamber at 27 ± 1°C and mortality was assessed at day 7.

Statistical Analyses for Experiment I. Bioassay data were analyzed using the Proc Probit procedure (SAS Institute, 1985) after correction for control mortality with Abbott's (1925) formula and then judged for suitability using the overlapping fiducial limits criteria described by Vandekar and Dulmage (1982). Control mortality was less than 10%.

Experiment II—Interactions of UV Radiation, B. thuringiensis, *and Psoralens on Development and Survival of* S. exigua. For diets containing phototoxic furanocoumarins (Aldrich Chemical Company, Milwaukee, Wisconsin), psoralen (14.94 μg/ml diet), bergapten (5-methoxypsoralen; 37.75 μg/ml), and xanthotoxin (8-methoxypsoralen; 82.4 μg/ml) were incorporated at the levels found in celery leaves following a single acidic fog incident (pH 2.0, Dercks et al., 1989). These materials were dissolved in ethanol and adsorbed onto alphacel following removal of the ethanol by vacuum as described by Chan et al. (1978). The amount of alphacel constituted 5% of the entire diet media. The ethanol and alphacel procedure was used for all treatments including the control. Diet media then was added to the alphacel and blended for 5 min. *B. thuringiensis* (Dipel 2X, Abbott Labs) was added last, and blended for 5 min prior to dispensing into 30 ml clear plastic cups. The *B. thuringiensis* was incorporated at a level (25 μg/ml diet) expected to kill 25% of the test population as estimated in Experiment I. *B. thuringiensis* and the psoralens were incorporated individually and in combination in the diets.

Diet cups were covered with Teflon FEP Fluorocarbon film (E.I. DuPont de Nemours & Co., Wilmington, Delaware). This film is much more transparent to ultraviolet light than glass. For treatments exposed to UV radiation, cups with larvae were placed beneath UV-producing fluorescent lamps (40-W Sylvania 350 Blacklight, Inland Lighting Supplies, Riverside, California). UV lamps with a peak intensity at 350 nm were chosen because wavelengths between 300 and 400 nm are believed to be critical for activation of the psoralens (Musajo and Rodighiero, 1962). The lamps were adjusted in height such that the intensity of UV light beneath a layer of the Teflon film was 1.023 mW/cm^2, a value less than the 1.3–1.6 mW/cm^2 range observed in coastal southern California at midday in September (Trumble, personal observation) and more typical of the early morning. All UV measurements were made with a System 371 Optical Power Meter equipped with a model 268 detector head (United Detector Technology, Hawthorne, California).

A 2-hr exposure was chosen on the basis of a study by Griswold and Trum-

ble (1985), which showed the first through third instars to be positively photoactic and the fifth and sixth instars to be negatively phototactic. Thus, due to either thermoregulation or light aversion, larvae are directly exposed to UV radiation at the canopy surface only for approximately 2 hr. Our results may be somewhat conservative for early instars in that test larvae were not exposed to additional low levels of UV that would be encountered beneath foliage. Exposure times for larger larvae should be accurate, as later instars often hide beneath the soil and would not be exposed to UV radiation during the peak intensity periods. Insects not exposed to UV radiation were kept in the same room and protected from UV radiation by wooden barriers. An incandescent bulb maintained photoperiod during the 2-hr exposure. When not being exposed, all insects were held at 27 $\pm$ 1°C in a photoperiod of 16:8 hr light–dark.

Thirty neonate larvae were placed on each treatment (all combinations of psoralens, *B. thuringiensis*, and exposure to UV radiation = eight treatment combinations). This test was replicated three times. Larvae were examined daily for mortality, development to the pupal stage, and emergence of the adults. Examinations were stopped when all insects were dead or had emerged as adults. Mean time to pupation was calculated for each treatment by averaging the number of days required to pupate for those larvae reaching the pupal stage. The mean time to emergence was calculated similarly for those insects successfully emerging as adults.

The mean time of mortality (after Moar and Trumble, 1987) was calculated for each treatment by dividing the number of larvae dying on a given day by the total mortality at the end of the study. This value then was multiplied by the respective day. Values for all days then were summed to produce a weighted average time of death.

Statistical Analyses for Experiment II. An analysis of variance of the 2 $\times$ 2 $\times$ 2 factorial was used to compare the survival variables among the eight treatment combinations following an arcsine square root transformation. Each of the factors (psoralens, *B. thuringiensis*, UV radiation) was treated as a fixed effect, each with two levels (presence or absence). A blocking factor was included as a random effect in the model because the experiment was replicated three times. The error mean square of the 2 $\times$ 2 $\times$ 2 factorial was used to construct the F tests. If a three-way interaction was present, dependency of the two-way combined effects on a third factor was removed; the two-way interaction sums of squares were calculated within each level of the third factor (Steel and Torrie, 1980, Chapter 15).

All four treatment combinations with UV radiation exposure were absent when analyzing mean time to emergence and mean time spent as pupae (all insects died before or during the pupal stage). Three treatment combinations with UV radiation exposure were missing when analyzing the mean time to pupation variable (only the insects from the "no psoralen $\times$ no *B. thuringiensis*

× UV radiation'' treatment survived to pupation). The effect of the psoralens and *B. thuringiensis* treatments, in the absence of UV radiation, therefore, was considered with a two-way ANOVA comparing four treatment combinations within a replicated experiment. This analysis allowed comparisons of psoralen and *B. thuringiensis* treatments and their interactions in the absence of UV exposure.

RESULTS AND DISCUSSION

Experiment I—Effects of Acidic Fogs on B. thuringiensis *Activity.* Exposure of *B. thuringiensis* to acidic fogs with a pH of 2.0 produced no significant effects on *S. exigua* as compared to the control treatment by the criteria of Vandekar and Dulmage (1982). In the first repetition, the LC_{50} (95% fiducial limits) values were 185 (144–234) μg formulated material/ml diet and 166 (103–249) μg/ml for the acidic fog-treated *B. thuringiensis* and the control fog-treated *B. thuringiensis*, respectively. Slopes (± SEM) of log dose probit lines were 1.86 (0.211) and 1.86 (0.287), respectively. In the second repetition, conducted several months later, LC_{50} values were 340 (253–461) μg formulated material/ml diet and 384 (306–477) μg/ml for the treated *B. thuringiensis* and the untreated *B. thuringiensis*, respectively. Slopes (± SEM) of log dose probit lines were 1.63 (0.238) and 2.60 (0.390), respectively.

The variability in LC_{50} values between repetitions probably is due to changes occurring in susceptibility over time in colonies due to founder effects and the introduction of new genetic material. Such variability is not uncommon among populations of other noctuid moths (Vandekar and Dulmage, 1982). The LC_{50} values found in this study are similar to those reported previously (Moar et al., 1986, LC_{50} = 196; Moar and Trumble, 1987, LC_{50} = 299). Thus, even in populations with variable susceptibility to *B. thuringiensis*, no differences in treatment effects were detected.

Experiment II—Interactions of UV Radiation, B. thuringiensis *and Psoralens on Development and Survival of* S. exigua. Mean time to pupation in the absence of UV radiation (survival was too low to conduct the analysis for insects exposed to UV) was significantly extended by the addition of either psoralens ($F = 13.11$; $df = 1,6$; $P < 0.01$) or *B. thuringiensis* ($F = 73.55$; $df = 1,6$; $P < 0.01$) (Figure 1). Developmental rate reductions on diets containing *B. thuringiensis* were not unexpected as *Bacillus* species-induced feeding inhibition has been reported previously (Hegazy and Antonious 1987; Salama and Sharaby 1988a). Larvae developing on diets containing *B. thuringiensis* plus psoralens required nearly 40% longer to pupate than controls, but the effects were additive as the interaction was not significant ($F = 0.02$; $df = 1,6$; $P = 0.883$).

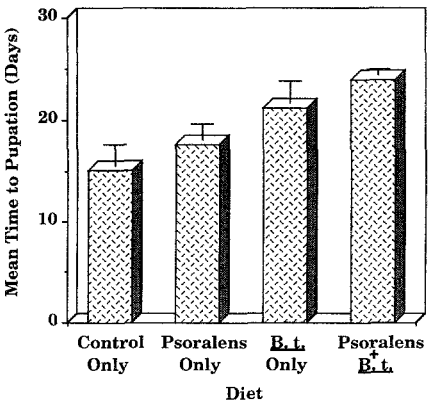

FIG. 1. Mean time to pupation of *S. exigua* in the absence of UV radiation on diets containing psoralens, *B. thuringiensis*, or combinations of both. Thirty neonate larvae were placed on each treatment (all combinations of psoralens, *B. thuringiensis*, and exposure to UV radiation = 8 treatment combinations). This test was replicated three times. Extensions above bars denote standard errors.

This increase in developmental time during the larval stage could have substantial implications for the population dynamics of *S. exigua* in the celery system. Because the majority of the mortality observed in the field occurs in the larval stage (Hogg and Gutierrez, 1980), increased time in this susceptible stage, as opposed to the more protected egg and underground pupal stages (Oatman and Platner, 1972; Tingle et al., 1978), may allow additional opportunity for parasites and predators to reduce populations. Such increases (or decreases) in longevity of larvae previously have been implicated as critical factors in population regulation for other insects (Cardona and Oatman, 1971; Trumble et al., 1987).

The time to emergence of the adult stage in the absence of UV radiation was significantly prolonged by the addition of either psoralens (control mean = 23.64 days; psoralens mean = 26:33; $F = 60.93$; $df = 1,6$; $P < 0.01$) or *B. thuringiensis* (mean = 30.59 days; $F = 431.65$; $df = 1,6$; $P < 0.01$). However, because the mean time spent in the pupal stage (range = 8.5 to 9.3 days) did not vary significantly for either psoralens ($F = 0.03$; $df = 1,6$; $P = 0.88$) or *B. thuringiensis* ($F = 1,63$; $df = 1,6$; $P = 0.25$) as compared to the controls, the increases in developmental time during the larval stage therefore were responsible for the observed decrease in developmental rate. As in the mean time to pupation analysis, there were no significant interactions between psoralens and *B. thuringiensis* for mean time to emergence ($F = 0.16$; $df = 1,6$; $P = 0.70$).

Mean time to mortality, a weighted average time of death, was not signif-

icantly different between treatments ($F = 1.721$; $df = 4,9$; $P = 0.229$). Substantial differences would have suggested either a variable mode or site of action, or the presence of an additional toxic component or interaction. Just such a change in mortality rate was an important factor leading to the discovery of toxic impurities in another insecticidal compound (Umetsu et al., 1981). Because no differences were detected in mean time of mortality for larvae feeding on diets containing psoralens or *B. thuringiensis* does not necessarily suggest that the modes or sites of action may be similar; we simply conclude that this analysis does not clearly separate modes or sites of action.

Larval survival to the pupal stage was variable. In the absence of UV radiation, larval survival on diets containing psoralens > diets with *B. thuringiensis* alone > diets with both psoralens and *B. thuringiensis* (Figure 2A). In

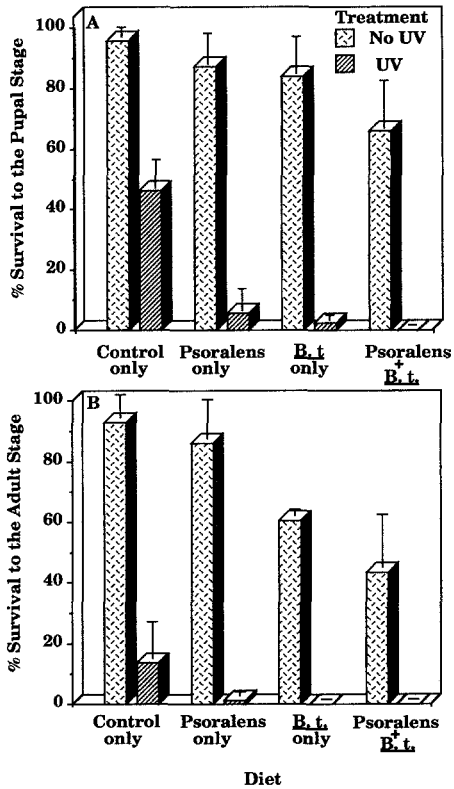

FIG. 2. Percent survival of *S. exigua* to the pupal (A) or adult (B) stages in the presence or absence of UV radiation on diets containing psoralens, *B. thuringiensis*, or combinations of both. See Figure 1 or Methods section for sample sizes. Extensions above bars delineate standard errors.

the presence of UV radiation survival was always reduced, but the same trend was evident.

All main effects (psoralens, *B. thuringiensis*, UV radiation) were significant ($P < 0.01$), with UV radiation being the predominant mortality factor ($F = 239$; $df = 1,14$; $P < 0.01$). Mean square error was 0.0208. Nearly all larvae (95.5%) on control diets that were not exposed to UV light survived to pupate (Figure 2A). Because first to third instars of *S. exigua* prefer to feed on foliage rather than petioles in celery, and the larvae are positively phototactic in the first three stadia (Griswold and Trumble, 1985), the low survival observed in the field (Hogg and Gutierrez, 1980) may be explained in part by the toxic effects triggered by UV light. However, in the aforementioned study all of the phototaxis experiments with early instar larvae were conducted at a single temperature, and larval movements associated with potential thermoregulating activities were not investigated.

The survival of larvae to the pupal stage was reduced significantly by the three-way interaction of exposure to psoralens and *B. thuringiensis* in the presence of UV light ($F = 5.01$; $df = 1,14$; $P < 0.042$) (Figure 2A). Thus, since UV radiation is ubiquitous in field situations, concerns that antagonistic interactions with psoralens would reduce the effectiveness of *B. thuringiensis* are unwarranted.

No two-way interactions were detected ($P > 0.10$) in the $2 \times 2 \times 2$ factorial analysis. However, three-way interactions may mask the two-way combined effects (Steel and Torrie, 1980). Therefore, pairs of main effects were nested within the two levels (presence and absence) of the other main effect to determine if combined two-way effects were important.

Nesting Psoralen and B. thuringiensis *Treatments within UV Radiation Treatment.* The psoralen × *B. thuringiensis* interaction was not significant ($F = 0.14$; $df = 1, 14$; $P = 0.72$) when the diet was not exposed to UV radiation (Figure 3A). When the additional stress of UV exposure was added, the psoralen × *B. thuringiensis* interaction produced a significant decrease in survival rate ($F = 7.79$; $df = 1,14$; $P = 0.015$; Figure 3B). However, this interaction should be interpreted with caution because adding the mortality caused by psoralens and *B. thuringiensis* in combination cannot equal less than 0% survival. Therefore, because the lower bound (0%, Figure 3A) of the mortality measure was reached, the psoralen × *B. thuringiensis* interaction may be constrained by the statistical approach and may not have biological meaning.

Results from similar studies presented in the literature provide no consistent antagonistic trend between potentially defensive plant chemicals and bacteria. Krischik et al. (1988) demonstrated that plant allelochemicals could interfere with microbials such that specialist herbivores feeding on plants or plant parts with high levels of toxins could gain protection from *B. thuringiensis* var. *kurstaki*. Although *S. exigua* is a generalist, the levels of psoralens in our study

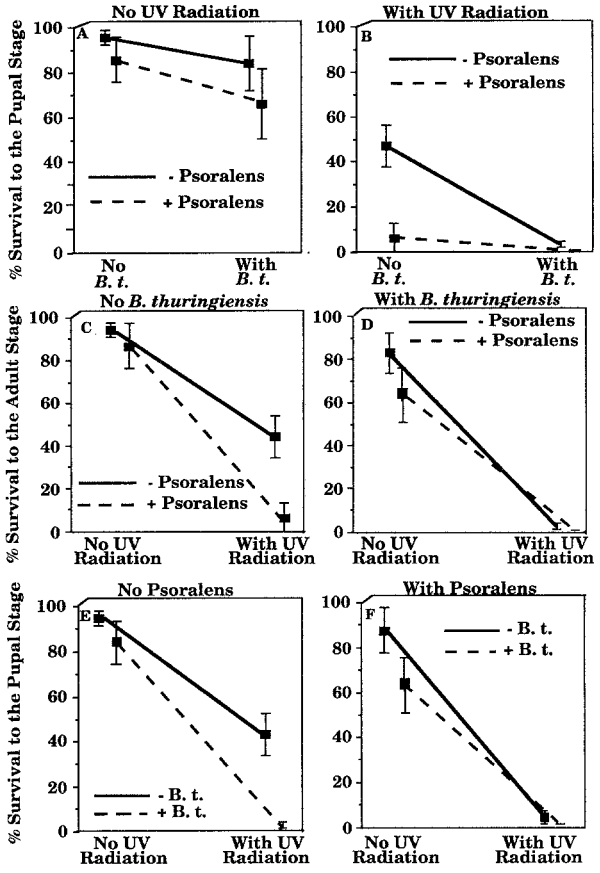

FIG. 3. Nested interaction plots for a 2 × 2 × 2 factorial with the main factors psoralens, *B. thuringiensis* (*B.t.*), and UV radiation. See Figure 1 or Methods section for sample sizes. Two-way interactions were calculated within each level (presence or absence) of the third factor (see text for details). Extensions above bars delineate standard errors. Data points were slightly offset to allow discrimination of standard error bars.

were high, and the percent survival resulting from a combination of *B. thuringiensis* and psoralens was less than observed for either chemical alone (Figure 2A,B). Thus, antagonistic interactions between psoralens and *B. thuringiensis* that would cause the combination of chemicals to become markedly less effective were not indicated. In contrast, our data were not in agreement with the findings of Salama and Sharaby (1988b), where an increase in potency of *B. thuringiensis* was observed in combination with powdered plants known to contain allelochemicals active against another *Spodoptera* species. Similar in vivo

studies with *Manduca sexta* (L.) indicated an enhanced effect of *B. thuringiensis* in the presence of cavanine (Felton and Dahlman, 1984). Unfortunately, direct comparisons are difficult because these studies were conducted in environmental chambers, and the UV radiation exposure levels were not specified.

Nesting Psoralen and UV Radiation Treatments within B. thuringiensis *Treatment.* The psoralen × UV interaction was significant ($F = 5.71$; $df = 1,14$; $P = 0.032$) when larvae were not exposed to *B. thuringiensis* (Figure 3C). Similar results have been summarized by Murray et al. (1982) for a variety of species. In the presence of *B. thuringiensis*, the psoralen × UV interaction was not significant ($F = 0.60$; $df = 1,14$; $P = 0.45$; Figure 3D). Even if photoactivation of the psoralens was occurring in the presence of *B. thuringiensis*, the mortality level could not exceed 100% (the level reached). Under these conditions the interaction would not appear statistically significant.

Nesting B. thuringiensis *and UV Radiation Treatments within Psoralen Treatment.* The *B. thuringiensis* × UV radiation interaction significantly increased mortality beyond a simple additive effect ($F = 7.23$; $df = 1,14$; $P = 0.018$) when the psoralens were not incorporated in the diet (Figure 3E). One potential explanation for this effect is that a partial paralysis resulting from feeding on could serve to enhance the effect of UV light by preventing larvae from moving away from exposed foraging positions. Although this interaction may be enhanced in our study by incorporating the *B. thuringiensis* into the diet (thereby providing some UV radiation protection), the effect would be similar to what can occur if *B. thuringiensis* protein production is incorporated in plants or if commercially available *B. thuringiensis* is applied in the evening.

The *B. thuringiensis* × UV radiation interaction was not significant ($F = 0.23$; $df = 1,14$; $P = 0.64$) when the additional stress of psoralen was added in the diet (Figure 3F). As noted for the previous analysis, survival reaches the lower extreme of the measure (0%), and any potential interaction may be masked by the additional mortality factor of the psoralens.

Survival to Adult Stage. No interactions were detected when measuring survival to the adult stage. UV radiation again triggered the single most important mortality factor, resulting in significant (80–100%) decreases in percent survival as compared to treatments in which larvae were protected from UV exposure ($F = 149$; $df = 1,14$; $P < 0.01$) (Figure 2B). In addition, approximately 65% more mortality occurred during the pupal stage on control diets for those insects exposed to UV light as larvae. Examination of these "pupae" indicated that many had not entirely completed metamorphosis. While this response is typical for nutritionally deprived larvae, no attempt was made to determine the mechanism responsible for the incomplete metamorphosis in our study.

The main effect of *B. thuringiensis* exposure was also significant ($F =$

17.8; $df = 1,14$; $P < 0.01$). This was not unexpected as survival-threatening physical defects and low weights in pupae developing from larvae that have ingested *B. thuringiensis* have been reported previously (Salama and Sharaby, 1988a).

Several conclusions can be drawn from these results. First, acute incidences of acidic fogs as low as pH 2.0 will not reduce the efficacy of *B. thuringiensis* if the bacteria are not physically washed from the leaves. In agricultural systems, spray adjuvants can provide "rain fastness," but the impact of fogs during naturally occurring epizootics has not been quantified. Second, a three-way interaction between psoralens, *B. thuringiensis*, and UV radiation significantly increases mortality, indicating that, in the field, antagonistic interactions with psoralens would not reduce the effectiveness of *B. thuringiensis*. Third, *S. exigua* larvae feeding on celery with high content of psoralens following acidic fog episodes will suffer substantial additional mortality (survival reduced from 50% to 8%, Figure 2A), with the resulting reduction in survival likely to produce substantial economic consequences (Trumble, 1990). Because the psoralens are strong mutagens, and adult fitness (oviposition capacity, longevity, etc.) was not examined, the potential impact on subsequent generations may be greater from psoralens than this study suggests. However, effects on adult populations will be mitigated by migratory movements in the Los Angeles Basin from (1) outside agroecosystems, (2) other geographic locations, or (3) crops that do not contain psoralens providing a consistent supply of fit adults. (Trumble and Baker, 1984). One caveat of this study is that a single concentration of psoralens was used; no effort was made to determine the variability of larval responses with dose.

In addition, the activity of *B. thuringiensis* and the psoralens, individually or in combination, was enhanced by the levels of UV radiation used in this study. While this response was not surprising for the psoralens (Berenbaum, 1978, 1981), which are reportedly activated by UV radiation (Scott et al., 1976), the results for *B. thuringiensis* were unexpected given previous reports that UV radiation rapidly degrades insecticidal activity (Pozgay et al., 1987; Dunkle and Shasha, 1988). We suspect that the enhanced effect of *B. thuringiensis* may have been due to UV radiation causing a general weakening of the larvae, which interferes with their normal immune response.

Acknowledgments—The assistance of J. McFall, E. Younce, and A. Jones in the laboratory is appreciated. Support for this project was provided, in part, by the Academic Senate of the University of California and the California Celery Research Advisory Board. The critical reviews of R. Redak, T. Paine, and T. Meade improved this manuscript and are appreciated.

ROLE OF STEROIDAL GLYCOALKALOID α-TOMATINE IN HOST-PLANT RESISTANCE OF TOMATO TO COLORADO POTATO BEETLE

J.D. BARBOUR and G.G. KENNEDY*

Department of Entomology
North Carolina State University
Raleigh, North Carolina 27695-7630

(Received July 30, 1990; accepted January 28, 1991)

Abstract—The role of the steroidal glycoalkaloid α-tomatine in the host-plant resistance of tomato to the Colorado potato beetle, *Leptinotarsa decemlineata* (Say) was examined in short- (24 hr; using first- and fourth-instar larvae) and long-term (first-instar larvae reared through the prepupal stage) feeding experiments. Consumption rate, growth rate, efficiency of conversion of ingested food to body mass, and survival were compared for *L. decemlineata* provided foliage from susceptible (*Lycopersicon esculetum* Mill. cv. Walter), resistant (*L. hirsutum* f. *glabratum* C.H. Mull accession PI 134417), and F_1 hybrid plants. Values obtained for dietetic indices were regressed against corresponding values for α-tomatine content of foliage provided to larvae. Differences in dietetic indices could not be attributed to variation in foliar α-tomatine content despite a long-standing literature showing the *ex planta* α-tomatine inhibits feeding and growth by *L. decemlineata*.

Key Words—Host-plant resistance, host-plant selection, glycoalkaloids, *Leptinotarsa decemlineata*, Coleoptera, Chrysomelidae, *Lycopersicon*, α-tomatine.

INTRODUCTION

The Colorado potato beetle, *Leptinotarsa decemlineata* (Say) (Coleoptera: Chrysomelidae) is an oligophagous insect (*sensu* Otte and Joern, 1977) that feeds, except under extraordinary conditions, exclusively on several species of plants belonging to the Solanaceae (Hsiao and Fraenkel, 1968; Hsiao, 1981).

*To whom correspondence should be addressed.

0098-0331/91/0500-0989$06.50/0

Although most commonly known as an egregious pest of potato (*Solanum tuberosum* L.), *L. decemlineata* is also a pest of several other solanaceous crop plants including tomato, *Lycopersicon esculentum* Mill. (Hofmaster, 1977; Lange and Bronson, 1981). Feeding and economic damage to tomato by *L. decemlineata* can be substantial, particularly in the mid- and northeastern Atlantic states (Schalk and Stoner, 1979; Kennedy et al., 1983). Although resistance in tomato to *L. decemlineata* has been known for some 30 years (Buhr, 1956; Schalk and Stoner, 1976), to date, there are no commercial tomato cultivars resistant to this insect.

The wild tomato species *L. hirsutum* f. *glabratum* C.H. Mull accession PI 134417 has been shown to express a high degree of resistance to many insect pests of tomato including *L. decemlineata* (Kennedy et al., 1985). The type VI glandular trichomes (sensu Luckwill, 1943), which abound on the foliage of PI 134417, play an important role in the resistance of this plant to *L. decemlineata*. The methyl-ketone 2-tridecanone, a major constituent of the glandular tips of these trichomes, is toxic to *L. decemlineata* at levels occurring in PI 134417 foliage (Kennedy and Dimock, 1983) and resistance that results from its presence is manifest as extensive mortality of young larvae (Kennedy and Sorenson, 1985).

Although 2-tridecanone plays an important role in the trichome-based resistance of PI 134417 to *L. decemlineata*, other, nontrichome factors are also involved. Type VI trichome glands, and hence 2-tridecanone, can be removed by washing PI 134417 foliage. *L. decemlineata* fed such washed foliage suffer extensive mortality during the late larval and pupal stages, whereas those fed PI 134417 foliage with glandular trichomes intact suffer extensive mortality during the first larval instar. In both instances mortality is greater than that of larvae fed susceptible, *L. esculetum* cv. Walter foliage or hybrid (Walter × PI 134417) tomato foliage containing or divested of type VI trichome glands (Kennedy and Sorenson, 1985).

Several alkaloids occurring in tomato, most notably the leptines and α-tomatine, have been shown to inhibit feeding and growth in *L. decemlineata* when provided to adults and larvae *ex planta* (Kuhn and Löw, 1955; Buhr et al, 1958; Schreiber, 1968; Sturköw and Löw, 1961; Sinden et al, 1980, 1986). Largely on the basis of these and similar studies, reduced feeding by *L. decemlineata* on resistant hosts has been attributed to the feeding-deterrent properties of these compounds when present in planta (Hsiao, 1969; Hsiao and Fraenkel, 1968; Schreiber, 1957, 1968; Sinden et al., 1978, 1980, 1986).

Sinden et al. (1978) suggested that α-tomatine is involved in the resistance of PI 134417 to *L. decemlineata*. In experiments using adult beetles, they demonstrated a positive relationship between inhibition of feeding and the level of α-tomatine infiltrated into *L. esculetum* cv. C28 leaflet disks. They also found that feeding on foliage from cv. C28 and PI 134417 plants of different ages or

grown under different photoperiod regimes was negatively correlated with α-tomatine content. Although their data are suggestive, they are difficult to interpret since the experiments were confounded by both the presence of glandular trichomes, hence 2-tridecanone, on PI 134417 foliage (Kennedy et al., 1985) and by differences in photosynthate levels between plants grown under long and short day regimes (Kennedy et al., 1981).

In other studies, inhibition of feeding by *L. decemlineata* has been observed to vary directly with the amount of α-tomatine used to treat tomato and potato foliage (Sturköw and Löw, 1961; Sinden et al., 1978) or artificial diets (Hsiao and Fraenkel, 1968; Hare, 1983, 1987). However these studies fail to distinguish clearly between preingestive behavioral effects (i.e., deterrency) and postingestive physiological effects (i.e., toxicity) of α-tomatine on *L. decemlineata* (Mitchell and Harrison, 1985; Harrison and Mitchell, 1988). Neither is there any work, of which we are aware, demonstrating that the effects of α-tomatine on *L. decemlineata* observed *ex planta* are operative as resistance factors *in planta*.

α-Tomatine has been found in all *Lycopersicon* species surveyed and has been detected in all plant tissues examined, although epigeal plant tissues, especially fruits and flowers, tend to have higher α-tomatine levels (Roddick, 1974). Since α-tomatine has been found, at least in the commercial *L. esculentum* cultivars examined thus far, to be associated with the leaf lamella and not with glandular trichome exudate (Duffey and Isman, 1981), it is possible that the resistance of PI 134417 to *L. decemlineata* results from the combined effects of trichome-based 2-tridecanone resistance and lamellar-based α-tomatine resistance. The study reported herein was undertaken to determine what role, if any, α-tomatine plays in the resistance of PI 134417 to *L. decemlineata*.

METHODS AND MATERIALS

Tomato Plants. Susceptible (*L. esculetum* cv. Walter), resistant (*L. hirsutum* f. *glabratum* accession PI 134417), and F_1 hybrid (cv. Walter × PI 134417) plants were grown in a greenhouse from seed germinated directly in soil (Terra Lite Metro Mix 220®), in 9.1-cm clay pots (greenhouse-grown plants) or plastic transplanting trays (field-grown plants). Plants were fertilized weekly (Peters Professional® 20:20:20), and natural light was augmented with radiation from metal halide lamps to provide a 16-hr photophase. At four weeks, plants to be used for greenhouse experiments were transplanted into 20-cm pots. Plants to be used for field experiments were placed outdoors to condition for two weeks before transplanting into methyl bromide-fumigated soil at the Agricultural Research Station at Clayton, Johnston County, North Carolina, in early May (first planting) and early June (second planting). Fertilizer (12:6:24 N-

P-K at 896 kg/ha) was incorporated at planting, and weeds were controlled with biodegradable plastic mulching.

The field plants were arranged in a randomized complete block design with six rows (= blocks) and five single-plant plots of each plant line per row. Plants within a row were separated by 1.5 m with 3.0 m separating rows. Maneb®, applied at 2.24 kg/ha, was used for control of foliar disease. In the greenhouse, each plant line was maintained on individual, adjacent benches in the same greenhouse.

Insects. L. decemlineata were obtained from colonies maintained in a greenhouse on potato (*Solanum tuberosum* cv. Pungo) foliage. Colonies were initiated from, and infused annually with, beetles collected from potato at Plymouth, Washington County, North Carolina. Photoperiod was maintained as described above for plant rearing.

Short-Term Feeding Experiments: Fourth Instar. Insects molting to fourth instar within a 24-hr period were collected and placed in individual 5.5-cm Petri dishes containing filter paper disks moistened with four to five drops of water. The Petri dishes were sealed with Parafilm® and the larvae held 24 hr at 27°C to allow voiding of gut contents. The starved insects then were weighed to provide an initial wet weight (IWWL) for each larva. Twenty-four starved larvae were frozen, oven dried (40°C) to a constant weight, and individually reweighed to provide a proportion dry weight (PDWL) estimate for larvae used in experiments.

Larvae, maintained individually in Petri dishes, were provided excess foliage, containing or divested of glandular trichome exudate, as whole leaflets, preweighed to provide an initial wet weight (IWWF) for foliage provided to each insect. A proportion dry weight (PDWF) estimate of foliage provided to larvae was obtained, analogously to PDWL, for each foliage treatment, using leaflets on the opposite side of the rachis from those provided to larvae. Insects were held in sealed Petri dishes for 24 hr at 27°C before tests were halted by freezing (−20°C).

Frozen larvae and uneaten foliage were rinsed with clean water to remove feces. Final dry weight of larvae (FDWL) and foliage (FDWF) was determined directly by weighing oven dried material. Initial dry weight of larvae (IDWL) and foliage (IDWF) was calculated as the product of their initial wet weight values and their respective proportion dry weight (e.g., IDWL = IWWL × PDWL). The quantity of foliage consumed (FC) was calculated, for each larva, as IDWF − FDWF, and consumption rate (RCR_i) as FC/IDWL. The weight gained by larvae during the feeding period (WGL) was calculated as FDWL − IDWL. Growth rate (RGR_i), was calculated analogously to consumption rate, as WGL/IDWL. Efficiency of conversion of ingested food to body weight (ECI) was calculated, for each larva, as the weight gained during the test period divided by the amount of foliage consumed during that same time interval (WGL/FC).

Since *L. decemlineata* produces a semiliquid feces, the amount of food digested (AD) and the efficiency of conversion of digested food (ECD) were not calculated.

Short Term Feeding Experiments: First Instar. The protocol for first-instar experiments was similar to that used in fourth-instar experiments, although some changes were required to accommodate first-instar biology and to reduce error in estimated parameters. After they had dispersed from egg masses, first instars were starved 6 hr instead of the 24 hr used in fourth-instar experiments. This was necessary since the duration of this stadium is ca. 1.5 days under experimental conditions. Individual observations in first-instar experiments were based on the results of five larvae per Petri dish rather than the single larva used in fourth-instar experiments. Whole leaflets provided to fourth-instar insects were replaced with leaflet disks in first-instar experiments. Leaflet disks were excised from the distal portion of leaflets (divested of or containing a full complement of type VI trichome glands) with a No. 10 cork borer (1.91 cm^2), one disk per leaflet. Leaflet disks excised from leaflets on the opposite side of the rachis from those provided to larvae were used to obtain a percent dry weight estimate for each foliage treatment. These changes were required since preliminary experiments indicated that consumption and weight gain by first-instar insects were small compared to the dry weight of foliage when provided as whole leaflets.

It is important to note that the explicit (RCR_i, RGR_i) or implicit (ECI) divisor used in construction of dietetic indices was the initial (after Farrar et al., 1989; denoted by the subscript "i"), rather than the mean (see Waldbauer, 1968) dry weight of larvae used in tests. This was done, since we were interested primarily in the behavioral response of insects to their food source, to avoid confounding preingestive and postingestive effects of food source on the insects (see Farrar et al., 1989).

Foliage used in short-term experiments consisted of the first fully expanded leaflets below the shoot apex of 10- to 12- (greenhouse-grown) or 10- to 14- (field-grown) week-old plants. Trichome- and lamellar-based effects of foliage were partitioned by providing larvae with foliage either divested of, or containing a full complement of, intact type VI trichome glands, providing a 3 × 2 factorial arrangement of treatments (3 plant lines × 2 trichome conditions). Removal of trichome glands was accomplished by first gently wiping foliage with a dry cotton ball, then with a cotton ball saturated with a 0.1% solution of Triton X-155®, a nonphytotoxic emulsifying agent. Foliage was then rinsed, first in 0.1% Triton X-155®, then in clean water. Excess moisture was removed from washed foliage by gently pressing between several layers of clean tissue paper.

All short-term experiments were conducted using foliage from both greenhouse- and field-grown plants. Experiments consisted of 10 observations per

treatment and were repeated five and six times for greenhouse- and field-grown plants, respectively. Data from plants grown at the different locations were analyzed separately by factorial ANOVA using the GLM Procedure (SAS Institute, Cary, North Carolina).

Long-Term Feeding Experiments. Neonate *L. decemlineata* were weighed and placed into individual 7 × 10-cm (h × diam.) plastic cups containing a filter paper disk moistened with water. Larvae were provided preweighed foliage, which was replaced after 48 hr and every 24 hr thereafter with similarly prepared foliage. Water was added as required to maintain adequate humidity. Uneaten foliage was removed, washed to remove feces, and oven dried to determine the final dry weight of foliage remaining after each feeding period. After larvae molted to the fourth instar, ca. 3 cm of soil was added to cups to provide a substrate for pupation. When they died or became prepupae (indicated by burrowing behavior), larvae were frozen, oven dried, and final dry weight determined.

Amount of foliage consumed (FC) and percent survival were determined for each feeding period, and values were accumulated over the entire larval period, which for experimental purposes was considered to end when larvae either died or became prepupae. Foliage consumed was calculated similarly to RCR_i but contained no correction for initial insect weight. ECI was calculated as WGL (determined at the time of death or pupation), divided by the total amount of foliage consumed by the larvae. ECI in the long-term experiments thus represents an overall ECI of larvae from neonate to death or pupation. Except that only greenhouse-grown plants were used, foliage used in long-term experiments was similar to that used in short-term experiments. Experiments consisted of 20 observations per treatment, and the entire experiment was repeated four times. Data were analyzed by factorial ANOVA.

Analysis of Foliage for α-Tomatine Content. Procedures for extraction and quantification of α-tomatine were modified from Juvick and Stevens (1982). Uneaten foliage from insect experiments was pooled according to plant line, oven dried, and ground to a fine powder. Aliquots (ca. 100 mg) were Soxhlet extracted in 100 ml of 95% MeOH for 12 hr and the resulting extract concentrated to 2 ml on a rotary evaporator. The samples were acidified with 2 ml of 1.0 N HCl and washed with 4 ml of benzene. After phase separation (12 hr), the organic phase was discarded, the aqueous phase adjusted to pH 7.9–8.1 with 1.0 N NaOH, and the final volume adjusted to 10.0 ml with 95% MeOH.

Quantification of α-tomatine was by red blood cell hemolysis (Arneson and Durbin, 1968). Sheep red blood cells in Alsever's solution (Cleveland Scientific Co.) were centrifuged (3500*g* for 15 min), and 2.5 ml of packed cells diluted to 1.0 liter with normal saline. Samples (50–200 μl) were added to 10.0-ml portions of the sheep red blood cell reagent, the contents vortexed, centrifuged (1500*g* for 15 min), and the optical density (540 nm) of the supernatent

determined as the average of three replicate readings per sample. α-Tomatine content of samples was determined by reference to the mean optical density of triplicate readings of similarly prepared standards [0.05–0.30 mg/ml α-tomatine (Sigma Chemical Co.) in MeOH]. Percent recovery was determined for each plant line by comparing the α-tomatine content of plant material containing no added α-tomatine with that of similar plant material containing a known amount of α-tomatine in standard solution. Analysis was performed separately for foliage from short- and long-term bioassays.

To confirm that α-tomatine was responsible for the observed hemolysis, samples for each plant line, a standard α-tomatine solution, and an MeOH blank were divided into equal (2.0-ml) portions. One of each pair received 2.0 mg cholesterol (Sigma Chemical Co.). Both portions were vortexed, incubated (15 min at room temp.), centrifuged (5000*g*, 20 min), and analyzed for α-tomatine as described above. Cholesterol forms a 1 : 1 molecular complex with α-tomatine in methanolic solution (Roddick, 1979), and its addition to samples containing α-tomatine should inhibit hemolysis.

To test assumptions concerning the role of α-tomatine in the lamellar-based resistance of PI 134417 to *L. decemlineata*, performance, as measured by the previously defined dietetic indices, was regressed against corresponding values for foliar α-tomatine content. In order to avoid confounding of trichome- and lamellar-based resistance effects on *L. decemlineata* (see Kennedy et al., 1985), only observations using foliage from which glandular type VI trichome glands had been removed were used in this analysis.

RESULTS

Short-Term Experiments: Fourth Instar. When type VI glandular trichomes were intact, RCR_i, RGR_i, and ECI were significantly lower for larvae provided PI 134417 foliage, than for larvae provided cv. Walter or F_1 foliage (Table 1). When the type VI trichome glands were removed by washing, plant line had no significant effect on either RCR_i, RGR_i, or ECI of *L. decemlineata* provided foliage from either field- or greenhouse-grown plants. Removal of type VI trichome glands consistently and significantly improved the RCR_i, RGR_i and ECI of larvae provided PI 134417 foliage. The removal of type VI trichome glands on cv. Walter foliage enhanced the RCR_i but not the RGR_i and ECI of *L decemlineata*; this effect was not seen with greenhouse grown plants. Removal of trichome glands did not affect insect performance on F_1 foliage.

Short-Term Experiments: First Instar. Results of first-instar experiments were similar in all essential details to the results of fourth-instar experiments. In the presence of type VI trichome glands, dietetic indices, except for the ECI of larvae fed field-grown foliage, were lower for larvae provided PI 134417

foliage. In the noted exception, the ECI of larvae fed F_1 foliage was higher than the ECI of larvae fed cv. Walter or PI 134417 foliage (Table 2). When type VI trichome glands were removed, the dietetic indices of larvae provided PI 134417 foliage were always as high or higher than the corresponding indices of larvae provided cv. Walter or F_1 foliage. While removal of type VI trichome glands did not, in general affect the performance of larvae fed cv. Walter or F_1 foliage, ECI was higher and RCR_i lower for first-instar larvae provided field-grown

foliage lacking trichome glands As in the fourth-instar experiments, removal of type VI trichome glands always increased the RCR_i, RGR_i and ECI of larvae provided PI 134417 foliage compared to the same indices for larvae provided cv. Walter or F_1 foliage.

Long-Term Experiments. Total amount of foliage (mg dry weight) consumed by *L. decemlineata*, reared from neonate to prepupae, was significantly affected by plant line in both the presence and absence of type VI trichome glands (Table 3). The presence of type VI trichomes significantly reduced the total amount of foliage consumed by larvae provided F_1 and PI 134417 foliage but did not affect the amount of foliage consumed by larvae provided cv. Walter foliage. The ECI of *L. decemlineata*, over the entire larval period, also was affected by plant line in the presence and absence of type VI trichome glands. When these glands were present, ECI was significantly lower for larvae provided PI 134417 foliage than for larvae provided either F_1 or cv. Walter foliage (Table 3). When type VI trichome glands were absent, the ECI of larvae provided PI 134417 foliage was lower than that of larvae provided cv. Walter foliage, but not lower than the ECI of larvae provided F_1 foliage. The presence of glandular type VI trichomes significantly lowered the ECI of larvae provided F_1 and PI 134417 foliage, but not that of larvae provided cv. Walter foliage. Survival of larvae to prepupal stage in the presence of type VI trichome glands was lower for larvae provided F_1 and PI 134417 foliage than for larvae provided cv. Walter foliage (Table 3). When these glands were removed, survival of larvae provided PI 134417 foliage was lower than survival of larvae provided cv. Walter foliage but not lower than the survival of larvae provided F_1 foliage.

TABLE 3. MEAN FOLIAGE CONSUMED (FC[a]), ECI, AND MEAN PERCENT SURVIVAL OF *L. decemlineata* REARED FROM NEONATE TO PREPUPAE ON FOLIAGE FROM INDICATED PLANT LINE

	FC		ECI		Percent survival to prepupal stage	
Plant line	Trichomes present	Trichomes absent	Trichomes present	Trichomes absent	Trichomes present	Trichomes absent

PI 134417[c]	0.57 Cn	16.76 Cm	−0.331 Cn	−0.042 Bm	0 Bm	10.0 Bm

[a] Measured as mg dry weight foliage consumed over the entire test period.
[b] Vertical means (capital letters) separated by protected LSD (Snedecor and Cochran, 1980) ($P > 0.05$). Horizontal means (lowercase letters) separated by F test ($P > 0.05$).
[c] Although all larvae died before becoming prepupae, calculation of FC and ECI was possible since most larvae consumed some foliage before dying.

For a given plant line, the presence of type VI trichome glands did not significantly affect the number of larvae surviving to the prepupal stage.

α-Tomatine Analysis. When grown under field conditions α-tomatine content differed significantly among the plant lines test. α-Tomatine was higher in foliage from F_1 plants than in foliage from cv. Walter or PI 134417 plants and lowest in foliage from PI 134417 plants. There was no significant difference, among plant lines, in the α-tomatine content of foliage from greenhouse-grown plant lines. Analysis of foliage from greenhouse-grown plants used in long-term experiments yielded patterns of α-tomatine content resembling those of similarly grown plants from short-term experiments (Table 4). The α-tomatine content of F_1 foliage in these tests was significantly higher than that of either PI 134417 or cv. Walter foliage. Levels of α-tomatine found in the foliage of all greenhouse-grown plant lines and in foliage from F_1 plants grown in the field were consistent with α-tomatine levels found, by other researchers, to inhibit feeding and growth of *L. decemlineata* (Sturcköw and Löw, 1961; Sinden et al., 1978; Hare, 1987).

Hemolysis of sheep red blood cells (as indicated by optical density) by α-tomatine in standard solution was linear over the range of concentrations tested ($y = 0.0323 + 0.0044x$, $R^2 = 0.96$, $P > F = 0.05$; short-term tests: $y = 0.0215 - 0.0018x$, $R^2 = 0.95$, $P > F = 0.05$; long-term tests). Recovery of α-tomatine was high but variable (98.34 ± 13.78% in short term experiments; 94.35 ± 20.9% in long-term experiments). There was no significant difference in the percent recovery of α-tomatine among plant lines tested. Results of the cholesterol inhibition test (Table 5) demonstrate that the addition of cholesterol to standards and/or samples containing α-tomatine quenches the production of color in this assay. The results of this test provide confirmation that α-tomatine is the principal agent of hemolytic activity in the samples examined (Juvick and Stevens, 1982).

TABLE 4. MEAN α-TOMATINE CONTENT (mg/g DRY WEIGHT) OF FOLIAGE USED IN SHORT AND LONG-TERM EXPERIMENTS

[a] Test solutions prepared as described in text.
[b] Optical density at 540 nm.
[c] 1 mg/ml of test solution.
[d] 0.20 mg α-tomatine/ml MeOH.
[e] MeOH, no α-tomatine or plant material.

Regression Analysis. Regression analysis demonstrated no significant relationship between *L. decemlineata* performance, as measured by RCR_i, RGR_i, and ECI, in short-term feeding experiments (Table 6) or, as measured by FC and ECI, in long-term feeding experiments (Table 7) and α-tomatine content of foliage provided to larvae.

DISCUSSION

Results of the short-term experiments indicate that poorer performance of *L. decemlineata* fed PI 134417 foliage from field- and greenhouse-grown plants can be explained largely by the presence of type VI trichome glands. When foliage is divested of these glands, dietetic indices of *L. decemlineata* fed PI 134417 foliage are as high or higher than dietetic indices of larvae fed F_1 or cv. Walter foliage (Tables 1 and 2). There is no evidence, in these short-term experiments, that PI 134417 foliage, divested of glandular trichomes, is deterrent or repellent to *L. decemlineata* since, in the absence of type VI trichome glands, larvae consume as much or more PI 134417 foliage as they do F_1 or cv. Walter foliage. Neither do these short-term tests provide evidence that PI 134417 foliage, in the absence of type VI trichome glands, is acutely toxic to *L. decemlineata* larvae. Growth rate and ECI of larvae provided PI 134417 foliage divested of trichome glands are at least as great as the growth rate and ECI of larvae provided similarly prepared F_1 and cv. Walter foliage (Tables 1 and 2).

Results of the long-term feeding experiments clearly demonstrate that in

[a] Foliage from field-grown plants was not used in long-term experiments.

both the presence and the absence of type VI glandular trichomes, PI 134417 is resistant to *L. decemlineata* as compared to *L. esculentum*: consumption, ECI, and survival to prepupa are all lower for *L. decemlineata* provided PI 134417 foliage divested of glandular trichome exudate compared to similarly prepared cv. Walter foliage.

However, regression analysis demonstrated that differences in *L. decemlineata* performance observed in feeding experiments were not associated with variation in foliar α-tomatine content (Tables 6 and 7). Examination of mean foliar α-tomatine content (Table 4) and measures of performance for larvae in short- (Table 2) and long- (Table 3) term feeding experiments provide further evidence. In short-term feeding experiments, foliar α-tomatine content varies significantly among plant lines (ca. 2.5-fold). Despite these differences in α-tomatine content, no differences in performance of *L. decemlineata* larvae were observed. Conversely, in long-term experiments, significant differences in the performance of *L. decemlineata* provided cv. Walter and PI 134417 foliage were demonstrated, even though α-tomatine content of foliage from these plant lines did not differ.

Mitchell and Harrison (1985) examined the role of the sensory system in the feeding deterrence of α-tomatine and other steroidal glycoalkaloids to *L. decemlineata*. They demonstrated that although steroidal glycoalkaloids, including α-tomatine clearly damage chemosensilla, there was no evidence for the existence of cells, in the galeal or tarsal sensilla of *L. decemlineata* capable of providing differential sensitivity to the alkaloids tested. Although deterrent-specific receptors are not essential for disruption of feeding behavior (Schoonhoven, 1982, Mitchell and Sutcliffe, 1984), Mitchell (1987) and Harrison and Mitchell (1988) found no evidence that α-tomatine acted in any capacity to reduce feeding by *L. decemlineata*. Harrison and Mitchell (1988) suggested that rather than acting to modify feeding behaviorally, α-tomatine may disrupt feeding by exerting toxic effects. Our results demonstrate that the lamellar-based resistance of PI 134417 to a tomato-adapted *L. decemlineata* population does not result from deterrent or acute antibiotic properties of α-tomatine. Further, they provide no evidence that α-tomatine exerts a chronic, antibiotic effect that could be associated with this resistance.

Previous work linking α-tomatine to feeding deterrence against *L. decemlineata* has been performed using relatively artificial systems. α-Tomatine has been found to deter feeding by *L. decemlineata* when offered to the insects in artificial diets (Hare, 1987; Hsiao and Fraenkel, 1968) or when using potato (Sturköw and Löw, 1961; Barbour, 1987) and tomato (Sinden et al., 1978) foliage coated or infiltrated with α-tomatine. To our knowledge, in the only previous experiments in which in planta α-tomatine levels were determined for foliage provided to *L. decemlineata* (Sinden et al., 1978), measurements of consumption were confounded by differences in photosynthate levels in plants

tested and by the presence of type VI trichome glands, and hence 2-tridecanone, on PI 134417 foliage. It is possible that the effects of α-tomatine observed *ex planta* are simply not manifest *in planta.*

α-Tomatine is known to form a stable 1 : 1 molecular complex with steroids having a free 3-β-hydroxyl group (Schultz and Sanders, 1957; Roddick, 1979). Alleviation of α-tomatine-induced toxicity by addition of steroids to artificial diets has been shown for both herbivorous insects (see reviews by Dimock and Tingey, 1985; Duffey and Bloem, 1986) and insect parasitoids (Campbell and Duffey, 1981; Duffey and Bloem, 1986). Whether the feeding deterrent properties of α-tomatine are likewise affected is not known. It also has been demonstrated that addition of protein to diets containing α-tomatine increases the growth rates of *L. decemlineata* larvae compared to the growth rates of larvae fed a similar diet containing α-tomatine but without additional protein (Hare, 1987). Both the trichome-and lamellar-based resistance of PI 134417 can be reduced dramatically by increasing the rate and/or frequency of fertilizer applications (Barbour et al., 1990; see also Hare and Dodds, 1987 and Janssen and Smilowitz, 1986a,b for similar work in tomato and potato, respectively).

Compared to potato, tomato is a poor host for *L. decemlineata* (Latheef and Harcourt, 1972; de Wilde and Hsiao, 1981). α-Tomatine has been found in all *Lycopersicon* accessions assayed but has not been found in *S. tuberosum* accessions (Roddick, 1979). Our work was conducted with tomato-adapted *L. decemlineata* and included no plant line completely lacking α-tomatine. Therefore, the role of α-tomatine, if any, in the relative quality of *Lycopersicon* and *S. tuberosum* as hosts for *L. decemlineata* is not addressed by our experiments. However, in view of the lack of a deterrent or antibiotic response to α-tomatine of the tomato-adapted *L. decemlineata* used in this study, and the absence of a deterrent response to α-tomatine of beetles from several *L. decemlineata* populations (including both potato and tomato adapted populations) tested by Mitchell and Harrison (1988), raises questions concerning the role of α-tomatine in the relative suitability of *L. esculentum* and *S. tuberosum* as hosts for *L. decemlineata* merit further study.

In this study, no difference in *L. decemlineata* performance could be attributed to variation in the foliar α-tomatine content of tomato plant lines expressing different levels of the alkaloid. These results appear to be at odds with much of the previous work demonstrating that α-tomatine inhibits feeding and growth in *L. decemlineata* (but see Mitchell and Harrison, 1985; Mitchell, 1987; Harrison and Mitchell, 1988). However, the expression of α-tomatine-based resistance in tomato may depend on concurrent levels of phytosteroids, proteins, and/or other as yet undetermined factors. Although demonstrated to have a genetic basis (Juvick and Stevens, 1982), foliar α-tomatine content is also sensitive to environmental factors, as demonstrated in the present study (see also Sinden et al., 1978). It is difficult to imagine how a compound, whose expres-

sion and effects are so readily influenced by its immediate environment, could be reliably useful in the protection of cultivated crops from insect pests.

Acknowledgments—We wish to thank D. Bumgarner, V. Covington, and E. Eckenrode for their technical assistance; S. Chilton and R. M. Roe for providing material, equipment, and advice towards the completion of study; and S. Chilton, R. M. Roe, and J. Walgenbach for their comments on earlier drafts of this document. This research was funded in part by grant 85-CRCR-1-1615 from the USDA Competitive Research Grants Program and the North Carolina Agricultural Research Service, Raleigh.

(Received October 24, 1990; accepted January 30, 1991)

Abstract—Competitive field tests with α-fluorinated analogs of compounds III and IV (III-α-F and IV-α-F, respectively) of the boll weevil, *Anthonomus grandis* Boh., aggregation pheromone showed these compounds, when combined with the other pheromone components [(±)-I and II], to be as attractive as grandlure [(±)-I, II, and III + IV]. Dose–response curves constructed from electroantennograms of male boll weevils to serial stimulus loads of III, IV, III-α-F, IV-α-F, and the corresponding acyl fluorinated analogs (III-acyl-F and IV-acyl-F) showed the α-fluorinated analogs to be as active as the pheromone components (threshold = 0.1 μg), while the acyl fluorinated analogs had a 10–100 × higher threshold (= 1–10 μg). Single-neuron recordings showed that IV neurons and II neurons (Dickens, 1990) responded to IV-α-F and III-α-F, respectively, while IV-acyl-F and III-acyl-F were inactive. Since a previous study showed compounds I, II, and IV to be essential for behavioral responses in the field, it seems likely that the activity of the α-fluorinated analogs observed here is due to the stimulation of IV neurons by IV-α-F as indicated in single neuron recordings.

Key Words—Pheromone, analog, parapheromone, behavior, neurobiology, olfaction, single neuron, electroantennogram, boll weevil, *Anthonomus grandis*, Coleoptera, Curculionidae.

INTRODUCTION

Chemical signals emitted by insects may communicate the location of mates as for sex attractants, or host plants and mates as for aggregation pheromones (Dickens and Payne, 1985). The use of pheromones for detection of emergent insect populations has been valuable for the timing and application of pest control strategies (Mitchell, 1981). Pheromones also have been used to disrupt chemical signaling in indigenous insect populations, e.g., for lepidopterous species (Sanders, 1981) and coleopterous pests (Vité et al., 1976; Richerson et al., 1980), including the boll weevil (Villavaso, 1982). Alternatively, analogs of pheromone molecules have been designed and synthesized and found to inhibit response to the pheromone (Mitchell et al., 1975, 1976; Camps et al., 1990), enhance response to the pheromone (Camps et al., 1988; Bengtsson et al., 1990), or mimic the pheromone component (Camps et al., 1988; Briggs et al., 1986; Eidmann et al., 1986). The acyl fluoride analogs of *Heliothis* pheromone components acted as hyperagonists, eliciting aphrodisia and disorientation in male moths (Prestwich et al., 1986).

Pheromone analogs have potential not only for use in alternative pest control strategies, but also as probes of olfactory mechanisms. For example, functional, geometric, and fluorinated analogs of compound II of the boll weevil aggregation pheromone have been used to elucidate the nature and specificity of receptor sites on identified olfactory neurons (Dickens et al., 1990), while fluorinated analogs of moth pheromones have been used to probe local hydrophobicity requirements of receptor sites on pheromone-sensitive neurons (Sun and Prestwich, 1990; Prestwich et al., 1990).

Fluorinated analogs of bioactive molecules offer the advantage of isosteric substitution of a fluorine atom for a hydrogen atom while modifying the charge distribution of the molecule by the electrophilic nature of the fluorine atom (Pavlath, 1986; Prestwich, 1986). Fluorinated analogs of various molecules have been synthesized, including potential pesticides (Pavlath, 1986) and naturally occurring compounds such as hormones and pheromones (Briggs et al., 1986; Prestwich, 1986, 1987). Acyl and α-fluorinated analogs of the aldehyde components of the boll weevil pheromone were synthesized and evaluated for activity in female boll weevils using electroantennograms (EAGs) (Prestwich et al., 1988). While the α-fluoro analogs were as active as the pheromone components in these tests, the acyl fluorides showed little activity.

Here we sought to evaluate the behavioral activity of the α-fluorinated analogs of the aldehyde components of the boll weevil pheromone and to further elucidate the mechanisms by which these compounds are perceived by olfactory receptors on the boll weevil antenna.

METHODS AND MATERIALS

Insects

Adult *A. grandis* used in field releases and electrophysiological experiments were obtained from a small laboratory colony annually infused with feral insects. Upon emergence, insects were sexed and fed either cotton squares or an artificial diet (Lindig, 1979). Insects were not used until substantial olfactory receptor maturation at four days postemergence (Dickens and Moorman, 1990). For electrophysiological studies, groups of five insects of the same sex were maintained on moist filter paper (Whatman No. 1) in Petri dishes until use at 4–6 days of age. For field experiments, groups of 50 insects of the same sex were held in paper cartons (ca. 0.5 liter) with screen tops. Insects used in field releases were 6–13 days postemergence and were fed cotton (STV-213) at least two days prior to use. All insects were held in incubators at 26°C under a photoregime of 16 hr of light (ca. 700 lux) and 8 hr of darkness.

Chemicals

The boll weevil aggregation pheromone, grandlure, is composed of compounds I [racemic grandisol, (±)-*cis* -2-isopropenyl-1-methylcyclobutaneethanol]; II (*cis*-3,3-dimethyl-$\Delta^{1,\beta}$-cyclohexaneethanol); and III + IV (a 50:50 *cis–trans* mixture of 3,3-dimethyl-$\Delta^{1,\alpha}$-cyclohexaneacetaldehyde) (Tumlinson et al., 1969) (Figure 1). Each component was >95% chemically pure as obtained from Albany International, Controlled Release Division, Buckeye, Arizona. Isomeric pure III and IV were obtained by separation of a commercially available mixture of III and IV as previously described (Dickens and Prestwich, 1989; Dickens et al., 1990).

Selectively fluorinated analogs of components of compounds III and IV of the boll weevil pheromone have been described previously (Prestwich et al., 1988). These compounds were: (*E*)- and (*Z*)-3,3-dimethylcyclohexane-$\Delta^{1,\alpha}$-α-fluoroacetaldehyde [(*E*vt)- = III-α-F]; [(*Z*)- = IV-α-F]; and (*E*)- and (*Z*)-3,3-dimethylcyclohexane-$\Delta^{1,\alpha}$-acetyl fluoride [(*E*)- = III-acyl-F; (*Z*)- = IV-acyl-F] (Figure 1). While quantities of the individual geometric isomers of the fluorinated compounds were adequate for our electrophysiological experiments, it was necessary to use a mixture of geometric isomers of the α-fluorinated compounds, i.e., III-α-F + IV-α-F, in field tests. Serial dilutions of experimental odorants were prepared in hexane. 1-Hexanol used as a standard in EAG studies was diluted in pentane as in previously reported experiments on boll weevil olfaction (Dickens, 1984; Dickens and Mori, 1989; Dickens and Prestwich, 1989).

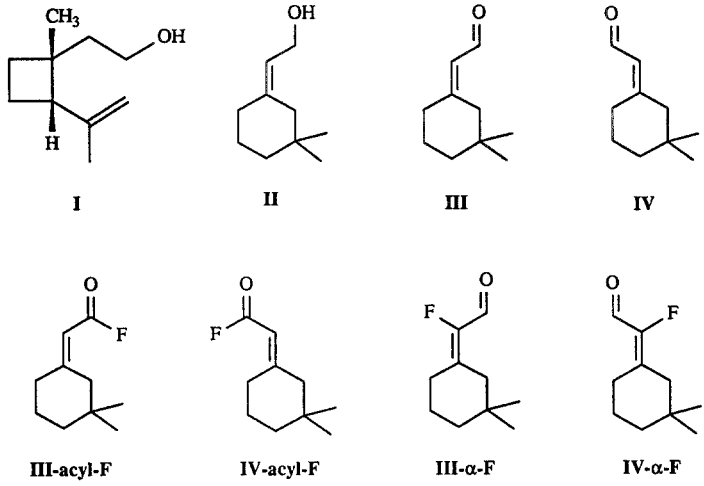

FIG. 1. Structure of boll weevil pheromone components I–IV and fluorinated analogs.

Behavior

Traps used for all field experiments were those currently used by the Boll Weevil Eradication Program (BWEP) and were a modification of a previously described trap (Mitchell et al., 1976).

Competitive Field Tests with Released Weevils. A competitive field test involving released boll weevils in which (±)-I (0.6 mg):II (0.8 mg):III + IV (0.6 mg) (= 2 mg total) in a ratio of 3:4:3 (grandlure) was placed in competition with (±)-I (0.6 mg):II (0.8 mg):III-α-F + IV-α-F (0.6 mg) (= 2 mg total) in the identical ratio. This experiment involved an array of four traps. One trap was placed at each corner of a 20-m square. The two treatments being tested simultaneously in this competitive arrangement were placed alternately in the traps; i.e., the two traps baited with the same treatment were located diagonally across from each other. In order to avoid competition with cotton or pheromone-producing boll weevils, both this initial test and the second series of experiments described below were conducted in open fields located more than 1 mile from cotton fields. Cigarette filters were used as release substrates for the experimental odorants, which had been diluted in 0.5 ml of the following mixture by weight: polyethylene glycol 1000, 20%; methanol, 42.5%; glycerol, 25%; and distilled water, 12.5% (McKibben et al., 1980). The ratio of the pheromone components used in the cigarette filters was that currently used in the BWEP [I(3):II(4):III + IV(3)]. This ratio was chosen for use in the BWEP based on economic considerations even though the ratio of components in the natural pheromone was more attractive in competitive tests (Hardee, 1974). One hundred insects (50 males and 50 females) were released along a

20-m line parallel to each side of a square at a distance of 20 m (400 insects total) at ca. 0900 hr, prior to baiting of the traps at 1200 hr. On the first day, traps were checked and insects removed at 1400 and 1600 hr. On the second day, traps were checked at 0900 hr and their positions rotated at 1630 hr. Following this rotation of the traps, collections were made at one- to four-day intervals for the next 11 days. The same filters remained in the traps for the entire test period.

A second series of experiments also involved an array of four traps. In this experiment, (±)-I, II, III + IV, and III-α-F + IV-α-F diluted in hexane were released from 2.2-ml vials as 10 μg/μl dilutions using glass capillaries (Dickens and Mori, 1989). One vial placed in each trap contained (±)-I (0.4 mg); the second vial in each trap contained either II (0.3 mg) and III + IV (0.1 mg), or II (0.3 mg) and III-α-F + IV-α-F (0.1 mg). The ratio of pheromone components used in this experiment [I(4) : II(3) : III + IV(1)] approximated that of the natural pheromone as identified from the frass of male boll weevils (Tumlinson et al., 1969). One hundred insects (50 males, 50 females) were released along a 20-m line parallel to each side of the square at a distance of 20 m (400 insects total) at 1400 hr. Traps were then immediately baited. In each test, traps were checked and insects removed at 1530 and 1700 hr on the day of release and before 0900 hr the next day, at which time the test was terminated. This test was replicated five times.

Competitive Test in Cotton Field with Indigenous Boll Weevil Population. A third experiment was also a competitive test and involved an indigenous population of boll weevils in a cotton field. This experiment was conducted in October 1989 in a field of mature cotton located at Mississippi State, Mississippi. The experimental design consisted of placing one trap at each corner of a 20-m square within a cotton field. Four additional traps were placed ca. 2 m outside the cotton field at a distance of ca. 40–60 m from the traps in the field and located near imaginary diagonal lines extending through the corners of the square within the field. The result resembled an "X" array of traps placed across the field with each arm of the "X" consisting of four traps, two within and two outside of the field. Cigarette filters prepared as in the first experiment released either (±)-I (0.3 mg), II (0.4 mg), and III + IV (0.3 mg)(1 mg total), or (±)-I (0.3 mg), II (0.4 mg), and III-α-F + IV-α-F (0.3 mg)(1 mg total). Traps within one arm contained (±)-I, II, III + IV; those within the other arm were baited with (±)-I, II, III-α-F + IV-α-F. Insects were collected daily from the traps for six days, at which time the test was terminated.

Electrophysiology

Electroantennograms. EAG techniques were described in detail elsewhere (Dickens, 1979, 1984). Briefly, two glass microcapillaries filled with physiological saline (Pantin, 1948) were inserted into the antenna of an intact animal:

the ground electrode was placed into the distal end of the scape and the recording electrode into the distal end of the club. Electrical contact was provided by a Ag–AgCl wire placed into the shank of each capillary. Electrical activity was amplified by a Grass P-16 DC preamplifier. EAGs were recorded using a stripchart recorder.

Serial dilutions of the pheromone components and their fluorinated analogs were delivered from the lowest to the highest concentration. Odorous stimuli were delivered as 1-μl aliquots placed on filter paper (8 mm $\times$ 18 mm) inserted into glass cartridges (80 mm $\times$ 5 mm ID) oriented toward the preparation from a distance of 1 cm. Molecules evaporating from the filter paper were carried over the preparation by hydrocarbon-free air, which also had been filtered and dried. Stimulus duration was 1 sec. Three minutes were allowed between stimuli at lower doses; 5–7 min were allowed at doses greater than 1 μg. These times were adequate for complete recovery of the EAG (Dickens, 1984).

Three replicates were recorded for serial dilutions of each odorant for both male and female *A. grandis*. 1-Hexanol (100 μg; 10 μl of 10 μg/μl dissolved in pentane) served as a standard to: (1) normalize responses; (2) control for viability and constancy of the preparation; and (3) allow relative comparisons with previously recorded species (Dickens, 1984; Dickens and Boldt, 1985). Stimulation with the standard both preceded and followed each serial dilution level. Although preparations were stimulated with a solvent control, seldom was a response noted. EAGs to test chemicals were expressed as a percent of the mean of the two nearest responses to the standard (Dickens, 1981, 1984). The threshold of response was considered to be the stimulus load at which a statistically significant response was noted.

Single-Neuron Recordings. Single-neuron recording techniques are described in detail elsewhere (Dickens, 1979, 1990; Dickens and Mori, 1989). In brief, microelectrodes were constructed from 50.8-μm-diameter tungsten wire electrolytically sharpened to a tip of 1–2 μm. The recording electrode was positioned near the proximal edge of one of the three sensory bands encircling the club. The ground electrode was inserted in the distal end of the scape. Action potentials were amplified by a Grass P-15 preamplifier and stored on cassette tapes using a Teac R51-D data recorder. Action potentials were analyzed using a microcomputer equipped with software designed for the acquisition and analysis of insect chemoreceptor data (SAPID; Department of Entomology, University of Alberta, Edmonton, Alberta, Canada).

Upon obtaining a single neuron preparation, the first two stimuli tested were volatiles emanating from 1 μg of grandlure, followed by volatiles emanating from a crushed cotton square. These two stimuli served to determine whether the neuron was activated by the aggregation pheromone of the boll weevil and/or volatiles emanating from its host and food source. If the neuron were activated by grandlure, stimulation with 1-μg doses of the individual pher-

omone components followed. Once a neuron was found to be responsive to II, III, or IV, stimulation with the various analogs followed. Serial dilutions were delivered from the lowest to the highest concentration.

Apparatus for stimulus delivery and airflow were the same as described for EAGs. Stimulus duration was 0.5 sec with an airflow of ca. 1 liter/min. Two or three minutes were allowed between each stimulation. The number of impulses given by a neuron in response to a stimulus was tabulated over the 0.5-sec stimulation period.

Statistical Analyses

EAGs were evaluated by analysis of variance (Ostle, 1963). Where differences were noted among compounds, comparisons were made using Duncan's new multiple-range test (Duncan, 1955).

Numbers of released weevils captured using the four-trap array in the second field experiment were analyzed for significant differences by a paired t test (Ostle, 1963). Competitive tests in cotton fields with natural boll weevil populations also were evaluated by a paired t test. Daily trap captures of boll weevils were compared over the six-day test period.

RESULTS

Behavior

Competitive Field Tests with Released Weevils. Results of our initial field test with released weevils indicated that III-α-F and IV-α-F could be substituted for compounds III and IV of the boll weevil aggregation pheromone in a slow-release formulation without loss of activity over the 13-day test period (Table 1A). Not only were numbers of insects captured by each treatment nearly identical, but the sex ratios were also similar.

A second field test with released weevils, which utilized a different method of pheromone delivery and a shortened test period, showed no significant difference in either the number of weevils captured in traps or the sex ratio of responding weevils ($P < 0.05$) (Table 1B).

Competitive Field Tests with Indigenous Population of Weevils. Our results showed that the combination of ($\pm$)-I, II, and III-α-F + IV-α-F captured as many insects as ($\pm$)-I, II, and III + IV in cotton fields (Table 1C). In fact, the numbers of weevils captured each day of the six-day test period were nearly identical except that the combination with the fluorinated compounds was still active on the final day while the combination with pheromone components was not (Figure 2).

TABLE 1. COMPETITIVE FIELD TESTS WITH RELEASED BOLL WEEVILS USING SLOW-RELEASE FORMULATION OVER AN EXTENDED PERIOD, 13 DAYS, (A), AND SECOND METHOD OF RELEASE REPLICATED SEVERAL TIMES OVER A SHORTER PERIOD (B), AND COMPETITIVE FIELD TEST USING SLOW-RELEASE FORMULATION IN COTTON FIELD WITH INDIGENOUS POPULATION OF BOLL WEEVILS (C)

A. Total number of boll weevils captured in a competitive field test of (±)-I, II, III + IV vs. (±)-I, II, III-α-F + IV-α-F in four-trap array. Test was conducted over 13-day test period (May 14–26, 1988) and utilized slow release formulation.

Treatment	Total trap capture	Sex ratio (M/F)
(±)-I, II, III + IV (2 mg)	101	0.61:1
vs		
(±)-I, II, III-α-F + IV-α-F (2 mg)	102	0.65:1

B. Mean number of boll weevils captured in five replicates of competitive field test in four-trap array with (±)-I, II, III + IV vs. (±)-I, II, III-α-F + IV-α-F. Tests were conducted from May 16–September 23, 1988.

Treatment pair	Mean ± SE weevils/replicate	Sex ratio (M/F)
(±)-I, II, III + IV (0.8 mg)	35.6 ± 10.0	0.80:1
vs		
(±)-I, II, III-α-F + IV-α-F (0.8 mg)	25.4 ± 7.6	1.44:1

C. Mean (±SE) daily trap capture of boll weevils in competitive field tests in cotton field with traps baited with (±)-I, II, III + IV or (±)-I, II, III-α-F + IV-α-F. Test was conducted over six days (October 27–November 1, 1989) and utilized slow release formulation.

Treatment	Mean ± SE daily weevil capture	Sex ratio (M/F)
(±)-I, II, III + IV (1 mg)	5.7 ± 2.03	0.48:1
vs		
(±)-I, II, III-α-F + IV-α-F (1 mg)	5.7 + 1.25	1.00:1

Electrophysiology

Electroantennograms. Dose–response curves constructed from EAGs of male boll weevils to III and IV and their fluorinated analogs show significant differences in activity of the various compounds (Figure 3). IV and IV-α-F were the most active compounds tested with responses to either compound not differing significantly except at the highest stimulus load tested. EAGs in response to III-α-F did not differ from those to IV-α-F at any stimulus load. III, III-acyl-

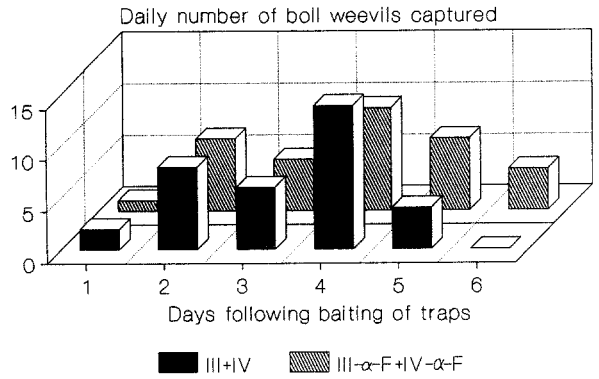

FIG. 2. Daily number of boll weevils captured in traps in cotton fields in traps baited with the slow-release formulation of (+)-I (0.3 mg), II (0.4 mg), and III + IV (0.3 mg) (III + IV in figure) versus (+)-I (0.3 mg), II (0.4 mg), III-α-F + IV-α-F (0.3 mg) (III-α-F + IV-α-F in figure).

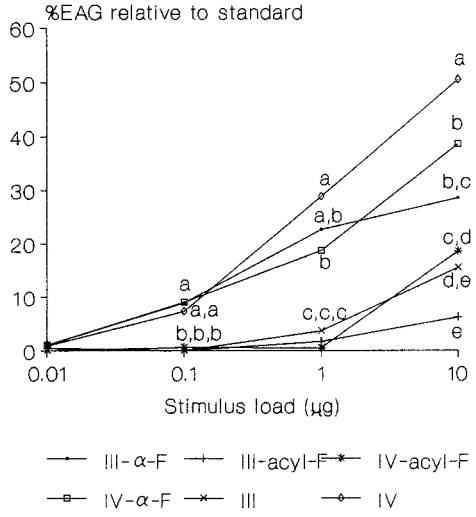

FIG. 3. Dose–response curves constructed from EAGs of male boll weevils to serial stimulus loads of III-α-F, IV-α-F, III-acyl-F, IV-acyl-F, III, and IV. Means followed by different letters are significantly different at that stimulus load.

F, and IV-acyl-F had a threshold stimulus load of 1–10 μg and were thus considerably less active than the other compounds except for IV-acyl-F, which was as active as III-α-F at the highest dose tested ($P < 0.05$). EAGs of female boll weevils to III, IV, and their α-and acyl fluorinated analogs have been reported previously (Prestwich et al., 1988).

Single-Neuron Recordings. While neurons responsive to IV are infrequently encountered in single-neuron recordings from boll weevil antennae (ca. 2% of neurons recorded are responsive to IV) (Dickens, 1990), responses of one IV neuron associated with a type I sensillum within the sensory band region of an *A. grandis* female was recorded to serial dilutions of IV, IV-α-F, and IV-acyl-F (Figure 4A). Responses of this single neuron substantiated the EAG results by clearly showing that IV-α-F could stimulate the IV neuron while IV-acyl-F was inactive.

Since previously reported single-neuron recordings from boll weevil antennae revealed no specialized neurons for III (Dickens, 1990), II neurons that were shown to respond to a lesser degree to III were stimulated with the fluorinated analogs of III and IV (III is the aldehydic analog of II). Results from neurons in a male and a female showed III-α-F to be nearly as active as III, while III-acyl-F and IV showed little activity (Figure 4B).

DISCUSSION

Behavior

The ability of III-α-F + IV-α-F to substitute for III + IV in the boll weevil pheromone blend is clearly demonstrated in our field experiments involving both released and indigenous boll weevil populations (Table 1). This is the first report of a compound capable of substituting for a boll weevil pheromone component and, to our knowledge, the only report of a fluorinated analog as active as the targeted pheromone component in Coleoptera. A previous report of boll weevil pheromone analogs had shown that certain derivatives may inhibit boll weevil pheromone responses in laboratory behavioral bioassays (Hedin et al., 1985). Although a 2-fluorinated analog (4-methyl-2-fluoro-3-heptanol) of the pheromone component, 4-methyl-3-heptanol, in the European elm bark beetle, *Scolytus multistriatus*, was active in EAG and laboratory bioassays, the analog showed little activity in field tests (Pignatello and Grant, 1982).

Electrophysiology

The activity and similarity in dose–response curves for IV and IV-α-F, as well as the lack of activity of the acyl fluorinated analogs, in EAG tests is not surprising (Figure 3). Similar results were found for females in a previous study (Prestwich et al., 1988). The activities of these analogs is further elucidated in our current study by results of our single-neuron recordings (Figure 4). The IV neuron recorded responded with increasing doses of IV and IV-α-F, while little response was elicited by IV-acyl-F even at the highest dose tested. Similarly, III and III-α-F elicited significant numbers of impulses from II neurons, while

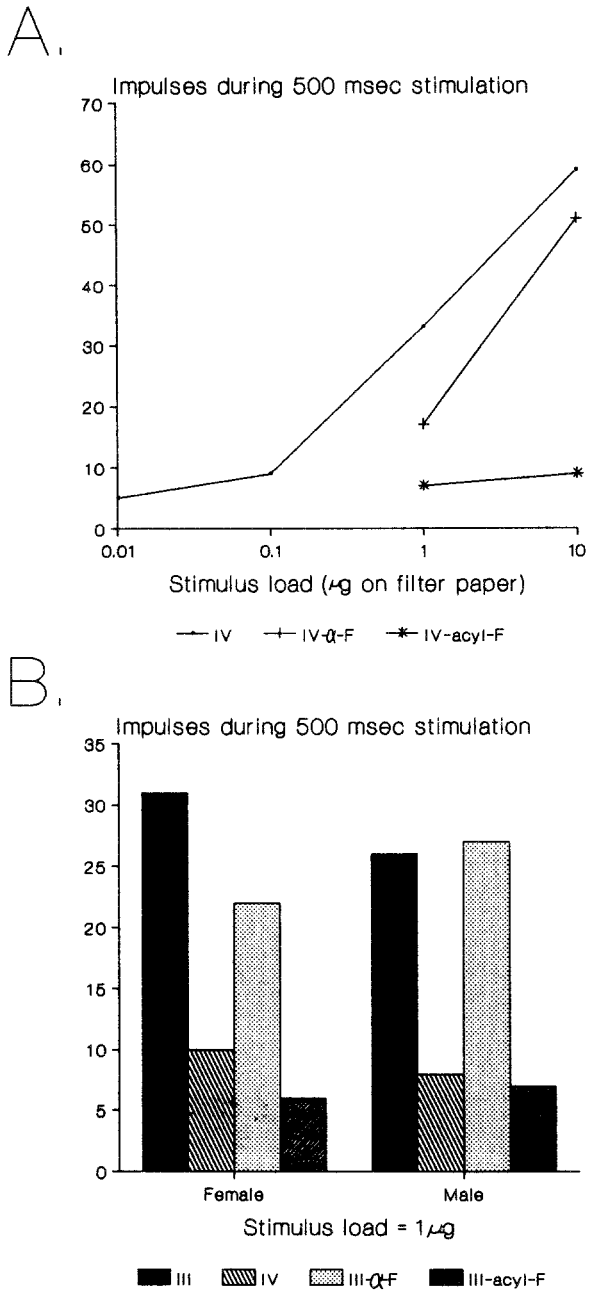

FIG. 4. (A) Dose–response curve of a IV neuron associated with a type I sensillum in a male boll weevil to serial stimulus loads of IV, IV-α-F, and IV-acyl-F. (B) Number of impulses elicited from II neurons associated with a type I sensilla in male and female boll weevils by 1 μg stimulus loads of III, IV, III-α-F, and III-acyl-F.

III-acyl-F was inactive. We recognize that stimulus loading and not the number of molecules available for interaction with responsive receptors is being compared in our study. The number of molecules of a compound reaching the receptors would be a result of its volatility and release rate from the filter paper. A measure of volatility, Kovats indices (Kovats, 1958), calculated for each of the compounds (III = 1253; III-α-F = 1211; III-acyl-F = 1167; IV = 1261; IV-α-F = 1217; IV-acyl-F = 1170) shows them to differ by less than one methylene group. Thus, it seems that the large differences observed in activity of the compounds is largely due to differences in their interaction with the receptors.

The lack of activity of the acyl fluorides is in contrast with the activity of the acyl fluoride analogs of the aldehyde components of the pheromone of *Heliothis virescens* (Prestwich et al., 1986). Despite the ease of hydrolysis of saturated acyl fluorides to the corresponding acids, conjugated unsaturated acyl fluorides are quite stable. For example, a 3-year-old sample of the mixed III-acyl-F and IV-acyl-F still contained 25% acyl fluoride and 75% acid. Nonetheless, we cannot rule out the unlikely possibility that the low activity of the acyl fluoride of the boll weevil pheromone is due in part to selective hydrolysis in the receptor lymph.

In conclusion, the α-fluorinated analogs of the boll weevil pheromone components, III and IV, are active in stimulating identified neurons sensitive to the pheromone components. Furthermore, a mixture of these geometric isomers combined with the other pheromone components, ($\pm$)-I and II, is as active as the combination with III + IV in behavioral tests in the field. Since boll weevils require only compounds (+)-I, II, and IV for attraction to pheromone traps in the field (Dickens and Prestwich, 1989), it seems likely that the mechanism for this attraction is the stimulation of IV neurons (Dickens, 1990) by IV-α-F as indicated in single neuron recordings.

As a final note, the α-fluorinated analogs are substantially more stable than III + IV, as indicated by our experience in chemical oxidation of the α-fluorinated compounds, which require more vigorous conditions than chemical oxidation of the parent compounds, III + IV (Prestwich et al., 1988). Thus the α-fluorinated analogs of III + IV may be useful as substitutes for these pheromone components in baits for survey traps used in the Boll Weevil Eradication Program and in an attracticide bait that is currently being developed.

(Received October 24, 1990; accepted January 31, 1991)

Abstract—The megaspilid *Dendrocerus carpenteri* (Curtis) is a solitary ecto-hyperparasitoid of aphid primary parasitoids. It avoids superparasitism, but the avoidance rate depends on the amount of time elapsed after the first oviposition. In addition, females discriminate in a time-dependent manner between hosts parasitized by themselves and hosts parasitized by conspecifics. They recognize parasitized hosts by means of two externally perceivable chemical markers that are deposited on the mummy shell. One of the markers is highly active, short-lived, not passable through gas chromatography (GC), and freezing sensitive; the other is moderately active, persistent, GC-passable and freezing tolerant. Using two markers is believed to be advantageous for the hyperparasitoid female, as their ratio provides information on mark age and on the producer of the mark (the female herself or a conspecific female).

Key Words—*Dendrocerus carpenteri*, Hymenoptera, Megaspilidae, hyperparasitoid, primary parasitoid, marking pheromone, host discrimination, self-recognition, superparasitism.

INTRODUCTION

Aphid hyperparasitoids develop on or in the body of aphid primary parasitoids and can be important secondary pests. Even though their detrimental effect on

primary parasitoids has still to be clearly demonstrated, many field data suggest that at least the more polyphagous hyperparasitoids are significant promoters of pest outbreaks (Bennett, 1981; Van den Bosch, 1981; Sullivan, 1988). The species dealt with here, *Dendrocerus carpenteri* (Curtis) (Hymenoptera, Megaspilidae), is a polyphagous hyperparasitoid. It parasitizes a wide range of primary parasitoid hosts associated with many aphids and plants (Dessart, 1972; Takada, 1973; Stary, 1977).

The efficiency of aphid primary parasitoids cannot usually be enhanced by inundative releases, because this would lead to the augmentation of hyperparasitoids in opposition to the desired effect (Höller, 1988). Instead, an indirect enhancement through the manipulation of hyperparasitoids is much more promising. The use of marking pheromones could perhaps achieve this goal by dispersing hyperparasitoids from areas where pest populations increase and thus freeing primary parasitoids from their attack (Vinson, 1977). Marking pheromones have been shown to be produced for host discrimination by a number of primary parasitoids (see for reviews: van Lenteren, 1981; Vinson, 1984; van Alphen and Visser, 1990), but they have not been documented for hyperparasitoids. Marking pheromones produced by parasitoids are either patch marks, i.e., pheromones used to label the substrate, or host marks, which are applied on or injected into the host. In this paper, we deal with marking pheromones as host marks exclusively. We investigated the biological activity of the marking pheromones of *D. carpenteri*, and we attempted partial chemical characterization of the compounds.

D. carpenteri is a solitary ectohyperparasitoid of aphidiids and aphelinids. Primary parasitoid hosts are attacked after death of the aphid host during the postparasitic phase of development in the mummy (= the cocoon surrounded by the remaining aphid cuticle wherein the primary parasitoid pupates). The female drills a hole through the mummy shell, applies venom, and lays her egg on the surface of the host (Bocchino and Sullivan, 1981). Fecundity is rather low in *D. carpenteri*, since, on average, only 75 progeny are produced per female (Walker and Cameron, 1981).

METHODS AND MATERIALS

Insect Cultures

Two different plant–aphid–primary parasitoid systems were used to investigate the biological activity of the marking pheromone (system 1) and to attempt chemical characterization (system 2). System 1: oat (cv. Bojar)–*Sitobion avenae* F.–*Aphidius rhopalosiphi* De Stefani-Perez maintained at 20°C in a 16:8 hr light–dark cycle. Experiments using system 1 were conducted in Kiel, Germany. System 2: wheat (cv. McGregor)–*Schizaphis graminum* (Rondani)–

Aphidius matricariae Hal. maintained at 26°C in a 16:8 hr light–dark cycle. Experiments using system 2 were conducted in College Station, Texas. *A. rhopalosiphi* ex *S. avenae* and *A. matricariae* ex *S. graminum* were similarly suitable hosts for the hyperparasitoid *D. carpenteri*. A choice experiment in which both hosts were offered simultaneously could not be conducted due to quarantine laws.

Bioassay

Six hosts were offered to one female *D. carpenteri* for 1 hr in a 3.5-mm-diameter Petri dish. The hosts were mummies containing a primary parasitoid larva, prepupa, or young pupa. Mummies containing a diapausing larva, an older pupa, or an adult, as evidenced by their dark appearance, were not used. The six hosts were glued on their ventral side in a matrix of equal distances to a 15 × 30-mm cardboard rectangle, which was placed in the Petri dish. To investigate the biological activity of the marking pheromone, an experienced and mated hyperparasitoid female taken directly from the rearing culture was allowed to oviposit in three of the six hosts and then was removed (females that did not parasitize three hosts within 20 min were discarded). After a given time interval elapsed, the same female or another female with the same amount of experience was again confined with these hosts, half of which had been attacked previously. Any completed drillings were noted during an observation period of 1 hr. The hosts attacked were later dissected in order to verify oviposition. Eggs laid on hosts attacked twice were classified as having been laid during the first or the second attack, as evidenced by visible development of the first-laid egg. The minimum amount of time necessary for accurate classification of eggs was 6 hr. For every combination, 20 replicates were performed.

For experiments with time intervals of 6 hr or longer, storage of hosts at 15°C prevented rapid development of unparasitized primary parasitoids. The longest time interval investigated was 48 hr, as longer intervals result in hatching of unparasitized primary parasitoids. Hyperparasitoid females were stored at 15°C between experiments and were fed during this time with 15% sucrose solution.

The experimental procedure had to be modified when time intervals of 5 min or 1 hr were investigated: only two hosts were offered, the female was allowed to oviposit only once, the same female was used, the recording time was 20 min, and 60 replicates were performed. This modification was necessary because of the time required for oviposition (about 1 min 14 sec) in *D. carpenteri* (Le Ralec, 1988).

The same bioassay was used during efforts to characterize the chemical nature of the marking pheromone. However, this time the hosts were arranged in the matrix

1 5 3
4 2 6

where 1–3 are controls and 4–6 are treatments, with a single female being observed for 1 hr as described above. The matrix was used to investigate the response of *D. carpenteri* females towards: (1) artificial drilling hole (one hole ca. 0.3 mm diameter drilled in 4–6 each; none in 1–3); (2) a piece of mummy shell from a host parasitized previously (one mummy shell piece ca. 0.7 mm^2 surrounding the drilling hole of a host parasitized ca. 24 hr ago detached and glued on 4–6 each; similar piece of unparasitized host mummy shell on 1–3); and (3) solvent extracts (1 μl solvent extract applied dorsally on 4–6 each; 1 μl solvent on 1–3).

Solvent Extraction

Preliminary studies revealed that methanol was a better extraction solvent than acetone, diethylether, hexane, or water. Three different extracts were prepared:

Extract A (Female Body Rinses). Live *D. carpenteri* females (25 at a time) were placed in 100 μl methanol in a 1-ml beaker. After 2 min, the methanol was decanted into a glass reactivial. The 25 females were again extracted with 100 μl of solvent, which was added to the first extract. In total, 800 rinsed females yielded 6.5 ml extract. The extract was concentrated under nitrogen to 1.5 ml, which corresponds to a concentration of 0.53 female equivalents (FE) per microliter and was stored at $-60°C$.

Extract B (Host and Egg Extracts). Parasitized hosts were dissected within 24 hr after oviposition. The mummified aphid cuticle, the primary parasitoid, and the egg of the hyperparasitoid (numbers were identical between fractions but differed between samples) were placed together and separately into glass reactivials. The meconium was discarded. A given amount of methanol was added to obtain a concentration of 0.6 HE (host equivalents)/μl. After 10 min, the extract was carefully withdrawn by means of a syringe. Higher concentrations of mummified aphid cuticles (24 HE/μl MeOH) also were prepared. Mummified aphid cuticle and primary parasitoid extracts (0.6 and 24 HE/μl MeOH) from unparasitized mummies were used as controls. All extracts B were stored at $-60°C$.

Extract C (Female Reproductive System Extracts). The reproductive system is the source of the marking pheromones in *D. carpenteri* (Höller and Vinson, in preparation). Females of the hyperparasitoid were dissected in Pringle's saline solution (Pringle, 1938) by gently pulling out the ovipositor and the adjacent reproductive system. The latter was disconnected by exerting pressure with a minute needle on the caudal part of the common oviduct until detachment. Subsequently, the reproductive system was immediately transferred in a reac-

tivial containing methanol. The extract was concentrated under nitrogen to 0.4 FE/μl MeOH. Extract C was divided in two parts of equal sizes, one being stored at 4°C and one at −60°C for 24 hr before being bioassayed.

Gas Chromatography

Analytical GC was performed using a 0.22-mm-ID × 25-m vitreous silica capillary column coated with a 0.5-μm film of BP1 (SGE) methyl silicone stationary phase using a Varian 3700 instrument equipped with an on-column injector and a flame ionization detector (FID). Injection sizes were 1 or 2 μl. For preparative purposes, a Tracor 550 chromatograph equipped with a 4-mm-ID × 1.8-m glass column packed with 3% OV-101 on chromosorb 750 (100–120 mesh) was used. A 100-0:1 variable glass splitter divided the effluent between a Brownlee-Silverstein collector (Brownlee and Silverstein, 1968) and an FID detector. Sample sizes between 15 and 50 μl were injected for preparative separation, using a temperature of 60°C at injection (held for 1 min) to 300°C at 20°C/min.

RESULTS

Biological Activity of Female-Deposited Marking Pheromone

These experiments were conducted using the plant–aphid–primary parasitoid–hyperparasitoid system (1). Females were strongly repelled by their own mark when this mark was 5 min old, but showed a significantly (chi-squared goodness-of-fit test, $P < 0.070$) weaker response towards marks having been applied by themselves 1 hr or more previously (Figure 1). Responses towards self-produced marks of 1, 6, 12, 24, and 48 hr old were similar ($P > 0.376$). Females encountering a host marked by a conspecific female 6 or 12 hr before were repelled to the same degree as to their own marks of the same age. In contrast, conspecific marks 24 or 48 hr old led to a significantly ($P < 0.099$) higher acceptance of hosts than the corresponding self-produced marks (Figure 1).

Egg-laying was the last step in a series of behaviors following the encounter of a *D. carpenteri* female with a suitable host: (1) the host was thoroughly examined with the antennae, (2) a hole was drilled through the mummified aphid cuticle and the underlying cocoon of the primary parasitoid, (3) the contents of the mummy were palpated by means of the ovipositor, and (4) the motionless ovipositor remained in contact for some time with the mummy contents. Rejection of a marked host occurred either after step 1, i.e., hole drilling was suppressed as a result of exterior antennal examination of the host, or at steps 3–4, i.e., the host was attacked but an egg was not laid. Seventy-four to

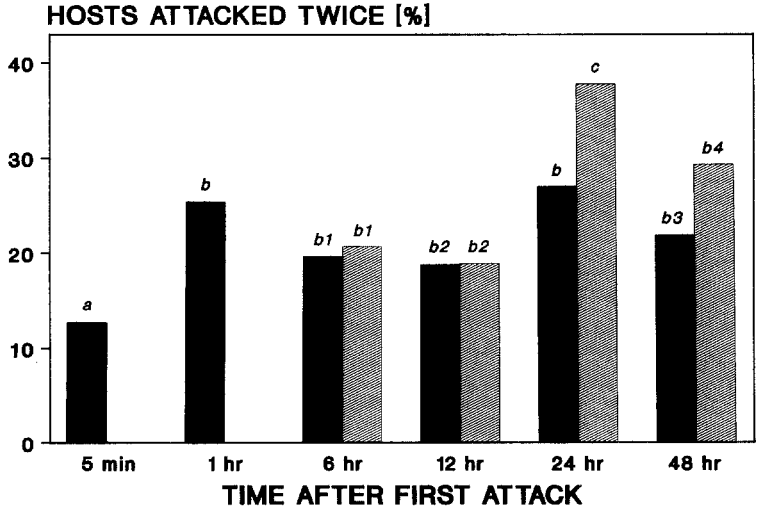

FIG. 1. Percentages of hosts attacked twice as a time-dependent phenomenon in *Dendrocerus carpenteri*. Solid bars: hosts previously attacked by the same female; shaded bars: hosts previously attacked by another female. Different letters and numbers indicate significant differences between bars at all time intervals or at one time interval, respectively (chi-squared goodness-of-fit test, $P < 0.070$ and $P < 0.099$, respectively); all values were significantly different from 50% ($P < 0.055$).

90% of the females oviposited on a primary parasitoid that had not been attacked previously, but only 35–67% did so when the host had been attacked before, and thus in most cases already contained an egg (Table 1). Hence, *D. carpenteri* was able to recognize parasitized hosts externally with the antennae and internally with the ovipositor. The data presented in Table 1 give no evidence for internal discrimination between self-laid eggs and eggs laid by a conspecific female.

In order to prove that host discrimination in *D. carpenteri* is not a result of visual, tactile, or acoustical stimuli, hosts with artificial drilling holes were offered. No differences were recorded between treated and untreated hosts (Table 2). In another experiment, a piece of mummy shell surrounding the drilling hole of a parasitized host was detached and glued on a healthy host. The treated hosts were offered to females that had not initially made the hole. This time, significantly less treated hosts were attacked in comparison to the control (Table 2). Thus, host discrimination in *D. carpenteri* was based on chemical markers.

Activity of Extract A (Female Body Rinses)

These and all following experiments were conducted using the plant–aphid–primary parasitoid–hyperparasitoid system (2). The complete collection of extract A after GC separation was not as active as the crude extract (data not

shown). Analysis of various GC fractions revealed activity only from a fraction eluting from 18.30 to 27.00 min (fraction A3; Table 3). Doubling the injected concentration from 1.06 to 2.12 FE/μl MeOH (fractions A3 and A6, respectively; Table 3) did not increase the response of the hyperparasitoids. A10 was the narrowest fraction yielding activity. A comparison with hydrocarbon standards showed that fraction A10 eluted between the C-31 and C-33 hydrocarbon fractions. However, it was impossible to visualize any peaks in the chromatograms of the active fractions, which indicates that the active compound(s) were present only at very low concentrations. Rates of oviposition did not differ between attacked extract-treated and methanol-treated control hosts.

Activity of Extracts B (Host and Egg Extracts)

Hyperparasitoid eggs, freshly parasitized primary parasitoids, and the corresponding mummy shells were extracted together and separately in methanol. As shown in Table 4, joint extracts, primary parasitoid extracts, and mummy shell extracts (0.6 HE/μl) alone provoked a significant (chi-squared goodness-of-fit test, P values given in Table 4) response in terms of activity. In contrast,

[e] Concentration 24 HE/μl MeOH, collected from preparative GC.

hyperparasitoid egg extracts were not or at most slightly active. Rates of oviposition did not differ between attacked extract-treated and methanol-treated control hosts.

Highly concentrated mummy shell extracts (24 HE/μl MeOH) were prepared to enable a GC comparison between healthy and parasitized hosts. The chromatograms differed in two peaks (Figure 2), but the peak appearing at 18.05 min was an artifact of contamination as it was lacking in an active additional replicate. The second peak (retention time 20.36 min), however, was present in both replicates. Therefore, and because this peak fell within the retention time of the active fraction A10 prepared from extract A, peak 20.36 was subsequently purified by means of preparative GC. A dotriacontane (hydrocarbon C-32) standard injection yielded a peak of very similar retention time, i.e., 20.18 min (Figure 2). By comparing peak 20.36 to the peak obtained from dotriacontane, an amount of 0.3 ng/ml of pheromone was estimated to be deposited per *D. carpenteri* female during host marking. Dotriacontane, applied in a concentration of ca. 100 ng/ml MeOH (maximum solubility at room temperature), was not active when bioassayed (data not shown). Apparently, the marking pheromone was not dotriacontane, despite its retention time being similar to the retention time of the active compound.

Treating hosts with a crude highly concentrated mummy shell extract (24 HE/μl MeOH) resulted in increased activity (approximately two times greater than the standard concentration 0.6 HE/μl MeOH; see Table 4). The biological

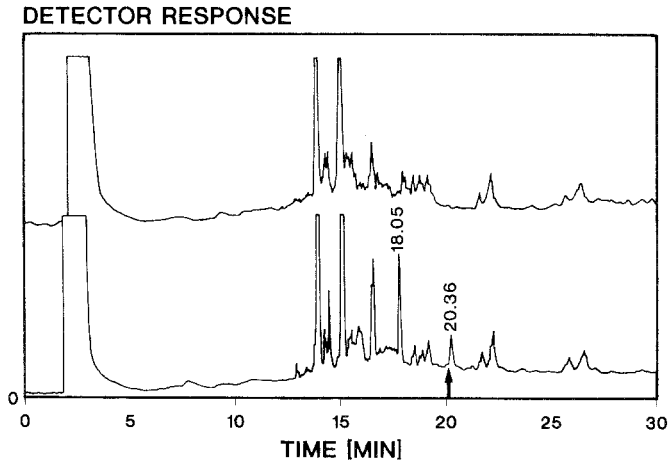

FIG. 2. Gas chromatograms of highly concentrated methanol mummy shell extracts (24 HE/μl MeOH). Above: unparasitized hosts; below: parasitized hosts; arrows: peaks appearing in chromatogram of parasitized hosts, exclusively; retention times 18.05 and 20.36 min (average values of two replicates, calculated from hundredth sec).

activity of the mummy shell extract, although present, was significantly reduced when totally collected following preparative GC. In contrast, similar activities were obtained from the totally collected GC-passed mummy shell sample and its one purified peak at 20.36 min (fraction B3; Table 4).

Activity of Extract C (Female Reproductive System Extracts)

Extract C was highly active when stored overnight at 4°C but lost much of its activity when frozen in the same time interval at −60°C (Table 5). Thus, freezing significantly decreased activity of the female reproductive system extract. Rates of oviposition did not differ between attacked extract-treated and methanol-treated control hosts.

DISCUSSION

The data of the present study clearly demonstrate that the hyperparasitoid *D. carpenteri* uses marking pheromones for host discrimination. Many parasitoids do so, but most of the cases reported so far concern endoparasitoids. Host discrimination of ectoparasitoids, and especially solitary ones, has been studied only occasionally (Lloyd, 1956; van Lenteren and De Bach, 1981) and is reported here for the first time in a hyperparasitoid.

The following results provide evidence that the marking pheromone of *D. carpenteri* consists of at least two different components:

1. Persistence. The avoidance rate of already parasitized hosts was high when a time interval of 5 min elapsed between the first attack and subsequent encounter. After 1 hr, the avoidance level had significantly decreased. However, it remained stable between 1 and 48 hr. Apparently, one component caus-

TABLE 5. ACTIVITY LEVELS OF EXTRACT C (FEMALE REPRODUCTIVE SYSTEM EXTRACTS)

Treatment	No. hosts attacked[a]	Attacks on treated hosts (%)	Chi^2 value[b]	P

Extract C, not previously frozen[d]	52	17.3	22.23	0.001

[a] Totals of 20 replicates.
[b] Chi-squared goodness-of-fit test; expected: No. attacks on treated hosts is not different from half of total attacks.
[c] Concentration 0.4 FE/μl MeOH; frozen overnight at −60°C.
[d] Concentration 0.4 FE/μl MeOH; stored overnight at 4°C.

ing strong responses became inactive quickly, whereas another component was not so repellent, but much more long-lasting.

2. Transferability. Gluing the piece of mummy shell surrounding the drilling hole of a host parasitized ca. 24 hr to an unparasitized host resulted in a decreased attack rate. The rate of avoidance was comparable to that of hosts having been attacked 24 or 48 hr earlier by a different female. Thus, a stable component was transferable and was deposited on the mummy shell.

3. GC stability. Methanol extracts from mummy shells resulted in a concentration-dependent response by searching hyperparasitoid females. However, after passing the extract through a preparative GC and collecting all fractions combined, the extract lost much of its activity. The remaining activity probably was due to a stable component, a more active component failing to be collected following GC fractionation.

4. Freezing stability. Extracts of the female reproductive system stored overnight at 4°C yielded high activity the next day. In contrast, the same extracts caused significantly weaker responses when stored for the same time at −60°C. Thus, one component was sensitive to freezing, in opposition to a stable component that was still active after freezing.

Taken together, points 1–4 allow the conclusion that a two-component marking pheromone system is used for external host discrimination in *D. carpenteri*. One component is highly active, but unstable (sensitive to GC conditions and freezing), whereas a second component is less active but persistent (GC stable and freezing tolerant). The possible advantages of using a two-component mixture as an externally perceivable marking pheromone are:

1. Information on mark age. Simultaneously applying two components with different levels of persistence would enable a female to deduce the mark's age from the ratio of components. In fact, it has been shown repeatedly that parasitoid females recognize the age of marks (e.g., Rogers, 1972; Chow and Mackauer, 1986; Hofsvang; 1988), but the question of how a parasitoid tells the time interval between successive ovipositions was never answered (see Hubbard et al., 1987).

2. Self-recognition. There is now considerable evidence that at least some parasitoid species differentiate between self-produced marks and marks produced by conspecifics (Hubbard et al., 1987; Völkl and Mackauer, 1990; see also results of this study). Again, self-recognition might be enabled through specifities in the ratios of components.

3. Dispersal after oviposition. Parasitoids like *D. carpenteri* are not easily disturbed once they are in contact with a suitable host. Contact kairomones originating from the mummy shell elicit thorough examination of the area (Höller, unpublished data). Hence, after oviposition there must be some stimulus strong enough to cause the female to leave before beginning to search for a new host. We believe that the unstable, highly active component has this function

in *D. carpenteri*, being a dispersal pheromone (Vinson, 1984). Once the female has left, the dominance of the this component attenuates and its less active, but the much more stable counterpart prevails, which allows a careful examination of the host when encountered again. The alternative explanation for the function of short-lived marking pheromones given by Roitberg and Mangel (1988) does not apply here, considering the persistence of the stable compound.

The two-component theory is also helpful in explaining other data. For instance, Hubbard et al. (1987) recorded striking differences in self- and conspecific superparasitism of *Nemeritis canescens* (Grav.) 0–24 hr after the first oviposition, but not thereafter (2–8 days). The combined action of an unstable and highly active (towards the same female) component and a persistent component might have been occurring here too. The theory is further substantiated by the fact that many parasitoids discriminate not only externally through information perceived at receptors located on the antennae, but also internally after ovipositor insertion in the host. This behavior was first observed in *Trichogramma evanescens* Westw. (Salt, 1937). Since then, numerous examples have been published (including this study). It seems not unlikely that the secretion deposited in the host's body (or, in *D. carpenteri*, on the host's cuticle inside the mummy) remains externally detectable for a short time after oviposition, before being metabolized, moved, or diffused. Thus, the highly active, nonpersistent component and the secretion are possibly identical.

In spite of this sophisticated marking system, levels of superparasitism were quite high throughout the study. Self-superparasitism can be advantageous, i.e., when two or more eggs in or on a host increase the probability of gaining an offspring from that host (van Alphen and Visser, 1990). This would be the case when there is a high risk of a later attack by a conspecific female or when defense mechanisms from the host reduce the survival rate of the offspring. Obviously, a mother benefits from conspecific superparasitism when hosts are scarce and when the probability of the second egg to win is reasonably high. If the ovipositions are sufficiently close together, then the probability of the second egg winning may be great enough to warrant the risk (Hubbard et al., 1987). However, just the contrary happened in the present study, since only 24 and 48 hr after the first oviposition were higher levels of conspecific superparasitism recorded. We believe the reason for this is the following: females laid more eggs in hosts bearing older eggs or early larvae of conspecifics because the survival rate of their offspring would be enhanced if they act as tertiary parasitoids (or, in this case, autoparasitoids). Haviland (1920) showed very early that tertiary and even higher levels of parasitism occur in *D. carpenteri*, with conspecifics or other hyperparasitoids as hosts. We hypothesize that the venom that is applied prior to oviposition toxifies both the primary parasitoid host and a possibly concurrent hyperparasitoid, as long as the latter has hatched from its egg. Should this hypothesis prove true, conspecific superparasitism on hosts

parasitized 24 or 48 hr before (time required from egg deposition until hatching of the first instar larva; Le Ralec, 1988) must be regarded as being advantageous to the second female.

The source of the marking pheromone is often one of the accessory glands, either the Dufour gland (Guillot and Vinson, 1972; Vinson and Guillot, 1972; Harrison et al., 1985; Hubbard et al., 1987) or the poison gland (Yamaguchi, 1986). Guillot et al. (1984) identified hydrocarbons, sterol esters, and free fatty acids as active fractions from the poison gland of *Cardiochiles nigriceps* Viereck. Even though each of the neutral lipid fractions proved to be active at a given concentration, much higher activities were recorded from the composite sample, indicating synergism among the active fractions. These findings support the two-component theory. Mudd et al. (1982) identified volatile hydrocarbons from the Dufour gland of *N. canescens* and suggested that heneicosane (C21) acts as an external marker pheromone in this parasitoid. In the present study, the stable component had a GC retention time near that of dotriacontane (C32), which itself was not active. The pheromones used for host marking in *D. carpenteri* are not yet identified.

Acknowledgments—We thank Dr. Franco Pennacchio and Tom Syvertsen for their suggestions and ideas, Dr. Jacques van Alphen and an anonymous referee for reviewing the manuscript, and Dr. Eline Hågvar and Dr. Trond Hofsvang for commenting on an earlier draft of the manuscript. Leslie McKinney provided the initial parasitoid and aphid material in Texas, which is gratefully acknowledged. (Received October 31, 1990; accepted January 31, 1991)

Abstract—Hydroxamic acids (Hx) produced by some cereal crops have been associated with allelopathy. However, the release of Hx to the soil by the producing plant—an essential condition for a compound to be involved in allelopathy—has not been shown. GC and HPLC analysis of roots and root exudates of wheat (*Triticum aestivum* L.) and rye (*Secale cereale* L.) cultivars, with high Hx levels in their leaves, demonstrated the presence of these compounds in the roots of all cultivars analyzed and in root exudates of rye. Moreover, bioassays employing root exudates collected from wheat and rye seedlings demonstrated that only rye exudates inhibited root growth of wild oats, *Avena fatua* L., a weed whose root growth is inhibited by Hx. These results suggest that rye could potentially interfere with the growth of *Avena fatua* in nature and that this interference could be due to the release of Hx to the soil by way of roots.

Key Words—Hydroxamic acids, root exudates, allelopathy, *Triticum aestivum* L., *Secale cereale* L., wild oats, *Avena fatua*.

INTRODUCTION

Hydroxamic acids (Hx) isolated from wheat and other cereals, have been proposed to impart plant resistance to pests and diseases (Niemeyer, 1988). Hx

isolated from rye, 2,4-dihydroxy-1,4-benzoxazin-3-one (DIBOA), and its decomposition product, benzoxazolin-2-one (BOA), have been implicated as potential allelopathic agents of residues of this crop (Barnes and Putnam, 1987; Barnes et al., 1987). Recently, it was reported that these compounds are decomposed by microorganisms in the soil to 2,2′-oxo-1,1′-azobenzene (AZOB) or its methoxy derivative (MAZOB) and that these transformed compounds have stronger herbicidal activity than the original molecules (Nair et al., 1990). Previous results obtained by us indicated that 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA), the main Hx isolated from wheat, and its decomposition product, 6-methoxybenzoxazolin-2-one (MBOA), inhibit root growth of wild oats (Pérez, 1990), a weed that normally infests wheat fields (Bell and Nalewaja, 1968; Cudvey et al., 1989).

One of the essential features of allelopathic interactions between plants is that phytotoxins or substrate for phytotoxins must be released from a plant to the soil and absorbed by a second plant (Rice, 1984). In this paper we present data on Hx levels in roots and root exudates of three different wheat cultivars and two rye cultivars. The presence or absence of toxicity of root exudates collected from wheat and rye plants was assessed with wild oat bioassays.

METHODS AND MATERIALS

Reference Compounds. DIMBOA was isolated from ether extracts of *Zea mays* L. cv. T129 s, as described by Queirolo et al. (1983). DIBOA was synthesized as described by Jernow and Rosen (1975).

Seeds. Seeds of spring wheat cultivars Andifén, Alifén, and Likay-INIA and of wild oats (*A. fatua*) were obtained from the Agricultural Experimental Station, La Platina (INIA). Seeds of rye cultivar Forrajero Baer and Tetra Baer were obtained from E. von Baer Seeds Co., Temuco, Chile.

Collection of Root Exudates. Seeds of wheat and rye cultivars were germinated in Petri dishes containing Whatman No. 1 filter paper. After radicle emergence, seeds were transferred to a continuous root exudate trapping system using vermiculite as an inert medium (Tang and Young, 1982). The system was autoclaved for 40 min at 15 psi before use and covered with aluminum foil. Thirty seedlings of each cultivar were planted in vermiculite and grown in a light bank at 20 ± 5°C and a 12 light–12 dark photoregime. Each pot was irrigated continuously by recycling distilled H_2O at a rate of 15 ml/min until the seedlings reached the first leaf stage. At this point, the Amberlite column was removed from the system and washed with 10 ml of distilled H_2O. Adsorbed organic materials were eluted from the column with 100 ml MeOH. The MeOH solution was evaporated to dryness under reduced pressure at a temperature of 35°C, and the residue was redissolved in 1 ml MeOH. This latter solution was

employed for the bioassays, HPLC, and GC analysis. Control solutions were obtained by the same procedures from systems without seedlings.

Root Extracts. Once the seedlings reached the first leaf stage, roots were removed from the vermiculite in the root exudate system and washed with distilled H_2O. Root tissue (100–150 mg) was macerated successively with 3 × 0.33 ml of distilled H_2O. The extract was adjusted to pH 3 with 0.1 N H_3PO_4 to avoid Hx decomposition and then centrifuged at 6000 *g*. The resulting supernatant was analyzed by HPLC (Niemeyer et al., 1989).

HPLC Analysis. Analysis was performed in a Knauer HPLC system equipped with two pumps (type 364), mixing chamber, variable UV-Vis detector and HPLC software package interfaced to a personal computer. Isolations of the compounds of interest were obtained by using a reverse-phase Zorbax ODS C-18 (4.6 × 25) column with a 5-μm particle size. A linear gradient of H_2O (pH 3)–MeOH, 80:20 to 50:50 for the first 10 min with an additional 20 min at 50:50 was used. The flow was 1.0 ml/min, and the eluate was analyzed at 254 nm. Samples were filtered through a 0.45-μm filter prior to injection. The volume injected was 20 μl. Concentrations of DIBOA and DIMBOA in the samples were obtained by extrapolation from the corresponding calibration curves obtained with pure compounds.

GC Analysis. Aqueous root extracts (1 ml) were evaporated to dryness and redissolved in 100 μl MeOH. Fifty microliters of this solution were derivatized with 50 μl of *N*, *O*-bis(trimethylsilyl) acetamide for 20 min at 50°C. Methanolic solutions of root exudates and standard samples were derivatized in the same way. GC analysis was performed in a Shimadzu GC-PA system equipped with a capillary column and a FID detector. The N_2 was used as carrier gas and the injector and detector temperatures were 250°C. Samples were run with a temperature gradient between 180 and 206°C at a rate of 8°C/min.

Bioassays. Bioassays were carried out in Petri dishes containing Whatman No. 1 filter paper. Different volumes of root exudates dissolved in MeOH ranging from 100 to 250 μl were added to the filter paper. After solvent evaporation, 3 ml of distilled H_2O were added and 10 seeds of wild oats were placed on each disk. Root lengths were measured after 72 hr of incubation in the dark at 20 ± 3°C.

RESULTS

HPLC and GC Analysis of Hx in Roots and Root Exudates of Wheat and Rye Plants. Figure 1 depicts typical HPLC chromatograms of root extracts and root exudates from wheat and rye plants. The peak at 8:06 ± 0.05 min was identified as DIBOA and the peak at 10:15 ± 0.15 min was identified as DIMBOA. Identification was based on retention times and UV spectra of authentic

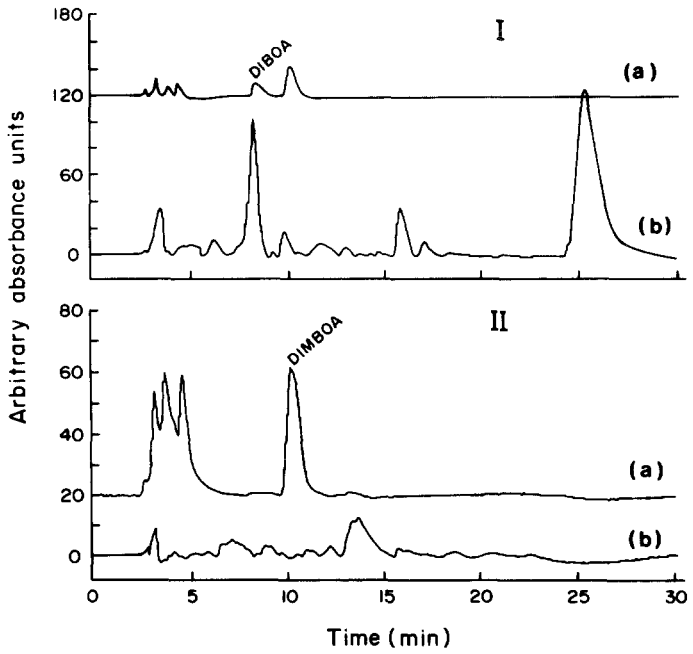

FIG. 1. HPLC chromatograms of root extracts (a) (100–150 mg tissue in 1 ml H_2O) and root exudates (b) (collected from 30 plants and dissolved in 1 ml MeOH), of rye cultivar Forrajero Baer (I) and wheat cultivar Andifén (II).

standards. The same samples were also analyzed by capillary GC and its retention times compared with those of DIBOA 3.1 ± 0.01 min and DIMBOA 5.0 ± 0.01 min. In the HPLC chromatogram of root extracts from rye, a peak appeared with a similar retention time as DIMBOA, but the UV spectrum of this peak did not correspond with the standard nor was DIMBOA observed in the GC chromatogram.

In root extracts, DIBOA was detected by HPLC and GC in wheat and rye cultivars, while DIMBOA was detected only in wheat cultivars. In root exudates, DIBOA was the only Hx detected, and it was found only in rye (Table 1).

Bioassays. Root exudates collected from the wheat cultivar Andifén and from the rye cultivar Forrajero Baer between emergence and the first leaf stage were tested for toxicity on seeds of *A. fatua*, a weed whose root growth is inhibited by Hx (Pérez, 1990). The results (Figure 2) demonstrate that only root exudates collected from rye inhibited root growth of wild oats and that the level of inhibition was determined by the volume of exudate tested.

TABLE 1. QUANTITATION OF HYDROXAMIC ACIDS IN ROOT EXTRACTS AND ROOT EXUDATES COLLECTED BETWEEN EMERGENCE AND FIRST LEAF STAGE FROM WHEAT AND RYE CULTIVARS

	Root extracts (mmol/kg fr wt)[a]		Root exudates (μmol/kg fr wt)	
Cultivar	DIBOA	DIMBOA	DIBOA	DIMBOA
Rye				
Tetra Baer	0.8	nd[b]	0.07	nd

DISCUSSION

Root Exudates. It has been known for many years that organic compounds are exuded from healthy undamaged plant roots (Rovira, 1969). "Normal exudates" are thought to be composed of soluble, low-molecular-weight compounds that are mixed in the rhizosphere with root mucilage, root cap cells, dead root hairs, and epidermal cells (Nye and Tinker, 1977). Thus the distinction between "normal exudates" and other organic materials in the rhizosphere is unlikely even in hydroponic cultures (Barnes et al., 1986) and washings of rooting medium such as sand (Abdul-Wahab and Rice, 1967) include materials that were initially part of the plant structure. However, the results in Table 1 show that hydroxamic acids retained by the XAD-4 column are not a product of cell rupture; i.e., they are "normal exudates," since the levels found in the rhizosphere do not correlate with levels in the roots. Thus, it would seem plausible that exudation of hydroxamic acids is an active process.

Specifity of Root Exudates. DIBOA was the only Hx detected in root exudates and was found only in rye. The amount of DIBOA exuded by rye plants is not proportional to its content in the roots. Additionally, the wheat variety Alifén contained both Hxs in its roots and none of them was exuded. These results suggest that root exudation of Hx depends on a specific regulating factor that is not related with either concentration or type of Hx present in the root tissue.

These observations suggest that simply identifying roots with high contents of Hx is not adequate for the selection of varieties with allelopathic potential. Root exudate analysis will also be required. It has been reported that stress and other factors such as plant age, plant nutrition, light, and moisture can greatly increase root exudation (Nye and Tinker, 1977). The assessment of these factors, together with the search for rye germplasm with a high capacity to exude Hx by its roots, are of interest relative to the potential of Hxs as weed inhibitors through root exudation.

Toxicity of Root Exudates. In a previous paper we demonstrated that Hx can inhibit root growth of wild oats (Pérez, 1990), a weed normally associated with wheat. On the other hand, it has been suggested that rye interferes with the growth of wild oats among other plants (Barnes et al., 1986). The findings that Hx is not lost from roots and is not leached from leaves (Argandoña et al., 1987) of wheat suggest that Hx is not an important allelopathic agent associated with living wheat plants. The detection of DIBOA in root exudates of rye plants and that these root exudates inhibited the growth of wild oats suggest that Hx or its transformation products (Nair et al., 1990) may be important in inhibiting the growth of wild oats in nature.

(Received October 31, 1990; accepted February 1, 1991)

Abstract—Soil core (0–2.5 and/or 0–10 cm) samples were taken from wheat–no till, wheat–conventional till, and fallow–conventional till soybean cropping systems from July to October of 1989 and extracted with water in an autoclave. The soil extracts were analyzed for seven common phenolic acids (*p*-coumaric, vanillic, *p*-hydroxybenzoic, syringic, caffeic, ferulic, and sinapic; in order of importance) by high-performance liquid chromatography. The highest concentration observed was 4 μg/g soil for *p*-coumaric acid. Folin & Ciocalteu's phenol reagent was used to determine total phenolic acid content. Total phenolic acid content of 0- to 2.5-cm core samples was approximately 34% higher than that of the 0- to 10-cm core samples. Phenolic acid content of 0- to 2.5-cm core samples from wheat–no till systems was significantly higher than those from all other cropping systems. Individual phenolic acids and total phenolic acid content of soils were highly correlated. The last two observations were confirmed by principal component analysis. The concentrations were confirmed by principal component analysis. tions of individual phenolic acids extracted from soil samples were related to soil pH, water content of soil samples, total soil carbon, and total soil nitrogen. Indirect evidence suggested that phenolic acids recovered by the water-autoclave procedure used came primarily from bound forms in the soil samples.

INTRODUCTION

Straw residues of wheat, barley, oats, rye, grain sorghum, and sudangrass have effectively suppressed weeds, primarily annual broadleaf weeds (Barnes and Putnam, 1983; Putnam and De Frank, 1983; Putnam et al., 1983; Shilling et al., 1985, 1986b; Liebl and Worsham, 1983). In North Carolina, for example, Worsham (1989) noted that straw management and tilling in no-till-planted crops affected the level of early-season weeds. He found that: (1) removing wheat or rye straw plus tilling resulted in a 9–30% suppression; (2) removing straw without tilling resulted in a 43–50% suppression; (3) removing straw, tilling, and then replacing the straw resulted in a 60% suppression; and (4) leaving straw without tilling resulted in a 76–81% suppression of broadleaf weeds such as redroot pigweed, common lambsquarters, common ragweed, morning-glory, prickly sida, and sicklepod, when compared to no-cover-crop–tilled plots.

Studies have suggested that inhibition of germination and seedling growth by small grain mulches may be due, in part, to allelopathic interactions (Chou and Patrick, 1976; Liebl and Worsham, 1983; Shilling et al., 1985, 1986a,b; Barnes et al., 1986). To actually establish the role of allelopathic interactions in such systems will require: (1) identification of inhibitors involved; (2) determination of the rates of uptake of inhibitors by seeds or roots; and (3) establishing that uptake was of a sufficient magnitude to bring about the observed levels of inhibition.

Concentrations of inhibitors available to interact with seeds and roots of seedlings in soils are determined by the rate of release of potential allelopathic compounds from plant debris, the action of microorganisms, the fixation by the soil, and the rates of soil leaching (Skujins, 1967; Haider and Martin, 1975; Huang et al., 1977; Hartley and Whitehead, 1985, Blum et al., 1987; Dalton et al., 1987; Blum and Shafer, 1988). The level of inhibition observed for a given species will depend on the sensitivity of the species, on an adequate "source" and rate of release of inhibitors, and on the activity and strengths of the various "sinks" (i.e., clays, organic matter, microbes, seeds, and roots) within the soil. Seeds and roots are essentially in "competition" for inhibitors with other sinks in the soil. The "available" fraction in the soil (i.e., that which has not been irreversibly bound, leached, taken up by seeds and roots, or metabolized by microorganisms) at any time represents a residual but dynamic pool through which inhibitors move.

A variety of potentially allelopathic compounds have been identified from small grain mulches, including phenolic acids (Chou and Patrick, 1976; Liebl and Worsham, 1983; Shilling et al., 1985; Barnes et al., 1986). The presence

of simple phenolic acids, usually in bound form, such as caffeic, ferulic, *p*-coumaric, *p*-hydroxybenzoic, protocatechuic, sinapic, syringic, and vanillic, is almost universal in plant tissue (Bates-Smith, 1956; Harborne, 1980). All of the above listed phenolic acids have been isolated from soils (Whitehead et al., 1982; Hartley and Whitehead, 1985; Kuiters and Denneman, 1987) and have been identified as potential allelopathic agents (Rice, 1984).

The objectives of this research were to characterize the phenolic acid pools in soils of no-till and conventional-till wheat/soybean cropping systems and to establish correlations between easily obtained soil characteristics and phenolic acid pools. Good correlations between soil characteristics and phenolic acid pools could help in the rapid identification of systems with potential allelopathic interactions.

METHODS AND MATERIALS

General Background Information. A long-term rotation study was initiated in the fall of 1985 to study various low-input cropping systems on a 6-hectare site located 5 km south of the North Carolina State University campus. Forty treatments (only five of which were used for this study) were arranged in a randomized complete block design with four replicates (only three replicates were used for this study). Blocking was based on landscape position and soil texture. Plots of 30 × 8 m with eight rows were used throughout the study. Tillage, planting, spraying, cultivating, and harvesting were done with two-row farm equipment. A Case International no-till planter was used to plant corn (*Zea mays* L. Dekalb 798 or 689), and soybeans (*Glycine max* L. Merill Deltapine 417), and a KMC no-till drill was used to plant wheat (*Triticum aestivum* L. Coker 916) and clover (*Trifolium incarnatum* L. Tibbee or *Trifolium pratense* L. Kenland). Beginning in 1988, a Hiniker cultivator was used to cultivate for weed control. A partial history of the treatments sampled and their codes is outlined in Table 1. Wheat was harvested on June 14, and soybeans were planted on June 19 or 20, 1989.

Sampling. Treatment plots were divided into four sections (15 × 4 m) for sampling. On July 3 and 31, August 31, and October 12, 1989, two soil cores (5.5 cm in diameter; 0–10 cm) per section were taken and combined. For some treatments, additional cores were taken to a depth of 2.5 cm adjacent to the previous sampling locations. The 0- to 2.5-cm core samples were taken for wheat–no till (WNT) and wheat–conventional till in four-year rotation (WT4R) for all sampling dates and for all treatments at the final sampling date. Soil samples were sieved (3 mm sieve), placed in plastic bags, and frozen (−20°C). Maximum storage in the freezer before soils were extracted was three months. Most soil samples were extracted within a month.

TABLE 1. HISTORY OF TREATMENTS SAMPLED AND IDENTIFICATION CODES[a]

1985–86	1986–87	1987–88	1988–89	Weed control summer of 1989	Code for 1988–1989 season
fallow/corn	wheat/soybean	fallow/corn	wheat/soybean	herbicides	WNT
C clv/corn	wheat/soybean	C clv/corn	wheat/soybean	cultivated	WT2R
C clv/corn	R clv/R clv	R clv/corn	wheat/soybean	cultivated	WT4R
fallow/soybean	fallow/corn	fallow/corn	fallow/soybean	herbicides	FTH
fallow/soybean	fallow/corn	fallow/corn	fallow/soybean	cultivated	FTC

[a] WNT = wheat-no till; WT2R and WT4R = wheat-conventional till in two and four-year rotation, respectively; FTH and FTC = fallow-conventional till with weed control by herbicides and cultivation, respectively; C clv = crimson clover; R clv = red clover; herbicides on soybeans, 1989: 3.4 kg glyphosate, 3.4 kg alachlor + 0.14 kg imazaquin per hectare were applied at planting on June 19; 0.3 kg sethoxydim was applied per hectare on August 7; cultivated: tilled with field cultivator (maximum depth 15 cm) on June 14, disked (maximum depth 8 cm) on June 15 or 16, cultivated for weed control (maximum depth 5 cm) on July 3 and 27.

Aboveground soybean and weed biomass were determined on June 13, July 3 and 31, and August 31 by clipping 0.5-m^2 quadrats centered around the soil cores in each section. Standing and surface debris were collected from the quadrats in the no-till plots on the same dates plus October 12. The soybean, weed, and debris samples in each section were combined by type, oven dried (70°C), and weighed.

Aboveground wheat biomass for litter bags was collected on June 13. Litter bags ($N = 54$; 19 × 19 cm; constructed of plastic screen with 1-mm mesh) containing 10 g of dried (40°C for five days) material were half buried between soybean rows on June 26 in the winter wheat plots. Two litter bags per plot were recovered on July 31, August 31, and October 12. Material in the litter bags was freeze-dried. Organic remains were separated from the soil material and weighed.

Site Description. Treatment plots were chosen among available plots of a low-input sustainable agriculture (LISA) cropping system rotation study. Soybean plots selected (see Table 1) included plots with wheat stubble (WNT), plots in which the wheat stubble had been tilled under (WT2R, WT4R), and plots without wheat (fallow plots; FTH, FTC). The soils were Cecil and Appling gravelly sandy loams (Typic Kanhaludults) with 2–6% slope and moderate erosion. Soils were composed of 67 ± 2% (mean ± SE, $N = 15$) sand, 18 ± 0.5% silt, and 16 ± 2% clay with 22 ± 2% gravel. Due to timing of herbicide applications, cultivation, and sampling, weed biomass and surface debris were highly variable (Table 2).

June to November mean maximum and minimum temperatures were 27.8

and 17.2°C, respectively. There were 54 rain events, which provided a total of 76 cm (maximum event = 9.52 cm). Weather data were collected 1.6 km from the research site. The max/min temperatures and precipitation were 0.65°C lower/0.94°C higher, and 21 cm higher than normal for Raleigh, North Carolina, respectively.

Soybean plant biomass was not significantly affected by any of the treatments selected during July and August of 1989 (Table 2). Soybean biomass/m row increased 100-fold from July 3 to August 31. This rapid increase was partially due to excellent weather conditions. There were four rain events over 2.54 cm during this period.

The decline of wheat straw in the half-buried litter bags was not significantly different for the WNT, WT2R, and WT4R treatments. A 35% reduction (after adjusting for water content) in biomass was observed in the litter bags after 109 days. No significant differences in surface debris, however, were observed for the WNT plots over the same interval. This is consistent with the observations of Summerell and Burgess (1989) that the rate of decomposition of partially incorporated and buried wheat residue is much faster than that of surface debris.

Soil and Litter Analyses. Soil samples were defrosted overnight in a refrigerator (10°C). Three soil subsamples were taken to determine soil pH, water content, and phenolic acid content. The pH was determined by mixing 25 g soil with 100 ml deionized water and reading the pH 60 min later. Water content was determined gravimetrically on 10–15 g of soil before and after oven drying (100°C). Nitrogen and carbon content of soil samples were determined with a Perkin-Elmer 2400 C, H, N analyzer (Perkin-Elmer, Norwalk, Connecticut).

To determine phenolic acid content, 50 g of soil was placed in a 500-ml Erlenmeyer flask with 100 ml deionized water. Loosely capped flasks were autoclaved for 45 min at 1.2 kg/cm^2 and 121°C, removed from the autoclave, and then allowed to come to room temperature (20–30 min). The slurry in the flask was centrifuged for 10 min at 27,200 *g*. The resulting supernatant was filtered (Whatman No. 42). The filtered supernatant (extract 1) was adjusted to pH 2 with HCl, centrifuged for 10 min at 27,200 *g*, and the resulting supernatant was adjusted to pH 7 with NaOH (extract 2).

To determine the phenolic acid content of wheat litter samples, freeze-dried litter samples were ground in a Wiley mill (20 mesh), and 400-mg samples were extracted by the same procedures used for the soil samples.

HPLC Analysis. Protocatechuic acid (200 μl; 0.25 mM; pH 7) was mixed with 1.8 ml of extract 2 from soil and litter samples. The resulting solution was filtered through a 0.2 -μm Supor-200 filter (Gelman Sciences Inc., Ann Arbor, Michigan). Phenolic acids were determined with a Waters (Milford, Massachu-

setts) HPLC at 245 nm, using a model 440 absorption detector and a Baseline 810 Chromatographic Workstation (Dynamic Solutions, Ventura, California). A Waters reverse-phase 5-μm Nova-Pak C_{18} column was used to isolate and quantify eight different phenolic acids [i.e., caffeic (CAF), ferulic (FER), *p*-coumaric (PCO), *p*-hydroxybenzoic (POH), protocatechuic (PRO), sinapic (SIN), syringic (SYR), and vanillic (VAN)]. Standard phenolic acids were obtained from Sigma Chemical Company (St. Louis, Missouri). Extracts were analyzed using two mobile phases: (A) 2% methanol, 0.25% ethyl acetate, and 0.5% acetic acid, and (B) 80% methanol, 1% ethyl acetate, and 2% acetic acid. Linear gradients starting with 92% A and ending with 66% A were used over the first 40 min of a 60-min run. The flow rate of the mobile phase was 0.5 ml/min. Protocatechuic acid was used as a marker in each sample. Identification and quantification were confirmed by comparing retention times and areas with those of the appropriate standards (prepared in deionized water) and by spiking unknown samples with standards. Additional confirmations of the identity of the extracted phenolic acids were obtained with paper chromatography and by UV spectral comparisons in ethanol and ethanol plus sodium hydroxide (Harborne, 1984).

FC Method. Extracts 1 or 2 (0.5 ml) of soils plus 4.5 ml deionized water or 2.5 ml of standard phenolic acid solution plus 2.5 ml deionized water (pH 7) were mixed with 0.75 ml of 1.9 M Na_2CO_3, and 0.25 ml Folin & Ciocalteu's phenol reagent (Sigma Chemical Company, St. Louis, Missouri). This mixture was allowed to stand in darkness at room temperature (20–25°C) for at least 1 hr before its absorption was read at 750 nm (Box, 1983). Ferulic acid was chosen as the standard because it has been identified as an allelopathic agent in wheat mulch (Liebl and Worsham, 1983), and it was somewhat intermediate in color development when compared to the other phenolic acids (Figure 1). Units of total phenolic acid in soils determined by the FC method are thus in micrograms ferulic acid equivalents per gram of soil.

Data Analyses. Data were analyzed, using statistical analysis system programs for analysis of variance, regressions, correlations, and principal component analysis (SAS Institute Inc., 1988). Principal component analysis was run on mean plot values. Phenolic acids in soils were analyzed either as a split-plot design with whole plot subsampling (0- to 10-cm core samples for all sampling dates), a bivariate split-plot design with whole plot subsampling (0- to 2.5- and 0- to 10-cm soil core samples for treatments WNT and WT4R at all sampling dates), or a bivariate randomized block design with whole plot subsampling (0- to 2.5- and 0- to 10-cm soil core samples for all treatments at final sampling date). The bivariate was core type, the whole plot was treatment, and the subplot was sampling date. Means comparisons were based on Bonferroni *t* tests.

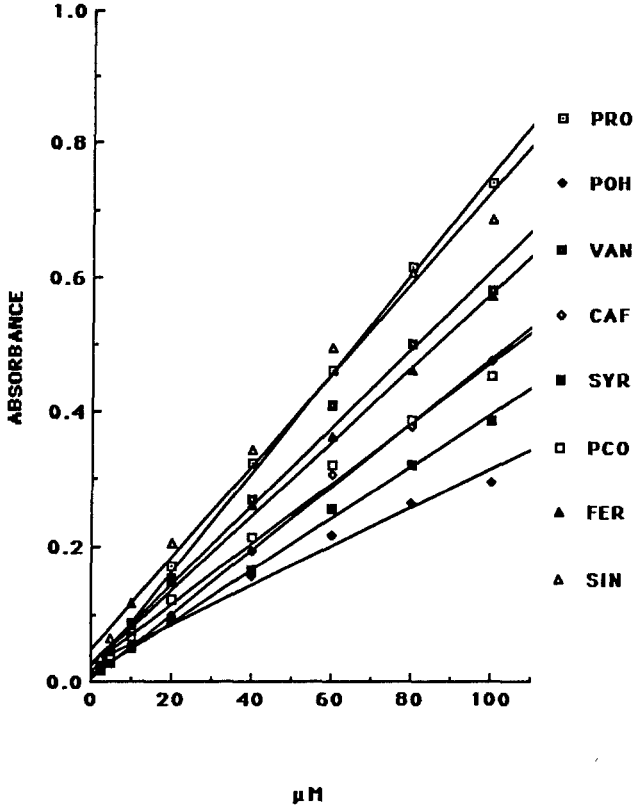

FIG. 1. Standard curves for protocatechuic (PRO), *p*-hydroxybenzoic (POH), vanillic (VAN), caffeic (CAF), syringic (SYR), *p*-coumaric (PCO), ferulic (FER), and sinapic (SIN) acids determined by the FC method. Order based on HPLC retention times.

RESULTS

Soil Extraction Procedures. To determine how the extraction procedures might affect the stability of phenolic acids, we autoclaved, filtered, etc. (see Methods and Materials), a mixture of caffeic, ferulic, *p*-coumaric, *p*-hydroxybenzoic, protocatechuic, sinapic, syringic, and vanillic acids (0.25 mM each, 100 ml, pH 5.5). Caffeic acid and sinapic acid were reduced 20 $\pm$ 0.004% (mean $\pm$ SE) and 61 $\pm$ 0.03% in extract 1 and 28 $\pm$ 0.002% and 69 $\pm$ 0.02% in extract 2, respectively. No other major losses or gains were observed. Values subsequently presented have not been adjusted for these losses, because changes noted in these solutions may not be representative of changes in soil extracts. This information is presented only to alert the reader to limitations of this extraction procedure.

To estimate the proportion of "available" to "bound" phenolic acids in the extract, soil samples (75 g) from all the treatments ($N = 60$) were placed into Petri dishes with 25 ml water or 25 ml Hoagland's nutrient solution and incubated in the dark at 30°C. Soils were extracted and analyzed by HPLC at the start and after one and two weeks. Total phenolic acid content for the 0- to 2.5-cm soil samples decreased by 8% and 13% in the water treatment and increased by 3% and 18% in the nutrient solution treatment at the ends of week 1 and 2, respectively. When water was added to 0- to 10-cm soil core samples, total phenolic acid content of the samples was not changed. When nutrient solution was added, the total phenolic acid content was reduced by 10% by the end of week 1, but no additional reduction occurred during week 2. This suggested that phenolic acids in these soils were primarily in a bound form and that decomposition in these soil samples was nutrient-limited. Since, however, we do not have data on actual flows in and out of the phenolic acid pools, these conclusions are lacking in certainty. It is also not certain what proportion of the "bound" phenolic acids extracted by the autoclave procedure may be released into the soil solution by the action of microorganisms.

Soil Phenolic Acids. Treatment effects ($P \leq 0.05$) were noted only for *p*-coumaric acid (PCO). PCO of WNT (2.24 μg/g) and FTH (0.97 μg/g) were significantly different (Table 3). Significant effects of sampling date were noted for all but total phenolic acid (sum of seven phenolic acids determined by HPLC). Highest concentrations (μg/g) were observed for *p*-hydroxybenzoic (POH, 0.95), caffeic (CAF, 0.68), syringic (SYR, 0.80), and PCO (1.80) on August 31 and for vanillic (VAN, 1.43), sinapic (SIN, 0.18), and ferulic (FER, 0.53) on October 12. Lowest concentrations (μg/g) were observed for POH (0.82), CAF (0.48), VAN (0.94), and SYR (0.57) on July 31; for SIN (0.05) and FER (0.42) on August 31; and for PCO (1.30) on October 12. The coefficients of variation for all but PCO, FER, and SIN were less than 45% over all sampling dates for each treatment (Table 3).

Sampling dates (for all but PCO and SIN), core depth, and core depth by sampling date interactions (for all but PCO and SIN) were significantly different ($P \leq 0.05$) when individual and total phenolic acid values were compared for WNT and WT4R. For these treatments both 0- to 2.5- and 0- to 10-cm cores were taken at all sampling dates. The 0- to 2.5-cm soil core samples had on average 34% higher concentrations than the 0- to 10-cm soil core samples (Table 3). For example, the micrograms per gram of total phenolic acids for the 0- to 2.5-cm cores were 10.22, 8.14, 9.26, and 11.15 for sampling dates 1, 2, 3, and 4, respectively (July 3 and 31, August 31 and October 12, 1989, respectively). The values for the 0- to 10-cm cores were 6.14, 5.85, 7.27, and 6.41 μg/g, respectively. The differences between cores were 4.08, 2.29, 1.99, and 4.74 μg/g for sampling dates (SD) 1, 2, 3, and 4, respectively. Thus, values of 1.79, 2.09, 0.66, 0.30, 2.45, and 2.75 were observed for SD1–SD2, SD1–

[a] POH = *p*-hydroxybenzoic acid CAF = caffeic acid; VAN = vanillic acid; SYR = syringic acid; PCO = *p*-coumaric acid; FER = ferulic acid; SIN = sinapic acid; WNT = wheat–no till; WT2R and WT4R = wheat–conventional till in two- and four-year rotation, respectively; FTH and FTC = fallow–conventional till with weed control by herbicides and cultivation, respectively. Number for 0 to 2.5-cm cores: WNT $N = 47$; WT4R $N = 48$; WT2R, FTH, and FTC $N = 12$ (last sample date only). Number for 0 to 10-cm cores: $N = 48$.

SD3, SD2–SD3, SD4–SD3, SD4–SD2, and SD4–SD3 comparisons, respectively (LSD = 1.26). In each case the first sampling date cited had the greater difference between the cores. Thus, the differences in concentration between the core depths for the sampling dates were significantly different for all but SD2–SD3 and SD4–SD3. For a discussion of a bivariate split-plot design with whole plot subsampling, see chapter 15 for factorial experiments and chapter 16 for split-plot designs in Steel and Torrie (1980).

For the final sampling date, a sampling date where both core depths were taken for all treatments, treatment, core depth, and the treatment by core depth interactions were significant ($P \leq 0.05$) for all phenolic acids and for the total phenolic acid content of soil sampled. Only concentrations of WNT and FTH were significantly different. For example, total phenolic acid concentrations for WNT and FTH were 10.18 and 4.42 μg/g, respectively. The 0- to 2.5-cm soil core samples were 32% higher in phenolic acid concentration than the 0- to 10-cm core soil samples. In all instances, the difference in phenolic acid concentrations between the core depths for WNT was greater than that of all other treatments. All other comparisons were not significantly different. For example, the micrograms per gram of total phenolic acids for the 0- to 2.5-cm core samples were 14.09, 7.18, 8.13, 4.94, and 5.88 for WNT, WT2R, WT4R, FTH, and FTC, respectively. The values for the 0- to 10-cm cores were 6.28, 5.66,

6.54, 3.90, and 4.88, respectively. The differences between cores were 7.81, 1.52, 1.59, 1.04, and 1.00 μg/g for WNT, WT2R, WT4R, FTH, and FTC, respectively (LSD = 5.18). For a discussion of a bivariate randomized block design with whole plot subsampling, see chapters 15 and 16 in Steel and Torrie (1980).

Principal component analysis (PCA) has been successfully used in interpreting patterns of objects with several attributed variables. Objects in this case were treatments and the attributed variables were the seven different phenolic acids. PCA takes data that initially have a high dimensionality and creates new variables, called components, which are linear combinations of the original variables. Typically, the first two or three components (referred to as axes in this paper) account for much of the variation in the data. This results in an efficient summarization, which lends itself well to visual presentation and interpretation (Gauch, 1982).

PCA on the 0- to 10-cm core data did not result in clear groupings of treatments or in significant correlations between phenolic acids and any axes; thus only PCA on 0- to 2.5-cm core data are presented. The results of the PCA on phenolic acid content for WNT and WT4R are given by sampling date in Figure 2. Treatments are grouped with the exception of replicate plot 3 (block 3) of WNT, which appears to be more closely related to WT4R than WNT. The soil in this WNT plot was very sandy (78% sand, 17% silt, and 6% clay) compared to the other WNT plots (mean = 60% sand, 19% silt, and 21% clay). The first PCA axis accounted for 88% of the variation (Table 4). All phenolic acids, as well as total phenolic acid, were positively correlated with the first axis. Individual phenolic acids were also highly correlated with total phenolic acid.

The results of the PCA on phenolic acid content of soils sampled (0–2.5 cm) for all treatments at the final sampling date are given in Figure 3. Treatments are generally grouped with some overlapping of treatments. WNT is the most distinct in its distribution. The first PCA axis accounted for 95% of the variation (Table 4). All phenolic acids, as well as total phenolic acid, were positively correlated with the first axis. Individual phenolic acids were also highly correlated with total phenolic acid. Not only were individual phenolic acids correlated with total phenolic acid, but individual phenolic acids were also correlated with each other (Table 5). This latter correlation was based on an independent phenolic acid analysis of randomly chosen soil samples.

Phenolic Acid Concentrations in Litter Bag Samples. Concentrations of individual phenolic acids in extract 2 from litter bag samples for the WNT, WT2R, and WT4R treatments and the three litter sampling dates (July 31, August 31, and October 12) were not significantly different. The mean values and standard errors (N = 18) for POH, VAN, CAF, SYR, PCO, FER, SIN, and total were 12.49 $\pm$ 1.17, 33.35 $\pm$ 2.90, 61.52 $\pm$ 3.77, 40.03 $\pm$ 6.63,

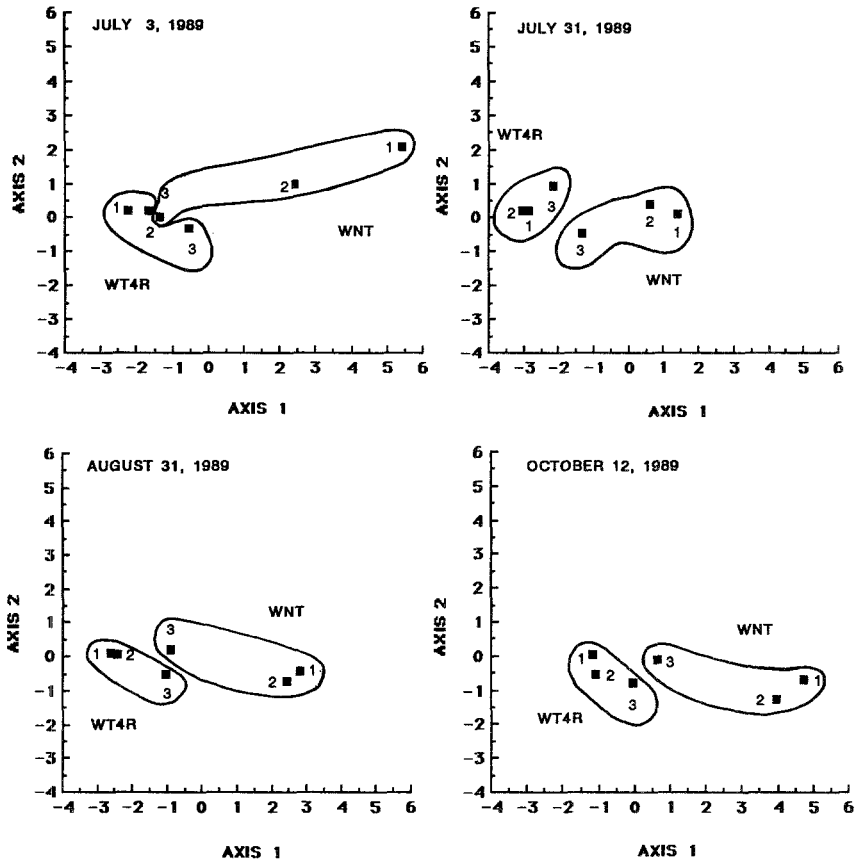

FIG. 2. Principal component analysis for phenolic acid content of soils (0- to 2.5-cm cores) from wheat–conventional till (WT4R) and wheat–no till (WNT) plots. Numbers associated with points are blocks. PCA analysis was based on all four sample dates. Sample dates presented individually only for ease of interpretation.

260.96 ± 26.19, 43.58 ± 3.45, 97.22 ± 22.96, and 549.15 ± 32.41 μg/g, respectively. Concentrations of the individual phenolic acids extracted from wheat straw placed into the litter bags (starting material) were similar to those extracted from the partially decomposed wheat straw, with the exception of FER, SIN, and SYR. FER content was 23% higher and SIN and SYR contents were 49% and 60% lower, respectively.

A 35% reduction in biomass was observed in the partially buried litter bags after 109 days (Table 2). No significant differences in surface debris, however, were observed for the WNT plots over the same interval.

Estimates of Total Phenolic Acids in Soils by FC Method. Phenolic acid

[a] Correlations of individual phenolic acids with total phenolic acid (HPLC analysis) are also presented.
[b] POH = *p*-hydroxybenzoic; VAN = vanillic; CAF = caffeic; SYR = syringic; PCO = *p*-coumaric; FER = ferulic; SIN = synapic.

content of soil was determined on both extract 1 and extract 2 (injected into the HPLC). Extract 1 (crude extract) was adjusted to pH 2, centrifuged, and then adjusted to pH 7 to produce extract 2. Centrifugation of the acidified extract produced a reddish brown pellet, probably humic acid. The supernatant was straw-yellow in color, probably due to fulvic acid (Stevenson, 1982). Total phenolic acid of extract 2 (μg ferulic acid equivalents/g soil) estimated with the Folin & Ciocalteu's reagent was highly correlated, except for SIN, with the individual phenolic acids and the total phenolic acid (sum of seven phenolic acids) estimated by HPLC (Table 5; Figure 4). Thus, total phenolic acid determined by the FC method could be used for these soil samples to estimate total phenolic acid based on HPLC, as well as individual phenolic acid content of extract 2 (Table 6).

Finally, total phenolic acid of extract 1 based on the FC method was highly correlated with total phenolic acid of extract 2 based on the FC method (Figure 4). This suggested that the amount of reddish brown precipitate removed by acidification and centrifugation of extract 1 was proportional to total concentration, since the relationship of total phenolic acid estimated for extract 1 and extract 2 was linear.

Soil Characteristics and Total Phenolic Acid Content of Extract 1. Total phenolic acid of soil samples estimated by the FC method for extract 1 was

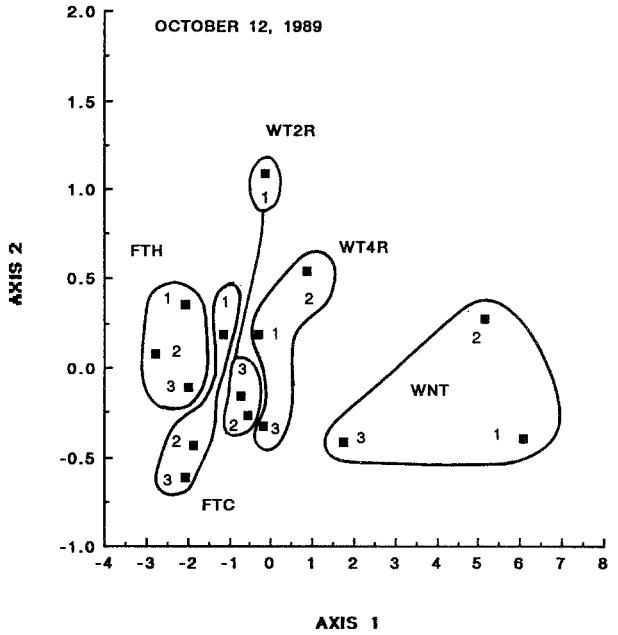

FIG. 3. Principal component analysis of phenolic acids in soils (0- to 2.5-cm cores) from fallow–conventional till (FTH, FTC), wheat–conventional till (WT2R, WT4R) and wheat–no till (WNT) plots for the last sampling date. Numbers associated with points are blocks.

correlated with carbon (C), nitrogen (N), soil pH, and soil water content. R values ranged from 0.51 to 0.83. Stepwise regression with maximum r^2 improvement was used, subsequently, to generate the best one, two, etc., variable models for total phenolic acid. Only nontransformed and squared values (i.e., no interaction terms) were included in the stepwise regressions. The best single-variable model was obtained with N ($r^2 = 0.69$) and the best two-variable model was obtained with N and pH ($r^2 = 0.76$). No improvement in r^2 values occurred with the addition of other variables. Regressions for total phenolic acid content in extract 1 with C, N, soil water content, and pH are presented in Figure 5.

Since C and N were linearly correlated ($r = 0.92$; $\%N = -0.0076 + 0.0527\ \%C$, $r^2 = 0.843$, $P \leq 0.0001$, $N = 48$), N was removed from the data set and the stepwise procedure was repeated. The best single-variable model was now obtained with C ($r^2 = 0.54$), the best two-variable model was obtained with C and the squared soil water content ($r^2 = 0.66$), and the best three-variable model was obtained with C, pH, and the squared soil water content (r^2

Extract 2 data.

= 0.66). No improvement in r^2 values occurred with the addition of other variables.

DISCUSSION

Soil Extraction Procedures. An unequivocal quantification of the "available" fraction of phenolic acids in soil pools has not been made for any soil. The amounts of phenolic acids recovered from a given soil depend on a variety of factors, including the extractant and the extraction procedures used (Hartley and Whitehead, 1985; Dalton et al., 1987). In general, however, most researchers would agree that extractants such as water, low concentrations of calcium hydroxide, sodium acetate, or mild chelating agents provide the most biologically meaningful estimates of the "available" phenolic acid pools. The "available" fraction in the soil is essentially the "free" and/or "readily freed" phenolic acids present at any time.

Phenolic acids, such as ferulic, *p*-coumaric, vanillic, etc., generally are slow to dissolve in water at ambient temperatures. The speed with which phenolic acids solubilize and the amount that can stay in solution can be increased by raising the pH and/or the temperature of the solution. Increasing the temperature and/or the pH of an extraction solution may at times be more desirable than using long-term extractions, because of the presence of microbes. Blum and Shafer (1988), for example, noted that $<1\%$ of exogenously applied phe-

[a] Soil samples were chosen at random from all soil samples collected during 1989 ($N = 64$). Soil samples in Tables 5 and 6 are identical. POH = *p*-hydroxybenzoic acid; VAN = vanillic acid; CAF = caffeic acid; SYR = syringic acid; PCO = *p*-coumaric acid; FER = ferulic acid; SIN = synaptic acid; $P \leq 0.0001$ in all cases; NS = not significant at 0.05; dependent and independent variables in μg/g of soil. Extract 2 data.

nolic acids could be extracted with water 24 hr after addition to nonsterilized Portsmouth soil, but >90% could be recovered from sterilized Portsmouth soil. Thus, shaking field soil samples for long periods to extract "available" phenolic acids could lead to substantial underestimations of these pools. On the other hand, extractants with artificially high pH or extractions at high temperatures will lead to the extraction of both "available" and some "bound" phenolic acids.

We chose water as the extractant and an extraction procedure that was rapid [i.e., high temperature (121°C) and pressure (1.2 kg/cm^2)], that had only a minimal impact on soil pH, and that eliminated the concern about microbial activity. With the exception of caffeic and sinapic acid, which were reduced in concentration, this procedure appeared to be satisfactory for extracting some of the common phenolic acids found in soil and litter samples. The proportion of "available" and "bound" phenolic acids extracted cannot be stated with certainty, but indirect evidence would suggest that the phenolic acids extracted came primarily from "bound" forms.

Individual Phenolic Acids. With the exception of sinapic acid, the individual phenolic acids were not only correlated with total phenolic acid determined by the FC and HPLC methods, but also to each other. Soil samples analyzed to establish these relationships included samples from all treatments, i.e., WNT, WT2R, WT4R, FTH, and FTC. This indicated that differences in soil phenolic acid content between the crop management systems were primarily quantitative

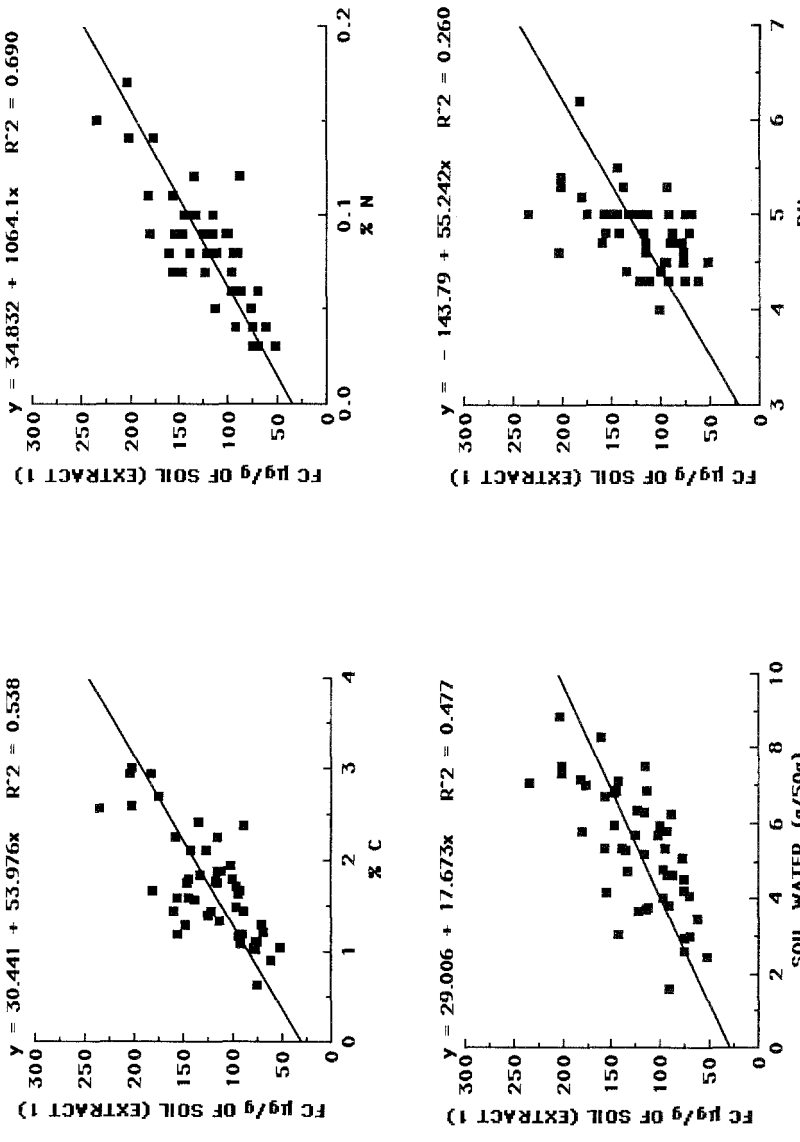

FIG. 5. Relationship of total phenolic acid content of soil and %C, %N, soil water content, and pH. Total phenolic acid values were based on extract 1 and are in ferulic acid equivalents.

and not qualitative. One arrives at the same conclusion by the use of principal component analysis (PCA). For both PCAs (Figures 2 and 3), the strong positive correlations of all individual phenolic acids with the first axis, and the large amount of variance accounted for by the first axis, were indicative of the high level of multicollinearity among the phenolic acids. There is evidently little residual variation that may be attributed to independent behavior of any of the phenolic acids. The first axis, then, is a surrogate for joint variation of all the phenolic acids, as evidenced by its strong positive correlation with total phenolic acid. Positioning of the treatments along the first axis is a reflection of the substantially higher concentrations of all phenolic acids in the WNT treatment and of somewhat greater concentrations in the WT2R and WT4R treatments, relative to the FTH and FTC treatments. This is not to say that concentrations of the individual phenolic acids recovered from soil did not differ from each other. With minor exceptions, PCO > VAN > POH > SYR > CAF > FER > SIN. The benzoic acid derivatives (i.e., POH, SYR, and VAN) were higher in concentration than the cinnamic acid derivatives (i.e., CAF, FER, and SIN), with the exception of PCO.

The types and amounts of plant residue present in the soil and the action of various soil processes (i.e., microbes, soil fixation, leaching, etc.) would obviously be important in determining the absolute and relative amounts of individual phenolic acids present. Such factors may account for the higher concentrations of phenolic acids in the 0- to 2.5-cm than in the 0- to 10-cm core samples (the former were approximately 34% higher than the latter), and the quantitative differences between individual phenolic acids extracted from soil and litter bag samples (i.e., soil samples: PCO > VAN > POH > SYR > CAF > FER > SIN; litter bag samples: PCO > SIN < CAF > FER > SYR > VAN > POH). That the importance of individual phenolic acids in soils is influenced by plant species growing in the soil has been demonstrated by Whitehead et al. (1981, 1982) and Kuiters and Denneman (1987), among others. Whitehead et al. (1981) suggested that substantial proportions of the phenolic acids extracted from soil were either derived from organic residues more than 4 years old or were the result of microbial synthesis. This last observation may suggest one possible reason for the lack of clear differences in the importance of individual phenolic acids in the wheat–no-till (WNT), wheat–conventional-till (WT2R, WT4R), or the fallow–conventional-till (FTH, FTC) system soils.

Phenolic Acids and Sampling Dates. No dramatic changes or clear trends for soil phenolic acid concentrations were observed over the first 109 days of the growing season. Maximum changes for the total phenolic acid content based on HPLC analysis were on the order of 20–30%. Slow changes of phenolic acid concentrations in these nutrient limited soils would be expected if the major sources of these phenolic acids were a result of microbial action on plant litter and/or organic residues (Turner and Rice, 1975; Lodhi, 1978; Whitehead et

al., 1979). We suspect that the fluctuations observed were, in part, a result of the proximity of rain events to the soil sampling dates. This observation is based on the correlations between water content of the soil samples and total phenolic acid content. Additional fluctuations resulted from the variation in litter distribution. As stated before, we do not have data on flows in and out of the phenolic acids pools and, thus, cannot state these conclusions with certainty.

Total Phenolic Acid Content of Soil Extracts. The sum of the individual phenolic acids in extract 2 determined by HPLC analysis (μg/g of soil) was highly correlated with total phenolic acid estimated by the FC method (μg ferulic acid equivalents/g soil) for extract 2. Values for extracts 1 and 2 based on the FC method were also highly correlated with each other. Total phenolic acid content of soil extracts estimated by the FC method was 1.11 times greater for extract 1 than for extract 2. The difference between extracts 1 and 2 was most likely the result of the removal of humic acid by acid precipitation. The small difference observed between extracts 1 and 2 suggested that little humic acid was extracted by the procedure. This was not unexpected, since humic acid is only sparingly soluble in water (Hartley and Whitehead, 1985). The total phenolic acid estimated for extracts 1 and 2 by the FC method were 16.75 and 15 times higher, respectively, than that determined by the HPLC method. Extracts 1 and 2 would include phenolic acids not identified, humic and/or fulvic acid, and other compounds that reduce the Folin & Ciocalteu's phenol reagent. Box (1983) provides a list of organic substances with or without a phenolic hydroxyl group and inorganic substances that reduce the FC reagent. Others have used the FC method to estimate total phenolic acid content of soils (for example, Kuiters and Denneman, 1987), but this is the first time that correlations between the FC and HPLC methods have been made. Whether such correlations will occur for data of other soil systems is not certain. Similar correlations between the FC and HPLC methods, however, have been found for Durham sandy loam soils underneath crimson clover, hairy vetch, subterranean clover, and rye cover crops (unpublished data). Once such correlations are defined for a given soil and management system, the FC method would appear to be useful in surveys to identify potential systems in which allelopathic interactions due to phenolic acids may be important. We would, however, not recommend the use of the FC method to estimate absolute total phenolic acid concentrations in soil extracts, since the Folin & Ciocalteu's phenol reagent reacts differently with individual phenolic acids (Figure 1) and also reacts with other organic and inorganic substances (Box, 1983).

Total phenolic acid content of soil as determined by the FC method was also correlated with soil carbon (C), nitrogen (N), pH, and water content. Since the total amount of phenolic acids dissolved is determined by the volume of water and the pH of the solution, this was not entirely unexpected. The percent C for the soil samples was 2% $\pm$ 0.17 for WNT, 1.7% $\pm$ 0.12 for WT2R,

1.9% ± 0.11 for WT4R, 1.3% ± 0.09 for FTH, and 1.5% ± 0.16 for FTC. The C/N ratios of the soils were 20 ± 0.77 for WNT, 21 ± 1.98 for WT2R, 20 ± 0.60 for WT4R, 26 ± 2.17 for FTH, and 24 ± 1.79 for FTC. C/N ratios above about 14 are a strong indication that the soil contains much partially decomposed plant material (Wild, 1988). Both Iritani and Arnold (1960) and Harmsen and Van Schreven (1955) suggested that a C/N ratio of 20 was the approximate dividing line between positive and negative release of N in soils. The relationships between C, N, and total phenolic acid content suggest that the phenolic acid concentrations in this soil were closely related to organic matter content of the soil. This latter relationship may also help to explain the observed soil phenolic acid content of the various treatments and the patterns observed in the principal component analysis, particularly the small distinction between fallow plots (FTH, FTC) and wheat–conventional till plots (WT2R, WT4R).

Concluding Remarks. Pools of "available" phenolic acids in these soils were small. The majority of phenolic acids recovered, by the procedure used, were released from "bound" forms, which were not necessarily recent in origin. The primary source of "available" phenolic acids would be from the action of microorganisms on plant litter and/or organic residues. Thus, the most likely place for allelopathic interactions in these soils would be in the soil surface of the no-till plots.

Since it appears that a substantial portion of the phenolic acids extracted by the autoclave procedure came from plant litter and/or soil organic residues, the procedure used here in conjunction with the FC method could be used to identify potential soil systems for more detailed study. Total C and/or N content of soil also may be helpful in this regard. However, data on phenolic acid pools ("available" and/or "bound") in soils are, by themselves, unlikely to provide much insight concerning allelopathic interactions unless flows in and out of these pools are determined and source–sink relationships within a given soil are understood.

RESPONSE TO PREY CHEMICAL CUES BY HATCHLING PINE SNAKES (*Pituophis melanoleucus*): EFFECTS OF INCUBATION TEMPERATURE AND EXPERIENCE

JOANNA BURGER

Department of Biological Sciences
Rutgers University
Piscataway, New Jersey 08855-1059

(Received October 24, 1990; accepted February 4, 1991)

Abstract—The ability of hatchling pine snakes (*Pituophis melanoleucus*) to select and follow or avoid chemical odors of prey (mice, *Mus musculus*) on a shavings and paper substrate was investigated in Y-maze experiments, as a function of incubation temperature and experience. Incubation temperature affected behavior in the maze, and the maze choices of naive snakes, but not of snakes that had already eaten a mouse. The data indicate that snakes that have eaten, preferentially enter the arm bearing chemical stimuli from mice, whereas those that have not eaten show no preference.

Key Words—Chemical cues, incubation temperature, experience, predation, pine snake, *Pituophis melanoleucus*, mice, *Mus musculus*, learning, olfaction.

INTRODUCTION

Pheromonal communication, as demonstrated in controlled laboratory experiments on trailing of conspecifics or prey by chemical means, occurs in snakes (Brown and Maclean, 1983; Chiszar et al., 1986; Ford, 1982; Ford and O'Bleness, 1986; Gehlback et al., 1971; Heller and Halpern, 1981) and lizards (Cooper and Vitt, 1986a). Reptiles use chemical sensory abilities in several important contexts (Von Achen and Rakestraw, 1984; Mason 1991), including recognition of prey (Burghardt, 1973, 1980; Chiszar et al., 1986; Cooper, 1989, 1991; Cooper and Alberts, 1990; Cooper and Vitt, 1989; Krekorian, 1989), detection of conspecifics (Cooper and Vitt, 1984) and related congeners (Cooper

0098-0331/91/0600-1069$06.50/0

and Vitt, 1986c,d), trailing of conspecifics to hibernacula (Brown and Maclean, 1983) or to mates (Ford and Schofield, 1984; Ford and O'Bleness, 1986), and recognition of ophiophagous snakes (Weldon and Burghardt, 1979; Weldon, 1982; Burger, 1989a). Reptiles often respond to chemical stimuli by increased tongue flicks (Cooper and Vitt, 1984, 1985, 1986b; Cooper et al., 1986). Most of the studies dealing with prey detection have relied on examinations of tongue-flicking (i.e., Cooper, 1989; Krekorian, 1989) rather than examination of choice behavior in individuals.

In this report I examine the behavior of hatchling pine snakes (*Pituophis melanoleucus*) experimentally exposed to shavings with and without the odor of mice (*Mus musculus*). I was particularly interested in whether hatchling snakes could discriminate between odors and no odors and whether incubation temperature or prior experience with live mice affected their responses. In nature, pine snake eggs experience differences in temperature similar to those used in this experiment (Burger and Zappalorti, 1986).

METHODS AND MATERIALS

Under appropriate state permits, pine snake eggs were collected from the Pine Barrens of southern New Jersey (Ocean, Cumberland, and Monmouth counties) in 1986 (247 hatchlings), 1987 (221 hatchlings), and 1988 (230 hatchlings). In 1986 the clutches from each female were divided in thirds; one third was incubated at 23°C, another at 28°C and a third at 33°C. In 1987 and 1988 all eggs were incubated at 28°C.

Date of hatching was noted. Snakes were maintained in individual plastic (30 × 15 × 19 cm) cages at 24–26°C. Cages contained paper for shelter. They were given the opportunity to drink water daily. Snakes were sexed by eversion of the hemipenes (Fitch, 1963; Gregory, 1983; Gutzke et al., 1985).

To determine the response of hatchlings to potential prey, I performed two experiments: one to examine the effect of both incubation temperature and experience on response (1986), and the other to examine the effect of experience alone (1987 and 1988). All experiments were conducted at 24–26°C.

In 1986 all hatchlings were exposed to a live mouse, whereas in 1987 and 1988 some hatchlings were exposed to a live mouse and others were not. Hatchlings exposed to a mouse either caught and ate the mouse or they did not. This design (Table 1) allowed evaluation of the effects of different types of experiences on hatchling response in the maze. Because incubation temperature affected behavior in the Y maze in 1986, all eggs were incubated at the same temperature in 1987 and 1988.

In 1986, hatchlings that had shed (15–20 days of age) were individually placed in an aquarium with a live laboratory mouse (12–18 g) for 20 min and

TABLE 1. EXPERIMENTAL DESIGN FOR HATCHLING PINE SNAKE EXPOSURE TO MOUSE ODORS—EXPOSURE TO LIVE MICE AND NUMBER OF HATCHLINGS IN EACH CATEGORY

Prior experience	1986	1987 and 1988

[b] Snake tested prior to shedding.

were allowed to eat the mouse if it was caught within this time. Ten days following their exposure to a mouse, the hatchlings were tested in a Y-maze apparatus (after Burger, 1989a). The base arm of the Y maze was 1 m long and 15 cm wide with 15-cm-high wooden sides. The two experimental arms extended at a 45° angle from the base and were of the same dimensions as the base arm. Plexiglas was placed over the maze to prevent the hatchlings from escaping, but the ends of the maze were open, allowing snakes to crawl out. The base arm had shavings with no odor, the experimental arms had shavings with no odor on one side and shavings from a mouse cage in which three mice had lived for five days on the other. The floor of all three arms was covered with paper. After every test the paper with the shavings was removed, and the arm with the mouse shavings was switched (to avoid possible position effects).

In 1987 and 1988 all snakes were incubated at the same temperature, but only half the snakes were exposed to a live mouse prior to experimentation (Table 1). The remaining hatchlings were tested without exposure to a live mouse, either before shedding (10–12 days of age) or after shedding (25–30 days of age). Pine snakes normally do not eat until they have shed (Burger, 1989b). In 1987 and 1988 hatchlings were randomly assigned to condition (whether to be exposed to a mouse or not), but some hatchlings within each clutch were assigned to each of the exposure categories.

In all test experiments the hatchlings had a choice of selecting the experimental arm with shavings with no odor or the experimental arm with shavings from a mouse cage. We did not touch the shavings with our hands. Each snake was tested only once. Following experimentation all pine snake hatchlings were returned to their original nest sites in the field, together with their siblings and egg shells.

For each trial the hatchling was placed by hand into the base arm with its head facing the entrance. The hatchling was allowed to move freely up the base arm to the intersection, where it usually moved into one of the experimental

arms. The trial ended when the hatchling left the Y maze through one of the experimental arms. Two experimenters were necessary to time various behaviors. The time each hatchling was in the base and experimental arm, time at the Y junction (where the two experimental arms diverge from the base arm), and the number of tongue flicks when the snake was in each location were recorded.

Contingency table χ^2 tests were used to determine differences in responses, and two-tailed Kruskal-Wallis χ^2 tests were used to determine differences in the distribution of response time and tongue flicks under several conditions. The percent of hatchlings that entered the arm with the mouse shavings as a function of experience did not differ significantly between 1987 and 1988 (contingency table χ^2 test), so these data were combined. Data are presented as means $\pm$ 1 SE. Probability levels of less than 0.05 were accepted as significant.

RESULTS

In the 1986 experiment, 71% (68 of 96) of the hatchlings that had eaten a mouse selected the experimental arm with mouse shavings ($\chi^2 = 16.6$, $df = 1$, $P < 0.001$), whereas only 33% (38 of 114) of those that had not eaten a mouse did so ($\chi^2 = 12.6$ $df = 1$, $P < 0.001$), In the above analysis, I tested the null hypothesis that there were no differences in response; thus, half the hatchlings should choose each experimental arm. Hatchlings that ate when exposed to a mouse selected the experimental arm with mouse odor significantly more often than did those that had not eaten ($\chi^2 = 29.2$, $df = 1$, $P < 0.001$).

Incubation temperature (28°C vs. 33°C) did not affect the frequency of mouse eating ($\chi^2 = 2.7$, not significant), but did affect Y-maze choices (Table 2). Hatchlings incubated at 28°C showed no significant difference in their response when they had eaten a mouse, but showed a significant difference when they had not previously eaten. Hatchlings incubated at 33°C showed the opposite response; significantly more hatchlings that had eaten chose the experimental arm with mouse shavings whereas there was no difference if they had not eaten (Table 2). I could not examine a sufficient sample incubated at 23°C in 1986 for a two-way analysis.

In the Y maze, hatchlings normally moved quickly down the base arm, stopped momentarily at the Y junction (called time motionless hereafter), explored in the junction by moving their head back and forth with rapid tongue flicking, and then moved down one of the experimental arms. The time hatchlings spent in the base arm and at the choice point in the Y junction, and the number of tongue flicks in the base arm varied significantly by incubation temperature (Table 3). Movement time in the base arm and time motionless were inversely related to incubation temperature.

The number of tongue flicks in the base arm was directly related to incu-

used a similar number of tongue flicks to assay the situation when they encountered mouse odor.

There were significant differences in their choices as a function of experience ($\chi^2 = 46.1$, $df = 6$, $P < 0.001$). Over 75% of the hatchlings that had eaten chose the experimental arm with the shavings, whereas only 34–40% of the snakes with all other experiences (those exposed to mice but did not eat and those not exposed) did so.

Hatchling behavior in the maze also varied significantly with respect to experience (Table 4). The time in the various parts of the Y maze varied significantly (except for exploring in the Y junction), even though this was a novel situation for all hatchlings. In general, hatchlings exposed to live mice spent less time in every section than those not exposed.

DISCUSSION

Role of Experience. Pine snake eggs in the Pine Barrens normally hatch from late August to late September (Burger and Zappalorti, 1986). Most pine snakes travel to hibernacula in October, and by early November have entered the hibernacula or are near its entrance (Burger et al., 1988). Thus, pine snake hatchlings have only a few weeks to find food and a suitable hibernaculum.

Presumably, snakes that find food have higher overwintering success than those that do not find food. Thus, it would be adaptive to be able to recognize rodent runs or burrows by chemical means, increasing the likelihood of encountering prey. Field observations of hatchlings released in the New Jersey Pine Barrens indicate that 12 individuals encountered mouse runs and immediately changed their direction of movement, following them below ground (J. Burger, unpublished data). Indeed, in two cases the hatchlings found, caught, and ate *Peromyscus leucopus*.

I had initially predicted that hungry snakes (i.e., those that had not eaten) would show the highest preference for the mouse shavings. Yet the experiments indicate that experience with eating a mouse leads to the preference for prey odors. Hatchling pine snakes that have already eaten a mouse detect and follow the odor of mice, whereas those that have not eaten show no preference for a mouse trail.

Some hatchlings may never learn to forage, an experience amateur herpetologists and zoo keepers report for some snakes. With repeated exposure to live mice in the laboratory, about 15% of hatchlings fail to eat by 50 days of age.

Role of Incubation Temperature. In a variety of reptiles incubation temperature affects mortality and body structure (Burger et al., 1987; Deeming and Ferguson, 1989a; Gutzke et al., 1985; Vinegar, 1974), thermal selection (Deeming and Ferguson, 1989b, Lang, 1987; Lang et al., 1989), adult sexuality (Gutzke and Crews, 1988), secondary sex ratios (Burger and Zappalorti, 1988; Webb and Cooper-Preston, 1989), sexual differentiation (Charnier, 1966; Ferguson and Joanen, 1982; Yntema, 1976, 1979) and locomotion, agility, and antipredator behavior (Burger, 1989b, 1990). Thus it is no surprise that incubation temperature can affect chemoreception or feeding behavior.

In these experiments hatchlings incubated at 33°C showed a greater preference for the experimental arm with the mouse shavings than did those incubated at 28°C. These results suggest that hatchlings incubated at higher temperatures will respond more quickly to mouse trails or runs than those incubated at lower temperature. Even if these differences are developmental (i.e., in another week the 28°C hatchlings would behave similarly), the slight advantage suggested by these data for snakes that hatch from warmer nests may be enough to effect overall survival since hatchlings have only limited time to find their hibernacula before cold weather sets in.

Pine snake hatchlings incubated at low temperature (23°C) moved more slowly in the Y maze than did hatchlings from eggs incubated at higher temperatures. This corraborates my previous findings with pine snakes where locomotion was examined directly (Burger, 1989b). Similarly, black racer (*Coluber constrictor*) hatchlings incubated at 22°C moved more slowly than those incubated at 28°C (Burger, 1990).

More generally, however, the added time hatchlings incubated at low temperatures spend motionless or exploring at a decision point in nature may cause the difference between catching a mouse or not. That is, hatchlings hunt by searching for mouse burrows (J. Burger, unpublished data), and the extra time may allow prey to escape. Thus hatchlings from nests incubated at low temperatures may be at a disadvantage with respect to hunting compared to other hatchlings. In these experiments, previous experience with catching and eating a mouse affected responses to the chemical odor trials of mice, confirming that experience sharpens the hunting ability of pine snakes.

Acknowledgments—I thank R.T. Zappalorti for companionship in the field; M. Gochfeld, J. Sollazzo, M. Mikovsky, and B. Lauro for help with the experiments; and W. Cooper and M. Gochfeld for valuable suggestions on an earlier draft of the manuscript.

(Received July 30, 1990; accepted February 4, 1991)

Abstract—Phytoalexin responses were measured by modified drop-diffusate and facilitated diffusion techniques after fungal inoculation of leaves of 32 Rubiaceae species from Brazilian forest and savanna. Such responses presented a trend similar to that previously observed for a broad sample of dicotyledonous plants and are more frequently positive for the more primitive (or slower growing) trees than for the advanced (or faster growing) herbs. Fifteen of these species analyzed during a one-year period showed that positive phytoalexin responses are stronger for the rainy (and hotter) than for the dry (and cooler) season. Species that contain relatively large quantities of phenolics gave invariably negative responses. Positive responses are not necessarily associated with the appearance of new substances within leaf tissue and are thus caused by inhibitins rather than by phytoalexins. These results are discussed recognizing that the tested plants are subject to the multifarious influences of their natural environment and of a possible conjugate-caused compartmentation of plant metabolites.

Key Words—Phytoalexins, fungitoxins, inhibitins, Rubiaceae, seasonal variations, leaf diffusates, leaf extractives, fungitoxin–phenol conjugation.

INTRODUCTION

Observation of phytoalexin induction is strongly influenced by the experimental techniques used. Application of the drop-diffusate (dd) procedure results in the

predominance of positive phytoalexin responses in cultivated (rather than in wild) species, while a modified facilitated diffusion (fd) procedure leads to comparable results for cultivated and wild species. Positive phytoalexin responses by both procedures are more common in summer, the rainy season, than in winter, the dry season. These correlations were encountered during a survey of phytoalexin formation involving 169 species belonging to 43 dicotyledonous families (Braga et al., 1986). Such broad sampling answered the main query of the investigation: the evaluation of the ubiquity of the phenomenon, but was of course not suited to reveal phylogenetic and environmental constraints.

It was the purpose of the present work to verify if morphologically closely related species could reveal clearly interpretable trends. To this end, sampling was reduced to 33 specimens of 32 species of the family Rubiaceae, substantially all of which had already been carefully marked and identified in a previous work (Braga et al., 1986). The number of species, even if minute in comparison with the ca. 7000 recognized species of the family, is nevertheless representative since it includes 44% and 48% of the species known to exist in the examined habitats, a forest (Jung-Mendaçolli, 1984) and a savanna (Mantovani, 1983), respectively, of southeastern Brazil.

METHODS AND MATERIALS

Recently collected leaves from adult plants were used in all tests. The plants occur either in the Reserva Biológica, Instituto de Botánica, São Paulo, SP (forest) or in the Estação Ecológica e Experimental de Moji Guaçu, Fazenda Campininha, SP (savanna) and are listed in Table 1. The data on climate were obtained from Instituto Astronómico e Geofísico, Universidade de São Paulo, SP (forest) or from Estação Ecológica e Experimental de Moji Guaçu, SP (savanna).

All experimental details, including collection of leaves, nature and administration of *Trichoderma pseudokoningii* Rifai, the inducer fungus, and *Cladosporium cladosporioides* (Fresen) de Vries, the detector fungus by the modified drop-diffusate (dd) and facilitated diffusion (fd) techniques have been described in a previous paper (Braga et al., 1986). After the initial screening of 32 species for phytoalexin response, 15 individuals of 15 species (eight from forest and seven from savanna) were selected in order to follow up these responses during a one-year period. Phenolic content in leaf diffusates of 14 of these plants assayed in autumn was measured by the Folin-Denis procedure (Swain and Hillis, 1959), using phenol as the standard.

Fungitoxic substances were extracted from leaves of eight of these species by Keen's technique (Keen, 1978). Aliquots of extracts were submitted to thin-layer chromatography, using hexane–ethyl acetate–methanol (60:40:1) fol-

lowed by chloroform–methanol (50 : 1) as solvent systems. The fungitoxic zones were detected using a spore suspension of *Cladosporium sphaerospermum* Pemzig according to the bioautography technique (Homans and Fuchs, 1970).

RESULTS

Table 1 shows the taxonomic arrangement of the tested species. Data were taken partly from our previous work (Braga et al., 1986) and partly from the seasonal analyses performed in the present work. Inspection of the data in Table 1 show the following concerning phytoalexin induction in leaves of Rubiaceae: (1) The phenomenon is practically absent from herbs [11 species, positive responses by dd 0 (0%), by fd 1 (9%)], but generally present in shrubs [14 species, positive responses by dd 2 (14%), by fd 8 (57%)] and chiefly in trees [9 species, positive responses by dd 3 (33%), by fd 6 (67%)]. (2) Responses are equally negative for the species belonging to the more advanced tribes (see Table 1, footnote) of the two subfamilies. (3) The dd technique is applicable only to some of the forest species; savanna species gave positive results only by the fd technique. (4) Reproducibility of data is higher in autumn or in spring, when most measurements were taken. At the height of the rainy season (summer), even a herb (*Coccocypselum condalia*) shows a slightly positive result; at the height of the dry season (winter) even a forest tree (*Psychotria cephalanta*) may show a negative result. (5) For at least one genus (*Alibertia*) results are negative even for trees.

Extending the measurements to different monthly periods (Figure 1) in 15 selected species, revealed other facts: (1) Forest and savanna species usually are highly variable with season, tending towards positive response maxima in summer and minima in winter. (2) Responses for forest and savanna species of *Alibertia* are negative all year round. This situation is summarized most clearly observing either the means of the inhibition halos registered for all species providing positive phytoalexin responses per month (Figure 2) or the percentage of positive phytoalexin responses based on all species analyzed per month (Figure 3). Minimum values coincide with the slightly cooler (temperature difference 10°C) and drastically drier (pluviometric difference 200 mm) weather (Figure 3).

Analyses of the phenolic content of the diffusates obtained by the dd technique led to the following observations (Table 2): (1) In most cases fungal induction alters the amount of phenolic substances only slightly. No correlation of this alteration and phytoalexin response was noted. Increase in phenolic content is no guarantee for a positive response. (2) The species of *Alibertia*, for which only negative phytoalexin responses had been obtained under all conditions, contain considerable quantities of phenolics. (3) With respect to the vicar-

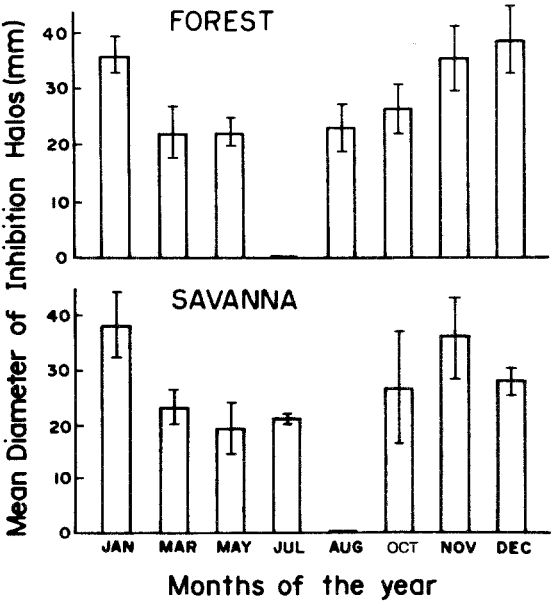

FIG. 2. Mean variation of phytoalexin induction (recorded as the mean diameter for all species providing positive responses in mm of the inhibition halos, fd technique) and standard deviation of the mean in leaves of Rubiaceae from forest and savanna in months of 1985.

ious *Alibertia*, the savanna species is much richer in diffusable phenols than the forest species.

Examination of extracts from leaves, inoculated with spores of the inducer fungus, by TLC revealed (Table 3): (1) The same fungitoxic compounds exist in extracts of inoculated leaves and their non-inoculated controls. (2) Among the five species with positive phytoalexin responses, only *Bathysa meridionalis* and *Palicourea rigida* possessed one fungitoxic compound not found in control leaves. (3) Fungitoxins were extracted even from the *Alibertia* species, which had given solely negative phytoalexin responses by the fd technique.

DISCUSSION

The results suggest that phytoalexin responses are subject to exogenous and endogenous factors. With respect to the former, it is well known that tropical plants, in contrast to plants in temperate regions, are highly sensitive to small environmental variations (Figueiredo-Ribeiro and Dietrich, 1983). Thus, although summer and winter temperatures differ by only a few degrees, they

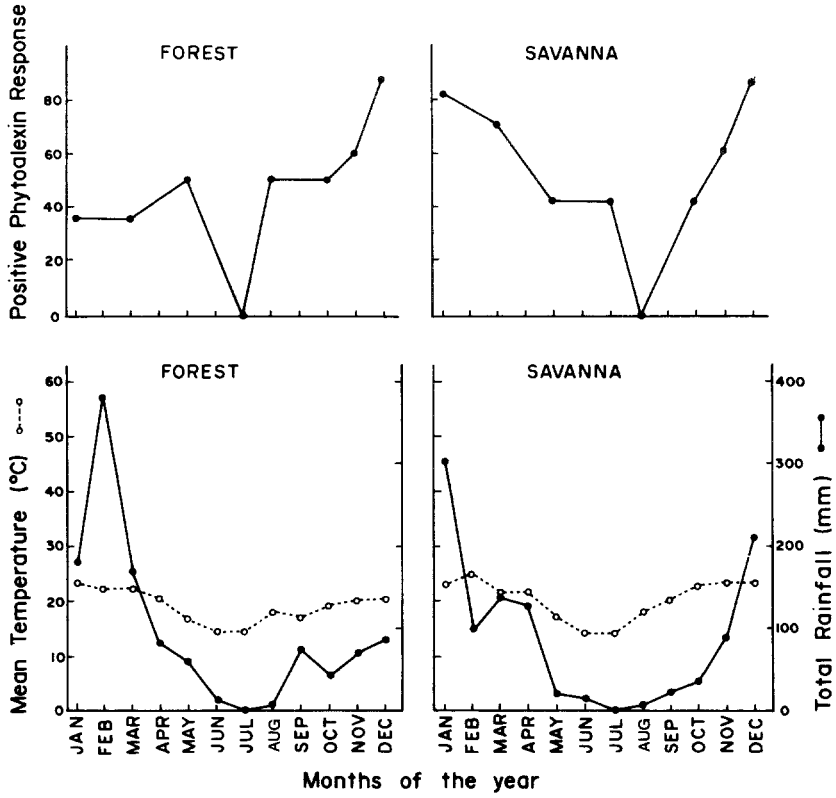

FIG. 3. Top: Mean variation of phytoalexin induction (recorded as the percentage of positive phytoalexin responses, fd technique) for leaves of Rubiaceae from forest and savanna in months of 1985. Bottom: Variations of mean temperature (°C) and rainfall (mm) in months of 1985.

may well play a decisive role. It also must be remembered that the readings represent mean temperatures and cooler or hotter periods would have compensated for each other and escaped registry. Furthermore, although the results are seen to depend dramatically on atmospheric humidity, this may be affected by an additional superimposed variable, the developmental stage of the specimen. However, preliminary analyses of phenological stages seem to suggest this to be a minor factor, which only accentuates positive responses for plants in the flowering and fruiting stage. Lack of phytoalexin response in winter is most probably due to difficulty of metabolite synthesis or diffusion through the dry tissue towards the leaf surface.

The evolutionary trend in angiosperms is usually considered to involve transition from woody to herbaceous habit. Because phytoalexin response is

consistently negative in herbs, it should thus be a primitive phenomenon in Rubiaceae. Indeed, the tribes Coffeeae and Spermacoceae, for which thus far only negative results have been reported (Table 1), are placed near the terminals of the tribal lists of their subfamilies (Kirkbride, 1982). Presumably these terminals incorporate the more highly evolved plant groups. However, it has been reported that fast rate of growth, as would be typical of herbaceous rather than of arboreous species, represses the production of defense compounds (Coley et al., 1985), a phenomenon that at least partly may well account for the observed facts.

The two *Alibertia* species are ligneous and hence would be expected to show positive phytoalexin responses. This is not the case. Thus again for *Alibertia*, as already suggested by the uniformity of the data for Spermacoceae (Table 1), phylogenetic factors seem to predominate. Nevertheless, the *Alibertia* species possess a totally different chemical makeup than all other analyzed species, accumulating tannins, i.e., immobile defense material sensu Coley et al. (1985). It is consequently surprising to find that both also contain constitutional fungitoxins (Table 3). However, these are not revealed as tannins in the dd and fd tests. It is hence highly probable that strong hydrogen bonding between the large quantities of macromolecular tannin and the relatively small quantity of micromolecular fungitoxin obstructs diffusion of the latter, which is of course essential for the manifestation of a positive response. Absence of exudated fungitoxins also occurs in *Palicourea marcgravii* (Table 3). *Rudgea jasminoides*, *R. viburnioides*, and *Tocoyena formosa* gave positive phytoalexin responses, although in this case none of the extracted fungitoxins could be defined as responsible for the effect, since they were present prior to fungal infection under these experimental conditions. Of course it must be considered that, in contrast with the plants used in most previous studies on phytoalexins, which were cultivated in greenhouses (Ingham, 1982), our plant material comes from the wild where the leaves are exposed to natural populations of fungi (Bailey, 1971) since their inception. Although de novo synthesis of fungitoxins in wild plants must occur, such true phytoalexins (Harborne, 1988) may not be detected by diffusion tests due to conjugate formation or compartimentalization (Barz and Koster, 1981). However, if an inducer fungus is subsequently supplied experimentally, an additional quantity of the same fungitoxins may be formed. Now, unless retention continued to be caused by excess of phenolic material, a positive phytoalexin response, at this time better designated inhibitin response (Harborne, 1988), will appear.

CONCLUSION

The analyses of phytoalexin responses in a group of taxonomically related species belonging to the family Rubiaceae reinforced the trends observed for a large sample of dicotyledonous species previously studied (Braga et al., 1986)

in terms of influence of environmental conditions and systematic relationships. Furthermore, leaves of wild Rubiaceae species contain phytoalexins probably as the result of interaction with naturally occurring fungi. Experimental inoculation of an inducer fungus frequently increases the quantity of these fungitoxins beyond the retention limit and leads to their diffusion onto the leaf surface, exhibiting positive phytoalexin or, more precisely, inhibitin (Harborne, 1988) responses. When the retention limit is high, due to strong conjugation with relatively large quantities of phenolics, responses continue negative.

(Received October 18, 1990)

Abstract—*Ilex opaca* and *Ilex verticillata* are woody species bearing low-quality, bird-dispersed fall fruits that persist for several months. Tests of secondary chemistry show that fruits of both species contain phenolics and saponins as major classes of secondary metabolites. Soluble carbohydrates are the major nutrients in both species. Ripe fruits from ten trees in both wild and cultivated populations of each species were collected during 1986, 1987, and 1988 and analyzed for phenolic and carbohydrate content using Folin-Denis and anthrone methods, respectively. Fruits from 1987 and 1988 were analyzed for saponin content using hemanalysis. Significant differences were found in the average content of the above chemical classes between the two species and among individuals within each species. The fruits of *Ilex opaca* are more persistent, higher in phenolics, and lower in saponins and carbohydrates than *I. verticillata* fruits. Generally, there are greater differences in fruit chemistry among plants within a year than within one individual between years. Mechanical defenses were tested by puncturing fruits in situ. No differences in decay were found between punctured and unpunctured fruits.

Key Words—Saponins, phenolics, carbohydrates, *Ilex opaca*, *Ilex verticillata*, bird-dispersed fruit, Folin-Denis, secondary chemistry, plant–herbivore interaction.

INTRODUCTION

Secondary compounds in green fruits are generally changed or diminished during ripening, rendering ripe fruits more susceptible to attacks by microbes and

*To whom correspondence should be addressed.

0098-0331/91/0600-1091$06.50/0

herbivores. The fruit pulp of *Heteromeles arbutifolia*, a desert shrub, contains a cyanogenic glycoside which is relocated to seeds upon ripening (Dement and Mooney, 1974). Tannins in persimmons, grapes, and bananas become more highly polymerized and so less astringent upon ripening (Joslyn and Goldstein, 1964; Palmer, 1971; Peynaud and Ribereau-Gayon, 1971). Apples become more susceptible to fungal attack as chlorogenic acid content falls during ripening (Hulme and Rhodes, 1971) and antibacterial activity of preclimactic avocado fruits disappears in postclimactic fruit (Biale and Young, 1971). Some factors, however, such as thick epidermal cells, sclerified tissues, and low moisture content, may afford protection to ripe fruits against fungal infection (Moore-Landecker, 1982; Agrios, 1988).

Most of the bird-dispersed fruits in eastern deciduous forests are low-quality fall fruits (Stiles, 1980). These fruits ripen in late summer or early fall and persist for several months, sometimes remaining on the plants until the following spring. Chemical defenses in persistent ripe fruits must deter fungi and insects without deterring dispersers (Kear, 1968; Freeland and Janzen, 1974; Janzen, 1977; Herrera, 1982).

In this study we: (1) tested for differences in secondary chemistry and nutrient content between two congeneric species that have dissimilar fruit persistence patterns. We hypothesized that species with more persistent fruits would have higher levels of secondary compounds and lower levels of nutrients including water. (2) We also examined the variations in secondary chemical content among fruits of individuals within a species. (3) To test for differences between chemical and mechanical defenses, we punctured fruit skins and observed rates of decay. We hypothesized that the species more dependent on physical defenses would have higher rates of decay in punctured than in unpunctured fruits.

METHODS AND MATERIALS

Research Species. We studied two species of *Ilex* (holly) as models of differential fruit persistence in plants with low-quality fruit. *Ilex opaca* (American holly) is a long-lived, evergreen tree found in the eastern United States (Art, 1976; Stalter, 1980). Fruits ripen in November and may be retained until the following June (Hume, 1953; personal observation). Fruits are usually red, occasionally yellow. Fruits and leaves of *I. opaca* contain saponins (West et al., 1977; Potter and Kimmerer, 1986) and fruit skin contains two layers of sclereids (Ives, 1923).

Ilex verticillata (common winterberry, black alder), is a deciduous shrub found in swampy areas throughout the Northeast, Midwest, and into Canada (Sakai and Sulak, 1985). Fruits are usually red, rarely yellow (Hume, 1953). They ripen in September and generally become wrinkled and brown by late

January (personal observation). Secondary chemistry of *I. verticillata* has not been studied.

We evaluated differences in total soluble phenolics, hemolytic saponins, and soluble carbohydrates between species and among fruits within species. Phenolic compounds contain a hydroxylated aromatic ring and occur universally among plants. Many are known to act as antifungal agents (Friend, 1979; Swain, 1979). Saponins are glycosylated polycyclic compounds with soaplike properties. They are toxic to some insects, act as fungistatic agents, and bind to cell membranes, causing hemolysis of red blood cells (Applebaum et al., 1969; Applebaum and Birk, 1979). The major soluble carbohydrates found in most fruit include glucose, fructose, and sucrose (Whiting, 1970).

Methods. Ten plants of each species were studied for three years: 1986, 1987, and 1988. Six of each were in wild populations, *I. opaca* at Sandy Hook National Recreation Area on the New Jersey coast and *I. verticillata* at Cheesequake State Park, New Jersey. The other four plants of each species were in the display gardens at Cook College, Rutgers University.

Two of the *I. opaca* trees (02 and 03) at Cook bear yellow fruit. There is a single yellow-fruited *I. verticillata* shrub at Cook (VY), but it did not bear fruit during 1986. Another, red-fruited shrub (V3) has a yellow-fruited ramet, and these fruits were analyzed in 1988.

Ripe fruits from several areas of each plant were collected each year. Fruit ripeness was assured by taking samples several weeks after fruit skin was fully red and fruit pulp was yellow and soft. Studies of fruit chemistry during ripening show drops of over 90% in saponin content and 50% in phenolic content as fruits of both species change color (Gargiullo and Stiles, unpublished data). Fruits were frozen in liquid nitrogen, freeze-dried, and then stored at $-10°C$. Before extraction, seeds were removed and fruit pulp was ground to powder using a glass mortar and pestle.

Seed Loads and Pulp Water. Seed loads of fresh fruits were measured using 10 or 20 fruit from each of seven *I. verticillata* shrubs and eight *I. opaca* trees. Fruits were weighed, fruit pulp was rubbed off seeds, and seeds from each plant were weighed. Seeds were freeze-dried and reweighed to measure seed water content. This averaged $18.27 \pm 1.68\%$ for both species together (*I. opaca* 17.60 ± 1.33, *I. verticillata* 19.02 ± 1.82). Percent seed load was calculated as fresh seed weight divided by fresh fruit weight times 100. Fruit pulp water was estimated as follows: a fruit sample was weighed before and after freeze drying. Pulp then was removed by grinding fruit, and dry seeds were weighed. The following formula was used to calculate percent fruit pulp water: $[(W - F - 0.22D)/W] \times 100$ where W = fresh fruit weight, F = dry fruit weight, and D = dry seed weight. The constant, 0.22, results from back-calculating 18% water lost from seeds.

Puncture Test. Mechanical defenses of ripe fruit were tested by puncturing

10 fruit in situ on five different branches of each plant. This was done to simulate damage by insects or other trauma to fruit skins. The numbers of punctured and unpunctured control fruit that turned brown during the following three weeks were counted. Ten *I. verticillata* and eight *I. opaca* plants were tested during the autumn of 1989. Data were analyzed using *t* tests (SAS Institute, 1985).

Chemical Tests. Extracts for phenolic and saponin analysis were made using 40% methanol. Five hundred milligrams of dry, ground fruit pulp was extracted with 4 ml of solvent three times for 30 min each time. Methanol was removed from pooled extract under reduced pressure, and the volume was brought to 10 ml with distilled water. Residual fruit pulp was brown, indicating the presence of insoluble, oxidized phenolic compounds.

Tannins were sought using the radial diffusion method of Hagerman (1987), which involves precipitation of protein in an agarose gel. The method can detect as little as 0.025 mg of tannin. Tannic acid was used as a standard.

Total soluble phenolic content of fruit extracts was determined using the Folin-Denis test (Folin and Denis, 1912; Swain and Hillis, 1959, Schultz and Hollis, personal communication). Phenolics were reported as percent dry weight tannic acid.

The Folin-Denis test has been criticized because it only measures aromatic hydroxyls and gives results that differ with molecular structure (Martin and Martin, 1982; J.C. Schultz, personal communication). However, it does measure the degree to which a phenolic can be oxidized (Folin and Denis, 1912), and oxidized phenolics have been shown to be more toxic than unoxidized phenolics (Van Buren, 1970; Byrde et al., 1960).

Saponins were analyzed by combining the hemolytic methods of Wall et al. (1952), O'Dell et al. (1959), and Segelman and Farnsworth (1969). For each saponin analysis 1 ml of fruit extract was mixed with 4 ml of a 1% suspension of washed human erythrocytes (pH 7.4) and incubated for 2.5 hr at 31°C ± 1°C. Tubes were remixed every 15 min to keep cells in suspension. Unlysed blood cells were spun down in a desktop centrifuge and the absorbance of hemoglobin remaining in the supernatant was read at 520 nm. Hemolytic saponins were reported as percent dry weight Sigma saponin.

Hemanalysis of saponins, like the Folin-Denis, test, is not qualitative. However, it does measure the capacity of saponins to lyse cell membranes and is, therefore, relevant as a measure of fruit defense against fungi and bacteria.

Carbohydrates were analyzed by the anthrone method (Yemm and Willis, 1954; Allen, 1974) using a 2-hr hot-water extraction, 10-min color development, and glucose standards. This test measures mono- and disaccharides known to be assimilated by birds (Ziswiler and Farner, 1972). Soluble carbohydrates were reported as percent dry weight glucose.

Data Analysis. Data for phenolics, saponins, and carbohydrates were ana-

lyzed using analysis of variance (SAS Institute, 1985). Differences among fruits of individual plants were analyzed using Scheffe's tests (Day and Quinn, 1989). Data were also analyzed by ANOVAs using years as replicates to see if differences between fruits of individual plants were greater than differences within one tree over time. Linear regressions were used to evaluate correlations between carbohydrates, phenolics, and saponins. Data for saponins from 1986 were not analyzed due to inadequate freeze drying.

RESULTS

Tannin Analysis and Puncture Test. The analysis for tannins was performed on 24 samples of fruit using sufficient extract to detect 0.5% tannin in dry fruit pulp, but none was found in fruit of either species. A preliminary study, using the dye-labeled BSA method of Asquith and Butler (1986) also showed no tannins. Tannins are known to interfere with saponin hemolysis (Segelman et al., 1969) and, if present, should have prevented hemolysis, but this did not occur.

There were no significant differences in discoloration between punctured and unpunctured fruits on any plant of either species.

Differences between Species. Seed loads and fruit pulp water content of the two species were significantly different from one another (Table 1) with *I. opaca* having a higher seed load and lower water content than *I. verticillata*.

The ANOVAs showed highly significant ($P < 0.0001$) differences for carbohydrates, phenolics, and saponins between the two species for all years (Table 2).

Soluble carbohydrate content of dry fruit pulp ranged from 45.8% to 66.6% dry wt for *I. opaca* and from 51.7% to 86.7% dry wt for *I. verticillata* for all three years. Fruit pulp of *I. verticillata* had significantly more carbohydrate than did *I. opaca*.

Total soluble phenolics ranged from 1.67% to 3.64% dry wt for *I. opaca* and from 0.86% to 2.26% dry wt for *I. verticillata* for three years. *Ilex opaca* fruit had significantly higher phenolic content than did *I. verticillata* fruit. How-

[a] All means are significantly different from one another at $P > 0.0001$.

ever, differences in results between the two species may be caused by qualitative as well as quantitative differences in phenolic compounds (Goldstein and Swain, 1963).

Saponin content of fruit was more variable than either phenolic or carbohydrate content. Hemolytic saponins ranged from 0.00% (undetectable by this method) to 3.41% dry wt for *I. opaca* and from 0.00% to 3.37% dry wt for *I. verticillata* for two years. *Ilex verticillata* had a significantly higher mean saponin content than *I. opaca*. As with phenolics, differences in saponins between species may be qualitative as well as quantitative.

Differences within Species. There were significant differences in chemistry among fruits of some plants within species in each year (Table 3).

Carbohydrates. Scheffe's tests (Figures 1 and 2) for carbohydrate content of *I. opaca* fruits showed one tree with consistently high carbohydrate content (03) and one tree with low carbohydrate content (07) across all years. There was no significant difference between carbohydrate content of fruit from the two sites for *I. opaca* except in 1986 when Cook trees had significantly ($P < 0.006$) higher carbohydrate content than those from Sandy Hook.

Scheffe's tests for fruits of *Ilex verticillata* (Figures 1 and 2) showed fruit of VY (Cook) high in carbohydrates. Shrubs V5 and V9 (Cheesequake) had fruit with low carbohydrates. There were significantly more carbohydrates in *I. verticillata* fruit from Cook ($P < 0.0001$) than from Cheesequake. Yellow fruit of both species tended to be relatively high in carbohydrates.

Phenolics. There were more variations in phenolic content than in carbo-

1987	8.27	<0.0015	6.77	<0.0034
1988	13.69	<0.0002	11.19	<0.0002
Phenolics				
1986	856.93	<0.0001	6367.81	<0.0001
1987	365.22	<0.0001	5783.65	<0.0001
1988	413.90	<0.0001	112.06	<0.0001
Saponins				
1987	99999.99	<0.0	21045.70	<0.0001
1988	95659.42	<0.0001	1755.91	<0.0001

hydrate content among fruits of individual plants of both species (Figures 3 and 4). Differences between the two *I. opaca* sites were significant ($P < 0.0001$) for all three years, with fruit at Cook having higher phenolic content than those at Sandy Hook.

Fruits of *I. verticillata* shrubs at Cheesequake were significantly ($P < 0.0001$) higher in phenolic content than those at Cook during all three years.

Saponins. Saponin content of fruit was more variable than either carbohydrate or phenolic content for both species in both years (Figures 5 and 6). There was a highly significant difference between sites for *I. opaca* (Figure 6, $F = 99999.9$, $P = 0.0$) in both years, with fruits of trees at Sandy Hook having greater saponin content (means 0.82% in 1987, 1.25% in 1988) than those at Cook (means 0.17% in 1987, 0.12% in 1988).

Saponin content of *I. verticillata* fruits (Figures 5 and 6) were significantly different between sites ($P < 0.0001$) with fruits of trees at Cheesequake having more saponins (means 1.49% in 1987, 1.48% in 1988) than those at Cook (means 0.34% in 1987, 0.17% in 1988). Yellow fruits of both species tended to be low in saponins.

Additional Findings. Analysis of variance for each class of compounds within species, using years as replicates, had significant *F* statistics for everything except carbohydrates in *I. opaca* (Table 4), indicating greater variation among individuals than within an individual plant.

There were no significant correlations between carbohydrates and phenolics, carbohydrates and saponins, or between saponin and phenolics for *I. opaca* fruits. There were no significant correlations between carbohydrates and sapo-

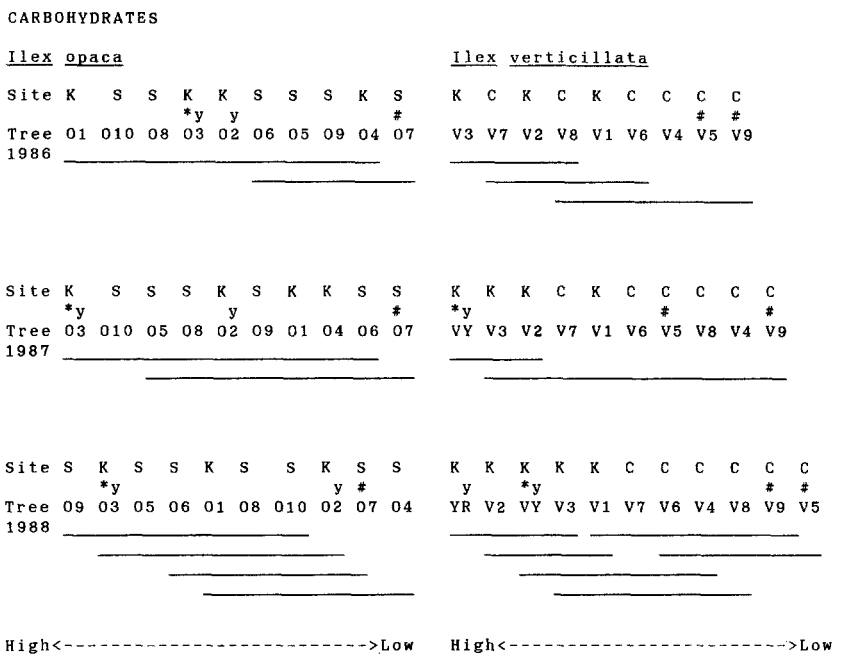

FIG. 1. Scheffe's tests for differences in carbohydrate content among fruits of individual plants. All $P < 0.005$. Plants are listed in descending order of carbohydrate content from left to right. nins or between saponins and phenolics for *I. verticillata* fruits. However, the correlation coefficient for carbohydrates and phenolics for *I. verticillata* was negative and significant at $P < 0.001$ ($r = -0.639$, Table 1 and 3).

DISCUSSION

Differences between Species. Persistent fruits must maintain barriers to fungal invasion and frost damage for weeks or months. Fruits of the two species in this study are both persistent, but they have clear differences in secondary chemical content, nutrient content, and longevity. Given the results of the puncture experiment, chemical rather than mechanical factors appear to be most important for defense against pathogens in both species.

Our hypothesis, that more persistent fruit should be higher in secondary compounds and lower in nutrients, was partially supported by this study. *Ilex*

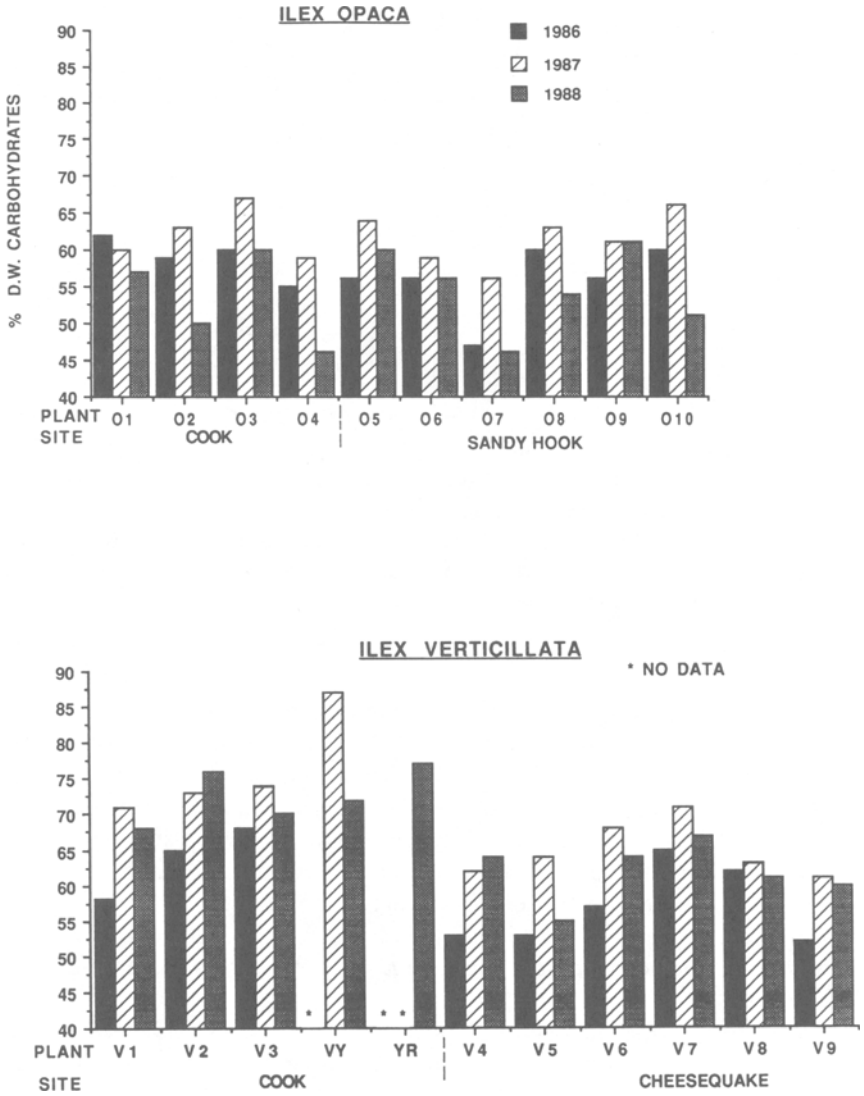

FIG. 2. Percent dry weight (D.W.) of carbohydrates for three years for fruit from each plant. O = *I. opaca*, V = *I. verticillata*.

opaca, the more persistent fruit, was lower in water and soluble carbohydrates, and higher in phenolics than *I. verticillata*. These factors, high phenolics, low nutrients and low water, have all been shown to inhibit fungal infections (Agrios, 1988; Moore-Landecker, 1982). Another study has shown that frugivorous birds prefer *I. verticillata* over *I. opaca* (Gargiullo and Stiles, unpublished data). This seems to indicate a trade-off between fruit persistence and palatability. *Ilex opaca* fruits are ripe from November through winter into the following spring, making them available to resident birds in late winter and to spring migrants. However, the characteristics that preserve *I. opaca* fruits also make them poor-quality food.

Ilex verticillata fruits ripen in September, are generally removed or brown and desiccated by late January, and so must be dispersed principally by late fall migrants and winter residents. Although *I. verticillata* fruits have a higher mean saponin content than *I. opaca* fruits (Table 2), saponin content is very variable in ripe fruits of both species and lower saponin content is not correlated with shorter life-span in *I. opaca* fruits. The shorter life-span of *I. verticillata* fruit limits time available for dispersal. High carbohydrate, low phenolic content and

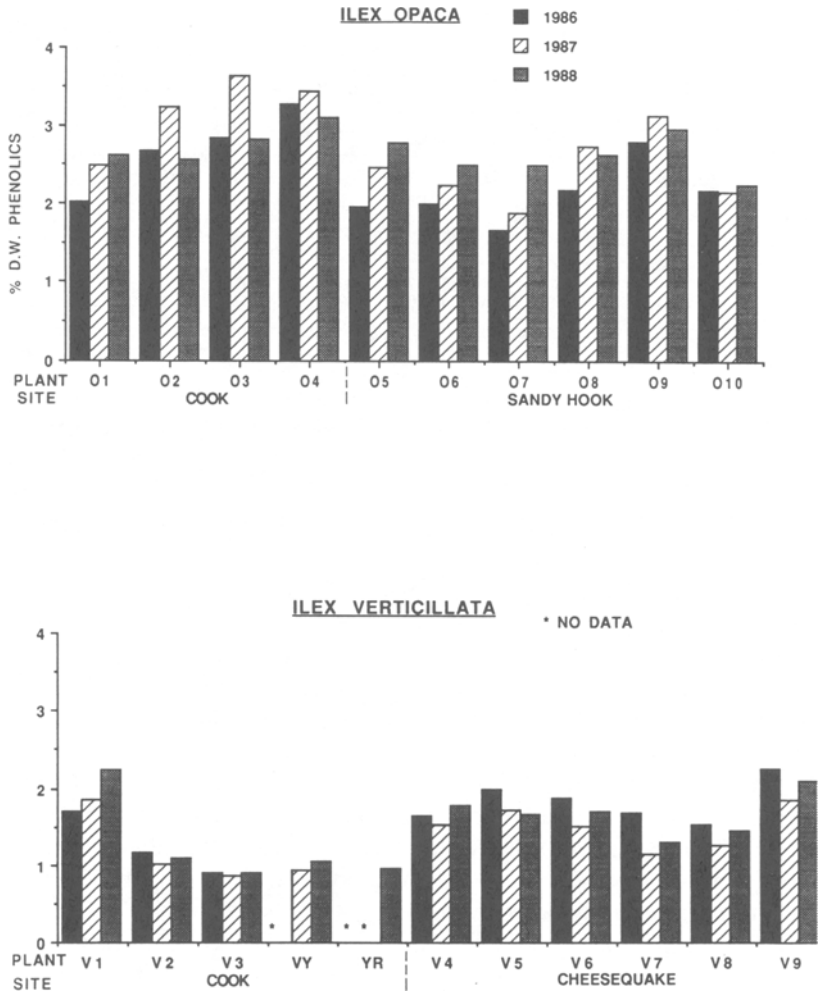

FIG. 4. Percent dry weight (D.W.) of phenolics for three years for fruit from each plant.

low seed load (Herrera, 1981) make them more attractive to dispersers than *I. opaca* fruits.

Differences within Species. Carbohydrate content in fruits of these two species varied considerably, indicating dependence on both environmental and genetic factors (Figure 2). Mean carbohydrate contents of *I. opaca* fruits were significantly different between sites only for 1986, so environmental factors such as soils were probably not directly related to carbohydrate production. *Ilex verticillata* fruits did have significant differences in carbohydrate content

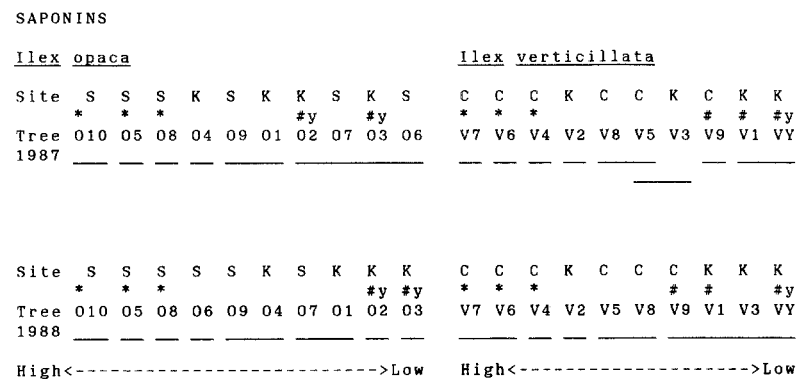

FIG. 5. Scheffe's tests for differences in saponin content among fruits of individual plants. All $P < 0.005$. Plants are listed in descending order of saponin content from left to right. Plants with yellow fruit are labeled "y." *high saponins, #low saponins in both years.

between sites. Shrubs at Cheesequake were shaded more heavily by other vegetation than those at Cook, and this may have influenced carbohydrate content of fruits.

Phenolic content of *I. opaca* fruits was significantly higher at Cook than at Sandy Hook. This may have been related to infestation of all four of trees at Cook by holly midges (*Asphondylia ilicicola*). The larva of this insect lives inside the carpellary cavity and prevents fruit ripening (Highland, 1964). It is possible that chronic infestation may have induced an increase in phenolic content of all fruit (Bell, 1981). Only a few fruit on two trees at Sandy Hook (08 and 09) were affected (Gargiullo, personal observation). None of the trees at either site was shaded by other vegetation.

Yellow fruit lacks anthocyanins and may have other differences in phenolics that influence fruit longevity. The pigments in yellow fruits are probably phenolics (Vickery and Vickery, 1981) rather than carotenoids, as the yellow color appeared in the fruit extracts and carotenoids are not water soluble.

Differences between sites were especially evident in fruit saponin content of both species ($P < 0.0001$ for both species in both years) (Figures 5 and 6). Plants with the highest saponin content in both species were from the two wild populations. It is likely that plants in these wild populations are related, whereas those at Cook are all different cultivars. Trees studied on Sandy Hook grow in a single large population and are within about 500 m of one another. Shrubs studied at Cheesequake are within about 150 m of one another. Although mean saponin content was higher for *I. verticillata* than for *I. opaca*, overall saponin content was highly variable among individuals (Table 1).

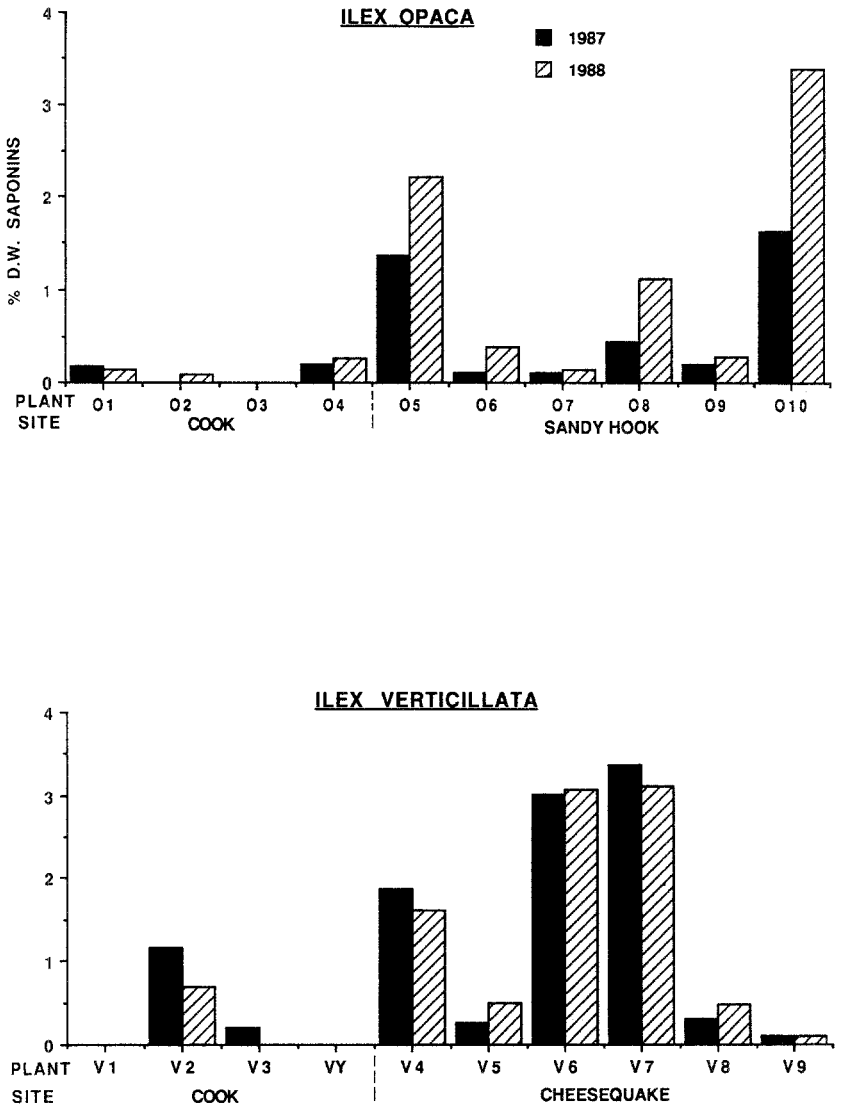

FIG. 6. Percent dry weight (D.W.) of saponins for two years for fruit from each plant.

These two species have disparate sets of characters to attract dispersers. *Ilex verticillata*, with lower chemical and higher nutrient content, is less persistent and available only in early winter. *Ilex opaca* is more highly defended, less nutritious, more persistent, and available at a time of scarcity in late winter. The wide variations between fruits of individual trees appear to be due to both

EFFECTS OF COTTON PLANT ALLELOCHEMICALS AND NUTRIENTS ON BEHAVIOR AND DEVELOPMENT OF TOBACCO BUDWORM

PAUL A. HEDIN,* WILLIAM L. PARROTT, AND JOHNIE N. JENKINS

Crop Science Research Laboratory
USDA-ARS
Mississippi State, Mississippi 39762-5367

(Received November 9, 1990; accepted February 7, 1991)

Abstract—Female moths of the tobacco budworm, *Heliothis virescens* (F.), oviposit in the terminals of the cotton plant, *Gossypium hirsutum* (L.). The hatched larvae migrate to the terminal area and then to small squares (buds), on which they feed, finally burrowing into the anthers where they grow and develop. They attempt to avoid gossypol glands as they feed. Chemically related evidence explains, in part, these observations. The calyx crown of resistant lines (which is avoided) is high in the terpenoid aldehydes (TAs) including gossypol. HPLC data showed that the gossypol content of both susceptible and resistant glanded lines is equal, while the hemigossypolone and heliocides H_1 and H_2 are greatly increased in resistant lines and presumably are more closely associated with resistance. Analysis for total amino acids in cotton square tissues showed that there was a gradation from the calyx and calyx crown, which were lowest, to the anthers, the site of final insect development, which were highest. Synthetic diets mimicking amino acid distribution in anthers were found to be successful for larval growth and development.

Key Words—Tobacco budworm, *Heliothis virescens*, Lepidoptera, Noctuidae, cotton, *Gossypium hirsutum*, plant resistance, plant-insect interaction, terpenoids, gossypol, allelochemicals.

INTRODUCTION

The female moths of the tobacco budworm, *Heliothis virescens* (F.), oviposit in the terminals of the cotton plant, *Gossypium hirsutum* L. There is no evi-

*To whom correspondence should be addressed.

dence that they are specifically attracted to the terminals by chemical cues, but rather that they are most proximate to the terminals during an overflight. Most of the eggs are placed singly on the small terminal leaves approximately 12 cm^2 in size (Ramalho, 1983). Three days after oviposition, the eggs hatch. Immediately after hatch, the young larvae will feed on the leaf tissue for a brief period before they migrate into the terminal area, which is comprised of meristematic tissue (immature squares and leaves). The young larvae spend about three days feeding on small squares with the potential of destroying a maximum of four squares each during this feeding period (Parrott, unpublished data).

During this period, gossypol is toxic to the larvae (Hedin et al., 1988), which also are observed to avoid consuming glands that contain gossypol. However, when the larvae molt into the second instar at about 72 hr, they can nonselectively consume the glands (Parrott et al., 1983). Earlier, Shaver and Parrott (1970) reported young larvae to be more sensitive to gossypol than older larvae. This finding was later supported by laboratory studies in which gossypol and two other allelochemicals were fed in diets to 1-, 3-, and 5-day-old tobacco budworm (TBW) larvae. All three allelochemicals were toxic to 1- and 3-day-old larvae, but they were not toxic to 5-day-old insects. Evidence was obtained that the insects biosynthesized detoxifying enzymes, mixed function oxidases (MFOs), because piperonyl butoxide, a known inhibitor of MFOs, inhibited growth when added to the diets (Hedin et al., 1988).

When the larvae leave the terminal, they move onto small squares that arise at position one of the fruiting branch (Ramalho et al., 1984). They then prefer to feed along the margin area of the calyx crown. Using laboratory feeding tests in which larvae fed on squares from several experimental lines, Parrott et al. (1989) found that they fed less on squares from plants that have high gland density in the calyx crown, a normally preferred feeding site of young larvae.

During the later second and third instars, the larvae burrow through the calyx or petals of the cotton squares into the anthers. Once they reach the anthers, their growth rate immediately accelerates. Work by Shaver et al. (1977) showed that the major source of nutrients for tobacco budworm larvae in detached cotton buds is in the anthers. The nutritional requirements, however, have never been defined chemically, in part because the tobacco budworm has never been reared on synthetic amino acid diets. However, the expectation is that if this could be achieved, it would provide the basis for more reliable evaluation of the effects of natural and synthetic constituents.

The objectives of this study were to determine whether the migration of the tobacco budworm from the terminal leaf, terminal area (meristematic tissue), calyx crown, and finally to the anthers can be at least partly explained by, or associated with, the gradient concentrations of allelochemicals and nutrients.

METHODS AND MATERIALS

Cultivars and Agronomic Practices. In 1988, three lines with demonstrated resistance to the TBW—DH-118, DH-126, and DH-118 × ST 213 H—were planted on the Plant Science Farm, Mississippi State, Mississippi. For comparison, four susceptible lines, DH-118 × ST-213 L, ST-213, ST-825, and ST-213 gl, were also planted. Not all lines were used in every test. Standard cultural practices were followed during the growing season, except that some of the replicated plots were not protected from insects. All plant material was collected from cotton plants of similar maturity.

Gathering and Processing of Plant Tissue. Terminal leaves, squares, and square parts were harvested, frozen, freeze-dried, and then ground through a 40-mesh screen. The powders were stored in vials at −20°C until they were evaluated. A portion of the freshly gathered squares was dissected into the following parts: anthers, petals, bracts, calyx, and calyx crown. These tissues were also freeze-dried, ground to a powder, and stored at −20°C to await subsequent evaluations.

Insects and Diets. Neonate tobacco budworm larvae used in the various tests were obtained from a colony at the Crop Science Research Laboratory, Mississippi State, Mississippi, maintained as described by Jenkins et al. (1982). Larvae (20 per test) in some tests were placed in 30-ml clear plastic cups containing 10 g/cup of a Nutrisoy–wheat germ diet (Bioserv, Frenchtown, New Jersey).

In tests where the synthetic amino acids replaced the Nutrisoy–wheat germ protein as a source of nitrogen, the amino acids were procured either from Bioserv, or from Sigma Chemical Co. (St. Louis, Missouri). The amino acid distribution and levels in these diets were based on protein and amino acid analyses of the soy flour, wheat germ, and cotton anthers (methods and results described later in the text). The nonprotein dietary ingredients [and a separate vitamin mixture (Pack C)] were also provided as dry mixes by Bioserv. The dietary ingredients are listed in Table 1.

Analytical Procedures. The Association of Official Analytical Chemists (AOAC) method (Horwitz, 1975) for total protein, 2.049 (percent nitrogen × 6.25) was used to determine that the crude protein content of the Bioserv Pack B containing soy flour and wheat germ as protein sources was 22.7%; i.e., the quantity of amino acids that was required for addition to the Pack B less protein to provide an equivalent amount to that supplied by the soy flour and wheat germ.

Analysis of Allelochemicals. Analyses for gossypol and related terpenoid aldehydes were performed on cyclohexane–ethyl acetate–acetic acid (500:500:1; CHEA) extracts of plant (whole square and anther) tissue by the

phloroglucinol reaction [2% in absolute EtOH-concentrated HCl (1:1)]; let stand 1 hr, with subsequent spectrometric analysis at 550 nm. The concentration was determined by comparison with data obtained from authentic gossypol and is expressed as gossypol equivalents. Condensed tannin analyses were performed on 70% aqueous methanol extracts of tissue. The anthocyanidin chromophore was developed from the tannin by boiling 1 hr with 1-butanol–HCl (95:5) (Hedin et al., 1983b). The concentration was determined by comparison with the color obtained at 550 nm from a purified cotton condensed tannin sample, the structure of which was elucidated by Collum et al. (1981). The anthocyanin content was determined by measuring the absorbancy at 540 nm of freeze-dried tissue extracted with methanol–water–HCl (79:19:3), using the molar extinction coefficient (E) of cyanidin 3-β-glucoside (Hedin et al., 1967). Flavonoids were determined after extraction of freeze-dehydrated tissue with 70% aqueous acetone. Diphenylboric acid–ethanolamine complex (Natural Product Reagent A, Aldrich Chemical Co., 1%) in methanol was added, and the chromophore absorptivity at 440 nm was determined and compared to that obtained from a purified sample of isoquercitrin, the most prevalent flavonoid in cotton.

HPLC Analyses of Terpenoid Aldehydes and Amino Acids. HPLC analysis

of the gossypol-type terpenoid aldehydes was performed on a reverse-phase C_{18} column according to the procedure of Stipanovic et al. (1988), who also kindly provided samples of hemigossypolone, and heliocides H_1 and H_2 for column calibration. Amino acids were determined by HPLC analyses after acid hydrolysis, employing their phenylthiocarbamyl derivatives (Cohen et al., 1986).

Procurement of Chemicals. All commercially available chemicals (other than the amino acids) were obtained from Sigma Chemical Co. Gossypol was a gift from the Southern Regional Research Center, USDA, New Orleans, Louisiana.

Statistical Procedures. Data obtained from the various analyses and measurements were subjected to the analysis of variance, and LSD values were calculated using SAS (1985) except for the HPLC analyses on the terpenoid aldehydes where standard errors of the mean are provided. No statistical analyses were obtained on the custom-procured amino acid data.

RESULTS AND DISCUSSION

Allelochemicals in Cotton Leaves, Squares, and Their Parts. The whole squares and square parts, anthers and stigma, bracts, calyx, calyx crown, and petals were analyzed for the major cotton allelochemicals (Table 2). The strains most resistant to TBW, DH 118 and DH 118 × ST 213 H, were highest in gossypol in the whole square and in the square parts. The DH 118 × ST 213 L strain was very similar to ST 213 in the level of gossypol and level of resistance to TBW, whereas the DH 118 × ST 213 H strain was very similar to DH 118 in the level of gossypol and the level of resistance to TBW in all square parts.

The tannins were highest in ST 213 glandless and in ST 213, the two strains most susceptible to TBW. This agrees with previous data of Hedin et al. (1983a,b) where tannin of glandless (susceptible) lines was about 20% higher than that of glanded resistant lines. The anthocyanin content should be somewhat correlated with gossypol because it often occurs as a halo around gossypol glands (Hedin et al., 1983a,b), but this was the case only in the anthers and bracts. The flavonoids were higher in petals and bracts of the resistant DH 118 and the DH × ST 213 H lines than in the DH 118 × ST 213 L and ST 213 lines. The same was true for flavonoids in whole squares.

Terpenoid Aldehydes (TAs) in Cotton Squares. Because gossypol is known to coexist in the plant with a number of related TAs, the gossypol fractions of three susceptible and two resistant double haploid lines were investigated by HPLC. Of the six major TA components listed in Table 3, the identities of four had previously been established, and their HPLC elution times were identical

FIG. 1. Structures of gossypolone and gossypol lactone.

sample of gossypolone (Figure 1a) prepared by us (Phillips and Hedin, 1990) showed that the fragmentation patterns were nearly identical.

EI-MS analysis of the maximum at 10.7 min gave an apparent $[M]^+$ of 514. The most prominent ion fragments were as follows: *m/z* 514(100), 499(75), 482(65), 465(35), and 439(15). Repeated attempts to isolate sufficient quantities of this component for NMR and IR by liquid chromatography using silica gel and Sephadex LH-20 were unsuccessful because of degradation.

It was proposed that the apparent molecular ion could be accounted for if the gossypol aldehydic functions were oxidized to the dicarboxylic acid and subsequently dehydrated to form the dilactone. Therefore, gossypol was oxidized by stirring in air with MnO_2 in acetone or benzene. Both preparations dehydrated rapidly to the presumed dilactones, without the use of a dehydrating agent, and gave fragmentation patterns essentially identical to that of the isolate. Again, efforts to prepare sufficient samples in pure form for spectral work were unsuccessful. The presumed structure (Figure 1b) is 6,6′,7,7′-tetrahydroxy-3,3′-dimethyl, 5,5′-bis(methylethyl)-2,2′-binaphthalene-8,8′-γ-dibutyrolactone. The trivial name "gossypol lactone" is suggested.

The total TA content was lower for each of the three susceptible lines than in the two resistant lines (Table 3). It is noteworthy that the gossypol content was essentially the same in squares of all of the glanded lines (0.12–0.15%). This suggests that resistant and susceptible lines both biosynthesize equal (basal) amounts of gossypol, and thus resistance is determined by other factors, perhaps other terpenoid aldehydes.

Hemigossypolone (Table 3) accounts for less than 10% of the TAs in squares of susceptible lines but over 20% of the TAs in resistant lines. The heliocides H_1 and H_2 are also increased sharply in resistant lines (two to fourfold). On the other hand, neither square gossypolone or gossypol lactone (M^+514) is increased above the "basal" levels in resistant lines. While they, along with gossypol, can be presumed to contribute some resistance, they do not appear to account for the increased resistance of the DH lines.

Gossypol lactone is probably an artifact arising from the oxidation and subsequent lactonization of gossypol during processing and/or storage. The distribution of TAs in leaves (Table 3) is somewhat different. The gossypol content is low compared to hemigossypolone and heliocides H_1 and H_2 in both a susceptible and a resistant line. The latter three are again higher in the resistant line than the susceptible line as compared with gossypol.

Chan et al. (1978), Stipanovic et al. (1977, 1978), and Hedin et al. (1983a,b) determined the inhibition of TBW larval growth expressed as ED_{50}, percent of diet, for several TAs including gossypol, hemigossypolone, and heliocide H_1. They averaged about 0.10%. Therefore, at least when reconstituted in diets, they have about the same level of toxicity. If this relationship

also exists in the plant sites that are encountered by the insect, resistance as mediated by TAs is related to the concentration in the tissue of importance.

Relationships of Cotton Plant Amino Acids to TBW Growth and Development. For background information, the total amino acids, free and bound, were determined by HPLC analysis (Cohen et al., 1986). Amino acid analysis data for ST 213 leaves, squares, and their parts; ST 213 gl anthers; DH 118 calyx crown; and the TBW Pack B (soy flour plus wheat germ) are summarized in Table 4. The total amino acid contents of calyx and calyx crown are the lowest (13.1% and 14.8%). Bracts and petals are intermediate (17.0% and 17.3%), and anthers are highest (22.5% and 23.7%). It is of apparent significance that the larvae migrate to, and complete their growth and development in, the tissue of highest protein content.

The total sugar content of anthers is known to be high relative to other square tissues and also is higher in lines susceptible to boll weevil oviposition (Hedin and McCarty, 1990). Nutritionally, therefore, anthers appear to be the most favorable cotton tissue development site for insects.

The distribution of the amino acids in the various tissues is similar, and the ratio of essential to nonessential amino acids (45–47%) has been found adequate for larval growth of the fall armyworm [*Spodoptera frugiperda* (J.E. Smith)] (Hedin et al., 1990). The only likely growth constraints may be that methionine (6.8%) in DH 118 calyx crown and arginine (9.9%) in Pack B are high relative to the other essential amino acids for optimum growth. The high arginine of Pack B is contributed mostly by the wheat germ. Wheat germ amino acids, as a synthetic amino acid diet, failed to support fall armyworm larval growth (Hedin et al., 1990). Analysis of cotton plant amino acids has been reported on numerous occasions in the literature, including Parrott et al. (1969) and Lindig et al. (1980). The results are similar.

Tables 5 and 6 provide information about the synthetic amino acid contents of diets that were formulated and used to investigate whether they could successfully support growth and development of TBW larvae. Using synthetic amino acids as the sole source of nitrogen is not novel. Evidently the first report of the use of synthetic amino acids for the growth of a cotton insect was that of Vanderzant (1965) for the boll weevil *Anthonomus grandis* Boh. Dadd (1985) reported in a review article on the rearing of several other insects on amino acid diets. We recently reported on the rearing of the fall armyworm with synthetic amino acid diets (Hedin et al., 1990). The replacement of plant protein with amino acids in diets being tested for effects of allelochemicals removes from conjecture the possibility that some unknown factor, perhaps bound to the protein, also may be affecting growth and development.

In these tests (Table 5) amino acid diets were formulated at the same nitrogen level supplied by the protein (diets 1 and 4), at a level increased 50% to

[a] Diets 2 and 5 were increased in the amino acid content by 50%; diets 3 and 6 were increased only with methionine and tryptophan.

determine whether the amino acid concentration was limiting (diets 2 and 5), and at the base level of diets 1 and 4 but with increased amounts of methionine and tryptophan whose analysis was thought to be low. Diets 1–3 were based on the distribution of amino acids in cotton anthers, and diets 4–6 were based on the distribution in the soy–wheat germ diet (Table 4).

Tables 1 and 6 give the ingredients of the formulated diets. Table 6 also lists larval weights at nine days, pupal weights, and days to pupation, along with the statistical information. As expected, insects fed the standard laboratory diet grew more rapidly and pupated sooner. However, insects on the three cotton anther amino acid diets (diets 1–3) achieved pupation having pupal weights only somewhat lower than those on the standard diet. The days to pupation were longer. Increasing the level of amino acids by 50% (diet 2) had an adverse effect compared to diet 1. Increasing the methionine and tryptophan (diet 3) improved the growth rate through nine days, but the improvement was not sus-

tained through pupation. Larval growth on the soy-wheat germ-based amino acid diets 4 and 5 did not occur. With added methionine and tryptophan (diet 6), however, acceptable growth and development took place.

The growth lag can perhaps be explained by the need for insects to develop mechanisms to transport and metabolize the free amino acids. The somewhat poorer growth observed on the cotton anther-based amino acid diet 2 can probably be explained by the high amino acid-carbohydrate ratio. Phytophageous insects have been reported to grow best on diets in which the protein and carbohydrates each contribute about one third of the nutrients (Dadd, 1985). The poorer performance of the soy-wheat germ diets relative to the cotton anther diets may be in part explained by the high arginine content of diets 4–6.

The overall performance of these amino acid diets is similar to that observed with the fall armyworm (Hedin et al., 1990). In these present tests, all 10 amino acids reported as essential for rats were included in each of the tests. Dadd (1985), in reviewing the literature, reported that for specific insects additional

amino acids were found to be essential for insect growth. As previously stated, the growth and development observed in these tests was not as rapid as with the standard diet, but presumably could be optimized if desired. However, the present results established that the TBW can be reared successfully on synthetic amino acid diets, evidently for the first time. Moreover, the establishment of effective amino acid diets means that the effects of allelochemicals can be evaluated free from the effects of undefined growth factors.

SUMMARY

Chemical evidence has been obtained that explains, in part, observations about the migration of tobacco budworm larvae from terminal leaves to the square, their avoidance of calyx crowns that are high in gossypol glands, and their burrowing into the anthers where they develop.

The calyx crown of resistant lines was found to be higher in terpenoid aldehydes than in susceptible lines. HPLC data showed that the gossypol content of both susceptible and resistant lines is equivalent (basal), while the hemigossypolone and heliocides H_1 and H_2 are greatly increased in resistant lines and presumably are more closely associated with resistance.

Analysis for total amino acids in cotton square tissues showed that there was a gradation of levels from the leaves, calyx, and calyx crown, which were low; to the petals and bracts, which were intermediate; and to the anthers, the site of final development, which was highest. Amino acid diets based on their distribution in anthers were found to be successful for larval growth and development.

(Received November 9, 1990; accepted February 11, 1991)

Abstract—The iridoid glycoside antirrinoside was found to be sequestered by highly aposematic larvae of the geometrid moth *Meris paradoxa* and two noctuid moth *Lepipolys* species feeding on *Maurandya antirrhiniflora* (Scrophulariaceae), a natural food plant from southern Arizona. The antirrinoside content of leaves and petioles being consumed, early-instar larvae, late-instar larvae, larval frass, regurgitant, reflex-bleeding emission (*Meris paradoxa*), cocoons, pupae, meconium emitted upon eclosion, and adult moths was determined. Larvae, other than the earliest instars, did not excrete antirrinoside in the frass, but sequestered it in amounts of 3–11% of the dry weight. Small amounts of antirrinoside remained in various pupal or cocoon parts and some was emitted in the meconium upon eclosion. The total antirrinoside accounted for was, however, considerably below that expected based upon the remarkably high 20% content of the leaves and petioles being consumed. The adult cryptic moths of both species contained little or no antirrinoside. This is the first report of a natural food plant and larval stages for *M. paradoxa* and a previously undescribed *Lepipolys* species. It is also the first report of antirrinoside sequestration and utilization by insects.

Key Words—*Meris paradoxa, Lepipolys perscripta*, Lepidoptera, Geometridae, Noctuidae, *Maurandya antirrhiniflora, Antirrhinum majus*, Scrophulariaceae, antirrinoside, iridoid glycosides, herbivory, sequestration.

INTRODUCTION

Specialist Lepidoptera whose larvae feed on plants containing iridoid glycosides ("iridoids") process and sequester these bitter substances in a variety of ways (Bowers and Puttick, 1986; Stermitz et al., 1986, 1988; Franke et al., 1987; Bowers, 1988; Gardner and Stermitz, 1988; L'Empereur and Stermitz, 1990a,b). In previous studies, sequestration of the iridoids catalpol, aucubin, and macfadienoside in several percent of the dry weight of the insect has been established. In cases where esters of catalpol are the major food-plant iridoids (Gardner and Stermitz, 1988; L'Empereur and Stermitz, 1990b), larvae hydrolyze the esters, sequester the resultant catalpol, and excrete or metabolize the acylating acid. Where both larval and adult stages of the insect are aposematic (boldly patterned and/or colored), both contain sequestered iridoids. Where the larval stage is aposematic and the adult stage is cryptic, the adults contained little or no iridoids, having left most in the meconium emitted upon eclosion.

In one such case (Stermitz et al., 1988), the larvae of two different taxa, *Meris alticola* and *Neoterpes graefiaria* (both geometrids), were both black and white striped with gold–yellow spots; it was suggested that Müllerian mimicry might be involved. Recently, similarly colored black and white banded geometrid larvae were observed utilizing *Maurandya antirrhiniflora* (Scrophulariaceae; Antirrhineae) in southern Arizona. These larvae were determined to be the previously undescribed immature stage of the moth *Meris paradoxa*, whose food plant was also previously unknown. The same plant species also supported noctuid larvae exhibiting a pattern of bright yellow, black-ringed spots on a gray background. These were determined to be larval stages of a previously undescribed moth, closely related to *Lepipolys perscripta*. Finally, a winter-collected adult female of *L. perscripta* was collected at a UV light, and larvae from its eggs were found to readily consume *Maurandya antirrhiniflora*. *Maurandya* belongs to the tribe Antirrhineae of the Scrophulariaceae, and the tribe is known to characteristically contain the iridoid antirrinoside. We therefore undertook a study designed to identify iridoid(s) of *Maurandya*, to determine if any were sequestered and, if so, to quantify the patterns of processing and sequestration among the various life stages of the hosted moth species.

METHODS AND MATERIALS

Organisms. The original collections of larvae on the food plant were made on August 23, 1986, above the town of Bisbee, Cochise County, Arizona, on the north slope of Higgins Hill. The food plant, determined to be the perennial *Maurandya antirrhiniflora* Willd., is also cultivated in Arizona gardens and is known as the snapdragon vine. In a recent revision of the tribe Antirrhineae (Sutton, 1988), readoption of its previous designation as *Maurandella antir-*

rhiniflora (Willd.) Rothm. was suggested. The taxon will simply be called *Maurandya* in this report. Additional plants were grown from seed in Ash Canyon, south of Sierra Vista, Arizona, and in the greenhouse at Colorado State University.

One collected group of 3- to 4-cm-long larvae were boldly patterned with black and white bands and black and yellow–orange spots (Figure 1). These were fed on *Maurandya* until pupation. Gray, slightly dark-spotted adults emerged from hanging, hammocklike cocoons 25–30 days after pupation. These were identified as *Meris paradoxa* Rindge by Frederick H. Rindge of the American Museum of Natural History, New York. The moth had been described from collected adult males as a new species (Rindge, 1981), whose food plant, larval stages, and female adult stage were unknown. Three Arizona field-collected moths (one female and three males) also were available for analysis.

The second group of collected larvae, also 3–4 cm long, were boldly patterned in gray, yellow, and black (Figure 2). Gravid adult females were collected at a UV light in the SE Huachuca mountains (5354 Ash Canyon Road, Cochise County, Arizona) on September 20, 1989. Their progeny were raised

FIG. 1. Larva of *Meris paradoxa*.

FIG. 2. Larva of *Lepipolys* (undescribed).

from eggs on *Maurandya*. Pupae were bare if last-instar larvae were placed in empty jars but were contained within a sand-covered capsule if the larvae were placed in a jar containing sand or sandy soil. The emergent adults were identified as an undescribed species of *Lepipolys* (Noctuidae) by Robert W. Poole, Systematic Entomology Laboratory, United States Department of Agriculture, Washington, D.C. The larvae were identical to those field-collected on *Maurandya*. The moth will be denoted as *Lepipolys* (undescribed), awaiting a complete description by Poole.

True *L. perscripta* Gn. (also identified by Poole) were obtained from eggs from a gravid female collected at the UV light on March 20, 1988. Larvae were colored and patterned considerably differently from those of *Lepipolys* (undescribed) but corresponded to the original description of *L. perscripta* (Dyar, 1903). The larvae were virtually identical with those depicted in a black-and-white drawing (Comstock, 1958). They were raised to adults on *Maurandya*.

Because of the large number of September 1989 brood larvae, insufficient *Maurandya* was available to carry all larvae to pupation on that food plant. Larvae did, however, readily consume leaves and flowers of the common garden snapdragon, *Antirrhinum majus* L., and this proved to be a useful alternate host.

Larvae were held in Petri dishes with fresh *Maurandya*, and frass was collected and air-dried before weighing and analysis. Larvae and pupae were weighed, crushed into methanol, and the mixture allowed to stand for 24 hr at room temperature (or more extended periods in the refrigerator or freezer). After the mixture was filtered, the methanol was evaporated to dryness and the residue used directly for iridoid analyses. Adult moths were treated similarly. Agitation of larvae of *Meris paradoxa* resulted in emission of yellow droplets from intersegmental membranes. Reflex-bleeding droplets were collected in a microliter pipet and the volume recorded. The material was washed out with a little methanol and the residue, after evaporation (unweighed), was analyzed for total antirrinoside. Pupae were placed in a large glass vial containing filter paper in the bottom, which collected meconium emitted upon eclosion or shortly thereafter. The paper was extracted with methanol, the methanol evaporated, and the residue (unweighed) analyzed for total antirrinoside.

Iridoid Glycoside Analyses. Quantitative iridoid glycoside analyses of plants or plant parts, larvae, excretion products, pupae, and adult moths were by gas chromatography (GC) of the trimethylsilyl ether derivative as previously described in detail (Gardner and Stermitz, 1988).

In a large-scale determination, 100 g fresh weight of *Maurandya antirrhiniflora*, collected in Arizona, was soaked in methanol for 48 hr, filtered, and the methanol evaporated to leave a gum, which was triturated with water. The water layer was washed with diethyl ether, evaporated, and the residue triturated with absolute methanol. The methanol was evaporated to leave 2.0 g of

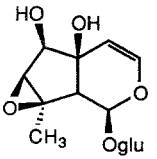
a semisolid "crude" iridoid preparation, the content of which was examined by NMR and GC analysis.

RESULTS

Plant Analyses. [^{1}H]NMR analysis of the "crude" iridoid residue from field-collected *Maurandya* showed that this preparation was at least 95% antirrinoside (Scheme 1). This was confirmed by [^{13}C]NMR and GC analysis. Pure antirrinoside for a GC standard was obtained by vacuum liquid chromatography (VLC). The large-scale isolation indicated an approximate antirrinoside content of 2% wet weight or about 10% dry weight based on 80% volatiles (see below).

More detailed analyses of the antirrinoside content of two large greenhouse-grown plants (whose leaves were used for larval feeding) were conducted at various times during the course of the study, using the quantitative GC method of analysis. Individual green stems contained 14–20%, petioles 12–31%, and leaves 4–36% dry weight antirrinoside. Older living, but not green stems contained 1–9%. Larvae consumed only petioles and leaves, with the petioles (N = 5) averaging 22% and the leaves (N = 11) averaging 18% antirrinoside. Since larvae consumed many dozens of leaves and petioles during their growth, the average antirrinoside content of about 20% dry weight is probably a reasonable estimate of intake in spite of a high variability among individual leaves and petioles. The percent volatiles (loss of weight on drying) were 69–75% for stems, 71–83% for petioles, and 77–87% for leaves. The garden snapdragon, *A. majus*, used to supplement larval feeding in one experiment, showed a leaf analysis of 5.8% dry weight antirrinoside.

Lepipolys perscripta. Data from an April 1988 study was limited to six larvae raised on *Maurandya* and is not complete through all life stages because of the small number available. Some useful data were obtained, however, particularly those resulting from frass analysis (Table 1). Early-instar larvae were not completely efficient at sequestration or at plant digestion, since considerable antirrinoside was found in the frass. Insignificant antirrinoside was found in frass throughout the remainder of the instars, except for the final, reddish-col-



antirrinoside

[f] Wild-caught.

ored frass excreted just before entering diapause. When larvae would no longer consume plant material and began to wander, they were transferred to vials containing filter paper on the bottom. Larvae continued to wander rapidly for several days before pupating. During this time they attempted to chew the filter paper (but would not consume plant material), and deposited mouth secretions on the paper. This secretion or regurgitant contained antirrinoside, as did the last instar skin molt (Table 1). Four pupae (Nos. 1–4, Table 1; two living and

then frozen and two that did not develop) contained small amounts of antirrinoside as did the pupal case and meconium of the one adult (No. 5) that emerged. The adult (from which the abdomen had been removed for dissection and identification) contained a trace amount of antirrinoside. Four adult moths (Nos. 6–9, Table 1), collected in the field in March 1988, showed at most traces of antirrinoside, as did the eggs from two.

Lepipolys (undescribed). Of two last-instar larvae obtained from *Maurandya* in the field (September 1987), one was analyzed for antirrinoside after it was removed from food for 24 hr. The larva (114 mg dry weight) contained 11.6 mg (10%) antirrinoside. The second larva was placed on sandy soil for pupation, but did not survive. The same site was searched in 1988 and 1989, but no larvae were found. Subsequent studies were performed on insects lab-raised from eggs laid by wild-caught females.

[a] Larvae fed *M. antirrhiniflora.*
[b] Larvae fed *A. majus.*
[c] Pupae died and desiccated before eclosing.

Five larvae (Nos. 1–5, Table 2, fed on *Maurandya*) contained 3.7–10.7% dry weight antirrinoside, while three larvae (Nos. 9–11, Table 2, fed on *A. majus*) contained 5.5–11.2% antirrinoside.

Last-instar larvae, which had been raised on greenhouse *Maurandya*, were provided with jars containing sand and a few leaves for pupation. For pupation, larvae constructed capsulelike pupal cells of sand particles, which enclosed the pupae proper. Pupae contained only traces of antirrinoside, whether they died and desiccated (Nos. 13–16) or were analyzed while still apparently viable (Nos. 17–22). The pupal cells contained no antirrinoside (Nos. 18–23) nor did the emergent adult moths (Nos. 24–32). The combined meconium from these moths contained a small amount of antirrinoside.

Meris paradoxa. Data on this moth (Table 3) were limited since gravid

females were not captured. Six larvae, collected in the field from *Maurandya* in September 1987, were available for study. No larvae were found in 1988 or 1989. Of the six larvae, two succumbed before data collection. Of the four remaining, two yielded larval data (Nos. 2 and 3, Table 3), while two were raised through to adulthood. Of the two adults, only part of one (No. 1, Table 3) was available for antirrinoside analysis. The abdomen of that one and the entire other (No. 4) were needed for taxon identification. Adults from earlier McFarland field collections however, were available for analysis (Nos. 5–7).

DISCUSSION

With this work, we have established *Maurandya antirrhiniflora* as another lepidopteran larval food plant that serves as a source for a sequestered iridoid glycoside. Antirrinoside has been identified as an additional sequesterable iridoid. Highly aposematic larvae of a geometrid moth (*Meris paradoxa*) and two noctuid moths (*Lepipolys* species) have been shown to contain large amounts of antirrinoside, while their cryptic adult stages contain at the most traces of the iridoid. This aposematic larva/cryptic adult correlation with the presence/absence of an iridoid glycoside is similar to those previously identified for the sphingid *Ceratomia catalpae* (Bowers and Puttick, 1986) and the two geometrids *Meris alticola* and *Neoterpes graefiaria* (Stermitz et al., 1988).

Leaves and petioles of *Maurandya* were found to contain remarkably high concentrations of antirrinoside, averaging 20% dry weight, while the highest concentrations observed in any insect life stages were around 10% in larvae. Total plant material and total iridoids consumed by larvae were not measured in any of the experiments, but rough estimates of food intake can be made from the weight of frass excreted and the weight of larvae or newly formed pupae. These estimates (along with the average plant iridoid content) suggest that individual larvae are consuming on the order of 30–80 mg of iridoid glycoside. The most found (sequestered, excreted, and emitted) is of the order of 5–10 mg per individual. This indicates that consumed iridoids are being metabolized. How much of this is due to the larvae themselves or to gut microflora is not known. It seems likely that iridoids continue to be metabolized during the pupal stage, but since none are taken in, the concentration drops markedly.

Catalpol was found previously in a reflex-bleeding secretion emitted by disturbed larvae of *N. graefiaria* (Stermitz et al., 1987). A similar secretion by *Meris paradoxa* was found in the present case, with about 0.7 mg of antirrinoside being emitted in a typical 10-μl drop. Whether the secretion represents hemolymph or that of a special organ is not known, but the high iridoid concentration should give the secretion a bitter taste. The secretion is usually a clear yellow–orange color, and a droplet is nearly identical in both size and

color to the series of lateral spots on the larvae. Although we have no direct evidence for the possible deterrence of the secretion, one might hypothesize that the larval spots are mimics of the secretion.

Larvae fed on *A. majus* (about 6% dry weight antirrinoside) appeared to contain slightly more iridoid than those fed on *Maurandya* (20% dry weight antirrinoside), but the number of larvae analyzed (three of each; Nos. 7–12, Table 2) was small and a statistical analysis was not warranted.

The larval stage and food plant of *Meris paradoxa* were not previously known nor was the larval stage for the undescribed species of *Lepipolys*. An official description of this taxon, whose adults are present in a number of collections, will be published elsewhere (R. Poole, personal communication). *L. perscripta* larvae were reported previously to utilize *Linaria canadensis* Dum. (Dyar, 1903) and *Antirrhinum nuttallianum* Benth. (Comstock, 1958). These belong to the tribe Antirrhineae, many of whose taxa contain antirrinoside (Sutton, 1988, pp. 54–56). It seems likely that other lepidopteran sequestrations of this iridoid glycoside will be discovered.

(Received October 23, 1990; accepted February 12, 1991)

Abstract—The saponin and canavanine concentrations and pattern were analyzed in growing alfalfa seedlings (*Medicago sativa* L.). Accumulation of saponins and canavanine was found to follow different time courses. During the first eight days, saponin concentration rose from zero in alfalfa seeds to 8.7% in roots and 1.8% in shoots on eighth day and then slowly decreased to 7.6% in roots and 0.8% in shoots present on the 24th day. Canavanine was found in seeds at a concentration of 1% then increased to 3.2% in seedlings on the sixth day and rapidly decreased to 0.2% per dry mass in roots and shoots on the 24th day. The effect of saponins—medicagenic acid sodium salt and medicagenic acid glycosides—on the growth of *Amaranthus* and *Lepidium* in Petri dishes and tomato (*Lycopersicon*) cell growth in tissue culture also was investigated. In contrast to medicagenic acid glycosides, a very strong inhibition of plant and cell growth was found as an effect of medicagenic acid.

Key Words—Saponins, medicagenic acid, medicagenic acid glycosides, canavanine, biological activity, alfalfa.

INTRODUCTION

Alfalfa contains some biologically active substances like saponins (Pfüller, 1976; Birk, 1969; Oleszek and Jurzysta, 1987), toxic amino acids (Bell, 1980),

*To whom correspondence should be addressed.

0098-0331/91/0600-1135$06.50/0

phenolics (Abdul-Rahman, 1989), and quaternary ammonia bases (Pfüller, 1976), some of which are recognized as allelochemicals (Wilson and Bell, 1978; Rosenthal, 1983; Oleszek and Jurzysta, 1987). Saponins were found to show inhibitory effects on plant germination (Jurzysta, 1970; Ream et al., 1977; Oleszek and Jurzysta, 1986; Read and Jensen, 1989) and fungal growth (Assa et al., 1975; Polacheck et al., 1986). These compounds also act as antifeedants to animals (Birk, 1969) and cause hemolysis of red blood cells (Gestetner et al., 1971). Saponins were found to be present in the soil, and their allelochemical function was shown. Alfalfa contains biologically active saponins of medicagenic acid which, among other effects, causes blood hemolysis and fungal growth inhibition (Oleszek and Jurzysta, 1987).

Another plant constituent, canavanine, also exhibits high biological activity affecting microorganisms, plants, animals, and especially insects. This toxic secondary plant product is related structurally to arginine and can be activated by arginine-tRNA synthetase yielding aberrant proteins in insects as well as in other animal organisms (Rosenthal, 1977; 1982). In plants canavanine acts as an allelochemical and reduces, e.g., the growth of radicles (Wilson and Bell, 1978), but the biochemical cause is still unknown. Chemical structures of both compounds are presented in Figure 1.

The present paper deals with changes of saponin and canavanine concentrations in growing alfalfa seedlings, and we attempt to determine whether these compounds are released into the environment. In addition the effect of pure saponins on germination of test plants and growth as well as the effect on tomato suspension culture growth was investigated.

METHODS AND MATERIALS

Plant Material. Seeds of alfalfa (*Medicago sativa* L. var. Verko), collected in 1987, were purchased from the Station of Plant Production, Langenstein, Germany. For cultivation of seedlings under sterile conditions the seeds were surface sterilized for 1 min in an aqueous solution of 0.1% of mercury chloride and washed six times with 5 ml of double-distilled water. Subsequently, the seeds were germinated for two days in darkness at 27–29°C and 80% humidity on paper disks in Petri dishes of 8 cm in diameter. After three to four days two seedlings were transferred to one plastic holder in centrifuge tubes of 50 ml containing 6 ml of Knop solution (per liter double-distilled water: 1 g $Ca(NO_3)_2$; 0.25 g $MgSO_4 \cdot H_2O$; 0.25 g KH_2PO_4; 0.25 g KNO_3; 50 mg $FeSO_4$, and 1 ml of trace element solution: 55 mg $Al_2(SO_4)_3$; 28 mg KJ; 28 mg KBr; 55 mg TiO_2; 28 mg $SnCl_2 \cdot H_2O$; 28 mg LiCl; 389 mg $MnCl_2 \cdot 4H_2O$; 614 mg $Ba(OH)_2$; 55 mg $ZnSO_4$; 59 mg $Co(NO_3)_2$; 55 mg $CuSO_4 \cdot 5H_2O$ per liter). Furthermore, the seedlings were cultivated for 24 days at 27–29°C and 80%

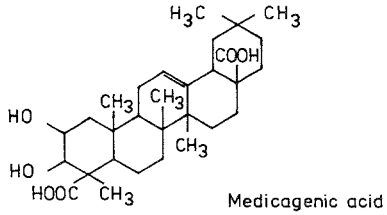

FIG. 1. Chemical structure of medigagenic acid and canavanine.

humidity with a 12 : 12hr light–dark period. After 10 days 2 ml of Knop solution was added to each tube. The seedlings were grown under sterile as well as nonsterile conditions in plastic pots of 7 × 9 cm with a sandy bed 2.5 cm high (mesh size 0.6–1.9 mm, at 20°C, in daylight) and 10 ml Knop solution.

Biotests. The influence of canavanine, medicagenic acid, and medicagenic acid glycosides on cell growth of tomato suspension culture (*Lycopersicon esculentum* Mill cv. Lukullus) was measured as described by Grancharov et al. (1985). The experiment was begun by inoculation of cells and the applications of a filter-sterilized solution of the compounds at concentrations of 10^{-3}–10^{-7} M. Inhibition of radicle growth of amaranth (*Amaranthus caudatus* L.) and cress (*Lepidium sativum* L.) was estimated during a period of seven days at 20°C and 6000 lux. The plant seeds were numbered on a paper disk in Petri dishes of 9 cm diameter (*Lepidium*) or 5 cm diameter (*Amaranthus*) saturated with 5 ml of water (control) or 5 ml water containing the compounds. After two to four days, the radicle length was measured and analyzed statistically by F, t, and χ^2 test.

Chemical Analysis. Canavanine sulfate was purchased from Serva (Heidelberg, Germany) and isolated according to Rosenthal (1973) and Natelson and Bratton (1984). Canavanine-containing fractions obtained from biological materials were purified by cation-exchange chromatography and calibrated by colorimetric estimation with pentacyanoammonium ferrate according to Natelson and Bratton (1984). Canavanine was analyzed by TLC of dansylated canavanine (Miersch et al., 1990). Medicagenic acid glycosides were extracted from alfalfa shoots with 80% ethanol. The ethanol was largely evaporated and the water phase extracted five times with *n*-butanol. The butanol was removed, and the crude saponins contained in residue were dissolved in water. Subsequently, saponins were precipitated with cholesterol and isolated after centri-

fugation. After decomposition of the saponin–cholesterol complex with hot pyridine, the saponins were precipitated from pyridine with ethyl ether. The precipitate contained a mixture of some medicagenic acid glycosides. Pure medicagenic acid was obtained by acidic hydrolysis of the glycosides. Because this compound is practically insoluble in water, the disodium salt of medicagenic acid was prepared (Gorski et al., 1984). Saponin concentrations were determined by *Trichoderma viride* biotest measured the inhibition of fungal growth (Jurzysta, 1979a) and hemolytic test (hemolysis of red blood cells) according to Jurzysta (1979b).

RESULTS AND DISCUSSION

Saponin and Canavanine Content and Pattern in Alfalfa Seedlings. In alfalfa seedlings, the accumulation of medicagenic acid and canavanine was found to follow different time courses. During the first eight days, the amount of medicagenic acid rose from zero in seeds to 2 mg per 10 seedlings of alfalfa, whereas canavanine increased from 0.2 to 0.4 mg. In older seedlings, the saponin reached 11 mg present on the 24th day. In this time range, the amount of the toxic amino acid canavanine decreased to 0.25 mg (Table 1). If we use the terms in relation to dry mass, the concentration of canavanine was about 1% in alfalfa seeds, while no biologically active saponins were present. During the time of seedling growth, the concentration of these two compounds changed rapidly (Figure 2). The most important finding is that the maxima of saponin and canavanine concentrations are different in different stages of seedling development.

[a] Data obtained are given per 10 seeds or seedlings.
[b] Calculated according to Miersch et al. (1988, 1990).

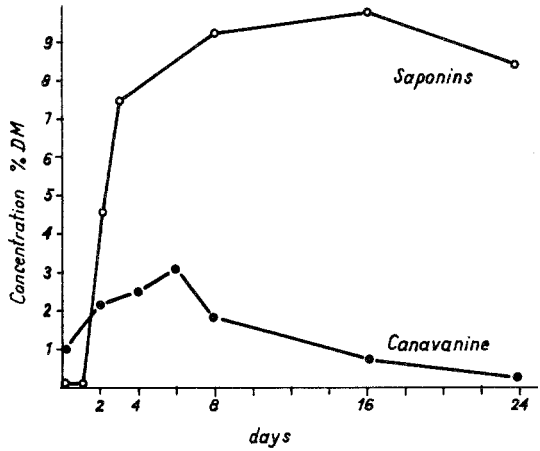

FIG. 2. Concentration of saponin and canavanine in alfalfa seedlings.

Concentrations of saponins and canavanine in alfalfa seedlings were analyzed under both sterile and nonsterile conditions. With respect to chemical composition, no differences were found in the two samples.

During the experiment we also analyzed the release of saponin and canavanine from seedling to culture medium and paper disks. In the nutrient solution of 8-, 16-, and 24-day-old healthy seedlings, no saponin was found. Hemolysis tests with seedlings also proved that saponins did not penetrate from roots as long as they were intact. In contrast, saponin efflux was detected from cut and dead sections of both roots and shoots. As shown previously, canavanine penetrates from alfalfa roots into the nutrient solution; however, when the seedlings grew in water, no canavanine was found (Miersch et al., 1988).

Effect of saponins on growth of radicle of Lepidium *and* Amaranthus. Medicagenic acid sodium salt has a very strong effect on the growth of *Lepidium* and *Amaranthus*. The results obtained are shown in Table 2. *Lepidium* proved to be more sensitive than *Amaranthus*, especially at higher concentrations. Saponins have a similar influence on the growth of cereal, cotton, and some other plants (Jurzysta, 1970) and animal cell cultures (Slotwinska, 1983).

Growth inhibition on *Lepidium* and *Amaranthus* caused by pure canavanine sulfate is remarkable: 21% and 13%, respectively, were found at concentrations of 10 μM. Statistical analysis of these data showed high significance: *Lepidium* $\chi^2 = 17$ (table = 15, 0.05%) and *Amaranthus* $\chi^2 = 47$ (table = 28, 0.01%). The sulfate ion in canavanine sulfate has no effect in the used concentration of 10 μM as was controlled by potassium sulfate. In contrast to the findings with seedlings of amaranth and cress, the growth inhibition of tomato cell suspen-

TABLE 2. EFFECT OF MEDICAGENIC ACID SALT ON RADICLE GROWTH OF *Lepidium* AND *Amaranthus*

Plant	Concentration (M)	Length of radicle ± SD (mm)	Inhibition of growth (%)
Lepidium sativum 3 days	0	21.24 ± 7.81	0
	5×10^{-6}	20.95 ± 6.05	0
	10^{-5}	24.88 ± 5.21	−17[a]
	2.5×10^{-4}	9.50 ± 7.30	55

	2.5×10^{-3}	12.08 ± 4.23	53

[a] = 17% increase.

sion, measured to be 35% in four days, was more sensitive (Miersch et al., 1988).

In experiments with alfalfa seedlings grown together with other plants (e.g., *Brassica oleracea*), we also found growth inhibition (Miersch et al., 1988). The release of canavanine from roots of alfalfa was observed and a concentration of 3–57 μM was calculated under experimental conditions (Miersch et al., 1990). Because canavanine was found in the solution, sand, or on the paper disks (Miersch et al., 1990), these inhibitory effects seem to be caused by canavanine or some other substances rather than by saponins.

Effects of Saponins on Tomato Tissue Culture. In the tissue culture experiment, we used aqueous solutions of medicagenic acid as its sodium salt (because of better water solubility) and medicagenic acid glycosides isolated from alfalfa. In contrast to medicagenic acid, its sodium salt and glycosides are highly water soluble.

As shown in Table 3 and Figure 3, a very strong inhibitory effect on tomato cell growth was found. At 10^{-5} M, all cells were lysed on fourth day of the experiment. In contrast, for unknown reasons, medicagenic acid glycosides caused only low inhibition (Table 4).

During seedling development (see Figure 2 and Table 1), different amounts

of saponins and canavanine were observed. In addition, penetration of both substances into the root space is different. Therefore, we assume that under our experimental conditions: (1) There is no release of saponins from intact alfalfa seeds and seedlings to the environment, and no allochemical influence of saponins on other plants surrounding the alfalfa seedlings may be expected. Oleszek and Jurzysta (1987) found medicagenic acid to be present and active in soil after cultivation of alfalfa; however, these saponins were released into the soil from decomposed roots and stems after harvesting. (2) Further experiments are needed to clarify the release of small amounts of other phytotoxic and nontoxic compounds present in the green parts of alfalfa (Pfüller, 1976; Read and Jensen, 1989). (3) Furthermore, the question arises whether there is any synergistic effect of canavanine and saponins with other compounds, as was discussed for canavanine and amino acids during the growth of *Lemna* by Rosenthal et al. (1975).

Acknowledgments—The authors wish to thank Dr. M. Jurzysta of Institute of Soil Science and Plant Cultivation for the donation of the sample of medicagenic acid glycosides and Mrs. M. Dübler for her skillful assistance. We are grateful to Prof. Dr. W. Francke of Institute of Organic Chemistry, University Hamburg, for kindly reading the manuscript.

SEASONAL VARIABILITY IN RESPONSE OF *Ips pini* (COLEOPTERA: SCOLYTIDAE) TO IPSDIENOL IN NEW YORK

STEPHEN A. TEALE* and GERALD N. LANIER[1]

(Received October 29, 1990; accepted February 12, 1991)

Abstract—In May, *Ips pini* in New York did not respond in the field to 50–98.5% (*R*)-(−)-ipsdienol (synthetic). In September, beetles responded strongly to 50–60% (*R*)-(−)-ipsdienol (synthetic). In May and June, New York beetles showed marked preference for their own males over Arizona males, which produce an average of 94.1% (*R*)-(−)-ipsdienol. This suggested that ipsdienol stereochemistry alone does not ensure activity and that an additional compound is necessary for attraction in May. In the second year of field tests, attraction to synthetic ipsdienol and male beetles was tested in the spring, summer, and fall. There was response only to males in the spring and mid-summer and to both males and synthetic ipsdienol in the late summer and fall, causing a significant treatment × sampling period (date) interaction. Laboratory-reared beetles were not significantly more attracted to ipsdienol than to a blank airstream in laboratory assays, while male volatiles were significantly more attractive than ipsdienol and the blank. These data demonstrate that there is one or more unknown semiochemicals necessary for pheromonal response and that the behavioral activity of synthetic ipsdienol varies seasonally.

Key Words—Insecta, Coleoptera, Scolytidae, *Ips pini*, pheromone, ipsdienol, seasonal variation, bioassay.

INTRODUCTION

Several bark beetle species undergo seasonal changes in their pheromone systems. Female *Dendroctonus brevicomis* LeConte were totally unresponsive to

*To whom correspondence should be addressed.
[1]Deceased.

0098-0331/91/0600-1145$06.50/0

their pheromones from October to January in laboratory bioassays (Silverstein et al., 1968). Laboratory studies also found that *Ips paraconfusus* Lanier were least responsive to their pheromones during January and February (Wood and Bushing 1963; Borden 1967). Birch (1974) found that in *Ips pini* (Say) the intensity of both response in laboratory bioassays and pheromone attractiveness decreased in winter. Hagen and Atkins (1975) reported that overwintered *I. paraconfusus* contained significantly more fat and were less responsive to attractants than the spring generation. Likewise, *D. pseudotsugae* with high fat content tend to be unresponsive to attractants, and those with low fat content tend to be more responsive to attractants (Atkins 1966). Hagen and Atkins (1975) predicted that the overwintered generation of *I. paraconfusus* would be less amenable to semiochemically based management compared to the spring generation due to their lower responsiveness to attractants.

The terpene alcohol ipsdienol (2-methyl-6-methylene-2,7-octadien-4-ol) was reported as the male-produced "aggregation" pheromone of the pine and spruce infesting bark beetle *I. pini* (Lanier et al., 1980; Birch et al., 1980). More recently, we observed lack of responsiveness of *I. pini* to synthetic ipsdienol in the field in the early summer. Previous field tests in which synthetic ipsdienol was attractive to *I. pini* in New York were done in August and September (Lanier et al., 1980). At least two changes occur in the biology of *I. pini* between spring and late summer. First, there is typically an increase in population density in late summer as the spring and early summer broods emerge (Schenk and Benjamin 1969). Second, in the late summer, *I. pini* frequently engage in high-density feeding attacks in the western states (Sartwell et al., 1971) and in New York (authors' personal observation). The changes in population density and colonization behavior may be related, and both may be related to an intergenerational difference in fat content such as that reported by Hagen and Atkins (1975). It appeared to us that there may be seasonal changes in the pheromone system of *I. pini* associated with seasonal changes in biology. We report a series of experiments that measured the response of *I. pini* to synthetic ipsdienol and natural attractants in the field in the spring, summer, and fall, and laboratory bioassays comparing response to synthetic ipsdienol and natural attractants.

METHODS AND MATERIALS

Field Sites. In 1987, experiments were conducted in a mixed stand of red (*Pinus resinosa* Ait.) and Scots (*P. sylvestris* L.) pine in the southwestern Adirondack Mountains, near Forestport, New York. Thinning in parts of the stand in late 1986 and throughout 1987, and previous logging in adjacent stands, provided abundant host material in which a large population of *I. pini* devel-

oped. In 1988, an experiment was conducted in a mixed red and Scots pine stand 25 km south of Syracuse, New York, which had been thinned the previous summer and fall. A large amount of slash was available for colonization by *Ips*.

Field Test of Synthetic Ipsdienol Enantiomers in Two Seasons. This experiment was designed to determine if the specificity of response to ipsdienol enantiomeric blends varied with season. The enantiomeric compositions were 98.5%, 90%, 80%, 70%, 60%, and 50% (*R*)-(−)-ipsdienol (Phero Tech Inc., Delta, British Columbia) and a solvent (ethanol) control. Each dispenser contained 10 mg ipsdienol in ethanol, except for an additional treatment of 10 mg 50% (−)-ipsdienol in pentane. The optical purity of the ipsdienol enantiomers was 98.5% (*R*)-(−) and 98% (*S*)-(+). The dispensers were 3.7-ml polyethylene vials (Olympic Plastics), which released 35 μg/day. The release rate was determined by aerating the release device ($N = 3$), collecting volatiles on Porapak Q over seven days at 22°C, and quantifying on capillary GC. Sixteen eight-unit multiple-funnel traps (Lindgren, 1983) (Phero Tech Inc.), were spaced 10 m apart in two rows. Each row received one of each treatment in randomized order. The experiment started on May 26, 1987, and insects were removed from the traps on May 29. The treatment positions were rerandomized and new attractants with the same type of dispenser and release rate were placed in the traps on September 3, 1987. Insects were removed from the traps and treatment positions were rerandomized on September 6, 8, 11, 14, and 17. Treatments of 25% and 40% (−)-ipsdienol were used in May and September, respectively, to determine if there was greater response below 50%, but were not included in the analysis.

Field Test of Beetle-Produced Ipsdienol Enantiomers. This experiment compared the specificity of response to natural ipsdienol enantiomers with that to synthetic enantiomers. If the specificity of response was different for synthetic ipsdienol and natural material with the same range of enantiomers, then compounds other than ipsdienol must play a role in specificity. A range of enantiomers could be obtained by using various proportions of males from eastern and western populations of *I. pini* (Stewart, 1975; Birch et al., 1980; Miller et al., 1989). The treatments were the following numbers of emergent New York and Arizona male *I. pini* introduced into 15 × 30-cm fresh red pine logs from Tully, New York (NY–AZ): 20–0, 15–5, 10–10, 5–15, and 0–20 (20 males/log/trap). The Arizona beetles were taken from a laboratory colony originating in *Pinus ponderosa* Laws. in Young, Arizona, in August 1986 and reared on red pine in the laboratory. Males from the Arizona laboratory colony produce an average of 94.1% (−)-ipsdienol based on aerations of individual males on red pine, collection of volatiles on Porapak Q (Byrne et al., 1975), and enantiomeric determination (Slessor et al., 1985). The New York beetles were collected from red pine near Tully, New York. Beetles were introduced into the phloem through 5-mm-diam. holes and covered with a patch of aluminum win-

dow screen. The logs were enclosed in fiberglass mesh bags to prevent feral attacks. An uninfested log served as a control. The logs were nailed to plywood covers (40 × 40 cm) and suspended in hardware cloth cylinders (30 cm diam. × 40 cm high) coated with insect trapping adhesive (Tangle-trap, Tanglefoot Company, Grand Rapids, Michigan), which were placed on the ground 10 m apart on plywood bases. The experiment was arranged in a 6 × 6 Latin square design with two sampling periods: May 8–18 and May 18–June 9, 1987. The lengths of the sampling periods were determined by periodically inspecting the numbers of trapped beetles to ensure that the catches from the two sampling periods were approximately equal. This compensated for the effects of changes in the numbers of flying beetles due to variable weather and phenology. The traps and baits were rotated among positions between sampling periods. At the end of the experiment, the logs were peeled to determine the actual numbers of actively boring males.

Field Test of Trap Type and Source of Volatiles. Five treatments were tested to determine if volatile and trap types were significant factors. Male and host volatiles were collected by introducing 150 male New York beetles from a laboratory colony into a red pine log (8 cm diam. × 50 cm) in a glass cylinder (10 cm diam. × 55 cm) and collecting the volatiles on Porapak Q for 72 hr. The Porapak Q was extracted with pentane and the solution concentrated to contain 10 μg ipsdienol/μl, as determined by capillary gas chromatography. The extract contained male-produced volatiles and host odors, which volatilize from both the pine log and beetle frass. The treatments were: (1) 1 mg synthetic racemic ipsdienol, (2) 10 mg synthetic racemic ipsdienol, (3) 1 mg natural ipsdienol (Porapak Q extract), (4) a red pine log with 20 New York male *I. pini* hung adjacent to funnel traps, and (5) a red pine log baited with 20 New York male *I. pini* in a sticky trap. Treatments 1–3 were in ethanol (total volume 100 μl each), were eluted from polyethylene vials (3.7 ml, 1-mm hole in cap), and were suspended in hardware cloth sticky traps. Fifteen traps were placed 10 m apart in three rows. Each row received a complete set of treatments in randomized order. The experiment started on August 12, and insects were taken from the traps and trap positions were rotated on August 25 and 31 and September 6, 1987.

Field Test of Synthetic, Racemic Ipsdienol across Seasons. The response of *I. pini* to synthetic ipsdienol was also measured in the spring, summer, and fall of 1988. The treatments were (1) 1 mg, (2) 10 mg synthetic racemic ipsdienol in ethanol, (3) 20 male New York beetles boring in a red pine log, and (4) ethanol. Synthetic stimuli were placed in polyethylene vials (3.7 ml) and were hung on eight-unit funnel traps. Twelve traps were placed 30 m apart in three rows. Each received a complete set of treatments in randomized order. All stimuli were replaced and their positions were rerandomized on May 6, July 22, and August 22. The male beetle treatments were also replaced on September

14. Insects were removed from the traps and treatment positions were rerandomized on May 10, 13, and 17; July 27; August 8, 12, and 31; September 9, 16, and 28; and October 17.

When trap catches were large (over 500), the numbers of beetles and sex ratios were estimated by sexing and counting a subsample and counting the remainder, or sexing, counting, and weighing a subsample and weighing the remainder. This method was accurate within 6.8% based on weighing and counting a subset of the samples.

Laboratory Bioassay of Synthetic, Racemic Ipsdienol. This experiment tested synthetic ipsdienol in laboratory bioassays using a modification of the Wood and Bushing (1963) olfactometer. Odor sources were placed in 14.6-cm disposable Pasteur pipets placed 30° apart, 10 cm from the point of convergence of the airstreams. The odors were removed by a vacuum at the downwind end of the olfactometer. Stimulants were deposited on filter paper strips (4 × 30 mm) placed within a pipet in position 2 and tested singly. The airflow through each pipet was 120 ml/min. Laboratory reared beetles were allowed to emerge from their brood host and were tested within 24 hr. The laboratory colony originated in Tully, New York, in 1973 and had been maintained on red pine and kept at approximately 21°C in constant darkness. Periodically, field collected beetles were added to the colony to prevent inbreeding. Bioassays were conducted in December 1987. Previous bioassays with beetles from this laboratory colony (unpublished data) indicated that beetle response specificity was uniform throughout the year. This is not surprising because *I. pini* is multivoltine, does not exhibit obligate diapause, and shows no signs of seasonal activity in our laboratory colony. Only females were used due to their higher level of response. Beetles were tested in groups of 10 at 21°C under red light to minimize spontaneous flight. Each group of 10 beetles was tested against all three stimuli at each concentration. Seventy beetles were tested at each stimulus concentration. Beetles were kept on the arena for up to 5 min, or until they responded by clear orientation upwind to the point of contacting the odor-bearing pipet. The paper substrate of the arena was changed between assays.

To determine if ipsdienol alone was attractive, we tested four concentrations (10^{-3} μg, 10^{-2} μg, 10^{-1} μg, and 1 μg) of synthetic racemic ipsdienol, male and host volatiles (see above: Field Test of Trap Type and Source of Volatiles) and a blank airstream. Dilutions of male and host volatiles were determined based on the quantity of ipsdienol in the extract, as determined by capillary gas chromatography. The enantiomeric composition of natural (from male volatiles) and synthetic ipsdienol was determined (Slessor et al., 1985).

Statistics. Data from the first, second, and fourth experiments were log(rank) transformed (Conover and Iman, 1981) and analyzed by multifactor ANOVA. This allowed us to partition the variance due to temporal replication and to test for interaction effects. The data from the third experiment were log

$(Y + 1)$ transformed and analyzed by one-way ANOVA. Sex ratios of trap catches with over 50 individuals were compared as population proportions (Mendenhall, 1983). The bioassay data were log $(Y + 1)$ transformed and analyzed by one-way ANOVA.

RESULTS

Field Test of Synthetic Ipsdienol Enantiomers in Two Seasons. Significantly ($P < 0.001$) more beetles were trapped in September (4.6 ± 1.6 beetles/trap/sampling period) than in May (0.0 beetles/trap/sampling period). There were no significant ($P > 0.05$) effects of replication over time in September, nor was there a significant difference between the mean trap catch of the 50% (−)-ipsdienol treatment in ethanol (14.7 ± 7.8) and in pentane (8.6 ± 3.1) ($P > 0.05$). The effect of ipsdienol enantiomeric composition was highly significant ($P << 0.001$). Only the 50% and 60% treatments attracted significantly more beetles than the controls (Figure 1). Because the same range of enantiomers [50–98.5% (−)-ipsdienol] was covered in the spring and late summer, these data suggest that the lack of attraction in the spring was not due to the enantiomeric composition of ipsdienol. Additional monitoring with ipsdienol enantiomers in May, June, and July using release rates of 26–74 μg/day also found no attraction to synthetic ipsdienol.

Field Test of Beetle-Produced Ipsdienol Enantiomers. In the field test of

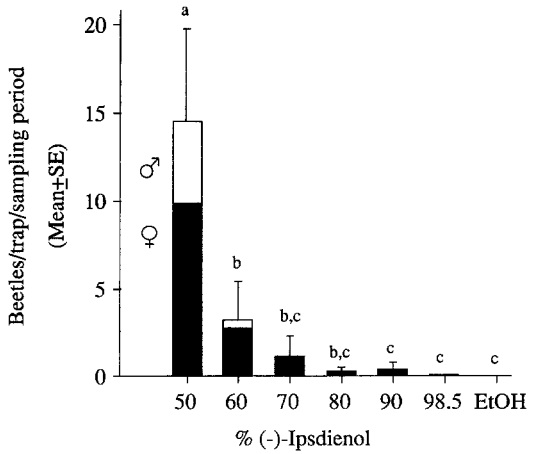

FIG. 1. Mean number of *I. pini* trapped (±SE) at different proportions of ipsdienol enantiomers near Forestport, New York, September 3–9, 1987. Different letters indicate significant differences between means ($P < 0.05$; LSD test).

actively boring New York and Arizona male beetles during May and June 1987, treatments with at least half New York beetles attracted significantly more beetles than all other treatments (Figure 2). Traps with all Arizona beetles did not attract significantly more than the uninfested log, while the 5:15 New York–Arizona baits attracted significantly more than the uninfested log.

Examination of the bait logs after termination of the experiment revealed that 70% of the New York beetles and 83% of the Arizona beetles had constructed nuptial chambers. Most of the males that did not construct nuptial chambers were dead. The proportions of ipsdienol enantiomers may have been slightly different from those expected based on the proportions of beetles introduced but were consistent across treatments. The actual enantiomeric composition of ipsdienol produced was not directly measured, but we estimate that the 15–5, 10–10, 5–15 (New York–Arizona) treatments produced disproportionately more (−)-ipsdienol due to the higher mortality of New York beetles and the greater production by western populations compared to the New York population (Miller et al., 1989).

This experiment established the presence of flying, responsive beetles in the area during the spring portion of the synthetic enantiomer experiment reported above. Furthermore, the enantiomeric composition of natural ipsdienol affected catches, but stereochemistry was not the basis for lack of attraction to synthetic ipsdienol in May in the experiment with synthetic enantiomers.

Field Test of Trap Type and Source of Volatiles. The 10-mg ipsdienol treatment attracted significantly ($P < 0.05$) more beetles than all other treat-

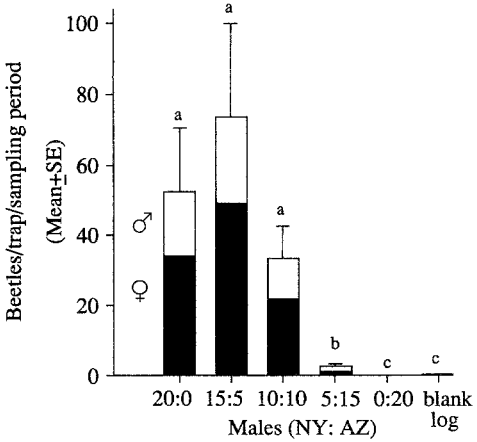

FIG. 2. Mean number of *I. pini* trapped (±SE) at red pine logs with ratios of New York and Arizona male *I. pini* near Forestport, New York, May 8–June 9, 1987. Different letters indicate significant differences between means ($P < 0.05$; confidence intervals).

ments except the funnel trap with 20 males (Figure 3). The mean of the sticky trap/20 males treatment was inflated by a single replicate and was slightly higher than that of the funnel trap/20 males treatment, yet it was significantly less attractive than the 10-mg ipsdienol treatment. This experiment excludes both trap design and release rate as explanations for the disparity of results between the first two experiments.

Field Test of Synthetic, Racemic Ipsdienol across Seasons. From May 6 through August 8, the 10-mg ipsdienol treatment caught 4% of the total, and from August 9 through October 17 it caught 31% of the total (Figure 4), causing a significant treatment × sampling period interaction ($P = 0.002$). The 1-mg ipsdienol treatment was never significantly more attractive than the control ($P > 0.05$) and the 20 male beetle treatment was always more attractive than the control ($P < 0.01$). The mean trap catches were two to three orders of magnitude higher from August 8 through October 17 than from May 6 through August 8 (Table 1). Although the means of the 1.0 mg, 10 mg, and male beetle treatments from August 8 to October 17 varied considerably, there were no significant differences among them due to large variances. We monitored attraction to ipsdienol with a lower dose (0.1 mg) in May and a higher dose (100 mg) from July through October. Both doses attracted fewer beetles than the 1.0 mg and 10 mg treatments.

In the field experiments, the mean sex ratios for treatments ranged from

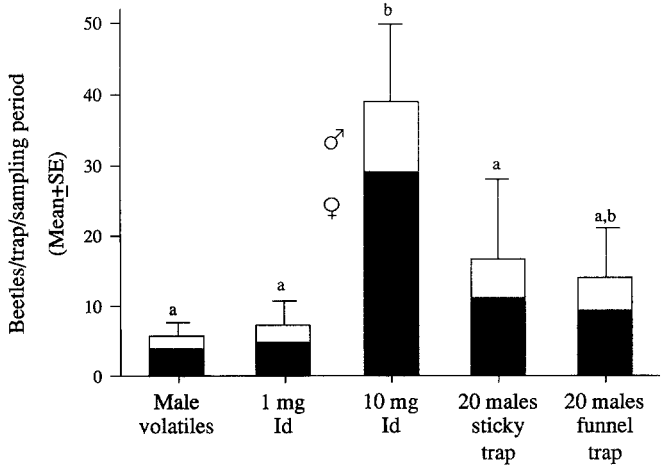

FIG. 3. Mean number of *I. pini* trapped (±SE) at male *I. pini* (New York) frass volatiles collected on Porapak, synthetic racemic ipsdienol, and male *I. pini*, near Forestport, New York, August 25–September 6, 1987. Except where noted, all treatments utilized sticky traps. Different letters indicate significant differences between means ($P < 0.05$; LSD test). Id = ipsdienol.

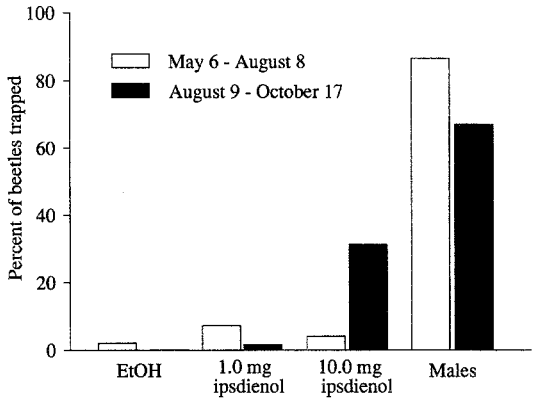

FIG. 4. Percent of *I. pini* trapped within each of two time periods, near Syracuse, New York, May 6–October 17, 1988. Attractants were synthetic ipsdienol, logs with 20 male *I. pini* from New York, and an ethanol control. Different letters indicate significant differences between means ($P < 0.01$; confidence intervals).

TABLE 1. SEASONAL VARIATION IN RESPONSE BY *Ips pini* TO SYNTHETIC RACEMIC IPSDIENOL NEAR SYRACUSE, NEW YORK, MAY 6–OCTOBER 17, 1988

Time period	Treatment	*N*	Mean ± SE[a]	Males (%)

[a] Beetles/trap/sampling period; means within a column for each time period followed by the same letter are not significantly different ($P < 0.01$, Tukey's multiple mean comparison test).

25.5% to 41.8% males. There were no significant differences among sex ratios within any of the experiments ($P > 0.05$).

Laboratory Bioassay of Synthetic, Racemic Ipsdienol. In the laboratory bioassays, ipsdienol was not significantly more attractive than the blank airstreams at any concentration tested (Figure 5). The male volatiles were significantly more attractive than both the blank airstream and synthetic ipsdienol at the three higher concentrations. The enantiomeric composition of ipsdienol from male beetles and the synthetic formulation was 1:1 (±1%), which excludes

stereochemistry as an explanation for the lack of attraction to synthetic ipsdienol.

DISCUSSION

These data demonstrate that one or more compounds in addition to ipsdienol are necessary for behavioral response by *I. pini* in New York and that the role of this compound varies seasonally. The origin of this semiochemical may be the host (a kairomone) or the insect (a pheromone). (*E*)-Myrcenol is produced by *I. pini* in British Columbia (Greis et al., 1988); when placed on fresh logs it increases the number of attacks, but because it is inhibitory when combined with ipsdienol (Miller et al., 1990), it is probably not the compound that enhances attraction to ipsdienol in New York. Other reports that found attraction to ipsdienol alone in the field were conducted in the late summer or fall. Lanier et al. (1980) tested synthetic ipsdienol in August and September in New York. Birch et al. (1980) began their tests in late July in California, and Miller et al. (1990) conducted experiments in July and August. Field tests of western populations in the spring are needed to determine if compounds in addition to ipsdienol are required for response.

In our laboratory bioassays, response by female beetles was similar to the response of beetles in the field in the spring, i.e., ipsdienol was not significantly more attractive than blank controls. However, Lanier et al. (1980) reported that ipsdienol was attractive in laboratory bioassays. Lanier et al. (1980) used ipsdienol extracted and isolated from beetles, which could have contained small amounts of impurities that enhanced attraction to ipsdienol. Positive response to synthetic ipsdienol in the lab bioassays of Lanier et al. (1980) is more difficult

to reconcile. It is possible that their scoring method (Lanier et al., 1977) produced false positives, that their release rates could have been very high (no quantitative measure of ipsdienol delivery rate or dosage was given), or that their synthetic ipsdienol was contaminated with a synergist. The use of walking beetles in laboratory bioassays for testing bark beetle attractants was criticized for being an oversimplified representation of a complex series of behavioral steps (Vité, 1967). However, when coupled with field data, laboratory bioassays are an indispensable tool in studies of bark beetle pheromones (Wood et al., 1967). The variability in response to ipsdienol in our field tests at different times of the year indicates that simple field tests alone should not be uncritically accepted as yielding a more correct or meaningful result than laboratory bioassays.

The enantiomeric composition of ipsdienol has been implicated (Lanier et al., 1980) as the basis for geographic variation in response specificity in three populations of *I. pini* (Lanier et al., 1972). Populations in California (Birch et al., 1980; Miller et al., 1989) and Idaho (Plummer et al., 1976) produce predominantly the (−) enantiomer, while New York populations have been found to produce racemic ipsdienol (Stewart, 1975; Miller et al., 1989). Our results, comparing the attractiveness of New York and Arizona males in New York show substantial interpopulational differences (Figure 2). The enantiomeric composition of ipsdienol varies between these populations, but in our tests synthetic enantiomers did not attract beetles in the spring, indicating that more than stereochemistry is involved in eliciting response. The relative roles of additional compounds and ipsdienol stereochemistry in interpopulational specificity remains to be investigated.

The seasonal variation in the response to ipsdienol by *I. pini* is qualitatively different from seasonal variation in pheromone systems previously reported in *I. pini* as well as other species. Other reports involve decreases in the level of response of field-collected bark beetles to complete pheromone blends in laboratory bioassays during adverse seasons when the beetles are not normally active (Wood and Bushing, 1963; Borden, 1967; Silverstein et al., 1968; Birch, 1974; Roberts et al., 1982). Birch (1974) found that the level of attractiveness of male frass of *I. pini* also declined during the fall and winter. During diapause and quiescence insects undergo physiological changes, including the diminution of reproductive functions (Tauber et al., 1986). Apparently, reduced reproductive activity includes diminished use of the pheromone system.

In contrast, the qualitative change in the response to ipsdienol by *I. pini* in New York occurs during the active season. Beginning in early to mid-August in New York, *I. pini* generally do not initiate breeding attacks. Instead, they engage in feeding attacks during which beetles continue to produce and respond to pheromones (as evidenced by the aggregation itself), but the density of arriving beetles in the host is about 10 times higher than that of breeding attacks.

The beetles' primary activity in feeding attacks is feeding, while attempts at reproduction are generally unsuccessful (unpublished data). These feeding attacks have been reported from a population in Idaho (Sartwell et al., 1971) and probably occur throughout the range of *I. pini*. Interestingly, they coincide with the onset of response to synthetic ipsdienol alone. Whether there is a direct relationship between the change in response to ipsdienol and attack behavior has yet to be determined.

The change in response to ipsdienol may also be associated with seasonal changes in the fat content of beetles and their general level of responsiveness. In the late summer there is an increase in population density after two or, under favorable conditions, three generations have developed and emerged (Clemens, 1916; Thomas, 1961). Hagen and Atkins (1975) showed that overwintered *I. paraconfusus* had a higher mean fat content and were less responsive to attractants than the spring generation. Seasonal variation in fat content also has been found in *D. frontalis* (Hedden and Billings, 1977; Roberts et al., 1982). Hagen and Atkins (1975) suggested that seasonal variation in fat content may be due to variability in the conditions under which different generations develop. Population and colonization densities increase between overwintered and summer generations of *I. pini* in Wisconsin (Schenk and Benjamin, 1969). A negative correlation between colonization density and the fat content of offspring has been demonstrated in *I. typographus* (Anderbrant et al., 1985; Botterweg, 1983) and *D. pseudotsugae* (Atkins, 1975). Fat content is negatively correlated with responsiveness to attractants in *D. pseudotsugae* (Atkins, 1966) and *I. paraconfusus* (Hagen and Atkins, 1975).

We hypothesize that, in *I. pini*, intergenerational variability in host abundance and population density can lead to variability in intraspecific larval competition, fat content, and responsiveness to semiochemicals. Responsiveness to semiochemicals in our investigation was represented as specificity of response to synthetic ipsdienol compared to male and perhaps host odors. The decrease in specificity that we saw in the late summer and fall may be a manifestation of increased responsiveness.

Acknowledgments—We thank J.R. West and R.M. Silverstein for determinations of enantiomeric compositions and related GC work and D.K. Jewett for assistance in handling field-trapped beetles. The New York State Department of Environmental Conservation assisted in locating suitable pine stands and granted permission for their use. We are grateful to T.W. Phillips, S.J. Seybold, D.L. Wood, R.A. Norton, S. Palmer, and anonymous reviewers for critical reviews of the manuscript. This research was funded by NSF grant DCB8608077 and USDA-CSRS grant 8802317.

(Received October 29, 1990; accepted February 12, 1991)

Abstract—A new pheromone component, lanierone, (2-hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-1-one) was isolated and identified from a Porapak Q collection of volatiles from male *Ips pini* from New York through GC fractionation, bioassay, and spectrometry. In both the laboratory and the field, synthetic lanierone, in a 1 : 100 ratio with synthetic ipsdienol, is as attractive as natural pheromone sources. Synthetic ipsdienol alone is not attractive in the laboratory and only weakly attractive in the field. Varying the ratio of lanierone to ipsdienol in the field from 10^{-4} : 1 to 1 : 1 in 10-fold increments resulted in an increased number of beetles trapped at the three lower ratios, but also in an increase in the proportion of males trapped. In the field, all combinations of lanierone to ipsdienol attracted proportionately fewer males than did pheromone-producing male beetles. GC and GC-MS analyses of Porapak Q-trapped volatiles revealed that lanierone is produced in an amount equal to about 0.2% of that of ipsdienol and is produced exclusively by males. The small amount of lanierone produced, together with a GC retention time similar to that of ipsdienol on a nonpolar column, probably confounded its detection in earlier studies.

Key Words—Insecta, Coleoptera, Scolytidae, *Ips pini*, pheromone, isolation, identification, bioassay, ipsdienol, lanierone.

INTRODUCTION

The pine engraver, *Ips pini* (Say), breeds in pines and spruces throughout most of North America. Upon locating a host tree, males bore into the phloem–cambium region and release a chemical attractant that mediates further colonization of the host by responding males and females. The pheromone was reported to consist of a single compound, ipsdienol (Birch et al., 1980; Lanier et al., 1980). More recently, Greis et al. (1988) reported that *I. pini* in British Columbia produce (*E*)-myrcenol, and Miller et al. (1990) reported that (*E*)-myrcenol was behaviorally active for *I. pini* in British Columbia. In addition, β-phellandrene, a major constituent of the terpene fraction of lodgepole pine oleoresin (*Pinus contorta* var. *latifolia* Engelmann) is attractive to *I. pini* in British Columbia (Miller and Borden, 1990).

Interpopulational pheromonal specificity (Lanier et al., 1972) has been reported to be based on ipsdienol enantiomeric composition (Birch et al., 1980; Lanier et al., 1980). In general, western populations produce and respond to blends of over 90% (−)-ipsdienol [less than 10% (+)] and eastern populations produce and respond to a nearly racemic mixture of ipsdienol [roughly 50:50 (−):(+)]. The specificity of response to pheromones can also vary seasonally within a population. Teale and Lanier (1991) reported that a New York population of *I. pini* responded in the spring and early summer to natural pheromone sources but not to racemic ipsdienol, while in the late summer and fall, the numbers of beetles trapped by ipsdienol and natural sources were not significantly different. In addition, laboratory-reared beetles originating in New York were attracted to a pheromone extract, but not to ipsdienol in laboratory bioassays (Teale and Lanier, 1991). This demonstrated that one or more additional compounds were required for response. Here we report the isolation and identification of a new pheromone component for *I. pini* through the use of the fractionation, spectrometry, and bioassay method of Silverstein et al. (1967). The new component is also a new natural product, and we give it the name "lanierone" in recognition of the late Gerald N. Lanier and his valuable contributions to bark beetle chemical ecology.

METHODS AND MATERIALS

Insect Rearing. Beetles used for pheromone collection, laboratory bioassays, and bait logs for field experiments were reared in a laboratory colony originating in red pine (*Pinus resinosa* Ait.) 25 km south of Syracuse, New York, in 1973. Beetles captured at the original locality were periodically added to the colony to prevent inbreeding. Fresh red pine logs were sealed at the ends with hot wax and placed in the colony weekly. Beetles were collected by placing infested logs in metal containers (40 cm diam. × 60 cm) fitted with glass col-

lection jars (1 liter). For bioassay, beetles were removed and used within 24 hr of emergence. For pheromone collections, beetles were collected daily, sexed, and then stored on damp toweling at 5°C for up to two weeks.

Pheromone Collection. Two large collections of volatiles were made by introducing individual male beetles into the phloem of fresh red pine logs (about 15 cm diam. × 1 m) through cork borer holes (5 mm diam.) covered with aluminum screen patches. The infested logs were placed in a metal container (152 × 43 × 69 cm) and aerated with charcoal-filtered air. Volatiles were trapped on two Porapak Q (Byrne et al., 1975) filters (50 ml each) connected in series. The volatiles were extracted from the Porapak Q with pentane (100 ml, combined) and the pentane solution was concentrated by distillation.

The purpose of the first aeration (aeration 1) was to obtain a large amount of active material for fractionation and bioassay (Silverstein et al., 1967). Male beetles (1040) were aerated (4 liters/min) for 168 hr on five logs (15 cm diam. × 120 cm). The second aeration (aeration 2) was used to quantify production of ipsdienol and lanierone and for use in laboratory and field bioassays comparing natural and synthetic materials. Male beetles (1250) were aerated (1 liter/min) for 80 hr on five logs (15 cm diam. × 120 cm). To determine the origin of lanierone, males and females (150 each) were simultaneously aerated for 105 hr in separate glass columns (15 cm ID × 50 cm) while boring in red pine logs (12 cm diam. × 48 cm), which were cut from adjacent sections of a single tree. Volatiles were collected separately on Porapak Q (50 ml). Due to the small quantity of lanierone in the male aeration, both extracts were analyzed by GC-MS using selective ion monitoring (*m/z* 109).

Fractionation. The concentrated Porapak Q extract from the first aeration was sequentially fractionated on four packed columns in a Varian Aerograph Series 2700 gas chromatograph with a splitter (Brownlee and Silverstein, 1968) and flame-ionization detector. The four columns and the retention times of the fractions were as follows: (1) 5% OV-101 (Applied Science, State College, Pennsylvania), on Chromosorb WAW-DMCS 100/120 mesh, 3 m × 7.5 mm (OD) glass, 90°C for 30 min, then 4°C/min until 140°C, F1 5–25 min, F2 25–27 min, F3 27–60 min; (2) 4% Carbowax 20 M (Applied Science) on Chromosorb WAW-DMCS 100/120 mesh, 6.1 m × 6.4 mm (OD) glass, 120°C for 20 min, then 4°C/min until 140°C, F3.1 0–9 min, F3.2 9–15 min, F3.3 15–24 min; (3) 5% FFAP (Supelco, Inc., Bellefonte, Pennsylvania) on Chromosorb G-HP, 100/120 mesh, 3 m × 6.4 mm (OD) glass, 130°C isothermal, F3.2.1 0–24.5 min, F3.2.2 24.5–26.5 min, F3.2.3 26.5–29 min, F3.2.4 29–40 min; (4) 6% TCEP (Supelco, Inc.) on Chromosorb WAW-DMCS 100/120 mesh, 80°C initial, then 4°C/min until 110°C, F3.2.3.1 33–38 min, F3.2.3.2 38–43 min, F3.2.3.3 43–56 min, F3.2.3.4 56–66 min. For all the columns, the carrier gas was nitrogen (60 ml/min), the injector temperature was 150°C, and the FID temperature was 160°C. Active fractions were analyzed by injection

on BP-1, 50 m × 0.33 mm (ID), at 45°C for 1 min, then 5°C/min until 200°C in a Hewlett Packard 5890 gas chromatograph to determine the number of compounds present. The enantiomeric composition of ipsdienol in F2 (OV-101) was determined by the method of Slessor et al. (1985).

Chemical Analyses. Volatiles were analyzed by injection on BP-1, 50 m × 0.33 mm (ID), at 45°C for 1 min, then 1°C/min until 200°C in a Hewlett Packard 5890 gas chromatograph. Ipsdienol and lanierone peaks were identified by coinjection with synthetic samples and by GC-MS using selective ion monitoring (*m/z* 109) in a Finnigan model 4500 fitted with a 30-m SPB-5 capillary column (Supelco, Inc.) and with the injector temperature set at 250°C. Coupled GC-MS was performed on a Finnigan model 4500 fitted with a 30-m SPB-5 capillary column (Supelco, Inc.), run in splitless mode, and with the injector temperature set at 250°C. All samples were run at 70 eV.

An infrared spectrum of natural lanierone was obtained on a Hewlett Packard 5965A Fourier transform infrared spectrometer coupled to a Hewlett Packard 5890 gas chromatograph fitted with an HP-5 capillary column (25 m × 0.3 mm ID).

A proton nuclear magnetic resonance spectrum of about 5 μg of pure natural lanierone was obtained on a GE GN-500 (500 MHz) NMR spectrometer in C_6D_6 with a pulse sequence to suppress solvent and water peaks.

Synthesis of Lanierone: Preparation of 2-Hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-1-one. Lanierone was synthesized using the method of Frimer et al. (1989). Isophorone (Aldrich Chemical Co.) (3,5,5-trimethyl-2-cyclohexen-1-one), (3.0 g, 21.74 mmol), 18-crown-6 (Aldrich Chemical Co.) (8.62 g, 32.60 mmol) and potassium superoxide (Aldrich Chemical Co.) (6.18 g, 86.96 mmol) were dissolved in 30 ml benzene and stirred under dry argon for 2 hr. Water (50 ml) was added and the solution was acidified with 6 N hydrochloric acid. The product was extracted with methylene chloride, washed with water followed by saturated sodium bicarbonate, and dried over sodium sulfate. The solvent was removed in vacuo to yield the crude product (3.55 g) as an oil, which was purified by flash column chromatography (Still et al., 1978) using 20% ethyl acetate in hexane to yield lanierone (1.14g, 7.5 mmol, 35%). The enol was recrystallized from hexane as white needles with a melting point of 59–60°C. MS *m/z* (% rel. inten.): 152 (M^+, 30.20), 137 (M^+-CH_3, 28.10), 124 (M^+-CO, 52.00), 109 (M^+-CH_3-CO, 100). [^{1}H]NMR (C_6D_6): δ 6.71 (s, 1H, OH), 6.10 (m, J = 2.8 Hz, $J_{allylic}$ = 1.4 Hz, 1H), 5.85 (d, J = 2.8 Hz, 1H), 1.85 (d, $J_{allylic}$ = 1.4 Hz, 3H), 0.80 (s, 6H) [^{13}C]NMR (C_6D_6): δ 182.17, 154.87, 145.94, 130.85, 124.40, 36.60, 26.96, 15.26.

Laboratory Bioassays. Female beetles were tested in groups of 10 in a modified Wood and Bushing (1963) choice olfactometer (Teale and Lanier, 1991). Positive responses were scored when a beetle followed an airstream for at least 3 cm before coming within 5 mm or contacting the pipet. When testing

fractions, each group of 10 beetles was used for each stimulus or combination of stimuli being compared. The order in which stimuli were presented was randomized between groups of beetles to minimize possible interaction effects. The raw bioassay data were analyzed by ANOVA and decisions were made at the $P < 0.05$ level. The OV-101 fractions were assayed at dilutions equal to 1.0, 0.1, 0.01, and 0.001 of an amount of starting material containing 1 μg ipsdienol. All subsequent fractions were assayed with 1 μg synthetic racemic ipsdienol added. The concentrations of test fractions were increased at two steps in the sequence to compensate for material lost during collection.

When synthetic materials were tested, each group of 10 beetles was used once, then discarded. The test stimuli were pentane (negative control), synthetic racemic ipsdienol (1 μg), lanierone (10 ng), ipsdienol plus lanierone (1 μg + 10 ng), and male volatiles (second aeration; 1 μg + 10 ng). The raw data (homoscedastic; Bartlett's test, $P > 0.05$) were analyzed by one-way ANOVA followed by the LSD range test.

Field Experiments. Field experiments were conducted in a mixed stand of red and Scots (*P. sylvestris* L.) pine, 25 km south of Syracuse, New York. The purpose of the first experiment was to determine the attractiveness of lanierone using treatments similar to those of the laboratory bioassays. The treatments were: (1) hexane, (2) male volatiles (aeration 2; 1.0 mg natural ipsdienol, 10 μg lanierone), (3) synthetic racemic ipsdienol (1.0 mg) and synthetic lanierone (10 μg), (4) synthetic lanierone (100 μg), (5) synthetic racemic ipsdienol (10 mg), (6) synthetic racemic ipsdienol (10 mg) and synthetic lanierone (100 μg), and (7) 20 male beetles in a red pine log. Treatments 1–6 were placed in 3.7-ml polyethylene vials with a 1-mm hole in the cap, and the total volume including solvent (hexane) was 1 ml. The release rate of ipsdienol in treatments 5 and 6 was estimated to be about 67μg/day. The release rate was determined by aerating the release device ($N = 3$), collecting volatiles on Porapak Q over seven days at 22°C, and quantifying by injection on capillary GC. Baits were covered with aluminum foil for protection from sunlight. Chemical baits were hung in eight-unit multiple-funnel traps (Lindgren, 1983) (supplied by Phero Tech Inc., Delta, British Columbia) from the lower middle funnel; logs with male beetles were hung adjacent to the lower middle funnels. The treatments were randomized in 10 rows. Traps were spaced at a minimum distance of 20 m. Due to the limited quantity of male volatiles (5 mg ipsdienol) only five replicates of treatment 2 were possible; all other treatments received 10 replicates. The experiment was conducted from July 26 to August 1, 1990.

The purpose of the second field experiment was to determine the effect of varying the amount of lanierone relative to a fixed amount of ipsdienol. The treatments were the following amounts of lanierone in combination with synthetic racemic ipsdienol (10 mg): 10 mg, 1.0 mg, 0.1 mg, 0.01 mg, and 0.001 mg. In addition, there were two controls: hexane, and 20 male *I. pini* boring

in a red pine log. The seven treatments were arranged in a randomized complete block design with 10 replicates. Traps were spaced at a minimum distance of 20 m. The experiment was conducted from August 10 to 16, 1990, at the same location as the first field experiment.

RESULTS

Isolation. The concentrated Porapak Q extract from aeration 1 contained 20 mg of ipsdienol as determined by comparison with a synthetic standard on capillary GC. A dose of the extract containing 1 μg ipsdienol elicited 67% positive response in the laboratory bioassay (Figure 1). Fractionated material for the laboratory bioassays was quantified in the following manner. Because the starting material contained 20 mg ipsdienol and because an aliquot of the starting material containing 1 μg (or 5×10^{-5} of the total) ipsdienol elicited maximal response, each fraction was diluted and tested in a fraction of 5×10^{-5} of the total, so that the ratio of ipsdienol to the fraction of starting material was 5×10^{-5}:5×10^{-5}, or 1:1.

The three fractions from OV-101 were collected so that F1 contained all peaks eluting before ipsdienol, F2 contained one large ipsdienol peak, and F3 contained all peaks eluting after ipsdienol. A GC-MS analysis of F2 detected no significant (<1.0%) impurities. In bioassays comparing the extract, F2, and synthetic racemic ipsdienol, F2 was not significantly less attractive than the

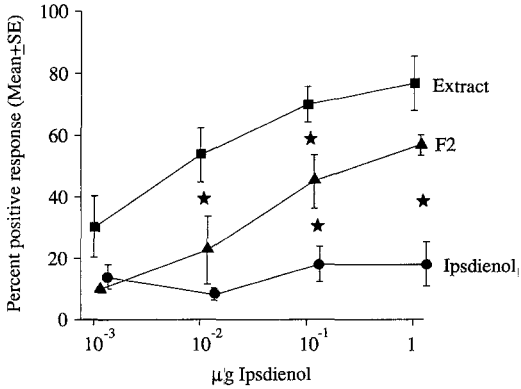

FIG. 1. Percent positive response by female *I. pini* in laboratory bioassays of OV-101 fraction 2 (F2), starting extract (aeration 1), and synthetic racemic ipsdienol. $N = 30$ beetles at each concentration; concentrations are μg ipsdienol. Stars indicate significant differences between means ($P < 0.05$; LSD test).

extract ($P < 0.05$, ANOVA) at all but the 10^{-2} dilution (Figure 1). Ipsdienol was significantly less attractive than the extract at all but the lowest concentration and was significantly less attractive than F2 at the two higher concentrations. The enantiomeric composition of ipsdienol in F2 was 46%(−):54%(+). There are no significant differences in response in the field to 30, 40, 50, and 60% (−)-ipsdienol (unpublished data). Therefore, we feel that the small difference in enantiomeric composition between F2 and synthetic racemic ipsdienol is insufficient to account for the difference in laboratory responses. This suggests that F2 contained an amount of a synergist below the limits of GC detection, but detectable by beetles. Lanierone may have been split between F2 and F3.

Further bioassays of the OV-101 fractions (Figure 2) showed that F3 and recombined F1 + F3, each in combination with ipsdienol in a 1:1 ratio, were not significantly less attractive than the extract at all dilutions. Fraction 1 in combination with ipsdienol was significantly less attractive than the extract at the 10^{-2} and 10^{-1} dilutions and less attractive ($P = 0.07$, ANOVA) than the extract at the highest concentration. The recombined F1 + F3 without ipsdienol added was significantly less attractive than the extract at all but the lowest concentration. Because the largest differences between stimuli occurred at the higher concentrations, subsequent bioassays utilized the single highest concentration (i.e., 1μg ipsdienol).

Only one Carbowax 20 M (C20M) fraction (F3.2) in combination with

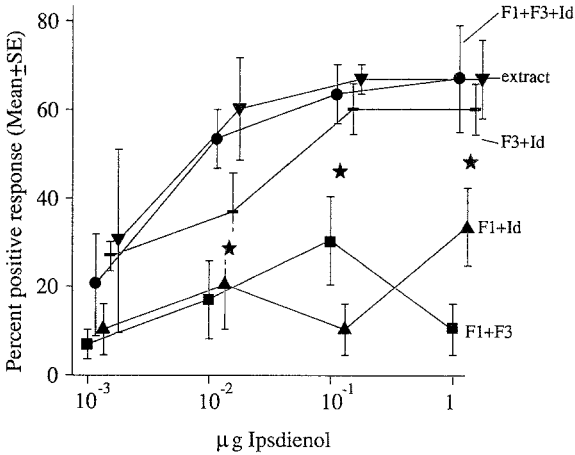

FIG. 2. Percent positive response by female *I. pini* in laboratory bioassays of starting extract (aeration 1) and OV-101 fractions 1 (F1) and 3 (F3). Stars indicate significant differences between stimuli and the extract ($P < 0.05$; LSD test). $N = 30$ beetles at each concentration; concentrations are μg ipsdienol. Id = ipsdienol.

ipsdienol elicited a level of response (47%) that was not significantly less attractive than that of the recombined fractions (68%) (Figure 3). When this fraction was refractionated on FFAP, only one fraction (F3.2.3) was not significantly less attractive (70%) than the recombined fractions (58%). The concentration of the fractionated material used in the assays was increased 10-fold in order to maintain levels of response comparable to those of the extract. We attributed the need to increase concentration to material losses incurred in the GC fractionation.

Of the TCEP fractions, F3.2.3.1, F3.2.3.2, and F3.2.3.4, when recombined, elicited a significantly lower level of response (7%) than all four fractions recombined (47%) (Figure 3). Fraction 3.2.3.3 elicited the same level of response (47%) as all four fractions recombined. Fraction 3.2.3.3 alone and the recombined F3.2.3.1, F3.2.3.2, and F3.2.3.4 were assayed in this configuration because F3 manifested a characteristic odor that we had detected in all previous attractive fractions and the extract. [There is a report in the patent literature that lanierone masks unpleasant phenolic flavors for humans (Demole, 1975)]. Again, the concentration was increased (sixfold) in order to maintain a satisfactory level of response. Capillary GC analysis of F3.2.3.3 revealed the presence of a single peak.

Identification. In the mass spectrum of the compound in F3.2.3.3 (Figure 4) the M^+ ion was judged to be *m/z* 152. The next highest fragment ion was 137, $M^+ - CH_3$. Assuming that there is only C, H, and O present, three likely molecular formulae were $C_{10}H_{16}O$, $C_9H_{12}O_2$, and $C_8H_8O_3$.

The FT-IR spectrum (Figure 5) indicated absorptions at 3462 ν OH, 2974 ν CH_3, 1659 ν C=O, 1434 δ_{as} CH_3, 1367 δ_s CH_3, and 1264 ν C—O, cm^{-1}.

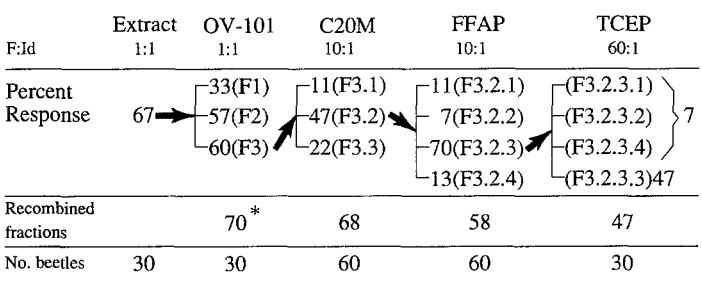

FIG. 3. Summary of laboratory bioassay data on four sequential fractionations of Porapak Q-collected volatiles from 1040 male *Ips pini* (aeration 1). The numbers in parentheses are referenced in the text. F:Id = ratio of fraction to ipsdienol. Quantification of fractions is based on the quantity of ipsdienol (20 mg) in the starting material (i.e., 1 μg ipsdienol is equal to 1 μg/20 mg, or 5×10^{-5} of the total; see text). *GC total.

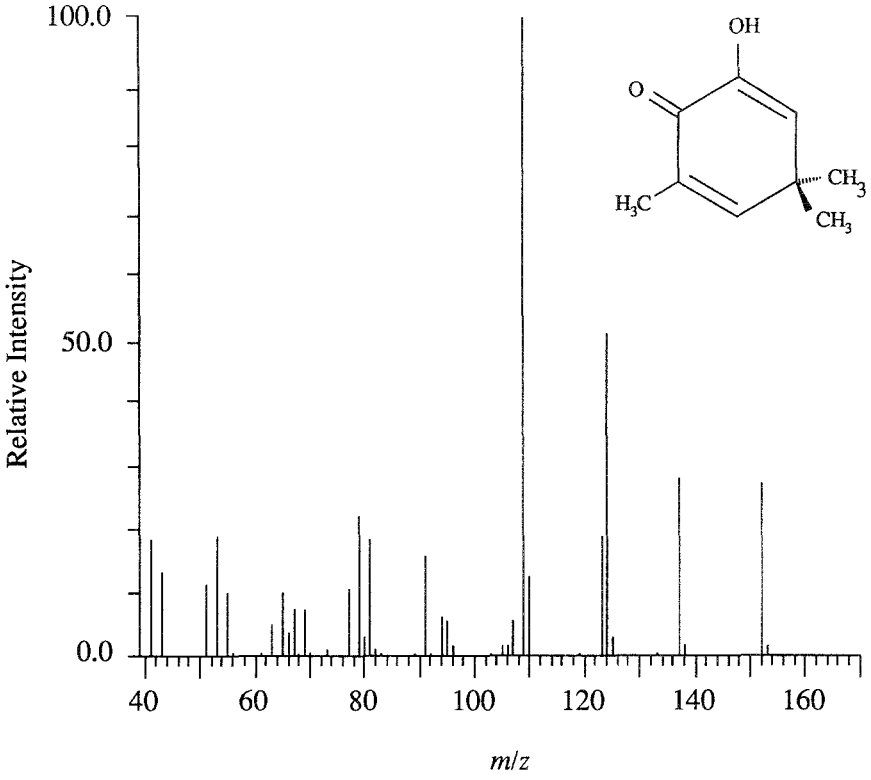

FIG. 4. Mass spectrum of natural lanierone isolated from Porapak Q-collected volatiles from 1040 male *Ips pini* (aeration 1).

The presence of two types of oxygen-containing functional groups excludes the molecular formula $C_{10}H_{16}O$.

The [^{1}H]NMR spectrum is shown in Figure 6. The singlet at δ 0.70 (6H) indicates that there are two identical methyl groups on a quaternary carbon (no coupling); the doublet at δ 1.80 (3H) indicates a methyl group on an olefinic carbon; the doublet at δ 5.78 (1H) and the multiplet at δ 6.03 (1H) indicate protons on olefinic carbons; and the singlet at δ 6.53 (1H) is a hydrogen-bonded hydroxyl proton. The indication of three methyl groups (9H) excludes the molecular formula $C_8H_8O_3$. On the basis of the MS, FT-IR, and NMR spectra of the natural and the synthetic compound, the structure was determined to be 2-hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-1-one (Figure 4).

Analyses of Beetle Aerations. On the normal-scale GC trace (Figure 7) of aeration 2, ipsdienol was represented by a peak that was small relative to several others, representing host volatiles. Only when the scale was increased 100-fold

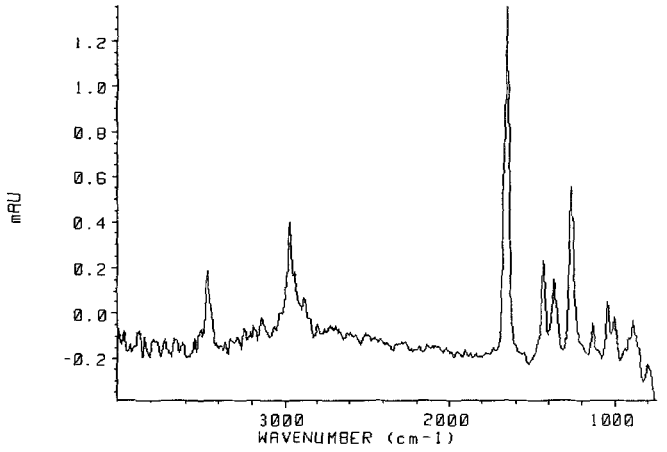

FIG. 5. Infrared spectrum of lanierone isolated from Porapak Q-collected volatiles from 1040 male *Ips pini* (aeration 1).

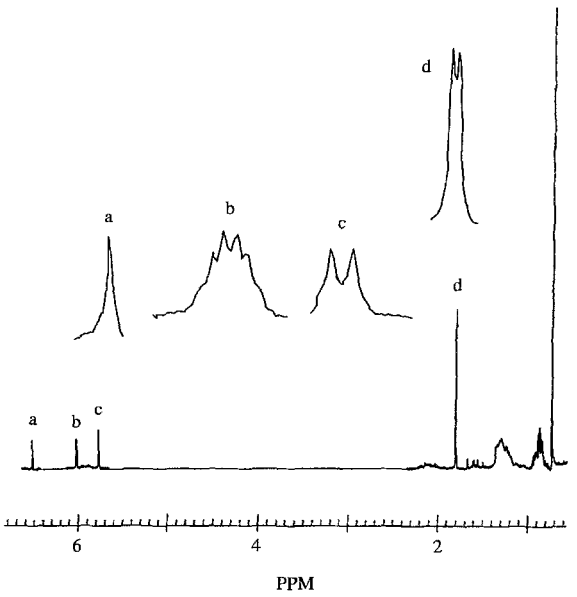

FIG. 6. NMR spectrum of natural lanierone isolated from Porapak Q-collected volatiles from 1040 male *Ips pini* (aeration 1).

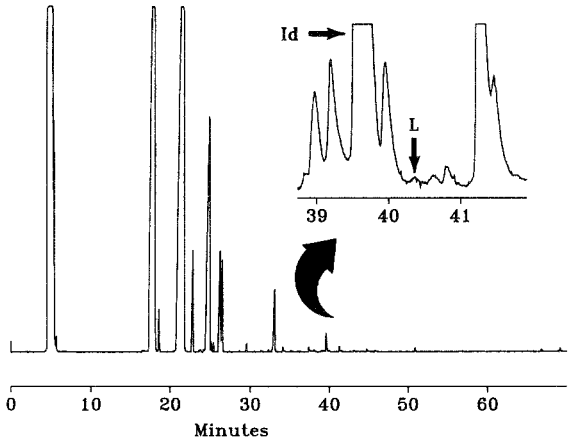

FIG. 7. GC tracings of volatiles from 1250 male *I. pini* boring in red pine collected on Porapak Q (aeration 2; see text for details). Normal scale and 100 × (inset).

The selective ion monitoring mass spectra (*m/z* 109) of the male and female aerations (Figure 8) revealed both ipsdienol and lanierone in the male extract but neither compound in the female extract. Because the female (and male) aeration was made with beetles feeding on host material (red pine), and no lanierone was collected, lanierone must not be produced by the host or females. Rather, lanierone is exclusively male-produced.

Laboratory Bioassays. In laboratory bioassays, neither synthetic ipsdienol nor lanierone alone was significantly more attractive to females than the solvent (pentane) control (Figure 9) ($P > 0.05$; ANOVA followed by LSD range test). The male volatiles and the combination of synthetic ipsdienol (1 μg) and synthetic lanierone (10 ng) were significantly more attractive than the solvent control, ipsdienol, and lanierone alone. There was no significant difference between the levels of attraction elicited by the male volatiles and the combination of synthetic ipsdienol and synthetic lanierone. These data indicate that ipsdienol and lanierone function in a synergistic manner.

Field Experiments. The treatments of the first field experiment fell into three homogeneous groups [Figure 10; $P < 0.05$; ANOVA on $\log(Y + 1)$ transformed data followed by LSD range test]: (1) hexane control, male volatiles and lanierone, (2) ipsdienol plus lanierone (low dose) and ipsdienol (high dose), and (3) ipsdienol plus lanierone (high dose) and males. The large number of beetles attracted by ipsdienol plus lanierone (high dose) compared to the small numbers attracted by ipsdienol and lanierone alone supports our laboratory result that these two compounds function in a synergistic, rather than an additive, manner. The sex ratios varied significantly between the ipsdienol plus

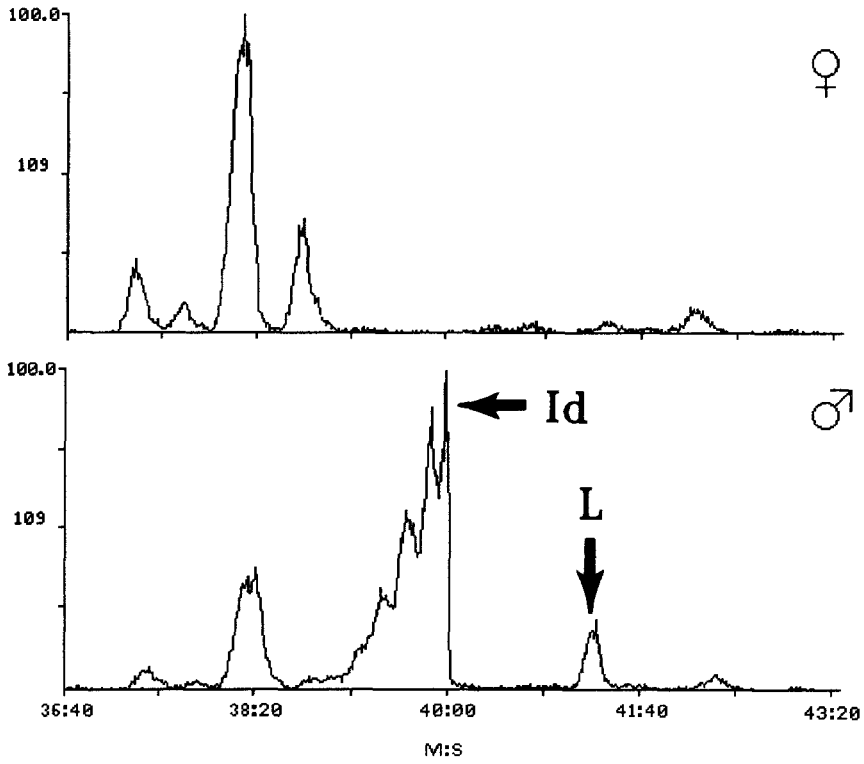

FIG. 8. Selective ion monitoring mass spectra (*m/z* 109) of male volatiles (bottom) and female volatiles (top). Note that peak sizes are not proportionate because *m/z* 109 is the base peak for lanierone, but only a minor fragment for ipsdienol. See text for details.

lanierone (high dose) ($m/f + m = 0.38$) and the male beetle ($m/f + m = 0.49$) treatments [$P < 0.01$, test for population proportions (Mendenhall, 1983)].

The male volatiles collected by aeration on Porapak Q (aeration 2) contained amounts of ipsdienol and lanierone equal to those of the synthetic mixture at low dose. Therefore, the small number of beetles attracted by the male volatiles must have been due to either the presence of large quantities of terpenes from the aerated host material, the presence of repellent microbial oxidation products, insufficient replication ($N = 5$ for the male volatile treatment, for all others $N = 10$), or other factors.

In the second field experiment, the amount of lanierone had a significant effect on the numbers of beetles trapped (Figure 11). The three higher doses together with the male treatment formed a homogeneous group [$P > 0.05$; ANOVA on $\log(Y + 1)$ transformed data followed by LSD range test]. The treatment with 0.01 mg lanierone in combination with 10 mg ipsdienol attracted

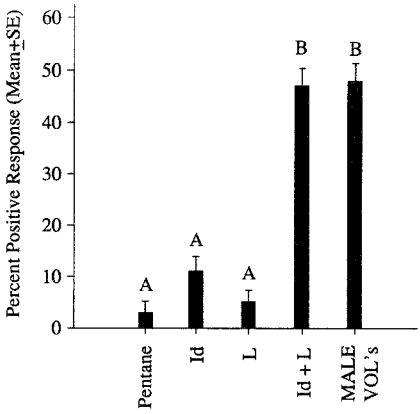

FIG. 9. Percent positive response in the laboratory bioassay by female *I. pini* to synthetic lanierone and ipsdienol. Id = ipsdienol; L = lanierone; MALE VOL's = volatiles from aeration 2 (see text for details). Different letters over bars indicate significant differences (ANOVA on raw data followed by LSD range test).

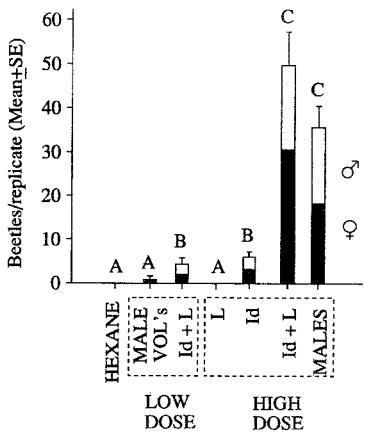

FIG. 10. Field test of lanierone at two doses 25 km south of Syracuse, New York, July 26–August 1, 1990. Id = ipsdienol; L = lanierone; MALE VOL's = male volatiles (aeration 2, see text); MALES = 20 males boring in a red pine log. LOW DOSE: Id = 1 mg; L = 0.01 mg. HIGH DOSE: Id = 10 mg; L = 0.1 mg. Different letters over bars indicate significant differences (ANOVA on log $(Y + 1)$ transformed data followed by LSD range test).

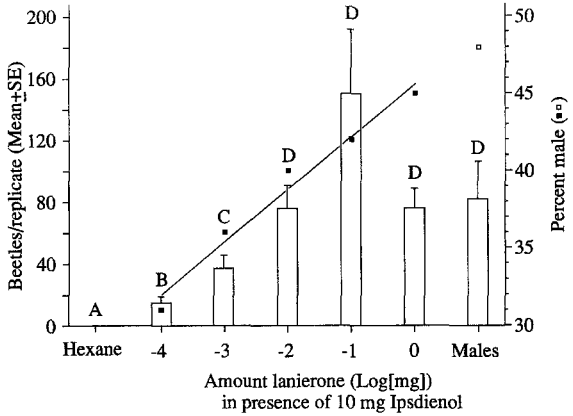

FIG. 11. The effect of varying the proportion of lanierone with a fixed amount (10 mg) of ipsdienol on the mean number (left axis, bars) and percent male (right axis, regression) of *I. pini* trapped in multiple-funnel traps 25 km south of Syracuse, New York, August 10–16, 1990. Different letters over bars indicate significant differences among mean numbers of beetles trapped (ANOVA on log $(Y + 1)$ transformed data followed by LSD range test). For the regression of sex ratio on proportion of lanierone, $R^2 = 0.97$, $P = 0.002$, $Y = 3.4 \log X + 45.6$.

fewer beetles than the higher doses, but more than the solvent control and the lowest dose. The lowest dose (0.001 mg lanierone) attracted significantly more than the solvent control. There was a close positive relationship between the percentage of males in the responding beetles and the quantity of lanierone in the presence of 10 mg ipsdienol ($R^2 = 0.97$, $P = 0.002$; Figure 11).

DISCUSSION

Our results demonstrate that the principal male-produced pheromone components of *Ips pini* in New York are racemic ipsdienol and lanierone (2-hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-1-one). The bioassay of the starting extract showed that we had collected attractive volatiles in the aeration of male beetles on Porapak Q. The attractiveness was retained during fractionation, and the fraction that contained lanierone (F3) was attractive in combination with synthetic ipsdienol but not alone. Furthermore, laboratory bioassays and field experiments demonstrated that only the combined mixture was as attractive as natural pheromone. Previously, we found that ipsdienol alone is not attractive in laboratory bioassays (Teale and Lanier, 1991). Thus, lanierone and ipsdienol have a synergistic, or multiplicative, effect.

The amount of lanierone produced is small relative to ipsdienol. We iso-

lated only about 5 μg lanierone and about 20 mg ipsdienol from the starting material. However, because our GC collection efficiency was less than 100%, there must have been more lanierone present in the starting material. The GC analysis of aeration 2 (Figure 7), which was not fractionated, showed that the proportion of lanierone to ipsdienol is about 1 : 500. Byers et al. (1990) reported a similar situation in the scolytid *Pityogenes chalcographus* (L.) in which one component, methyl decadienoate [(*E*,*Z*)-MD], is present as a minute fraction of another, chalcogran. The cryptic nature of pheromone components like (*E*,*Z*)-MD and lanierone emphasizes the importance of the fractionation and bioassay method (Silverstein et al., 1967) for identifying pheromone components from complex mixtures of plant and insect compounds. Another method is the differential diagnosis of Vité and Renwick (1970) or variations thereof (e.g., Smith et al., 1985; Greis et al., 1988). In this method, GC traces of attractive and nonattractive extracts are compared and the peaks that are unique to the attractive extract are considered potential pheromone components. This method can be used to detect pheromone components if they do not coelute with other peaks and if the peaks are reasonably large. Lanierone in *I. pini* presents an ideal example of a situation that would be extremely difficult to resolve by differential diagnosis methods. Lanierone coelutes with ipsdienol on at least one nonpolar GC column and its peak is only about 0.2% as large as that of ipsdienol.

Our isolation of lanierone represents the first isolation of this compound from a natural source, and lanierone is the only known scolytid pheromone component with a carotenoid-ring structure. Birgersson et al. (1984) reported the presence of a reduced form of lanierone, β-isophorone, in the hindguts of *I. typographus* females. However, its behavioral significance, if any, is unknown.

The sex ratio differences among responders to synthetic (lanierone plus ipsdienol) and natural (20 males in red pine) baits (Figure 10 and 11) suggest that other factors may be important in the host colonization process. Using a differential diagnosis technique, Greis et al. (1988) found that (*E*)-myrcenol is produced by *I. pini* in British Columbia. Miller et al. (1990) found that (*E*)-myrcenol had an inhibitory effect on attraction by *I. pini* in British Columbia when released with ipsdienol. In contrast to the New York population (Teale and Lanier, 1991) *I. pini* in British Columbia are attracted to synthetic ipsdienol in July (Miller et al., 1990). Higher release rates of (*E*)-myrcenol, in combination with a fixed amount of ipsdienol, attracted more males than the lower release rates, but the experiments were conducted consecutively so it was not possible to exclude the possibility that the sex ratios of flying beetles were different during the two experiments (Miller et al., 1990). In addition, when (*E*)-myrcenol was placed on freshly cut lodgepole pine logs, the increase in the number of *I. pini* colonizing the log was proportional to the amount of (*E*)-myrcenol released (Miller et al., 1990). More experiments are needed to eval-

uate interactions between ipsdienol, lanierone, (*E*)-myrcenol, and the kairomone, β-phellandrene (Miller and Borden, 1990) as well as geographic variation in the use of these compounds.

The fact that neither of two previous investigations (Birch et al., 1980; Lanier et al., 1980) into the chemical identification of the pheromone of *I. pini* had found lanierone is perplexing. In addition, our findings that ipsdienol alone was not attractive in laboratory bioassays or in the field in the spring and early summer appears contradictory with the reports of Birch et al. (1980), Lanier et al. (1980), and Miller et al. (1990), in which ipsdienol alone was reported to be attractive. Birch et al. (1980) and Lanier et al. (1980) utilized the rigorous fractionation and bioassay method (Silverstein et al., 1967) that is designed to find synergistically active behavioral components. This made the apparent incongruity between our results and those of Lanier et al. (1980) and Birch et al. (1980) especially difficult to reconcile.

Three factors interacted to make the detection and isolation of lanierone difficult: (1) the similar retention times of ipsdienol and lanierone, (2) the small quantity required for response, and (3) seasonal variation in response to pheromone. Together, they can explain why lanierone was not detected by Lanier et al. (1980). First, the incomplete separation of ipsdienol and lanierone that we observed on OV-101, as indicated by laboratory bioassay of fraction 2, suggests that Lanier et al. (1980) may not have achieved complete separation of ipsdienol and lanierone. Lanier et al. (1980) used apparently pure, natural ipsdienol in the laboratory, but we now have reason to suspect that it could have contained lanierone, which would have caused an apparent response to ipsdienol. Positive response to synthetic ipsdienol in the lab bioassays of Lanier et al. (1980) is more difficult to explain. It is possible that the less stringent scoring method (Lanier et al., 1977) produced false positives; that the airflow rates of the Moeck (1970) olfactometer were not equal, which could cause differential anemotaxis; that their release rates could have been very high (no quantitative measure of ipsdienol delivery rate or dosage was given); or that their synthetic ipsdienol was inadvertently contaminated with natural lanierone.

Lanier et al. (1980) tested the attractiveness of synthetic ipsdienol in the field and observed a level of response equivalent to 20 male beetles boring in red pine. Attraction to synthetic material under natural field conditions is often considered the final, conclusive test of a pheromone identification (Silverstein et al., 1967; Vité, 1967). Yet, it has been shown that the response of *I. pini* to pheromone can vary during the flight period (Teale and Lanier, 1991). In the spring and early summer, *I. pini* only responded to male beetles and not to synthetic ipsdienol. In the late summer and fall, there was no significant difference between the numbers of beetles attracted to synthetic ipsdienol and male beetles. This seasonal variation in response to pheromone is associated with population density, which is usually highest in late summer and fall (unpub-

lished data). Lanier et al. (1980) conducted field tests of synthetic ipsdienol in August and September when *I. pini* frequently responds to an incomplete component blend (i.e., ipsdienol). Stewart (1975) described the field site of Lanier et al. (1980) as having been thinned in the spring of the year previous to the field test. If Lanier et al. (1980) had conducted their field tests in the spring or at a lower density site (undisturbed), they probably would not have observed attraction to synthetic ipsdienol. The role of lanierone is the key to understanding seasonal variation in response to ipsdienol in New York. Because variation in response to ipsdienol is dependent on population density (unpublished data), production of lanierone probably does not vary significantly with season. This can now be determined by direct measurement.

There is no a priori contradiction between our results and those of Birch et al. (1980) and Miller et al. (1990). In view of the differences in ipsdienol stereochemistry between New York and western populations, the possibility of geographic variation in the presence of lanierone cannot be ruled out. It is not known if lanierone is produced by the California population, and unless this is demonstrated, there is no inherent incongruity between our results and those of Birch et al. (1980).

(Received November 26, 1990; accepted February 13, 1991)

Abstract—Field experiments indicate that the foliar concentration of condensed tannin affects the selection of leaf material of *Inga oerstediana* Benth., a tropical legume tree, by leaf cutter ants. In one study an increase in tannin concentration was correlated with a decrease in the acceptability of leaves to leaf-cutter ants, except at low tannin concentrations. Protein concentration was not correlated with acceptability nor was the ratio of protein to tannin. Results from a second study suggest that when the concentration of tannin was low the ants appear to select leaves on the basis of nutrient availability. Laboratory assays with the ants indicated that quebracho tannin, a commercially available condensed tannin, inhibits foraging ants. Again, at lower concentrations, quebracho tannin appeared to have little affect on the ants.The fungus the ants cultivate is a wood-rotting Basidiomycete that produces enzymes, such as polyphenol oxidase (PPO), that are capable of inactivating tannins. The activity of these PPOs may explain why leaf-cutter ants are undeterred by low concentrations of condensed tannins. I hypothesized that PPO activity would be absent from fungal cultures without tannin and that only high concentrations of tannin would inhibit the fungus. Cultures with and without tannin showed similar PPO activity. Thus PPO activity is constitutive. In fact, as fungal biomass increased, so did PPO activity. As hypothesized, only high concentrations of quebracho tannin inhibited PPO activity and fungal growth. However, it is not clear whether the ants can discriminate between concentrations that do and do not inhibit the fungus.

Key Words—*Atta cephalotes*, attine ants, Hymenoptera, Formicidae, *Inga oerstediana*, plant-herbivore interactions, host selection, condensed tannins, fungal performance, polyphenol oxidase.

INTRODUCTION

The concentrations of nutrients and phenolics typically differ in leaves of plants growing under different environmental conditions and in leaves of different ages, and these chemical traits may influence patterns of herbivory (Fox and Macauley, 1977; Chandler and Goosem, 1982; Coley, 1983a,b; Waterman et al., 1984; Meyer and Montgomery, 1987; Mole and Waterman, 1988; Denslow et al., 1990; Nichols-Orians and Schultz, 1990). Tannins are one class of phenolics that may influence selection of leaves by herbivores (Waltz, 1984; Mole and Waterman, 1988; Schultz, 1989). However, Wint (1983) and Mole and Waterman (1988) suggest that selection would not depend upon the concentration of nutrients or tannins, but upon the ratio of the two.

Leaf-cutter ants exhibit strong intraspecific preferences for host foliage (Fennah, 1950; Cherrett, 1968, 1972; Rockwood, 1976, 1977; Nichols-Orians and Schultz, 1990), and this appears to be related to the availability of nutrients and the concentrations of secondary chemicals (Barrer and Cherrett, 1972; Howard, 1990; Nichols-Orians, 1991a,b). Although terpenoids are widely recognized for their ability to deter leaf-cutter ants (Hubbell and Wiemer, 1983), some plant species appear to contain tannins in sufficient quantities to deter foraging ants (Howard, 1990; Nichols-Orians and Schultz, 1990).

Leaves of sun plants growing in nutrient-poor soils are generally less susceptible to leaf-cutter ants than leaves of plants growing in nutrient-rich soils (Nichols-Orians, 1991b; R. Marquis, personal communication). This may be because these growth conditions result in elevated concentrations in some plant species of carbon-based secondary compounds like tannins (Chandler and Goosem, 1982; Nichols-Orians, 1991b). However, leaves of plants growing in the sun and in nutrient-rich soil often have higher concentrations of both condensed tannins and foliar nutrients than the leaves of plants growing in the forest understory (Field and Mooney, 1986; Denslow et al., 1990; Nichols-Orians, 1991a), and these sun leaves have been found to be more acceptable to leaf-cutter ants than understory leaves (Nichols-Orians, 1991a; R. Marquis, personal communication). Thus, moderate concentrations of condensed tannins do not appear to deter foraging ants.

In addition to environmentally based differences in chemistry and acceptability, there may be phenological differences as well. Young leaves usually contain higher concentrations of nutrients and usually are more acceptable to leaf-cutter ants than mature leaves (Barrer and Cherrett, 1972; Waller, 1982). However, in one study (Nichols-Orians and Schultz, 1990), we found young leaves to be less acceptable chemically to leaf-cutter ants than mature leaves, despite higher concentrations of nutrients. These young leaves had much higher concentrations of condensed tannins. Young leaves of neotropical trees often have higher concentrations of tannins and other phenolics than mature leaves (Coley, 1983a,b), which suggests that leaf-cutter ants often may find young

leaves less acceptable. Recently, Coley and Aide (1989) found that as anthocyanin concentration increases leaves are less acceptable to leaf-cutter ants. Anthocyanin is structurally similar to tannins and, like tannins, has antibiotic properties. All these studies suggest that the chemical acceptability of leaves to leaf-cutter ants may depend upon both the concentrations of nutrients and tannins and perhaps upon the ratio of the two.

Here, I evaluate trade-offs in host plant acceptability with respect to levels of foliar protein and condensed tannin. I divided this study into two parts. First, using leaves from plants growing in different light and soil nutrient conditions, I investigated how quantitative differences in the concentrations of protein and condensed tannins influence the selection of leaves by leaf-cutter ants, and compare these results to those of previous studies on this system (Nichols-Orians and Schultz, 1990; Nichols-Orians, 1991a,b). Second, I determined how varying the concentration of a commercially available condensed tannin, quebracho tannin, influences selection by the ants and performance of the symbiotic fungus the ants cultivate. The first part of the study was done with field colonies in Costa Rica and the second part with laboratory colonies at Pennsylvania State University.

The symbiotic fungus is a Basidiomycete fungus that produces enzymes, polyphenol oxidases and tannases, which are capable of inactivating tannins via polymerization (Cherrett et al., 1989). The ability of the fungus to inactivate tannins may explain why leaf-cutter ants appear insensitive to relatively low concentrations of tannin (Nichols-Orians, 1991a). As with many fungal enzymes (Cooper and Wood, 1973, 1975), polyphenol oxidases (PPOs) can be induced by the presence of certain chemicals, such as gallic acid, a precursor of tannin (Mayer, 1987). The PPOs produced by the ants' fungus may be induced by the presence of condensed tannin and, once produced, polymerize and inactivate the tannins. Therefore, I hypothesized that PPO activity would only be present in fungal cultures containing tannin. Furthermore, I predicted that low concentrations of tannin would be quickly inactivated and so would not inhibit PPO activity or fungal growth. Since high concentrations of tannin may inhibit PPOs (Lyr, 1962), fungal growth may be inhibited as well. Because PPOs are produced extracellularly, as evident from the formation of colored oxidative products following addition of fungus to media containing tannins and other phenolics (Bavendamm's test) (Kirk and Kelman, 1965; unpublished data), it is easy to quantify PPO activity.

METHODS AND MATERIALS

Site

The study was conducted at the Organization for Tropical Studies' La Selva Biological Station (10°26′N, 83°59′W) in the Atlantic lowland near Puerto Viejo de Sarapiqui, Costa Rica. This forest is a tropical wet premontane forest

(Holdridge et al., 1971) and receives a mean annual rainfall of 4000 mm (Hartshorn, 1983), with a short dry season from late January to April (La Selva, unpublished records). The field portion of this study was conducted from January to July 1987.

Laboratory assays with the ants and the fungus were conducted in 1989–1990 with colonies maintained at Pennsylvania State University. Colonies were collected from La Selva in January 1987 and maintained on a diet of frozen *Forsythia* and fresh cabbage during the experiments.

Leaf-Cutter Ants/Fungus

Colonies of a leaf-cutter ant, *Atta cephalotes* (L.) (Hymenoptera: Formicidae: Attini), are abundant within La Selva and naturally encounter plants growing under different environmental conditions (personal observation). Leaf-cutter ants use the harvested leaf material to support the growth of a symbiotic fungus, which is the sole food source of the developing larvae (Quinlan and Cherrett, 1979). Hydrolyzable tannins have been shown to inhibit the growth of an attine fungus (Seaman, 1984), but condensed tannins appear to be even more effective inhibitors of the fungi (Cherrett et al., 1989). This result is consistent with the observation that condensed tannins are very effective inhibitors of fungi and their enzymes (Zucker, 1983). Therefore leaf-cutter ants would be expected to avoid leaves with tannin levels sufficient to inhibit the fungus. If tannin levels are low, then nutrients would be expected to dictate acceptability (Berish, 1986; Waltz, 1984).

Plant Species

The tropical legume tree, *Inga oerstediana* Benth. [formerly *Inga edulis* var. *minutula* Schery, (Nichols-Orians and Schultz, 1990)] (Fabaceae: Mimosoideae) is naturally attacked by leaf-cutter ants (personal observation). Yet *Inga* is regarded as being relatively resistant to leaf-cutter ants (Arckoll, 1984). *Inga* spp. produce high concentrations of tannins (Koptur, 1985; Nichols-Orians, 1990, 1991a,b), so the low susceptibility of *Inga* to leaf-cutter ants may be due to these tannins.

Plant Treatments

In a previous study I showed that light and soil nutrient conditions influence foliar chemistry and the acceptability of leaves to leaf-cutter ants (Nichols-Orians, 1991b). For a subset of the plants used in the above study ($N = 48$), I measured foliar chemistry and conducted bioassays with the leaves to determine their acceptability to the ants. This study evaluates the relationship between chemistry and acceptability.

The following is a brief description of the growth conditions. Initially, field-collected seedlings were grown in pots containing either nutrient-rich alluvial or nutrient-poor residual soils (Vitousek and Denslow, 1987) at 20%-of-full-sunlight. After 13 weeks half the seedlings were transferred to 2%-of-full-sunlight and grown for an additional seven weeks. At the same time I altered light conditions, I initiated fertilization treatments. Thus, there were eight treatments with six seedlings in each treatment (Figure 1). I noted when leaves matured throughout the experiment so that at the end of the 20 weeks two different leaf types were harvested from each plant: (1) those that had matured during the first 13 weeks (PRE leaves) and (2) those that developed and matured during the last seven weeks (POST leaves).

Leaf Material

Both PRE and POST leaves were collected seven weeks (±4.5 days) after light and nutrient manipulation. Seedlings were first transported in their pots to the study colony and a minimal amount of leaf material was used during the bioassays with the ants. *I. oerstediana* leaves are compound. Bioassays to determine how leaves differed in acceptability were conducted with disks from the distal leaflets only in order to avoid confounding leaflet position effects (Gall, 1987). Although I have not detected position effects on acceptability (personal observation), Gall (1987) found that basal leaflets in a number of Juglandaceae species were less acceptable to various *Catocala* larvae (Noctuidae) than either lateral or terminal leaflets.

Once bioassays were complete (approximately 30 min), all remaining leaf material was removed, immediately frozen, freeze-dried, and ground to a powder, with a UDY Cyclone Mill, at La Selva before being transported back to Pennsylvania State University for chemical analyses. Because of the large amount of leaf material required for chemical analyses, chemistry was deter-

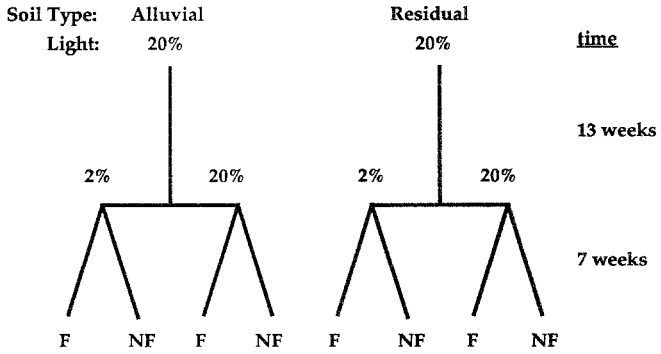

FIG. 1. Schematic diagram of treatments. F = fertilized, NF = not fertilized.

mined from the analysis of entire leaves minus the petiole. Although removal of leaf material during the bioassays could conceivably cause a change in chemistry, I found no change in chemistry 24 hr after damaging *I. oerstediana* seedlings (Nichols-Orians, 1991a).

Unfortunately there was not enough leaf material from some plants to conduct bioassays and do chemical analyses. Therefore, the correlation between chemistry and acceptability was done on a subset of leaves ($N = 37$). Even with the reduced sample size, there was extensive variability in leaf chemistry. In fact, the range of values reported here very nearly expand the full range measured previously in *I. oerstediana* leaves (Nichols-Orians, 1990, 1991a,b).

Chemical Analyses

For analysis of protein concentration, I extracted approximately 20 mg of leaf powder in 10 ml of 0.1 N NaOH for 2 hr in a boiling water bath and used Bio-Rad reagent to quantify protein content (Snyder and Desborough, 1978; Compton and Jones, 1985). This extraction technique is designed to measure the concentration of protein in leaves high in tannin (Jones et al., 1989).

For the analysis of the various phenolic traits, leaf powder (300–400 mg) was washed with ether for 30 min. Phenolics were extracted with 70% acetone for 3 hr at 40°C. The acetone was removed under reduced pressure, and the extracts were diluted to 10 ml with distilled water. Extracts were analyzed for proanthocyanidin condensed tannins (butanol–HCl method; Bate-Smith, 1977), leucoanthocyanin condensed tannins (vanillin method; Broadhurst and Jones, 1978; Butler et al., 1982), and protein-binding capacity using hemoglobin as the substrate (Schultz et al., 1981). Relative concentrations are expressed as wattle tannin (*Acacia* sp. from Leon Monnier, Inc., Peabody, Massachusetts) equivalents per milligram of dry weight (%WTE) for the two condensed tannins and as tannic acid (Sigma, Lot No. 11F-0559) equivalents per milligram of dry weight (%TAE) for protein-binding capacity. I also measured total phenolics (Folin-Denis assay; Swain and Hillis, 1959), but because they were over 90% correlated with the two condensed tannins I am restricting my discussion to the two tannins and protein-binding capacity. Thus far, surveys indicate that tannins are the only secondary compounds in *Inga* (Koptur, 1985), and only condensed tannins are abundant in *I. oerstediana* (unpublished data).

Bioassays with Leaves

All bioassays were done with a single colony. Previous work has shown that the relative acceptability of leaf types of *I. oerstediana* to leaf-cutter ants is similar among ant colonies (Nichols-Orians and Schultz, 1990; Nichols-Orians, 1991a).

I conducted the "pickup" assay to assess the chemical acceptability of

each leaf type to leaf-cutter ants (Howard, 1987; Nichols-Orians and Schultz, 1990). The pickup assay is designed to determine preferences based on chemical differences, defensive or nutritional, between leaf types (Howard, 1987). Two leaf disks produced with a standard paper punch, were placed beside two disks of a highly preferred control, *Hamelia patens* (Rubiaceae). When one disk was removed it was replaced by a like disk. To ensure that the assays with the various leaf types were independent, I separated them by 9 in. and randomized the order of presentation each day. The chemical acceptability of a given leaf type was expressed as the number of leaf disks removed when 20 control disks had been removed. The final acceptability of each leaf type was the average number of leaf disks removed during two replicate trials.

The use of a control indicated whether ants were willing to pick up leaf disks on any given day and standardized for fluctuations in ant activity during each assay replication. *H. patens* was used as the control because of its high acceptability to leaf-cutter ants and because numerous plants can be found growing under similar conditions. It is abundant in a clearing near the study colony. The use of *H. patens* as a control yields very consistent results (Nichols-Orians and Schultz, 1990; Nichols-Orians 1991a,b).

Physical features of a leaf (e.g., trichomes) could influence disk removal, but I did not identify any such physical features in *I. oerstediana*. Conceivably, leaf mass could influence disk removal as well. However, the leaf disks were small enough that all foraging ants could easily pick up these leaf disks. In fact, the toughest and heaviest leaves assayed to date were highly acceptable to the ants (Nichols-Orians and Schultz, 1990). Thus, leaf mass differences among these treatments would not have influenced the results.

Researchers often employ a "cutting" assay when testing whether physical features interfere with the harvesting of leaves by leaf-cutter ants (Howard, 1988; Nichols-Orians and Schultz, 1989, 1990). I did not employ this assay because I was only interested in determining the relationship between nutrients and tannins on the initial selection of leaves by leaf-cutter ants.

Laboratory Bioassays

Bioassays with Ants. I determined whether quebracho tannin influences foraging ants using two laboratory-maintained colonies (collected from La Selva, Costa Rica, in January 1987). Quebracho tannin was obtained from the Van Dyke Supply Co. (Woonsocket, South Dakota). Seven different tannin treatments (concentrations) were tested: 10, 5, 2.5, 1, 0.5, 0.25 and 0.1% (w/v). Distilled water was used at all times. Organic rye (1 g) flakes were soaked for 2 min in 2 ml of solution (one of the seven tannin treatments or a water only control). The flakes were drained and dried at 25°C overnight.

During each assay, 50 treatment flakes and 50 control flakes were placed

on a glass plate above a randomly generated grid on a foraging platform (design similar to Hubbell and Wiemer, 1983). Treatment and control flakes were placed on one of two patterned boxes. Ants were allowed access to the foraging platform and the number of control and treatment flake types remaining was determined every 2 min. The assay was terminated when the ants removed 25 of either flake type. After each run the access holes were plugged and the ants removed before initiating another assay. Because control flakes often were placed during subsequent assays where treatment flakes had been, and visa versa, the glass plate was wiped with acetone to prevent pheromone carry-over. The acceptability of each treatment is expressed as the number of treatment flakes removed when 25 control flakes had been removed. (Occasionally 25 treatment flakes were removed first. For these assays the number treatment flakes/25 control flakes was calculated algebraically.)

All treatments were tested on both colonies on the same day. The order in which the different concentrations were tested was randomized each day for each colony. Also treatment flakes were randomly assigned to one of the two patterned boxes for each assay. In all, there were five replicate assays for each colony. On the first day, only three treatments (10%, 1%, and 0.1%) were tested.

Fungal Bioassays. The fungus from one of the two colonies tested above was isolated, maintained on potato dextrose agar (PDA) plates, transferred to Sabaroud's dextrose broth (SDB), and later grown in a liquid medium designed to test for the effects of tannins on fungal performance (Seaman, 1984). This FPT medium contained the following components per liter of distilled water: (1) major components (g)—KH_2PO_4 (1), $MgSO_4 \cdot 7H_2O$ (0.5), NaCl (0.1), $CaCl_2 \cdot 2H_2O$ (0.1), NH_4 tartrate (5.0), and dextrose (20); (2) minor components (mg)—$ZnSO_4 \cdot 4H_2O$ (4), $MnSO_4 \cdot 4H_2O$ (4), and ferric tartrate (4); (3) organic supplement (mg)—4-methyl-5-thiazole ethanol (0.180), and 4-amino-5-aminomethyl-2-methylpyrimidine dihydrochloride (0.250). In these experiments, 500 ml of distilled water was replaced with 500 ml of 0.05 M dimethyl glutaric acid buffer (pH 5.5) (Powell and Stradling, 1986).

Three basic in vitro experiments were conducted. First, at each tannin concentration I determined the effect of tannin on polyphenol oxidase (PPO) activity. Second, I measured changes in PPO activity in liquid cultures of fungi incubated with quebracho tannin for different lengths of time (10, 30, 60, or 120 min, and 2, 7, or 21 days). In a separate experiment, there were three replications per treatment at day 2. Finally, I measured differences in fungal biomass after 21 days of incubation and regressed PPO activity against biomass.

Fungal Growth Assays. Fungus obtained from PDA plates was placed in 65 ml SDB and blended for 1 min in a Vertis blender at low speed. Five milliliters of the fungal suspension were pipetted into Erlenmeyer flasks containing 45 ml of SDB. The cultures were then grown for 10 weeks in the dark. After

10 weeks, the fungus was filtered, resuspended in modified FPT (50 ml FPT/flask of fungus), and blended for 1 min at low speed. The fungus was kept evenly suspended using a stir bar and magnetic plate.

One milliliter of fungal suspension was added to 8 ml of modified FPT in sterile test tubes and placed for four days in the dark at room temperature. After four days 1 ml of one of four quebracho tannin solutions was added to the suspension to give a final concentration of 0, 0.0025, 0.025, and 0.25% quebracho tannin. At various time intervals from 10 min to 21 days, the activity of polyphenol oxidase (PPO) was determined (using the protocol described below), and at 21 days the dry mass of the fungus in each treatment was determined.

PPO Activity. Catechol is commonly used as a substrate to measure PPO activity (Flurkey and Jen, 1978). Liquid cultures of fungus were centrifuged at 1000 rpm for 10 min and the supernatants placed on ice. In test tubes, 0.75 ml of the supernatant from the fungal cultures were combined with 2 ml 0.1 M citric acid–sodium citrate buffer (pH 5.5). Following the addition of 0.25 ml of catechol (or distilled water for controls), the test tubes were vortexed and incubated at 30°C for 30 min, and then the final absorbance was determined (420 nm) with a spectrophotometer. After subtracting the absorbance of the controls, a final PPO activity was obtained.

Finally, because the concentration of tannin in solution influences pH, I also determined whether differences in pH would influence PPO activity. Using a 0.1 M citric acid–sodium citrate buffer, the effects of three different pH solutions (4.0, 5.0, 6.0) on PPO activity were tested. Solutions were incubated for two days before measuring PPO activity.

Statistical Analyses

All statistical analyses were done using SAS (SAS Institute, 1985). Chemistry data were natural log transformed prior to analyses.

Bioassays with Leaves. The number of leaf disks removed during the pickup assay was regressed against each of the chemical traits measured. In the process, three outliers were identified (based on studentized residuals) and removed. Because Mole and Waterman (1988) suggested that the ratio of protein to tannin may be the key to the susceptibility of plants to herbivores, I also divided the concentration of protein by each of the three phenolic traits (the two condensed tannins and protein-binding capacity) and regressed the number of leaf disks removed against each of these ratios.

Laboratory Bioassays with Ants. Neither the order in which the treatments were tested nor the colony tested had a significant effect on leaf pickup assays. Therefore the effects of increasing tannin concentration on the acceptability of rye flakes was determined using the following one-way ANOVA model: flakes removed ($\bar{X}$) = constant + ln (tannin concentration). A Bonferroni test was

used to compare differences in acceptability among the different tannin concentrations.

Laboratory Fungal Bioassays. The effect of increasing tannin concentration on PPO activity also was analyzed with an ANOVA model with tannin concentration as the main effect. A Bonferroni test was used to compare treatment means. Unfortunately, the quebracho tannin bound to the fungus, so I was unable to determine the effects of tannin concentration on fungal growth. A regression analysis was used to determine the relationship between fungal biomass and PPO activity.

RESULTS

Bioassays with Leaves

Results from the regression analysis indicate that the acceptability of leaves to leaf-cutter ants was negatively correlated with protein-binding capacity (PBC) and the two condensed tannins (Figure 2A–C). The fact that all three traits gave similar negative correlations was because PBC and the two condensed tannins were all highly correlated ($P \geq 0.91$). For both condensed tannin traits, proanthocyanidin (PA) and leucoanthocyanin (VN) condensed tannins, a quadratic model provided the highest correlation. This suggests that lower concentrations of tannins did not deter the ants. However, linear and quadratic models provided identical correlation coefficients for PBC. Protein (PRT) concentration was not correlated with leaf acceptability ($R^2 = 0.02$, $P = 0.651$) and the ratio of PRT to PBC, PA, or VN did not improve the correlation (PRT/PBC, $R^2 = 0.31$; PRT/PA, $R^2 = 0.23$; PRT/VN, $R^2 = 0.24$).

Laboratory Bioassays

Bioassays with Ants. An analysis of variance indicates that the concentration of quebracho tannin (QT) affected the acceptability of rye flakes to leaf-cutter ants (Figure 3). Lower concentrations did not deter the ants, while higher concentrations did deter them.

Fungal Bioassays. Quebracho tannin did inhibit fungal PPO activity. Although the addition of QT to the fungal suspensions lowered pH, the inhibitory effect was not due to a change in pH (Table 1). I found no difference in the PPO activity of fungal cultures buffered at pH 5.0 and 6.0. Only at pH 4 was there a reduction in PPO activity (PPO = 0.075).

Incubation of QT with the fungus culture for two days demonstrated that PPO activity is inhibited only at the highest concentration (Figure 4). Only high concentrations appeared to inhibit the fungus as well. After 21 days, fungal cultures in 0.25% QT had died, whereas those at the lower concentrations were still growing vigorously.

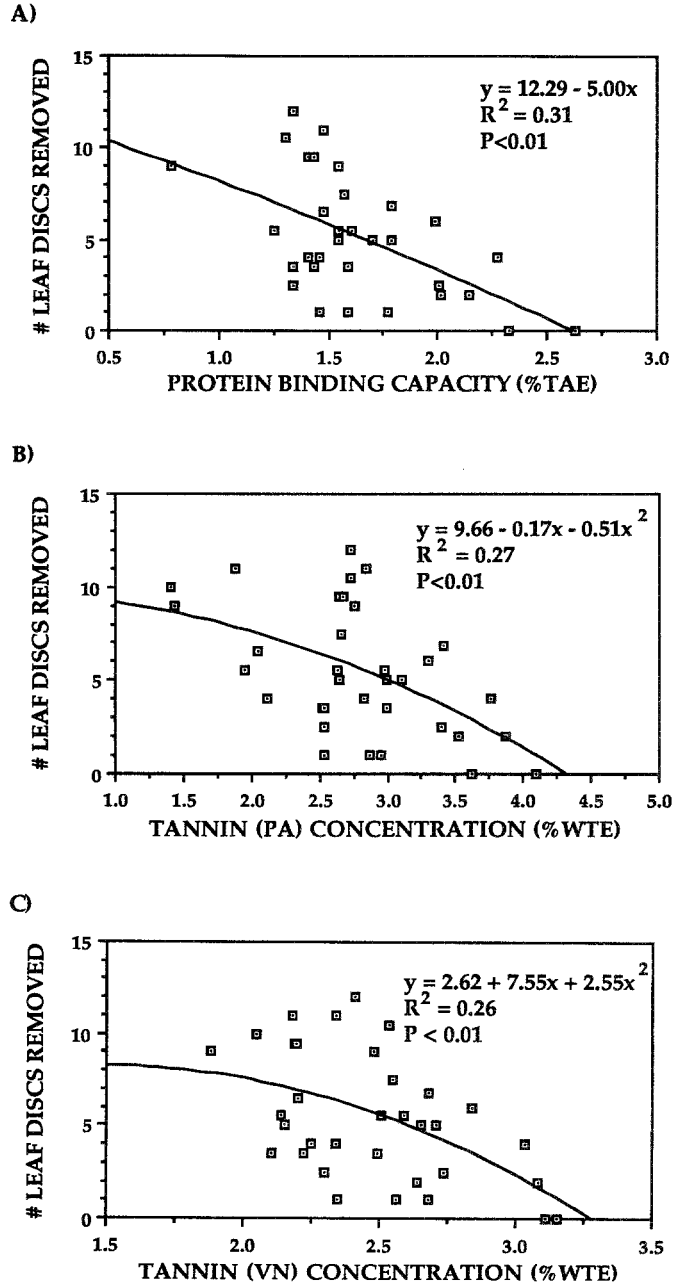

FIG. 2. Regression analysis showing the relationship between the acceptability of leaf disks to leaf-cutter ants and three phenolic traits: (A) protein-binding capacity, (B) proanthocyanidin (PA) condensed tannin, (C) leucoanthocyanin (VN) condensed tannin. Chemical data were natural log transformed.

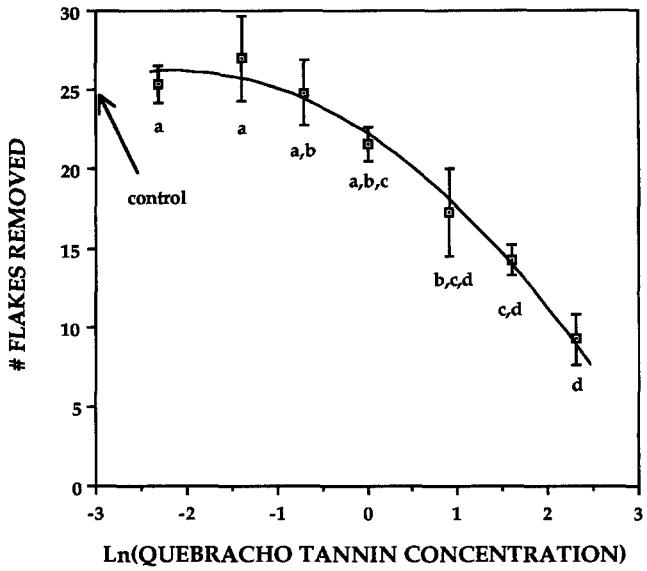

FIG. 3. Analysis of variance results showing the relationship between the acceptability of rye flakes (± standard error) to leaf-cutter ants and the concentration of quebracho tannin. Chemical data were natural log transformed.

TABLE 1. EFFECTS OF QUEBRACHO TANNIN (QT) AND pH ON PPO ACTIVITY[a]

Concentration (%)	pH	PPO
A. Quebracho tannin		
0	5.32	0.105
0.0025	5.28	0.114
0.025	5.28	0.093
0.25	5.16	0.015
B. Buffer		
	6.0	0.085
	5.0	0.086
	4.0	0.075

[a] PPO activity was measured as the change in absorbance following incubation of fungal suspension with catechol for 30 minutes. (A) The effects of QT on pH and PPO activity, and (B) the effects of pH on PPO activity. In (B), a 0.10 M citric acid–sodium citrate buffer was used to manipulate pH.

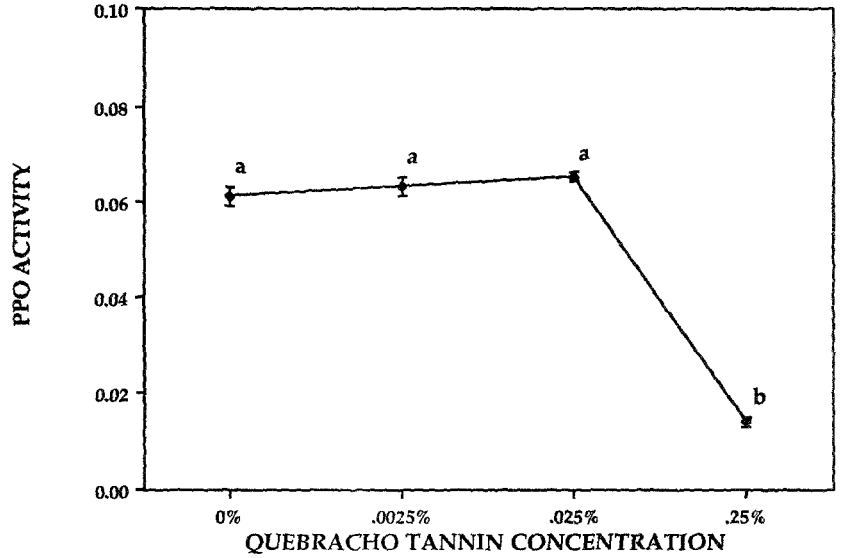

FIG. 4. Polyphenol oxidase activity (± standard error) after two days in fungal cultures containing different concentrations of quebracho tannin. *x* axis is log scaled.

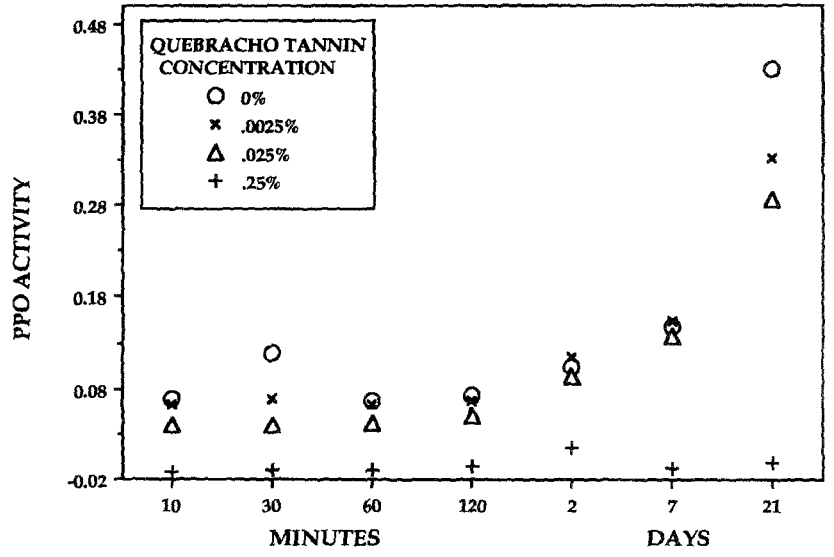

FIG. 5. The effects of different concentrations of quebracho tannin on the polyphenol oxidase activity through time.

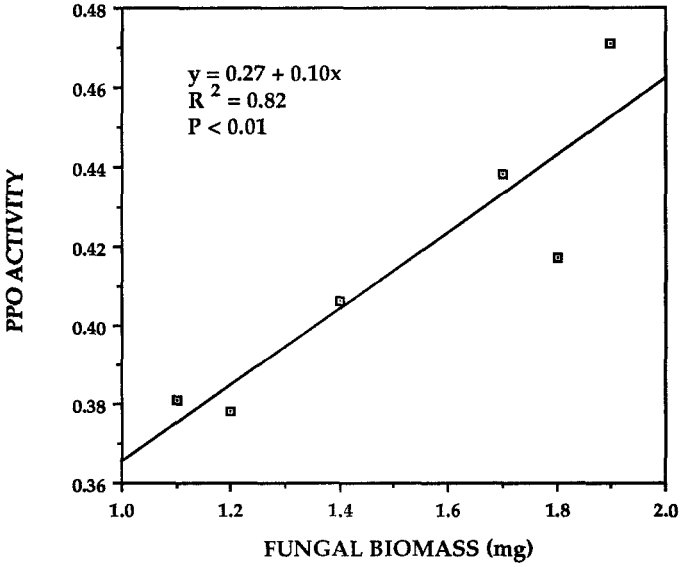

FIG. 6. The effects of fungal biomass on polyphenol oxidase activity. All measures taken from 21- day-old tannin-free fungal cultures.

There was no evidence that the presence of tannin was necessary for the production of PPO (Figures 4 and 5). PPO activity in supernatants without tannin was as high if not higher than in supernatants with tannin at several sampling periods (Figure 5). Rather, PPO activity is correlated with fungal biomass (Figure 6). In 21-day-old control (0% QT) cultures, the greater the biomass the higher the PPO activity.

DISCUSSION

Tannins do not deter herbivores uniformly (Bernays, 1978, 1981; Schultz, 1989). Some herbivores appear adapted for consuming high tannin leaves (see Schultz, 1989). For others, some dietary tannin may actually be beneficial (Bernays, 1978; Keating et al., 1988). Previous research on the interactions between *I. oerstediana* and leaf-cutter ants suggests that only higher concentrations of tannin deter the ants (Nichols-Orians and Schultz, 1990; Nichols-Orians, 1991a,b). Since the fungus the ants cultivate produces enzymes that facilitate the inactivation of phenolic substances (Cherrett et al., 1989), the fungus may be adapted to handle lower concentrations of tannin. I had hypothesized that leaf-cutter ants may not be sensitive to lower concentrations of tannin because the fungus is capable of inactivating the tannins.

Results of the bioassays with leaves and rye flakes indicate that the condensed tannins of *I. oerstediana* and QT inhibited leaf–fungal substrate selection by leaf-cutter ants (Figures 2 and 3). I should note that the protein-binding capacity of *I. oerstediana* leaves was as high or higher than the flakes (unpublished data), which suggests that the concentrations of QT selected were appropriate. Consistent with previous research (Nichols-Orians, 1991a), very low concentrations did not deter the ants (Figures 2 and 3).

I had hypothesized that only in the presence of QT would there be PPO activity (sensu Mayer, 1987). I further suggested that only higher concentrations of tannin would inhibit PPO activity and, therefore, the fungus. Contrary to my hypothesis, fungal cultures without QT showed PPO activity (Figures 4 and 5). In fact, PPO activity increases with fungal biomass (Figure 6). Thus, the production of PPO is constitutive and does not appear to be induced by QT. However, the results are not definitive because QT can inhibit the enzymes directly (unpublished data). This could have masked an increase in PPO activity above constitutive levels at the lower tannin concentrations. Studies of gene activation are needed to determine whether QT or other phenolics can induce PPO production.

As hypothesized, only a high concentration of quebracho tannin strongly inhibited PPO activity (Figures 4 and 5). This may explain why leaf-cutter ants were most inhibited by higher concentrations of condensed tannins. Unfortunately, it was not possible to compare directly the concentration of QT in the liquid media to the concentration applied to the flakes. Therefore, it is not clear from these results whether leaf-cutter ants can discriminate between a tannin concentration that does and does not inhibit the fungus. Future experiments should investigate this possibility.

Tannins are not the only chemicals that vary among leaves of different ages and among plants in different environments; nutrients vary as well. Both nutrients and secondary chemicals may be responsible for differential acceptability of leaves to herbivores (Fox and Macauley, 1977; Mattson, 1980; Wint, 1983; Waltz, 1984; Mole and Waterman, 1988). Wint (1983) and Mole and Waterman (1988) hypothesized that the selection of leaves by herbivores would not depend upon the concentration of protein or tannin but upon the ratio of protein to tannin. The data presented here do not provide support for their hypothesis.

In a previous study (Nichols-Orians, 1991a), leaves of seedlings growing in full sun had a higher concentration of protein and were more acceptable to leaf-cutter ants than were leaves of understory seedlings, despite a higher concentration of tannin (Figure 7). [Since the concentration of other nutrients, such as nonstructural carbohydrates, may also increase with increasing light availability (Nichols-Orians, 1991a), the preference for sun leaves may not have been due changes in protein concentration specifically.] In another study

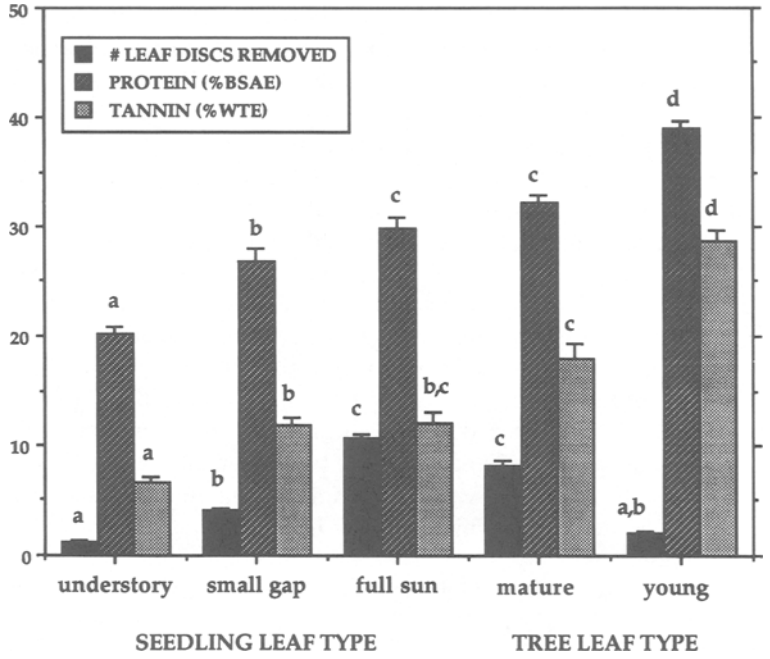

FIG. 7. Relationship between the acceptability of leaf disks to leaf-cutter ants (± SE) and the protein and condensed tannin (leucoanthocyanin) concentration (± SE) in various leaf types. (Included are mature leaves of seedlings growing in different light environments, and young and mature leaves of trees growing in full sun. Chemical data were natural log transformed prior to statistical analyses. Bars (within category) with different letters are different at $P \leq 0.05$. (Data from Nichols-Orians and Schultz, 1990; Nichols-Orians, 1991a).

(Nichols-Orians and Schultz, 1990), young leaves of juvenile trees growing in full sun had a higher protein concentration than mature leaves, yet were less acceptable to the ants. The rejection of the young leaves appeared due to the higher concentration of tannin in young leaves as compared to mature leaves (Figure 7). These studies suggest that, although the ratio of nutrients to tannin appears unimportant, both nutrients and condensed tannins do influence leaf selection by leaf-cutter ants.

Researchers have not always found tannins to deter leaf-cutter ants (Littledyke and Cherrett, 1976; Kawanashi and Raffauf, 1986; Howard, 1987, 1988, 1990). Most of these studies have been qualitative. Since most woody plants produce tannins, yet many produce only a low concentration (Coley, 1983a), qualitative studies may not detect tannin effects on acceptability. Relative to other species (Denslow et al., 1990), *I. oerstediana* produces a high concentra-

tion of tannin (Nichols-Orians, 1990), yet even in this species an increase in tannin does not necessarily lead to a decrease in the acceptability of leaves to leaf-cutter ants (Nichols-Orians, 1991a). Clearly, the inhibition of ants and their fungus by condensed tannins is concentration dependent.

Acknowledgments—H. Appel, J. Cazin, W. McCarthy, C. Mullin, and D. Wiemer provided suggestions for the experimental protocol. The Organization for Tropical Studies (OTS) helped make this research possible. A special thanks go to David and Deborah Clark and Victor Chavarria of OTS for making it possible to live in Puerto Viejo. Marc Pacchioli helped me conduct laboratory bioassays with the ants. Early versions of this paper benefited from the comments of J. Schultz, H. Appel, J. Howard, S. Keating, and two anonymous reviewers. CATTLE FEEDING DETERRENTS EMITTED FROM CATTLE FECES

H. DOHI,* A. YAMADA, and S. ENTSU

(Received October 4, 1990; accepted February 14, 1991)

Abstract—Cattle avoid grazing forage near their feces on pasture for more than a month. The relation of cattle feces odor to the rejection was studied in feeding choice tests using cattle. The feeding deterrent of feces odor was investigated using a trough partitioned to allow passage of feces odor through test food to the cattle. The cattle did not feed from the trough containing feces 0–35 days after excretion. Volatile chemicals isolated from feces 0–35 days after excretion by a cold trap method also inhibited cattle from feeding. These results demonstrated that feces odor is a major cause of the unpalatability of forage around cattle feces. The volatile chemicals were separated into ether and aqueous fractions. The ether fraction inhibited the feeding behavior of cattle. Furthermore, the ether fraction was separated into neutral, acidic, and basic fractions. The neutral fraction of the three was bioactive. These results suggested that specific volatile chemicals emitted from cattle feces were deterrents to the feeding behavior of cattle.

Key Words—Cattle, dung patch, feces odor, feeding deterrents, volatiles.

INTRODUCTION

On pasture, it is widely observed that cattle selectively graze plants and their olfactory sense appears to be involved in that selection. In particular, the phenomenon that cattle reject eating grass near their feces is frequently observed (Tayler and Large, 1955; MacLusky, 1960; Marten and Donker, 1964a, b; Tayler and Rudman, 1966; Greenhalgh and Reid, 1968). The ungrazed area is called a dung patch. It is also known that cattle readily eat grass cut from dung

*To whom correspondence should be addressed.

0098-0331/91/0600-1197$06.50/0

patches, reject dung-affected grass by night as much as by day, and reject the grass after their marked audible inhalations near the feces. Thus, Voisin (1959) and Arnold and Hill (1972) concluded that undesirable odor from cattle feces is probably a cause of the rejection by cattle. Cattle accept forage clipped from dung patches (Marten and Donker, 1966), and the grazing pattern between blindfolded and non-blindfolded cows on a pasture containing dung patches is similar (MacDiarmid and Watkin, 1972). However, there is very little evidence for the direct deterrent activity of feces odors and which classes of chemicals are involved.

We studied the direct feeding deterrent activity of feces odor and preliminarily separated the deterrent chemicals from cattle feces.

METHODS AND MATERIALS

The cattle used for all feeding choice tests were Japanese Black cattle and were allowed to graze on pasture unless they were used in the feeding choice tests. A total of 5 kg of fresh feces, collected immediately after the excretion during grazing, was put on an isolated pasture for the fecal sampling. A series of seven samplings was made at 0, 1, 7, 14, 21, 28, and 35 days, collecting a total of 1 kg feces from the simulated dung for the feeding choice tests and the isolation of volatile chemicals. After those experiments, all feces were put back onto the same simulated dung. This sampling was repeated five times sequentially in late autumn to avoid worm contamination in the feces. For the separation of isolates, feces more than two weeks after excretion was collected.

Test of Odors from Feces. Figure 1 shows the troughs used to investigate the inhibitory effect of cattle feces odor on feeding. The trough consisted of two boxes. The bottom of the top box had many holes to allow passage of the feces odor. The upper box contained 300 g of artificial diet, which the cattle liked, and the lower box contained 1 kg of feces 0, 1, 7, 14, 21, 28, or 35 days after excretion. The trough without feces in the lower box was prepared as a

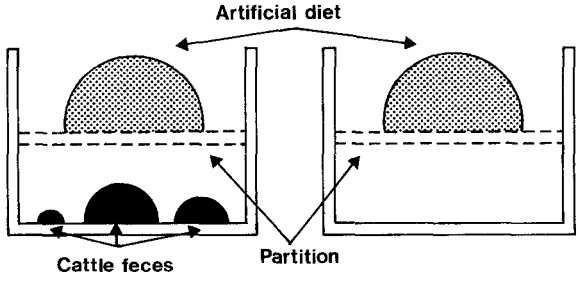

FIG. 1. Trough used to investigate deterrent effects of odor from cattle feces.

control. The two troughs were simultaneously presented to cattle for 2 min and the time cattle fed from each trough was measured. The artificial diet for the choice tests was in pellet form, and its ingredients were milo, maize, barley, rice bran, soybean oilcake, and minerals.

Test of Volatile Chemicals. The solution of volatile chemicals was isolated from 1 kg of feces 0, 1, 7, 14, 21, 28, or 35 days after excretion with an apparatus as shown in Figure 2 and then sprayed on the artificial diet. Distilled water in place of feces was sprayed on the artificial diet in the desiccator as the control. The two choices were presented to cattle for 2 min, and the amount of time the cattle fed on the two choices was measured.

Test of Isolate Fractions. Ether from each fraction of isolates was removed by flowing nitrogen gas at −10°C, and volatile chemicals in the fraction were dissolved in 20 ml distilled water. Artificial diets sprayed with these fractions were presented to cattle and their responses to two or three choices were observed. The degree of feeding was ranked on a scale of −, ± or +. The − represented no feeding or a trace of feeding on diet sprayed with the fraction, ± represented feeding on diet after the end of feeding on other diets, and + represented feeding readily.

Isolation and Separation of Volatile Chemicals. Volatile chemicals of feces were isolated with the apparatus shown in Figure 2. The feces in the desiccator were maintained at 50°C. The volatile chemicals of feces or distilled water were swept from the desiccator by the air filtered through silica gel and a 5 Å molecular sieve and then condensed in two cold traps, which were cooled with iced water and liquid nitrogen. The air was pumped at a flow rate of 500 ml/min and the total volume of air pumped was 500 liters. The isolates obtained by two repeated operations for feces on the day after excretion were combined and used for the feeding choice tests.

For the separation of isolates, a desiccator (25 × 30 cm, ID × H) was filled with 1.5 kg of feces two or more weeks after excretion. Volatile chemicals

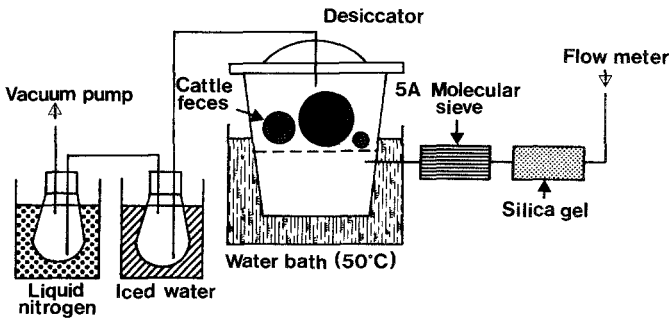

FIG. 2. Apparatus used to isolate volatile chemicals from cattle feces.

were isolated by the same method as described above. The isolates obtained from six repeated operations were combined, extracted with diethyl ether, and separated into ether and water fractions. The solution was also separated into neutral, acidic, and basic fractions by adjusting pH with HCl and NaOH.

RESULTS AND DISCUSSION

The inhibitory effect of feces odor on feeding by cattle is shown in Figures 3 and 4. The cattle almost totally rejected feeding from the trough containing feces 0–35 days after excretion and on food sprayed with the volatile chemicals

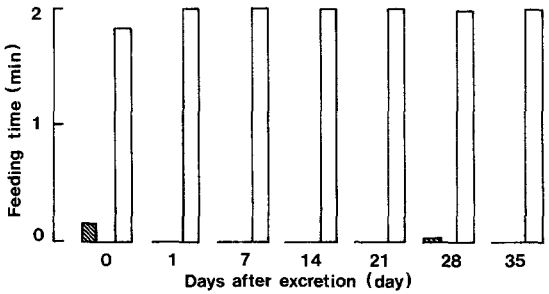

FIG. 3. The amount of time cattle fed on diet from trough with feces (▨) and trough without feces (□) was measured after the two choices were simultaneously presented to cattle for 2 min. Feces were used 0, 1, 7, 14, 21, 28, and 35 days after excretion. Five different cattle were tested for each age of feces. Results are the mean of five determinations.

FIG. 4. The amount of time cattle fed on diet sprayed with the solution of volatile chemicals from feces (▨) and diet sprayed with the control solution (□) was measured. The solution of volatile chemicals was isolated from feces 0, 1, 7, 14, 21, 28, or 35 days after excretion and the control solution from distilled water. Five different cattle were tested for each age of feces. Results are the mean of five determinations.

that were isolated from feces 0–35 days after excretion. These results demonstrated the feces odor had an inhibitory effect on feeding. Grass affected by feces remains unacceptable to cattle over a long period of time (Norman and Green, 1958; Marten and Donker, 1964a; Weeda, 1967; Castle and MacDaid, 1972; MacDiarmid and Watkin, 1972). For an explanation of the long-term rejection by cattle, Norman and Green (1958) hypothesized that the initial refusal of herbage near droppings was due to the dung itself and that the ungrazed herbage then became unpalatable due to its increased maturity. Plice (1951) reported that changes in chemical composition of grass heavily fertilized with cattle dung caused the forage to become unpalatable. However, our studies showed that odors and volatile isolates from feces 35 days after excretion were deterrent to cattle. This suggested that odors from dung are a major cause of the rejection by cattle over the period when dung patches were maintained.

In various phytophagous insects, it is well known that stimulants in plants cause their selective feeding. Many chemicals that stimulate insects have been identified from plants. Arnold (1966a,b) and Arnold et al. (1980) reported that the olfactory sense is involved in food selection using sensory impaired sheep and that the food intake by sheep was regulated by some chemicals found in plants that sheep grazed. The food intake of cattle was increased by flavoring agents (Weller and Phipps, 1989), and feeding by cattle on pine trees was prevented by repellents (Marnane, 1982). Their results led us to the possibility that the selective grazing behavior of cattle, like the behavior of insects, is partially caused by specific stimulant chemicals contained in natural products on pasture. Thus, we hypothesized that some specific chemicals of all volatile chemicals emitted from feces are responsible for the reluctance of cattle to feed in a dung patch. In order to confirm the hypothesis, the volatile chemicals isolated from

Fraction	Degrees of feeding				
(Test 1)					
Ether	−	−	−	±	−
Water	+	+	+	+	+
(Test 2)					
Neutral	−	±	−	−	−
Acidic	+	+	+	+	+
Basic	+	+	+	+	+

[a] (−) represents no feeding or a trace of feeding. (±) represents feeding after the end of feeding on another diets. (+) represents feeding readily. Each fraction was tested with five different animals.

feces were separated and the deterrent activity of fractions was investigated in feeding choice tests (Table 1). In the fraction with diethyl ether, feeding deterrents appeared in the ether fraction (test 1). Among acidic, neutral, and basic fractions obtained by further separation with diethyl ether, the neutral fraction had an inhibitory effect (test 2). These results suggested the presence of specific feeding deterrents to cattle in the odors of cattle feces.

(Received October 9, 1990; accepted February 14, 1991)

Abstract—Analysis of ovipositor washings of female *Maliarpha separatella* from Sierra Leone by high-resolution gas chromatography (GC) linked to a male electroantennograph (EAG) indicated the presence of three electrophysiologically active compounds. The GC retention times of these compounds were consistent with those of (*Z*)-9-tetradecen-1-ol, (*Z*,*E*)-9,12-tetradecadien-1-ol, and (*E*,*E*)-10,12-tetradecadien-1-ol. Analysis by EI and CI mass spectrometry of ovipositor washings confirmed these identifications and also indicated the presence of the saturated analog, tetradecan-1-ol. There was no evidence, from these analyses, of the corresponding aldehydes or acetates. The EAG-active compounds were present in the ovipositor washings in a ratio of approximately 2:3.5:1, with the major component constituting approximately 0.4 ng per ovipositor. GC-MS analysis of entrained female effluvia confirmed that the EAG-active compounds were released by virgin females. Field testing of the EAG-active compounds indicated that (*Z*,*E*)-9,12-tetradecadien-1-ol and (*E*,*E*)-10,12-tetradecadien-1-ol were attractive to male moths in ratios of between 9:1 and 39:1, while (*Z*)-9-tetradecen-1-ol was found to reduce trap catch when added to blends of the other two compounds.

Key Words—*Maliarpha separatella*, (*Z*)-9-tetradecen-1-ol, (*Z*,*E*)-9,12-

*To whom correspondence should be addressed.

tetradecadien-1-ol, (*E,E*)-10,12-tetradecadien-1-ol, sex pheromone, Lepidoptera, Pyralidae.

INTRODUCTION

The African white rice stem borer, *Maliarpha separatella*, is the predominant rice stem borer in West Africa. It is specific to the genus *Oryza* (Akinsola and Agyen-Sampong, 1984) and is capable of inflicting considerable economic damage with the number of rice grains reduced by 70% (Akinsola, 1984) and yield losses of up to 1000 kg/ha being reported (WARDA, 1977). In addition secondary damage can be caused by rice blast, *Pyricularia oryzae*, which gains entrance through the emergence holes of adult moths (Pollet, 1978).

The presence of stem borer larvae of other species usually can be assessed by the number of "white heads" or empty rice panicles formed in a crop. However, the larvae of *M. separatella* rarely cause this condition in West Africa, nor do they cause "dead heart," presumably because of their habit of residing in the lower internodes of the rice culm (Akinsola, 1979; Akinsola and Agyen-Sampong, 1984). The absence of visual damage makes detection difficult, and although adult populations have been monitored by use of paraffin lamp traps (Agyen-Sampong and Fannah, 1987) these traps are not selective. Sex pheromone traps could provide an inexpensive, sensitive, and selective trapping method for monitoring populations of the adult moths (Campion and Nesbitt, 1983, Campion et al., 1987). The presence of a female-produced sex pheromone in *M. separatella* had been demonstrated by Ho and Seshu Reddy (1983), and this paper describes the results of our investigation into the chemical composition of the sex pheromone of *M. separatella* from Sierra Leone and the preliminary field trials with the electrophysiologically active compounds identified with a view of producing a species-specific lure for monitoring this pest species.

METHODS AND MATERIALS

Insect Material. Pupae were collected from susceptible rice plants grown at the WARDA Research Station, Rokupr, Sierra Leone, and dispatched by air to NRI. There they were placed in individual test tubes and maintained on a reversed 12-hr light, 12-hr dark cycle with temperatures alternating from 28°C to 24°C, and a relative humidity of approximately 90%. Emerging adults were sexed and kept in groups of up to 20 in Perspex containers (28 × 15 × 9 cm) with access to a 10% sucrose solution.

Pheromone Collection. Ovipositor washings were prepared in hexane 1–6 hr into the scotophase using virgin females 0–2 days old as described by Sower

et al. (1973). Effluvia from individual virgin females in glass vessels were collected on charcoal filters (5 mg) by air entrainment for 24-hr periods, as previously described (Grob and Zurcher, 1976; Nesbitt et al., 1979; Tumlinson et al., 1982).

Gas Chromatography (GC). GC analyses of natural and synthetic compounds were conducted on a Carlo Erba 4160 instrument with flame ionization detector. Fused silica capillary columns were used throughout the study, coated with either nonpolar CP Sil 5CB (chemically bonded methyl silicone, 50 m × 0.32 mm ID, 0.12 μm film thickness; Chrompack) or polar CP Wax 57CB (chemically bonded Carbowax 20 M; 25 and 50 m × 0.32 mm ID, 0.2 μm film thickness; Chrompack). The carrier gas was helium with a linear velocity of 23 cm/sec. Injections were made with a Grob split–splitless injector at 220°C in the splitless mode, with the valve closed for 40 sec. The analytical column was held at 70°C for 2 min, then temperature programmed as indicated in the tables. GC retention times for isothermal analyses are quoted in minutes, while retention times from temperature-programmed analyses are quoted in equivalent chain lengths (ECLs) relative to the retention times of straight-chain saturated acetates; thus, for example tetradecyl acetate = 14.00 (Harris and Habgood, 1966).

Mass Spectrometry (GC-MS). Electron impact mass spectra (EI-MS) were obtained from a Finnigan MAT Ion Trap Detector (ITD) model 700 under continuous ion monitoring between *m/z* 30 and 250 at 220°C with a filament emission current of 70 μA. The ITD was connected to a Carlo Erba Mega Series 5160 GC via a 1-m fused silica capillary column coated with a chemically bonded, nonpolar methyl silicone liquid phase, heated to 220°C and 1 : 1 open-split interface. Samples were introduced into the GC through a Grob type split–splitless injector held at 220°C with the split valve closed for 40 sec after injection. Chromatographic separations were conducted on fused silica capillary columns coated with CP Wax 52CB (25 m × 0.32 mm ID, 0.2 μm film thickness, Chrompack), a polar chemically bonded Carbowax 20 M equivalent, and CP-Cyclodex B (50 m × 0.25 mm ID, 0.25 μm film thickness, Chrompack), a cyclodextrin-β-2,3,6-M-19 column. The GC columns were held at 70°C for 2 min, then the CP Wax 52CB column was temperature programmed to 120°C at 20°C/min and subsequently at 4°C/min to 210°C, while the CP-Cyclodex B column was temperature programmed at 20°C/min to 190°C. The carrier gas was helium, with an inlet pressure of 0.4 kg/cm^2 for the CP Wax 52CB and 1.0 kg/cm^2 for the CP-Cyclodex B column. Chemical ionization mass spectra (CI-MS) also were obtained with the ITD using isobutane as reagent gas, but holding the ion trap at 200°C and reducing the filament emission current to 35 μA. Scans were either made over the range *m/z* 60–250 or under selective ion monitoring.

Electroantennography (EAG). Combined GC-EAG analyses were recorded essentially as described by Cork et al. (1990). EAG responses elicited by syn-

thetic pheromone analogs were recorded from different doses of compounds applied to filter papers (1.5 cm diameter circle, Whatman No. 1) in 1 μl of pentane and placed in a disposable Pasteur pipet. Nitrogen (250 ml/min) was passed through the Pasteur pipet for 10 sec to remove the solvent. Samples then were presented to the EAG preparation in 1-sec pulses of charcoal-filtered nitrogen (250 ml/min). Chemicals were tested in a randomized order, although the lowest doses were tested first. The EAG preparation was given a 1-min recovery period between stimuli, and each sample was tested five times on each of three males. Samples were stored under nitrogen at −30°C when not in use.

Synthetic Chemicals. (*Z*,*E*)-9,12-Tetradecadien-1-ol was obtained from Food Industries, Ltd., in 1978 and contained 99.4% *Z*,*E*, <0.1% *E*,*Z*, 0.2% *Z*,*Z*, and 0.36% *E*,*E* isomers and 0.01% of the related (*Z*,*E*)-9,12-tetradecadienal.

(*E*,*E*)-10,12-Tetradecadien-1-ol was prepared by Grignard coupling of 1-bromo-10-(2-tetrahydropyranyloxy)decane and (*E*,*E*)-2,4-hexenyl acetate in THF in the presence of $LiCuCl_4$. The reaction product was further purified by recrystallization twice from hexane at −20°C to give material containing 99% *E*,*E* and 1% *E*,*Z* isomers. The mother liquors were isomerized to the thermodynamically most stable mixture with iodine in sunlight and recycled.

Monounsaturated alcohols were prepared by standard acetylenic and Wittig coupling reactions (Henrick, 1977) and were at least 97% isomerically and chemically pure by GC analysis. (*Z*)-9-Tetradecen-1-ol was further purified by argentation chromatography (Houx et al., 1974) to give 99.9% stereochemically pure material.

(*Z*,*E*)-9,12-Tetradecadienal, (*E*,*E*)-10,12-tetradecadienal, and (*Z*)-9-tetradecenal were prepared from the corresponding alcohols by oxidation with pyridinium chlorochromate in dichloromethane using sodium acetate as a buffer (Corey and Suggs, 1975). Traces of alcohol in the products were removed by liquid chromatography on Florisil (80–200 mesh) using gradient elution with hexane and diethyl ether followed by short-path Kugelrohr distillation. Subsequent analysis by GC-EAG and GC-MS did not detect any of the corresponding alcohol with a limit of detection of 0.01%. A similar procedure was followed to remove trace amounts of the aldehydes in samples of the corresponding alcohols.

Field Trials. Field trials of synthetic compounds were conducted in rice paddy fields at the WARDA Rice Research Station, Rokupr, Sierra Leone. Pheromone dispensers were white rubber septa (Aldrich, catalog No. Z10,072-2) impregnated with 0.1 ml of a hexane solution containing 200 μg of the chemical blend and an equivalent weight of 2,6-di-*tert*-butyl-4-methylphenol (BHT) as antioxidant.

White delta shaped traps (20 × 22 cm base, 12 cm height) with sticky bases (Agrisense-BCS, UK) were used throughout the trials fastened to an

inverted L-shaped pole positioned in such a way that the trap was just above crop height. Traps were placed out in lines containing one replicate of each treatment with each trap in a line separated by at least 25 m, and the lines were separated by at least 50 m. Trap catch was recorded daily and discarded. Traps in a replicate were moved one position in the line daily in order to minimize the effect of trap position on catch. All trials were run for a number of nights equal to a multiple of the number of treatments in the trial so that each treatment occupied all trap sites an equal number of times. Trap catches for each treatment were totaled for each complete rotation, converted to log $(x + 1)$ and subjected to analysis of variance. If this indicated there was a significant difference between the treatments at better than the 5% level of confidence, then the means were ranked by Duncan's new multiple-range test (DNMRT) (Duncan, 1955).

RESULTS AND DISCUSSION

Structure Determination. Ovipositor washings were initially analyzed by GC-EAG using the polar CP Wax 57CB column under temperature programmed conditions. A typical GC-EAG analysis was conducted with between two and five ovipositor equivalents.

EAG responses elicited by compounds eluting from the GC column were consistently observed at 15.3, 16.1, and occasionally at 16.8 ECL on the polar column with relative amplitudes in the ratio of approximately 1:2:0.5. However, the GC peaks associated with these responses were highly variable in amount and rarely constituted more than 1 ng per compound (Table 1). The GC ECL values were indicative of mono-, nonconjugated di-, and conjugated diunsaturated straight-chain, 14-carbon primary alcohols, respectively. Analysis of the same ovipositor washings on a nonpolar CP Sil 5CB column under isothermal conditions confirmed these findings with EAG responses observed to components at 12.49, 12.56, and 13.08 ECL (Table 1).

Comparison of the GC retention times of the EAG-active compounds with a range of synthetic straight-chain, 14-carbon primary alcohols on both GC phases under isothermal GC conditions indicated that the retention times of the active components were consistent with those of (*Z*)-9-tetradecen-1-ol (*Z*9–14:OH), (*Z,E*)-9,12-tetradecadien-1-ol (*ZE*9,12–14:OH) and (*E,E*)-10,12-tetradecadien-1-ol (*EE*10,12–14:OH) (Table 2). However, *ZE*9,12–14:OH could not be separated from the *E,E* isomer on either of these liquid phases.

Analysis of the ovipositor washings by GC-MS on a polar CP Wax 52CB column in EI mode indicated compounds with GC retention times and mass spectra that were consistent with those of synthetic *Z*9–14:OH, *ZE*9,12–14:OH and *EE*10,12–14:OH, although none of the compounds gave molecular ions and only *EE*10,12–14:OH produced $M-H_2O$ ions at *m/z* 192. However, the

[a]Retention times in equivalent chain length units relative to the retention times of straight-chain saturated acetates.
[b]Oven temperatures 70°C for 2 min then programmed at 20°C/min to 140°C, and then at 2°C/min to 220°C.

m/z 31 (CH_2OH^+) ions that Attygalle et al. (1988) have shown to be produced by long-chain primary alcohols were observed at the GC retention times of *Z*9-14:OH and *ZE*9,12-14:OH, but the abundance of *EE*10,12-14:OH was too low to confirm the presence of *m/z* 31 ions in that compound. The ratio of the three compounds obtained on the MS in EI mode was 2:3.5:1 respectively. Further analysis of the ovipositor washings was undertaken in CI mode with isobutane as reagent gas. Strong ions consistent with M+1 were observed at *m/z* 213 for *Z*9-14:OH and *m/z* 211 for *ZE*9,12-14:OH and *EE*10,12-14:OH. These GC-MS analyses also showed trace quantities of a compound with the same ECL value (14.7 ECL) and EI and CI mass spectra as those of tetradecan-1-ol. However, as this compound had not elicited an EAG response in the GC-EAG analyses, it was not investigated further.

CI-MS analysis of effluvia collected from entrainment of virgin females confirmed that 14:OH, *Z*9-14:OH, *ZE*9,12-14:OH and *EE*10,12-14:OH were released, but their abundance was too low for quantitation.

Recent work by Hall et al. (unpublished) has shown that the cyclodextrin-β-2,3,6-M-19 liquid phase, originally developed by Nowotny et al. (1989) for the separation of optical isomers, is also effective at separating *Z* and *E* isomers of long-chain primary alcohols and their analogs. Under the GC conditions used, the *Z,E* and *E,E*-isomers of 9,12-14:OH were readily resolved (GC retention times of the *E,E*, *Z,E*, *E,Z*, and *Z,Z* isomers were 32.80, 33.17, 34.43, and 34.51 min, respectively). GC-MS analysis of ovipositor washings on this col-

umn showed a peak with retention time and mass spectrum identical with that of *ZE*9,12–14:OH and no peak at the retention time of the *E,E* isomer.

Comparison of EAG responses elicited by the three unsaturated alcohols identified from female ovipositor washings at different doses indicated that the responses were dose dependent with the magnitude of responses elicited increasing in the order of *EE*10,12–14:OH < *Z*9–14:OH < *ZE*9,12–14:OH for a given dose (Figure 1). The small amplitude of the EAG responses elicited by *EE*10,12–14:OH was probably indicative of a small number of olfactory receptors sensitive to this compound. It would also explain why EAG responses to this compound in the GC-EAG analyses were not observed from all the extracts analyzed.

The related aldehydes, (*Z*)-9-tetradecenal (*Z*9–14:Ald) and (*Z,E*)-9,12-tetradecadienal (*ZE*9,12–14:Ald) have been identified in the sex pheromone of *M. separatella* from Madagascar (H. Arn, personal communication). Thus the EAG responses elicited by *Z*9–14:Ald, *ZE*9,12–14:Ald, and (*E,E*)-10,12-tetradecadienal (*EE*10,12–14:Ald) were compared with those elicited by the corresponding alcohols identified in this study at a single dose of 1000 ng. The results (Table 3) showed that the aldehydes elicited responses of similar ampli-

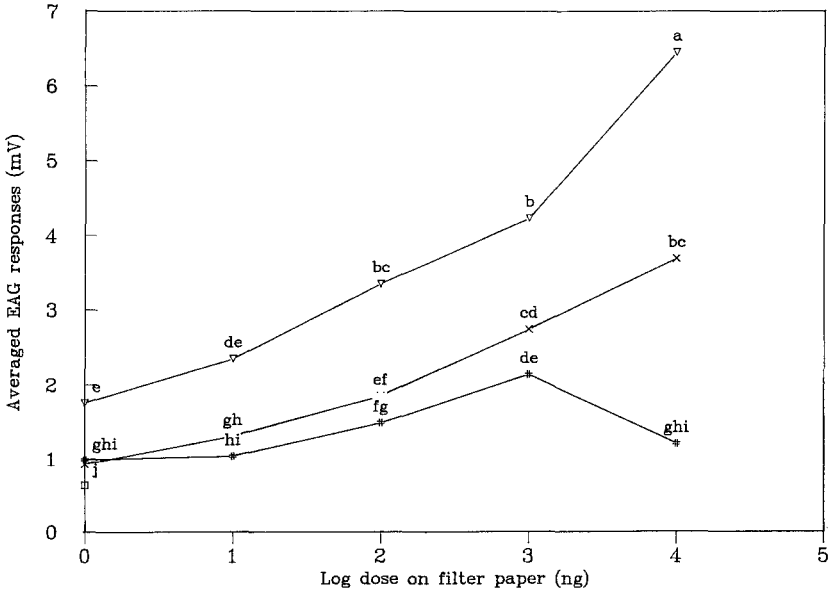

FIG. 1. EAG responses from male *M. separatella* to *Z*9–14:OH (X), *ZE*9,12–14:OH (∇), and *EE*10,12–14:OH (#). Each value represents the mean of five replicates from each of three males. Means followed by different letters are significantly different at the 5% level by DNMRT.

tude to those elicited by the related alcohols, indicating that if the aldehydes had been present in the ovipositor washings or female effluvia in quantities comparable to the alcohols, then they would have been detected in the GC-EAG analyses.

Field Tests. Initially all three EAG-active alcohols were assumed to be required for the pheromone lure, and the first trial was undertaken to optimize the ratio of *Z*9–14:OH and *ZE*9,12–14:OH, while keeping *EE*10,12–14:OH fixed at 10% of the total loading. The results of this trial (Table 4) showed that the compounds were attractive to male moths and that, as the proportion of *ZE*9,12–14:OH was increased with respect to *Z*9–14:OH over the range tested, trap catch also increased significantly.

[a] Total catches followed by the same letter are not significantly different at the 1% level by DNMRT using log $(x + 1)$ transformed data.

In order to determine whether all three EAG-active compounds identified in the female-derived extracts were required to attract male moths, the effect of removing individual components from the three-component mixture was tested (Table 5). This demonstrated that both *ZE*9,12–14:OH and *EE*10,12–14:OH were essential for catching male moths and also that the presence of *Z*9–14:OH significantly reduced catch at the level tested.

Different ratios of *ZE*9,12–14:OH and *EE*10,12–14:OH were then tested in order to optimize the ratio of these compounds in the lure. No significant differences were observed between the treatments tested, although the highest catches were obtained with between 5% and 10% *EE*10,12–14:OH in *ZE*9,12–14:OH (Table 6).

To demonstrate that the *Z,E* isomer, not the *E,E* isomer, of 9,12–14:OH

was a natural pheromone component, the attractiveness of binary blends containing one of the 9,12–14 : OH isomers and *EE*10,12–14 : OH were compared. Irrespective of whether lures were changed every four days or not changed throughout the duration of the trial, blends containing the *E,E* isomer of 9,12–14 : OH were essentially unattractive to male moths, while lures containing the *Z,E* isomer were significantly attractive (Table 7).

In view of Arn's results from Madagascar (personal communication) and the ease with which some species of Lepidoptera are known to convert alcohols to aldehyde or acetate functionalities (Morse and Meighen, 1984; Silk et al., 1980; Silk and Kuenen, 1988; Teal and Tumlinson, 1986; Tumlinson and Teal, 1987), ternary blends of the corresponding aldehydes and acetates were compared with the alcohols in a 3 : 6 : 1 ratio at 200-μg loading. The results showed that only the blend of alcohols caught male moths (Table 8), as would have been expected from the CI-MS analysis of the entrained female effluvia.

However, the GC-EAG and GC-MS studies could not rule out the possibility that very small quantities of the corresponding aldehydes were released by female moths, so 9 : 1 ratios of *ZE*9,12–14 : OH and *EE*10,12–14 : OH were field tested with between 0% and 1% of the corresponding aldehydes added. This field trial was repeated in two successive seasons without showing any clear evidence that the aldehydes influenced trap catch at the levels tested (Table 9).

Numerous attempts were made to catch male moths with caged virgin females. However, despite a high level of survival among the female moths used, no male moths were caught in the traps used. The reason for this is uncer-

tain, although light and synthetic pheromone-baited traps did catch significant numbers of moths during the same periods. However, Ho and Seshu Reddy (1983) only caught a maximum of 11.25 moths/trap/night with virgin female-baited traps during a period when a high population level would have been anticipated, as indicated by a 70% tiller infestation.

On the basis of the above field trials, it was evident that although three EAG-active compounds were present in the extracts prepared from female *M. separatella* only *ZE*9,12–14:OH and *EE*10,12–14:OH could be considered to

be components of the female sex pheromone. *Z*9–14:OH has been identified in the female sex pheromones of other Lepidoptera (Arn et al., 1986), notably in the Noctuidae *Spodoptera exigua* (Tumlinson et al., 1981; Wakamura, 1987) and *Euxoa plagigera* (Steck et al., 1982). It also has been reported to be a component of the pheromones of some Pyralidae, and the Phycitinae in particular. Examples include the lesser cornstalk borer, *Elasmopalpus lignosellus* (Lynch et al., 1984), the sunflower moth, *Homoeosoma electellum* (Underhill et al., 1979) and the driedfruit moth, *Vitula edmandsae serratilineella* (Struble and Richards, 1983).

The most commonly identified nonconjugated tetradecadien-1-ol in the sex pheromones of the Lepidoptera is the methylene-interrupted diene *ZE*9,12–14:OH (Arn et al., 1986) identified in this study. It is particularly prevalent in the pheromones of other Phycitinae, such as *H. electellum* (Underhill et al., 1979), Indian meal moth *Plodia interpunctella* (Sower et al., 1974) and *V. e. serratilineella* (Struble and Richards, 1983). To our knowledge the conjugated tetradecadien-1-ol *EE*10,12–14:OH has not been identified in any other lepidopterous sex pheromone to date, although the corresponding acetate was identified by McDonough et al. (1982) in the female sex pheromone of the western avocado leafroller, *Amorbia cuneana*, together with (*E*)-10-tetradecenyl acetate.

As a result of the differences found in the female sex pheromone of *M. separatella* originating from Sierra Leone and Madagascar (H. Arn, personal communication), the taxonomic status of the adults is being investigated at the British Museum (Natural History). Differences have been found in the genitalia of both males and females, but at present it is uncertain whether they should be reclassified as subspecies, *M. separatella separatella* from Sierra Leone, and *M. separatella vectiferella* from Madagascar or as separate species (M. Shaffer, personal communication).

While blends of *ZE*9,12–14:OH and *EE*10,12–14:OH are effective attractants of male *M. separatella* when formulated on white rubber septa, they only have an effective field life of approximately one week. The reason for this is not known, although no change in the amounts of other isomers was found in analyses of field exposed septa. Despite this drawback, preliminary experiments suggest that pheromone trap catches can be related to subsequent larval infestations (Fannah, unpublished), so that trapping systems based on the synthetic pheromone lure could provide farmers with a monitoring system for predicting potentially damaging infestations of this pest.

Acknowledgments—The authors would like to thank Mrs. J.L. Smith and Dr. P.H. Adams for technical assistance with the laboratory studies. This study was partially supported by EEC DG XII contract TSD.A.204.UK(H). The insects were imported under MAFF licence No. PHF 1172/24.

Abstract—Field trapping of the American palm weevil (APW), *Rhynchophorus palmarum*, showed that the combination of caged male APWs and palm stem was much more attractive to APWs of both sexes than palm stem alone. Caged female APWs did not enhance the attractiveness of the palm. Caged APWs without palm stem were not attractive. Virgin laboratory-bred males were highly attractive to APWs of both sexes in a two-choice pitfall olfactometer, whereas virgin laboratory-bred females were not. Adsorbent-trapped volatiles from virgin laboratory-bred males reproduced the effect of living males, giving evidence for a male-produced aggregation pheromone in this species. Wild-mated APWs of both sexes were as responsive to the aggregation pheromone as virgin laboratory-bred APWs. This is the first record of chemical communication in this species. These results have prompted investigations into the chemical identification of the aggregation pheromone.

Key Words—Aggregation pheromone, field trapping, laboratory bioassay, Coleoptera, Curculionidae, *Rhynchophorus palmarum*.

INTRODUCTION

The American palm weevil (APW), *Rhynchophorus palmarum* (L.), is a serious pest on coconut, *Cocos nucifera* L., and oil palm, *Elaeis guineensis* Jacq., trees in the neotropical region (Lepesme et al., 1947; Genty et al., 1978). It is occasionally a pest on sugarcane, *Saccharum officinarum* L. (Restrepo et al., 1982). The APW adult is the major known vector of red ring disease caused by the nematode *Rhadinaphelenchus cocophilus* Goodey (Griffith, 1968, 1987). APW larvae develop in the stems, buds, and rachis of leaves and inflorescences within a large variety of Palmae species (Lepesme et al., 1947; Hagley, 1965). The only way to prevent red ring disease is to eliminate the adults and larvae of the APW, since the difficulty and cost of nematicide treatments are extreme.

Extensive studies have been conducted on the development and larval rearing of palm weevils from the genus *Rhynchophorus* (Wilson, 1963; Giblin-Davis et al., 1989). In contrast, not much is known about the chemical ecology of the adults. They have been caught in traps baited with palm pieces (Morin et al., 1988; Rochat, 1990). It has been observed for a long time that wounds on palms are attractive to the APW (Mariau, 1968), but nothing is known about the role of the APW itself in the aggregation of the weevils on trees.

This study reports investigations carried out in the field and in the laboratory and presents evidence to document the existence of a male-produced aggregation pheromone in the APW.

METHODS AND MATERIALS

Field Experiments

The attractiveness of seven combinations of living APWs and oil palm stem was studied (Table 1). The experiment was conducted in an oil palm plantation of northern Colombia. The bait weevils were caught on oil palm trees felled before the experiment. These weevils were mated as shown by the hatching of the eggs laid by females trapped in the field. Four insects (four males or four females or two males + two females) were placed in wire mesh cages (8 × 5 × 3 cm). The traps consisted of plastic jerricans (38 × 30 × 17 cm) from which one side had been removed. Palm-baited jerricans were filled with stem pieces from the same freshly felled oil palm tree. Other jerricans were filled with wood shavings as shelters for the insects. Cages containing weevils were placed at the bottom of the jerricans onto a half mango as food for the weevils. The bait weevils could also feed on palm stem pieces in palm-baited traps. Wire cages were hidden by the stem pieces or the shavings. No killing agent was added to the trap because of the use of living weevils as bait, and

TABLE 1. APW CAPTURES OBTAINED WITH DIFFERENT COMBINATIONS OF 4 LIVING APW AND PALM STEM

Treatment	Mean captures ($\Sigma n_i/4$) per 4-day period (range)[a]	Sex ratio (Male : Female)

[a] Data were subjected to a log ($n_i + 1$) transformation for homoscedasticity purposes. Statistical reference is to a one-way analysis of variance on the transformed variate. Treatments followed by the same letter do not differ significantly at 5% level according to Newman-Keuls test on the means of transformed values.

lured weevils could freely leave the jerricans. Seven traps were baited with each of the different combinations of palm and APW. The 49 traps were placed 80 m apart on the ground according to a Latin-square design, each one at the base of a palm tree. The weevils caught in the traps were collected twice a day at ca. 2 hr after dusk and ca. 3–4 hr after sunrise. This regime took into account the daily rhythm of the APW flights (Hagley, 1965; Lucchini and Morin, 1985; Rochat, 1990). Weevils were collected for only four consecutive days since we observed that older pieces of palm stem were not attractive to APWs (Rochat, 1990).

The experiment consisted of four four-day trapping periods with, each time, random permutation of the Latin-square design, random redistribution of bait weevils into the wire cages, and replacement of the decaying palm material by fresh material. Two consecutive trapping periods were separated by three days.

The data were subjected to a one-way analysis of variance on the transformed variate log ($n_i + 1$), n_i being the total number of insects caught in the seven traps of the i^{th} palm–APW combination during one four-day period. Differences between means were tested using the Newman-Keuls test at the 5% level (Dagnelie, 1975).

Laboratory Bioassays

Insects. Weevils of two distinct histories were used: wild-mated weevils from Equador or Colombia and virgin weevils reared on sugarcane in the laboratory from a strain that originated in Equador. Sexes were separated on arrival

of the wild insects or when the reared adults eclosed. These large weevils (35–45 mm long) were kept individually in cylindrical plastic boxes (105 × 75 mm) with a wire mesh cover and fed with sugarcane. They were maintained at 27 ± 2°C and 85 ± 10% relative humidity on a 12 : 12 light–dark regime.

Volatile Collections. Five virgin APW males were placed in a cylindrical glass jar (6 × 22 cm) with three sugarcane pieces. Three pieces of the same size and from the same stem were placed in a similar jar as a control. Volatiles emitted by APWs and/or sugarcane were simultaneously trapped onto two glass cartridges connected downstream to the jars during a two-day period. Each cartridge was filled with 0.5 g of Supelpak-2 adsorbent (16–50 mesh; purified Amberlite XAD-2 resin, Supelco). The volatiles were collected in a room maintained at 27 ± 2°C with a 12 : 12 light–dark regime. A regulated airflow (500 ml/min) passed through the glass systems. The cartridges were eluted with 2.5 ml of methylene chloride (HPLC grade, Waters). The eluates were then concentrated at 100 μl under a nitrogen flow (150 ml/mn) and stored at −30°C until use.

Insect Bioassays. Insects were bioassayed using a two-choice pitfall olfactometer adapted from Pierce et al. (1981). The olfactometer consists of a circular arena (40 × 14 cm) connected to two glass jars. The floor of the arena is made of Plexiglas and covered with white paper to allow the weevils to walk. A filter paper disk closes each jar at 4 cm from below the floor of the arena to prevent any visual stimulus when weevils are introduced into the jar as bait. Filter papers also close the two jars when volatiles are used as bait. The pitfall olfactometer is placed at the center of a 70 × 70-cm arena surrounded by white walls and homogeneously lighted with four red painted fluorescent tubes (18 W, daylight type D) giving a 40-lux lighting at the olfactometer level.

Bioassays were run during the first half of the scotophase at 27 ± 2°C. The weevils were transferred to the testing room in their individual boxes half an hour prior to an experiment. A single weevil was released at the center of the olfactometer arena and its position was recorded after 30 min. Weevils were classified as responding only if they fell into a jar (stimulus or control) or clung to the underside of the arena floor in a jar.

Male and female individual responses to three different stimuli versus a control were recorded: (1) three virgin laboratory-bred males versus no insects; (2) three virgin laboratory-bred females versus no insects; (3) virgin laboratory-bred male effluvia + sugarcane volatiles versus sugarcane volatiles alone. One microliter of methylene chloride extract containing the volatiles to be tested (0.1 male-day-equivalent) was applied to a filter paper (17 × 17 mm) placed into a glass jar just prior to the test.

The responses of APWs also were recorded in a control treatment with two empty jars. Twenty to 35 of both wild-mated and virgin laboratory-bred weevils were bioassayed in each of the different cases.

Data Analysis

Two criteria were used to quantify the APW responses. First, the proportion of tested weevils that responded after 30 min; the proportions of weevils that responded in presence of a stimulus (living males, living females, male + sugarcane volatiles) were compared with that obtained in the absence of a stimulus (control treatment) using the χ^2 test for two independant samples (Siegel, 1956). Secondly, the number of APW choices for the stimulus jar was compared with the number of choices for the associated control jar using the nonparametric binomial test (Siegel, 1956) with the null hypothesis of an equal probability of choosing the control or the stimulus.

Comparisons between sexes for the same situation and between wild-mated and virgin laboratory-bred insects were analyzed by χ^2 tests.

RESULTS

Field Experiments (Table 1)

The bait of palm stem + four males was very attractive to APWs, significantly more so than all other baits. The baits of palm stem + four females and palm stem without caged APWs were equally attractive to APWs and significantly more attractive than the three baits that did not contain palm stem but only caged APWs.

Laboratory Bioassays

Few APWs responded in the absence of an experimental stimulus (control treatment with two empty jars), and the responses occurred randomly between the two empty jars (Table 2).

The introduction of three virgin laboratory-bred males as bait induced a significant response by both virgin laboratory-bred and wild-mated APWs after 30 min. Weevil choice for the male-baited jar was highly significant (Table 2).

There was very little response to three virgin laboratory-bred females as bait (Table 2). Only virgin laboratory-bred females had a slightly heightened activity level. No significant choices occurred to the female-baited jar by any category of test weevils.

The volatiles from males and sugarcane induced high numbers of weevils to respond (Table 2). The effect was slightly stronger in virgin females than males. Both laboratory-bred and virgin APWs preferred the male + sugarcane volatiles to the sugarcane volatiles alone.

TABLE 2. APW RESPONSES TO VARIOUS STIMULI IN TWO-CHOICE PITFALL OLFACTOMETER AFTER 30 MINUTES

Source of test weevils	Treatment	Sex tested	Number tested	Number of responses[a]	Percent response		Binomial probability stimulus vs. control[b]
					Stimulus	Control	
Laboratory-bred, virgin	2 empty jars (control)	Male	30	8	50	50	.637
		Female	20	2	50	50	—
	3 living males vs. no insects	Male	30	21***	90	10	.0002
		Female	22	17***	94	6	.0002
	3 living females vs. no insects	Male	28	11 ns	73	27	.113
		Female	20	8*	38	62	.363
	Virgin male + food volatiles vs. food volatiles	Male	31	21**	71	29	.021
		Female	21	14***	93	7	.001
Wild, mated	2 empty jars (control)	Male	30	17	47	53	.395
		Female	30	8	63	37	.363
	3 living males vs. no insects	Male	30	21 ns	81	19	.004
		Female	30	19**	89	11	.0004
	3 living females vs. no insects	Male	23	7 ns	57	43	.363
		Female	25	12 ns	67	33	.194
	Virgin male + food volatiles vs. food volatiles	Male	35	17 ns	82	18	.006
		Female	35	27***	81	19	.0007

[a] Difference from the control (χ^2 test) indicated by: ns: not significant, * $P < 0.05$, ** $P < 0.01$, and *** $P < 0.001$.
[b] Under the null hypothesis to respond to the stimulus and to the control with an equal probability of 1/2.

The percentages of wild-mated males responding to any stimulus were not statistically greater than the responses obtained in the control treatment (Table 2), probably because many males entered unbaited jars in the control treatment.

No significant differences appeared between responses of wild-mated and virgin laboratory-bred APWs within each sex.

DISCUSSION

The requirement for palm stem to be a component of an attractive stimulus for APWs agreed with previous observations that palm tissues were attractive to the palm weevils (Nadarajan, 1984; Morin et al., 1988). The male effect in combination with palm stem volatiles was aggregative since male as well as female APWs were caught in a nearly 1 : 1 sex ratio. Synergy for attraction between beetle-produced and host-plant chemicals has been found frequently in Coleoptera, especially in bark beetles and stored-product insects (Borden, 1985). A similar synergistic relationship was shown for the pea and bean weevil, *Sitona lineatus* L., (Blight and Wadhams, 1987). Meksongsee and Sakulpanich (1975) showed that coconut + male *Rhynchophorus vulneratus* Panzer baits were much more attractive than coconut + female *R. vulneratus* baits, but synergy between males of this species and the host plant has not been proved.

The presence of APW females with males seemed to modify the male-produced aggregating effect, but the lower number of males (two instead of four) used for this bait could explain in part the weak catches. However, recent field trapping data (Lacerda Moura,[1] personal communication) support the hypothesis that females modify the release by males of an aggregation pheromone or that females release a antiaggregative stimulus.

The few weevils caught in traps baited only with caged APWs might indicate either that males do not release the aggregation stimulus in the absence of host-plant volatiles or that flying weevils might be lured only by the simultaneous perception of host and male APW stimuli. The hypothesis of sonic communication (Dumortier, 1963; Haskell, 1974; Rudinsky and Ryker, 1977) in APWs was refuted by the laboratory observations in which attraction was induced solely by captured host-plant plus male volatiles.

Among the numerous olfactometers described in the literature to investigate aggregation pheromones in adults of coleopteran species (Hardee et al., 1967; Payne et al., 1976; Borden et al., 1979; Phillips and Burkholder, 1981; Pierce et al., 1981; Faustini et al., 1982b), the two-choice pitfall olfactometer

[1] CEPLAC/CEPEC, Km 22, Rod. Ilheus/Itabuna, CX. Postal 7, 45.600-Itabuna-Ba., Brazil.

proved to be highly discriminative. This type of olfactometer gave accurate responses by the APW too. Our single-insect laboratory bioassay eliminated the need to work with large olfactometers adapted for multiple-insect tests with these very large beetles. Furthermore it avoided any possibility that bioassayed weevils could have emitted pheromones that biased the results. It avoided also any tactile and visual interaction between individuals, which are extremely strong in APW group formation, especially under artificial conditions (Rochat, 1987).

The attractiveness of the living males without palm in pitfall bioassays appears to contradict the results in the field. However, the time and space scales were totally different in the two experiments, as was the physiological stage of the bait weevils.

Mating seemed not to modify the response by APWs to the aggregation pheromone since the responses of mated and virgin APWs did not differ. This result is consistent with the fact that APWs have considerable longevity and are able to copulate several times during their life (Wilson, 1963). The retention of a high response capability would ensure that weevils are able to aggregate on favorable sites throughout their life. Phillips and Burkholder (1981) reported that mated and virgin *Sitophilus oryzae* L. were equally responsive to aggregation pheromone. O'Ceallachain and Ryan (1977) also demonstrated that mating did not affect the response of *Tribolium confusum* L. to its aggregation pheromone.

The APW (*Rhynchophorus palmarum*) belongs the subfamily Rhynchophorinae as do the *Sitophilus* spp. Male-produced aggregation pheromones have been reported in three species from this latter genus (Phillips and Burkholder, 1981; Faustini et al., 1982a; Walgenbach et al., 1983). The existence of a male-produced aggregation pheromone in the APW is a new report of such a pheromone system in this Curculionidae subfamily.

This first record of chemical communication in this pest has opened new fields of investigation for a potential improvement of APW and red ring disease control. These results have prompted chemical investigations to identify the APW aggregation pheromone. Synthetic pheromone could be used as a weevil lure in combination with either palm stems or synthetic host-plant kairomones. Studies on the chemical identification and synthesis of the APW aggregation pheromone are underway.

(Received December 3, 1990; accepted February 19, 1991)

Abstract—Alate and apterous virginoparae of *Aphis fabae* Scop. and alate virginoparae of *Brevicoryne brassicae* (L.), walking in a linear track olfactometer, were attracted by odor from leaves of their host plants. *A. fabae* responded to odor from undamaged but not damaged bean leaves. Gynoparae (autumn migrants) of *A. fabae*, however, did not respond to their host plant (spindle, *Euonymus europaeus*) odor. Odors of certain nonhost plants masked the attractiveness of the host plant leaves, but tansy (*Tanacetum vulgare*) and summer savory (*Satureja hortensis*) volatiles repelled *B. brassicae* and *A. fabae*, respectively. 3-Butenyl isothiocyanate attracted *B. brassicae* and *Lipaphis erysimi* (Kalt.), the latter species being more sensitive in both behavioral and electrophysiological studies. Isothiocyanate receptors were found on the antennae of *A. fabae*, which was repelled by these compounds, 4-pentenyl isothiocyanate being the most active.

Key Words—Aphid, *Aphis fabae*, *Brevicoryne brassicae*, Homoptera, Aphididae, *Lipaphis erysimi*, olfaction, plant volatiles, isothiocyanate, electrophysiology, repellent, odor masking.

INTRODUCTION

The role that host plant odor plays in aphid host finding and selection is still uncertain. For many years, odor was thought not to be involved in long-range host finding. Field studies demonstrated equal landing rates on host and nonhost plants by gynoparae and alate virginoparae of *Myzus persicae* and *Aphis fabae* and alate virginoparae of *Brevicoryne brassicae* (Kennedy et al., 1959a,b; Müller, 1962), suggesting that hosts were only selected after landing, with aphids having differential leaving rates from hosts and nonhosts. However, electrophysiological responses to plant volatiles have been shown in *Nasonovia ribis-nigri* (Bromley and Anderson, 1982), *Sitobion avenae* (Yan and Visser, 1982), *Lipaphis erysimi* (Dawson et al., 1987), and *A. fabae* (Wadhams, 1990), and behavioral responses have been shown in olfactometers (*A. fabae*, Alikhan, 1960; *B. brassicae* and *Rhopalosiphum padi*, Pettersson, 1970, 1973; *Aphis gossypii*, Pospisil, 1972), in the field (*Cavariella aegopodii*, Chapman et al., 1981; *Phorodon humuli*, Campbell et al., 1990), and in a wind-tunnel experiment on walking *Cryptomyzus korschelti* (Visser and Taanman, 1987), which demonstrated an odor-conditioned upwind anemotaxis. In addition, herbs have been recommended in the popular and organic gardening literature for many years as a means of repelling or deterring aphid pest species. For example, savory (*Satureja* spp.) and tansy (*Tanacetum vulgare*) are suggested as companion plants to deter aphids (e.g., Yepson, 1984) and reductions in *M. persicae* populations on bell peppers (*Capsicum luteus*) were reported after interplanting with tansy (Matthews et al., 1983). Thus, there is evidence that volatiles are implicated in host finding and that this behavior can be modified by nonhost odors.

This study was designed to reassess the role of host and nonhost plant odors in the orientation behavior of the black bean aphid, *A. fabae*, the cabbage aphid, *B. brassicae*, and the turnip aphid, *Lipaphis erysimi*. *A. fabae* alternates between a primary host, usually spindle (*Euonymus europaeus* L.), and a range of herbaceous secondary hosts, including broad bean (*Vicia faba* Moench). *B. brassicae* and *L. erysimi* complete their life-cycles on plants in the Cruciferae (Brassicaceae) and Resedaceae, families characterized by the presence of glucosinolates. These compounds have been implicated in the attraction of *B. brassicae* to rape buds and flowers (Pettersson, 1973); they are also reported to stimulate feeding in *B. brassicae* (Wensler, 1962) and *L. erysimi*, but to deter feeding in other species, including *A. fabae* (Nault and Styer, 1972). Glucosinolates are decomposed by enzymic action to produce volatile isothiocyanates (Kjaer, 1960; Ju et al., 1982). Behavioral responses of *B. brassicae*, *L. erysimi*, and *A. fabae* to a range of isothiocyanates were therefore examined in an olfactometer. As *L. erysimi* is known to possess olfactory receptors for isothiocyan-

ates (Dawson et al., 1987), such receptors were also sought in *A. fabae* and *B. brassicae*.

METHODS AND MATERIALS

Insects. A. fabae were reared on tick beans (*Vicia faba*) in environmental cabinets held at 15°C. Apterae were obtained from continuous cultures, while alate virginoparae (summer migrants) were produced by crowding early instar aphids in long-day (light–dark 16 : 8) conditions. Gynoparae (autumn migrants) were induced by short days (light–dark 12 : 12). *B. brassicae* and *L. erysimi* were reared on Brussels sprouts (*Brassica oleracea* L., Bedford Darkmar) and turnip (*Brassica campestris* var. *rapifera* Metz.), respectively, in long days, with alates again being induced by crowding. All experimental aphids were young adults, starved for 24 hr, and used only once.

Plant Material. Host plants, bean (*Vicia faba*: Sutton dwarf bean or tick bean) and Brussels sprouts (*B. oleracea*: Bedford Darkmar) were greenhouse-grown, while spindle (*Euonymus europaeus*) leaves were field-picked. Non-hosts, winter savory (*Satureja montana* L.), summer savory (*Satureja hortensis* L.), tansy (*Tanacetum vulgare* L.), basil (*Ocimum basilicum* L.), thyme (*Thymus vulgaris* L.), and sage (*Salvia officinalis* L.) were grown in the greenhouse. All host and nonhost plant leaves were freshly picked and weighed prior to experiments.

Olfactometer. A linear track olfactometer, based on a design by Sakuma and Fukami (1985) and modified for aphids (Hardie et al., 1990), was constructed from transparent Plexiglas tubing and steel rods. The rods formed a T junction at the point where equal airstreams met from two side arms in the olfactometer. Twenty-five adult aphids were placed in a Fluon-lined dish at the base of the vertical rod and those that climbed up were scored for their direction of turn along the horizontal rod. All subsequent movement was ignored. An airflow of 1 liter/min was maintained in all experiments, with the air being subsequently exhausted from the room. The apparatus was housed within a black box and aphids were attracted upwards by a diffuse light. When plant material was used as a treatment, filter papers (Whatman No. 1; 4.25 cm) saturated with water were included to create equivalent humidities. Treatment and control sides were alternated for each new replicate and runs lasted for 10 min. Experiments were conducted at 19–23°C; between replicates the olfactometer was washed with methanol and soapy water. All data were analyzed using paired t tests, with means quoted $\pm$ SE and significance taken as $P < 0.05$.

Responses of alate and apterous *A. fabae* to three different levels of host plant leaf damage were tested: (1) undamaged, where leaves were gently picked

off the plant; (2) light damage, where leaves were rolled between the fingers; and (3) heavy damage, where leaves were crushed prior to use. All treatments employed whole leaves weighing 2 g (± 0.2 g). In bioassays with *B. brassicae*, and all host and nonhost experiments, undamaged leaf material was used. Host and nonhost leaves were presented together, and separately, in experiments with alate virginoparae of *A. fabae* and *B. brassicae*. Two ratios of host to nonhost leaf weight were used (2.0:2.0 g and 2.0:0.5 g).

Chemicals. Allyl, 3-butenyl, 4-pentenyl, and phenylethyl isothiocyanates (Figure 1) were obtained commercially or synthesized by standard methods. Isothiocyanates in hexane (10 μl) were applied to filter paper (Whatman No. 1; 4.25 cm) and placed in the treatment side of the olfactometer. Hexane (10 μl) alone served as the control.

Electrophysiology. Recordings from cells associated with the olfactory receptors on the proximal primary rhinaria of alate virginoparous *A. fabae* and *B. brassicae* were obtained using tungsten microelectrodes. Signals were amplified and recorded by standard methods (Wadhams et al., 1982; Dawson et al., 1987). The stimulus was delivered into a purified airstream (1 liter/min) that flowed continuously over the preparation. The delivery system, which utilized a filter paper in a disposable Pasteur pipet cartridge, has been described previously (Wadhams et al., 1982). The impulse frequency was determined as the number of impulses elicited during the first 1 sec after stimulus application.

RESULTS AND DISCUSSION

There was no preferred direction of turn for apterous or alate *A. fabae* or for alate *B. brassicae* when the two chambers of the olfactometer contained only damp filter paper. However, *A. fabae* virginoparae were attracted to undamaged, but not to damaged, bean leaves (Table 1); apterae were attracted

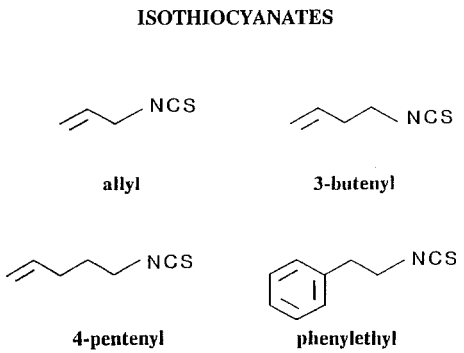

FIG. 1. Structures of isothiocyanates.

TABLE 1. RESPONSE (±SE) OF APTEROUS AND ALATE VIRGINOPARAE OF *Aphis fabae* TO BEAN LEAVES[a]

	Apterous virginoparae		Alate virginoparae	
	Treatment	Control	Treatment	Control
1. Undamaged tick bean	7.1 ± 0.5	4.6 ± 0.5 A	8.3 ± 0.8	6.4 ± 0.5 ns
2. Undamaged Sutton bean	6.9 ± 0.5	4.3 ± 0.5 A	7.9 ± 0.8	5.4 ± 0.4 A
3. Lightly damaged bean	4.6 ± 0.6	5.4 ± 0.8 ns	6.5 ± 0.6	6.3 ± 0.7 ns
4. Heavily damaged bean	4.3 ± 0.5	5.5 ± 0.7 ns	6.4 ± 0.8	6.5 ± 1.0 ns

[a] 3 and 4: apterous virginoparae with tick beans and alate virginoparae with Sutton dwarf beans, respectively. A = attraction, ns = not significantly different at $P < 0.05$, two-tailed paired t tests (eight replicates).

to both undamaged tick beans and Sutton dwarf beans, while alates were only significantly attracted by the Sutton dwarf beans. The lack of response to damaged plants may be due to an inability to recognize the altered volatile profile as that of a host plant. The degree of leaf damage, however, would have been greater than that normally encountered in the field. Alate virginoparae were not attracted to odor from mature leaves of spindle, the primary host (6.8 ± 0.4 cf. 6.4 ± 0.6; $N = 8$), and gynoparae did not respond to bean leaves or to mature (7.4 ± 0.7 cf. 6.1 ± 1.1; $N = 8$) or scenescent spindle leaves (6.5 ± 0.5 cf. 6.8 ± 0.4; $N = 8$). No response to spindle was observed even after 72 hr of starvation (3.6 ± 0.5 cf. 2.8 ± 0.3; $N = 8$), which should have ensured that the insects had completed any migratory or host-ignoring behavioral phase associated with olfactory cues, i.e., comparable to that observed with visual cues (Nottingham and Hardie, 1989). Previous olfactometer studies have produced variable results for responses of *A. fabae* to host plant odor. Alikhan (1960) reported attraction of apterous and alate virginoparae to bean and sugar beet leaf extracts, while Jones (1944) found no evidence for olfactory responses of alate virginoparae to bean, spindle, or leaf extracts. The present results suggest that plant volatiles play a role in host location by some aphid morphs.

Although alate virginoparae of *A. fabae* were attracted to Sutton dwarf beans alone and to beans in 4:1 ratios with winter savory and tansy and in a 1:1 ratio with sage, no significant attraction was elicited from 1:1 ratios of beans with winter savory, summer savory, tansy, thyme, or basil (Table 2). Summer savory alone appeared to be repellent. Similarly, alate virginoparae of *B. brassicae* were attracted to Brussels sprouts (host) odor, but combinations

of sprouts and winter savory or tansy odor were either unattractive or repellent (Table 3). Tansy alone also proved to be repellent.

It thus appears that attraction of aphids to host leaves can be disrupted by the presence of nonhost plant odor. This may be due to repellency, i.e., oriented movement away from an odor source (Dethier et al., 1960) or to odor masking,

TABLE 2. RESPONSE (±SE) OF ALATE VIRGINOPARAE OF *Aphis fabae* TO COMBINATIONS OF HOST AND NONHOST PLANT LEAVES[a]

	Ratio	Treatment	Control
Sutton beans		7.0 ± 0.4	4.0 ± 0.6 A

implying neutralization of an insect's orientation response without repellency (Thiery and Visser, 1986). Both effects were probably operating in this study; for example, tansy proved repellent to *B. brassicae*, while winter savory and thyme masked the attraction of *A. fabae* to host plant odor without in themselves being repellent. It is also of interest that the repellent action of tansy was masked by Brussels sprout odor.

Electrophysiological recordings from the proximal rhinaria on the antenna showed the presence of cells in *B. brassicae* (Figure 2) and *L. erysimi* (Dawson et al., 1987) that responded to isothiocyanates. Both species displayed strong electrophysiological responses to 3-butenyl isothiocyanate and were attracted by this compound in the olfactometer (Table 4). However, the electrophysiological threshold concentration was considerably lower for *L. erysimi* (ca. 10^{-11} g) than for *B. brassicae* (10^{-7} g), and this is reflected in its greater behavioral sensitivity. In *L. erysimi* isothiocyanates have the additional function of synergizing the action of the alarm pheromone, (*E*)-β-farnesene (Dawson et al.,

1987). Thus, alone they are attractants, but in combination with (*E*)-β-farnesene their effect is to initiate an alarm response.

Alate virginoparae of *A. fabae* also were shown to have olfactory receptors sensitive to isothiocyanates (Figures 3 and 4), although these compounds are not associated with their host plants. The response characteristics of the cells were similar to those observed for *B. brassicae*, but the behavioral responses were markedly different. While 100 μg of 3-butenyl isothiocyanate attracted *B. brassicae*, it repelled *A. fabae* (Tables 4 and 5). Allyl isothiocyanate was also repellent to *A. fabae*, but only at high concentrations (Table 5). The low behavioral activity of this compound correlates well with its relatively low electrophysiological activity (Figure 3). 4-Pentenyl isothiocyanate was the most active compound in electrophysiological studies (Figure 3) and proved repellent at a

level of 10 μg (Table 5). Phenylethyl isothiocyanate did not elicit electrophysiological responses in either *A. fabae* or *B. brassicae* (Figures 2 and 3). Both 3-butenyl and 4-pentenyl isothiocyanates masked the attractant response of *A. fabae* to Sutton bean leaves at levels of 100 and 10 μg (Table 6). No repellency was observed. Therefore, the presence of host plant volatiles reduced the repellency of the isothiocyanates, presumably in a similar way to the interaction of tansy and host volatiles for *B. brassicae* described above.

It must now be accepted that plant volatiles play a role in host location and selection by aphids. The current study demonstrates behavioral responses of alate and apterous aphids, with attraction to host and repulsion by some nonhost odors. In addition, it reveals that nonhost volatiles can mask host attraction. In some cases, individual volatiles have been implicated, but the interaction of different odor components is undoubtedly complex. Although evidence of olfactory responses by flying aphids is restricted to *C. aegopodii* (plant volatiles; Chapman et al., 1981) and *P. humuli* (sex pheromone and plant volatiles; Campbell et al., 1990), these observations demonstrate a role for olfaction at a distance. After landing, local odor fields may also prove important. The present results indicate that host and nonhost odor interactions may provide a degree of crop protection in companion planting programs and suggest that manipulating behavior via plant volatiles or mimics may be a way forward for aphid control.

Acknowledgments—We thank Jill Nicholas and Nicola Taylor for technical assistance.

STABILITY OF PHENOLIC AND PROTEIN MEASURES IN EXCISED OAK FOLIAGE

KARL W. KLEINER

Department of Entomology, Pesticide Research Lab
The Pennsylvania State University
University Park, Pennsylvania 16802

(Received December 12, 1990; accepted February 19, 1991)

Abstract—The stability of protein and phenolic measures in excised foliage from two oak species was measured under conditions that simulated the handling and treatment of foliage during insect rearing trials. Excised foliage kept hydrated under refrigeration or insect-rearing conditions maintained stable levels of protein content, proanthocyanidins, gallotannins, total phenolics, and protein-binding capacity for up to 48 hr following field sampling. Measures of protein content, total phenolics, protein-binding capacity, and proanthocyanidins were significantly greater 48–72 hr after field sampling, followed by declines to near field levels within 120 hr.

Key Words—*Quercus rubra, Quercus prinus*, phenolics, tannins, foliage quality, insect-rearing trials.

INTRODUCTION

Investigations of the suitability of food plants for herbivorous insects usually require rearing trials with foliage. Ideally, such trials should be performed in situ, but logistical constraints (access to foliage on mature trees, location of food plants) and environmental variability (temperature, humidity) often make laboratory rearing with excised foliage more practical or useful. The stems or petioles of excised foliage used in laboratory trials are often inserted into a source of water to maintain leaf turgor and leaf shape (Scriber, 1977, 1978; Hough and Pimentel, 1978; Lawson et al., 1982, 1984). Although this procedure maintains the visible aspects of leaf freshness, stability in the dietary components of excised foliage has received little consideration (Miller, 1987). Changes in quantities or composition of leaf constituents, e.g., allelochemicals, in excised foliage could influence the validity of laboratory results.

0098-0331/91/0600-1243$06.50/0

Phenolics comprise a class of putative allelochemicals that is virtually ubiquitous in plants. They have been shown to have both positive (Bernays, 1981; Bernays et al., 1983) and negative (Bernays, 1981; Berenbaum, 1983; Manuwoto et al., 1985; Karowe, 1989) effects on the feeding behavior and performance of insect herbivores. For example, the secondary chemistry of oaks and other tree species favored by the gypsy moth (*Lymantria dispar* L.) is comprised primarily of phenolics (Gibbs, 1974), and several classes of these phenolics have been shown to influence gypsy moth growth, fecundity, and mortality (Keating et al., 1988; Kleiner, 1989).

In this study, stability in four phenolic measures and one protein measure in foliage from two oak species was examined over a range of handling and treatment stages identical to those used in laboratory rearing trials.

METHODS AND MATERIALS

Sampling

Experiment 1 (June 1986). One branch (0.5–1.0 m) was cut from each of five mature chestnut oaks (*Quercus prinus* L.) and five mature red oaks (*Q. rubra* L.) and recut under water in 19-liter buckets. Prior to transporting the branches to the lab, one foliage sample (four to five leaves) was taken from each branch (=tree) and flash frozen in liquid nitrogen. In the lab, one bouquet of foliage was made per tree by inserting the petioles of four to five leaves into a florists' Aqua-pic (Syndicate Sales, Kokomo, Indiana). These foliar bouquets are identical to those used in our lab for gypsy moth rearing trials (e.g., Kleiner, 1989). In addition, four pairs of single leaf bouquets were made per tree in the same manner and fed to gypsy moth larvae for 42 hr, then frozen for chemical analysis. All bouquets used in this experiment were kept at ambient conditions (26°C). After a portion of the foliage from each branch had been removed to make the foliar bouquet, the remaining branch was kept for additional foliage sampling. These branches were kept in the sample buckets in an unlit cooler at 5°C. Samples were frozen for analysis in the order shown in Table 1.

Multileaf bouquets were chemically analyzed as separate samples. Combining the paired single leaf bouquets (sample 7) for chemical analysis produced 20 samples per species (four per tree).

Experiment 2 (June 1987). One branch (0.5–1.0 m) was cut from each of five mature chestnut oak and five mature red oak trees and two samples of five to six leaves each were taken from each branch (day 1, zero hr). The branches were recut under water and transported to the lab in 19-liter buckets. Ten bouquets of foliage (five to six leaves in each bouquet) were prepared from each branch as described above. Foliar bouquets from each branch were placed in separate covered 31 × 17 × 9-cm plastic boxes in a growth chamber under

TABLE 1. DESCRIPTION OF OAK LEAF SAMPLES FOR EXPERIMENT 1

Sample	Source	N/species	Day	Hours
1	Field	5	1	0
2	Buckets	5	1	5
3	Aqua-pics	5	2	18
4	Buckets	5	2	18
5	Buckets	5	2	30
6	Buckets	5	3	42
7	Aqua-pics (fed to larvae)	20	3	42

conditions used for gypsy moth rearing (24°C with a 14:10 light–dark photoperiod). Two foliar bouquets were sampled from each branch every day for five days (days 2–6) for a total of 50 bouquets per species sampled throughout a 120-hr period. All samples were flash frozen in liquid nitrogen and stored at −34°C.

Statistical Analyses

To avoid pseudoreplication with sample 7 in experiment 1, the mean of the four samples per tree was used for statistical analysis, resulting in a balanced design of $N = 5$ per species. In experiment 2, red oak samples 2 and 3 were lost due to mishandling in the laboratory. For both experiments, differences among samples were analyzed by species, using one-way ANOVA (GLM, SAS Institute) with individual trees as the randomized blocks and sample time as the main effect. Samples different from sample 1 (the field sample) were detected with Tukey's studentized range test.

Chemical Analyses

Frozen leaf samples were lyophilized and thoroughly ground in a UDY Cyclone Sample Mill and a subsample was extracted in 0.1 N NaOH to reduce interference from phenolics (Jones et al., 1989). Protein concentration was analyzed using a modification of the micro method of Bradford (1976) (0.04 ml of extract was diluted with 0.76 ml of deionized water, then mixed with 0.20 ml of Coomassie brilliant blue G-250; Biorad dye reagent). Samples were read within 10 min at 595 nm against a distilled water blank, which resulted in higher protein values than reported elsewhere (Faeth, 1985; Jones et al., 1989). A portion of the remaining ground sample was extracted in 70% acetone, reduced to an aqueous extract via rotary evaporation, and analyzed for proanthocyanidins (vanillin assay; Swain and Hillis, 1959; Schultz and Baldwin 1982), gal-

lotannins (potassium iodate; Bate-Smith, 1977, as modified by Schultz and Baldwin, 1982), total phenolics (Folin-Denis), and protein-binding capacity using hemoglobin as a substrate (Schultz et al., 1981). Protein concentration is reported as percent dry weight bovine serum albumin equivalents (%BSAE); protein binding, Folin-Denis active phenolics, and hydrolyzable tannins are reported as percent dry weight tannic acid equivalents (%TAE; Sigma, Lot 11F-0559); and proanthocyanidins as percent dry weight wattle tannin equivalents (%WTE; *Acacia* sp., from Leon Monnier, Inc. Peabody, Massachusetts), derived from standard curves.

RESULTS AND DISCUSSION

Experiment 1. For both red and chestnut oak foliage, there was only one significant change in the five measures of leaf quality made among the seven samples taken over a 42-hr period (Figure 1). After 42 hr, chestnut oak foliage

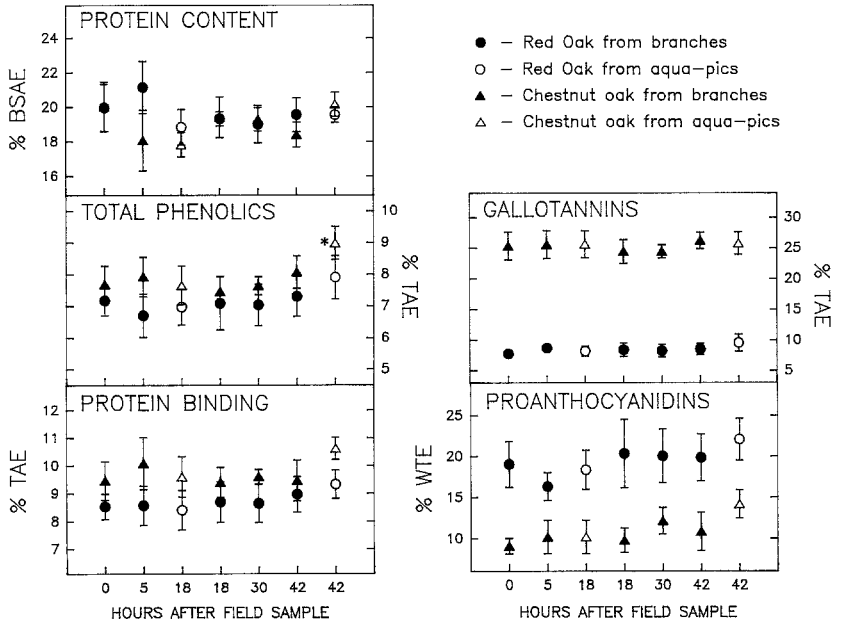

FIG. 1. Levels of protein content and phenolics in excised foliage of red oak and chestnut oak subjected to laboratory treatment to simulate handling during rearing trials. Each point is mean ± SE of five trees. * indicates sample is significantly different from sample 1 at $P < 0.05$. % BSAE = percent dry weight bovine serum albumin equivalents; % TAE = percent dry weight tannic acid equivalents; WTE = dry weight wattle tannin equivalents. See text for explanation of samples.

in Aqua-pics that had been fed to gypsy moth larvae had greater measures of total phenolics than the initial field sample (8.99% TAE vs. 7.68% TAE; $P \leq 0.05$). Interestingly, the smallest difference among means that the statistical analysis could have detected (regardless of species) ranged from low (1.27% TAE, protein binding; 1.29% TAE, total phenolics; 1.9% TAE gallotannins) to medium (4.4% BSAE protein) to high (8.17% WTE proanthocyanidins). In this study, significant differences between sample times only indicates changes in the measures of foliage quality. Because of the differential tolerance to tannins by various herbivores (Bernays, 1978; Berenbaum, 1983; Karowe, 1989), the biological impact of even the smallest change in phenolics will be species specific.

The results of experiment 1 show that after 42 hr of gypsy moth feeding, only small increases in phenolics were observed in the remaining foliage. This is surprising in light of many studies that have shown increases in secondary metabolites within hours of damage or insect feeding on intact foliage (Baldwin and Schultz, 1983; Tallamy, 1985; Niemeyer et al., 1989). Some inducible responses are limited to the site of damage, while others occur systemically and may require the response of the whole plant (Bowles, 1990). The limited response of excised foliage observed in this study suggests the latter, but without proper controls, this conclusion cannot be assumed.

Experiment 2. Gallotannin was the only measure for both red and chestnut oak that did not change significantly over a five-day period (120 hr). The measures of protein content, proanthocyanidin, total phenolics, and protein-binding capacity all displayed increases (with the exception of red oak protein content and protein-binding capacity) within 48–72 hr, followed by subsequent declines (Figure 2). Protein measures in chestnut oak foliage were significantly greater 72 and 96 hr following the field sample ($P < 0.0001$ from ANOVA), but were below field sample measures by 120 hr. The measure of red oak protein content displayed a marked decrease at 72 hr, a considerable increase at 96 hr ($P < 0.0001$ from ANOVA), and a return to near field sample levels by 120 hr. The measures of total phenolics in red oak and chestnut oak foliage were significantly greater 72, 96, and for red oak, 120 hr after field sampling ($P < 0.0001$ from ANOVA for each species).

The results of experiment 1 indicate that oak foliage can be collected, returned to the laboratory, and stored under refrigeration for up to 42 hr without significantly changing these measures of protein content and phenolics. Both experiments indicate that the most stable period for the measures of protein and phenolics in excised foliage is during the first 24 hr following field sampling. In experiment 2, some of these measures (protein content, total phenolics) did not differ significantly until 48 or 72 hr.

The patterns of change observed in this study are not readily explained by the natural variation among samples. Although there was significant variation

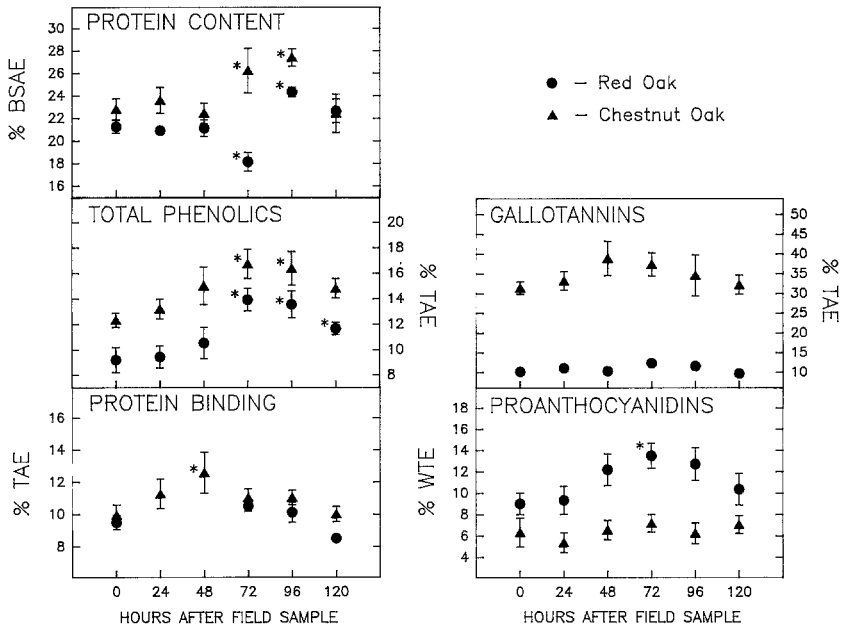

FIG. 2. Levels of protein content and phenolics in excised foliage of red oak and chestnut oak from the field (0 hr) and at five 24-hr intervals while under insect rearing conditions. Each point is mean ± SE of 10 trees. * indicates sample is significantly different from field sample at $P < 0.05$. Axis labels defined in Figure 1.

among trees of both species within any sample period, this variation was exceeded by the magnitude of change in the measures over the 120-hr period (Figure 2).

The increases in the measures of total phenolics after 120 hr were similar to those observed by Miller (1987) in excised birch and willow foliage after 144 hr. However, the increases in some of the phenolic measures cannot be interpreted simply as changes in the quantity of the compounds (proanthocyanidins and gallotannins) that were measured in the initial field samples. The results of assays that are specific for a class of tannins (potassium iodate and vanillin assays) indicate that no change occurred in the quantity of red oak gallotannins or chestnut oak proanthocyanidins. However, the measures of total phenolics and protein-binding capacity, which are sensitive to both proanthocyanidins and gallotannins, suggest that these tannins did increase. Because the Folin-Denis and protein binding assays are sensitive to a wide array of phenolics, they may reflect changes in other foliar constituents not measured in the more specific assays. These changes could include the synthesis and/or restructuring in excised foliage of nontannin phenolics or tannins not measured by the

analyses used here. Alternatively, the patterns observed in this study may reflect a process of phenolic degradation, which may involve oxidation and restructuring, followed by the complete breakdown of these products. This would result in the greater measures of phenolic activity observed at 72–96 hr, followed by the lower phenolic measures observed by 120 hr. As a consequence, it would appear that after 120 hr, hydrated, excised foliage is quantitatively the same as samples taken from the first 48 hr. However, it cannot be assumed that such foliage is qualitatively the same.

The maintenance of leaf turgor for insect-rearing trials cannot assure the integrity of some dietary constituents for more than 48 hr. Such an assumption may lead to uninterpretable or incorrect biological indices, particularly when results are compared across different host species or foliage treatments (Scriber, 1977; Hough and Pimentel, 1978). Cautious interpretations should be made from larval performance and/or leaf quality studies in which foliage used for chemical analyses may have been handled differently from foliage for rearing trials (Fox and MacCauley, 1977; Wint, 1983; Barbosa et al., 1983, 1986; Puttick, 1986). Researchers who hydrate excised foliage and change it within 48 hr or use refrigerated foliage within 48 hr (Raupp et al., 1988) are likely to maintain the foliage traits that were measured in this study.

(Received October 1, 1990; accepted February 19, 1991)

Abstract—The chemical basis underlying orientation to fruit and fungal odors was investigated for the dried-fruit beetle, *Carpophilus hemipterus* (L.). In wind-tunnel bioassays of walking and flight response from 1.8 m, beetles were attracted to odors of the yeast *Saccharomyces cerevisiae* on agar, aseptic banana, or banana inoculated with *S. cerevisiae*, although both banana substrates elicited greater response than the yeast alone. When presented in a two-choice bioassay, the yeast-inoculated banana attracted approximately twice as many beetles as did the aseptic banana. GC-MS analysis of the headspace volatiles above these odor sources revealed a somewhat more complex and concentrated volatile profile for yeast-inoculated banana than for aseptic banana. The odor from yeast on agar had fewer components, and these were present at lower concentrations than the odors of either banana substrate. By blending mineral-oil or aqueous solutions of the 18 components of inoculated-banana odor in varying concentrations, it was possible to mimic closely the headspace profile of the natural odor. This synthetic odor also elicited beetle attraction in the wind tunnel at levels comparable to the inoculated banana. Through a series of bioassays in which individual components were subtracted from or added to a synthetic odor blend, it was determined that ethyl acetate, acetaldehyde, 2-pentanol, and 3-methylbutanol comprised the simplest blend of compounds evoking full behavioral response. However, 2-methylpropanol or butanol were apparently interchangeable with 3-methylbutanol in this blend, and comparable response could also be elicited by replacing acetaldehyde with a combination of both 2-pentanone and 3-hydroxy-2-butanone. Thus, our results suggest that this generalist insect

herbivore locates its hosts by a long-range response to a variety of blends of common fruit volatiles, whose concentrations are enhanced by fungi.

Key Words—Coleoptera, Nitidulidae, *Carpophilus hemipterus*, dried-fruit beetle, host-finding, yeast, wind tunnel, attraction, volatiles, headspace.

INTRODUCTION

The dried-fruit beetle, *Carpophilus hemipterus* (L.), is a cosmopolitan species that causes damage to a large number of agricultural products by direct infestation or by transmission of phytopathogenic fungi (Hinton, 1945). Fruit baits are used commonly to monitor this and other nitidulid beetles in the field, and response to fruits can be enhanced in *C. hemipterus* if the fruits are inoculated with fungi (Wildman, 1933; Blackmer and Phelan, 1991); however, monitoring populations using fruit baits is made difficult by the confounding variability in volatile release from living tissue, especially during the chemically dynamic period of ripening. Smilanick et al. (1978) demonstrated that a synthetic mixture of ethanol, ethyl acetate, and acetaldehyde could be used to attract *C. hemipterus* in the field, and propyl propionate or butyl acetate can be used to selectively trap another nitidulid, *Glischrochilus quadrisignatus* (Alm et al., 1986); however, in both cases the release rates used for the lures were much higher than that expected from a plant, and thus it is difficult to determine the role that these compounds may play in host-finding for these species. To date, no attempt has been made to investigate systematically the components of a natural odor source to determine which constituents may be mediating long-range host-finding in any nitidulid species. In this study, we: (1) measure the relative attractiveness of aseptic banana, the yeast *Saccharomyces cerevisiae* Hanson, and banana inoculated with yeast in a wind-tunnel bioassay; (2) chemically characterize the odor profiles in the headspace above these substrates; and (3) determine the relative activity of odor components for *C. hemipterus* host finding by their systematic elimination from and addition to synthetic odor blends.

METHODS AND MATERIALS

Insects. C. hemipterus was maintained in the laboratory on artificial diet using the methods of Hall et al. (1978) under the conditions of 24 ± 1°C, 16:8 light–dark, and 75–85% relative humidity. After emergence from the pupae, adults were kept as mixed sexes in 12-oz. plastic cups with moisture, without contact with food or food odors.

Natural Odors. Banana (var. Cavendish) was used to investigate host-finding in *C. hemipterus* because it was found to elicit high levels of upwind flight

in wind-tunnel studies (Blackmer and Phelan, in preparation) and because fresh samples were available on a year-round basis in local grocery stores. The role of fungi in host finding was measured using *Saccharomyces cerevisiae* var. Montrachet, which was maintained in the laboratory on YM agar (Difco Laboratories, Detroit, Michigan) at 24 ± 1°C. Four natural-odor combinations were prepared for chemical analysis and behavioral bioassays: YM agar, *S. cerevisiae* on yeast medium, aseptic banana, and banana inoculated with *S. cerevisiae*. Samples of 30 g freshly peeled banana or 30 ml yeast medium were prepared in 240 ml Qorpak straight-sided jars that had been sterilized with 1% NaOCl and rinsed with sterile doubly deionized water. The lid of each jar was equipped with a 0.20 μm Bacterial Air Vent (Gelman Sciences, Ann Arbor, Michigan), to allow free air exchange while precluding microbial contaminants, and with a sleeve-type rubber septum (Thomas Scientific) for collection of headspace samples. Banana samples were placed in the jars, sterilized by treatment with 70% ethanol for 5 min, and then rinsed five times with 100–150 ml doubly deionized water passed through the Bacterial Air Vent. In rare instances where sterilization was unsuccessful (<1%), contamination became visible within three to four days and these samples were discarded; otherwise, substrates remained aseptic for greater than a month. To determine the degree to which the ethanol used in sterilizing the banana may have contributed to the occurrence of ethanol in the headspace of aseptic substrates, we compared the headspace profiles of bananas sterilized using the above procedures with those of bananas sterilized with 1% NaOCl. For inoculated samples, *S. cerevisiae* was transferred in a sterile transfer hood to sterilized banana samples by scratching the surface of the fungal culture with a flame-sterilized wire loop and then smearing the surface of the banana. All samples were incubated in the jars for seven days prior to testing in the wind tunnel and headspace analysis.

Headspace Volatile Identifications. Headspace volatiles were trapped using a device integral to a Hewlett-Packard 5890A gas chromatograph (GC) that allowed thermal desorption of constituents directly to the GC column (Phelan, unpublished). Briefly, the device consisted of a six-port two-position capillary valve (Valco Instruments, Houston, Texas) and a 60-cm × 0.1-cm-ID capillary volatile trap filled with Tenax GC (60/80 mesh). When placed in the trapping position, the valve allowed volatiles to be carried via a helium flow to the capillary trap. After a designated collection period, the trap was ballistically heated to 200°C and the valve position was switched to reverse the helium flow in the trap such that retained volatiles were desorbed and back-flushed to the GC analytical column. For this study, jars containing odor sources were opened for 5 min, resealed, and a 1-ml headspace sample immediately collected through the rubber septum using a gas-tight syringe. The 1-ml sample was then slowly injected onto the volatile trap and desorbed as above. Because the headspace profile was greatly dominated by ethanol, a second method was used to reduce

the amount of ethanol desorbed to the analytical column while enriching minor components of the headspace samples. A 20-ml headspace sample was collected and injected onto the trap as described; however, at this point the trap was flushed with helium for 6 min at a flow of 20 ml/min. This flush period allowed the preponderance of ethanol and acetaldehyde to be removed from the trap, which we have determined to have breakthrough volumes of approximately 90 ml and 45 ml, respectively; the next smallest breakthrough volume for the components encountered in this study was 450 ml for propanol, so that all other components were concentrated on the trap without breakthrough for desorption to the analytical column.

Headspace components were chromatographed on either DB-1 (30 m × 0.32 mm ID, 5.0-μm film thickness) or DB-FFAP (30 m × 0.25 mm ID, 0.25-μm film thickness) capillary columns (J & W Scientific, Folsom, California), with a temperature program of 30–200°C increased at 10°C/min. Helium flow was 0.9 ml/min on the DB-1 column and 0.7 ml/min on the DB-FFAP column. Tentative identifications of the components were made using a HP 5970C Mass Selective Detector with a direct interface to the GC. Chemical assignments were confirmed by comparison of GC retention times on the two columns and mass spectra with those of authentic samples; no attempts were made to determine enantiomeric identity of chiral compounds. The concentration of each component in the headspace was quantified by comparison of its peak areas with that of synthetics.

Synthetic Odors. Synthetic odors were created by blending compounds identified from *S. cerevisiae* -inoculated banana. All chemicals were obtained from Aldrich Chemical Co. (Milwaukee, Wisconsin) and were prepared individually as mineral-oil solutions, except ethanol, which was diluted with double-deionized water due to low solubility in mineral oil. Mineral-oil solutions were applied to cotton wicks in 240-ml Qorpak straight-sided jars. Solution concentrations and volumes were adjusted to mimic the natural odor by comparing the concentration of each component in the headspace above the synthetic blend with that of the natural source. A total combination of 18 synthetic compounds was used in the first three bioassays, but this blend was reduced to 13 components for subsequent bioassays as the elimination of five minor compounds (four esters and 2-butanone) did not significantly affect the attractiveness of the synthetic blend. Synthetic odor blends were used for bioassay immediately after preparation, and new mixtures were prepared for each replicate.

Wind-Tunnel Bioassays. Odor-modulated responses of *C. hemipterus* were evaluated in a previously described wind tunnel that measured 2.5 m long × 1 m wide × 0.5 m high (Phelan et al., 1991). Bioassays were conducted 4–0 hr prior to lights out at 35–65% relative humidity, 24–27°C, with a wind speed of 0.5 m/sec. The tunnel was illuminated from above by three 60-W bulbs

operated at 80 V to provide 17 lux on the tunnel floor. During wind-tunnel bioassays, two jars were placed on the floor 10 cm away from the center line of the upwind end of the tunnel. Unless otherwise indicated, one of the jars was empty and served as a negative control for possible odor contamination. The position of the jars was randomized for each treatment, and the test beetles were released on the floor at the center of the downwind end of the tunnel at a distance of 180 cm from the odor sources. Smoke tests showed that plumes from the two jars merged before reaching the beetle-release site. Ten 6- to 7-day-old beetles were released per replicate, and beetles were used only once. Beetles that oriented to test odors within 10 min and that walked or flew up the odor plume to within 10 cm downwind of the jar were counted as responders. The 10-cm criterion was used since the top of the jar, and thus the source of the odor, was 8.7 cm above the floor, and those beetles that walked to within 10 cm of the jar would lose the odor plume. A final bioassay measuring flight response alone was conducted to confirm that the synthetic blends eliciting the greatest walking response also evoked a flight response equivalent to that to inoculated banana. For this bioassay, the sample jars were set on 15-cm-high tripods and beetles were released from a platform on a similar tripod. The locations of jars and distances between odor and beetle-releasing site were the same as in previous bioassays. A positive response was recorded for those individuals that flew up the odor plume and landed on the jar. Since beetles were never observed to respond to an empty jar, these bioassays effectively were operated as single-choice tests, with a randomized complete-block presentation of treatments. Beetle response was measured as the percent of each group of 10 beetles released. Response data were analyzed by two-way ANOVA after transformation by $\sin^{-1}\sqrt{X}$, with mean separations performed using LSD on data sets where ANOVA indicated a significant F value (SAS Institute, 1985). In addition to the single-choice bioassays, beetle response to *S. cerevisiae*-inoculated banana was compared with that to aseptic banana as a two-choice bioassay in the wind tunnel.

RESULTS

Attraction to Natural Odors. All four natural odor sources elicited significant levels of upwind orientation by *C. hemipterus* (Figure 1). The *S. cerevisiae*-inoculated and the aseptic bananas elicited comparable beetle responses, both of which were significantly greater than that to the yeast on agar medium or the medium alone; however, when given a choice between the inoculated- and aseptic-banana odors, beetles showed a strong preference for the former, with more than twice as many orienting to the inoculated substrate (Figure 1).

Headspace Volatile Identifications. A total of 18 compounds (eight esters,

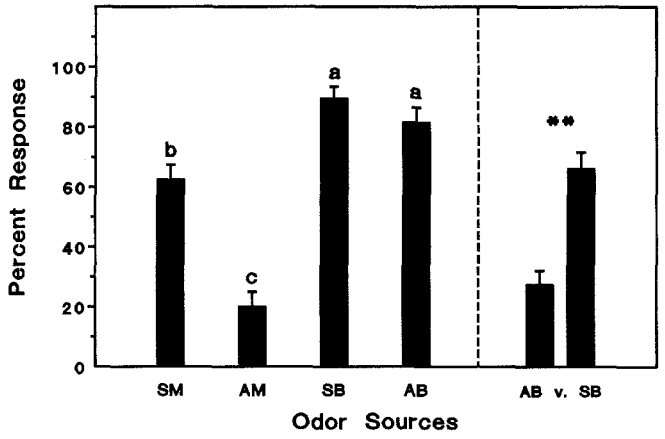

FIG. 1. Orientation of *Carpophilus hemipterus* to four natural odor sources in a wind tunnel: *Saccharomyces cerevisiae* on agar medium (SM), aseptic agar medium (AM), *S. cerevisiae*-inoculated banana (SB), or aseptic banana (AB). Response bars (±SEM) marked by the same letter are not significantly different (LSD, $N = 8$ groups of 10 beetles, $P < 0.05$). Orientation to SB versus AB compared in a two-choice experimental design ($\chi^2 = 17.62$, 7 *df*, $P < 0.02$).

six alcohols, three ketones, and one aldehyde) were identified from the four substrates, as listed in Table 1 with the major mass ions used for their identification; ethanol was by far the dominant component in the odor of all four substrates. The possibility that ethanol in the headspace was a result of the use of ethanol for sterilizing substrates was ruled out by the fact that the headspace of 7-day-old aseptic banana sterilized by 1% NaOCl contained ethanol at levels identical to that sterilized with 70% ethanol [peak areas ($\times 10^7$) ± SEM = 2.41 ± 0.32 and 2.48 ± 0.21, respectively; $t = 0.19$; $P = 0.86$; $N = 5$]. Table 2 shows the relative abundance of these constituents in the volatile profiles of the four substrates, with the odor of yeast-inoculated banana possessing all 18 components (Figure 2a). The aseptic-banana odor was qualitatively similar, with 15 of these compounds present (Table 2); however, the two substrates were quantitatively distinct, with the inoculated banana producing roughly twice the concentration of volatiles overall and with the largest increase occurring in the production of alcohols. The concentration of nonethanol alcohols was about four times greater in the headspace of inoculated banana, and the concentration of propanol increased by more than 40-fold (Table 2). The headspace profile of *S. cerevisiae* on yeast medium was both qualitatively and quantitatively depauperate relative to that of the yeast on banana, with only seven compounds detected in headspace samples of yeast on agar medium.

Attraction to Synthetic Odors. When the 18 components of yeast-inocu-

lated banana odor were blended in the amounts and concentrations given in Table 2, a synthetic-odor profile was generated that closely mimicked the natural source both in overall quantity and in the ratio of individual components (Figure 2b). This synthetic banana odor also closely mimicked the natural substrate in behavioral activity, eliciting upwind attraction in *C. hemipterus* at levels comparable to the inoculated banana [87.8 $\pm$ 2.5% ($\bar{X}$ $\pm$ SEM) for the synthetic odor and 67.9 $\pm$ 6.3% for the natural odor, $N = 4$ groups of 10 beetles, $P > 0.05$). In addition, both the synthetic blend and the inoculated banana elicited beetle response at a level several times greater than that to a blend of ethanol, acetaldehyde, and ethyl acetate (9.5 $\pm$ 4.8%, $P < 0.05$), a combination previously reported to be an effective attractant for *C. hemipterus* in the field (Smilanick et al., 1978).

In the first of a series of bioassays of synthetic blends, the 18-component blend again was very similar to the inoculated banana in eliciting upwind orientation; however, the elimination of all members of any of the three groups of functionalities resulted in a reduction in beetle response (Figure 3). The per-

[e] Compound not included in 13-component total blend.

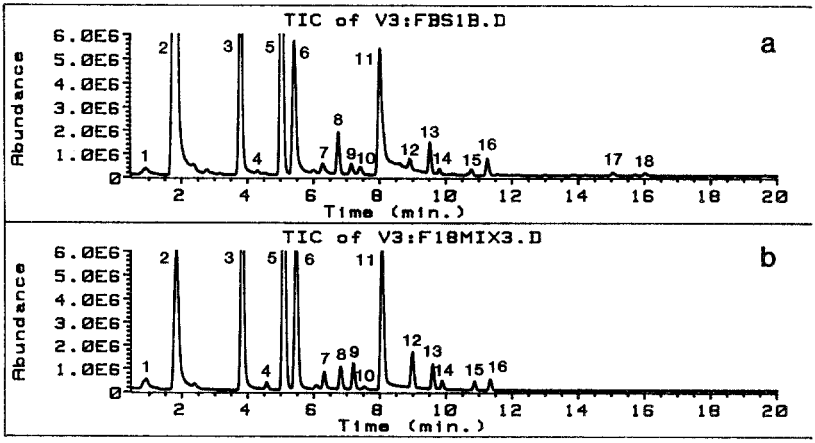

FIG. 2. Headspace volatile profiles for banana inoculated with *Saccharomyces cerevisiae* (a) and for a synthetic blend of constituents formulated to mimic the inoculated banana (b). Methods for collection and analysis are explained in the text; note that the collection method intentionally reduces the amount of ethanol and acetaldehyde relative to other components. See Table 1 for the identity of peaks and for the amount of each compound used in the synthetic odor.

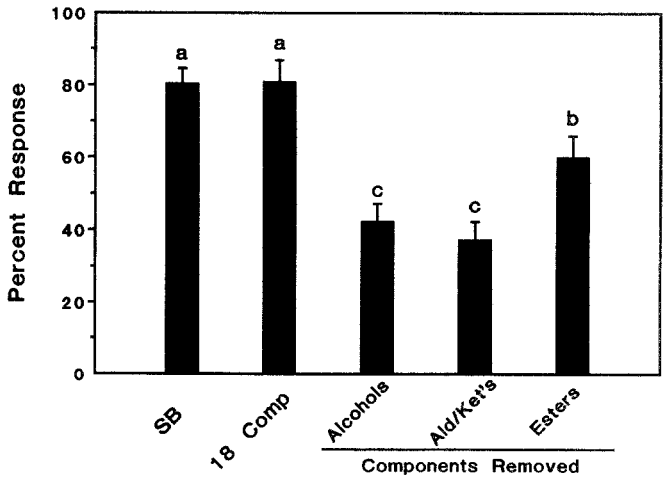

FIG. 3. Orientation of *Carpophilus hemipterus* to the odor of *Saccharomyces cerevisiae*-inoculated banana (SB), an 18-component synthetic blend, or synthetic blends with all members of each of three groups of functionalities removed: six alcohols, four aldehydes/ketones, or eight esters. Response bars (±SEM) marked by the same letter are not significantly different (LSD, $N = 4$ groups of 10 beetles, $P < 0.05$).

centage of beetles orienting to the source was lowest when either the alcohols or aldehyde/ketones were excluded, responses that were significantly lower than that to a blend that was lacking in esters. Focusing on the alcohol constituents, removal of five of the six alcohols individually did not significantly affect beetle response (Figure 4), only the synthetic blend that was lacking 2-pentanol attracted significantly fewer beetles than did the total combination of 18 components. Similarly, when esters were individually excluded from a 13-component total blend, which elicited response equivalent to that of inoculated banana, only the combination that omitted ethyl acetate evoked a significantly lower response than either the inoculated banana or the total blend (Figure 5). The response when ethyl acetate was removed was comparable to that elicited by a blend that lacked all the esters. Results from a bioassay of blends that individually eliminated acetaldehyde or the two ketones were less straight-forward. Although a blend lacking all three compounds was significantly less attractive than the total 13-component blend, the removal of any of the three individually did not significantly diminish response (Figure 6). In this group, acetaldehyde appeared to be the most important, as the removal of this component resulted in a beetle response not different from that to the blend lacking all three compounds, while blends that included acetaldehyde were significantly more active than the latter. In addition, the blend excluding acetaldehyde was significantly less active than the inoculated banana, as was the total synthetic blend in this

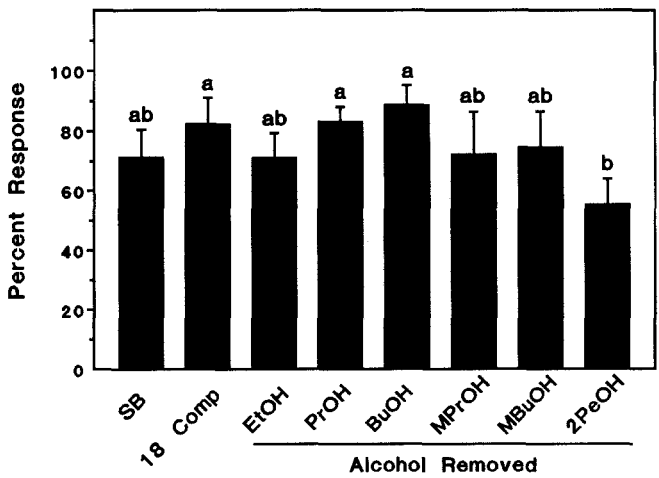

FIG. 4. Orientation of *Carpophilus hemipterus* to the odor of *Saccharomyces cerevisiae*-inoculated banana (SB), an 18-component synthetic blend, or synthetic blends with one alcohol removed. Response bars (±SEM) marked by the same letter are not significantly different (LSD, $N = 4$ groups of 10 beetles, $P < 0.05$). See Table 1 for explanation of compound abbreviations.

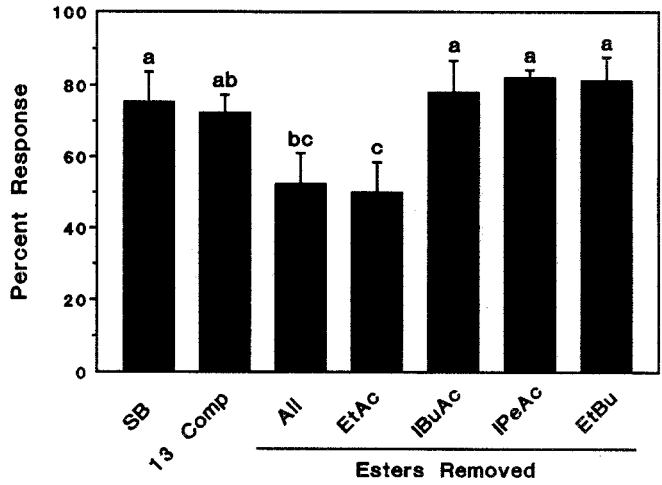

FIG. 5. Orientation of *Carpophilus hemipterus* to the odor of *Saccharomyces cerevisiae*-inoculated banana (SB), a 13-component synthetic blend, a synthetic blend with all ester components removed, or synthetic blends with one ester removed. Response bars (±SEM) marked by the same letter are not significantly different (LSD, $N = 5$ groups of 10 beetles, $P < 0.05$). See Table 1 for explanation of compound abbreviations.

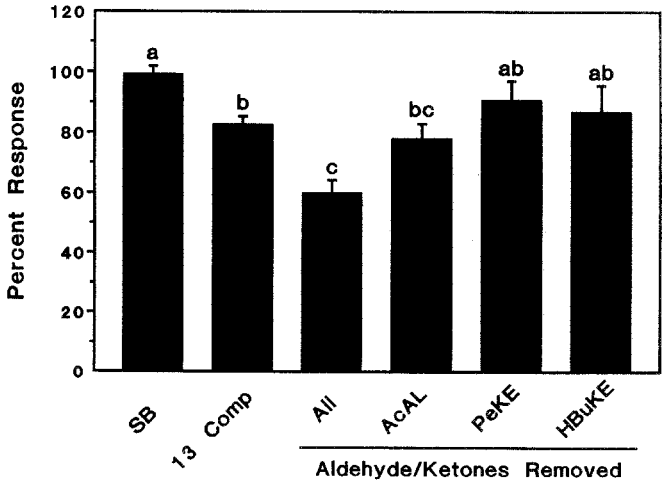

FIG. 6. Orientation of *Carpophilus hemipterus* to the odor of *Saccharomyces cerevisiae*-inoculated banana (SB), a 13-component synthetic blend, a synthetic blend with all aldehydes/ketones removed, or synthetic blends with one member of the latter group removed. Response bars (±SEM) marked by the same letter are not significantly different (LSD, $N = 4$ groups of 10 beetles, $P < 0.05$). See Table 1 for explanation of compound abbreviations.

test. The greater role of acetaldehyde in beetle attraction was confirmed by testing blends that added acetaldehyde or the ketones individually to the alcohols and esters. A blend that included only acetaldehyde from this group was significantly more active than a blend of alcohols and esters alone and was not significantly different from the total synthetic combination (Table 3). Similar blends with either 2-pentanone or 3-hydroxy-2-butanone were not significantly more active than the blend of alcohols and esters. In this bioassay, it also was confirmed that adding ethyl acetate as the only ester to a blend of alcohols, ketones, and acetaldehyde was sufficient for full beetle response (Table 3); however, a blend of acetaldehyde, ketones, and esters with 2-pentanol as the only alcohol was significantly less attractive than the total synthetic blend. This result suggested the requirement of additional alcohols for optimal response; thus a subsequent bioassay was conducted in which the other alcohols were added individually to a blend of acetaldehyde, ketones, ethyl acetate, and 2-pentanol. The addition of either ethanol or propanol did not significantly improve the attractiveness of the five-component base mixture (Figure 7). On the other hand, blends that included 1-butanol, 2-methylpropanol, or 3-methylbutanol were significantly more active than the base mixture, and beetle response to any of these blends was not significantly different from that to a mixture of acetaldehyde, ketones, alcohols, and ethyl acetate, to the 13-component blend, or to yeast-inoculated banana.

In the final bioassay based primarily on a walking response, the simplest combination of synthetic components to elicit attraction comparable to that to either the 13-component mixture or the natural odor source was a blend of ethyl acetate, 2-pentanol, 3-methylbutanol, and acetaldehyde (Figure 8). The addi-

[b] Means marked by the same letter are not significantly different (LSD, $N = 4$ groups of 10 beetles, $P < 0.05$).

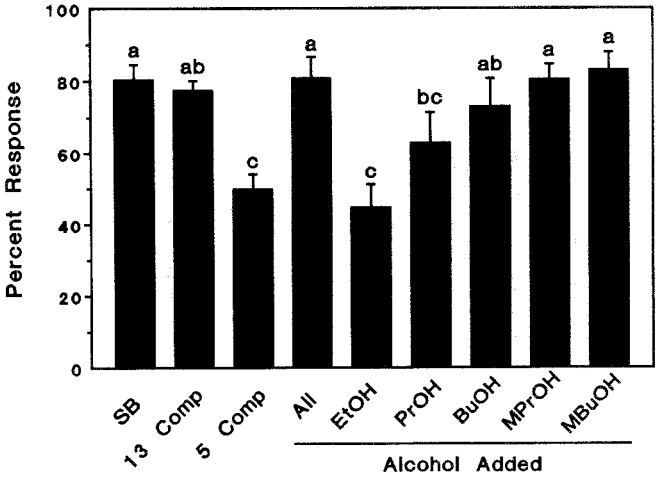

FIG. 7. Orientation of *Carpophilus hemipterus* to the odor of *Saccharomyces cerevisiae*-inoculated banana (SB), a 13-component synthetic blend, a five-component synthetic blend (acetaldehyde, two ketones, ethyl acetate, and 2-pentanol), or synthetic blends composed of the five-component blend with one of five remaining alcohols or all alcohols added. Response bars (±SEM) marked by the same letter are not significantly different (LSD, $N = 4$ groups of 10 beetles, $P < 0.05$). See Table 1 for explanation of compound abbreviations.

tion of either 2-pentanone or 3-hydroxy-2-butanone to this four-component blend did not significantly increase activity; however, a five-component blend that included both of these ketones in lieu of acetaldehyde did evoke activity comparable to the four-component and to the 13-component blends, as was also suggested by the bioassay of Figure 6. Unlike in previous bioassays, a six-component blend that included acetaldehyde and the ketones was significantly more attractive than either the four- or 13-component blends.

The bioassay based on flight-only response confirmed the previous findings on walking-and-flight response. The four-component and 13-component blends elicited a level of flight response comparable to that to the inoculated banana, while a three-component blend that lacked acetaldehyde was significantly less active (Figure 9). In addition, a blend that included acetaldehyde and the two ketones was no more active than the four-component blend.

DISCUSSION

Various fruit substrates commonly have been used as baits for trapping nitidulid species in the field (Foott and Timmins, 1977; Smilanick et al., 1978; Alm et al., 1986). In a wind-tunnel investigation of flight response to several

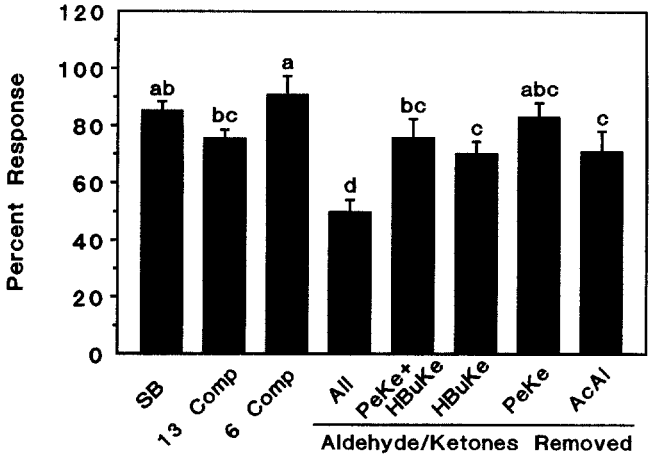

FIG. 8. Orientation of *Carpophilus hemipterus* to the odor of *Saccharomyces cerevisiae*-inoculated banana (SB), a 13-component synthetic blend, a six-component synthetic blend (acetaldehyde, two ketones, ethyl acetate, 2-pentanol, and 3-methylbutanol), or synthetic blends composed of the six-component blend with all aldehydes/ketones, both ketones, each ketone, or acetaldehyde removed. Response bars (±SEM) marked by the same letter are not significantly different (LSD, $N = 4$ groups of 10 beetles, $P < 0.05$). See Table 1 for explanation of compound abbreviations.

fruit substrates inoculated with one of two fungi or maintained asceptically, Blackmer and Phelan (1991) found *C. hemipterus* to exhibit a very broad response, with all substrates eliciting some level of attraction, but with most fungal-inoculated materials, particularly those inoculated with *S. cerevisiae*, eliciting significantly higher response than those maintained aseptically. One difficulty with using fruit baits to monitor insect activity in the field stems from the chemically dynamic nature of plant tissue, with the quantitative and qualitative aspects of the odor profile highly dependent on the stage of fruit ripening and on the degree and nature of microbial contamination of the substrate, as well as other environmental factors. This variability also was evidenced in our own wind-tunnel studies even though the condition of the substrate could be controlled to a much greater degree than in the field. During this series of bioassays, beetle response to *S. cerevisiae*-inoculated banana ranged from 68% to 99%, about twice the variability of that measured for the 13- or 18-component synthetic blends (73–89%), even though the mean responses across all experiments were virtually identical for the natural and synthetic odors, 82% and 81%, respectively.

In spite of the variability in inoculated banana as an odor stimulus, it is essential that a natural host be used as a benchmark for measuring the behavioral

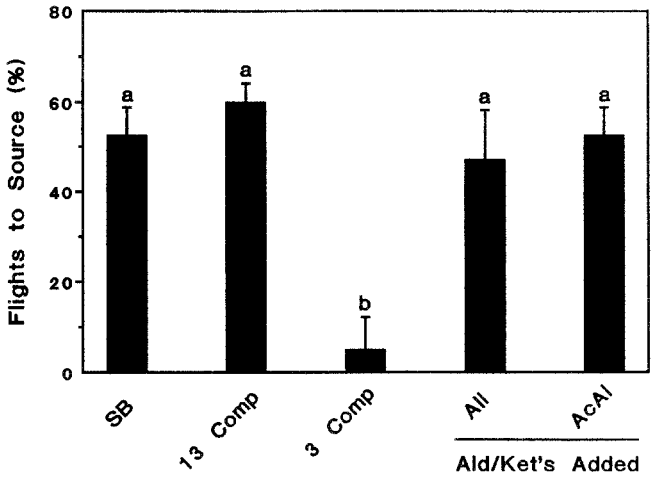

FIG. 9. Upwind flight orientation of *Carpophilus hemipterus* to the odor of *Saccharomyces cerevisiae*-inoculated banana (SB), a 13-component synthetic blend, a three-component synthetic blend (ethyl acetate, 2-pentanol, and 3-methylbutanol), or synthetic blends composed of the three-component blend with either all aldehydes/ketones or only acetaldehyde added. Response bars (±SEM) marked by the same letter are not significantly different (LSD, $N = 4$ groups of 10 beetles, $P < 0.05$).

activity of synthetic chemical blends (Miller and Strickler, 1984). Likewise, it is also important in determining the activity of a synthetic odor that the components be presented at quantitative levels corresponding to those of the natural source. For example, although Finch and Skinner (1982) found allylisothiocyanate to be as attractive as host-plant extracts in trapping *Delia brassicae*, the cabbage root fly, the concentration necessary for this response was far greater than that released from a plant. Similarly, Alm et al. (1986) found either propyl propionate or butyl acetate to be effective for trapping the nitidulid *G. quadrisignatus*; however, since a release rate of >1 g/day was needed for this response, we do not know what role this compound plays in host-finding for the species. By closely simulating the release rate for each of the volatiles identified from *S. cerevisiae*-inoculated banana in the present study, we were better able to examine the relative role played by these components in attracting *C. hemipterus* to the natural substrate and to deduce the complexity of interactions between the components in this host-finding system.

The role of the esters identified from yeast-inoculated-banana odor was clear: beetle orientation to the odor source was reduced only when ethyl acetate was removed (Figure 5); thus no combination of the other components could duplicate the behavioral activity of ethyl acetate, at least using the release rates measured in the natural odor. Furthermore, in later bioassays when ethyl acetate

was the only ester included in a synthetic blend, activity was comparable to the 13-component blend (Figures 7–9, Table 3). Among the banana-odor aldehyde/ketones, full behavioral activity was elicited by synthetic blends that included acetaldehyde as the sole member of this group (Figures 8 and 9, Table 3). Although the addition of either 2-pentanone or 3-hydroxy-2-butanone did not elicit a higher level of response than a blend that included no aldehyde/ketones (Table 3), when both of these compounds were present, response was increased to a level not significantly different from the 13-component blend (Figures 6 and 8). These bioassays also indicated that 2-pentanol was an alcohol essential for full beetle response, although an additional alcohol also was required. Three of the five alcohols identified from the natural odor led to a significant increase in beetle response: 3-methylbutanol, 2-methylpropanol, and apparently to a lesser extent, butanol (Figure 7). In total, of the 18 volatiles characterized from *S. cerevisiae*-inoculated banana: (1) ethyl acetate and 2-pentanol were essential for full upwind response; (2) acetaldehyde was important but could be replaced to some extent by the inclusion of both 2-pentanone and 3-hydroxy-2-butanone; and (3) one additional alcohol was also needed, with 2-methylpropanol, 3-methylbutanol, and possibly butanol interchangeable in this role. There apparently was no interchangeability among the three functionality groupings, because when all of the members of any functional group were removed, activity was diminished (Figure 3).

The bulk of the bioassays in this study were based primarily on a long-range walking response; across all these bioassays, 89% of beetles responded by walking the 1.8-m distance to the odor source and 11% responded by flying. The final bioassay, which only allowed a flight response, produced results that were congruent with those conclusions based primarily on a walking response. The four-component blend characterized as being the minimal blend sufficient for a full walking response also evoked levels of flight orientation similar to a six-component blend, the 13-component blend, or the natural odor source, and significantly higher flight response was elicited than by a three-component blend (Figure 9). Thus, orientation by flight or by walking appear to be mediated by similar blends of chemicals, although more subtle differences may exist between flight and walking responses to blends with intermediate levels of activity. In parallel studies of chemically mediated food finding in the congener, *C. lugubris*, results from a long-range walking bioassay in the wind tunnel were confirmed by trapping studies conducted in the field (Lin and Phelan, 1991, and in preparation). In total, these results suggest the long-range walking bioassay to be a good indicator of the blends of chemicals used by these beetles for host-finding in nature.

The results of our bioassays are in some ways congruent with, but also conflict with, the findings of Smilanick et al. (1978), who determined that none of a list of 17 fruit volatiles attracted *C. hemipterus* in significant numbers in

the field when used alone, but that a blend of acetaldehyde, ethyl acetate, and ethanol (1 : 1 : 1) did elicit high trap catch. Although they did not attempt to measure the response to various combinations of the 17 components, they did find that the three-component blend was at least as active as a natural substrate, fig paste. Furthermore, when any of the three compounds was removed from the blend, including ethanol, they measured a significant reduction in beetle response. Similarly, Bartelt et al. (1990) found that combining the three-component blend (1 : 1 : 1) with an aggregation pheromone for *C. hemipterus* increased the response to the pheromone in a synergistic fashion and that the three-component blend performed at least as well as yeast-inoculated banana even in the absence of the pheromone. In contrast, we found that when presented in the ratio found in the odor of yeast-inoculated banana (125 : 5 : 1), a blend of ethanol, acetaldehyde, and ethyl acetate was significantly less active than the natural odor; also we could find no evidence that the addition of ethanol increased behavioral response (Figures 4 and 7). Although we do not know the basis for this disparity, it may be due to differences in chemical release rates or ratios between the components, or due to intraspecific variation in beetle response.

Concerning the role that fungi may play in insect-plant interactions, there is considerable information linking fungi with nitidulid host-associations, as well as with the host preferences of other insects. For example, in dates, *Carpophilus* spp. were found preferentially in those fruits that were infested with fungi (Lindgren and Vincent, 1953). *C. hemipterus* is a transmitting agent of fig smut caused by *Aspergillus niger* (Caldis, 1930) and has been incriminated as a vector of brown rot in stone fruits and pome fruits, as well (Tate and Ogawa, 1975). A role of fungi in food-finding by *C. hemipterus* also was suggested by Miller and Mrak (1953), who found that short-range orientation in a multi-choice arena was greater to fig tissue inoculated with any of three fungi, but interestingly not to that inoculated with a bacterium. Similarly, flight response of this species in a wind tunnel was greater to various food substrates inoculated with *S. cerevisiae* than to aseptic substrates (Blackmer and Phelan, 1991).

The results of the present study confirm a preference in *Carpophilus hemipterus* for fermenting fruit and suggest a mechanism for the increased activity. In addition to the yeast-inoculated banana, both yeast alone and aseptic banana also elicited beetle attraction, although at a level below that of the combination of the two. This is distinct from the onion fly, *Delia antiqua*, for whom rot-causing bacteria elicit a higher response when inoculated in onion, but which elicit no attraction on their own (Dindonis and Miller, 1981). Honda et al. (1988) measured an increased ovipositional response in the yellow peach moth, *Conogethes punctiferalis*, to rice cakes contaminated with fungi, but oviposition was deterred by contamination with bacteria. Analysis of the volatiles from *S.*

cerevisiae on agar and from aseptic banana suggested that the attraction of beetles to these substrates was modulated by the same components as that in inoculated banana, as they produced similar volatiles but generally at lower rates than in the inoculated banana (Table 2). Yeast reared on agar had no volatile constituents that were unique or in a higher concentration than those in either aseptic- or inoculated-banana odor. Although the two banana substrates were more similar in their volatile profiles, of the six constituents with behavioral activity, acetaldehyde and 2-methylpropanol were released from inoculated banana at a rate more than twice as high as that from aseptic banana, 3-methylbutanol was 3.5 times higher, ethyl acetate and 2-pentanone were released at comparable levels, and 3-hydroxy-2-butanone was not detected in aseptic banana. The biggest change in volatile release between aseptic and inoculated banana was with propanol, which was more than 40 times greater in the latter substrate; however, this component appeared to contribute little behavioral activity to synthetic blends (Figures 4 and 7).

Thus, the yeast apparently increased beetle response by increasing the production of behaviorally active constituents rather than through a qualitative change in the odor profile. The constituents deemed to play a role in *Carpophilus hemipterus* host-finding are common volatiles of plants, produced through the catabolic pathways of fatty acid metabolism, which is accelerated during the postclimacteric phase of fruit ripening (Schreier, 1984). Despite the strong association of *C. hemipterus* with fermenting materials, the volatile constituents to which it was responsive in the present study are no more strongly associated with fermentation products than are the other inoculated-banana volatiles that had no behavioral activity (Maarse and Visscher, 1988). The yeast increased the production of these volatiles probably either through the combined effect of its own metabolism with that of the fruit or simply by causing an increase in fruit cell lysis.

As a final point, it is noteworthy that despite considerable interest in the field of insect–plant interactions, there is relatively little information on the chemical mediation of long-range host-finding. A number of studies can be cited that catalog specific compounds that influence insect host-finding behavior (Visser, 1986), but there is a notable paucity of studies in which a synthetic blend of chemicals has been determined to elicit orientation comparable to a natural host when presented at release rates found in the plant. Addressing the ecological pressures that may direct the evolution of host-finding systems, May and Ahmad (1983) and Lance (1983) have suggested that chemically mediated host finding should be much more prominent among specialist insect herbivores and that generalists would be likely to find their food plants by more random processes. However, long-range chemoorientation to hosts now has been documented for more generalists than for specialists, and it is questionable that breadth of host range has been a significant factor in whether insects evolve a

mechanism for locating potential hosts from a distance (Phelan et al., 1991). On the other hand, breadth of host range probably has determined the types of chemicals to which an herbivore does orient from a distance, or possibly the inverse is true; that the range of hosts utilized by an herbivore is determined by the chemical blends to which it is responsive (Jermy, 1988). Host-finding by insect herbivores with broad host ranges could be mediated by a response to ubiquitous plant volatiles or by a response to any of a number of more specific components. Food finding by *C. hemipterus* appears to represent a combination of both, as they respond to compounds commonly released by ripening fruit, but rather than respond to a specific combination of these, *C. hemipterus* and probably many other generalist feeders locate food and ovipositional sites by orientation to a number of different combinations of common volatiles. The conclusions drawn here concerning the relative behavioral roles of each of the 18 volatile constituents identified from yeast-inoculated banana odor for *C. hemipterus* are based on the concentration found in the natural odor profile. Expanding the investigation of chemically modulated host-finding in this species to other plant volatiles and to different ratios of those volatiles would very likely reveal an even broader and more complex response to plant odor blends.

Abstract—The chemical mediation of host-finding was investigated for the dusky sap beetle, *Carpophilus lugubris* Murray. GC-MS analysis of the headspace volatiles above whole-wheat bread dough inoculated with baker's yeast, a substrate previously determined to be an effective attractant, revealed seven major components in the following order of decreasing concentration: ethanol, acetaldehyde, 2-methylpropanol, 3-methylbutanol, propanol, 2-methylbutanol, and ethyl acetate. Solutions of these seven compounds blended so as to mimic the odor of whole-wheat bread dough elicited upwind orientation from 1.8 m in a wind tunnel by *C. lugubris* at a level comparable to that elicited by the bread dough. A series of bioassays investigating the role of individual components from the synthetic blend determined that all seven compounds contributed to behavioral activity; however, the simplest blend evoking attraction comparable to bread dough included acetaldehyde, ethyl acetate, 2-methylpropanol, and 3-methylbutanol. Of these compounds, acetaldehyde was essential, ethyl acetate was interchangeable with ethanol or partially replaceable with propanol, and 2-methylpropanol and 3-methylbutanol were partially replaceable with a combination of the other alcohols. Headspace volatiles above aseptic or fungus-inoculated tomato, banana, sweet corn, and strawberry were also qualitatively and quantitatively analyzed. This study suggests that *C. lugubris* locates its food sources by response to variable blends of common volatile constituents of plants and fungi.

INTRODUCTION

The dusky sap beetle, *Carpophilus lugubris* Murray, occurs throughout the temperate and tropical regions of North, Central and South America (Sanford and Luckmann, 1963), and infests a variety of fruits and vegetables, especially sweet corn (Connell, 1975). *C. lugubris* infestation is increased when corn plants are damaged by other insects, and adults are attracted to fermenting and decaying plant materials (Harrison, 1962). Economically, *C. lugubris* is considered one of the three major insect pests of sweet corn along with the corn ear worm and the European corn borer in some areas (Harrison, 1974). Furthermore, nitidulid beetles are considered the primary vectors of the oak wilt disease (Appel et al., 1986); *C. lugubris* has been demonstrated to be capable of transmitting the disease to healthy oaks (Dorsey et al., 1953) and can be one of the predominant species feeding on tree wounds (Dorsey and Leach, 1956).

Field traps with food baits including bread dough are commonly used to monitor this and other nitidulid beetles (Alm et al., 1985; Bartelt et al., 1990; Peng and Williams, 1991). In a wind-tunnel bioassay, *C. lugubris* exhibited stronger response to whole-wheat bread dough and to fungus-inoculated fruits than to aseptic substrates (Blackmer and Phelan, 1991). To better understand the mechanisms mediating host-finding in this species and to determine the potential for using semiochemicals in its control, the role of food odors attractive to the beetle need to be fully elucidated. In this study, headspace volatiles above whole-wheat bread dough were qualitatively and quantitatively characterized; the relative activity of the identified compounds in *C. lugubris* host-finding was determined; and the odors of aseptic and fungus-inoculated tomato, banana, sweet corn, and strawberry were analyzed to relate the relative attractiveness of these substrates to the presence of specific odor components.

METHODS AND MATERIALS

Insects. A laboratory colony of *C. lugubris* was maintained on an artificial diet (Hall et al., 1978) under the conditions of 24 $\pm$ 1°C, 16:8 hr light–dark and 75–85% relative humidity. After eclosion from the pupae, both sexes were held with moisture in 12-oz. plastic cups, but without contact with food or food odors.

Natural Odors. Thirty-gram samples of whole-wheat bread dough inoculated with baker's yeast or similar samples of fruits were incubated in 240-ml Qorpak straight-sided jars at room temperature for about 24 hr or five to seven days, respectively, before being used for volatile collections or for bioassays. Fresh tomato, banana, sweet corn, and strawberry were maintained aseptically or inoculated using a previously described method (Phelan and Lin, 1991) with either *Saccharomyces cerevisiae* or *Candida krusei*, two yeasts that are ubiq-

uitous in nature (Alexopoulos, 1979). The lid of each jar was installed with a 37-mm Bacterial Air Vent (Gelman Science, Ann Arbor, Michigan) for ventilation, and a sleeve-type rubber septum (Thomas Scientific) for collection of headspace samples.

Headspace Volatile Collection and Identification. Headspace volatiles were trapped on Tenax GC and then thermally desorbed to a capillary gas chromatograph (Phelan and Lin, 1991). Due to the high concentration and volatility of ethanol and acetaldehyde relative to the other odor components, two volatile collection methods were used. In the first method, a 20-ml headspace sample was injected into the volatile trap, which was then flushed with helium (20 ml/min) for 6 min at room temperature before desorption. During this time, most of acetaldehyde and ethanol were removed due to their low breakthrough volume on the trap (Phelan and Lin, 1991). The second method was used to quantify these two components by injection of a 1-ml headspace sample, followed by a helium flow for 0.5 min, which allowed the trap to retain all the volatile constituents for desorption to the capillary column. Jars containing natural samples were opened for 3 min before taking air samples, and those containing synthetic odor sources were sampled at 3 min after they were prepared.

Volatile constituents from natural substrates were quantified and tentatively identified using a Hewlett-Packard 5890A capillary gas chromatograph and a HP 5970C Mass Selective Detector. A capillary column, DB-1 (30 m × 0.32 mm ID, 5.0-μm film thickness), was used with a temperature program of 30–200°C increased at 10°C/min, and a helium flow of 0.7 ml/min. Chemical identifications were confirmed and concentrations were quantified by comparing retention times, mass spectra, and peak areas with those of known quantities of authentic compounds.

Synthetic Odors. Synthetic odors were prepared by applying compounds as mineral-oil solutions to cotton wicks at the concentrations and quantities listed in Table 1. Ethanol was the exception in that it was diluted with double-deionized water due to its insolubility in mineral oil. The synthetic odors were used for bioassay immediately after preparation, and fresh samples were prepared for each replicate. All chemicals were obtained from Aldrich Chemical Co. (Milwaukee, Wisconsin).

Wind-Tunnel Bioassay. The behavioral responses of *C. lugubris* to natural and synthetic odors were assessed in a horizontal wind tunnel (2.5 m long × 1 m wide × 0.5 m high) (Phelan et al., 1991). The conditions of the wind tunnel were 35–65% relative humidity, 24–27°C, 17 lux light at the level of wind-tunnel floor and a wind speed of 0.5 m/sec. Bioassays were conducted at 4–0 hr before scotophase using 6- to 8-day-old adults of mixed sex.

The bioassays were set up with two jars placed on the floor 10 cm apart from the center of the upwind end of the tunnel. One of the two jars was empty to serve as a check for possible odor contamination, and the other contained

[c] Concentrations (v/v) and volumes of mineral-oil solutions, except ethanol, which was diluted with distilled water.

odor samples; the positions of the two jars were rotated between replicates. Beetles were released on the floor at the center of the downwind end of the tunnel at a distance of 180 cm from the odor sources. Smoke tests showed that plumes from the two jars merged before reaching the beetle-release site. Ten beetles were released each time and were used only once. Beetles that oriented to odor sources by walking or flying up the odor plume to within 10 cm downwind of the jar in 8 min were counted as responders, and no beetle response to the empty jar was observed. Although both walking and flying responses were observed during bioassays, the majority of beetles (>95%) responded by walking to odor sources. The 10-cm criterion was set since the top of the jar, and thus the source of odors, was about 9 cm above the floor, and the beetles that walked to within 10 cm of the jar would lose the odor plume. Eight minutes were needed for most beetles to reach odor source, to which they were responding.

A randomized complete-block design was used in all bioassays with the sequence of odors in a block randomized. Data were recorded as percent response of each group of 10 beetles released, and these percentages were subjected to transformation by $\sin^{-1}(X^{1/2})$ before analysis of variances. LSD tests were used for comparing means of percent response to odor treatments where the ANOVA indicated a significant F value (SAS Institute, 1985).

RESULTS

Identification of Headspace Volatiles. A total of seven compounds (acetaldehyde, ethyl acetate, and five alcohols) was identified from the headspace of whole-wheat bread dough (Figure 1A) as listed in Table 1 with their retention times and mass spectra used for their identification. Quantification of this volatile profile showed that ethanol was the most abundant component (402.8 ng/ml) with the others present at 6.1–39.6 ng/ml (Table 1).

The volatile composition of fruit substrates was analyzed focusing on the components present in the bread-dough odor (Table 2). In this analysis only the first volatile collection method was used, so that acetaldehyde and ethanol were not quantified. The concentration of ethyl acetate in banana and tomato odor was not affected by fungus inoculation; however, in sweet corn and strawberry ethyl acetate was increased to about 1.4 times. Propanol was detected only in fungus-inoculated banana and the bread dough, and 2-methylbutanol was not detected in any of the fruit substrates. The increase in 2-methylpropanol production due to fungus inoculation ranged from onefold in *Candida*-inoculated sweet corn to 22-fold in *Candida*-inoculated strawberry. Inoculation also resulted in increased production of 3-methylbutanol, ranging from 1.6 times higher in *Candida*-inoculated banana to 14 times higher in inoculated straw-

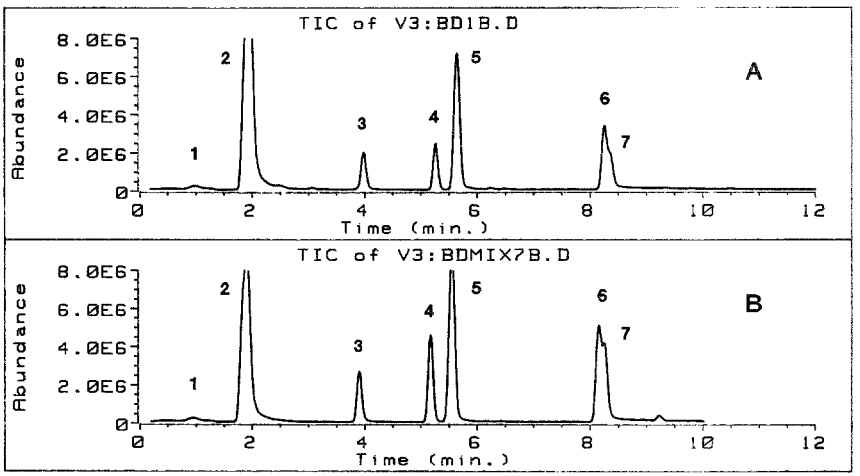

FIG. 1. Headspace volatile profiles from whole-wheat bread dough (A) and from a synthetic blend of constituents formulated to mimic bread-dough odor (B). See Table 1 for identity of peaks and amounts applied in synthetic blend, and see text for explanation of methods for collection and analysis. Note that the collection method intentionally reduced the amount of ethanol and acetaldehyde relative to other components.

berry. The concentrations of non-bread-dough components were reduced by fungus inoculation in banana and tomato and increased in sweet corn.

Beetle Attraction to Bread Dough and Synthetic Odors. The synthetic blend of seven components closely mimicked bread dough both in its odor profile (Figure 1) and in its attractiveness to beetles; the level of *Carpophilus lugubris* attraction to a blend of the seven compounds (97.4 $\pm$ 2.9%, $\bar{X} \pm$ SEM) was not significantly different from that to bread dough (93.8 $\pm$ 9.5%, $\bar{X} \pm$ SEM) (t test, $P < 0.05$). Beetles were never observed responding to an empty jar.

In the first of a series of subtractive and additive bioassays, the removal of either acetaldehyde alone or all five alcohols together resulted in a significant reduction in beetle attraction, while the elimination of ethyl acetate or any one of the five alcohols did not significantly affect beetle response (Figure 2). To determine the relative importance of each alcohol in attracting *C. lugubris*, the alcohols were next added individually to a base blend of acetaldehyde and ethyl acetate. The addition of any alcohol significantly increased beetle response above that of the base blend, with the order of decreasing activity being 2-methylpropanol, 2-methyl and 3-methylbutanol, propanol, and ethanol (Figure 3). Only the addition of 2-methylpropanol increased the beetle response to the level of the seven-component blend.

The next two bioassays focused on the role of ethyl acetate and its relationship with alcohols. The addition of this component to acetaldehyde and 2-methylpropanol significantly improved beetle attraction (Figure 4); however, the elimination of ethyl acetate from the total blend of seven compounds did

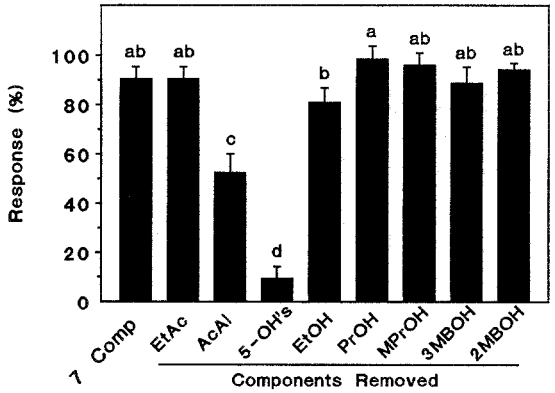

FIG. 2. Percent ($\bar{X} \pm$ SEM) upwind orientation in a wind tunnel by *C. lugubris* to the seven-component blend, to blends with individual components removed, or to a blend with all alcohols removed (5-OH's). Bars marked by the same letter are not significantly different (LSD, $N = 4$ groups of 10 beetles, $P < 0.05$). See Table 1 for explanation of compound abbreviations.

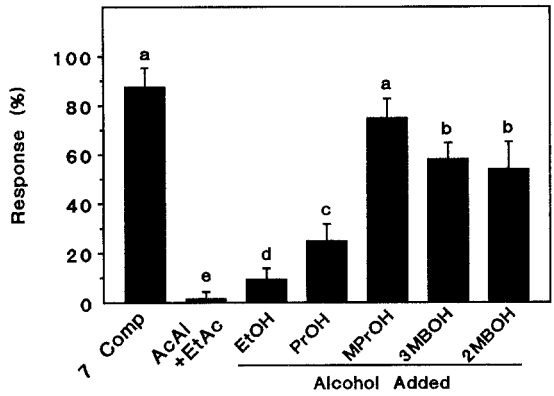

FIG. 3. Percent ($\bar{X} \pm$ SEM) upwind orientation in a wind tunnel by *C. lugubris* to the seven-component blend, a two-component blend of acetaldehyde and ethyl acetate, or three-component blends that added individual alcohols to the two-component blend. Bars marked by the same letter are not significantly different (LSD, $N = 4$ groups of 10 beetles, $P < 0.05$). See Table 1 for explanation of alcohol abbreviations.

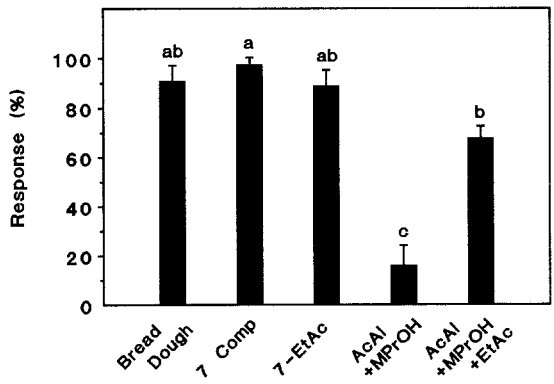

FIG. 4. Percent ($\bar{X} \pm$ SEM) upwind orientation in a wind tunnel by *C. lugubris* to whole-wheat bread dough, the seven-component blend, a six-component blend lacking ethyl acetate, a two-component blend of acetaldehyde and 2-methylpropanol, and the two-component blend with ethyl acetate added. Bars marked by the same letter are not significantly different (LSD, $N = 4$ groups of 10 beetles, $P < 0.05$). See Table 1 for explanation of compound abbreviations.

not affect the beetle response, confirming the result of Figure 2. Response to the seven-component blend again was similar to that to bread dough, as was that to the synthetic blends lacking ethyl acetate or to the combination of acetaldehyde, 2-methylpropanol, and ethyl acetate, although the latter was signifi-

cantly less active than the seven-component blend (Figure 4). The addition of ethyl acetate to a blend of acetaldehyde and 2-methylpropanol again significantly increased beetle response (Figure 5), this time to a level not significantly different from that to the seven-component blend. The addition of either ethanol or propanol to the base blend also significantly increased attraction; however, blends containing ethanol and propanol were less attractive than the seven-component blend. The addition of both 3-methylbutanol and 2-methylbutanol to acetaldehyde and 2-methylpropanol did not significantly enhance response.

In the final bioassay, which used a base blend of acetaldehyde, 2-methylpropanol, and 3-methylbutanol, the interchangeability between ethyl acetate and ethanol that was suggested by the data of Figure 5 was confirmed (Figure 6). A four-component blend containing either of these compounds possessed activity comparable to the seven-component blend and to bread dough. The addition of propanol to the three-component base blend did not significantly increase beetle response, and this combination was significantly less active than either of the other two four-component blends, the total synthetic blend, or bread dough.

DISCUSSION

This study demonstrated that a blend of seven compounds simulating the odor of whole-wheat bread dough could evoke a level of attraction in *Carpophilus lugubris* comparable to the natural odor. At the concentrations found in

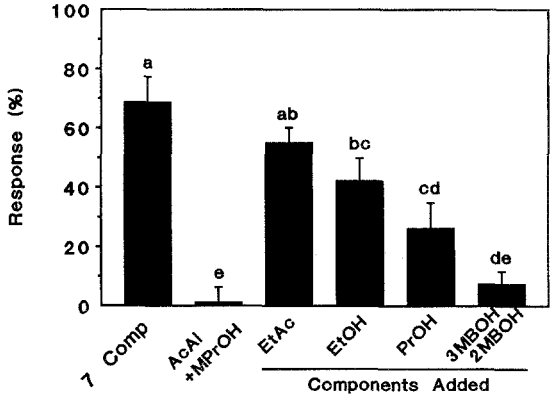

FIG. 5. Percent ($\bar{X} \pm$ SEM) upwind orientation in a wind tunnel by *C. lugubris* to the seven-component blend, a two-component blend of acetaldehyde and 2-methylpropanol, or three-component blends that added individual components to the two-component blend. Bars marked by the same letter are not significantly different (LSD, $N = 4$ groups of 10 beetles, $P < 0.05$). See Table 1 for explanation of compound abbreviations.

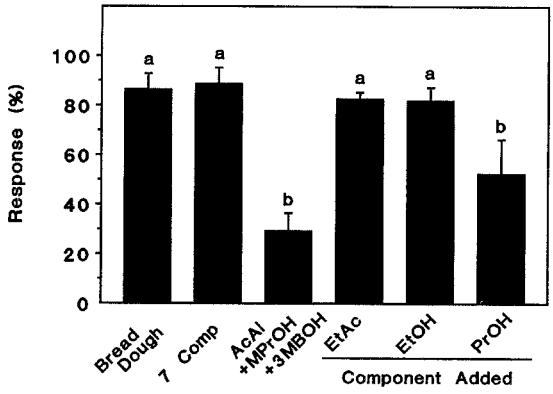

FIG. 6. Percent ($\bar{X} \pm$ SEM) upwind orientation in a wind tunnel by *C. lugubris* to whole-wheat bread dough, the seven-component blend; a three-component blend of acetaldehyde, 2-methylpropanol, and 3-methylbutanol; or four-component blends that added individual components to the three-component blend. Bars marked by the same letter are not significantly different (LSD, $N = 4$ groups of 10 beetles, $P < 0.05$). See Table 1 for explanation of compound abbreviations.

bread-dough odor, all seven components contributed to beetle attraction, but not all were needed for full response. The seven compounds could be clustered into three groups based on their interchangeability with other components in blends eliciting full host-finding response. Acetaldehyde represented the first group and was not replaceable with any other components identified from bread-dough odor; the elimination of this compound from the total synthetic blend resulted in a significant reduction in beetle response (Figure 2). Acetaldehyde also plays a role in the host-finding of another nitidulid beetle, *C. hemipterus* (Smilanick et al., 1978; Phelan and Lin, 1991) and was partially replaceable with other carbonyl components identified from banana odor (Phelan and Lin, 1991). Since acetaldehyde was the only carbonyl compound identified from bread-dough odor in the present study, its relationship to other carbonyl components of food odors attractive to *C. lugubris* is not known. The second group included ethyl acetate, ethanol, and possibly propanol, although to lesser extent. Of these three components, the removal of ethyl acetate from the total synthetic blend did not reduce beetle attraction (Figures 2 and 4), but its addition to a blend of acetaldehyde and 2-methylpropanol or to a blend of acetaldehyde, 2-methylpropanol, and 3-methylbutanol significantly enhanced beetle response (Figures 4–6). The replacement of ethyl acetate with ethanol did not significantly affect beetle response, while replacement with propanol reduced beetle attraction (Figure 5 and 6), although when added to acetaldehyde and 2-methylpropanol, propanol did enhance activity. Ethyl acetate also was determined

to be important to *C. hemipterus* host-finding (Smilanick et al., 1978; Phelan and Lin, 1991), but it was not replaceable by any of the other 17 banana-odor components tested (Phelan and Lin, 1991). The third active constituent group for *C. lugubris* included the five alcohols of bread-dough odor. The most important member of this group was 2-methylpropanol, which was only partially interchangeable with the other alcohols (Figure 3), but fully replaceable by some combination of these alcohols (Figure 2). The alcohols in bread-dough odor, with exception of 2-methylbutanol, also are emitted by fungus-inoculated banana. All of these except ethanol are active in attracting *C. hemipterus* (Phelan and Lin, 1991), although ethanol was shown to be attractive to *C. hemipterus* in combination with acetaldehyde and ethyl acetate at 1 : 1 : 1 ratio (Smilanick et al., 1978). Among the banana-odor alcohols, 2-pentanol plays a separate role from the others in attracting *C. hemipterus* (Phelan and Lin, 1991). Although 2-pentanol was not identified from bread-dough odor and not tested in this study, it is unlikely to play a separate role from the other bread-dough alcohols, since bread dough was more attractive than fungal-inoculated banana to *C. lugubris* (Blackmer and Phelan, 1991). In summary, based on a long-range walking response to the seven major components of bread-dough odor in the wind tunnel, maximum host orientation appears to be elicited by a blend of acetaldehyde, ethyl acetate, 2-methylpropanol, and 3-methylbutanol, of which ethyl acetate is interchangeable with ethanol, and 3-methylbutanol plus 2-methylpropanol are replaceable with some combination of the other alcohols. Field studies, which are necessary to confirm these results in nature, are planned.

Although it appears that plant odors play an important role in insect host-plant finding as a whole, there are few species for which we have characterized a synthetic blend of compounds to mimic the full behavioral activity of a natural attractive odor. Although a list of plant compounds may be cited that are attractive to a number of phytophagous insects (Visser, 1986), the fact that these chemicals have rarely been investigated at release rates comparable to that of a host plant makes interpretation of their ecological and behavioral significance difficult. Simulating the natural odor with the appropriate concentration of authentic components provides a more accurate method for elucidating the relative role of individual odor constituents in host-finding. The systematic investigation of the chemical constituents of food odors attractive to *C. lugubris* in this study and for *C. hemipterus* by Phelan and Lin (1991) has demonstrated considerable overlap in the blends of components responsible for chemically mediated host-finding in these congeners. Both species appear to possess broad host ranges and are attracted to a variety of food odors (Blackmer and Phelan, 1991), and not surprisingly the compounds eliciting attraction in these species are common to a wide variety of plant substrates (Maarse and Visscher, 1988). Nevertheless, differences are evident in the relative responsiveness of these two species to different plant odors, which probably are due more to quantitative

variations in the relative activity of individual components or in the ratio of those components rather than the presence or absence of specific volatiles. For example, it has long been suggested that fungus inoculation of plant substrates increases their attractiveness to many nitidulid species (Wildman, 1933; Neel et al., 1967); however, Blackmer and Phelan (1991) found a much greater level of discrimination between inoculated and aseptic substrates by *C. lugubris* than by *C. hemipterus*. Long-range response of *C. lugubris* measured in a wind tunnel was 3.2 times and 3.9 times higher for substrates inoculated with *Candida krusei* and *S. cerevisiae*, respectively, than for aseptic substrates, while these fungi only increased response in *Carpophilus hemipterus* by 1.3-fold and 1.5-fold, respectively. Whether this differential response has an adaptive basis, e.g., because *C. lugubris* has a more strongly saprophagous feeding habit, is not known.

Nitidulids are certainly not unique in their enhanced attraction due to the action of microorganisms. Similar responses have been documented for a number of phytophagous insects, mites, and nematodes (Dicke, 1988; Blackmer and Phelan, 1991, Phelan and Lin, 1991). Despite the widespread nature of microbially mediated response to plants, one of the questions needing to be addressed is whether increased attraction is due to microbes simply elevating the release of plant-produced volatiles or is due to a qualitative change in the odor blend resulting from the addition of volatile microbial metabolites. In this and our previous studies, increased attraction of both *C. hemipterus* and *C. lugubris* was probably due to a quantitative increase in fruit-derived volatiles rather than to novel compounds generated by fungal metabolism, as evidenced by our GC-MS analysis of inoculated and aseptic substrates. The only component unique to a fungal-inoculated substrate was propanol, which was found in inoculated banana; however, this compound was not associated with any other inoculated substrate. On the other hand, many of the behaviorally active components found in aseptic substrates showed increased production when these substrates were fungal-inoculated. Enhanced production was most dramatic for 2-methylpropanol and 3-methylbutanol in *Candida*-inoculated strawberry, where the absolute concentrations of these components in the headspace were 23 and 14 times higher, respectively, than in the odor of aseptic strawberry. Although the change due to fungal inoculation in the two most prominent odor components, ethanol and acetaldehyde, was not measured in this study, Phelan and Lin (1991) found these compounds were released at levels 1.8 and 2.1 times higher, respectively, in *Saccharomyces*-inoculated banana than in aseptic banana. Whether the role of microbes in enhanced attraction of other phytophagous insects is predominantly quantitative as well is not known. We do not suggest quantitative odor change and qualitative change to be mutually exclusive categories, but rather view these as two ends of a continuum. A model that we would propose concerning the mode of action of microbes in animal–plant interactions would be

that those animals with broad feeding habits might be more likely mediated by quantitative changes in an odor profile, while those animals with stronger microbial associations, especially those with obligatory relations, would be more narrowly responsive to compounds unique to or greatly enhanced by microbial activity. The extent of this proposed relationship between strength of microbial association and the nature of chemical signals eliciting attraction remains to be determined by conducting chemical and behavioral analyses in other systems similar to those now carried out for *Carpophilus hemipterus* and *C. lugubris*.

Book Review

Insect Defenses. Adaptive Mechanisms and Strategies of Prey and Predators. David L. Evans and Justine O. Schmedt. Albany: State University Press, 1990. 482 pp. $73.50 Hb; $20.95 Pb.

The scope of this interesting and stimulating book is broad since it includes not only reviews of various insect defensive strategies, but also, to a lesser extent, predator strategies, as pointed out by its subtitle. This broad scope has obvious merits, but also unavoidable limitations. Indeed, defense and predation must be considered together, although these two sides of the same interaction are too often analyzed more or less independently.

The editors must be congratulated for their attempt to assemble reviews on both aspects. However, defensive and predatory strategies are so diverse that a single volume of a little more than 400 pages cannot give an exhaustive overview of the subject. This is certainly not the aim of the book and was never claimed by the editors. Each chapter should be taken as a state of the art report on one facet of the complex interaction between predator and prey, and as an illustration of the diversity of the whole field.

The book is organized in four sections, each introduced briefly by one of the two editors: Evolution of Major Defensive Ensembles, Predatory Strategies and Tactics, Predation Prevention: Avoidance and Escape Behaviors, Predation Prevention: Chemical and Behavioral Counterattack.

The first part includes three excellent chapters by Edmunds, Guilford, and Sakaluk. Edmunds aptly comments on the evolution of cryptic coloration, considering successively the point of view of the predators and the evolutionary responses of the prey. Guilford gives the most cunning and subtle account of the evolution of aposematism I have ever read. He discusses the concept itself, how it works, and how it could have evolved, taking into account the complexities of predator psychology. He presents alternative hypotheses carefully, and makes clear distinctions between intuitively evident mechanisms and those that are demonstrated by unambiguous experiments. Sakaluk's interesting chapter discusses the increasing risks due to sexual activities, conflicting aspects of sexual and natural selection, and how predation pressure has influenced the evolution of arthropod mating systems.

In the second section, two chapters describe predatory tactics in two specific groups of predators, spiders and birds. Uetz's review of spider predatory behavior is restricted to web-building spiders, with some emphasis on the

0098-0331/91/0600-1287$06.50/0

behavior of *Micrathena gracilis* studied by the author's group in North American deciduous forest. Both selection of prey and avoidance of predators by prey (flies and moths) are considered. Schuler describes the behavior of insectivorous birds in response to prey density and prey profitability, discussing concepts such as optimal foraging, area concentrated search, or search image. In the last chapter of this section, Robinson advocates the idea that the complexity of prey–predator interactions in tropical rain forest, rather than the complexity of social interactions, was at the origin of the evolution of memory and "intelligence."

The third section is devoted to avoidance and escape behavior. Lederhouse describes primary defenses in lepidopteran caterpillars, i.e., defenses operating independently of predator presence. These include predator–prey allopatry, physical barriers (borers, miners, and galls, protective retreats), elimination of evidence of activity, mimesis, aposematism, and Batesian mimicry. Evans emphasises phenology (temporal distribution) as part of defensive strategy, whereas Fullard discusses possible coevolution between bats' echolocation mechanism and moths' tympanic organ structure and function.

The last six chapters in the fourth section are assembled under the subheading of counterattack by prey. Sargent gives a thorough critical analysis of startle as an antipredator mechanism. As in most other chapters throughout the book, a strong emphasis is placed on the few careful experiments demonstrating the mechanism as opposed to simple descriptions made by naturalists. The same attitude, critical and full of nuances, is adopted by Vulinec in her analysis of aggregation or gregariousness as possible defensive counterattack. Whitman, Blum, and Alsop's chapter is probably the best available introduction to the diversity of chemical defense in arthropods, considering not only the chemical diversity of defensive compounds, but also the diversity of modes of storage and release and the structures and behaviors related to these functions. They also discuss the modes of action of the secretions in deterring predators and other possible roles of these secretions. Bowers complements this overview of chemical defense in insects by considering how some herbivores are able to recycle plant natural products for defense. Schmidt details defense by stinging in Hymenoptera. He compares in different taxa the efficiency and the various modes of action of the venoms, and also describes counteradaptations in predators. In the last chapter, Starr gives a stimulating account of the various defensive strategies in primitive social wasps, e.g., primary defenses, including nest structures and locations, and individual and social defenses. An interesting discussion of threat as defensive strategy in wasps is included in this chapter, mainly based on his own research.

There are obvious overlaps among the different parts of the book and even some redundancies. For example, crypsis, aposematism, and various aspects of bird foraging behavior are considered several times. This is, however, a minor

fault, since, depending on the authors, the emphasis is different, thus enlightening theoretical controversies.

As stated above, some aspects of defense and predation are not discussed at all. For example, the selective pressure of important natural enemies, e.g., parasitoids or ants, and possible defensive counteradaptations to them, are not or only incidently considered. The complexity of defense in social insects is only described in primitive wasps. Again, these are shortcomings unavoidable without extending the scope and the volume of the book.

The absence throughout the book of an overall ecological perspective is, striking, however. Are predation risks and defenses different in various habitats? Is it possible to recognize different patterns in the defensive strategies adopted by, say, insect predators or herbivores, by insects living on the ground or on plants, by feeders on herbs in open habitats or on trees in forests? This seems to be more a drawback of the entire field than of the book itself. Very seldom are these questions addressed, and it is perhaps time to try to do so, despite the obvious difficulties in answering them.

However, the book covers a large diversity of topics, giving a fair idea of the main development in the study of insect defenses. The different chapters are uneven in their scope, but on average are good or even first-rate reviews of various aspects of insect defense. Undoubtedly, this book will be of great interest not only for those working on insect defense or predation, but also for those wishing to be informed of the present status of this field.

Book Review

Chemistry and Significance of Condensed Tannins. Richard W. Hemingway and Joseph J. Karchesy. New York: Plenum Press, 1989. 553 pp.

All chemists and ecologists who deal with, or have an interest in, tannins need to be aware of this book. As its title suggests, the focus is on chemistry but the more ecologically minded reader will find much of interest and perhaps inspiration. The coverage is diverse, with some 33 chapters organized into seven sections covering biogenesis, structure, analytical methods, reactions, complexation, biological significance, and the use of condensed tannins as specialty chemicals. The book was developed from the inaugural North American Tannin Conference held in August 1988 and reflects this in its organization. The majority of contributions are authoritative and well-written reviews, while a minority report new data or are short overviews.

The first section covers the biogenesis of tannins, which is timely in counterpoint to recent ecological literature on resource allocation and the general question of what regulates the accumulation of tannins in plants. At the biochemical level, we are ignorant about condensed tannin biosynthesis, to the point that it is still controversial as to whether an enzyme is involved in the condensation step. An understanding of regulatory control clearly lies in the distant future. Hergert's overview and Stafford's exposition of what is known about the enzymology of condensed tannin biosynthesis are valuable accounts of this area.

Hergert also begins the book with an introductory chapter on the development of the North American tanning industry and, with it, chemical studies of condensed tannins. This is a fascinating account and should dispel any lingering ideas among biologists that the tannins are single, uniform, and easily defined chemical entities. The present state of the art on condensed tannin structure is presented in four chapters, of which Hemingway's will be particularly useful as an eye-opening exposition of their chemical diversity. With this diversity exposed, chemical ecologists are now in the position to find out whether it has any ecological significance.

After structure, four chapters cover analytical methods including new NMR and FAB-MS methods. At the "low tech" end of the spectrum, an excellent chapter by Karchesy et al. covers chromatographic techniques from HPLC down to TLC and LC. This chapter should stimulate new research on tannins as these techniques are accessible to a wide range of biological laboratories. The follow-

0098-0331/91/0600-1291$06.50/0

ing section covers the reactions of condensed tannins. Much of the writing is from the perspective of exploiting tannins in commercial applications, but there is still material that will attract readers of this journal, such as the underlying chemistry behind the colorimetric assays used in ecological studies. "Complexation" is distinguished as a separate topic from "reactions," and here three chapters are devoted in turn to the interaction of tannins with carbohydrates, proteins, and synthetic biopolymers. The single chapter on tannin–protein interactions seems slight relative to their significance for biological systems. However, Hagerman provides an account that deserves to be read well.

Seven diverse chapters are devoted to the biological significance of tannins. Schultz provides a compelling account of how advances in plant–herbivore ecology can depend on chemical tools: This should signal ecologists that chemistry is worth learning and also inform chemists about the complexities of ecology and evolutionary biology. An interesting example of structural analyses for tannins in an ecosystem study is provided by Tiarks et al.

For all the sophistication in chemical analysis documented in this book, it is frustrating to see that the carcinogenicity of "tannin" is still being documented with epidemiological studies of bush-tea consumption and that histological studies on the distribution of "tannin" in plant tissues depend largely on nonspecific stains. Readers ought to worry about what the word "tannin" means chemically in these chapters. More explicit lapses from the title theme of condensed tannins are found in the discussion of hydrolyzable tannins in several chapters.

Some readers of this journal may also do a double-take at the final five chapters, which cover such topics as wood glue and other industrial uses of tannins. The one chapter of more than passing interest will be that of Laks, who reviews their use as substrates for the synthesis of novel biocides. In summary, not every page of this book will be relevant to chemical ecologists, but there is much here that is worth exploring.

CHEMICAL ORIENTATION OF LOBSTERS, *Homarus americanus*, IN TURBULENT ODOR PLUMES

PAUL A. MOORE,* NAT SCHOLZ, and JELLE ATEMA

Boston University Marine Program
Marine Biological Laboratory
Woods Hole, Massachusetts 02543

(Received December 13, 1990; accepted February 27, 1991)

Abstract—The lobster, *Homarus americanus*, relies upon its lateral antennules to make initial directional choices in a turbulent odor plume. To determine whether chemical signals provide cues for source direction and distance during orientation, we studied the search patterns of the lobster orienting within a turbulent odor plume. In an odor plume, animals walked significantly more slowly and most often up the middle of the tank; control animals (no odor present) walked rapidly in straight lines, frequently along a wall. Search patterns were not stereotyped either for the population of experimental animals or for individuals. Three different phases of orientation were evident: an initial stage during which the animals increased their walking speeds and decreased their heading angles; an intermediate stage where both the walking speed and headings were constant; and the final stage close to the source, where heading angles increased while walking speed decreased. During this last stage the animals appear to be switching from a distance orientation (mediated by the antennules) to a local food search (mediated by the walking legs) as evidenced by a great increase in leg-raking behavior.

Key Words—Chemotaxis, chemoreception, orientation, lobster, *Homarus americanus*, odor plume.

INTRODUCTION

Animals use many different behavioral mechanisms to orient to a chemical source. Various authors have categorized and labeled these behaviors during

the last century (Loeb, 1891, 1913, 1918, Kühn, 1919; Fraenkel and Gunn, 1961). Categories for different orientation behaviors have been established using a combination of criteria, including behavioral output, type of sensory receptors and sampling, and information available to and used by the animal. This has spawned a debate on the role of a chemical signal in controlling orientation, resulting in a proliferation of new terms (Schöne, 1984; preface for Bell and Cardé, 1984; Bell, 1984; Kennedy, 1986). To avoid ambiguity, we will use two broad categories of orientation: either the chemical signal plays a direct guidance role (e.g., tropotaxis in *Panulirus argus*, Reeder and Ache, 1980; nurse sharks, *Ginglymostoma cirratum*, Hodgson and Matthewson, 1971), or it serves to initiate maneuvers that depend on nonchemical stimuli (internally controlled motor program, i.e., counterturning in *Adoxophyes orana*, Kennedy, 1982; chemically-stimulated rheotaxis in lemon sharks, *Negaprion brevirostris*, Hodgson and Matthewson, 1971).

Turbulent odor plumes have two closely related sensory signals associated with them: odor patches and velocity gradients. We do not want to belabor here the fluid dynamics involved and refer to other literature (Murlis and Jones, 1981; Murlis, 1986; Atema 1985, 1988). Chemoreceptors respond to chemical concentration gradients and patches, while mechanoreceptors monitor velocity gradients. The term chemotaxis refers to the use of purely chemical information to orient to a source; anemotaxis and rheotaxis are terms referring to using velocity gradients in air or water, respectively. Further classifications have been used for animals that sample chemical signals temporally (klinotaxis) and spatially (tropotaxis). Until recently (Moore et al., 1989), it has been difficult to quantify, at the spatial scale of the receptor, the instantaneous odor distributions that exist in turbulent odor plumes. Therefore, the correlation of behavioral responses to patterns of turbulence has not been accomplished, and determining in detail the role of chemical signals in guiding orientation has not been possible for macroscopic animals.

Internal control refers to a motor program that produces the observed orientation path; the program is initiated and can be switched on and off by chemical stimuli (Bell and Tobin, 1982; Havukkala and Kennedy, 1984; Kennedy, 1978). It remains ambiguous whether control over orientation is completely internal or if external nonchemical signals are used (Kennedy, 1986). Counterturning is frequently cited as an example of internal control, and animals orienting by anemo- or rheotaxis may fit this description. For example, animals orienting under internal control may use wind (Kramer, 1986; Preiss and Kramer, 1986) but employ visual cues (David, 1986) as an external frame of reference.

The instantaneous structure of an odor plume, at the size scale of macroscopic animals (>1cm), is intermittent in structure (Moore et al., submitted; Murlis, 1986; Murlis and Jones, 1981; Atema, 1985). This patchy distribution

can result in packets of high odor concentration far away from the source and areas of low odor concentration near the source. Animals using the local odor profile for directional or distance information will need to extract information from the plume either by spatial/temporal sampling and/or by receptor filtering (Moore and Atema, 1988).

Chemical cues play an important role in food searching and manipulation for the lobster, *Homarus americanus*, but the sensory information that provides directional cues for orientation to the odor source is not known. Previous studies have shown that antennular chemoreception is necessary for initial directional cues and search efficiency within a turbulent odor plume (Devine and Atema, 1982), that chemosensory input from the walking legs is needed to locate and to recognize food, and that chemosensory input from the maxillipeds is needed to feed (Derby and Atema, 1982). The purpose of this study was to investigate the role of the two classes of orientation (internal vs. external chemical control) in a lobster's search for an odor source and to determine how that search pattern may reflect responses to the patchy distributions of odor signals typical of turbulent odor plumes.

METHODS AND MATERIALS

Lobsters ranging from 8.5 to 11.2 cm carapace length were caught from waters around Woods Hole and maintained in ambient running seawater tanks for at least two weeks before testing. Each lobster was fed twice weekly a mussel and squid diet, and deprived of food for 3–10 days prior to each trial.

Orientation Arena. All tests were performed in a flow-through flume (250 $\times$ 90 $\times$ 20 cm, Figure 1). Water depth varied from 19 cm at the front to 21 cm at the rear due to an intentional downward tilt of the flume. Unfiltered seawater entered through 15 holes at the head of the tank. Sheets of fluorescent light grating (egg crates, 16.9 mm^2 holes) wrapped with plastic screens (1 mm^2 holes) served as collimators (four upstream, one downstream). The carrier flow rate was 1.8 $\pm$ 0.1 liters/sec. Average flow velocity in the tank was 1.0 $\pm$ 0.1 cm/sec; velocities in the center were somewhat greater. The stimulus was gravity fed through a 1-mm Pasteur pipet at a rate of 50 $\pm$ 5 ml/min. The nozzle of the pipet was placed in the cross-sectional center of the tank 9 cm off the bottom, roughly at the antennular sampling plane of a 0.5-kg lobster. As a frame of reference for digitizing, the source was set at $x, y, z = 0$. Water temperature varied between 20 and 24°C. Illumination was provided by three 150-W floodlights mounted 1.2 m above the water surface. Light level was controlled with a dimmer switch to provide just enough illumination for low-light video taping. A camera (Panasonic WV 1850) equipped with a wide-angle lens was mounted on a track system 1.5 m above the water surface. This allowed

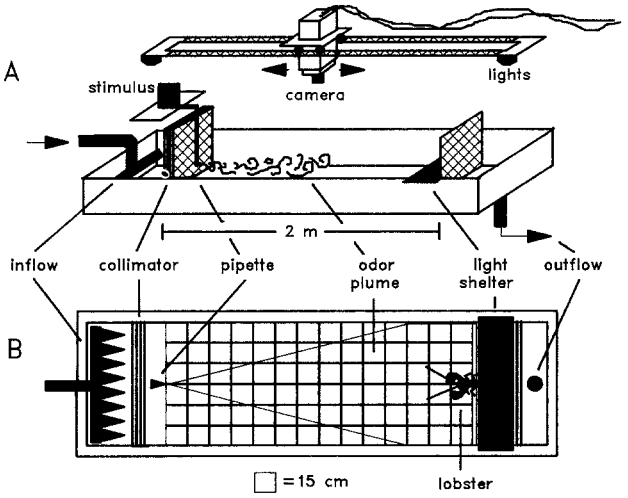

FIG. 1. Diagram of the behavioral arena. (A) Perspective drawing, showing flow (from left to right) in the flume, stimulus introduction (pipet), and position of camera and lights. Raw seawater flowed in through 15 holes in a T-section of PVC pipe and out through a single drain downstream. Both ends of the tank had flow collimators (downstream end not labeled). (B) Top view, showing scale of the lobster relative to tank and pipet (plume source). Grids (15 cm) were drawn on the bottom of the flume to serve as a reference for digitizing.

the camera to move with the animal, minimizing parallax problems that might have interfered with digitizing the responses. A large board was placed over the far end of the tank to provide a darkened shelter area for the lobsters.

The stimulus was an extract of homogenized and centrifuged mussel (*Mytilus edulis*) at a concentration of 5 g/liter wet weight in raw seawater (see Borroni et al., 1986, for further details). One batch was frozen to serve the entire experiment. For each test aliquots of 10 ml of mussel juice were diluted in 90 ml of seawater for a final concentration of 0.5 g/liter. Control tests were done under identical conditions, with raw seawater substituted for the mussel extract.

This stimulus and flow system was identical to the system used in the characterization of the three-dimensional structure of an odor plume (Moore et al., submitted). Electrochemical and dye tests showed that the stimulus released from the pipet reached the far end of the arena within 2 min.

Testing Methods. All orientation responses were recorded in a darkened room between 0900 and 1700 hr. Preliminary trials showed that low-level lighting did not prevent lobsters from leaving the shelter to search for food. Animals were placed within the tank and allowed to settle anywhere beneath the light

shelter (Figure 1). If the lobster did not settle within 30 min, it was removed and replaced with another lobster.

Once the lobster was settled, stimulus was introduced into the arena. A trial was stopped if the lobster did not move from the shelter within 10 min after the stimulus was introduced. A trial was considered successful only if the lobster approached within 20 cm of the pipet tip within 20 min after the start of stimulus introduction, and if it did not run into the up-current or side walls. Since we were interested in directional information extracted from odor plumes without additional cues provided by other physical features, such as solid walls, we excluded animals that found the source by walking along the arena walls. These quantitative criteria were reinforced by qualitative observations of changes in lobster behavior, e.g., raising themselves up, increased flicking of lateral antennules, or sweeping with legs. While orienting, most lobsters walked up the middle of the flume. Control animals were tested without chemical stimulus present. For appropriate comparison of orientation parameters, tracks were chosen specifically for those animals that walked up the middle of the flume without touching the walls and whose tracks passed through the area of the source.

Data Analysis. Orientation paths were digitized at 1/sec with the tip of the rostrum serving as the single reference point. The x and y values were determined from the 15 × 15-cm grids drawn on the bottom of the tank. Since lobsters can walk sideways and backwards without changing overall body orientation, a single reference point allowed us to follow the walking path of the animal without regard to body orientation.

Parameters chosen to quantify movement patterns included walking speed, turn angles, and headings (e.g., Akers, 1989; Kleerekoper, 1967; Kleerekoper et al., 1969). Walking speed was based on distance travelled (cm) per unit time (sec). Turn angle was defined as the angle between the path connecting the previous ($t = -1$) position to the present ($t = 0$) position and the path connecting the present and the next ($t = +1$) position (Figure 2). Right-hand turn angles were defined as positive. A lobster's heading was defined as the angle between a straight line towards the source and the direction from the present position to the next position on the track. Absolute turn angles and headings were defined as their absolute (positive) values.

Leg Raking Experiments. To test for the importance of walking legs in locating an odor source, we used the same flume with the same flow and odor source conditions. Lobsters were released at the downstream area of the flume and allowed to acclimate for 15 min, after which the odor was turned on. Every 5 sec the animal's location and the number of "rakes" over the preceding 5-sec interval were recorded. Raking is the lateral swinging movement of the first two pairs of walking legs described in Atema and Cobb (1980). Each trial lasted 3 min. Four animals were tested five times each with three different odor

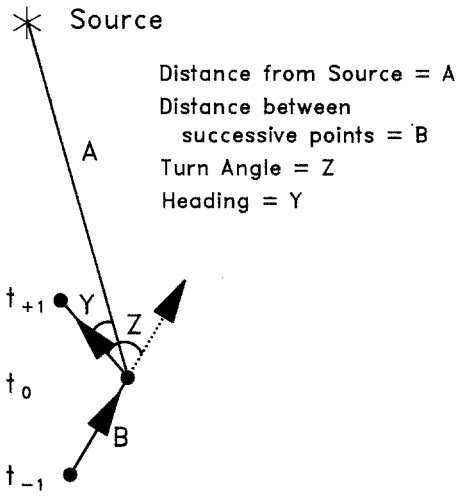

FIG. 2. Three successive positions ($t = -1$, 0, and $+1$; solid circles) on a hypothetical orientation path used to define behavioral parameters. The dotted line represents the lobster's projected path (if it had continued in a straight line), from which a turn angle value (z) at point $t = 0$ is calculated. A indicates distance to the source (asterisk), from which a heading value (y) is calculated at point $t = 0$. Walking speed at $t = 0$ is B cm/sec, since time between successive digitizing points on the path was set at 1 sec.

source concentrations—1, 2.5, 7.5 $\times$ 10^{-1}—of mussel extract prepared as the supernatant of 200 g/liter wet weight mussel flesh in artificial seawater.

RESULTS

Our criteria for orientation resulted in rejection of a large number of trials (140 of 166 trials or 84.3%; 62 different animals). Most of the rejections (122 of 140) resulted from the lack of any movement of the animals. Of the 18 animals that moved in the presence of stimulus but were rejected by our criteria, 15 walked slowly partway up the arena (a behavior characteristic of orienting animals, see below) but did not come within 20 cm of the source and returned to the shelter, and three hit one of the walls. The 26 successful trials were from 16 different animals. Repeated-measures ANOVA showed no difference between animals for walking speed, heading, and turn angles, so we group the trials for individual animals together for further analysis.

Detection of the odor caused the animal to switch into a different state. This is shown by a significantly lower walking speed in the experimental animals compared with controls (t test $P < 0.001$). Experimental animals walked at 5.94 $\pm$ 0.09 (SEM) cm/sec and control animals at 10.81 $\pm$ 0.35 cm/sec.

Other behaviors, such as increased antennular flicking and leg sweeping rates and animals raising themselves high up on their legs, also exemplified search behavior but were not quantified for this study. While orienting, experimental animals would frequently stop and walk backwards and sideways (Figure 3, left column). In contrast, control animals frequently would walk rapidly in a straight line without stopping until the up-current wall was approached or hit (Figure 3, right column). This also is seen in significantly lower heading and turn values for the control animals (Table 1). For experimental animals, the frequency distributions of heading and turn angle values were unimodal with normal distributions centered around 0–10 degrees and 10–20 degrees, respectively (Figure 4).

A search pattern characteristic for the population or for any one individual does not seem to be present. This can be seen qualitatively in the variation in orientation patterns both within the population (Figure 3, left column) and within individuals (Figure 5). Pattern variability also is reflected in large standard deviations for the orientation parameters. Experimental animals had significantly higher variability than control animals in all four orientation parameters quantified (Table 1). This large variability argues against a single characteristic search pattern that would result in low standard deviations around mean values. Furthermore, variability within single individuals suggests that individuals also do not have a characteristic search pattern. Since turbulent plumes tend to be quite different even under similar starting conditions, it is not unreasonable to think that observed differences are the result of different odor distributions.

To examine how orientation parameters changed with distance to the source, we calculated the mean and SEM for heading, turn angle, and walking speed within 5 cm bins (e.g., 0–5 cm, 5–10 cm, etc). These distances are the linear distance between the animal and the source (A in Figure 2). A second-order polynomial regression was fit to these values, with r values for heading and walking speed of 0.84 and 0.86, respectively. Animals appear to be orienting to the source in three different phases. These phases occur in all three parameters at the same distances from the source. Between 240 cm and 110 cm from the source, the walking speed gradually increased from 2.3 cm/sec to 7.8 cm/sec (Figure 6). At this point, the walking speed stayed fairly constant at 7 cm/sec until 40 cm from the source. From 40 to 5 cm, the walking speed decreased from 7 cm/sec to 4.7 cm/sec. A mirror image of these values is seen in the heading values (Figure 6). Between 240 and 110 cm, the headings gradually decrease from 98.8° to 20°. There was a constant heading of about 20° in the intermediate distances, and at 40 cm the headings began to increase again to 37° at 5 cm. Turn angle values followed the patterns of heading values, and this occurred at the same distances; however, the turn angle regression is not significant.

Mean raking rates for all animals and source concentrations increased dra-

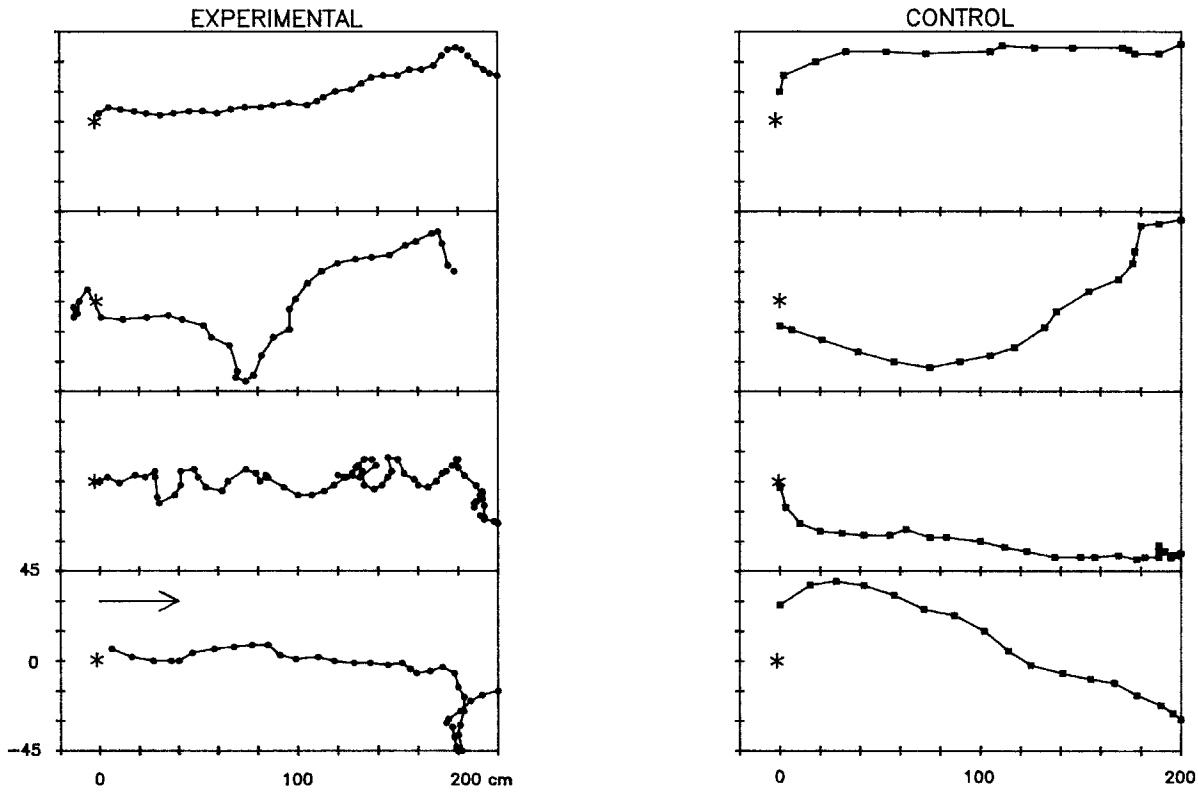

FIG. 3. Eight representative tracks (demonstrating variety) as lobsters move to the plume's source (asterisk). Left column, experimental animals; right column, control animals. (For control animals: plotting of tracks was stopped at level of the source.) Direction of flow is from left to right (arrow). Lines are derived from pathways digitized at 1/sec. The *x*-axis ticks indicate 20-cm intervals; *y*-axis ticks are 15 cm.

matically as distance to the source decreased; from 3.4/5-sec interval in the area nearest the source (r = 7 cm, radial distance) to 2.6 per interval in the next area (r = 7–15 cm) to 1.15 (r = 15–22 cm) and to 0.1 in the area beyond 22 cm from the source. More than three quarters of all rakes observed (79%) were in the three closest areas, i.e., less than 22 cm from the source. This total near-source area is only about 3% of the total tank bottom surface.

DISCUSSION

The results of this study indicate that lobsters use chemical signals to locate a food source. Other orientation mechanisms using the chemical stimuli only to turn on an internal motor program or to start a rheotactic orientation appear less important for the lobster.

An example of an internal motor program is seen in the counterturning of some moth species (e.g., Baker et al., 1984). These moths initiate left–right turns around 180–200° with a relatively high degree of accuracy and consistency. This type of orientation mechanism would produce a bimodal distribution of turn angles, with each mode centered on the positive and negative values of the repeated turn angle or heading. The lobsters used in this study did not show this type of orientation behavior. The turn angles and headings were both unimodal distributions centered around 15° and 5°, respectively (Figure 4). The coefficient of variance was greater than 100% for all parameters, indicating a

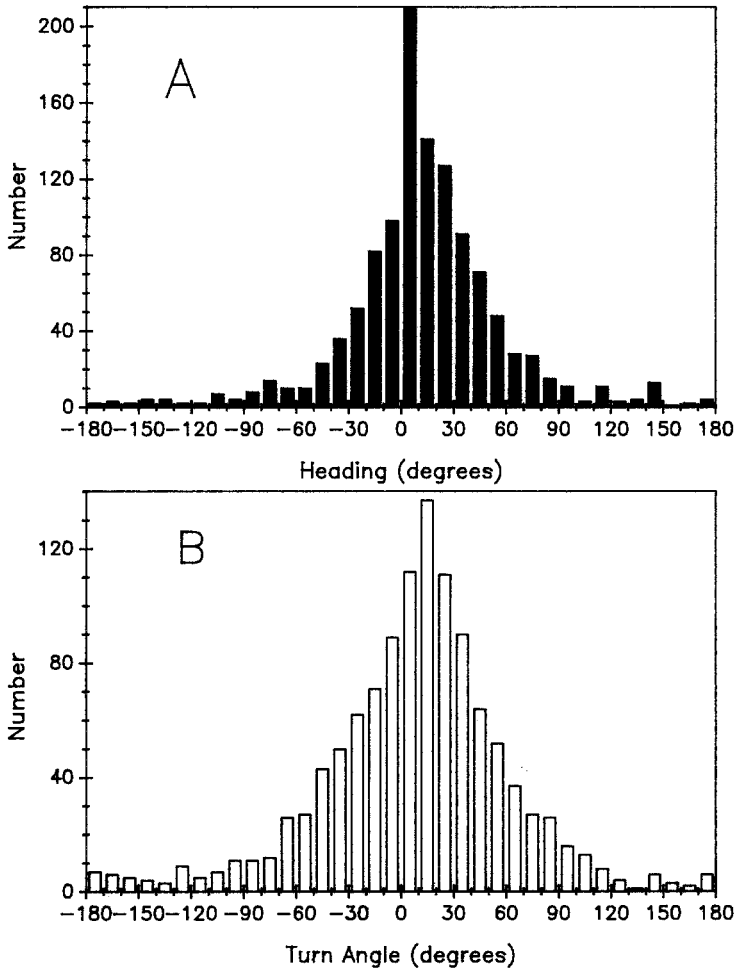

FIG. 4. Frequency distributions for 26 experimental runs (based on 1173 data points) for (A) heading and (B) turn angles. Bin width equals 10 degrees.

large degree of variability among the population. This indicates that for the experimental population there was not an "internally set" motor program that guides the orientation search pattern.

Another possible orientation mechanism is rheotaxis (or, in air, anemotaxis) where mean current direction guides the search path. Animals orienting rheotactically move directly up the mean water current. This mean is not the grand mean for the day but the local mean the animal can determine from inte-

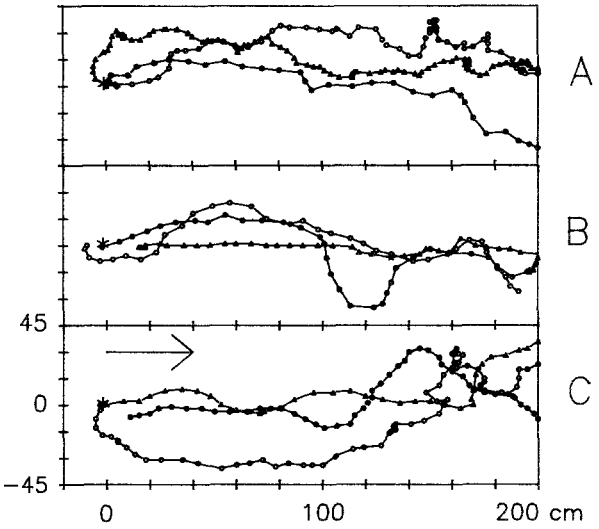

FIG. 5. Variability in orientation paths for three individual lobsters. Three repeated trials by three different lobster (A, B, and C) are shown. Direction of flow is from left to right in each figure. Vertical and horizontal distances are plotted in cm. Source at* (0,0 cm).

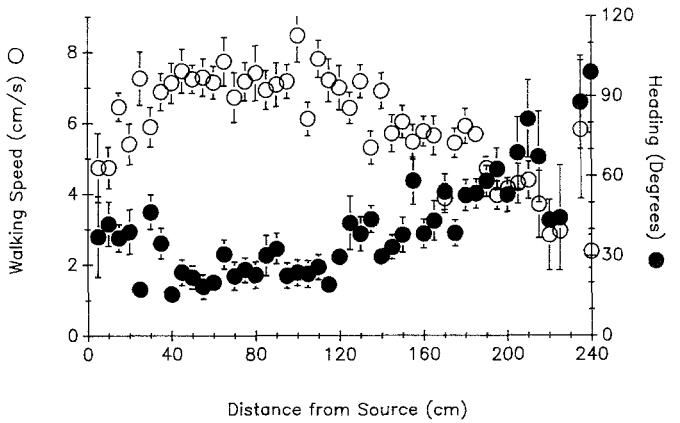

FIG. 6. Changes in behavioral parameters: walking speed (open circles) and heading (closed circles) along the track to the source. Distance from the source is distance between animal and source not distance along the x axis. Circles are mean values ($\pm$SEM) over 5 cm distances (N = 26 trials, 1173 data points).

gration over an unknown length of time. The animal will then stop and, depending upon the presence or absence of odor, will either move cross-current, further up-current, or turn around and move down-current. Evidence from tsetse flies in the field (Bursell, 1984) and nurse sharks in a laboratory setting (Hodgson and Matthewson, 1971) demonstrate this strategy. If the lobsters oriented rheotactically in our unidirectional flow tank, their straight up-current path would have resulted in an increase in heading values with decreasing distance from the source approaching 90° as it reaches the up-current wall (Figure 7). At the downstream end of the tank, heading values would have been small when facing directly into the current. If a lobster happened to start directly in front of the stimulus pipet, the heading values would have started and stayed around 0°. In no instance would a lobster approaching the source rheotactically have shown a decrease in heading values. However, since observed headings did decrease when the lobster approached the source (Figure 7), it is unlikely that the lobsters are using a rheotactic orientation in our system.

In a tropotactic behavior, the stimulus pattern arriving at (bilateral) receptors plays a direct role in steering the motor output of the orienting animal (Fraenkel and Gunn, 1961). Under this mechanism, the local stimulus profile is sampled spatially and/or temporally, and subsequent changes in the orientation path are made in response to the changes in certain features of the signal. Examples of this exist in the chemoreception literature (see Payne et al., 1986; Bell and Cardé, 1984, for reviews). The observed changes in heading values and walking speeds with distance together with the need for bilateral compari-

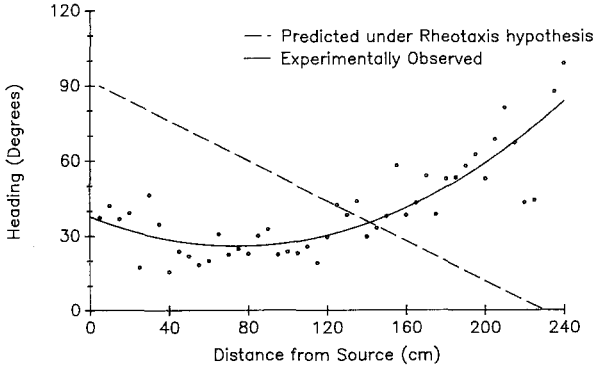

FIG. 7. Changes in heading values with decreasing distance from source. Data points are mean values from Figure 6. Experimental headings (solid line) vs. those predicted for a chemically mediated rheotactic response (dashed line). The solid line is a second-order polynomial regression fit to the observed headings from this study (least squares method; $r = 0.86$, $P < 0.01$ for $N = 26$ experimental runs). Distance from source as in Figure 6.

son (results from Devine and Atema, 1982) are most consistent with a chemotropotactic behavior for the lobster under the conditions tested. Ultimately, the changes in heading and walking speed with distance (and thus odor) may suggest a combination of taxis and kinesis. Further manipulations with both the water current and odor dispersal are needed to firmly establish the degree to which different sensory cues control orientation of the lobster.

The present results indicate that chemotactic orientation occurred in three different phases. Initially (far away from the source), the odor cue switches the lobster into a different state: sampling the local area an initial source direction is determined. At this stage, heading values are large while walking velocity is low. During this initial phase, lobsters accelerate and begin to walk more directly toward the source as seen in a decrease in heading values (Figure 6, 240–110 cm). At an intermediate range, it appears that the lobster has "locked on" to the source direction. A walking velocity of 7.5 cm/sec (triple that of the initial rate) is maintained, as well as a rather precise heading towards the source of approximately 20°. The final approach phase takes place relatively close to the source (40 cm or less) and seems to indicate a local food searching behavior. During this last stage, the animal slows down considerably (from 7.5 to 5 cm/sec) while increasing heading values 20° to 45°. We suggest that this may indicate a switch from a distance orientation, controlled by lateral (and possibly medial) antennular input, to a local food searching behavior, controlled by walking leg chemoreceptors.

Although in both *H. americanus* and *P. argus* the lateral antennules play a primary role in distance olfaction and orientation (Devine and Atema, 1982; Reeder and Ache, 1980), it is the walking legs of *H. americanus* that are used primarily for local food searching and recognition (Derby and Atema, 1982). The walking legs also play a secondary role in search path control (Devine and Atema, 1982). The leg behavior data obtained under these conditions of flow and odor distribution show that legs become increasingly involved in responses to odor plumes at distances less than 22 cm from the odor source. This distance corresponds to the area in which search paths begin to meander again close to the source. It may be at these distances the odor concentration reaches a threshold at which legs begin to take over from antennules in guiding the lobster to its food odor source.

The observed orientation pattern and the hypothetical switch from antennular to leg chemoreception may be controlled by information about the distance between the odor source and the lobster that is contained within the spatial patterns of the odor plume. This information does not necessarily have to be associated with average odor intensity; other parameters characteristic of turbulent odor plumes contain spatial information that may be useful for orientation (Moore and Atema, 1988; Murlis, 1986).

Although our experimental flow was purely unidirectional, the turbulent

odor signals generated within the arena (Moore et al., submitted) are similar to those signals that have been measured in natural environments (Atema et al., submitted; Murlis and Jones, 1981). Therefore, we suggest that similar orientation mechanisms could take place in the lobster's natural environment.

Acknowledgments—Special thanks to Lynn Lacomis for her assistance in data collecting; to Don Tremel, Kirsten Poling, and Pam Sexton for use of their data on leg clasping behavior resulting from their course projects during the Woods Hole Marine Semester 1989; and to Drs. Ring Cardé and Fred Wasserman for critically reviewing the manuscript as a chapter in P.M.'s PhD thesis at the Boston University Marine Program (BUMP). This research was supported by a grant from NSF (BNS 90-12952) to J.A. and a BUMP alumni award to P.M.

Abstract—When experienced by contact with feces from hosts feeding on cowpeas, laboratory-reared females of *Microplitis croceipes*, a larval parasitoid of *Heliothis* spp., orient and fly to odors of the same feces, whereas naive laboratory-reared females do not. Flight-tunnel studies revealed that associative learning occurs during female encounters with hosts and host products. When females antennate host feces, they learn to recognize the volatile odors associated with the feces. Females even can be conditioned to respond to novel and otherwise unattractive odors such as vanilla extract by exposure to these volatile substances in association with a water extract of the feces. They apparently link the volatile odors with a nonvolatile host-specific recognition chemical found in the feces. The antennating stimulant, 13-methylhentriacontane, was found to be a valuable ingredient, apparently as a facilitator of the initial antennation and subsequent linkage of the volatiles to the nonvolatile host recognition cue.

Key Words—*Microplitis croceipes*, Hymenoptera, Braconidae, parasitoid, host-finding, behavior, feces odors, attraction, 13-methylhentriacontane, associative learning.

INTRODUCTION

The survival of an insect parasitoid species is dependent upon the ability of the ovipositing females to locate host insects for attack. The host insects are often highly mobile and sporadically distributed among massive amounts of plant foliage or other habitat material. Furthermore, the host insects employ various evasive techniques to minimize exposure, such as feeding in concealed crevices, feeding in bursts and then moving, leaving sites, and falling from the plant when the parasitoid approaches. The hosts may be found in a variety of habitats including different parts or growth stages of a plant as well as different plant species. Consequently, parasitoids can be expected to employ a sophisticated repertoire of search tactics that includes an acute perception of physical and chemical cues that increase their host-location prospects. Moreover, they need the ability to make effective strategy adjustments for varying situations. Vet and Janse (1984) clearly demonstrated the ability of the two parasitoids of Drosophilidae, *Asobara tabida* (Nees) and *A. rufescens* (Foerster), to vary their preference for different habitats through associative learning of the different habitat odors after oviposition experience. Turlings et al. (1990) and Ding et al. (1989) demonstrated how parasitoids exploit plant odors to locate herbivorous hosts. Wardle and Borden (1986) showed that a parasitoid's prior experience on an artificial system may diminish its tendency to respond to the habitat of a natural host. Vinson (1984) and Van Alphen and Vet (1986) reviewed numerous other studies that present evidence of learning in parasitoids. Yet, relatively little is known about the mechanisms and role of learning in parasitoid foraging.

A number of studies have demonstrated the importance of chemical cues in the host-searching behavior of *Microplitis croceipes* (Cresson), a parasitoid specific to the larvae of the genus, *Heliothis*. Lewis and Jones (1971) demonstrated that *Heliothis zea* (Boddie) feces elicited intense host-seeking antennation, and Jones et al. (1971) identified 13-methylhentriacontane as the compound eliciting the antennation response. Gross et al. (1975) demonstrated that exposure of *M. croceipes* at time of release to *H. zea* larval frass reduced their dispersal and prolonged their retention in the area of release. Drost et al. (1986) demonstrated that *M. croceipes* females reared from hosts fed artificial diet rarely flew upwind to odors of hosts feeding on cowpea seedlings unless they were provided a previous "experience" consisting of contact with host feces. Herard et al. (1988a) demonstrated similar results with females of *M. demolitor* Wilkinson. Drost et al. (1988), while working with *M. croceipes*, and Herard et al. (1988b), while working with *M. demolitor*, found that inexperienced parasitoids reared from hosts fed cowpeas responded significantly more often to *H. zea* larvae feeding on cowpeas than those from artificial-diet-reared hosts. Herard et al. (1988b) further demonstrated that *M. demolitor* reared from hosts fed cowpeas obtain an important experience from the cocoons before or at the

time of eclosion that improves their flight response, while parasitoids reared from hosts fed on artificial diet lack such experience at eclosion, apparently due to a lack of the proper chemicals on the cocoons. Drost et al. (1988) showed that the flight-tunnel responses of *M. croceipes* females varied significantly based on interactions of the parasitoid's age and experience with the species, growth phase, and part of the host plant provided as an odor source.

Studies by Eller et al. (1988) showed that feces from the *H. zea* larvae are an effective source of attractants for *M. croceipes* females. Studies by Drost et al. (1986, 1988) showed that *M. croceipes* which had experienced only the feces from *H. zea* larvae responded as well in the wind tunnel as those that had a more complete experience that included contact with the feces and stinging a host larva. Thus, *H. zea* feces are a primary source of factors for conditioning the parasitoids for flight tunnel responses.

In a previous paper, Lewis and Tumlinson (1988) reported the discovery that during encounters with host feces, *M. croceipes* females associatively learn and subsequently fly to volatile odors linked with hosts without need of actual host contact. Here we present more detailed and further studies of this associative learning process.

METHODS AND MATERIALS

Parasitoid Rearing. The parasitoids used in this study were reared on *H. zea* larvae according to the procedure of Lewis and Burton (1970) and held in 30 × 30 × 20-cm cages at 26°C, 70% relative humidity, and a 14 : 10 hr light–dark photoperiod until ready for bioassay.

Bioassay Procedure. The wind tunnel was described by Drost et al. (1986). All flight responses were tested at 26–28°C, windspeed of 56 cm/sec, and light intensity of 2500 *lux* . The material to be tested as an attractant source was pipetted onto a triangular (9.5 × 6.5 cm) piece of Whatman No. 1 filter paper suspended from the tip of a disposable pipet placed in an inverted vertical position at the center of the upwind end of the chamber. The females were released from a 4-dram shell vial 80 cm downwind and directly in line with the odorant source. The females were allowed to walk to the rim of the vial and their behaviors were observed and recorded. Females either dispersed, i.e., flew to the sides, top, or bottom of the wind tunnel or responded with anemotactic flight. A positive response consisted of a complete flight and landing on the target source.

Feces and feces extracts were tested both as attractive sources in the wind tunnel and as preflight conditioners. Unless otherwise stated, the material tested as an attractant source consisted of 2.8 mg of raw feces or extract of 1.4 mg of feces. (Preliminary data showed that larger quantities of raw frass are required

as an attractant source, perhaps due to a slower emission rate.) The extract was pipetted in a 14-μl aliquot of solvent onto the triangular piece of filter paper, described above, from which it was emitted.

The materials tested as preflight conditioners were placed on a sheet of Whatman No. 40 filter paper positioned in a Petri dish, and the females were allowed to walk directly from a shell vial onto the material. Unless otherwise stated, the females were allowed to antennate the material for 45 sec; also unless stated otherwise, the amount of material with which females were given preflight experience was ca. 2 mg of feces or the extract of 1.4 mg of feces. The extract was dispensed onto the filter paper in 28 μl of solvent.

Feces Collection. H. zea and *Trichoplusia ni* were reared on artificial diet (Guy et al., 1985) at the Insect Attractants, Behavior and Basic Biology Laboratory, Gainesville, Florida. Larvae were removed from their diet cups when they were 3–4 days old and placed in individual compartments (2.8 × 4.1 × 1.6 cm) in polystyrene trays. They were held at 27°C and 70% relative humidity on a 15-hr light–9-hr dark cycle throughout the period they were used to produce feces. Leaves from 7- to 14-day-old pink-eye, purple hull cowpea [*Vigna unguiculata* (L.)] seedlings grown in a greenhouse were placed in the compartments, and the larvae were allowed to feed for 24 hr to clean their guts of artificial diet. Then, at about 5–6 days of age, the larvae were transferred to clean containers and furnished fresh cowpea leaves. Feces were collected daily from these containers, taking care not to acquire bits of leaves and other debris, and stored in glass vials with Teflon-lined screw caps at −60°C until it was extracted. Feces were collected from larvae until they were about 10 days old. The quantity of feces produced ranged from 2.2 mg/day/5-day-old larva to about 17 mg/day/10-day-old larva. The feces were weighed immediately after collection while still moist. At no time during collection or extraction were feces allowed to dry.

To collect feces of *H. zea* larvae fed on artificial diet, larvae were held in the individual containers of diet in which they had hatched. Feces were removed daily with a small spatula, taking care to avoid collecting diet, and stored as described previously.

Larvae of *Trichoplusia ni* (Hübner) were collected when 5–6 days old, placed in a large Plexiglas cage and fed cowpea leaves for two days to clear their guts of artificial diet. Then feces were collected daily for two days and stored as previously described.

Extraction of Feces. Feces were extracted sequentially either with hexane and then with water (both HPLC grade, J.T. Baker), or in the opposite order. The procedure is illustrated in the following example. Feces (1.35 g) collected over a period of five days from ca. 80 larvae were combined and extracted with 8 ml of hexane by vigorously mixing for ca. 1 min in a glass vial and then letting the mixture stand for about 30 min. Then the hexane was removed by

vacuum filtration through Whatman No. 1 filter paper and the feces residue was scraped from the paper, mixed with a second aliquot of about 5 ml of hexane and, after 30 min, filtered again. The procedure was repeated a third time, and the residual feces on the filter paper were rinsed with sufficient hexane to give a final filtrate volume of 13.5 ml and thus a concentration of 0.1 mg equivalents of feces per microliter. Considerable hexane was lost during the extraction, apparently to evaporation during vacuum filtration, and thus the final volume of 13.5 ml was less than the amount of hexane used for the extraction (18.0 ml). The extract was colored a deep straw yellow. It was stored in a glass vial with a Teflon-lined screw cap at −60°C until used. The feces residue was scraped from the filter paper, mixed vigorously with 15 ml of hexane, and allowed to soak for 24 hr. The hexane then was removed by filtration and stored separately from the previous extract.

After hexane extraction the feces residue was scraped from the filter paper, mixed with about 9 ml of water in a glass vial, and allowed to soak for 30 min. The same procedure was used for the water extractions as for the hexane. However, more water was required for extraction because the feces seemed to swell slightly in water. Also, water was not lost to evaporation. Therefore, the residue was finally rinsed with sufficient water to give a final filtrate volume of 27 ml or 0.05 mg equivalents of feces per microliter.

The second batch of feces was extracted in exactly the same manner except that it was extracted first with water and then with hexane. After extraction with water, it was allowed to soak for 24 hr in 15 ml of water; the water was removed by filtration before it was extracted with hexane.

Although they had been filtered, the water extracts prepared by either of the above procedures still contained suspensions of fine particulate matter. These extracts were designated as H_2O—F and maintained separately according to whether they were extracted before or after hexane extraction. For some experiments the H_2O—F extracts were filtered again by forcing 3–4 ml through a 0.22-μm Millex-Gv filter unit (Millipore Corporation) with a glass syringe. Extracts filtered through Millipore filters were designated H_2O—MF.

Because the water extract (H_2O—F) of feces from *H. zea* larvae feeding on cowpea leaves attracted *M. croceipes* females in the wind tunnel (see later), we decided to attempt to remove all the attractive volatiles by exhaustive extraction with pentane. In a Soxhlet extraction apparatus, 1184 mg of feces from *H. zea* larvae fed cowpea leaves was held in a Whatman 10 × 50-mm cellulose extraction thimble and extracted with about 40 ml of HPLC grade pentane (J.T. Baker) for 24 hr. Then the pentane extract was removed, replaced with fresh pentane, and the extraction was continued for another 24 hr. This procedure was continued, with extraction periods lasting as long as 134 hr until 10 extractions were completed, and the feces had been extracted a total of 393 hr. The feces residue, after this exhaustive pentane extraction, amounted to only 183

mg. This residue was extracted with three aliquots of water of about 7 ml each, as described before, to give a final concentration of the combined filtrates of 0.05 mg equivalents of feces per milliliter based on the weight of the feces before pentane extraction. This water extract was designated H_2O-R.

RESULTS

Experiment 1. Conditioning and Attractive Properties of Selected Feces Extracts. In preliminary tests, batches of the feces from *H. zea* larvae fed leaves (seedlings of cowpea plants) were extracted with either hexane, ether, methylene chloride, methanol, or water. When *M. croceipes* females were allowed to contact these extracts on filter paper prior to flight tests in the wind tunnel, only experience with the H_2O extract resulted in subsequent flights to the hexane extract. However, the hexane extract was the most effective source of attraction. Furthermore, the conditioning and attractive properties of the water and hexane extracts of feces were not affected by whether the feces were extracted first with water or hexane.

In experiment 1 the water and hexane extracts of raw fresh feces were tested to compare their effectiveness in preflight conditioning and as attractants in a wind tunnel. As shown in Table 1, the preflight conditioning properties of water extract of *H. zea* feces (H_2O-F) were equal to those of fresh feces. In contrast, very few of the naive females and females conditioned on hexane extract flew to the hexane extract source. The attractant properties of the different materials were compared using individuals given a preflight exposure to H_2O-F extract. The hexane extract of the feces was the most attractive, while the water extract and fresh feces were significantly less attractive (Table 1). Only 4% of the individuals flew to the pure hexane (blank). These results demonstrate that water is an effective solvent for extracting the substances responsible for the conditioning properties of feces and that hexane is the best extractant for the volatile components that attract *M. croceipes* females. While the water extract was also somewhat attractive to the females, the hexane extract had no conditioning properties.

Experiment 2. Conditioning and the Need for Direct Contact. When provided with feces or water extract for preflight conditioning, the female parasitoid would immediately antennate the material and often (but not always) would probe the active spot with the tip of her abdomen in an apparent attempt to find the host insect for oviposition. If permitted, this intense examination would continue sometimes for several minutes.

To determine if actual contact with the fecal material was required for effective conditioning, individuals were placed in a Petri dish that contained the H_2O-F (28 μl) on a filter paper. The filter paper containing the extract was

TABLE 1. FLIGHT CHAMBER RESPONSE OF *M. croceipes* FEMALES WITH INDICATED MATERIALS USED AS PREFLIGHT CONDITIONERS AND ATTRACTANT SOURCES

Indicated material tested as	Response (%)[a]					
	Host feces	Hexane extract	H_2O-F extract	Naive	Hexane blank	H_2O-F extract + vanilla
Preflight conditioner (hex. extract as source)	92a	8b	96a	4b	—	—
Attractant source (H_2O extract as conditioner)	21b	96a	38b	—	4c	—
Preflight conditioner (vanilla as source)	—	—	3a	0a	—	47b

[a]Responses (%) in the same row followed by different letters are significantly different ($P = 0.01$,

covered with a piece of cheesecloth separated by approximately 1.0 mm from the extract by a thin cardboard spacer with a hole in the center to coincide with the location of the extract. By inverting and rotating the Petri dish, the parasitoid was induced to walk continuously and in close proximity to the material for 1 min. The parasitoids could not contact the extract. Other than an occasional quick antennal palpitation of the cheesecloth, the parasitoid gave little attention to the extract.

Twenty individuals were treated in this manner and subsequently tested for response to the hexane extract in the flight chamber. No positive responses to the hexane odorants were obtained. Twenty females from the same group of parasitoids were provided 30 sec of direct antennation contact with an equal amount of the water extract. Of these, 18 made a positive response to the hexane extract source in the flight chamber.

These results show that direct contact with the material is required for conditioning and indicates that the active chemical is probably very nonvolatile. Consequently, the chemicals that elicit conditioning would be necessarily different (at least partially) from the attractant material.

To determine if the conditioning could be accomplished solely by contact of the antennae with the water extract, individual females were allowed to walk to the rim of a glass vial to antennate filter paper containing an aliquot of the

water extract for 30 sec, while the observer used care so that no other part of the individual touched the material. Of the 20 individuals treated in this manner, 16 flew to the hexane extract source when tested in the flight chamber. Thus, the conditioning stimuli can be perceived and processed by the antennae without involvement of sensory organs located on other appendages.

Experiment 3. Test for Longevity of Conditioned Responses. Tests were conducted to establish whether or not the conditioning process that increases the response of the parasitoid is simply excitation. Parasitoid females were provided a preflight experience on H_2O—F extract and tested for flight responses to hexane extract at 0, 24, and 48 hr following this experience.

Although the highest response was obtained at 0 hr with significant loss at 24 and 48 hr (Figure 1), the results indicate that there is a significant effect up to 48 hr, thereby demonstrating that the conditioning is not just an excitation response.

Experiment 4. Purification of Water Extract. Results of experiment 1 demonstrated that the water extract of the feces, while serving as an excellent conditioner for subsequent flight responses to hexane extracts, also possessed significant attractiveness. It was assumed that this attraction could be at least partially the result of contamination from the same components serving as attractants in the hexane extract. Therefore, it was not clear whether the conditioning of flight responses to hexane extract was caused by separate components in the H_2O—F extract acting independently of the material(s) in the hexane extract or by true associative learning as a result of contaminating hexane-sol-

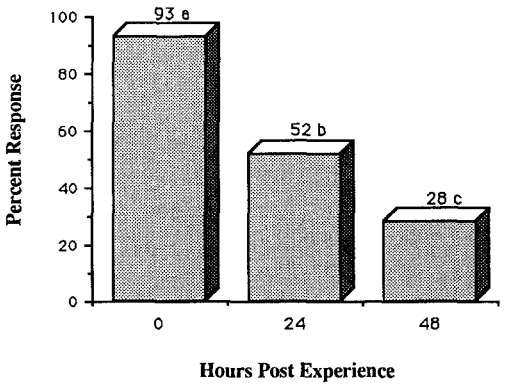

FIG. 1. Response of *M. croceipes* females to hexane extract of host feces at indicated time intervals after conditioning by exposure to water extract of host feces. Bars capped by different letters are significantly different ($P = 0.01$, Waller-Duncan k-ratio t test, $N = 40$ observations).

uble chemical(s) acting together with water-soluble chemical(s) in the water extract.

In an attempt to remove the attractant volatiles contaminating the H_2O-F extract, a batch of feces was extracted with pentane in a Soxhlet extractor. The feces residue was then extracted with water (H_2O-R) (see detailed procedure in Methods and Materials). Despite this exhaustive extraction, each successive pentane extract continued to remove attractant materials from the feces (14 of 22, or 64% of the females flew to the 10th pentane extract). Furthermore, the final after-pentane residue and the H_2O-R were still slightly attractive (four of 27 and three of 28 females flew to the after-pentane residue and H_2O-R extract, respectively).

However, comparison of the water extracts showed that fewer females responded to the hexane extract after preflight experience with H_2O-R (11 of 40, 28%) than after experience with H_2O-F (34 of 40, 88%). The conditioning property of H_2O-F remained stable for hours (38 of 54, 70% response after 2 hr on filter paper), whereas H_2O-R became essentially inactive within 30 min after application to filter paper (2 of 28, 7% response).

Since the H_2O-F extract contained a small amount of suspended fine particulates, it was filtered through a 0.22-μm Millipore filter in an attempt to remove contaminants that might be adsorbed to the particles. In preliminary tests conducted by the same procedure used above, the filtrate (H_2O-MF) appeared inactive as a preflight conditioner. However, H_2O-MF dried more rapidly than H_2O-F, and it was considered that moisture may be important to the conditioning process. Therefore, another bioassay procedure was used to compare the conditioning properties of H_2O-MF with those of H_2O-F.

An aliquot (40 μl) of either of the H_2O extracts was placed on a 2.3-cm-diam. semicircular filter paper held by the edge with a pair of spring-loaded forceps. The impregnated disk was kept lightly moist with small amounts of water applied with a Pasteur pipet. Parasitoids were allowed to examine the disk for 60 sec. Preflight exposure in this manner to H_2O-MF resulted in no flights to the hexane extract source compared with 53% flights by females exposed in a similar manner to H_2O-F (Figure 2).

These results indicate that some contaminant, perhaps the attractive hexane-soluble material, is involved in the conditioning of the parasitoids by the water extract. However, since the hexane extract does not show any conditioning properties and since this process requires direct contact with the antennae, it would seem that the conditioning is caused at least partially by a nonvolatile chemical present in the water extract and not in the hexane extract.

Experiment 5. Restoration of Conditioning Properties of Filtered Water Extract. A nonvolatile chemical vital to the conditioning process could remain present in the water extract after the activity apparently disappears; however, important volatile compounds and other materials necessary for antennation and

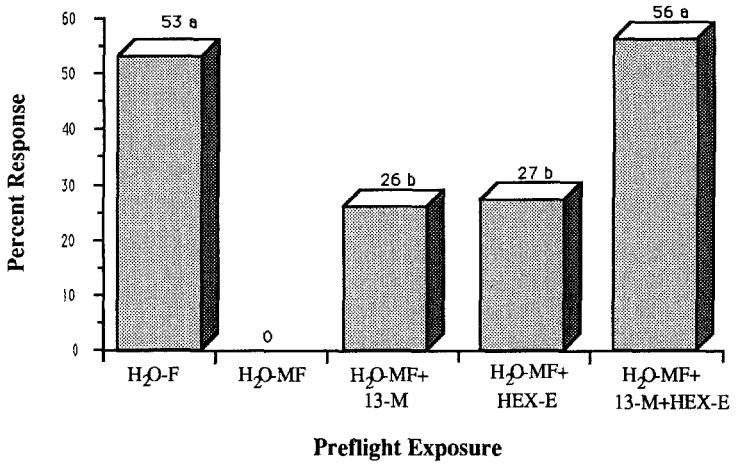

FIG. 2. Response of *M. croceipes* females to hexane extract of host feces after conditioning with indicated formulation of water extract of host feces. H_2O—F, water extract of host feces (40 μl aliquot); H_2O—MF, H_2O—F filtered through a Millipore filter (40-μl aliquot); 13-M, 13-methylhentriacontane (1 μg); Hex-E, hexane extract of host feces (10-μl aliquot). Bars capped by different letters are significantly different ($P = 0.01$, Waller-Duncan k-ratio, t test, $N = 30$ observations).

conditioning may be lost through filtering or extraction with hexane or pentane. A very low antennation response to H_2O—MF is obtained (10 sec or less) as compared with H_2O—F (30–60 sec).

This question was tested by use of an antennating stimulant. An aliquot (40 μl) of H_2O—MF was placed on 2.3-cm-diam. semicircular filter paper disks as described above. In addition, 1 μg of 13-methylhentriacontane (delivered in 10 μl hexane) was applied to the center of the disk and at least 2 min were allowed for the hexane to evaporate before testing. This compound was identified by Jones et al. (1971) as an antennating stimulant present in *H. zea* feces. Consistent 15- to 30-sec antennation responses were obtained by female parasitoids allowed to examine the disks.

Further, the antennating stimulant experiment was conducted to determine whether associative learning is a key part of the activation process and thus whether some amount of the volatile attractant must be present and antennated in conjunction with the nonvolatile water-soluble activation component. To answer this question, other disks were treated with 40 μl of H_2O—MF and 1 μg of 13-methylhentriacontane as above plus 10 μl of the hexane extract; Discs treated with 40 μl of H_2O—MF and 10 μl of hexane extract also were tested.

The results of these tests are presented in Figure 2. Antennation of these disks as induced by the addition of 13-methylhentriacontane to H_2O—MF

resulted in a significant increase in percentage of flights (26%). The addition of 10 μl of the hexane extract to H_2O—MF also resulted in a significant increase in percentage of flights (27%). However,the addition of both the hexane extract and 13-methylhentriacontane restored the flight percentage (56%) to the level obtained by H_2O—F (53%). The fact that the addition of a small amount of hexane extract along with 13-methylhentriacontane provided a much higher response than 13-methylhentriacontane alone, which induced antennation only, indicates that the conditioning process involves a nonvolatile chemical(s) that mediates responses to other chemicals, such as the hexane extract, through a type of associative learning. That is, the water-soluble nonvolatile compound, probably a host recognition material, serves as a type of unconditioned stimulus to which the parasitoid links various less-specific odorants to aid in finding its host. The low response to H_2O—MF plus hexane extract without the addition of 13-methylhentriacontane shows the need of the latter material as an antennation facilitator.

The significant response that resulted from the antennation induced by 13-methylhentriacontane could be from several possible causes. First, the induced antennation may facilitate detection of minute amounts of contaminating volatiles still present in the H_2O—MF. Alternatively, response tendencies to some key compound(s) in the hexane extract may be "hard-wired," and antennation of the water soluble material, prompted by the 13-methylhentriacontane, even in the absence of any hexane soluble material, may increase the central excitatory state and cause a response to these materials without their association.

Experiment 7. Assessment of Role of 13-Methylhentriacontane in Conditioning Process and Confirmation of Active Nonvolatile Chemical in H_2O—MF Extract. To further assess the role of 13-methylhentriacontane, two procedures were conducted. First, a test was conducted to determine whether 13-methylhentriacontane could effectively function together with the hexane extract to condition the flight response of female parasitoids. The females were given a preflight exposure to a range of doses of 13-methylhentriacontane in combination with the hexane extract. The 13-methylhentriacontane was applied at doses ranging from 0.1 to 100 μg to a moistened paper disk, as described earlier, along with 10 μl of the hexane extract. The individual parasitoids were exposed to the disks for 60 sec and subsequently tested for flights to the hexane extract. These responses were compared to those obtained after a preflight experience of the combination of these same two materials (1 μg 13-methylhentriacontane + 10 μl hexane extract) plus 40 μl of the H_2O—MF.

The 13-methylhentriacontane and hexane extract combination alone provided no significant conditioning at any dose. However, with the addition of H_2O—MF, significant conditioning was obtained (19 of 31, 61%).

The second procedure involved testing a range of doses of 13-methylhentriacontane in combination with both the hexane extract and filtered water

extract. Using the paper disk method, female parasitoids were given a 60-sec exposure to the three materials with doses of 13-methylhentriacontane ranging from 0–1 μg (hexane extract 10 μl, H_2O—MF 40 μl). The effect of 13-methylhentriacontane seemed to level out at dosages higher than 0.1 μg (Figure 3A). However, at dosages of 0.030 μg and lower, conditioning of the parasitoids was significantly reduced.

These data strongly support the hypothesis that 13-methylhentriacontane elicits antennation and thereby facilitates the associative learning interaction between the nonvolatile substances and the hexane odors.

As a final confirmation of the presence of a functional water-soluble component, the paper disk was used to compare the conditioning effect of a range of doses of the filtered H_2O in combination with the hexane extract and 13-methylhentriacontane. Doses of 0–2.0 mg feces equivalents of H_2O—MF (40-μl aliquot) were tested in combination with 1 μg of 13-methylhentriacontane and 10 μl of hexane extract.

The results presented in Figure 3B demonstrate a positive linear dose effect of the filtered water on conditioning for the flight response.

Experiment 8. Demonstration of Ability to Associatively Learn Novel Odors. The above results led to the question of whether the water extract could be used to condition the parasitoids to respond to novel compounds. Vanilla extract (Nielsen-Massey) was used as a novel odor. Females were provided with either no experience, preflight exposure to the standard H_2O—F extract, or exposure to H_2O—F plus 1 μl of the vanilla extract added to the center of the H_2O—F aliquot. These females then were tested for flights to 80 μl of the vanilla extract as the source attractant.

The results of these tests (Table 1) show that females conditioned on the H_2O—F extract made no response to the vanilla extract. However, significant responses to vanilla extract were obtained after they were given a preflight exposure to the vanilla extract in association with the H_2O—F extract. In a separate experiment, 10 females each were exposed to doses of 1, 5, and 10 μl of the vanilla extract and subsequently tested for flight responses to the vanilla extract source alone. None of the individuals would antennate or subsequently fly to the vanilla source. These results confirm that *M. croceipes* can learn to fly to odors by linking these materials to the water extract reference base (associative learning). Furthermore, this can be accomplished for novel odors that they would not encounter normally.

Experiment 9. Influence of Host Insect and Host Diet on Conditioning and Attractant Properties of Feces. Since the attractant and conditioning responses apparently were elicited by two different materials, it was important to test the interacting effects of these two responses when obtained from different host insects or diet sources. The conditioning and attractant properties of feces collected from *H. zea* feeding on cowpeas were compared with those of feces from

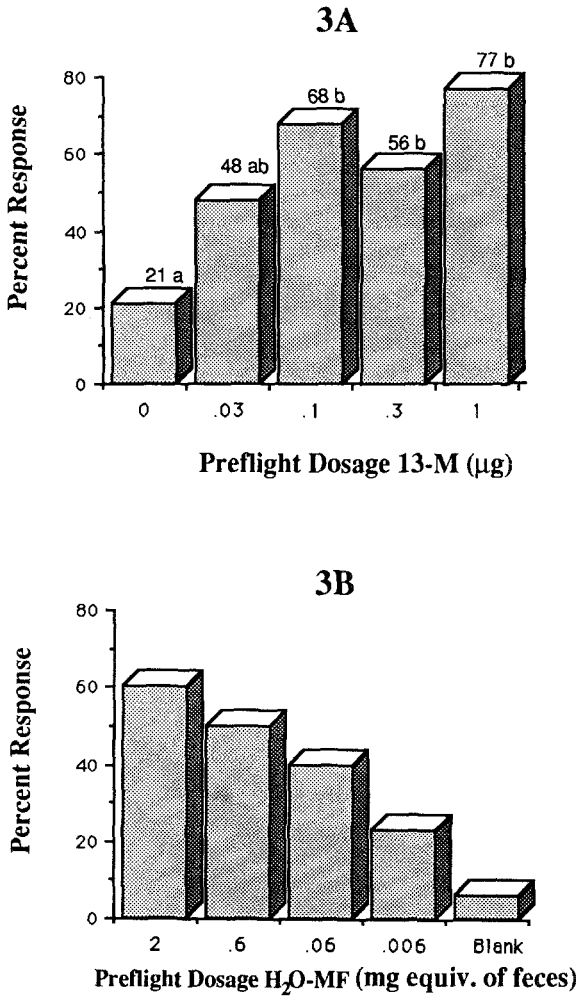

FIG. 3. Response of *M. croceipes* females to hexane extract of host feces. (A) After conditioning with indicated dosages of 13-methylhentriacontane (13-M) in formulation with Millipore-filtered water extract, H_2O—MF, (40-μl aliquot) and hexane extract (10-μl aliquot) of host feces. The linear dosage effect was not significant ($P = 0.05$) according to the general linear model procedure. Bars capped by different letters are significantly different ($P = 0.05$) as separated by the least square mean test, $N = 30$ observations. (B) After conditioning with indicated dosages (dilutions) of Millipore-filtered water extract, H_2O—MF (40-μl aliquot), of host feces formulated together with 13-methylhentriacontane (1 μl) and hexane extract (10-μl aliquot). There was a significant linear dosage effect of H_2O—MF ($P = 0.01$) according to the general linear model procedure.

the same species feeding on artificial diet. The properties of feces from *T. ni* and *H. zea*, both feeding on cowpeas, also were compared.

The results for feces of *H. zea* feeding on cowpeas versus artificial diet are presented in Figure 4A. Both conditioning and attractant properties were extracted from feces from both diets. However, the data show that the *H. zea* feces from cowpeas had stronger attractant properties, as would be expected since the artificial diet is lacking most green-plant compounds. The data also show that the parasitoids responded to the hexane extract attractant of a given diet best when they were conditioned on the water extract of the same diet. These findings fit earlier data that substantiate associative learning.

The results from studies of the comparative properties of feces from *H. zea* and *T. ni*, both fed on cowpeas, are presented in Figure 4B. As expected for *M. croceipes*, which is specific to *Heliothis*, the water extract of *T. ni* feces possessed no conditioning properties. However, the response to hexane extract of the *T. ni* feces was as a strong as that of *H. zea*, even though the parasitoid was conditioned on the water extract of *H. zea* feces.

The data indicate that the water-soluble conditioning material is host-specific and that the hexane-soluble attractant extract is predominantly host-diet associated. The question naturally arises as to whether *M. croceipes* would be equally attracted to *H. zea* and *T. ni* sites if both were feeding on the same plant. Preliminary tests indicate that there are differences that *M. croceipes* and other parasitoids distinguish under more discriminative conditions such as feeding naturally on a plant with all the host and plant components present (see Turlings et al., 1990).

CONCLUSIONS

These flight chamber studies show that the host-seeking behavior of *M. croceipes* is strongly influenced by feces from *H. zea* host larvae. Less than 5% of naive parasitoids reared from hosts fed on artificial diet would fly upwind to feces of hosts fed on cowpeas. However, over 90% of these females experienced by a brief (30-sec) contact with feces from a cowpea-fed host would subsequently orient and fly to cowpea feces. These effects on the parasitoid's behavior were found to be mediated by both a nonvolatile contact chemical and by volatile chemical cues. The nonvolatile substance is water-extractable and distinct from the hexane-soluble volatile cues that are highly effective in attracting the experienced females.

The nonvolatile, water-soluble compound is a host-specific recognition cue with which the parasitoid associates the volatile cues during antennal contact with the feces. Water extracts of *T. ni* frass failed to enhance subsequent flight responses. The antennation stimulant, 13-methylhentriacontane, previously

identified for *M. croceipes* and present in *H. zea* feces, was shown to facilitate the associative learning process. The volatile attractants present in the hexane extract of host feces are diet related and thus would be primarily plant-derived. However, the parasitoid was conditioned to fly to a novel and otherwise unattractive odor, vanilla extract, when it was antennated in conjunction with the water extract of the feces.

Larvae of *H. zea* spp. feed on a wide variety of plants and plant parts of various ages, often in diverse vegetational settings, along with many other actively feeding herbivorous insects. Consequently, their trail odors vary considerably and occur in the context of a vast array of other chemical signals. Furthermore, in a high percentage of cases, when *M. croceipes* females find host sites, the hosts are feeding within a crevice or within a fruiting part so that contact with the host is limited, or the host has moved recently to a new location. Linkage of various odorants associated with the site to a dependable host-recognition chemical in a host by-product, independent of host contact, provides the parasitoid with a valuable alternative means for ongoing reinforcement or adjustments of its foraging behavior.

This phenomenon provides a valuable way of finding hosts or prey species and may be widespread in parasitic and predatory systems, particularly for cryptic hosts or prey where the target organisms (but not their by-products) often elude the searching parasitoid or predator.

Abstract—A modified allomone collecting apparatus was designed that could be used under water with a scuba tank. This apparatus provides a simple method of obtaining naturally secreted chemicals from benthic marine organisms at scuba depths, for the first time without the necessity of using a bilge pump. Organic material from Sep-paks in the allomone collector confirmed the release of secondary metabolites from a soft coral into the surrounding water.

Key Words—Allomone, Sep-pak, bioactive substances, secondary metabolites, thin-layer chromatography.

INTRODUCTION

In the last 20 years it has been recognized that secondary metabolite synthesis by marine organisms, previously considered only a by-product of detoxification or an avenue for metabolic wastes, is an evolutionary event in which biologi-

*To whom correspondence should be addressed.

0098-0331/91/0700-1327$06.50/0

cally active compounds, or bioactive substances, enhance individual survival (Sondheimer and Simeone, 1970; Kittredge et al., 1974; Fenical, 1982). These metabolites are often thought to play an allelopathic role and are known as allelochemicals or allomones.

Until the work by Coll et al. (1982), chemical evidence to confirm the presence of marine allomones was lacking. In their study a submersible allomone collecting apparatus, operated by a bilge pump with its battery aboard a boat, was constructed, utilizing Sep-paks (C-18, reverse-phase, silica gel columns) to sample water from around two species of alcyonaceans or soft corals (*Sarcophyton crassocaule* and *Sinularia flexibilis*). Using thin-layer chromatography (TLC), they concluded that the lipophilic secondary metabolites known to exist within these species (i.e., sarcophytoxide and sarcophine from *Sarcophyton crassocaule* and flexibilide and dihydroflexibilide from *Sinularia flexibilis*) were also present in the surrounding water. Interestingly, in noncontact transplant experiments involving *Sinularia flexibilis* with the soft corals *Nephthea* sp. or *Alcyonium molle*, no necrotic effects were evidenced. However, over a four-week period all colonies exhibited growth ("movement") away from each other (La Barre et al., 1986). Exudation of bioactive metabolites also was reported for the sponge *Aplysina fistularis* (Thompson, 1985).

The main objective of this study was to develop an allomone collecting apparatus that could be used by scuba divers to collect secondary metabolites secreted from benthic marine organisms. This would allow chemical ecologists a considerable advantage over the system developed by Coll et al. (1982) because the latter were limited to a depth of about 6 m (20 ft) and the apparatus required a battery-powered, submersible bilge pump.

METHODS AND MATERIALS

An allomone collecting apparatus with a hemispherical Plexiglas collecting chamber was designed by one of us (B.A.S.) that could be placed over a sponge or soft coral without additional weights or supports to keep it in position. After extensive laboratory trials at UCSC and field tests over sponges, the apparatus was found to leak. Rather than place large O-rings in the system to prevent the leakage, a simpler collecting chamber was designed (R.d.N.). Four 18-mm-long hollow stainless-steel tubes 3 mm in diameter with a central opening 1 mm in diameter were brazed to a basal tube 60 mm long. A single 18-mm-long tube was then brazed to the basal tube (Figure 1). This configuration was duplicated and the two pieces (adaptors) connected by four Sep-paks. The lower metal adaptor was connected to an inverted funnel (Figure 2). The upper metal adaptor was connected to an outlet hose that received compressed air from a scuba tank.

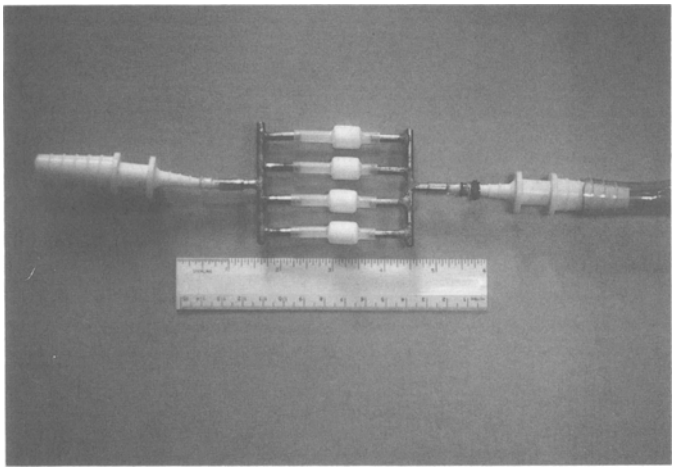

FIG. 1. Close-up photograph of the metal adaptors with Sep-paks *in situ*.

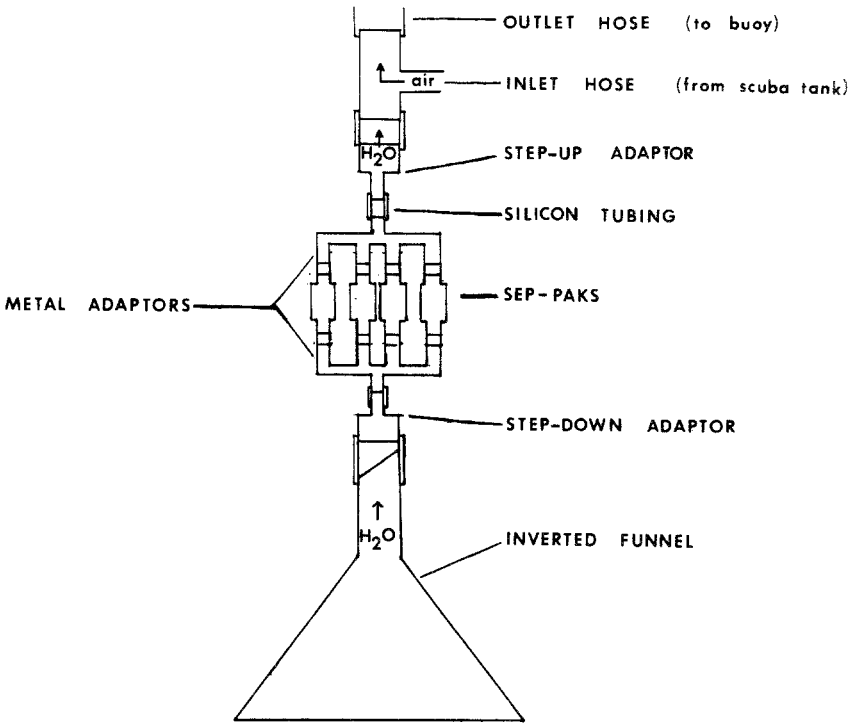

FIG. 2. Modified allomone collecting apparatus.

The allomone collecting apparatus is powered by compressed air from a scuba tank, whose flow is controlled by a needle valve in the high-pressure line connected to the low-pressure outlet of a scuba regulator. Water flow rates of 5–8 liters/hr are attainable by adjustment of this needle valve. At a rate of 7 liters/hr and a depth of 8 m (25 ft), the tank loses pressure at an average rate of 150 psi/hr. The allomone device was tested to depths of 13 m (40 ft) without any difficulties.

The modified allomone apparatus was first tested in a pool using neutral red. Field tests were carried out at Geoffrey Bay, Magnetic Island, near Townsville, Australia. A small colony of the soft coral *Sinularia flexibilis* was enclosed in the collector and cut to ensure release of metabolites. The Sep-paks were primed in MeOH (methanol), and the collector was operated for 4 hr. The Sep-paks were removed, returned to the laboratory, and eluted with 20 ml distilled water, 20 ml MeOH, and 20 ml dichloromethane (DCM). The MeOH extract was washed with DCM and the DCM extracts combined. The Sep-paks yielded 25 mg of yellow extract. A sample of the same colony of *Sinularia flexibilis* was also collected and extracted wet using MeOH and DCM. The MeOH extract was washed with DCM and the DCM extracts combined. A seawater control was run upstream of the soft coral. Comparison of the *S. flexibilis* extract, the Sep-pak extract, and the pure compounds flexibilide and dihydroflexibilide previously isolated and identified from the soft coral using TLC (Kazlauskas et al., 1978) allowed identification of compounds present in the Sep-pak extract. The TLC was carried out on silica gel (Keisel-gel 60F254) using a 30% petroleum ether–diethyl ether solvent system. The TLC fractions were visualized using a vanillin–concentrated sulfuric acid spray and the color developed on gentle warming. The Sep-pak extracts of *S. flexibilis* and the seawater control were examined by [^{1}H]-and [^{13}C]NMR.

RESULTS

When the modified apparatus was first tested in a pool using neutral red, the Sep-paks removed the neutral red from the water. The organic material eluted from the Sep-paks in the field experiments in Australia was compared with that of the soft coral tissue and the compounds flexibilide and dihydroflexibilide by TLC. Figure 3 confirms, by TLC, the release from *S. flexibilis* of flexibilide and a number of nonterpenoid compounds thought to be lipids and sterols into the water column. No dihydroflexibilide was detected. [^{1}H] and [^{13}C]NMR further confirmed the presence of lipids and sterols; however, no resonances for either flexibilide or dihydroflexibilide were detected because of low concentrations. TLC and [^{1}H]NMR of the Sep-pak extracts of the upstream seawater control show no flexibilide or dihydroflexibilide to be present. These

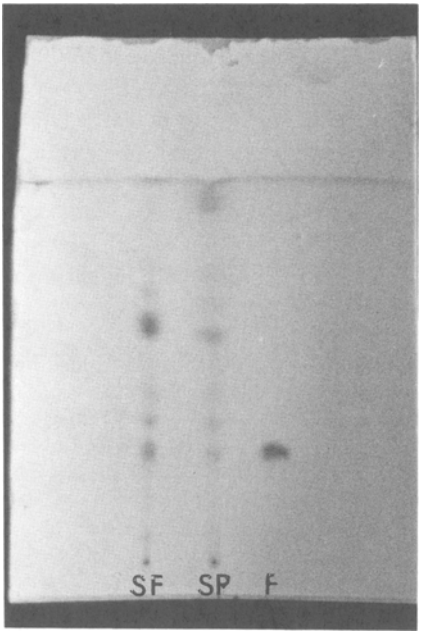

FIG. 3. Thin-layer chromatographic comparison of the tissue extract (SF), the Sep-pak eluent (SP), and flexibilide (F) of *Sinularia flexibilis;* solvent 30% petroleum ether–diethyl ether.

results confirm the release of metabolites from *S. flexibilis* and the ability of the modified allomone apparatus to concentrate organic compounds from the water column.

DISCUSSION

The modified allomone collecting apparatus will allow biologists and chemists to collect natural products (allomones and potential kairomones or pheromones) from marine organisms at any safe diving depth without the need of an accompanying boat containing a battery and cables connected to a submersible pump. The new model (Figures 1 and 2) is simpler and lighter than the original Plexiglas design and does not leak; however, weight does need to be added to the top of the chamber to stabilize it and keep the hood in position over the specimen being tested. The hood can be modified easily to accommodate organisms of different shapes and sizes. This apparatus continued to perform well during extensive field studies on soft corals in Australia conducted by one of us (R.d.N.). Through TLC, the presence of known bioactive second-

ary metabolites was confirmed in the whole-organism extracts of the soft coral species under study and in the water extracts surrounding the animal studied.

Examination of organisms other than soft corals would reveal whether allelopathy is a general marine phenomenon or not. Our failure to detect allomones from around marine sponges may be the result of leaks in the Plexiglas allomone model or some other cause (e.g., the sponges sampled may not release allomones). Further studies on sponges with the new model should clarify this issue. The modified allomone collecting apparatus will facilitate the study of waterborne chemical interactions by providing a simple means of sampling the water around aquatic organisms for bioactive substances.

Acknowledgments—We thank Drs. John Coll, Porfirio Aliño, Jim Kittredge, and Frederick Browand for making valuable suggestions on the design of the allomone apparatus. Drs. Richard Brusca, Russel Zimmer, and John Coll critically reviewed the manuscript, for which we are grateful. Support for this research was provided by a grant from the University of Southern California Institute for Marine and Coastal Studies (awarded to B.A.S.), by the U.S. Office of Naval Research (grant 00014-84-K-0375 awarded to G.J.B.), and by Sea Grant R/MP-33, U.R.E.P., and Syntex (awarded to P. Crews).

(Received August 21, 1990; accepted March 4, 1991)

Abstract—Using a chronically placed jugular catheter and a silver electrode, it was possible to monitor short-term changes in the plasma concentration of cortisol and catecholamine in the marsupial sugar glider (*Petaurus breviceps*) and to monitor both heart and respiration rates. Males judged to be low in the social hierarchy of a particular group were exposed to the whole-body odor of a dominant male from the same social group, a foreign dominant male, or a castrate male. While there was no evidence of a change in any of the physiological parameters when a male was exposed to either a castrate male or a female, a rapid increase occurred in heart rate and plasma concentrations of cortisol, glucose and catecholamine when the donor was a dominant male from the same or a different social group.

Key Words—Sugar glider, *Petaurus breviceps*, Marsupialia, heart rate, respiration rate, stress, cortisol, catecholamine.

INTRODUCTION

A relationship between rank order and testosterone levels has been shown to be significantly correlated in several species of primate (Rose et al., 1971; Eberhart et al., 1980). A more specific relationship between olfactory signals and sexual inhibition in males has been described in a primate (Schilling et al., 1984) and mice, rats, and rabbits (Brain and Nowell, 1970; Mykytowycz, 1973). The mechanism by which this inhibition is achieved is not clear, but it has been

known for some years that reproductive function in male primates, rodents, and domestic animals may be suppressed by stress (Rose and Sachar, 1982). It is accepted that glucocorticoids, β-endorphin, and prolactin, which are secreted during stress, are each capable of suppressing testosterone with the site of action varying within the hypothalamopituitary–gonadal axis. While the opioids appear to suppress testosterone concentration by inhibiting LHRH release (Hulse and Coleman, 1983), both glucocorticoids (Bambino and Hsueh, 1981; Johnson et al., 1982) and prolactin (McNeilly et al., 1983) are thought to act on the pituitary and testes to suppress testosterone secretion. In a study of the role of glucocorticoids in stress-induced suppression of testicular function in the baboon, Sapolsky (1985) concluded that most of the glucocorticoid action was exerted at the testicular level.

In studies using marsupials, few attempts have been made to investigate directly the link between social stimulation and physiological change. Scott (1986) used pheromonal cues from urine and feces to induce ovulation synchrony in isolated *Antechinus stuartii*. In this study social and pheromonal effects on plasma androgens were investigated in males, but the study did not investigate pituitary–adrenal effects. Other than the study of Scott (1987), which examined the effects of mating and agonistic experience on adrenal function of male *Antechinus stuartii*, we are not aware of any other work using marsupials that directly links stress response to social stimulation. More general aspects of stress response to social stimulation in small mammals are discussed by Lee and McDonald (1985).

Most of our knowledge of the physiological attributes of a stress response in marsupials is derived from studies on small dasyurid marsupials where, in several species, there occurs an annual total, synchronous stress-related male mortality (see Bradley 1987, 1990).

The object of this study was to investigate the feasibility of using repeated small blood samples as well as electrocardiography to assess the short-term pituitary adrenal and sympathetic nervous system effects induced by olfactory stimulation in a small mammal. The species used was the marsupial sugar glider (*Petaurus breviceps*, adult body mass 125–140 g).

METHODS AND MATERIALS

Surgical and Experimental Procedures. Anesthesia was induced with an intramuscular injection of 15 mg ketamine/kg (Ketalar; Parke Davis, Sydney, NSW, Australia) and maintained with further intraperitoneal injections of 250 mg chloral hydrate/kg. Salivation and nasopharyngeal secretion were minimized with an initial subcutaneous injection of 0.1 mg atropine sulfate/kg (Atrosine Mitis, Parnell Laboratories Pty. Ltd., Peakhurst, NSW, Australia).

Dual-lumen vinyl catheters (internal diameter 0.41 mm, external diameter 1.0 mm; Critchley Electrical Products, Auburn, NSW, Australia) were prepared by inserting a stainless-steel wire in one lumen and paring away the other channel to leave one side 10 mm shorter than the other. This procedure was repeated at the distal end of the catheter to facilitate the connection of separate tubing for infusion and blood sampling. The cannula was sterilized; then both channels were filled with sterile isotonic saline. The catheter was inserted into the right jugular vein and advanced until the aperture of the shorter lumen lay adjacent to the entry to the right atrium. The distance from point of insertion to the required position in the blood vessel was determined by measurements made at necropsy on an animal of similar size that had died of natural causes. The catheter was secured in the vein with a purse-string suture of 6-0 vascular silk, filled with 50,000 IU heparin/liter saline, and each lumen was plugged with a stainless-steel pin. The distal end of the catheter was passed subcutaneously to exit in the midline between the scapulae. Before closure of the incision, approximately 0.05 g amoxycillin sodium (Ibiomox, Protea Pharmaceuticals, Thornleigh, NSW, Australia) was puffed into the wound. No infections were ever seen as a result of this cannulation procedure. Animals were allowed two days to recover before commencement of experimental procedures. With daily flushing with saline and refilling with heparin–saline, some cannulae remained patent for up to 21 days.

Blood samples of 0.08–0.10 ml were collected using tubing of low dead space connected to the longer lumen of the catheter. Great care was taken during both intravenous injection and blood withdrawal since small pressure pulses were found to affect both heart and respiration rate.

A blood volume equivalent to the dead space of the sampling line was withdrawn before, and replaced after, the taking of the blood sample which was to be assayed for hormones and metabolites. Blood samples were collected into polypropylene centrifuge tubes and centrifuged at 4000 g for about 2 min in an Eppendorf 5414S centrifuge (Eppendorf, Hamburg, Germany) prior to removal of the plasma, which was stored at −25°C until later assay. Aliquots of plasma before freezing were flame sealed into plain hematocrit tubes (Blue Tip, Monoject Scientific, Sherwood Medical, St. Louis, Missouri) into which a sodium fluoride solution previously had been dried to give a concentration in the plasma sample of approximately 4 mg/ml.

To determine when the test animal had satisfactorily acclimatized to the testing chamber and monitoring equipment, plasma glucose concentrations were determined at intervals from a small drop of whole blood using Dextrostix (Miles Laboratories Australia, Pty. Ltd., Mulgrave North, Victoria, Australia) and a portable laboratory glucometer (Miles Laboratories). This provided a plasma glucose concentration with a known accuracy of at least 10%.

Recording and Odor Delivery. To facilitate recording of heart rate, a silver

electrode sheathed along its entire length with vinyl catheter tubing except for the 1-mm tip was placed subcutaneously in the left midthoracic position. A second electrode was provided by the tip of the saline-filled jugular catheter to which an electrical connection was made at the needle inserted into the distal end of the catheter. These electrodes were connected to a Gilson GME model M8PM Macro polygraph equipped with ECG and cardiotachygraph modules (Gilson Medical Electronics Inc. Middleton, Wisconsin) and to a Gould digital storage oscilloscope (model 0S1420, Hainault, England).

The odors used in this investigation were whole-body odors from sugar gliders deemed dominant or subordinate to the test animal. The donor animal was placed in a polypropylene chamber measuring 150 × 70 × 55 mm. In the control experiments air flowed through an identical, but empty, chamber.

Clean laboratory air was provided by a diaphragm-operated aquarium pump and delivered via Teflon tubing to either control or donor at a rate of 3.6 liters/min to the polypropylene recipient test chamber, which measured 200 × 50 × 40 mm. The recipient animal was loosely restrained in a clean calico bag with its nose adjacent to the inlet port at one end of the chamber. Connections were made to the jugular catheter and the silver electrode where they emerged from the skin in the midline suprascapular position. The recipient animal in the test chamber was placed in an earth-shielded cage and left undisturbed for at least 1 hr prior to the commencement of blood sampling; however, both heart rate and respiration rate were monitored during this period. The respiration rate could be determined by the effects of the alteration of intrathoracic pressure on the ECG trace during the respiratory cycles.

Determination of Social Rank. These studies were carried out between January and March prior to the commencement of the annual breeding season. Observations were made on each social group for 1 hr following the daily placement of a food container on each of five successive days. Individuals could be distinguished either by naturally occurring patches of white fur on the flank or tip of the tail or by the placement of a small piece of white insulating tape around the ear tag. The two stable social groups consisted of two females and three males and one female and four males. The social rank of each male within a group was judged by its response when approached by another male in the group. A male that invariably retreated from the food bowl when another male approached rapidly was designated the Ω male, while the male from which retreats were made by all other males was designated the α male. The relative social order of males of intermediate rank was less easily determined but is of little consequence for this particular study. In the group that consisted of one female and four males, the results of naturally occurring, rather than contrived, social encounters between males were scored as wins or losses. The results from highest to lowest in the hierarchy were 26/0, 11/5, 5/18, and 1/20, respectively. Males judged to be lowest in the social hierarchy of a particular group were

exposed to the whole-body odor of a dominant male from the same social group, a foreign dominant male, or a castrate male.

Hormone and Metabolite Analysis. The concentration of cortisol in the blood plasma was determined by RIA (intraassay variability 6.8%, interassay variability 6.9%), and the concentration of free cortisol was then determined. The methods employed have been described by Bradley (1990).

The plasma total catecholamine concentration was determined using the Cat-A-Kit assay system (Amersham, UK). Blood samples of 0.1 ml were collected into polypropylene centrifuge tubes which contained 5 μl of a solution (pH 6.0–7.4) of EGTA (ethyleneglycol-bis-*N*,*N*,*N*,*N*,-tetraacetic acid 45 mg/ml) and glutathione (30 mg/ml). These chemicals were purchased from the Sigma Chemical Co.

Plasma glucose concentration was measured by the glucose oxidase method of Hugget and Nixon (1957) using 10-μl plasma samples.

RESULTS

Odor of a Castrate Male (Figure 1). During this experiment a male of lowest social rank was placed in the test chamber and allowed a period of acclimatization during which the air flowed through an empty control chamber.

For 60 min the airflow was switched to expose the test animal to the whole-body odor of a castrate male, after which the air source was again switched back to the control chamber. The switching of the air supply did not result in any detectable changes in any of the parameters measured. When the airflow was passed to the test animal from an empty chamber, no change in any of the parameters was seen during the experiment.

Odor of Familiar Dominant Male (Figure 2). The exposure of a male of low social rank to the odor of a familiar dominant male from the same social group had some marked effects. Within 10 min of exposure to the test odor source, respiration rate increased from 64.5 $\pm$ 0.5 to 76.5 $\pm$ 1.5 (mean $\pm$ SEM) cycles/min ($N = 2$) while heart rate increased from 268 $\pm$ 7 to 393 $\pm$ 18 beats/min. The plasma concentration of glucose and catecholamine reached maximum values of 7.0 $\pm$ 0.1 nM and 4.5 $\pm$ 0.7 ng/ml, respectively, after 30 min of odor exposure. The plasma-free cortisol concentration did not reach the maximum concentration of 11.2 $\pm$ 1.1 nM until 10 min after switching the airflow source back to the control chamber.

Odor of Unfamiliar Dominant Male (Figure 3). The exposure of a male of lowest social rank to the odor of an unfamiliar dominant male had some marked effects. While respiration rate increased from 66 to 78 cycles/min within 10 min of the commencement of odor delivery from an unfamiliar dominant male, during this same period the heart rate increased from 270 to 465 beats/min. After

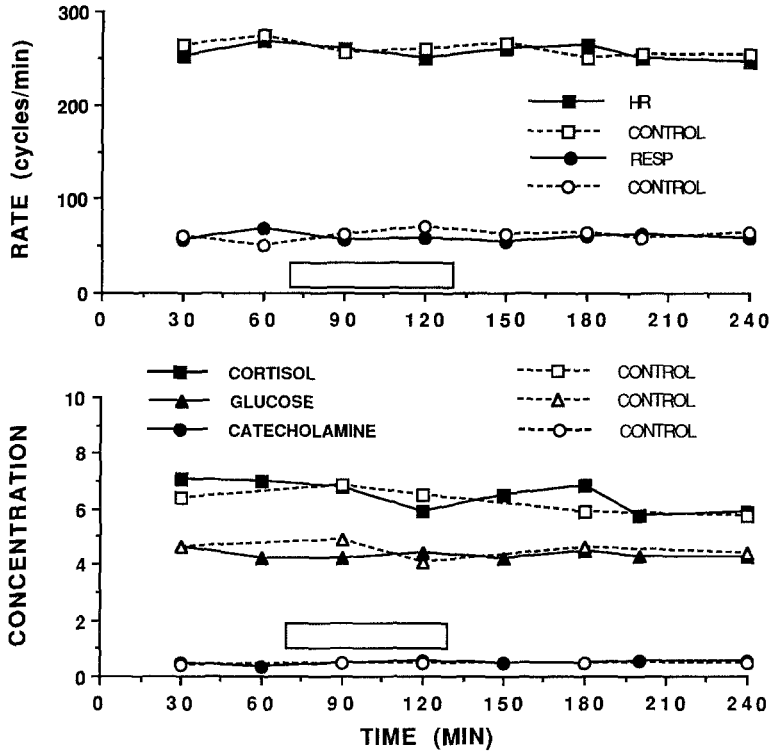

FIG. 1. The effect of the whole-body odor of a castrate male on heart and respiration rate, and on plasma concentration of cortisol, glucose, and catecholamine of a socially subordinate male sugar glider (*Petaurus breviceps*). The open rectangle denotes length of odor stimulation. (Concentration = nM cortisol; mM glucose; mg/ml catecholamine).

10 min of exposure to the donor odor, the plasma-free cortisol concentration had decreased slightly from 6.0 to 5.8 nM, plasma glucose concentration remained virtually unchanged, but catecholamine concentration increased from 0.46 to 3.2 ng/ml. The heart rate decreased from the maximum of 465 beats/min to reach the value in the control within 10 min of the airflow source being changed from donor animal chamber to control chamber. Plasma cortisol concentration continued to increase, reaching a peak value of 20.8 nM at 10 min after the diversion of the airflow to the control chamber. Plasma catecholamine concentration reached a maximum of 5.0 ng/ml after 40 min of exposure to the odor from the donor animal, thereafter decreasing to 0.77 ng/ml at 240 min. The plasma glucose concentration reached a peak of 6.8 nM 10 min after the

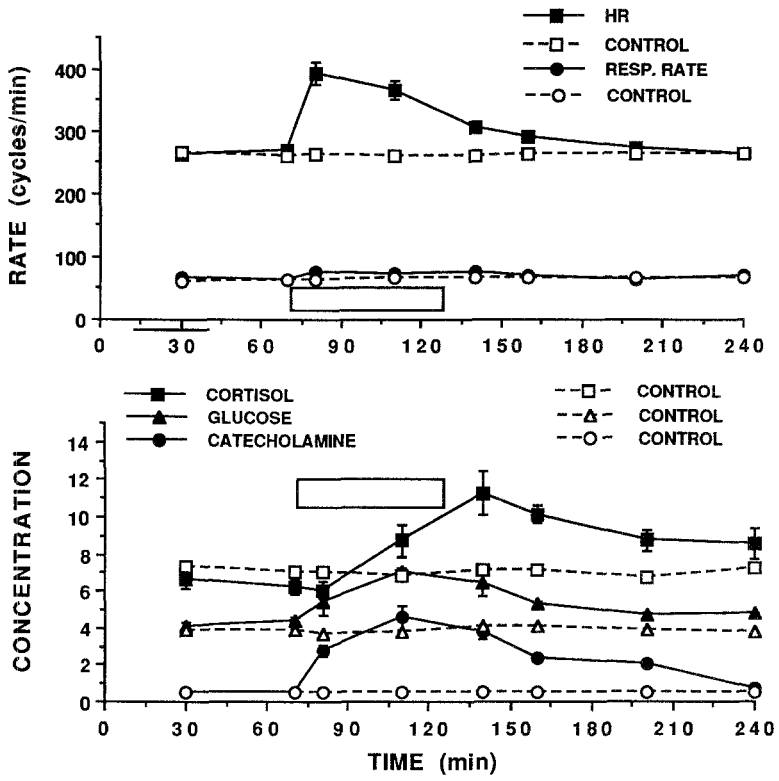

FIG. 2. As in Figure 1. Body odor of the socially dominant male from the test subject's colony (n = 2).

diversion of the airflow to the control chamber, thereafter declining to the preexposure concentration at 240 min.

DISCUSSION

Despite the preliminary nature of this investigation and the small number of replicates, it is apparent that serial blood sampling using a chronically implanted jugular catheter, together with electrocardiography, is a feasible technique for studying short-term physiological effects induced by various intraspecific odorants. The data suggest that socially subordinate males react differently to the whole-body odor of a castrated or a socially dominant intact male. A dominant male from an unfamiliar colony appeared to elicit a more intense reaction than one familiar to the test subject, but the significance of this observation cannot be assessed at this stage.

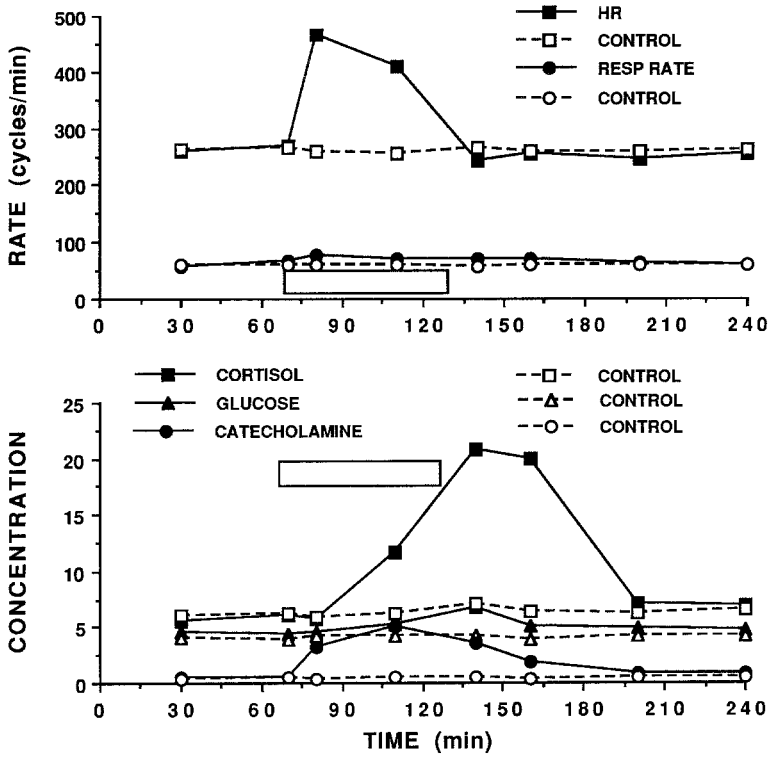

FIG. 3. As in Figure 1. Body odor of a socially dominant male from a colony unfamiliar to the test subject.

The most rapid and marked increases occurred in the heart rate; however, more delayed responses also occurred in the plasma concentration of free cortisol, catecholamine, and glucose. Since it has been shown previously that increases in the plasma concentration of either catecholamine or free cortisol will result in an elevation in the plasma glucose concentration in this species (Bradley and Stoddart, 1990), it is not surprising that rises in plasma glucose concentration were detected in this study. Because of this dual stimulatory effect, measurement of plasma glucose concentration would seem to be a useful means for assessing nonspecific psychosocial stress in *P. breviceps*.

The usefulness of this technique is that it allows repeated blood sampling in a small mammal. It is crucial, however, that the test animal be allowed adequate time, often up to 2 hr, to acclimatize to the loose restraint provided by the test chamber. From the physiological point of view, a nonstressed starting condition may be judged in the short term by measurement of the plasma glu-

cose concentration and in the longer term by determination of the plasma concentrations of free cortisol and catecholamine.

Acknowledgments—This investigation was assisted by grant number A18615564 from the Australian Research Council to DMS.

Abstract—A chemical agent contained in the rat pup preputial gland was found to regulate anogenital licking, a behavioral pattern crucial to pup survival. Combined gas chromatography and mass spectrometric analysis led to identification of four components in addition to high molecular alkanes (waxes). Independent synthesis added to behavioral observations were used to quantify the dam's response to these components. Among them, dodecyl propionate (DP), a pheromone-like compound, appears to be the only one efficient enough to induce, in the dam, behavior patterns similar to those observed with crude lipidic extract from the preputial gland secretion. Various esters previously were predicted in the adult rat preputial gland. DP is the first ester identified from mammalian infant tissue. These results, in combination with previous findings, allow discussion of the DP pheromonal role.

Key Words—Dodecyl propionate, rat pup, preputial gland, maternal behavior, anogenital licking, pheromone.

INTRODUCTION

The anogenital area of Wistar rat pups was shown to be very attractive to the dam (Charton et al., 1971). Brouette-Lahlou et al. (1991) have demonstrated recently that this attraction is a result of preputial gland secretion in pups; olfactory cues alone support this. This attraction is an important link in the mother–young bond. It regulates anogenital licking, a fundamental pattern of maternal care, crucial to pup survival (Brouette-Lahlou et al., 1991). Can this secretion act as a pheromone-like factor?

In insects, many pheromones have been identified since bombykol was isolated in 1959. In mammals, pheromones have been studied to a lesser degree, and sexual odors are most generally thought to sustain pheromonal activity. Many of these odors have been described, but only a few have been isolated and identified. First results were reviewed by Wheeler (1976), Albone (1977), and Müller-Schwarze and Mozell (1976). The concept of pheromones in mammals is now reviewed (Brain et al., 1987). As far as maternal behavior is concerned, dimethyldisulfide (DMDS) was shown to act as a nipple attachment pheromone in pup rats (Pederson and Blass, 1982); odor cues releasing nipple search behavior and nipple attachment are known to be present on the mother's ventral skin and on the nipples. Leon (1983) hypothesized that pup saliva, maternal saliva, and amniotic fluid all contain DMDS and that the pups respond to a single cue throughout lactation. In rabbits, the pheromone induced in nipple searching behavior has not yet been identified (Hudson and Distel, 1983); it appears to form a gradient on the doe's ventral skin, increasing in strength toward the nipples. The possibility that responsiveness to the pheromone is acquired in utero is not excluded (Hudson and Distel, 1984). In the same way, a maternal pheromone from feces of the rat dam promotes brain development in rat pups (Lee and Moltz, 1984): when pups were denied ingesting maternal feces, the reciprocal weight of the whole brain, cerebrum and cerebellum to body weight was significantly lower than in 21-day control young. The retardation in brain development was reflected in experimental young at 21 days in retarded motor development. The chemical nature of the maternal pheromone is not yet known. Moreover, pheromonal emission by pregnant rats protects pups against infanticide (Menella and Moltz, 1989).

In the mother–young bond, a chemical substance from amniotic fluid plays an important role in some species; amniotic fluid influence was well demonstrated in parturient ewes by Levy and Poindron (1984). In goats (Stoddart,

1976), the doe's first reaction is to lick the traces of birth fluid and membranes from the kid; if the kids are taken away before she has a chance to establish any contact with them, rejection in the form of butting and biting of the kid occurs in almost all cases. In rats, both parturient rats and a large percentage of virgin rats avidly consume placenta (Kristal et al., 1981), but the elimination of the ingestion of placenta at parturition by a previously induced taste aversion did not lead to obvious deficits in maternal behavior (Engwall and Kristal, 1977). In fact, results leading to the conclusion that amniotic fluid plays a role in the acceptance of new born rats were obtained in virgins and not in the lactating female (Mayer and Rosenblatt, 1980). Our recent work (Brouette-Lahlou and Vernet-Maury, 1991) is in accordance with these results: in the rat, amniotic fluid is not involved in the mother–young bond. It shortens the maternal sensitization latency in virgins, but it seems to be a negligible stimulus in lactating female rats.

Chemosignals from pup urine were found to be effective on contact, picking-up, retrieval, licking, and nest building by dams and may act as infant signals (Londei et al., 1989): the authors suggested that the urine might leave a persistent chemical signal on the skin of the pup and that this signal could contribute to symbolizing the infant identity. In mammals, these chemical substances are produced mainly by cutaneous glands. In a recent work, Vernet-Maury and Brouette-Lahlou (1985) identified pups' preputial glands secretion as the source of chemosignals regulating dams' specific behavior consisting of licking pups' anogenital areas. These glands were established by Moore and Samonte (1986) as providing chemosignals for maternal discrimination of a pup's sex, thus confirming the authors' previous work (Vernet-Maury and Brouette-Lahlou, 1985; Vernet-Maury et al., 1987).

Unique hypertrophic apocrine sweat glands are described in the neck, perineal, and inguinal skin of mink kids (Yager et al., 1988). These glands enlarge only after birth, regress rapidly and become vestigial by weaning age. Behavioral studies indicate a possible role for the glandular secretion in maternal recognition of the young.

Preputial glands also were described in sympatric voles (Welsh et al., 1988). Gas-chromatographic analysis revealed that the preputial glands of *Microtus montanus* contain a series of species-typical lipids that are not found in *Microtus pennsylvanicus*. Using gas chromatography–mass spectrometry and nuclear magnetic resonance spectrometry, the species-typical lipids were identified as esters of branched, saturated, and unsaturated C-5 and C-4 alcohols and straight-chain C-16, and iso branched C-17 fatty acids.

It is well known that the pup rat, born immature, has to be licked to be able to defecate; therefore, anogenital licking constitutes a fundamental pattern of maternal behavior. Thus, the analysis of preputial gland secretions responsible for this behavior is of the highest importance.

The aim of the study is to identify the chemical structure of the active part of the preputial secretion and investigate its contingent identification.

METHODS AND MATERIALS

Animals

Forty litters of primiparous, lactating females (Wistar SPF), each with eight pups, were involved in the experiment. Each behavioral test was performed on 20 dams.

Preputial glands are bilaterally symmetrical subcutaneous organs located on each side of the midline genitalia. Their excretory ducts run along the lateral surface of the penis or clitoris and empty via a pinpoint opening on the side of the urethral meatus; they do not connect with the terminal urethra. The glands can easily be detected through the still hairless skin in young pups.

The secretions were obtained(1) By pressing the preputial glands of the oldest pups (from 7 days old).(2) By extraction with the aid of a special glass syringe for the younger pups; in this case, the sterile needle of a sterile syringe containing dichloromethane as a solvent was introduced into gland openings. The preputial secretions thus obtained were dissolved in a lipophilic solvent (dichloromethane), as a lipidic nature of the secretions was suspected (Vernet-Maury and Brouette-Lahlou, 1985). We thus obtained the lipidic extract. (3) By gently stroking pups' (male or female) genitalia with cotton swabs impregnated with distilled water anogenital smears were obtained from perineal secretions. Perineal secretions also were obtained, paying attention not to remove urine and feces. Stroking was stopped before urine and/or feces were released. The glandular secretion was obtained from pups of various ages from birth to weaning: 10–100 pups were used according to pups' ages.

Chromatography and GC-MS Analyses

Material Used. In a first experiment, analytical chromatography (Intersmat IGC 120 DFB with flame ionization detector) with a packed column silicone oil (SE 30) was used to study the preputial gland lipidic extract, as first described by Beaver (1960), for adult rats. In a second experiment, a far more efficient capillary column chromatograph (with a OV-101, silicone oil, 25-m-long column, flame ionization detector) was used. To identify the signals, a third experiment using combined gas chromatography and mass spectrometric analysis was undertaken. A Perkin Elmer Sigma 3B chromatograph with a CP SIL5, 25-m-long column and helium as the carrier gas, and a VG 70-70 F mass spectrometer were used (Figure 1).

Organic Compounds and Mass Analysis. Isopropyl myristate (IM),

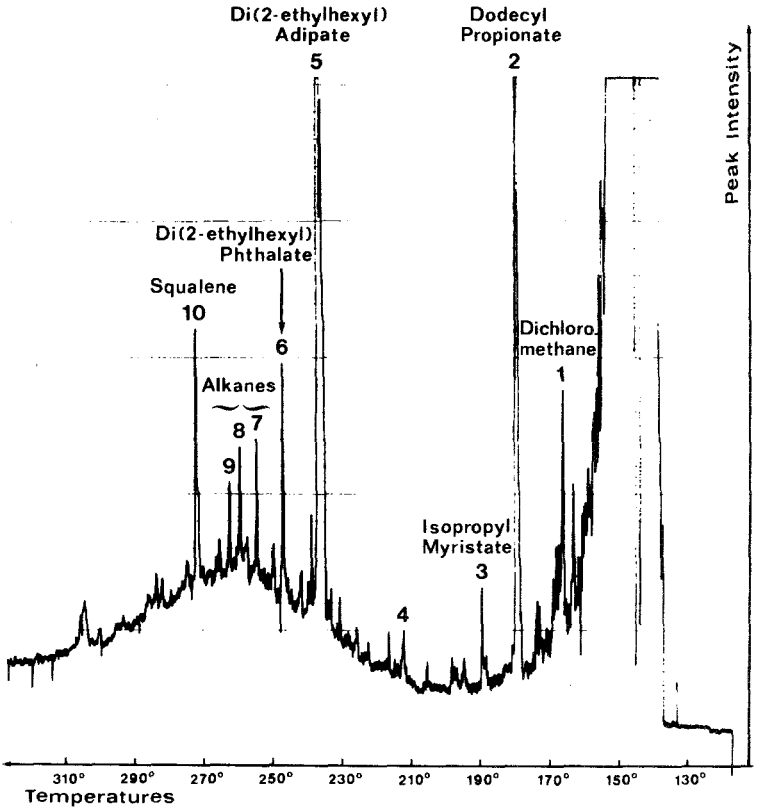

FIG. 1. Capillary column chromatogram (Perkin Elmer Sigma 3B); gas chromatography (GC): SIL 5, 25-m column, vector gas helium; injection temperature 250°C, four temperatures 100–310°C). Each compound giving raise to a signal is analyzed by mass spectrometry (coupled GC-MS) (see Figure 3).

di(2-ethylhexyl) adipate (EHA), and di(2-ethylhexyl)phthalate (EHP) are commercially available. Dodecylpropionate (DP) was synthesized by esterification of propionic acid with *n*-dodecanol (H_2SO_4, 12 hr, reflux), and distilled (bp_{0-1} = 77°C). Mass spectra were performed on a Varian MAT CH5 apparatus (70 eV) and compared with those of the natural extracts.

Behavioral Tests

Tested Odors. The above chemical compounds were compared with natural secretions (anogenital smears) or lipidic extracts obtained from preputial glands contents, using behavioral tests. Pure or mixed chemical compounds

were used according to the relative magnitude of their observed signals in the chromatographic analysis of the natural secretions.

Choice Behavior with Dual-Choice Apparatus. Two identical, perforated containers, depth 30 mm, diameter 50 mm with 6-mm holes at their facing extremities, were fitted to the opposite sides of a cage identical to dams' home cages. Dams were given access to this test cage 24 hr before the experimental test with a view to familiarizing them with these new surroundings (this experimental device has been fully described elsewhere (Brouette-Lahlou et al., 1991). For each test, these two perforated containers contained cotton swabs impregnated either with the sample to be tested or with (1) the control made up of evaporated dichloromethane used as a lipophilic solvent (organic compounds or lipidic extracts) or (2) distilled water (perineal smears). These containers were presented to 20 dams in a dual-choice test. Sniffing times toward the odorous or control container were recorded in a 3-min observation schedule.

Choice Behavior with Glass Dish Selection Test. In order to observe the choice and any ingestive behavior toward active compounds, 20 dams had access to three dishes containing preputial secretions: (A) from eight, 6-day-old pups (male or female), or (B) an equivalent male adult preputial secretion versus (control C) a 1-cm^2 filter paper impregnated with 0.5 ml distilled water. Similarly, after identifying the active compound, 20 dams were observed in the presence of the same dishes containing filter paper impregnated with (1) 0.5 ml dichloromethane with adequate concentration (8 ng) of the synthetic active identified component (D) or with (2) 0.5 ml dichloromethane (control E). Sniffing and any ingestion of contents (filter paper or glandular secretions) by dams from the glass dishes were recorded in a 3-min observation schedule.

RESULTS

Chromatographic Analyses

After preliminary analysis in which two signals were observed, capillary column chromatography separated more than 10 signals (Figure 1). GC-MS results were analyzed with the aid of computerized data bases. Excluding solvent and minor components, eight molecules were identified: dodecyl propionate (DP), (Figures 2 and 3); isopropyl myristate (IM), di(2-ethylhexyl)adipate (EHA), di(2-ethylhexyl)phthalate (EHP) (a well known chromatographic pollutant), and hydrocarbons of high molecular weight (waxes) (signals 7–10). As previously demonstrated (Vernet-Maury et al., 1987), only DP, IM, and EHA might have functioned as the active agents and would have to be subjected to further analysis.

The mass spectra of independently obtained DP, IM, EHA, and EHP were compared to those obtained from GC-MS analyses. The mass spectra were found

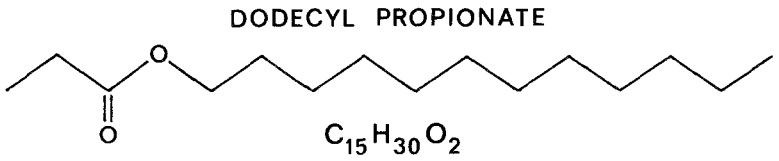

FIG. 2. Dodecyl propionate. Its molecular mass (242) is in agreement with typical values for pheromones (80–300).

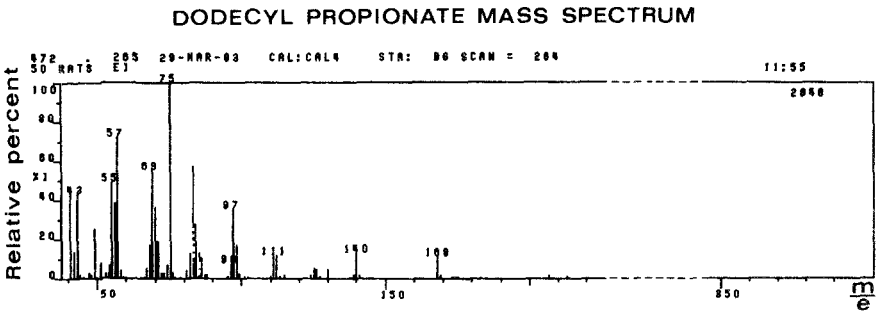

FIG. 3. Mass spectrum of dodecyl propionate (DP) as obtained from joint GC-MS analysis of the preputial extract, identical to the spectrum of the synthesized DP (VG 70-70F mass spectrograph, ionization energy 70 eV, intensity 200 μA, source temperature 200°C). Ion relative intensity (percent of the main ion) is plotted vs . ion ratio of charge to mass (m/e). The retention time of the corresponding signal on the chromatogram is indicated on the right (here 11 min, 55 sec). The main ions observed on the DP spectrum are typical of a propionate (m/e = 75) and of a $C_{12}H_{24}$ fragment (m/e = 168) that corresponds to a six-center rearrangement with expulsion of a neutral molecule of propionic acid and ion $[CH_3-(CH_2)_9-CH=CH_2]^+$. All mass spectra were analyzed and the chemical structures determined by comparison with computerized data bases from Dr. Stoffelsma's laboratory in Amersfoort.

to be clearly identical (the same ionized fragments were observed in both samples) (Figure 3 for DP). These results confirmed the chemical identification of DP, IM, EHA, and EHP. These four chemical compounds were then further studied in behavioral tests. According to the relative magnitude of the chromatographic signals, we used 8.3 ng of DP, 2 ng of IM, 8 ng of EHA, and 6 ng of EHP.

Behavioral Tests

The dams' responses in the dual-choice apparatus are plotted in Table 1. Only DP, either pure or mixed, attracted the dams. The other compounds isolated from pups' preputial glands were not detected significantly. The mixture

containing DP was efficient, but less so than pure DP (Table 1). With regard to dams' sniffing times, statistical differences between the odorous box and control box (Wilcoxon test) emerged for only three stimuli: anogenital smears, lipidic extracts from pups' preputial secretions, and DP; sniffing time was statistically longer toward these three stimuli. Moreover, from a Friedman analysis of variance, no difference was found between the dams' responses to these three stimuli ($\chi_r^2 = 2.9$; $P > 0.2$). In the same way, licking sequences toward the odorous box were observed only in response to DP and natural secretion, smears, or lipidic extract. In consequence, it can be concluded that DP (Figure 2) was the active part of all the extracts, and other tests were undertaken to justify this proposal.

As a main result obtained from the glass dish selection test, a specific ingestive behavior pattern on the part of the dam toward the contents of dishes A and D was observed: 14 dams from 20 actually ate the contents of dish A (pups' preputial gland secretion) (binomial test, $N = 20$, $X = 6$, $P = 0.058$) and 17 dams from 20 ate the contents of dish D (filter paper impregnated with DP) ($N = 20$, $X = 3$, $P = 0.001$). There was no significant difference in the dams' ingestive behavior toward DP (D) and natural secretions (A) (χ_r^2 test =

0.29, $df = 1$, $P > 0.50$). No dam ate the contents of other dishes: adult male preputial gland secretions or control filter papers (B, C, E).

DISCUSSION

Combined gas chromatography–mass spectrometry allowed us to isolate the active part of pups' preputial gland secretion implicated in dams' specific behavior: anogenital licking (AGL). Results obtained from the dual-choice apparatus established that DP is significantly more attractive than the other compounds isolated from rat pups' preputial glands. This attractiveness equaled that of preputial secretions themselves. Dams' ingestive behavior in the dish selection test confirmed the presence and activity of DP within natural preputial gland secretions and suggested that DP is the active part of the preputial gland secretion for which a pheromonal action was originally postulated. The characteristic ingestive behavior induced by DP or natural secretions renders inapplicable the classical criticism addressed to behavioral observations in response to odorants: a specific chemical or blend of chemicals does not elicit behavioral responses other than aspecific sniffing in mammals (Johnston, 1983).

From GC-MS analysis, the DP chemical structure was elucidated and was proven to be in accordance with previous work on rat preputial gland secretion (Stacewicz-Saptuntzakis and Gawienowski, 1977): analysis of the male preputial gland volatiles indicated the presence of ethyl, propyl, isopropyl, pentyl, and decyl acetates among other compounds, i.e., *n*-aliphatic acetates. Pietras (1981) reported that in the lipid composition of rodent preputial glands, wax esters predominate in the neutral lipid fraction, and that other significant classes include glyceryl ether diesters, triglycerides, and sterol esters. The description of such esters from preputial gland secretions confirms our preliminary results (Vernet-Maury and Brouette-Lahlou, 1985) and was verified recently in voles' preputial glands by Welsh et al. (1988). It should be added that esters are widely described in the pheromonal activity of numerous insects, particularly in *Drosophila* (Schaner et al., 1989; Collins and Cardé, 1989; Kou et al., 1989).

Furthermore, Gawienowski et al. (1976) pointed out many preputial components with molecular weights up to approx. 200 from rat preputial gland attractants, while Pietras (1981) estimated these molecular weights from 80 to 300. DP molecular weight (242) is in accordance with these previous values. The low volatility of DP may explain dams' behavior in the dual-choice apparatus: characteristic sniffing behavior is observed only when the dam's nose is about 5 mm from the perforated cover of the test container; vibrisse movements could be seen, sometimes associated with box-cover licking by dams.

Taking into account our recent statement (Brouette-Lahlou et al., 1991) resulting from behavioral assays led us to argue in favor of DP pheromonal activity; DP may act typically as a regulator but not as a signaling substance.

It is well known that preputial gland secretion provides a vehicle for sex pheromones. In mice, they possibly promote an aggression odor (Mugford and Nowell, 1971). In adult rats, the pheromonal nature of preputial gland secretion was well established by Pietras (1981); rat preputial glands elaborate a sex attractant pheromone. Therefore, the preputial gland functions in pups during the neonatal period are different: they produce chemosignals that are used by dams to sustain AGL behavior.

It must be noted that this attractant consists of one active compound only. Unlike insect pheromones, in which a "bouquet phéromonal" has been described (Masson and Brossut, 1981), and also unlike DMDS, which acts in conjunction with other active compounds, DP is as efficient as the whole preputial gland extract. Our ontogenetic analysis (Vernet-Maury et al., 1987) of the pups' preputial secretions confirms this particularity: when the dam begins to perform AGL, about 3 hr after the pup's birth, DP is the only active compound present in the anogenital smears.

Could this identification of the active part of pups' preputial gland secretion be helpful in explaining the mechanisms involved in dam AGL behavior? This would be of major interest, since after removal of the pups' preputial glands, AGL is disorganized: licking time is increased and some pups are never licked, and die (Brouette-Lahlou et al., 1991). The identification of the active part of pups' preputial gland secretion is the first description of such an ester in mammalian infants.

WIND-TUNNEL STUDY ON ATTRACTION INHIBITOR IN MALE *Coleophora laricella* Hbn. (LEPIDOPTERA: COLEOPHORIDAE)

PETER WITZGALL [1] and ERNST PRIESNER

Max-Planck-Institut für Verhaltensphysiologie
8131 Seewiesen, Germany

(Received November 26, 1990; accepted March 4, 1991)

Abstract—Modifying effects of (*Z*)-5-decenyl acetate, an attraction-inhibitor of male *C. laricella*, were studied at different levels of the pheromonal behavioral sequence. When blended with the attractant alcohol (*Z*)-5-decen-1-ol, 0.001% acetate significantly reduced and 1% almost abolished orientation flights followed by landing at the source. By contrast, 1000% of the acetate placed 5 cm apart did not suppress orientation flights to the alcohol source. Differential modifying effects of the acetate in blends vs. separate sources also occurred with respect to orientation flight duration, landing position, close-range behavior at the source, and the rate of unsuccessful orientation attempts. Our findings support the view that, in *C. laricella*, pheromonal inhibition results from simultaneous (as opposed to intermittent) perception of attractant and inhibitor. The various effects of the inhibitory acetate observed in the wind tunnel compare to results of earlier field observations.

Key Words—Pheromone, attraction inhibitor, (*Z*)-5-decen-1-ol, (*Z*)-5-decenyl acetate, orientation behavior, wind tunnel, *Coleophora laricella*, Coleophoridae, Lepidoptera.

INTRODUCTION

The suppression of pheromonal orientation by structurally related chemicals is a well-known phenomenon in Lepidoptera. Such "attraction inhibitors" or "pheromone-response antagonists" have been widely demonstrated by field

[1] Present address: Department of Ecology, Lund University, Helgonavägen 5, 223 62 Lund, Sweden.

0098-0331/91/0700-1355$06.50/0

trapping experiments, but there are few attempts to analyze their mode of behavioral action.

Earlier field studies have shown that (Z)-5-decen-1-ol (Z5–10:OH) is a strong attractant for male larch casebearer moths *Coleophora laricella* Hbn. (Priesner et al., 1982). This compound induces a sequence of pheromonal actions in wild males: activation from rest, upwind orientation flight, and close-range behaviors near the source after landing (Witzgall and Priesner, 1984). The corresponding acetate (Z5–10:Ac) is an attractant for various other *Coleophora spp.* (Priesner, 1987), whereas in *C. laricella* this compound strongly reduces trap catches when added to the attractant alcohol (Priesner et al., 1982). Field observations indicated multiple behavioral effects of this inhibitor (Priesner and Witzgall, 1984) and prompted the present wind-tunnel study.

METHODS AND MATERIALS

Insects. Male *C. laricella* were collected as pupae at several locations in southern Germany and the Swiss Alps. The time lag in adult emergence between these different sites permitted us to conduct experiments for about eight weeks, although local flight periods in the field last only one to three weeks (Witzgall, 1985). Pupae and adults were held under a 16:8 light–dark photoperiod.

Wind Tunnel. The tunnel was the one used by Preiss and Priesner (1988). The upwind and downwind ends of the flight compartment (80 × 50 × 50 cm) were covered by black screen. Air (20–22°C) was pulled through the tunnel at 0.25 m/sec and blown out of the building. The tunnel was lit diffusely from above at about 1000 lux.

Chemicals. The two compounds used in this study, Z5–10:OH and Z5–10:Ac were obtained from Dr. S. Voerman, Wageningen. Isomeric purity was approx. 99%. The compounds were applied as hexane solutions to filter paper (1.5 × 1.5 cm).

Stimulus Application. Blends of Z5–10:OH and Z5–10:Ac, and the respective amount of Z5–10:OH alone were tested using a single filter paper held by thin wire inside the tunnel, 1 cm from the upwind screen and 30 cm above the tunnel floor. In tests with separate sources, the two filter papers were fixed, at this position, 5 cm from each other perpendicular to the airstream. For a dosage series of pure Z5–10:OH, the filter paper was positioned inside a conical glass tube, which touched the upwind screen from outside, as in Preiss and Priesner (1988).

Test Procedures. For each test, one to five males were placed in a cotton-screen cage (10 × 8 × 8 cm) at 70 cm downwind from the source(s). Males were exposed to the test chemicals for 1 min. After opening the cage, responses were recorded over 5 min. Countings were made of (1) males leaving the hold-

ing cage by flight; males flying upwind and landing at either (2) <5 cm or (3) >5 cm from the attractant source; and (4) males flying upwind without reaching the source (interrupted orientation flights). Duration of upwind flight (from initiation of oriented flight to landing at the source) and close-range behaviors (walking or sitting on the upwind screen at <5 cm from the source) were taped. Flying males were recorded by two video cameras placed above and at the side of the tunnel. Males were tested once, at the end of the light period.

Test Program. Responses to pure Z5–10:OH were studied over eight decadic dosages, 10^{-5}–10 μg (N = 57–125 males). Blend sources were made of 10^{-1} μg Z5–10:OH plus 10^{-6}–10^{-1} μg Z5–10:Ac (N = 41–94); separate sources of 10^{-1} μg Z5–10:OH and 10^{-6}–1 μg Z5–10:Ac (N = 47–85). Each treatment was tested on at least four days. After an arcsin transformation of the percentages of males showing a specific behavior during each test session, we calculated an analysis of variance, followed by a Duncan test (P = 0.05).

RESULTS

Sources of Z5–10:OH. Behavioral responses of *C. laricella* males to different amounts of pure Z5–10:OH were studied with the source placed in the glass tube applicator. For the seven test doses, 10^{-5}–10 μg, takeoffs from the holding cage during 5 min ranged from 47.4% to 94.1% (Figure 1), compared to 57.9% on stimulation with air alone. Oriented upwind flights followed by landing near the source were displayed by 9.3% of the test males at 10^{-4} μg, while the response rate raised to 68.8% at 10^{-1} μg, but declined to 46.2% at 10 μg. At 10 μg the rate of interrupted upwind flights rose to 11%. The lowest dose of 10^{-5} μg did not elicit upwind flight attempts (Figure 1).

Mean flight duration, from initiation of upwind orientation until landing, ranged from 17.0 $\pm$ 16.3 sec at 10^{-4} μg to 22.9 $\pm$ 14.7 sec at 10 μg. Of the males reaching the source, 79.2% landed within 5 cm from the applicator outlet at 10^{-1} μg, but only 40.0% at 10 μg (Figure 1). Their mean stay within this 5 cm range was longest (37.8 $\pm$ 22.2 sec) at 10^{-2} μg and shortest (17.2 $\pm$ 13.3 sec) at 10 μg.

In addition to the rate of complete orientation flights, three further effects of increasing the amount of Z5–10:OH are apparent from these data: a longer duration of upwind flight, a tendency to land at a greater distance from the source, and a shorter stay near the source after landing.

Z5–10:Ac additions, considered further below, were mainly made to 10^{-1} μg of Z5–10:OH. This amount of Z5–10:OH was accordingly also tested with the filter paper placed inside the tunnel (rather than in the applicator). Responses were as follows: 94.6% males left the holding cage by flight, 3.2% males initiated upwind flight without reaching the source, 66.7% oriented upwind and

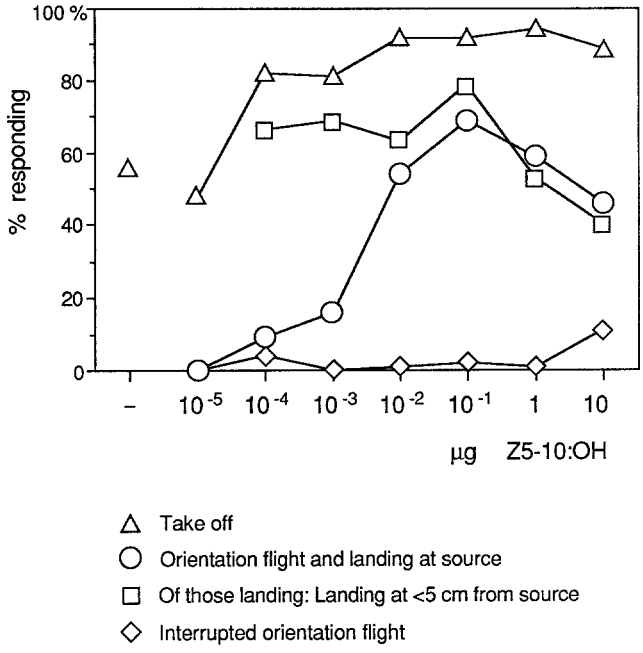

FIG. 1. Responses of *C. laricella* males to varying amounts of attractant alcohol Z5-10:OH in the wind tunnel.

landed near the filter paper; of those, 78.4% landed within 5 cm from the source (Figure 2). Mean flight duration to the source was 16.6 ± 11.3 sec and duration of walking within 5 cm from the source was 32.5 ± 22.5 sec.

Blend Sources of Z5-10:OH/Z5-10:Ac. Single filter papers containing Z5-10:OH (10^{-1} µg) plus Z5-10:Ac (10^{-6} µg to 10^{-1} µg) were placed inside the tunnel. For these six blends, male takeoffs ranged from 81.5% to 97.6%. The $10^{-1}/10^{-6}$ µg and $10^{-1}/10^{-5}$ µg blends elicited complete orientation flights from 39.2% and 40.4% males (significantly less than with 10^{-1} µg of Z5-10:OH alone), of these 56.9% and 42.6% landed at <5 cm from the source (Figure 2A). Flight durations in response to these two blends were 22.1 ± 11.3 sec and 23.7 ± 15.2 sec; the mean stays within the 5 cm range were reduced to 15.7 ± 13.7 sec and 18.4 ± 16.7 sec.

Only 9.6% to 3.7% test males successfully oriented to either the $10^{-1}/10^{-4}$ µg, $10^{-1}/10^{-3}$ µg, or $10^{-1}/10^{-2}$ µg blends (Figure 2A). All but one landed at >5 cm from the source. Interrupted orientation flights, rarely seen in tests of 10^{-1} µg Z5-10:OH alone (Figure 1), were observed with 10.6% to 28.9% males in response to the $10^{-1}/10^{-6}$ µg to $10^{-1}/10^{-3}$ µg blends. The $10^{-1}/10^{-1}$ µg blend did not elicit any upwind flights (Figure 2A).

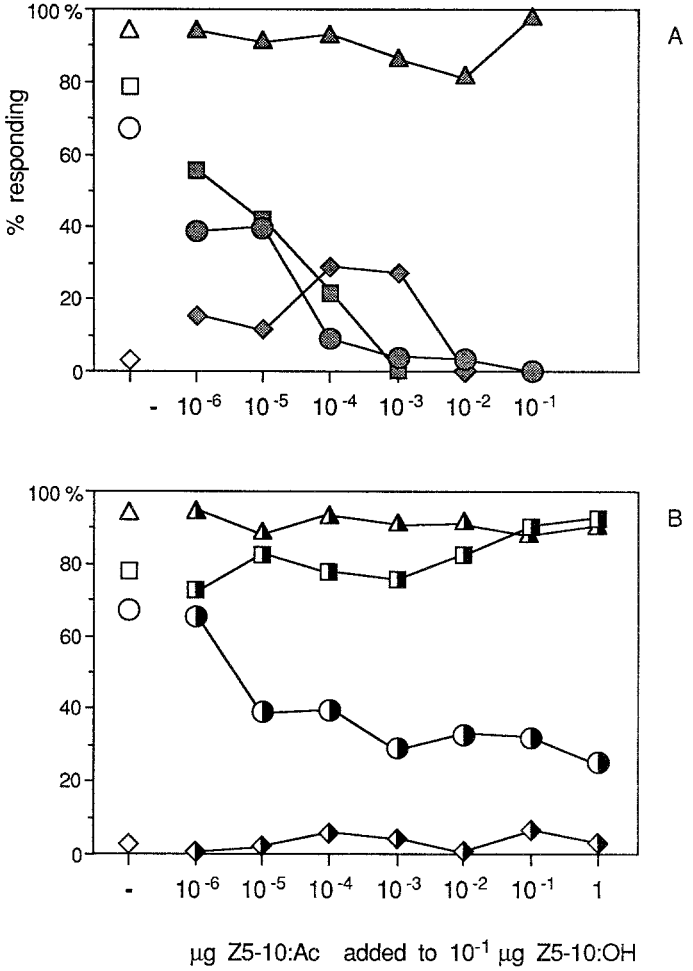

FIG. 2. Responses of *C. laricella* males to 10^{-1} µg Z5 -10:OH plus varying amounts of Z5 -10:Ac in the wind tunnel. (A) Blend sources; both compounds applied to the same filter paper. (B) Separate sources; compounds applied to two different filter papers placed 5 cm apart and perpendicular to the airstream. Plot symbols as in Figure 1.

These data show that Z5–10:Ac, when blended with the attractant alcohol Z5–10:OH, modifies the pheromonal behavior of *C. laricella* males in several respects: the rate of orientation flights to the source decreases, whereas the rate of interrupted flights increases; males land at a greater distance from the source, and they spend less time near it. The most sensitive behavioral criterion was the rate of successful orientation flights, which was significantly lower on addi-

tion of only 0.001% Z5-10:Ac (blend ratio $10^{-1}/10^{-6}$ μg). Visual inspection of video recordings showed that flights towards blends were rather erratic with wide excursions as compared to flights to alcohol alone.

Separate Sources of Z5-10:OH and Z5-10:Ac. The effects of seven different doses of Z5-10:Ac on responses to 10^{-1} μg Z5-10:OH were studied by placing the two filter papers 5 cm apart. Takeoff rates ranged between 88.9% and 95.7%. The rate of orientation flights that led to landing near the 10^{-1} μg Z5-10:OH source was not altered (65.9%) by 10^{-6} μg, but was significantly reduced (38.1%) by 10^{-5} μg Z5-10:Ac, decreasing further (25.5%) for the highest Z5-10:Ac dose of 1 μg (Figure 2B). In an additional test ($N = 49$ males), 10 μg of the acetate was placed only 1 cm from the 10^{-1} μg Z5-10:OH source. Even with this 100-fold amount of the "inhibitor," eight males still reached the Z5-10:OH source by oriented flight.

As in tests with blends, rapid changes in flight direction were observed frequently at some distance from the two sources, whereas over the last 20–30 cm males were often seen to advance to the alcohol source in rather straight flight. Accordingly, mean flight duration continually decreased with the dose of the separate Z5-10:Ac source, from 16.2 ± 9.7 sec at 10^{-6} μg to 8.4 ± 2.5 sec at 1 μg.

For all Z5-10:OH/Z5-10:Ac combinations, the majority of males that reached the Z5-10:OH source landed within 5 cm of it, such as in tests with 10^{-1} μg Z5-10:OH alone; at the high acetate doses of 10^{-1} μg and 1 μg even 90.5% and 92.7% (Figure 2B). After landing, the males generally remained longer within the 5 cm range compared to tests of Z5-10:OH alone; their mean stay within this area ranged from 38.2 ± 21.1 sec to 73.9 ± 58.3 sec for the different Z5-10:OH/Z5-10:Ac combinations. No landing responses directed to the Z5-10:Ac rather than the Z5-10:OH source were seen.

From these data, the following effects of a separate Z5-10:Ac source on responses of *C. laricella* males to Z5-10:OH are apparent: less males orient successfully towards the attractant source, flight duration is shorter, males land closer to the source and stay longer near it after landing. The separate Z5-10:Ac source did not raise the rate of uncompleted orientation attempts, thus again differing from its effects in the blend source tests.

DISCUSSION

As with "pheromone inhibitors" in other Lepidoptera, the effect of Z5-10:Ac on pheromonal attraction of *C. laricella* to Z5-10:OH was first established by field tests, using compound blends released from the same dispenser (Priesner et al., 1982). However, subsequent field observations showed quite

contrasting effects between blends and separate sources of attractant and inhibitor (Priesner and Witzgall, 1984).

The behavioral effects of the inhibitory acetate observed in this wind-tunnel study and the field (Priesner and Witzgall, 1984) appear analogous. In both tests, even small amounts of acetate in the blend reduced the rate of upwind flights to the source, induced landings further away from the source, and shortened the duration of postlanding behaviors. With separate sources of attractant and inhibitor, even high amounts of the acetate inhibitor did not suppress orientation flights, but flight duration was shorter and landings were directed closer to the alcohol source, both in the laboratory and the field.

The successful orientation of *C. laricella* males to a source of Z5–10:OH with a high dose of Z5–10:Ac placed only a few centimeters apart shows that the odor filaments emanating from the two sources were sufficiently separated to be distinguished by the flying moths, a conclusion compatible with current concepts of fine-scale characteristics of odor plumes (Murlis and Jones, 1981). Sanders (1981) expressed the view that a male moth, flying in an atmosphere permeated with attractant and inhibitor released from separate sources, would move towards the source as long as he encounters "pockets" of pure attractant.

In this context it has been proposed that the contrasting behavioral effects of the inhibitory Z5–10:Ac, on male *C. laricella*, observed in blend-source vs. separate-source experiments are primarily due to a different temporal pattern of perception of the two compounds (Priesner and Witzgall, 1984). It is, according to this view, the simultaneous (as opposed to intermittent) stimulation of the Z5–10:OH and Z5–10:Ac receptor neurons which appears to be particularly "inhibitory."

Some behaviors observed with separate attractant and inhibitor, such as landings closer to the alcohol source or certain modifications of flight tracks (Priesner and Witzgall, 1984), even suggest that males reduce perception of the acetate by active movements.

Using the same wind-tunnel setup, Preiss and Priesner (1988) studied effects of several attraction inhibitors in *Laspeyresia pomonella* as reflected by orientation flight rates and landing responses towards blend sources. Similarly, in wind-tunnel studies on *Trichoplusia ni*, *Mamestra suasa*, and *Ostrinia nubilalis*, antagonistic effects of chemicals blended with pheromone were evaluated by arrestment of upwind flight (Linn et al., 1984; Frérot et al., 1989; Glover et al., 1989). In male *Lymantria dispar*, the inhibitory (−)-enantiomer of disparlure lowered the percentage of males initiating upwind flight and reduced stabilization of altitude and speed during tethered flight but had little effect on preflight or postlanding male responses (Cardé and Hagaman, 1979; Cardé, 1981; Preiss and Kramer, 1983; Preiss, 1985). As shown here for *C. laricella*, an "attraction inhibitor" may affect not only upwind orientation flight but also

other pheromonal behaviors and may have quite contrasting modifying effects depending on its presentation with the pheromone stimulus.

Acknowledgments—We thank Dr. R. Preiss, Hamburg, for the use of his wind tunnel and Dr. J.A. Byers, Lund, for comments on the manuscript.

Abstract—The vertebrate hormone deoxycorticosterone is the most commonly occurring component of defensive secretions from aquatic beetles in the family Dytiscidae. Deoxycorticosterone and the structurally related steroids pregn-4-en-20α-ol-3-one and pregn-4-en-20β-ol-3-one were tested for their ability to inhibit feeding by bluegill sunfish, *Lepomis macrochirus*, in laboratory assays. Deoxycorticosterone at oral doses of 660 μg (2×10^{-6} mol) per pellet caused 94% inhibition in the acceptance of artificial food pellets. At the same molar dosage, pregn-4-en-20α-ol-3-one inhibited food consumption by 58%, while its epimer, pregn-4-en-20β-ol-3-one, did not significantly inhibit feeding. These results indicate that specific stereochemical conditions must be satisfied for the pregnenes to be noxious to *L. macrochirus* and suggest the existence of a receptor–ligand interaction. The potency of the three steroids in assays of feeding inhibition contradicts earlier results based on toxicity and anesthetic assays in which fish were immersed in solutions of steroids.

Key Words—Deoxycorticosterone, pregnene, Dytiscidae, chemical defense, structure–activity relationships, bluegill sunfish, *Lepomis macrochirus*.

INTRODUCTION

Aquatic beetles in the family Dytiscidae secrete from the prothoracic glands a complex mixture of steroids. The prothoracic gland discharges to the outer sur-

*To whom correspondence should be addressed.

0098-0331/91/0700-1363$06.50/0

face of dytiscid beetles and secretions of the gland provide a chemical defense against potential predators (reviewed by Scrimshaw and Kerfoot, 1987). A major component of the prothoracic secretions is the "vertebrate" hormone deoxycorticosterone (Schildknecht et al., 1966), an adrenocortical steroid that is involved in the regulation of salt and water balance. Pregnene derivatives structurally related to deoxycorticosterone also are present in the prothoracic secretions of dytiscid beetles.

Predatory fish reject dytiscid beetles, and fish immersed in aqueous solutions of dytiscid steroids become anesthetized and eventually die (Selye and Heard, 1943; Miller and Mumma, 1976a,b). The relative potencies of steroidal components of dytiscid secretions have been quantified using these toxicity assays (Miller and Mumma, 1976a). In toxicity assays, aqueous solutions of test agents are in contact for extended periods of time with the gill membranes and other external surfaces of fish. Miller and Mumma (1976b) suggested that the defensive steroids acted through the destabilization and lysis of fish membranes. Alternatively, the defensive steroids may be sensed by olfactory and/or gustatory receptors of fish and perceived as noxious (Clayton, 1964; Miller and Mumma, 1976b). Fish that attack dytiscid beetles frequently do not swallow the insects but rather spit them out, apparently after sensing the noxiousness of the beetle (Scrimshaw and Kerfoot, 1987).

The goals of this study were to: (1) determine whether deoxycorticosterone and two related pregnenes from dytiscid beetles (Figure 1) were distasteful to

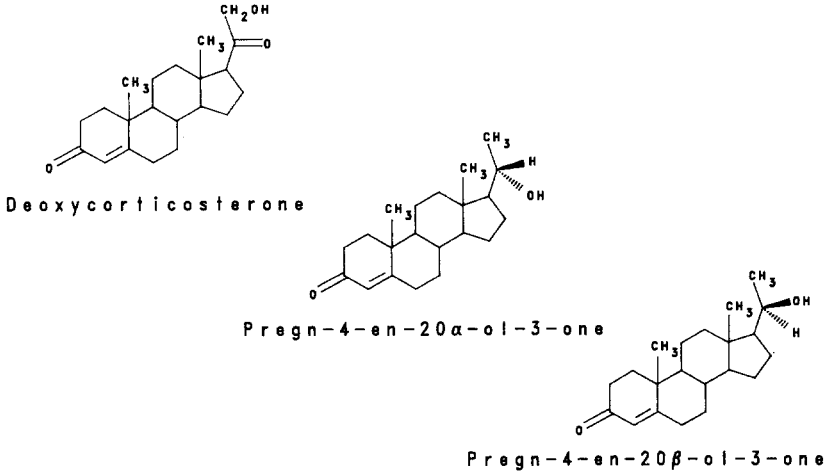

FIG. 1. Structures of deoxycorticosterone, pregn-4-en-20α-ol-3-one, and pregn-4-en-20β-ol-3-one. All three compounds are present in the prothoracic secretions of dytiscid beetles.

the sympatric, predatory fish *Lepomis macrochirus* (bluegill sunfish); (2) determine whether these three pregnenes varied significantly in their noxiousness to *L. macrochirus*; and (3) identify structural features of steroids associated with noxiousness to fish.

METHODS AND MATERIALS

Food pellets were produced by dissolving agarose in hot water to yield a 3% solution of agarose. Commercial fish food at a concentration of 5% (w/w) was added to the agarose as a flavoring agent. Deoxycorticosterone, pregn-4-en-20α-ol-3-one [= pregn-4-en-20(*S*)-ol-3-one], and pregn-4-en-20β-ol-3-one [= pregn-4-en-20(*R*)-ol-3-one, Figure 1] were dissolved in methanol to produce stock solutions of 1.8×10^{-1} M. Sufficient steroid solution then was dispersed through the agarose to yield 2×10^{-6} mol of steroid in a 50-μl aliquot of agarose mixture. Control pellets contained an equal amount of methanol but no steroids. Pellets were produced by cooling 50-μl aliquots of agarose mixture to room temperature. Steroid-treated pellets contained equimolar amounts of either deoxycorticosterone (660 μg), pregn-4-en-20α-ol-3-one (633 μg), or pregn-4-en-20β-ol-3-one (633 μg). Schildknecht (1971) noted that quantities of deoxycorticosterone can be as high as 1 m per beetle; therefore, the level of this steroid in the treated pellets was similar to levels that can occur in dytiscid beetles. The tested dosages of pregn-4-en-20α-ol-3-one and pregn-4-en-20β-ol-3-one were higher than those that occur in dytiscids and were employed to permit an assessment of potency relative to deoxycorticosterone.

Individual bluegill sunfish (*Lepomis macrochirus*) were placed in glass aquaria (25 × 15 × 18 cm) and randomly assigned to treatments. Following 24 hr of starvation, control and steroid-treated pellets were presented singly to the isolated fish in the following sequence: control pellet, steroid pellet, steroid pellet, control pellet. The initial action of each fish after pellet presentation was scored as acceptance (pellet swallowed) or rejection (pellet ignored or pellet mouthed and rejected). Only initial responses of the fish were used, since repeated mouthings and extended immersion can alter concentrations of test agents in the agarose pellets. The use of behavior scoring and sequential offering of single pellets allowed detection of facilitation or inhibition of feeding during the course of the experiment, such as satiation of the test fish or formation of a learned aversion to treated foods (Gerhart, 1984; Gerhart et al., 1988).

Rates of pellet acceptance for the different treatments were compared statistically using *G* tests for independence and employing Yates' correction (Sokal and Rohlf, 1981). Transition matrices (Legendre and Legendre, 1983) were constructed and analyzed to determine whether consumption or rejection of the

first treatment pellet significantly influenced the probability of consumption of the second. The percent inhibition of feeding caused by addition of each of the steroids relative to controls was calculated from the combined data. Inhibition was calculated as the difference between control and treatment acceptance rates, divided by the control rate.

RESULTS

Deoxycorticosterone significantly lowered rates of pellet acceptance relative to the rate of acceptance of controls (Figure 2A, Yates' corrected $G = 9.5$ for both the first and second treatment pellets, $df = 1$, $P < 0.005$). Pregn-4-en-20α-ol-3-one also significantly lowered rates of pellet acceptance relative to controls (Figure 2B; Yates' corrected $G = 8.6$, $P < 0.005$ for the first treatment pellet; Yates' corrected $G = 6.0$, $P < 0.025$ for the second treatment pellet; $df = 1$ for both comparisons). Addition of pregn-4-en-20β-ol-3-one did not significantly alter the rate of pellet acceptance relative to the rate of acceptance of control foods (Figure 2C; Yates' corrected $G = 0.04$; $df = 1$, $P > 0.5$).

The rate of acceptance of control pellets (Table 1) did not differ significantly between beginning and end of experiments for any steroid treatment (Yates' corrected $G < 0.6$, $df = 1$, $P > 0.1$ for each of the three treatments), or for the combined data for all experiments (Yates' corrected $G = 0.5$; $df = 1$, $P > 0.1$). Thus, there was no indication that fish became satiated through the course of the experiment. Furthermore, analysis of the transition matrices showed no sequence-dependent facilitation or inhibition (chi-square test for goodness of fit; $\chi^2 < 1.5$, $df = 3$, $P > 0.5$ for each treatment). Since there was no evidence that responses to the two treatment pellets were statistically dependent (Legendre and Legendre, 1983), the results for each of the three treatments were combined to calculate the relative potency of the steroids at the level employed in the feeding inhibition assays.

Analysis of the combined data (Table 2) showed that the degree of feeding inhibition was dependent upon the structure of the steroid added to the agarose pellets (Yates' corrected $G = 17.4$; $df = 2$, $P < 0.001$). Deoxycorticosterone was the most potent of the compounds, inhibiting pellet consumption by 94% relative to controls. Pregn-4-en-20α-ol-3-one was intermediate in potency, causing a 58% inhibition of feeding. Pregn-4-en-20β-ol-3-one, which did not significantly reduce pellet acceptance, inhibited consumption by 11%.

DISCUSSION

Deoxycorticosterone was the most active of the three steroids tested in this study. Pregn-4-en-20α-ol-3-one, which differs from deoxycorticosterone only in the structure of the C-17 side-chain (Figure 1), possessed decreased potency

Pregn-4-en-20α-ol-3-one	35 (*N* = 20)	58	0.620
Pregn-4-en-20β-ol-3-one	75 (*N* = 16)	11	0.113
Controls	84 (*N* = 56)		

in the bioassay. This result indicates that structure of the C-17 side-chain is important for inhibition of fish feeding.

Transformation of pregn-4-en-20α-ol-3-one to pregn-4-en-20β-ol-3-one by epimerization at carbon 20 is accompanied by a fivefold reduction in potency in the sunfish feeding assay. This high degree of stereospecificity suggests that, in order to be perceived as noxious by *Lepomis macrochirus*, dytiscid steroids must interact with gustatory receptors in the buccal or pharyngeal region of the fish. Detection of dytiscid steroids by the fish is followed by rejection of the food item.

The potency relationships of the three steroids differ from earlier relationships based on assays in which steroids were externally applied to fish. Miller

and Mumma (1976a) concluded that the steric positions of hydroxyl groups were of only slight importance with respect to potency of steroids in anesthetic and toxicity assays. Both Clayton (1964) and Miller and Mumma (1976b), however, suggested that the defensive properties of steroids could result from noxiousness and not from anesthetic or toxic properties. Assays of feeding inhibition mimic the way in which defensive steroids are delivered to potential predators more closely than do anesthetic or toxicity assays. Thus, the potency relationships found in this study should reflect more closely the defensive capability of dytiscid steroids in nature.

The potency of the three steroids as feeding inhibitors parallels the taxonomic breadth of distribution of the chemicals among families of aquatic beetles. Deoxycorticosterone, the most potent of the three tested steroids, is also the most broadly distributed prothoracic gland steroid in the family Dytiscidae, occurring in 15 species. Pregn-4-en-20α-ol-3-one, which was intermediate in effectiveness and 62% as potent as deoxycorticosterone at the tested levels, occurs in three beetle species. The least active of the three steroids, pregn-4-en-20β-ol-3-one, has been reported from two beetle species (Scrimshaw and Kerfoot, 1987). The two steroid epimers do not appear to co-occur in any single species of beetle (Scrimshaw and Kerfoot, 1987). Elegant studies have been performed to measure the chemical defensive titer of dytiscids and its rate of regeneration (Fescmeyer and Mumma, 1983). The results of the present study, however, suggest that the prothoracic gland steroids of dytiscids may not be equally potent predator deterrents. Future studies of the defensive titer of dytiscids may gain further insight by focusing on the steroids that are most effective at deterring predation.

Why do some species of dytiscid beetles contain significant quantities of pregn-4-en-20β-ol-3-one, as well as other pregnenes with a 20β-hydroxy functionality (Scrimshaw and Kerfoot, 1987), when these compounds appear to have little effectiveness against *Lepomis macrochirus?* One possible explanation is that the 20β-hydroxy steroids are effective against other predator species that have different steric requirements for noxiousness in their olfactory receptors. Alternatively, the presence of palatable steroids in dytiscids may reflect the use of prothoracic secretions for both antipredator and nondefensive roles. Eisner (1970) and Blum (1981) noted that earlier researchers believed the prothoracic steroids of dytiscids played an antimicrobial or hydrophobic role, and Scrimshaw and Kerfoot (1987) suggested that the prothoracic secretions could serve multiple functions. Additional experiments are required to elucidate further the ecological roles of dytiscid prothoracic secretions.

Abstract—Solutions of glucobrassicin (3-indolylmethyl glucosinolate) purified from foliage and sinigrin (allyl glucosinolate) elicited oviposition by the cabbage butterfly, *Pieris rapae*, at threshold concentrations as low as 10^{-6} M. At higher concentrations, glucobrassicin elicited a faster oviposition rate and a stronger visual response to the substrate through associative learning. Solutions of 10^{-5} M glucobrassicin and 10^{-2} M sinigrin stimulated equally. Their enzymic hydrolysis products failed to influence oviposition. The markedly greater potency of glucobrassicin is consistent with known glucosinolate profiles of crucifers which show indolyl glucosinolates predominant in foliage.

Key Words—Plant–insect interaction, *Brassica campestris*, oviposition, 3-indolylmethyl glucosinolate, learning, reflective spectra, *Pieris rapae*, Lepidoptera, Pieridae.

INTRODUCTION

The botanical specificity of insects restricted to crucifers has long been linked with the presence in host plants of a class of involatile sulfur compounds, the glucosinolates, whose toxicity has been overcome and which now induce feeding and oviposition by the specialized insects (Feeny et al., 1970; Blau et al., 1978; Städler, 1978; Koritsas et al., 1989). The chemical ecology of insects of crucifers has the potential to be understood thoroughly, although impediments

0098-0331/91/0700-1371$06.50/0

have been insufficient chemical analysis of glucosinolates (GSLs), and a lack of behaviorally interpretable bioassays. More than 70 GSLs are known, with 50 in the Brassicaceae, differing in a side chain derived from one of a range of amino acids (Kjaer, 1976; Fenwick, 1983). A major advance in GSL chemistry was the combination of a desulfonating enzyme with HPLC (Minchinton et al., 1982) to identify GSLs directly and more reliably than previously by inference from hydrolysis products. The new method confirmed the predominance of indolyl GSLs in brassica foliage (Sang et al., 1984). The present report seems to be the first concerning the influence of an indolyl GSL on the behavior of an insect. Nonindolyl GSLs have been compared as oviposition stimulants (Ma and Schoonhoven, 1973; Nair and McEwen, 1976) and feeding stimulants (Hicks, 1974; Nault and Styer, 1972), but no ecologically interpretable pattern emerged for different GSLs. Green cards treated with aqueous cabbage extracts elicited more oviposition by *P. rapae* than those treated with allyl GSL (sinigrin) solution (Renwick and Radke, 1983), and after further experiments with plant extracts, it was suggested that unknown substances that were not GSLs were involved (Renwick and Radke, 1988).

In field experiments, Jones (1987) recorded that a mated female *P. rapae* distributed several hundred eggs during several days by repeated, single ovipositions on host plants, in bouts of oviposition in which landings on potential host plants alternated with short flights. In the laboratory, also, flights alternated with oviposition on paper wetted with aqueous GSL solution, provided the paper was green, yellow, or pale blue. *P. rapae* learned to respond to the appearance of a chemically favorable substrate (Traynier, 1984, 1986) but did not learn to associate the presence of a chemical deterrent with the appearance of its substrate (Traynier, 1987). Interpretable bioassays of GSLs therefore required a consideration of visual responses including the influences of learning.

METHODS AND MATERIALS

In earlier experiments on oviposition by *P. rapae*, a traditional bioassay with different solutions offered on substrates of identical appearance revealed little preference for higher concentrations of sinigrin (Traynier, 1986). This lack of chemical discrimination probably resulted from butterflies learning to associate the presence of sinigrin with the appearance of the test substrate, and then responding sufficiently to visual stimuli to override chemical influences. In contrast, when butterflies were offered different solutions on disks of different but equally attractive appearance, they learned to land and oviposit on disks wetted with a 100-ppm rather than a 75-ppm solution of sinigrin. This assay method, with differently colored but equally attractive disks, was employed in the present experiments to measure oviposition by *P. rapae* elicited by different GSLs

offered at the same concentration. The insects were reared on Chinese cabbage, *Brassica campestris*.

Mated female *P. rapae*, 5–8 days old, without ovipositional experience and carrying about 100 oocytes, were tested in 60 × 60 × 60-cm cages under artificial light at 6000 lux from "daylight" tubes. Artificial blue flowers provided sucrose solution. A tray of damp peat moss in the floor of the cage humidified it to 70% relative humidity at 27°C. Experiments were made on a black bench surrounded by pink organza drapes (Sandoz dye, Nylosan Red N2RBL) within either one or a pair of cages made from a tubular frame covered by nylon mesh of the same color. Against this pink background, the green blotting papers (1) Ford's Great Green and (2) Australian Paper Manufacturers' Shoalhaven Green were accepted equally for oviposition when wetted with the same GSL solution. Butterflies oviposited on horizontal 58-mm-diam. disks made from a double layer of 0.15-mm thick celluloid supported horizontally by a central pin and covered on top with a disk of blotting paper of the same diameter. The paper was wetted with 0.8 ml of water or solution, and two disks were offered with centers 20 cm apart in tests of 20 min duration, to butterflies in groups of three, which were numbered on the hindwings for individual recognition. To start the tests, butterflies were taken in turn with their wings between the thumb and forefinger and made to walk on the oviposition sites for 10 sec to contact the test solution with their tarsal chemoreceptors and initiate oviposition behavior.

The landings and ovipositions of the butterflies were tape recorded by spoken commentary. After 10 min, 20% of the water had evaporated from the disks and was replaced around their edges with drops from a pipet. Air in the laboratory was stirred by a fan to encourage flight by the butterflies.

RESULTS

Reflectance spectra were obtained to define the oviposition substrates and cage fabric (Figure 1). Although the cage fabric was pink, it reflected a range of wavelengths including even more green and yellow (500–600 mm) than the wet green oviposition substrates. As *P. rapae* showed no ovipositional response to the pink fabric by tarsal drumming, we concluded that wavelengths additional to the green–yellow range might actively deter oviposition rather than being merely neutral.

Wet versus Dry Substrates. The most common GSL in experimental analyses of the chemical ecology of crucifers has been sinigrin (allyl glucosinolate) obtained from mustard seed. Since sinigrin and water were needed together to elicit oviposition by *P. rapae* (Traynier, 1984), we tested glucobrassicin with and without water. A green paper disk was wetted with 10^{-4} M glucobrassicin

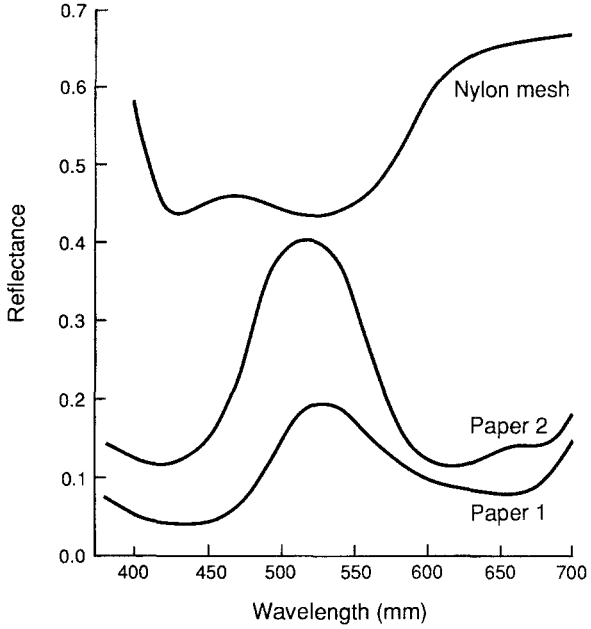

FIG. 1. Diffuse spectral reflectance from pink nylon mesh (Nylosan Red N2RBL Sandoz dye) and wetted blotting papers: (1) Ford's Great Green; (2) Australian Paper Manufacturers' Shoalhaven Green.

solution and allowed to dry. Ten naive, gravid female butterflies were made to walk on the dry paper to establish tarsal contact, then released. They all flew off, only one made a return flight, and none oviposited. In similar tests made with the same butterflies, and the same paper rewetted with water, nine of the 10 butterflies flew back to the disk to attempt oviposition and eight succeeded. We concluded that glucobrassicin, like sinigrin, elicited oviposition only in the presence of water. Our subsequent experiments used these GSLs in aqueous solution.

Threshold Concentrations. Previous results (Traynier, 1984) suggested a threshold concentration for sinigrin at about 10^{-6} M, and we tested sinigrin and glucobrassicin at this concentration. Gravid butterflies were made to walk on a green paper disk with a GSL solution for 10 sec to establish tarsal contact, then released. Of 30 butterflies placed on sinigrin solution, 14 made one or more return flights and nine of these laid a mean of five eggs (SE $\pm$ 2.2). Of 30 butterflies that contacted glucobrassicin, 17 returned and 16 laid a mean of nine eggs (SE $\pm$ 2.1). These differences were not significant, either between the number of butterflies landing or ovipositing (2×2 χ^2) or between mean oviposition per butterfly (Mann-Whitney). We concluded that both compounds had

closely similar threshold concentrations at about 10^{-6} M for ovipositional behaviors. Confirmatory evidence came from a comparison of 10^{-6} M and 10^{-8} M glucobrassicin, conducted as before, in which 10^{-8} M failed to elicit oviposition from any of 30 butterflies that contacted it, whereas 13 of 30 oviposited on disks with 10^{-6} M solution.

Comparisons above Threshold. To test concentrations above threshold, 10^{-4} M solutions of sinigrin and glucobrassicin were offered on different shades of green paper for 15 min. Each butterfly preferred to land and to oviposit on glucobrassicin disks ($P < 0.001$, sign test) irrespective of their shade of green (Figure 2). There were 78 ± 4% and 79 ± 4% of ovipositions by each butterfly on glucobrassicin disks of green shades 1 and 2, respectively, with respective landings of 65 ± 3% and 71 ± 3%. In contrast, when the solutions were offered in a separate experiment on disks of identical appearance (green 2), the butterflies showed no preference, with 7 ± 2 and 8 ± 2 ovipositions on sinigrin and glucobrassicin disks, respectively. The landing choice of butterflies paralleled the ovipositional choice, as in previous experiments in which butterflies learned to recognize the appearance of acceptable substrates (Traynier, 1984, 1986). We concluded that glucobrassicin was more stimulating than sinigrin at 10^{-4} M, but this influence could be overridden by visual learning with disks of the same color, as butterflies associated the presence of the most stimulating GSL with the appearance of its substrate and thereafter visual responses obscured differences between GSL solutions.

Glucobrassicin versus Water. The potency of the indolyl compound was

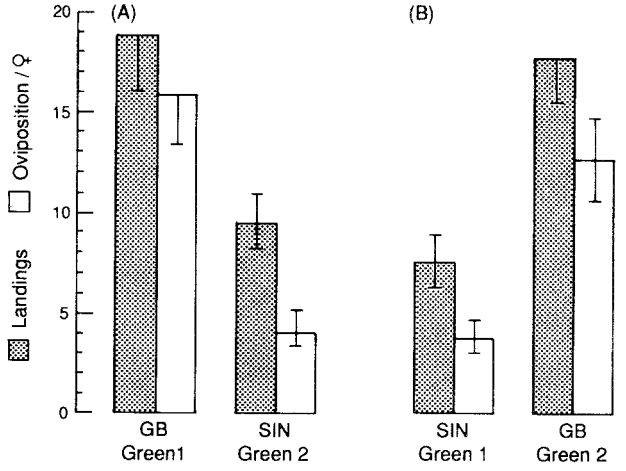

FIG. 2. Mean landings (shaded) and ovipositions (unshaded) (±SE) by 15 ovipositing *P. rapae* on a binary choice of green disks wetted with either sinigrin or glucobrassicin at 10^{-4} M, offered simultaneously in paired cages (A, B) on alternative green papers.

confirmed by a comparison of water and 3×10^{-4} M glucobrassicin applied to different shades of green. Glucobrassicin was markedly preferred with mean egg counts from 15 butterflies of 18 ± 3 vs. 2 ± 0.07 (respective solutions on green shades 1 and 2) and 16 ± 3 vs. 2 ± 0.05 (on shades 2 and 1). Oviposition on the water disks was 15% of the egg count in the first half of the test period, but only 3% in the second. The counts from individual butterflies showed an increase in oviposition preference between the first and second halves ($P < 0.001$, sign test). As *P. rapae* are known to learn, it seems likely they had learned to be more discriminating in the course of the test period.

Influence of Experience. In a comparison at even higher concentration (10^{-3} M) on different shades of green, glucobrassicin was again preferred to sinigrin (Figure 3). Two hours after these tests ended, the same butterflies were offered a choice of the two kinds of green disks, but wetted only with water. The butterflies tended to land initially on the same shade of green on which they had contacted glucobrassicin previously. Of 18 butterflies tested with GSLs, 17 landed later on water disks with a first landing choice of 15:2 in favor of the shade of green that mimicked the previously experienced glucobrassicin disk. Moreover, they oviposited with a preference for appearance corresponding to their earlier chemical preference ($P < 0.001$, Wilcoxon matched-pairs). Thus, these butterflies had learned a stronger response to the appearance of disks with glucobrassicin as opposed to sinigrin. In addition, a learned response to water

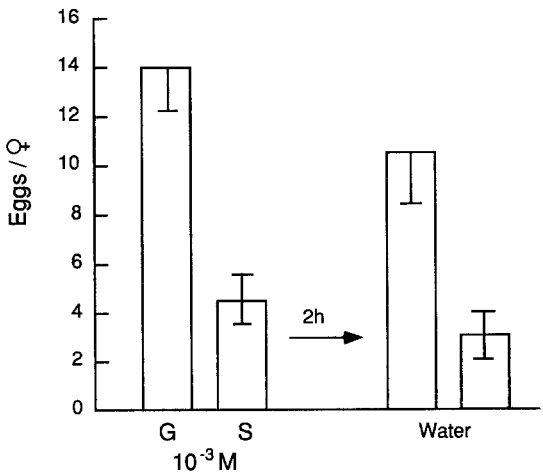

FIG. 3. *P. rapae* oviposition on alternative shades of green disks with either sinigrin or glucobrassicin at 10^{-3} M in an initial 15-min test, followed 2 hr later by oviposition on water disks of the same shade of green.

from the initial test might have contributed to the later oviposition on disks with water alone.

Equipotent Concentrations of Sinigrin and Glucobrassicin. As the responses to the two GSLs had been not significantly different at 10^{-6} M, the differences in experiments with 10^{-4}–10^{-3} M indicated a steeper dose–response curve for glucobrassicin. Oviposition equivalent to 10^{-5} M glucobrassicin was elicited by 10^{-2} M sinigrin; each induced a mean of 6 $\pm$ 1 eggs per butterfly offered these solutions on different shades of green disk.

Influence of Allyl Isothiocyanate. The question remained as to whether hydrolysis products were implicated, either singly or jointly, with GSLs. It was known that allyl isothiocyanate, derived from sinigrin, fails to elicit oviposition from *P. rapae* in the presence of water (Terofal, 1965; Traynier, 1984). As glucobrassicin and sinigrin hydrolyze to different chemical species at neutral pH, we tested the natural enzymic hydrolysis products of each in combination with the alternative GSL. We tested allyl isothiocyanate with potassium sulfate, the coproduct of enzymic hydrolysis at neutral pH, together with glucobrassicin, all three substances at 10^{-4} M in water on the one disk, against a solution of 10^{-4} M glucobrassicin on another disk of the alternative shade of green, to ensure good chemical discrimination by the butterflies. Mean oviposition by 12 butterflies given this choice yielded 7 $\pm$ 1.3 eggs on the mixture and 7 $\pm$ 1.4 eggs on the GSL with no significant preference. Clearly all oviposition had been elicited by the GSL alone.

Influence of Indolyl-3-carbinol. Enzymic hydrolysis of glucobrassicin at neutral pH, as can occur in leaves, yields indolyl-3-carbinol and the thiocyanate ion (Kjaer, 1976). Accordingly, a sinigrin solution with indolyl-3-carbinol in suspension and with potassium thiocyanate, all at 10^{-3} M, was compared with a 10^{-3} M sinigrin solution on the alternative shade of green paper. There was no significant difference. In another experiment, an aqueous suspension of indolyl-3-carbinol corresponding to 10^{-3} M was offered to *P. rapae*, together with a separate water disk, and a sinigrin solution disk, all three of green shade 2. Following contact with sinigrin, butterflies learned to oviposit on disks of the same appearance but treated with water only or with the aqueous carbinol suspension. This allowed a comparison between water with carbinol suspension for their effects on oviposition, knowing that oviposition deterrents do not contribute to associative learning. Ten butterflies oviposited 8 $\pm$ 1.2 eggs on sinigrin disks and 3 $\pm$ 0.8 eggs on both the carbinol and the water disks. Again the carbinol suspension showed no significant influence on oviposition as compared with water.

Glucobrassicin at acid pH can form indolyl-3-acetonitrile (Kjaer, 1976). This was tested like the carbinol and also showed no significant influence on oviposition.

DISCUSSION

It is known that crucifers vary in susceptibility to oviposition by *P. rapae* even after the butterfly has landed on them (Ives, 1978), and in previous attempts to analyze these effects, either total GSL content or GSL profiles without indole compounds were obtained (Nair et al., 1976; Rodman and Chew, 1980; Ahman, 1982). Although indolyl GSLs generally predominate in *Brassica* foliage, they occur in different amounts, and the oil-seed variety Zem 2 of *Brassica juncea* is unusual with sinigrin predominant in its foliage and indolyl GSLs present at low levels (Fenwick et al., 1983). From the present findings, such a plant might be expected to show a low chemical susceptibility to *P. rapae*. Another consideration, however, is that the leaf surface with which *P. rapae* makes only superficial contact (Traynier and Hines, 1987) might have a different GSL profile from the entire leaf. Taking visual responses into account, the least susceptible of all crucifers might not only lack indolyl GSLs but also be less stimulating visually and less distinguishable by *P. rapae* from other host plants by its appearance.

The finding that hydrolysis products of GSLs were ineffective oviposition stimulants for *P. rapae* differs from findings for cabbage root fly, *Delia radicum*, which oviposits in soil adjacent to the host following responses to both isothiocyanates and to GSLs (Finch, 1980; Schöni et al., 1987). The lack of responses of *P. rapae* to isothiocyanates might reflect a requirement for healthy, insect-free foliage as optimal larval food, whereas undamaged foliage might be less important to the root feeding larvae of *D. radicum*. Despite differences in responses to hydrolysis products, other insects that respond to crucifer foliage might, like *P. rapae*, be highly responsive to indolyl GSLs.

The suggestion arising from the spectral reflectance measurements that "red" wavelengths from foliage might actively deter oviposition may be of more general interest since some "red" brassicas are less preferred by other insects of crucifers as well as by ovipositing *P. rapae* (Dunn and Kempton, 1976; Rothschild and Schoonhoven, 1977; Latheef and Irwin, 1979; Myers, 1985), and it is known that additional wavelengths reflected from the sky by plastic or metal deter aphids from green foliage (Kring, 1972; Wyman et al., 1979).

(Received November 28, 1990; accepted March 14, 1991)

Abstract—Analogs of (*Z*)-5-decenyl acetate, a pheromone component of the turnip moth, *Agrotis segetum*, with a chloro, bromo, or iodo substituent in place of the terminal methyl group have been synthesized and tested by electrophysiological single-sensillum recordings. The electrophysiological results have been interpreted in terms of substituent size and hydrophobicity. Interaction energies based on receptor interaction models have been calculated using the molecular mechanics [MM2(85)] method. The results support our previously suggested receptor interaction model in which the terminal alkyl chain interact with a complementary hydrophobic receptor "pocket" with very limited flexibility.

Key Words—Lepidoptera, noctuidae, Agrotis segetum, (*Z*)-5-decenyl acetate, pheromone analogue, halides, structure-activity, single-sensillum recordings, receptor-interaction.

INTRODUCTION

Our previous structure–activity studies on chain-elongated (Liljefors et al., 1985, 1987), chain-shortened (Bengtsson et al., 1990), and alkyl-substituted (Jönsson et al., 1991) analogs of (*Z*)-5-decenyl acetate (**1**, Figure 1) a phero-

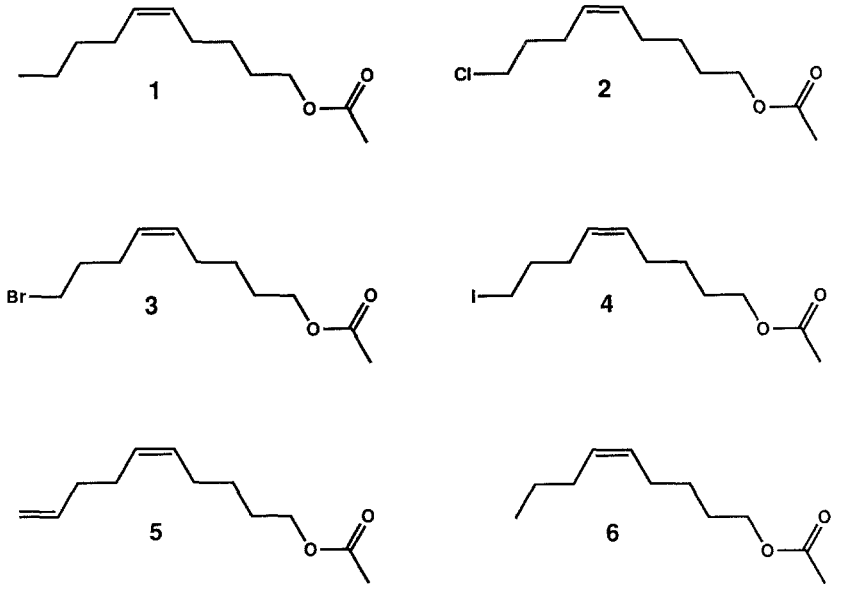

FIG. 1. Compounds studied.

mone component of the turnip moth, *Agrotis segetum*, have revealed a close fit between the receptor and the terminal methyl group of the pheromone component. The electrophysiological single-cell activities of chain-elongated and alkyl-branched analogs of **1** were found to be significantly reduced compared to that of **1**. This was explained by steric repulsive interactions between the substrate and the receptor, which in the chain-elongated case made it necessary for the substrate to undergo conformational changes. Chain-shortening of **1** by one methylene unit resulted in a drop of the electrophysiological activity by a factor of 16, indicating that the region of the receptor cavity which is interacting with the terminal part of the substrate must closely correspond to the natural substrate.

In addition to the *Z*-double bond and the acetate group, the importance of the terminal methyl group for the full activity of a pheromone component seems to be a general feature in structure–activity studies on moth sex pheromone components (Priesner et al., 1975; Priesner, 1979a,b). Recently, a few studies on structural modifications of the terminal methyl group in moth sex pheromone components have been reported. Schwarz et al. (1990) and McLean et al. (1989) have studied the replacement of a terminal CH_3 group by a CH_2F group. This small perturbation of the terminal methyl group resulted in retained or only slightly lowered biological activity (EAG, wind tunnel, field trapping) for the

species studied. However, Sun and Prestwich (1989) report that a 12,12,12-trifluoromethyl analog of (Z)-9-dodecenyl acetate analog is inactive in vivo.

To further characterize the important interaction between the terminal part of the pheromone component and its receptor, we have in the present work studied the replacement of the terminal methyl group in **1** by chlorine (**2**), bromine (**3**), and iodine (**4**) (Figure 1). These analogs provide a variation of the size and the hydrophobicity of the terminal group in a controlled way. We report the synthesis of compounds **2–4** and their biological activities determined by the single-cell technique. By using simple receptor–substrate interaction models, the steric and hydrophobic contributions to the receptor interaction and the ability of the receptor to adapt to terminal substituents of different size are investigated, employing molecular mechanics calculations. Two previously studied analogs, **5** (Bengtsson et al., 1990) and **6** (Bengtsson et al., 1987), are included in the discussions for comparison.

METHODS AND MATERIALS

Synthesis

All reactions were performed under a nitrogen atmosphere in oven-dried glassware. Anhydrous diethyl ether and tetrahydrofuran (THF) were distilled from solutions of sodium benzophenone. The final products were purified by high-performance liquid chromatography (HPLC) on a semipreparative straight-phase column (Kromasil, particle size 10 μm, 250 × 10 mm ID) and monitored with a differential refractometer. Analytical GC was performed with a Varian 3400 capillary GC fitted with a DB-Wax 30-m × 0.25-mm-ID column.

[^{1}H]-and [^{13}C]NMR spectra were determined in $CDCl_3$ solution on a Varian XL-300 spectrometer; chemical shifts (δ) are expressed downfield relative to TMS. The $CHCl_3$ signal was used as an internal reference (7.26 ppm). High-resolution mass spectra were obtained using a Jeol JMS-SX 102 spectrometer with GC inlet.

The synthetic scheme for the preparation of **2–4** is shown in Figure 2.

(Z)-5-Decenyl Acetate **(1)**. This was prepared as previously described (Olsson et al., 1983).

9-Chloro-(Z)-5-nonenyl Acetate **(2)**. To a stirred solution of lithium bis[(Z)-6-(1-ethoxyethoxy)-hex-1-enyl] cuprate (6 mmol) in 50 ml ether (Jönsson et al., 1991), was added at −30°C 1,3-dimethyl-3,4,5,6-tetrahydro-2(1H)-pyrimidinone (DMPU) (10 ml) in THF (25 ml) and then 1-bromo-3-chloropropane (5.0 ml, 50 mmol). After 6 hr of stirring at −30°C to −10°C, the mixture was hydrolyzed with 3 M HCl, worked up, and acetylated by acetic acid–acetyl chloride (10:1) at 35°C. The crude acetate was purified by flash chromatography with TLC-silica gel 60H (Merck) with petroleum ether–ethyl acetate

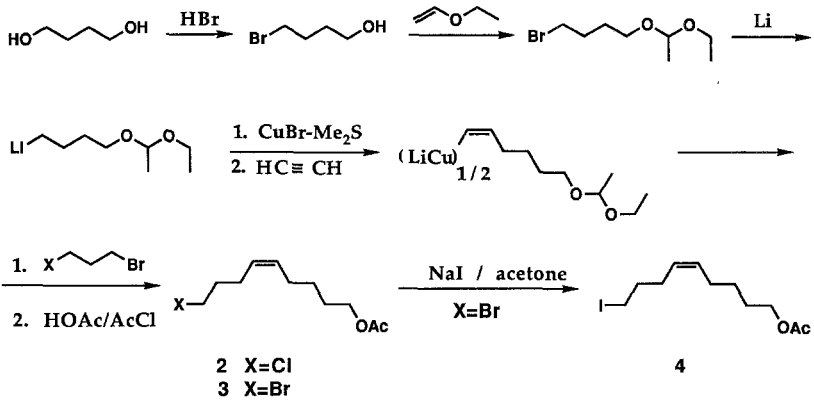

FIG. 2. Synthetic route to compounds **2–4.**

(20 : 1) as eluent, yielding 1.4 g of product. Part of this was then further purified by HPLC with petroleum ether–ethyl acetate (500 : 4). The purity of the isolated product was >99.5% (GC). δ_H (300 MHz) 1.36–1.46 (m, 2H, $=CCCH_2$), 1.59–1.68 (m, 2H, CH_2-C-O), 1.77–1.86 (m, 2H, $ClCCH_2$), 2.04–2.25 (m, 4H, $=CCH_2$), 2.04 (s, 3H, $COCH_3$), 3.53 (t, 2H, J = 6.5 Hz, $ClCH_2$), 4.06 (t, 2H, CH_2O), 5.28–5.46 (m, 2H, J = 10.8 Hz, CH=CH); δ_C (75.4 MHz) 21.0, 24.4, 26.0, 26.8, 28.2, 32.4, 44.5, 64.4, 128.2, 130.9, 171.2; MS (high-resolution), *m/e* calc. for ($C_{11}H_{19}ClO_2-C_2H_4O_2$) 158.0863, obs. 158.0829, ($C_{11}H_{19}ClO_2-C_4H_8O_2$) calc. 130.0549, obs. 130.0543.

9-Bromo-(Z)-5-nonenyl Acetate **(3)**. This compound was prepared in analogy with **2** from 1,3-dibromopropane to give 1.4 g of product. Part of this was further purified by HPLC, with petroleum ether–ethyl ether (10 : 1) as eluent, which gave a final product >98.5% pure (GC). δ_H (300 MHz) 1.36–1.47 (m, 2H, $=CCCH_2$), 1.59–1.69 (m, 2H, CH_2-C-O), 1.82–1.95 (m, 2H, $BrCCH_2$), 2.03–2.23 (m, 4H, $=CCH_2$), 2.04 (s, 3H, $COCH_3$), 3.41(t, 2H, J = 6.6 Hz, $BrCH_2$), 4.06 (t, 2H, CH_2O), 5.28–5.47 (m, 2H, J = 10.8 Hz, CH=CH). δ_C (75.4 MHz) 21.0, 25.6, 26.0, 26.9, 28.2, 32.6, 33.4, 64.4, 128.1, 131.0, 171.2; MS (high-resolution), *m/e* calc. ($C_{11}H_{19}BrO_2-C_2H_4O_2$) 202.0357, obs. 202.0353.

9-Iodo-(Z)-5-nonenyl Acetate **(4)**. Purified compound **3** (0.15 g, 0.7 mmol) was added to a solution of NaI (3.0 g, 20 mmol) in anhydrous acetone (15 ml). The solution immediately turned cloudy and was left stirring for 3 hr. Pentane (15 ml) was added, and the mixture was filtrated. The solvent was removed and the residue taken up in a new portion of pentane (10 ml). Repeated filtration and evaporation of the solvent gave 0.15 g of a yellow oil. Purification by HPLC using petroleum ether–ethyl ether (500 : 15) yielded a colorless oil of very high purity as judged by analytical HPLC (analysis by GC was not suc-

cessful due to thermal instability of the product). δ_H (300 MHz) 1.36–1.47 (m, 2H, $=CCCH_2$), 1.59–1.69 (m, 2H, CH_2-C-O), 1.82–1.92 (m, 2H, $ICCH_2$), 2.04–2.18 (m, 4H, $=CCH_2$), 2.04 (s, 3H, $COCH_3$), 3.19 (t, 2H, J = 6.8 Hz, ICH_2), 4.06 (t, 2H, CH_2O), 5.27–5.46 (m, 2H, J = 10.8 Hz, CH=C). δ_C (75.4 MHz) 6.6, 21.0, 26.0, 27.0, 27.9, 28.2, 33.3, 64.4, 127.9, 131.0, 171.2.

Electrophysiology

Electrophysiological activities were determined by the single-sensillum technique (Kaissling, 1974). Olfactory receptor cells specifically tuned to (*Z*)-5-decenyl acetate (**1**) are present in antennal sensilla type SW1 of *Agrotis segetum* and are readily accessible for single-cell recordings (Hallberg, 1981; Löfstedt et al., 1982, van der Pers and Löfstedt, 1983). The method used was modified according to van der Pers and Den Otter (1978) and has previously been described (Liljefors et al., 1987; Bengtsson et al., 1990). Dose–response curves were constructed using five different stimulus amounts from 10^{-4} μg to 1 μg for **1** and 10^{-3} μg to 100 μg for **2–4** in decadic steps. For each stimulus loading, 10 replicates were recorded, and the mean value of the number of action potentials generated during 1 sec from the onset of stimulation was used in the construction of the dose–response curves. Errors are expressed as standard errors of the mean (SEM). The relative activity of each compound is expressed as the reciprocal of the relative quantities required to elicit the same response from the receptor cell, as the natural pheromone component.

Corrections for differences in volatility have been made using relative vapor pressures, as previously described (Liljefors et al., 1985; Bengtsson et al., 1990). The correction factors used are 5.2 for compound **2**, 11.0 for compound **3**, and 29.5 for compound **4**. These factors are based on vapor pressure data for decane and its halogen-substituted analogs (Dykyj and Repás, 1979).

Molecular Mechanics Calculations

Energy-minimized geometries and intermolecular interactions were calculated using the molecular mechanics program MM2(85) (Burkert and Allinger, 1982). Starting structures for the energy-minimization program were obtained from the molecular modeling system MIMIC (Liljefors, 1983; von der Lieth et al., 1984).

RESULTS

Chemicals. Compounds **2–4** were prepared by carbocupration of acetylene followed by alkylation of the intermediate (*Z*)-dialkyl cuprate according to Alexakis et al. (1979). The synthetic scheme is shown in Figure 2. This syn-

thetic method is known to afford products of very high stereoisomeric purity without using argentation chromatography. The complete conversion of bromide to iodide was performed with a Finkelstein reaction in the conventional manner.

Electrophysiological Recordings. The electrophysiological single-cell activities for compounds **1–4** are shown as dose–response curves in Figure 3. Compounds **2** and **3** exhibit virtually identical receptor responses. The recordings show that the amount loaded on filter paper of these two compounds had to be about 150 times higher than that of **1** in order to elicit the same number of spikes/sec as the natural component **1**. The corresponding dose–response curve for compound **4** is significantly displaced to higher stimulus loadings. In this case the stimulus amount has to be about 1800 times higher than that of **1** in order to give the same receptor response as **1**. The relative amounts of the analogs delivered to the antenna, however, are not same as the relative amounts loaded on filter paper. For a final analysis, corrections for differences in volatility have to be included as described in the Materials and Methods section. The relative single-cell activities, including volatility corrections, for compounds **1–4** are shown in Figure 4 along with the activities for two previously studied related compounds (**5** and **6**) (Bengtsson et al., 1987, 1990) for comparison.

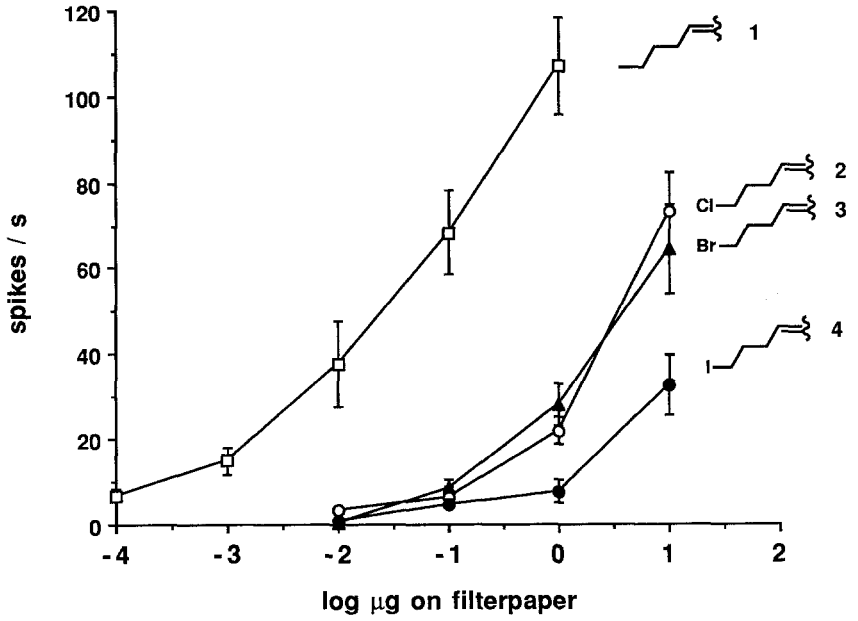

FIG. 3. Single-cell dose–response curves for compounds **1–4.**

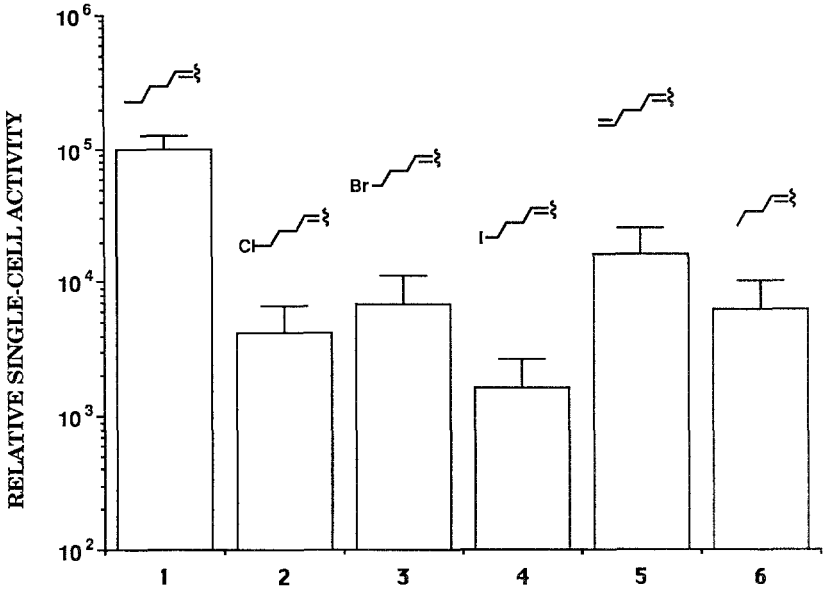

FIG. 4. Experimental single-cell activities (+SEM) for compounds **1–6.** The data are corrected for differences in volatility. The data for compounds **5** and **6** are taken from Bengtsson et al. (1987, 1990).

All analogs display a reduced activity compared to the natural pheromone component **1**. The chloro analog **2** displays an activity drop by a factor of 24, while the bromo analog **3** is less active than **1** by a factor of 14. The iodo analog **4** is the least active of the compounds studied. Its activity is lower than **1** by a factor of 60. In comparison to **5**, the halogen analogs **2–4** display significantly less activity and a comparison with the chain-shortened analog **6** shows that **2** and **3** have activities close to this analog. Thus, replacing the terminal methyl group in **1** by a chlorine or bromine substituent has about the same effect on the receptor cell response as chain-shortening by one methylene unit. Replacing the methyl group in **1** by iodine is in this respect approximately equivalent to chain-shortening by two methylene units (Bengtsson et al., 1990).

DISCUSSION

The replacement of the terminal methyl group in compound **1** by a halogen atom results in changes of the hydrophobic character and the size of the terminal substituent. Thus, hydrophobicity as well as substituent size must be taken into account in the interpretation of the experimental data.

The conformational properties of compounds **2–4** are virtually identical to those of compound **1** (Jönsson and Liljefors, unpublished results). Thus, conformational differences cannot rationalize the observed activity differences.

Hydrophobicity. The hydrophobic character of a compound is commonly expressed in terms of the logarithm of the partition coefficient (log P) describing the partition of the compound between an aqueous phase and *n*-octanol (Leo et al., 1971). Experimental log P data for some aliphatic *n*-alkanes and haloalkanes are given in Table 1. From these data it is clear that the methyl group has a higher hydrophobicity than the halogens and that the iodides are more hydrophobic than the chlorides and bromides. This is also reflected in the fragment constants developed by Hansch and Leo (1979) shown in Table 1. As log P may be predicted from addition of fragment constants (Hansch and Leo, 1979) and since the compounds studied are closely related, the differences between the fragment constants in Table 1 are identical to differences in predicted log P for compounds **1–6**.

If hydrophobic effects alone determine the affinity of a compound for a nonpolar site, a more hydrophobic compound should have a higher affinity. Assuming that the electrophysiological activity of a pheromone component or an analog is directly related to the affinity for the receptor, examination of Table 1 shows that the activities of compounds **1–4** are expected to decrease in the order **1** > **4** > **3** > **2**. The single-cell activities in Figure 4 show that **1** is indeed more active than its halogen analogs, but the order of the observed activities for **2, 3,** and **4** does not follow their relative hydrophobicities. Further-

more, on the basis of hydrophobicity arguments alone, compounds **5** and **6** should display essentially identical activities, in disagreement with experimental data (Figure 4). Consequently, hydrophobicity alone cannot rationalize the observed electrophysiological activities; the size of the substituent should also be of importance for the activity.

Substituent Size. The values of the van der Waals (vdW) radii for the terminal substituents in compounds **1–6**, employed by the MM2(85) molecular mechanics program, are tabulated in Table 2 along with the corresponding distances to a bonded carbon atom. The sum of these parameters [$D(X)$, Table 2] represents the size of a substituent X in an intermolecular interaction in the direction of the C—X bond. A particular problem is how to define the size of nonspherical substituents like the methyl group. An approach to this problem for symmetric top substituents is to calculate the effective length of the group in the C—X bond direction by simple geometry and trigonometry, using vdW radii and bond lengths (Charton, 1979). The value for the methyl group calculated in this way, using radii and bond lengths according to MM2(85) is 3.36 Å (Table 2). This shows, as expected, that the methyl group is significantly smaller in the C—X bond direction than the halogens. Verloop et al. (1976) have developed parameters (STERIMOL) that give a measure of the dimensions of a substituent in different directions. The STERIMOL-parameter L representing the length of a substituent is included in Table 2 for comparison. The L parameters and the D parameters give a very similar description of differences of substituent size. Thus, we can safely conclude that the relative size of the substituents in the C—X direction are H < CH_3 ≈ CH_2= < Cl < Br < I. Figure 5 illustrates the variation in the vdW size of the terminal substituents of the compounds studied in this work.

TABLE 2. PARAMETERS FOR DESCRIPTION OF SIZE IN C–X BOND DIRECTION OF TERMINAL SUBSTITUENTS IN COMPOUNDS **1–6**

Substituent X	vdW radius (Å)	Bond length C–X (Å)	$D(X)^a$ (Å)	STERIMOL parameter L (Å)
CH_3		1.53	3.36[b]	3.00

Br	2.18	1.95	4.13	3.82
I	2.32	2.15	4.47	4.23
H	1.50	1.11	2.61	2.06
$=CH_2$		1.34	3.41[b]	

[a] $D(X)$ = Σ [vdW radius (X) + C–X bond length].
[b] Calculated maximum length in C–X direction (see text).

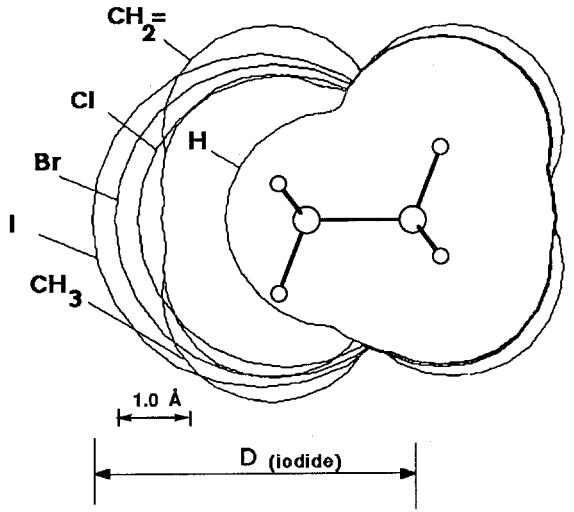

FIG. 5. Superimposed van der Waals contours of the terminal part of compounds **1–6**. The superimposed ethane molecule (corresponding to the contour marked CH_3) indicates the orientation of the contours. The parameter D is the sum of the C—X bond length and the van der Waals radius of atom X (see Table 2). The parameter D is exemplified for X = iodine.

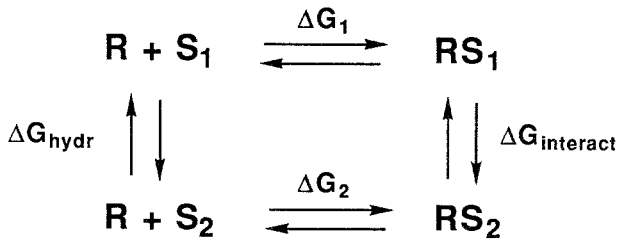
In a geometrically well-defined receptor "pocket" that is highly complementary to a methyl group, the halogen substituents will cause repulsive steric interactions due to their larger size in the C—X bond direction. The observed low activity of the iodo analog **4** is in line with this expectation, but the relative activities of compounds **2** and **3** cannot be rationalized in this way. Compound **6** is also less active and compound **5** more active than may be expected on the basis of size alone. Apparently, to fully rationalize the experimental data, hydrophobicity and size must simultaneously be taken into account. This requires a computational approach.

Molecular Mechanics Calculations. In order to simulate hydrophobic and repulsive steric interactions simultaneously, we have performed molecular mechanics calculations on the interaction between models of the terminal alkyl chain in compounds **1–6** and a lipophilic environment.

On comparing biological activities of molecules with different polarities, differences in free energies of hydration (ΔG_{hydr}) must be taken into account. Using the thermodynamic cycle (Scheme 1) it follows that

$$\Delta\Delta G = \Delta G_2 - \Delta G_1 = \Delta G_{interact} - \Delta G_{hydr} \quad (1)$$

$\Delta\Delta G$ corresponds to the difference in affinity of substrates S_1 and S_2 for



SCHEME 1.

the receptor R, and $\Delta G_{\text{interact}}$ is the difference in the interaction energies of the two substrate–receptor complexes RS_1 and RS_2 (Tembe and McCammon, 1984; McCammon, 1987). The equation above shows that if the interaction energies of the substrate–receptor complexes of the two substrates are identical, the substrate that is less soluble in water (most positive ΔG_{hydr}) will have the highest affinity for the receptor. If the substrates have identical free energies of hydration, the interaction energies of the substrate–receptor complex completely determine their relative affinities.

Differences of the free energies of hydration for alkyl chlorides, bromides, and iodides are very small, at most a few tenths of a kilocalorie per mole (Cabani et al., 1981). This is reflected in the additive group contributions to ΔG_{hydr} developed by Cabani et al. (1981). For Cl, Br, and I these contributions are -1.74, -1.85 and -1.90 kcal/mol, respectively. Thus, the order of the electrophysiolological activities for **2–4** should largely be determined by their interactions (repulsive and dispersive) with the receptor. ΔG_{hydr} for *n*-alkanes is ca. 2.5 kcal/mol more positive than that for the corresponding haloalkanes (the group contribution of CH_3 to ΔG_{hydr} is $+0.76$ kcal/mol). This must be taken into account in a comparison of the activities for **1** and its halogen analogs.

Since the structure of the receptor site is unknown, we have employed simple models for the interaction between the terminal substituents in compounds **1–6** and a lipophilic environment with defined geometrical properties. As a first model, two ethane molecules, simulating a fragment of the receptor site and the terminal part of the substrate molecule, were positioned as shown in Figure 6 and energy-minimized with molecular mechanics calculations [MM2(85)] in order to find the energetically most favorable distance between the molecules. In the calculation, the two C—C bonds were restricted to a common axis. The methyl group in one of the ethanes was in turn replaced by chlorine, bromine, iodine, and hydrogen to simulate the analogs **2–4** and **6**. Ethylene was used as a model for analog **5**. These complexes were then energy-minimized keeping the distance d in Figure 6 fixed to the value (5.18 Å) obtained from the minimization of two ethane molecules. This simple model simulates the interactions in the C—X bond direction due to repulsion and dis-

persion energies of the different substituents in a complex with a fixed geometry optimal for a methyl group. The energy of interaction is the difference in energy between the complex and the energy of the two separate parts of the complex. The calculated interaction energies are given in Table 3, model A. A negative energy indicates net attraction between the components. As interaction entropies should be very similar for the different cases, interaction energy differences should be close to free energy differences. As expected, the methyl substituent gives the most stable complex, while bromine and, in particular, iodine show strong repulsive interactions due to their larger size in the C—X bond direction.

To investigate the validity of the simple model above, a more elaborate model was constructed, simulating a three-dimensional lipophilic cavity optimally complementary to a methyl group. Five isobutane molecules were positioned around the methyl group in the terminal alkyl chain of **1** (simulated by a butane molecule), creating a three-dimensional cavity. The complex was energy-minimized by MM2(85), and the interaction energy between butane and the constructed lipophilic "receptor" was calculated as the energy difference between the complex and the two separate components. The energy-minimized

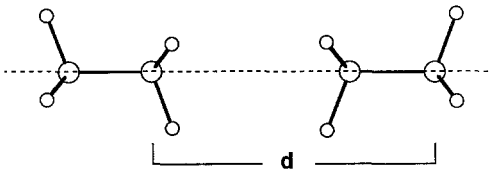


FIG. 6. Interaction complex describing model A. The figure shows the case in which the substituent is CH_3. The distance d is the optimal distance between the two ethane molecules. This distance is kept fixed in the calculations for other substituents.

TABLE 3. MOLECULAR MECHANICS [MM2(85)] CALCULATED INTERACTION ENERGIES (kcal/mol)

	Model A		Model B	
X	Interaction energy	$\Delta(X-CH_3)$	Interaction energy	$\Delta(X-CH_3)$
CH_3-	−1.0	0.0	−10.6	0.0
Cl—	−0.3	0.7	−9.4	1.2
Br—	1.2	2.2	−7.9	2.7
I—	6.4	7.4	−3.9	6.7
$CH_2=$	−0.8	0.2	−8.9	1.7
H—	−0.2	0.2	−7.8	2.8

complex is shown as a stereo-pair in Figure 7. The calculations then were repeated for models of the terminal alkyl chains of compounds **2–6** by replacing the interacting methyl group in butane by an appropriate substituent. The size of the "receptor" was kept fixed by completely restricting the motion of the central carbon in each isobutane molecule during energy-minimization. In addition, the position of the noninteracting methyl group in butane and its halogen-substituted analogs was kept fixed to assure that the substrate molecules have the same positions in the lipophilic pocket. This corresponds to a fixed distance *d* in the calculations described above (model A).

The results of these calculations are shown in Table 3, model B. Although the interaction energies are much larger in these calculations compared to the model A calculations, the differences in interaction energies [$\Delta(X-CH_3)$, Table 3] with CH_3 as reference substituent are similar for Cl, Br, and I in the two models, supporting the validity of the simple model A for these substituents. For the substituents $CH_2=$ and H, it is obvious that only the full treatment of model B gives a realistic description of the interactions between these substituents and a lipophilic cavity. Interestingly, the calculated interaction energy difference between **6** and **1**, 2.8 kcal/mol (model B, Table 3), which, after correction for differences in the loss of conformational entropy on binding becomes about 1.8 kcal/mol (Bengtsson et al., 1990), is almost identical to the energy value, 1.9 kcal/mol, which we previously deduced from the observed relative activities of **1** and **6** (Bengtsson et al., 1990). Furthermore, this energy value is in good agreement with the maximum hydrophobic binding energy for a methyl group in a perfectly complementary receptor pocket, determined from

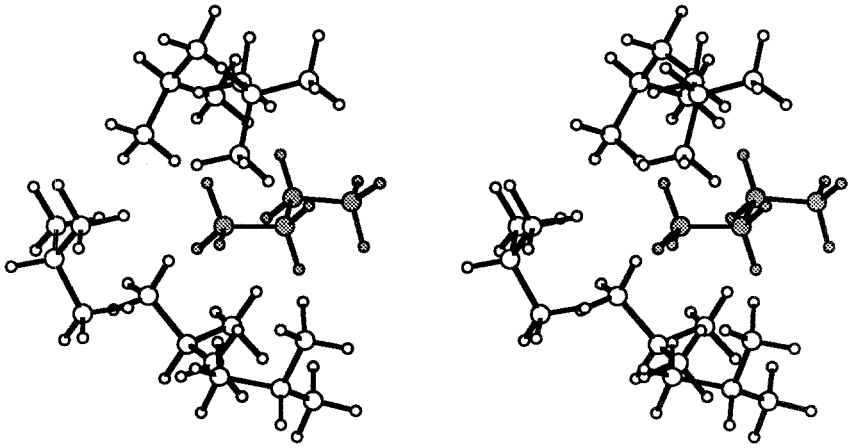

FIG. 7. Stereo-view of the energy-minimized structure of the hypothetical receptor "pocket" (model B) binding a butane molecule (filled atoms).

binding experiments with enzymes (Fersht, 1985; Bengtsson et al., 1990). This agreement indicates that the calculated interaction energies are realistic. Taking differences in free energies of hydration into account by subtracting 0.70 and 0.12 kcal/mol (Cabani et al., 1981) from the interaction energies for $CH_2=$ and H, respectively, in Table 3, the total differences in interaction energies between CH_3 and $CH_2=$, and CH_3 and H becomes 1.0 and 1.7 kcal/mol, respectively. These energies correspond to $\Delta\Delta G$ in equation 1 for the affinity of compounds **5** and **6**, in relation to compound **1**, for the constructed lipophilic "receptor" in Figure 7. The calculated energies predict the order of activities to be **1** > **5** > **6** in complete agreement with experiments (Figure 3).

From the calculated data in Table 3, it is clear that the interaction energies for the bromine and iodine substituents are too repulsive in a rigid receptor pocket that is "perfectly" complementary to a methyl group. For instance, the interaction energies for chlorine and bromine should be essentially the same in order to rationalize the experimental data in Figure 4. Thus, in order to rationalize these data, it is necessary to invoke some ability of the receptor site to respond to an increase in the size of the ligand through small changes of its geometry.

Interaction energies involving the halogen-substituted compounds, calculated as a function of the intermolecular separation, are shown in Figure 8. Since model A was shown above to be valid for the halogen substituents, we have used this simple model for these calculation. It is clear from Figure 8 that the interaction energies for the halides are strongly dependent on the intermolecular distance. The distance employed in the model A calculations in Table 3, 5.18 Å, is indicated by the left arrow in Figure 8. At this distance, the interaction energy of the methyl substituent is optimal, while the bromine and iodine substituents show large repulsive interactions. At somewhat larger intermolecular distances, the stability of the complexes with halogen substituents rapidly increases due to a decrease in the steric repulsions between the halogen substituent and the methyl group. At 5.7 Å (indicated by the right arrow in Figure 8), the interaction energies for the chlorine- and bromine-substituted compounds are identical, corresponding to a predicted equal affinity for the receptor. A further small increase of the distance d leads to stronger interaction for the bromine substituent than for the chlorine substituent, corresponding to a somewhat higher affinity for the bromo compound than for the chloro compound. Thus, if we assume a limited degree of flexibility of the receptor site corresponding to an increase of the distance d by ca. 0.5 Å, approximately one third of a C—C bond length, the calculated binding energy differences for the halogen-substituted compounds correspond very well to the order of the biological activities of these compounds. As may be inferred from Figure 8, a significantly larger degree of receptor flexibility leads to the prediction that the iodo

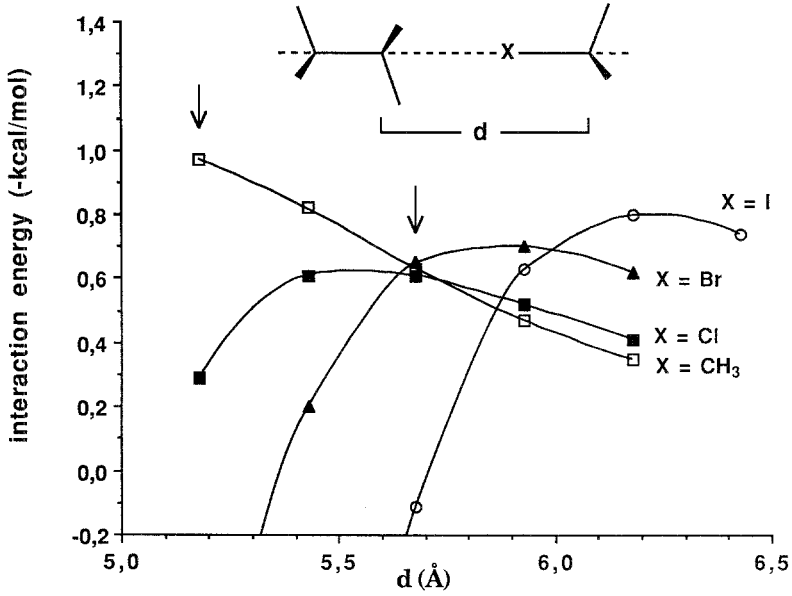

FIG. 8. Interaction energy as a function of the intermolecular distance d for the interaction between ethane and CH_3-X with various substituents X corresponding to the terminal substituent in compounds **1–4**.

compound should have a higher affinity for the receptor than at least the chloro compound. This is in disagreement with experimental data in Figure 4.

An alternative rationalization of the experimental data is that the receptor pocket binding the terminal methyl group of the natural component **1** is not perfectly complementary to a methyl group but slightly larger, approximately corresponding to the size (in the C—X bond direction) of a bromo substituent. Although the calculated interaction energies in Figure 8 then become very similar for CH_3, Cl, and Br, the more positive ΔG_{hydr} for the methyl group, as discussed above, implicates that compound **1** should still be significantly more active than the halogen substituted analogs **2–4**.

CONCLUSIONS

The replacement of the terminal methyl group in **1** by a chloro, bromo, or iodo group leads to a significant reduction of the electrophysiological single-cell activity. The observed decrease in activity is concluded to be determined by a combination of hydrophobic and sterically repulsive contributions to the

substrate–receptor interaction. The results support our previously suggested receptor interaction model in which the terminal alkyl chain interacts with a complementary hydrophobic receptor "pocket" with very limited flexibility. It is concluded that the receptor may have a small degree of flexibility approximately corresponding to the difference in vdW volumes between a methyl and a bromine substituent and/or that the steric repulsions in the receptor pocket may be relieved by a correspondingly small adjustment of the position of the terminal alkyl chain.

(Received December 18, 1990; accepted March 15, 1991)

Abstract—Four components, (*Z*)-9-tetradecenal (8.6%), (*Z,E*)-9,12-tetradecadienal (4.8%), (*Z*)-11-hexadecenal (49.5%), and (*Z*)-13-octadecenal (37.1%), were identified in extracts of female pheromone glands of the European sunflower moth, *Homoeosoma nebulellum* (Lepidoptera: Pyralidae) using GC and GC-MS analyses. EAG and single-cell recordings of male antennal receptors gave strong evidence for (*Z,E*)-9,12-tetradecadienal as the antennal key compound of sex pheromone detection in this species. This result was confirmed by field trapping; removal of (*Z,E*)-9,12-tetradecadienal from quaternary blends completely suppressed the male catches. The synthetic blends with this compound as a major component caught five times less males than the blends reproducing the ratio found in the female extracts [5% of (*Z,E*)-9,12-tetradecadienal only]. The occurrence of a minor component perceived as the most biologically relevant compound is discussed.

Key Words—Lepidoptera, Pyralidae, *Homoeosoma nebulellum*, European sunflower moth, sex pheromone, identification, multicomponent blend, (*Z,E*)-9,12-tetradecadienal.

INTRODUCTION

The European sunflower moth (ESM), *Homoeosoma nebulellum* (Den. & Schiff.) is a palearctic phycitid reported as a pest of sunflowers (*Helianthus*

*To whom correspondence should be addressed.

0098-0331/91/0700-1399$06.50/0

annuus L.) in eastern Europe (Balachowsky, 1972). In western Europe, the larvae usually develop in the inflorescences of wild Compositae, such as *Silybum marianum* L. or *Senecio jacobea* L. (ragwort) in the southern and northern parts of Europe, respectively (Goater, 1986).

The first damage on cultivated sunflowers in southern France was reported in 1983 in late crops (Permana et al., 1991). *H. nebulellum* has not yet been found on sunflower in temperate Europe, but with the recent development of cold hardy sunflower cultivars, the importance of this pest species may increase. We therefore decided to develop an effective monitoring technique to be used in control programs for this potential pest.

In this paper, we report on the identification of the components of the female sex pheromone in the ESM, and we propose an efficient attractant for field trapping.

METHODS AND MATERIALS

Insects. A laboratory colony was established on artificial diet for noctuids (Poitout and Bues, 1970), which was modified by addition of sunflower akene powder (100 g/5 liters) and sunflower oil (5 ml/5 liters). The colony was restocked annually using larvae collected near Montpellier (Hérault) and in the Camargue near St. Gilles (Gard) on *Silybum marianum* or sunflower. All rearing and testing were carried out at 23°C, 70% relative humidity under a 16:8 light–dark photoperiod.

Individuals were sexed as pupae and the two sexes held separately.

Females. Calling behavior was observed at 15-min intervals throughout the entire 24-hr period on 30 virgin 2- or 3-day-old females. Observations during the scotophase were made with a portable, incandescent red lamp.

The structure of the pheromone gland was examined histologically. The abdominal tips of 10 two-day-old virgin females were fixed for 22 hr in alcoholic Bouin's and subsequently stained with Masson-Goldner trichrome (Martoja and Martoja-Pierson, 1967). Sections were made of both invaginated glands (noncalling position) or with the ovipositor extended by injecting the fixing agent into the abdomen before removing the last few abdominal segments.

Pheromone Extraction and Analysis. The VIII–IX abdominal segments of 323 two- or three-day old females were clipped 1 hr prior to the onset of photophase and soaked for 2 hr in 1 ml hexane at room temperature. The extract then was filtered through glass wool, reduced to ca. 100 μl under a N_2 flow and kept at −30°C until used.

The sex pheromone extract was analyzed by gas chromatography (GC) and gas chromatography–mass spectrometry (GC-MS). GC analyses were performed on either a Carlo Erba Fractovap 2900 with flame ionization detector

(FID), equipped with a nonpolar column (50 m WCOT SE-52, 0.2 mm ID; Girdel, Suresnes, France) heated from 45° to 160°C at 25°/min and from 160° to 210°C at 5°/min, or with a Hewlett-Packard 5890 chromatograph (FID) equipped with a polar column (34 m WCOT Carbowax 20 M, 0.3 mm ID; Girdel), operated isothermally at 180°C. Separation of the isomers of dienic aldehydes was performed on the Hewlett-Packard 5890 chromatograph equipped with a polar column (50 m WCOT CPSil 88, 0.32 mm ID, Chrompack, Middelburg, The Netherlands), operated isothermally at 100°C. GC-MS was performed on a Girdel 32 gas chromatograph linked to a Nermag R 10-10C quadrupole mass spectrometer (electron impact at 70 eV). The chromatograph was fitted with a fused silica capillary column (25 m WCOT CPSil 5 CB, 0.22 mm ID; Chrompack) and operated isothermally at 180°C.

Electrophysiology. Electroantennograms (EAGs) were recorded on male ESMs secured in a styrofoam block. After a few antennal segments had been snipped off, the distal end of one antenna was inserted in the tip of the recording electrode. The indifferent electrode was implanted in the neck of the insect. Both electrodes were glass capillaries filled with Roeder's saline (NaCl, 9.0 g/liter; KCl, 0.2 g/liter; glucose, 4.36 g/liter). Electrodes were connected to a WPI preamplifier through chloridized silver wires. After filtration (DC to 300 Hz) the signal was fed into an oscilloscope and monitored directly on the storage display screen.

To stimulate the antenna, air was puffed (0.5 sec; 1.5 liters/min) on the antenna through a glass cartridge containing a piece of filter paper loaded with 0.5 μg of the test compound. Thirty-one pure compounds were screened, including those reported as pheromone components in the Phycitinae subfamily (Arn et al., 1986), those found in gland extracts of female ESMs, and a number of analogs.

EAG data, in millivolts, were corrected in order to eliminate differences of absolute sensitivity between individuals (Renou et al., 1988). The response of one individual to a given compound was divided by the mean of the responses of this individual to the 31 compounds. Measurements were replicated on one antenna of eight different males, and the means of the corrected EAG values were calculated to produce the EAG response profile.

Single-cell recordings were carried out on excised antennae, using the tip recording technique (Kaissling and Thorson, 1980; Lucas and Renou, 1989). The base of the antenna was inserted in a glass microelectrode filled with hemolymph saline (Kaissling and Thorson, 1980). The tip of a few sensilla trichodea were cut off with sharpened forceps, and the recording electrode, filled with receptor lymph saline, was slipped over the cut end of a single hair. The action potentials were filtered (150–5000 Hz), amplified ($\times$1000), and recorded on a electrostatic fast-recording chart system (Gould ES1000). Some of the recordings were digitized, with a 10-kHz conversion rate, by a A/D converter

board (Dash 16 of Metrabyte) integrated in a PC microcomputer. Then, the responses were analyzed using a specific program written in Asyst (Macmillan Software Company) language (Lucas and Renou, 1989).

The outlet of a Y-shaped glass tube was positioned 2 cm from the antenna and a permanent flow of humidified pure air (1.5 liters/min) was continuously blown out over the antenna through the lateral branch. A stimulation cartridge was introduced in the main branch of the Y tube. Stimulation was achieved by blowing a puff of air (1.0 sec; 0.5 liters/min) through the cartridge.

All the tested chemicals were synthesized at the Laboratoire des Médiateurs Chimiques, with a purity greater than 95%.

Field Trapping. Experiments were conducted in 1988 and 1989 in southern France at St. Gilles in the Camargue and Melgueil near Montpellier using chemicals synthesized at the Laboratoire des Médiateurs Chimiques, with an isomeric purity greater than 98%. In the first experiment (from July 8, 1988, to October 21, 1988), sticky traps (INRA-Carol, Bordeaux, France) were baited with one of six treatments, which included the candidate compounds from female extract analysis or male EAG studies. In all blends, the major component was the dienic aldehyde (*Z*,*E*)-9,12-tetradecadienal (*Z*9,*E*12–14:Ald), which gave the highest responses in electrophysiology (Table 1).

All tested blends were diluted in 1 ml hexane and loaded on methanol extracted rubber septa (SNL, Paris, France). Traps were hung 15 m apart in sunflower fields (var. Viki) on a metallic support in such a way that the base of the traps was 1.5 m above the ground. The catches were recorded every three days during three months, and dispensers replaced every three weeks. Two sets of six traps were tested at the same time, one at St. Gilles and one at Melgueil. Each three-day collection (sum of the St. Gilles and Melgueil identical treatments) was considered a replicate. The results (six treatments with 35 replicates) were submitted to Kruskal-Wallis test.

In a second experiment, nine blends were compared during 20 days (May 9–29, 1989), with three replicates at St. Gilles and three at Melgueil. This experiment was designed to compare the efficiency of blends with *Z*9,*E*12–14:Ald as the major component to blends containing components in the ratio found in gland extracts. Some of these treatments included (*Z*)-13-octadecenal, a compound not identified in the first experiment (Table 2).

Blend dilution and trap design were the same as in first experiment. The catches were recorded every three days, and the results were expressed as the total number of males caught in one trap location. The data were transformed to $\sqrt{(x + 1)}$ and the treatments with a variance significantly different from zero submitted to ANOVA, i.e. three treatments with six replicates, then the means were ranked using Newman-Keuls test (Statitcf software, ITCF, Paris, France).

A third experiment was performed in the autumn of 1989: seven synthetic

[b]Treatments with null variance, not included in the ANOVA (rejection of the χ^2 test of homoscedasticity). No significant differences found with Kruskal-Wallis test.

blends and a pair of virgin females were compared during 37 days (August 28 to October 4), with three replicates at St. Gilles and three replicates at Melgueil.

In this experiment, the effects of dosage of the quaternary blend were tested, using 1000 μg and 100 μg as the sum of the four compounds, in the ratio found in the gland extract. These quaternary blends were also compared to the four possible ternary blends (Table 3).

The female-baited traps consisted of two 1-day-old virgin females in a screened cage, replaced every three days. Blend dilution, trap design, and statistical analysis (seven treatments with six replicates) were the same as in second experiment.

RESULTS

Calling Behavior and Pheromone Gland Morphology. The calling behavior of *H. nebulellum* females occurred within 30 min of lights on and lasted for about 1 hr. Female moths exhibited a characteristic posture, with the abdomen bent anterodorsally to a 90° angle and the ovipositor fully elongated, similar to that shown by *Homoeosoma ellectellum* (Arthur, 1978).

A cross section of the female abdominal tip revealed a ventrolateral glandular layer in the membrane between segments VIII and IX (Figure 1). The cells are mid-sized (10 μm) and rather cubic, contrary to many other moth species, which show tall, hypertrophic cells (Percy and Wheatherston, 1974). The gland is situated into a simple fold and does not appear as an eversible sac as in many noctuid moths (Jefferson et al., 1968). Thus a complete evagination of the ovipositor is necessary for the pheromone to evaporate in the air.

Pheromone Analysis. The GC analysis of a 323-female gland extract showed four principal peaks. GC-MS data (in electron impact mode) identified two 14-carbon aldehydes, a monoene [*m/z* 41, 55 (100%), 67, 81, 95, 98, 192 (M−18)] and a diene [*m/z* 41, 55 (100%), 67, 68, 79, 81, 95, 208 ($M^{+}\cdot$)], one 16-carbon monoenic aldehyde [*m/z* 41, 55 (100%), 69, 81, 95, 98, 220 (M−18)], and one 18-carbon monoenic aldehyde [*m/z* 41, 55 (100%), 69, 81, 95, 98, 248 (M−18)]. Comparisons of the GC retention times with standards have shown the following structures: (*Z*)-9-tetradecenal (*Z*9–14 : Ald: 8.6%), (*Z*,*E*)-9,12-tetradecadienal (*Z*9,*E*12–14 : Ald: 4.8%; 500 pg per female in the extract), (*Z*)-11-hexadecenal (*Z*11–16 : Ald: 49.5%), and (*Z*)-13-octadecenal (*Z*13–18 : Ald: 37.1%). A complete GC resolution of the isomers of 9,12-tetradecadienal was achieved by means of a CPSil 88 column operated at 100°C.

To confirm the low amount of *Z*9,*E*12–14 : Ald found in the extract, washes of whole ovipositors during 10 sec in pentane were performed on three sets of 10, 20, and 30 virgin females, but the GC analyses gave similar results; the *Z*9, *E*12–14 : Ald was always found in minor proportions, never exceeding 10% of the whole blend.

[b]Treatment with null variance, not included in the ANOVA (rejection of the χ^2 test of homoscedasticity). Significant differences found with Kruskal-Wallis test between HN15 vs. HN16 and HN17.

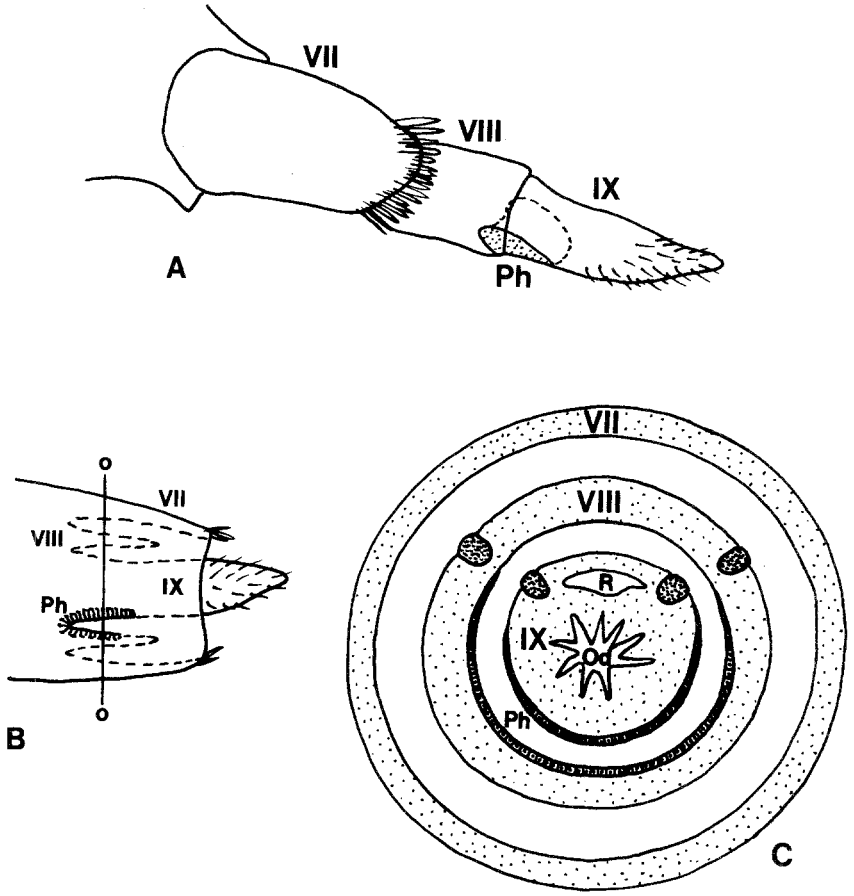

FIG. 1. Schematic view of the ovipositor of the female of *H. nebulellum:* (A) fully elongated; (B) invaginated; (C) cross section along the o-o axis. Ph: sex pheromone gland area; VII, VIII, IX: abdominal segments VII, VIII, and IX; R: rectum; Od: oviduct.

Electrophysiology. The EAG response profile of male ESMs (Figure 2) revealed that the active compounds were the C-14 aldehydes. The most active compound (EAG key compound) was *Z*9,*E*12–14:Ald followed by the monoene, *Z*9–14:Ald. The alcohols and acetate analogs of *Z*9,*E*12–14:Ald also elicited high amplitude EAGs, while *Z*11–16:Ald and *Z*13–18:Ald, two other components found in female glands, did not.

Recordings from single olfactory hairs revealed two classes of action potentials (Figure 3), indicating the presence of at least two olfactory neurons,

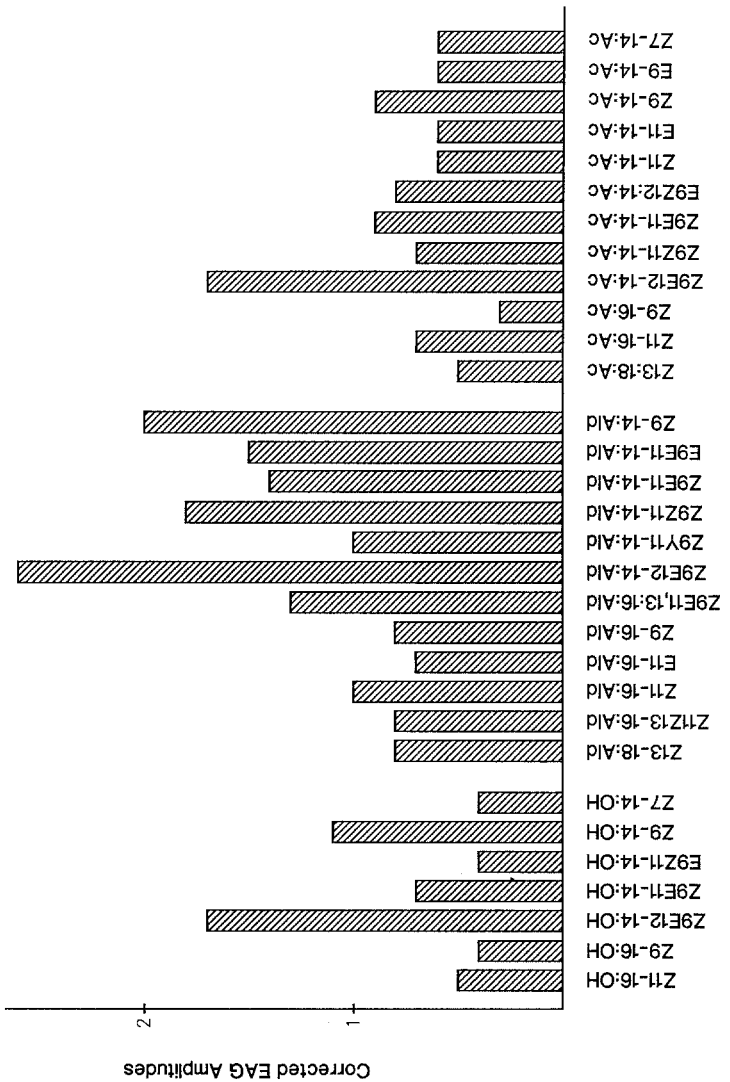

FIG. 2. Electroantennogram screening performed on male antenna with 31 compounds known as attractants or analogs in the Phycitinae or identified in the pheromone gland extracts of *H. nebulellum* females. Name of compounds were abridged as follows: Z9- geometry and position of the double bond; Y11- triple bond; -14: chain length; : OH, : Ald, : Ac, chemical function = alcohol, aldehyde, acetate.

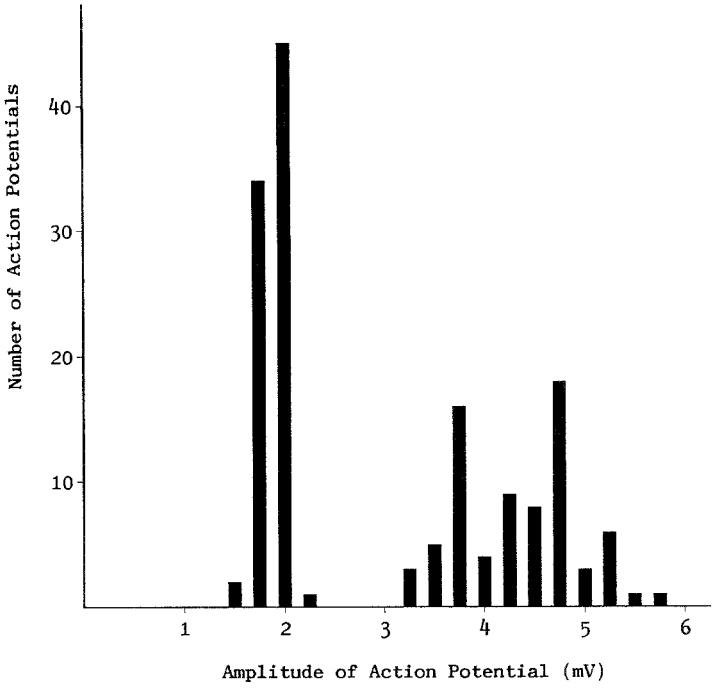

FIG. 3. Typical action potential histogram showing two classes of amplitude, recorded during spontaneous activity and stimulations with *Z*9,*E*12–14 : Ald and *Z*9,*E*12–14 : Ac from a single sensillum trichodeum.

housed within the sensilla trichodea of male ESMs. Type A neurons, with the highest amplitude action potentials, were stimulated almost exclusively by *Z*9,*E*12–14 : Ald, the EAG key compound, and slightly by *Z*9–14 : Ald (Figure 4A). Type B neurons with small amplitude action potentials were principally excited by *Z*9,*E*12–14 : Ac (Figure 4B). One female-equivalent of ESM gland extract elicited a strong firing of A but not B cells. Olfactory neurons sensitive to other components of the female pheromone secretion may exist, but none was detected within the sample of olfactory hairs from which we recorded.

Field Trapping. The first field trials with synthetic blends were carried out in 1988, when *Z*13–18 : Ald was not yet identified in the female secretion. The results (Table 1) reveal that the blends containing two compounds, *Z*9,*E*12–14 : Ald and *Z*11–16 : Ald, were attractive to the males. In contrast, *Z*9,*E*12–14 : Ac, which excited B cells in sensilla recordings, appeared to reduce the catches when added at the 10% ratio.

Further field tests were conducted in the spring of 1989 in order to determine the effects of the addition of *Z*13–18 : Ald to the mixtures that gave the

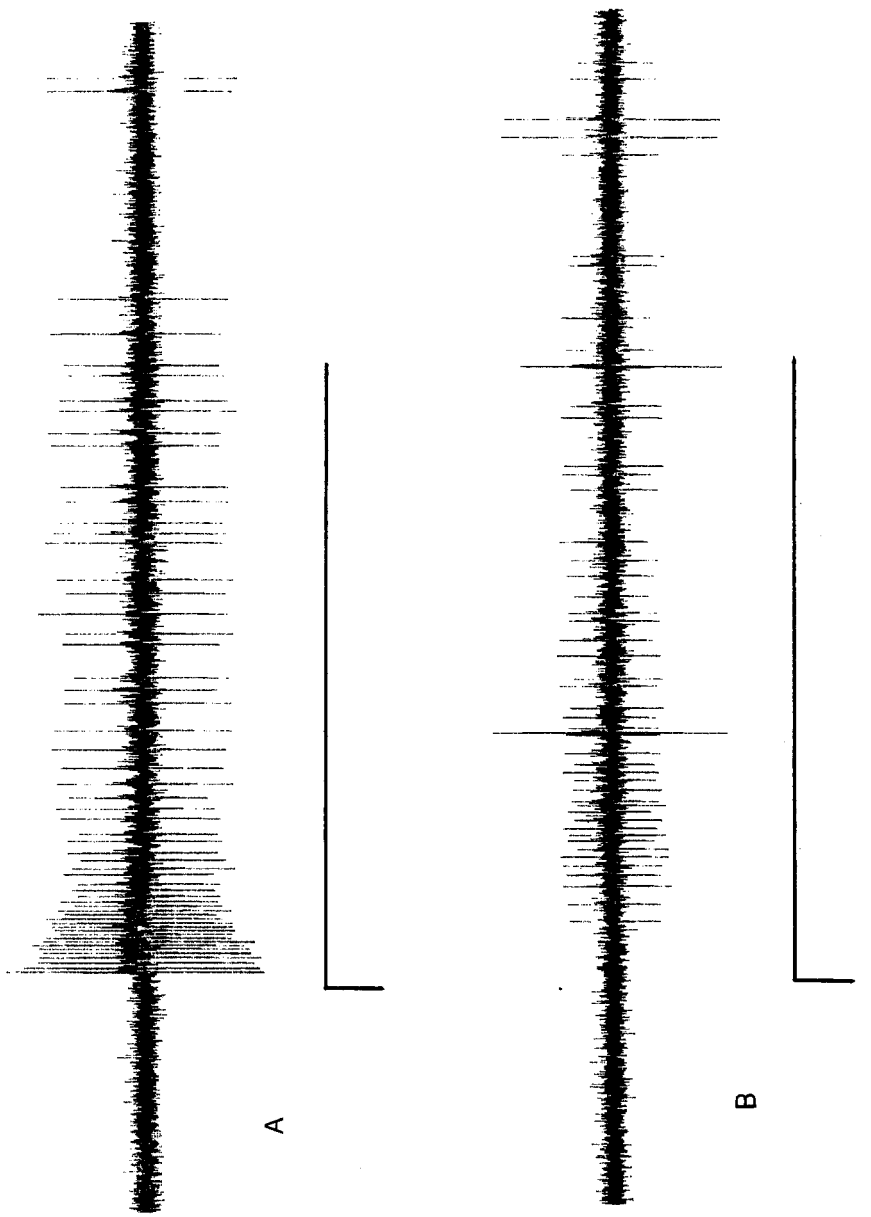

FIG. 4. Responses recorded from a single sensillum trichodeum in male *H. nebulellum*: (A) stimulation by 0.1 μg of Z9,*E*12–14:Ald during 1 sec; (B) stimulation by 0.1 μg of Z9,*E*12–14:Ac during 1 sec. Vertical scale: 1 mV; horizontal scale: 1 sec.

best results in 1988 (Table 2). This compound was proven to increase the attractivity of a ternary blend (HN5 vs. HN9), but the most important catches were obtained with the four-component blend in the same ratio as in the female extract, i.e., 4.8% of *Z*9,*E*12–14 : Ald. In contrast, a blend including this dienic aldehyde as the major constituent caught five times fewer males.

In another experiment in the summer of 1989, the role of single components was investigated by comparing the attractivity of three- component versus four-component blends (Table 3). The removal of *Z*9,*E*12–14 : Ald (HN15) completely suppressed the captures. The importance of *Z*11–16 : Ald (HN16) and *Z*13–18 : Ald (HN17) for attraction also was demonstrated, whereas *Z*9–14 : Ald did not seem to be involved in sexual attraction in our experimental conditions (HN14).

DISCUSSION AND CONCLUSION

The terminology of pheromone components used in moth communication systems is quite ambiguous for *H. nebulellum*. In many species, the major component of the female secretion is easily detected by EAG screenings (Roelofs, 1984), and sometimes it is sufficient to attract males when used alone or it dramatically suppresses catches when removed from a complex blend mimicking the natural pheromone (Linn et al., 1984). Most behavioral studies have shown the importance of minor compounds added to the major component to evoke complete mating sequences in olfactometers or higher capture levels in field tests.

The results obtained with *H. nebulellum* lead us to choose slightly different terms: (1) The analyses of gland extracts have shown that *Z*11–16 : Ald is the major component of female secretion (50%). (2) The EAG and single-cell recordings clearly demonstrated *Z*9,*E*12–14 : Ald to be the "antennal key compound." (3) From the field trapping results it appeared that *Z*9,*E*12–14 : Ald was not attractive when used alone but was essential to attraction in ternary blends, thus *Z*9,*E*12–14 : Ald is the behavioral key compound.

If *Z*9,*E*12–14 : Ald is the antennal or behavioral key compound, one would expect it to be the major component in the female secretion, as seen in nearly all previous identification studies that include GC analyses, EAG studies and bioassays (see Tamaki, 1985; Arn et al., 1986, for the most recent reviews). Nevertheless, extracts obtained by various methods in *H. nebulellum* have shown that the percentages of *Z*9,*E*12–14 : Ald never exceeded 10%. This low amount does not seem to be an artifact due to an inadequate extraction method, because the blends containing 5% of this compound are more attractive in the field than those containing 60% (HN9 vs. HN10, Tables 2 and 3). Furthermore, the most attractive blends in 1988, HN1 and HN5, with 65% of *Z*9,*E*12–14 : Ald

attracted five males only in 1989 when in competition with other blends containing 5% of this compound (Table 2). The role of Z9–14:Ald cannot be deduced from these experiments; in some cases, it appears as a slight but not significant inhibitor (Table 3). An evaluation of the blend really emitted by the female is needed before including it as a component of the sex pheromone.

A complete pheromone identification is generally achieved by the collection of airborne effluvia emitted by the calling females, but the heterogeneity of chain lengths of *H. nebullellum* pheromone compounds did not provide a suitable model for a collection of volatiles. The occurrence of 14, 16, and 18 carbon chain lengths could prevent a reliable quantification of relative percentages (and all subsequent EAG or behavioral studies) without previous studies on adsorbance and elution of these compounds on either glass or resin.

By examining the previous pheromone identification studies in Lepidoptera, we found that the antennal and behavioral key compound was always the major component of the female secretion (in many cases, a blend of two geometric isomers acts as a unit in the same way). Thus the chemical communication system used by *H. nebulellum* seems to be rather unusual. In another Phycitinae, *Elasmopalpus lignosellus*, the major component of the female secretion, (*Z*)-9-hexadecenol, is not essential to the male attraction (Lynch et al., 1984), but EAG data are not available for this species and the key compound does not appear clearly from this study.

The American sunflower moth, *Homoeosoma electellum*, is a species that seems to occupy the same ecological niche as *H. nebulellum* in Europe. In both species kairomonal relationships were reported between the female moths and a substance released by the pollen of sunflowers (Delisle et al., 1989,for *H. ellectellum*; Le Metayer, to be published, for *H. nebulellum*). Thus these species appear to be very closely related. By contrast, the sex pheromone system of *H. ellectellum* is quite different from the European species. The major component, (*Z,E*)-9,12-tetradecadienol (*Z*9,*E*12–14:OH), is able to attract more males than virgin females, even at low dosage (1 μg), and other compounds identified in the female secretion, (*Z*)-9-tetradecenol and tetradecanol, do not enhance the efficiency of the attractant tested (Underhill et al., 1979, 1982).

The occurrence of a key compound in the ESM that is not the major constituent of the female blend raises many questions about the perception of multicomponent sex pheromones. The importance of minor compounds essential to attraction was pointed out nearly 20 years ago by Klun et al. (1973). Since then, two different systems were proposed to explain the perception of complex blends. In the first one, the major component acts as a long-range releaser to evoke taking off and initial orientation. The minor compounds may act at short-range in eliciting subsequent behaviors in the mating sequence, like landing or courtship initiation. Then, each component, or a partial combination of components, would play a different role during the mating sequence (Bradshaw et

al., 1983). More recently, it appeared that, instead of different steps of behavior released by different components, the whole blend acts as a unit to evoke a behavioral sequence. This problem was reviewed by Linn and Roelofs (1989), who proposed the terms "component paradigm" and "blend paradigm" to define the two possible processes. According to the most recent works, the blend paradigm tends to be recognized as a general phenomenon (Linn and Roelofs, 1989).

At this time, the precise blend emitted in the air by the calling female remains unknown. If *Z*9,*E*12–14 : Ald really acts at very low percentages, the ESM could represent a new model to understand the perception of multicomponent pheromones in Lepidoptera. Work to investigate this further is in progress.

Acknowledgments—We are grateful to Dr. Jeremy N. McNeil for his helpful comments on the manuscript and reviewing the English text.

VOLATILE COMPONENTS IN DEFENSIVE SPRAY OF THE SPOTTED SKUNK, *Spilogale putorius*

WILLIAM F. WOOD,* CHRISTOPHER G. MORGAN, and ALISON MILLER

Department of Chemistry
Humboldt State University
Arcata, California 95521

(Received December 17, 1990; accepted March 18, 1991)

Abstract—GC-MS analysis of the anal sac secretion from the spotted skunk, *Spilogale putorius*, showed three major volatile components: (*E*)-2-butene-1-thiol, 3-methyl-1-butanethiol, and 2-phenylethanethiol. Minor volatile components identified from this secretion were: phenylmethanethiol, 2-methylquinoline, 2-quinolinemethanethiol, bis[(*E*)-2-butenyl] disulfide, (*E*)-2-butenyl 3-methylbutyl disulfide, bis(3-methylbutyl) disulfide. All of these compounds except 2-phenylethanethiol have been identified previously from the striped skunk, *Mephitis mephitis*. The thioacetate derivatives *S*-(*E*)-2-butenyl thioacetate, *S*-3-methylbutanyl thioacetate, and *S*-2-quinolinemethyl thioacetate found in the striped skunk were not seen in this species.

Key Words—Mustelidae, *Spilogale putorius*, spotted skunk, anal sac secretion, (*E*)-2-butene-1-thiol, 3-methyl-1-butanethiol, 2-phenylethanethiol, phenylmethanethiol, 2-methylquinoline, 2-quinolinemethanethiol, bis[(*E*)-2-butenyl] disulfide, (*E*)-2-butenyl 3-methylbutyl disulfide, bis(3methylbutyl) disulfide.

INTRODUCTION

The four species of skunks (Carnivora, Mustelidae, subfamily Mephitinae) found in North America are the striped skunk, *Mephitis mephitis*; the spotted skunk, *Spilogale putorius*; the hog-nosed skunk, *Conepatus leuconotus*; and the hooded skunk, *M. macroura*. All are known for their potent means of chemical defense: the spraying of a repulsive-smelling liquid from their anal glands. Only

the defensive secretion of the most common member of this group, the striped skunk, *M. mephitis*, has been reported and was the subject of many investigations (Swarts, 1862; Aldrich, 1896; Aldrich and Jones, 1897; Stevens, 1945; Andersen and Bernstein, 1975; Andersen et al., 1982; Wood, 1990). In this study, we report the volatile components of this malodorous secretion from the spotted skunk, *S. putorius*.

METHODS AND MATERIALS

Two spotted skunks, a male and a female, were obtained on removal from areas where they were a nuisance in Humboldt County, California. They were sacrificed with diethyl ether, and within an hour a sample of the defensive secretion was obtained by inserting a needle into the anal sac and withdrawing the contents. The secretion was immediately placed in a freezer at −20°C for several weeks until it could be analyzed by gas chromatography–mass spectrometry (GC-MS).

GC-MS was done on a Hewlett Packard gas chromatograph (model 5890) fitted with a mass selective detector (model 5970) using a 12-m cross-linked methyl silicone capillary column. The gas chromatograph was programmed so the oven temperature was kept at 40°C for 4 min, then increased to a final temperature of 250°C at a rate of 30°C/min, and kept at this temperature for 4 min. Mass spectral fragments below $m/z = 35$ were not recorded. An isotope peak ($M^+ + 2$) was observed for all sulfur-containing compounds that had a molecular ion. The relative amount of each component is reported as the percent of the total ion current.

Reference compounds were obtained as follows: (*E*)-2-Butene-1-thiol was obtained from the anal sac of a striped skunk (Andersen and Bernstein, 1975). 3-Methyl-1-butanethiol, phenylmethanethiol (benzyl mercaptan), 2-methylquinoline, and benzyl methyl sulfide were purchased from Aldrich Chemical Co. 1-Phenylethanethiol and 2-phenylethanethiol were prepared by the method of Urquhart et al. (1955) from (1-bromoethyl)benzene and (2-bromoethyl)benzene, respectively. 2-Quinolinemethanethiol was prepared as described by Wood (1990). Bis[(*E*)-2-butenyl] disulfide, (*E*)-2-butenyl 3-methylbutyl disulfide, and bis(3-methylbutyl) disulfide were prepared by treatment of the defensive secretion with iodine as described by Wood (1990).

Since the thioacetates detected from the striped skunk (Wood, 1990) were not found in this study, an experiment was done to see if they were lost on storage. A sample of the striped skunk secretion that had been kept in a freezer for six months was examined. GC-MS analysis showed the thioacetates had not been destroyed during storage.

RESULTS

GC-MS analysis of a diethyl ether solution of the anal sac secretion from the spotted skunks showed three major components (Figure 1). These compounds and their amounts (percentage male, percentage female) are (*E*)-2-butene-1-thiol (I; 36%, 30%), 3-methyl-1-butanethiol (II; 48%, 66%) and 2-phenylethanethiol (III; 5%, 2%). (*E*)-2-Butene-1-thiol was identified by comparison of the GC retention time and mass spectrum with a sample of this compound from the striped skunk. 3-Methyl-1-butanethiol had identical retention time and mass spectra as an authentic sample.

The mass spectrum of the third major component was: *m/z* 140 (M^++2, 0.9), 138 (M^+, 21), 105 (5), 104 (14), 103 (5), 92 (14), 91 (100), 78 (6), 77 (10), 65 (12), and 51 (12). Since an isotope peak at *m/z* 140 (M^++2) was 4% of the molecular ion (*m/z* 138), it indicates the compound contains one sulfur atom and suggests it has the molecular formula, $C_8H_{10}S$. The base peak at *m/z* 91 is likely a tropylium ion ($C_7H_7^+$) and indicates the sulfur to be on the side chain of a monosubstituted benzene. The three possible candidates that fit these criteria are benzyl methyl sulfide, 1-phenylethanethiol, and 2-phenylethanethiol. When these compounds were checked by GC-MS, only 2-phenylethanethiol had the same retention time and mass spectrum as the compound from the skunk.

A number of minor components (Figure 2) were identified from this secretion by comparison of GC retention times and mass spectra with reference compounds. These compounds and their amounts (percentage male, percentage female) are phenylmethanethiol (IV; 0.8%, 0.2%), 2-methylquinoline (V; 0.9%, 0.3%), 2-quinolinemethanethiol (VI; 0.3%, 0.2%), bis[(*E*)-2-butenyl] disulfide (VII; trace, trace), (*E*)-2-butenyl 3-methylbutyl disulfide (VIII; 0.6%, 0.2%), and bis(3-methylbutyl) disulfide (IX; 0.1%, 0.2%).

The thioacetate derivatives of thiols found by Wood (1990) in the striped skunk could not be detected in the spotted skunk. These compounds (Figure 3)

FIG. 1. The major volatile components of spotted skunk spray: (*E*)-2-butene-1-thiol (I), 3-methyl-1-butanethiol (II), and 2-phenylethanethiol (III).

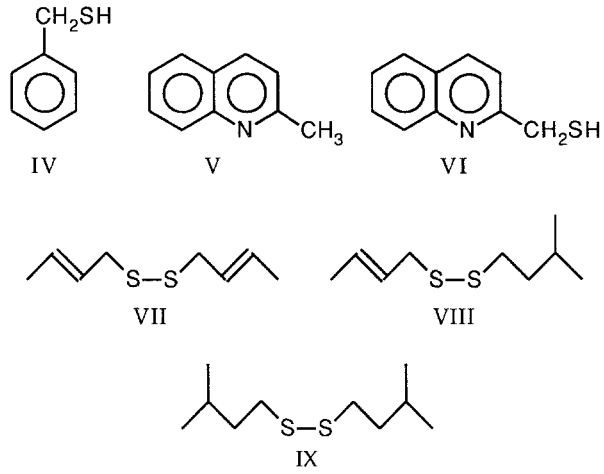

FIG. 2. The minor volatile components in spotted skunk spray: phenylmethanethiol (IV), 2-methylquinoline (V), bis[(*E*)-2-butenyl] disulfide (VII), (*E*)-2-butenyl 3-methylbutyl disulfide (VIII), and bis(3-methylbutyl) disulfide (IX).

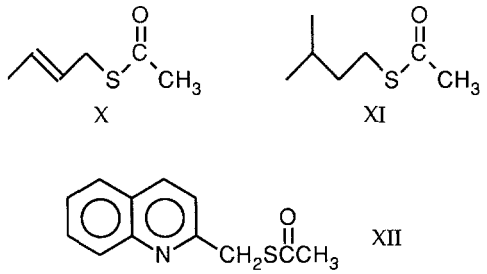

FIG. 3. The thioacetates found in striped skunk spray that are not found in the spotted skunk: *S*-(*E*)-2-butenyl thioacetate (X), (*S*)-3-methylbutanyl thioacetate (XI), and *S*-2-quinolinemethyl thioacetate (XII).

are *S*-(*E*)-2-butenyl thioacetate (X), *S*-3-methylbutanyl thioacetate (XI), and *S*-2-quinolinemethyl thioacetate (XII). To see if these compounds had been lost during the several weeks of storage, a six-month-old sample of striped skunk secretion stored at −20°C was analyzed by GC-MS. The thioacetates were still present.

DISCUSSION

The two major thiols in the spotted skunk secretion, (*E*)-2-butene-1-thiol and 3-methyl-1-butanethiol, are also the major components in the defensive spray of the striped skunk (Andersen and Bernstein, 1975). The ratio of these

compounds is the reverse of the striped skunk. (*E*)-2-Butene-1-thiol is the major volatile component of the striped skunk (Wood, 1990), while 3-methyl-1-butanethiol is the major volatile component of the spotted skunk. The third most abundant compound, 2-phenylethanethiol, has not been reported from the defensive secretion of the striped skunk. Andersen and coworkers (1982) did report an isomer of this compound, 1-phenylethanethiol, as a minor component from the striped skunk. It is clear that the compound from the spotted skunk is 2-phenylethanethiol as the 1-phenyl isomer had a different mass spectrum.

The minor components found in the spotted skunk defensive secretion have been identified previously in striped skunk defensive secretion. Andersen and coworkers (1982) identified phenylmethanethiol at less than 1%. They also found the three disulfides that form on oxidation of the two major thiols, bis[(*E*)-2-butenyl] disulfide, (*E*)-2-butenyl 3-methylbutyl disulfide, bis(3-methylbutyl) disulfide, as minor components (less than 1%). 2-Methylquinoline was first identified by Aldrich and Jones (1897), and 2-quinolinemethanethiol was found by Wood (1990) in the striped skunk.

A major difference in the secretions from the striped and spotted skunks is the lack of thioacetates in the spotted skunk secretion. Wood (1990) found a thioacetate derivative for each of the free thiols found in the striped skunk. It is clear that these thioacetates were not present in the spotted skunk secretion and were not lost on storage. The fact that the thioacetates are not present in the spotted skunk secretion may give a clue to the biosynthesis of these compounds and their corresponding thiols. The thioacetates also may play a part in the difference in effectiveness of the two secretions. The thioacetate derivatives will slowly hydrolyze and continue to release the offensive-smelling thiols over a period of time. Anecdotal reports from an individual whose pets have been sprayed by both species indicates the defensive secretion of the striped skunk is more persistent and harder to remove (W.C. Lancaster, Humboldt State University, personal communication). This individual also reports "skunk odor" to return to sprayed animals long after an encounter with a striped skunk when their hair is wet.

Acknowledgments—William Stanley, Assistant Curator, Vertebrate Museum, Humboldt State University, is thanked for obtaining one skunk and for confirming the identification of the species. Tom Borgers, Department of Chemistry, Humboldt State University, is thanked for helping collect one of the skunks. This study was partially supported by a Research and Creative Activity Award No. 1-11482 from the California State University.

Abstract—Host and conspecific discrimination were tested as reproductive isolating mechanisms between *Ips paraconfusus* Lanier infesting *Pinus coulteri* (Torrey) and *I. confusus* (Le Conte) infesting *P. monophylla* (Fremont). In two areas (one area largely Coulter pine and the other largely pinyon pine) where these bark beetles and hosts cooccur in southern California, we induced pheromone production in host and nonhost logs using males of each species. *Ips paraconfusus* females joined both heterospecific and conspecific males tunneling in both tree species in each area. *Ips confusus* females failed to join *I. paraconfusus* males in Coulter pine, but joined *I. paraconfusus* in pinyon pine. Sympatry was demonstrated when females of both sibling species joined conspecific males in their respective hosts. Males attacked all four beetle–host treatment combinations in both areas. Laboratory tests confirmed these results. Males did not displace heterospecific males from nuptial chambers in hosts, and they did not occupy a gallery in which heterospecific males produced frass. Females that left conspecific males in a host were readily accepted by heterospecific males and oviposited in a nonhost.

Key Words—Interspecific mating, *Ips confusus*, *Ips paraconfusus*, Coleoptera, Scolytidae, reproduction, reproductive isolation.

INTRODUCTION

The engraver bark beetle genus *Ips* contains about 60 recognized species in North and Central America, Europe, and Asia (Hopping, 1963, 1965; S. L.

*To whom correspondence should be addressed.

Wood, 1982). Three sibling species in species group *grandicollis* Wood (1982), *I. confusus* (Le Conte), *I. hoppingi* Lanier, and *I. paraconfusus* Lanier are virtually identical morphologically and electrophoretically (Cane et al., 1990b), which suggests a recent origin from a common ancestor. Their species status is based primarily upon their host association, geographic distribution, failure to hybridize, karyology, and differences in the striation density on the *pars stridens*, a cephalic stridulatory apparatus (Lanier, 1966, 1970, 1971, 1972). In the San Bernardino National Forest there are areas of nearly pure stands of Coulter pine, *P. coulteri* (Torrey), a host of *I. paraconfusus*, and single-leaf pinyon, *P. monophylla* (Fremont), a host of *I. confusus*, as well as narrow zones of host sympatry (Critchfield and Little, 1966). One potential postmating barrier, failure of heterospecific larvae to successfully develop in a nonhost, does not occur (Cane and Wood, unpublished). Another postmating barrier, failure to hybridize, demonstrated by Lanier (1971), was recently confirmed by Merrill (1991) when she reared beetles in the laboratory and paired them with virgin females of known identity. The study reported here continues our investigation (Cane et al., 1990a, b) of possible premating barriers to hybridization between *I. paraconfusus* and *I. confusus*.

Premating barriers likely involve discrimination of host from nonhost, conspecific from heterospecific pheromones, and mate recognition or proximal behavioral cues. Host discrimination by *Ips* species occurs prior to or after landing, or after penetration of the bark. Host discrimination by *I. paraconfusus* may be influenced by the presence of feeding stimulants and the absence of feeding deterrents in the host phloem (Elkinton and Wood, 1980; Elkinton et al., 1980). However, Cane et al. (1990a) concluded that host discrimination was not absolute for these populations because they demonstrated that: (1) both male and female *I. confusus* and *I. paraconfusus* colonize host and nonhost pine bolts (pinyon and Coulter pine) presented to populations adjacent to a zone of sympatry; and (2) pioneering *I. paraconfusus* and *I. confusus* males, under the influence of pheromones, are trapped in large numbers at uninfested pinyon and Coulter pine bolts in both habitats. Stridulation can be important for mate recognition in *Ips* species and other scolytids (Barr, 1969; Alcock, 1982). *Ips paraconfusus* and *I. confusus* have different densities of striae on the pars stridens of the stridulatory apparatus (Lanier, 1970; Cane et al., 1990a) but produce nearly identical fundamental frequencies of vibration. However, their bisyllabic chirps are temporally distinctive (Lewis and Cane, unpublished).

Pheromones may serve as premating barriers for bark beetles. *Ips* species produce pheromones that elicit behavior, resulting in aggregation of beetles on the new host. This aggregation must be both timely and of sufficient magnitude to exploit the new resource. Pheromones are produced in the insect gut and frass (fecal pellets with phloem and xylem fragments) after prolonged feeding on phloem and have been identified for *I. paraconfusus* and *I. confusus* (sum-

marized in D. L. Wood, 1982). Differences in response to and production of pheromones has been documented in *I. pini* and may account for some species differentiation (Lanier et al., 1972, 1980; Birch et al., 1980). Lanier and Wood (1975) tested the pheromone specificity of 17 species of *Ips* and discovered that species within the same species groups are cross-responsive, unlike species in different species groups. Species with broadly sympatric distributions in the same host are from different species groups, while members in the same species group are largely allopatric. *Ips paraconfusus* and *I. confusus* females were attracted to frass produced by males of the other species when presented individually in the laboratory olfactometer and in simultaneous, paired comparisons with conspecific frass. Cross-responsiveness and interspecific pairing (i.e., females joining male galleries) between *I. confusus* and *I. paraconfusus* has been demonstrated in the field, but intermating was not established (Lanier and Wood, 1975). Cane et al. (1990a) reported that for beetles in flight, discrimination of host volatiles and conspecific pheromones were incomplete and asymmetrical because female *I. paraconfusus* did not have the same degree of discrimination as female *I. confusus*.

In the San Bernardino National Forest, heterospecific pairing and natural colonization of nonhosts were not located in zones of sympatry despite persistent search in this and earlier studies (Cane et al., 1990a). Therefore, we further investigated whether this incomplete discrimination of host volatiles and pheromones, coupled with proximal behavioral cues subsequently available to beetles freely walking on the bark, may be sufficient to elicit associations with the native host and conspecific mates. First, we tested the hypothesis that beetles in the field can pair with heterospecifics and colonize nonhosts. Next, this hypothesis was partitioned into specific behavioral elements. In the laboratory, experiments were designed to determine: (1) the likelihood of beetles encountering a heterospecific at a nuptial chamber excavated by a conspecific male; (2) the ability of beetles to discriminate hosts and conspecifics in an atmosphere saturated with pheromones of both species; (3) the influence of host on conspecific discrimination; (4) if heterospecific pairing will occur when populations are limited; and (5) if conspecific-inseminated females will join heterospecific males.

METHODS AND MATERIALS

Field Tests

Two test sites were selected during June 1–15, 1986, in the San Bernardino Mountains of southern California. One test site was located near Lake Arrowhead, California, at approximately 1500 m elevation on U.S. Forest Service property along Hook Creek Road 2N26Y, Range 2W, and Township 2N. Here-

after, this site is referred to as Lake Arrowhead. The dominant canopy vegetation was mixed conifer, consisting of mainly Coulter and ponderosa pines with some incense cedar, white fir, and oaks. The nearest pinyon pines were estimated to be 5–7 km distant. An intensive Coulter pine thinning operation provided logging debris heavily infested with *I. paraconfusus*.

The second site was approximately 67 km east of Lake Arrowhead near Baldwin Lake at approximately 2000 m elevation on Highway 38, Range 2E, and Township 3N. Hereafter, this site is referred to as Baldwin Lake. Here the dominant vegetation was primarily pinyon pines, oaks, Joshua trees, and cacti. Pinyon pines weakened by blackstain root disease [*Leptographium wageneri* (Harrington and Cobb)] (Cobb et al., 1974) were attacked by *I. confusus*. The nearest ponderosa and Jeffrey pines, potential hosts to *I. paraconfusus*, were estimated to be 2–4 km distant. Coulter pines are not present at this locality. Both areas were monitored for bark beetle activity using multiple-funnel traps (Lindgren, 1983) baited with *I. paraconfusus* males tunneling in ponderosa pine. These traps consistently caught approximately 16 beetles/day for three days.

Ips paraconfusus in Coulter pine were collected 5 km north of Lake Arrowhead, and *I. confusus* in pinyon pine were collected at Little Pine Flat, 17 km east of Baldwin Lake. Four living pinyon pines and two Coulter pines, 20–25 cm in diameter, were felled, and 24 hr later, cut into sections each providing 2000 cm^2 surface area. Males of each species were paint-marked on the elytral declivity (which had no apparent effect on beetle behavior) and were singly confined using 2 × 2-cm aluminum screen stapled over artificial entrance tunnels formed in host and nonhost pines. There were 20 logs in both areas, five replicates of each treatment, each containing 25 males: (1) *I. confusus* on pinyon, (2) *I. confusus* on Coulter, (3) *I. paraconfusus* on pinyon, and (4) *I. paraconfusus* on Coulter pine. After 24 hr, each log had 20–25 beetles producing frass. Logs were assigned randomly over a grid pattern in a fairly uniform area of forest with each position separated from another by at least 25 m. Following placement, the small aluminum screens were removed and the logs were monitored every other day for fresh attacks, termed "volunteers."

After five days, the bark and phloem were cut and removed near the nuptial chamber. All adults were identified and galleries were recorded by tracing them onto clear acetate sheets. Test logs not dissected in the field were wrapped in aluminum screen, returned to Berkeley within 48 hr, and placed in cold storage. One hundred ninety-eight heads were examined by SEM (method described in Cane et al., 1990a), approximately 20 from each treatment at each site and 20 beetles captured as emergent adults from infested host trees at each site. Because a randomized block design was used where each block contains four treatments each with five logs at each of the two sites, the data from each treatment were analyzed using an ANOVA for randomized complete blocks (SAS, 1982). When the test indicated significant differences, all pairs of treatments were compared

by using the Studentized range test with Bonferroni's inequality (Bedard et al., 1980). Laboratory tests were analyzed using Bonferroni's inequality. All tests were made at the 5% level of significance.

Laboratory Behavior Tests

Experimental logs were placed in exclusion chambers measuring 1 m in each direction, producing an atmosphere which was assumed to be saturated with pheromones. Pinyon and Coulter pine hosts, stored at 5°C for one month, were cut into sections each providing 2000 cm^2 surface area. Factitious entrance tunnels were made in log sections using a drill, and beetles were confined in tunnels using 2 × 2-cm aluminum screen cages. All beetles used were uniquely paint-marked. At the terminus of the experiments, logs were quick-frozen at −30°C and dissected. Beetle identity, presence of an egg gallery, number of eggs and larvae, gallery length, and female and male position in the gallery were recorded on clear acetate sheets.

Displacement of Males in Nuptial Chambers. If female discrimination is important and if females are to reliably recognize a male's species status solely by the pheromone in his frass, which is produced during his excavation of the nuptial chamber, then males should remain associated with their nuptial chambers. If a heterospecific male usurps a nuptial chamber excavated by another male, unproductive pairings can occur. To test the hypothesis that males can displace resident males in nuptial chambers, 25 males of one beetle species were placed in a nonhost and 50 males of another beetle species that normally colonizes that host were released in the same chamber. After six days, these logs were removed from the boxes and external beetles were retrieved. The identity of the beetle occupying the nuptial chamber was observed.

Specific Mate Recognition with Host Discrimination. Conspecific pheromones emanating adjacent to heterospecific entrance tunnels may confound discrimination. To test this hypothesis, we examined the ability of beetles to discriminate conspecifics from heterospecifics when they were placed together in a host within an atmosphere saturated with pheromones of both species. Twenty each of *I. confusus* and *I. paraconfusus* were confined in one pinyon pine log and 20 each of both species were placed in one Coulter pine log, so that each male's nearest neighbor was a heterospecific. After 36 hr aluminum screen cages were removed from male entrance tunnels and both logs were placed in a box with 45 female *I. confusus* and 45 female *I. paraconfusus*. After six more days, the logs were removed and dissected.

Specific Mate Recognition with No Host Choice. Our field tests indicated that *I. confusus* females had a preference for their host. By eliminating host choice, we hoped to test conspecific discrimination only. We used one pinyon log only and 20 *I. confusus* and 20 *I. paraconfusus* males introduced into arti-

ficial entrance tunnels for 36 hr so that each male's nearest neighbor was a heterospecific. Next, the small aluminum screen cages were removed and the log was placed in a chamber with 45 *I. confusus* females. After six days, the log was frozen and dissected.

Heterospecific Females Mixed in Galleries. Conspecifics and heterospecifics may segregate when both species are plentiful, but join heterospecific males when populations are limited, because there may be an optimum number of beetles that improves the success of the family gallery (Kirkendall, 1983). To test this hypothesis, 20 *I. paraconfusus* males were introduced into artificial entrance tunnels in a Coulter pine log and placed in a separate chamber. Twenty *I. confusus* males were similarly placed in a pinyon pine log. After 36 hr the confining cages were removed and 15 females of each species were released into each chamber. After nine days the logs were frozen and dissected.

Females Leaving Conspecific Males and Pairing with Heterospecific Males. In the laboratory, interspecific-matings between these two species produce inviable eggs (Lanier, 1970). In the field we observed several males with heterospecific females producing larvae. One explanation for these observations may be that conspecific-inseminated females had joined the heterospecific male. To test this hypothesis, 20 male *I. paraconfusus* and 20 male *I. confusus* were confined in entrance tunnels on their hosts and placed in separate chambers for 36 hr. Conspecific females were introduced, one per day, into each male gallery until each male had accepted three females. Two days after this, a log containing only heterospecific males in their host was placed into each box. Therefore, females recovered from these nonhost logs containing heterospecific males could only come from the host logs containing conspecific males. To bracket the 14-day period that females may leave their egg galleries and possibly join heterospecifics, two other similar nonhost logs containing heterospecific males were added after 10 more days had elapsed. All logs were frozen and dissected.

RESULTS

Field Tests

Measurements of 10 striae of the pars stridens of 20 females that emerged from Coulter pine collected at Lake Arrowhead ranged from 0.42 to 0.49 μm ($\bar{X} = 0.46$). For 19 females emerged from pinyon pine collected at Baldwin Lake, the measurements ranged from 0.56 to 0.69 μm ($\bar{X} = 0.63$). These data generated a size range of the striae for both species (Table 1). Lake Arrowhead appears to be almost exclusively an *I. paraconfusus* population, with only 2% *I. confusus* present. Here only two of 79 females removed from the treatment logs were found with striae widths that did not fit the size ranges of either *I. confusus* or *I. paraconfusus* that had emerged from their respective hosts. We

I. confusus in pinyon pine	4	0	14
I. confusus in pinyon pine[b]	0	0	19

[a] Identification is based upon the width of 10 striations of the supracephalic stridulatory organ (*pars stridens*) of the female. Beetles were removed from experimental logs placed in the field or emerged from logging debris collected on site. Beetles within the range 0.51–0.54 μm could not be confidently identified and were designated as unidentified.
[b] Collected from naturally infested logging debris on site.

classed these females as "unidentified." A mixed species population was present at Baldwin Lake with a ratio of about two *I. confusus* to one *I. paraconfusus* and 15% of the female *Ips* population at Baldwin Lake were in the "unidentified" size range.

The mean number of males that formed nuptial chambers ranged from 21.4 to 24.4 for the 25 artificial entrance tunnels at both test sites. A nuptial chamber was formed if the engraving on the surface of the sapwood was similar in size and shape to other nuptial chambers that yielded a successfully joined male. At Lake Arrowhead, fewer *I. confusus* in pinyon pine produced frass than the other treatments and at Baldwin Lake fewer *I. paraconfusus* produced frass in Coulter

pine than the other treatments, but these differences were not significant. At Baldwin Lake fewer *I. paraconfusus* and *I. confusus* tunneling in pinyon produced frass than these species tunneling in Coulter pine. These differences were significant. Interestingly, more nuptial chambers were abandoned in pinyon pine than in Coulter pine at both sites.

At Lake Arrowhead, *I. paraconfusus* females joined all treatments. However, treatments with Coulter pine were significantly different from treatments with pinyon pine (Table 2). Thus *I. paraconfusus* females appear to be able to discriminate their host. At Baldwin Lake, no *I. confusus* females joined male

I. paraconfusus in Coulter pine (Table 1). However, *I. paraconfusus* females clearly preferred conspecific males in their host Coulter pine. The remainder of *I. paraconfusus* and a small number of "unidentified" females joining males were distributed almost equally among the other three treatments. At Baldwin Lake, *Ips confusus* females appeared to be capable of discrimination of the combination of *I. paraconfusus* in Coulter pine from all other host–species combinations.

There were no significant differences in mean number of females recovered per male (Table 3). At Lake Arrowhead, the mean number of egg galleries in pinyon pine was different (i.e., lower) from that in Coulter pine, due to the reduced female joining observed in pinyon pine (Table 2). Egg gallery length in pinyon pine with male *I. confusus* and *I. paraconfusus* also was reduced compared to other treatments in Coulter pine. At Baldwin Lake, mean egg gallery length in the treatment with Coulter pine and *I. paraconfusus* females was reduced. There were significant differences between abandoned nuptial chambers in both pine species at Baldwin Lake. More than twice as many nuptial

chambers were abandoned in pinyon pine than in Coulter pine. These differences were not observed at Lake Arrowhead.

Male "volunteer" attacks were significantly different between sites (Table 2). There were no significant differences between volunteers on Coulter and pinyon pine at Baldwin Lake. At Lake Arrowhead, there were significant differences between Coulter and pinyon pine, where Coulter pine was more frequently attacked and more eggs were produced (Table 3).

Laboratory Tests

Displacement of Males in Nuptial Chambers. Heterospecific displacement was observed in only two nuptial chambers. These were in artificial entrance tunnels that displayed no frass after 24 hr. Generally males of one species do not displace males of another species from nuptial chambers.

Specific Mate Recognition with Host Discrimination. The mean number of nuptial chambers for each species was 16.25 (range 14–18). An average of 11.25 females (range 7–20) were distributed among these nuptial chambers. There were no significant differences between species of females joining males and pines in each treatment. However, there was a significant difference for females joining host, i.e., more females joined males in Coulter than males in pinyon pine. In pinyon pine, *I. confusus* males were not joined by *I. paraconfusus* females. Five *I. paraconfusus* males in pinyon were joined by *I. confusus* females but they produced no larvae. In Coulter pine, two males of each species were joined by heterospecific females, but these crosses yielded no larvae.

Specific Mate Recognition with No Host Choice. Six female *I. confusus* joined male *I. confusus* and six female *I. confusus* joined male *I. paraconfusus* when both male species were placed in pinyon pine. Four egg galleries with eggs and larvae were formed by female *I. confusus* paired with *I. confusus* males. Two egg galleries were formed, one with larvae, when *I. confusus* females joined *I. paraconfusus* males in pinyon pine.

Heterospecific Females in Mixed Galleries. Two of 11 galleries formed by *I. confusus* males in pinyon pine contained only *I. paraconfusus* females but no galleries contained *I. confusus* and *I. paraconfusus* females together. The remaining male galleries contained conspecific females. For male *I. paraconfusus* in Coulter pine, there were no families with *I. confusus* females only. Four male galleries contained *I. confusus* and *I. paraconfusus* females together. One male gallery had only conspecific females. There were no differences in numbers of single versus multiple gallery systems found in pinyon pine treatments; five galleries had single females and six galleries had two or more females. In Coulter pine eight male galleries contained multiple females and two contained single females. Galleries more often contained heterospecifics than conspecifics.

Females Leaving Conspecific Males and Pairing with Heterospecific Males. In all situations, we found that females left conspecifics in their host and readily paired with or were admitted by heterospecific males in the nonhosts. Seven *I. confusus* females joined *I. paraconfusus* males in Coulter pine and 10 *I. paraconfusus* females joined *I. confusus* males in pinyon pine. These females produced eggs and larvae in gallery systems with the conspecific males, but only *I. paraconfusus* females produced eggs and larvae in heterospecific galleries in pinyon pine.

DISCUSSION

Speciation in engraver bark beetles must be accompanied by barriers to gene flow. For synchronistic and sympatric populations of two or more species, such barriers can exist as premating mate recognition systems or reproductive isolation mechanisms. One premating mate recognition system may involve the density of striae on the pars stridens of the female stridulatory apparatus, which are different between *I. paraconfusus* and *I. confusus*. The female of either species stridulates at the entrance tunnel to the male nuptial chamber, and this may provide an opportunity to discriminate conspecifics. However, Lewis and Cane (unpublished) recently demonstrated that for these species: (1) fundamental stridulatory frequencies are not different, (2) significant differences appeared in their stridulatory tempos, but (3) males in freshly established nuptial chambers accepted stridulating heterospecific females walking on the bark surface.

In 1986, SEM examinations revealed that the test area at Baldwin Lake contained a mixed population of these sibling species together with a sizable number of "unidentified" individuals. Species were indiscriminately joining with heterospecifics at both Baldwin Lake and Lake Arrowhead, except that *I. confusus* females did not join *I. paraconfusus* males in Coulter pine at Baldwin Lake.

The preferences of joining females in the field follow the asymmetrical prelanding patterns of beetles found by Cane et al. (1990a). Heterospecific females joined males in all of our laboratory tests, which supports our field observations; however, few gallery systems contained females of both species during these laboratory tests. Finally, larval production for heterospecific crosses can be explained by prior mating of the females (Anderson et al., 1979). From these results we concluded that there were incomplete premating reproductive barriers between these populations of *I. paraconfusus* and *I. confusus*.

In the laboratory, heterospecific males do not displace other males in nuptial chambers and do not use a nuptial chamber that has been excavated by a male of another species. In the field, males likely abandon a nuptial chamber if not joined by a female. At Baldwin Lake, where pinyon pine is the only

conifer present, *I. confusus* males abandoned their host more frequently than the nonhost, Coulter pine. At both sites, a number of nuptial chambers initiated by experimentally introduced males were occupied by females only, or by no beetles; however, larvae or eggs were present. Adults in some bark beetle species are known to leave after oviposition is completed (Coulson et al., 1978; Schultz and Bedard, 1987).

There were some beetles that exhibited strial density measurements between the size ranges of both sibling species taken from their respective hosts (Table 1). If these "unidentified" individuals represent errors in the SEM measurements, we would expect to find them distributed in all treatments. Instead, we find them mainly clustered in treatments at Baldwin Lake. At either site "unidentified" individuals did not join endemic, conspecific males in their hosts, i.e. *I. paraconfusus* in Coulter pine at Lake Arrowhead and *I. confusus* in pinyon at Baldwin Lake. The unusual combinations of beetles in pines provided by our experiments may favor beetles that have intermediate strial density measurements. These beetles may be of limited number in the population. Possibly, they may be hybrids of *I. paraconfusus* and *I. confusus*. A zone of sympatry for beetles but not for hosts has formed at Baldwin Lake. Blackstain root disease has weakened pinyon pines in this area, making them available for bark beetle colonization for decades (Ernest Del Rio, San Bernardino National Forest, personal communication). Surprisingly, we have not found these "unidentified" individuals or heterospecifics emerging from infested logs collected in (Table 1) or near (Cane et al., 1990a) either locations.

Ancestors common to both *I. confusus* and *I. paraconfusus* may have been allopatric and different in degree of polyphagy than these species are today. These ancestors may have had their diet restricted due to the reduction in the distribution of the more mesic pines or altered due to the invasion of these areas by the xeric pinyons. Isozyme studies suggest that these beetle species diverged hundreds of thousands of years ago (Cane et al., 1990b). Why haven't effective premating barriers arisen and spread from the regions of host sympatry, given the reproductive costs incurred by heterospecific parents in "fatal matings" (Kirkendall, 1983)? Perhaps the ecotones shared by the beetles' hosts have always been geographically limited (Wells and Berger, 1967). If discriminating premating behaviors were of some selective disadvantage outside of sympatry, such as mistaken rejection of conspecific mates, and there was limited gene flow into areas of sympatry (likely for these vagile beetles), then premating barriers may not be manifest. Relative to mortality caused by other factors during a generation (e.g., predators, parasites, disease, host defenses, and poor food quality), reduced fecundity due to a "fatal mating" may be rare, and of little reproductive consequence, especially if the female mates more than once (Lanier and Oliver 1966), or mates at least once with a conspecific male during her lifetime.

The preference for the host and conspecific pheromone displayed by *I. confusus* may further reduce the chance of a mating mistake (Cane et al., 1990a). *Ips paraconfusus* females displayed little olfactory preference among conspecific and heterospecific pheromones at Lake Arrowhead; however, this species exhibited considerable preference for conspecific males in Coulter pine at Baldwin Lake. Females can avoid a nonproductive mating by rejecting the heterospecific pheromone. Yet females may encounter a conspecific mate at a resource where pheromones are produced by heterospecifics, as our tests demonstrate. When mated females join heterospecific males, they procure resources for their progeny. Although these males have not contributed genes to these offspring, they may gain a female, which contributes to the overall success of the gallery system by diminishing individual risks due to predation and parasitism (Kirkendall, 1983). If this is so, then this could be why ancestral semiochemical recognition has persisted. Genes leading to the cytoplasmic incompatibility accounting for the postmating reproductive barriers may be more flexible than genes for premating barriers and set by genetic drift (Paterson, 1981; Wiley, 1978). For engraver beetles in southern California, reinforcement of postmating isolation by premating isolation has not played a significant role in the production of separate species (Sanderson, 1989).

Acknowledgments—We wish to dedicate this manuscript to the memory of Gerry N. Lanier who pioneered this research. We are appreciative of the dedicated field and laboratory work of Dr. Margaret E. Silliker, Dr. Stephanie Meyers, Lester Casher, and Linda Kervin. We thank Laura A. Merrill for her review of the manuscript. This research was made possible through NSF grant BSR-8415910 (D.L.W., J.H.C., Isao Kubo, University of California Berkeley; Molly Stock, University of Idaho) and USDA/SEA Regional Research Project W-110.

(Received December 10, 1990; accepted March 20, 1991)

Abstract—The first known sex pheromone for the family Miridae is reported for the mullein bug, *Campylomma verbasci* (Meyer) (Heteroptera: Miridae). Extracts of and Porapak Q-trapped volatiles from females were attractive to males in field bioassays. Butyl butyrate and hexyl butyrate were the predominant compounds in the females' volatiles, but these compounds previously had been found to be inactive when released alone or in combination. Butyl butyrate in combination with an isolated trace chemical, (*E*)-crotyl butyrate (which was inactive alone), rivaled the attraction elicited by five live females. When synthetic butyl butyrate and (*E*)-crotyl butyrate in a 16:1 ratio were released at 91 or 183 μg/day, they comprised an effective attractant for male bugs.

Key Words—*Campylomma verbasci*, mullein bug, Heteroptera, Miridae, sex pheromone, apple pest, butyl butyrate, (*E*)-crotyl butyrate, hexyl butyrate.

INTRODUCTION

The mullein bug, *Campylomma verbasci* (Meyer), is a sporadic pest of apples in several regions of North America (Thistlewood, 1986). Current management of *C. verbasci* is based on economic thresholds that correlate nymphal density

0098-0331/91/0700-1437$06.50/0

in the spring with subsequent fruit damage (Whalon and Croft, 1984; Thistlewood et al., 1989a). *C. verbasci* in apple trees is sampled by jarring a branch with several sharp blows from a stick and counting the fallen nymphs on a tray (B.C. Ministry of Agriculture and Fisheries, 1989, Hardman et al., 1984, Washington State University, 1988). Among other drawbacks (Smith, 1989), this time-consuming method requires many limb-tap samples per hectare for reliable prediction. In the fall, catches of adult male *C. verbasci* in traps baited with live females can be correlated with subsequent densities of nymphs the following spring (Smith and Borden, 1990). However, most monitoring programs cannot rely on such a variable and uncertain stimulus as live females.

Thistlewood et al. (1989b) found that female mullein bugs emit a sex pheromone that attracts males to female-baited traps in a manner similar to that found in the mirids *Lygus lineolaris* (P. de Beauvois) (Scales, 1968), *Lygocoris communis* (Knight) (Boivin and Stewart, 1982), *Distantiella theobroma* (Dist.) (King, 1973) and *Helopeltis clavifer* (Walker) (Smith, 1977; Staddon, 1986). Staddon (1986) also found that butyl butyrate and hexyl butyrate were female-produced compounds, the former sex-specific, but alone or in combination these compounds failed to attract male *C. verbasci*. The exact identity of the pheromones for any mirid is unknown (Aldrich, 1988).

Our objectives were: (1) to identify the sex pheromone components of *C. verbasci*, and (2) to determine the bioactivity of synthetic compounds in the field.

METHODS AND MATERIALS

Chemicals. Butyl and hexyl butyrate, butyryl chloride, (*E*)-crotonaldehyde, and 1-hexanol were purchased. Hexyl acetate was prepared by reaction of 1-hexanol with acetic anhydride in pyridine. Reduction of (*E*)-crotonaldehyde with sodium borohydride in 50% aqueous ethanol gave a (*E*)-crotyl alcohol containing 4.3% 1-butanol and 1.7% *Z* isomer. (*E*)--Crotyl butyrate was prepared by reaction of (*E*)-crotyl alcohol with butyryl chloride in ether in the presence of triethylamine. After work-up and distillation at reduced pressure, the ester was 90.6% pure and contained 4.5% butyl butyrate.

Analytical Instrumentation. Hewlett-Packard 5830, 5880, and 5890 gas chromatographs equipped with capillary inlet systems and flame-ionization detectors were employed for analyses by gas–liquid chromatography (GLC). Glass columns (30–40 m × 0.5 mm ID) coated with SP-1000 (Supelco, Bellafonte, Pennsylvania) or fused silica columns (15 m × 0.25 mm ID) coated with DB-1 (J & W Scientific, Inc., Folsom, California) were used. The injection port and detector temperatures were 260°C and 270°C, respectively. A Hewlett-Packard 5895B GC-MS-DS was employed for coupled gas chromatog-

raphy–mass spectroscopy (GC-MS). Fused silica columns (0.32 mm ID) coated with DB-1 (30 or 60 m) or DB-WAX (60 m) (J & W Scientific Inc.) were inserted directly into the ion source. The injection port, transfer line, and ion source temperatures were 260°C, 250°C, and 200°C, respectively. Helium was the carrier gas for GLC and GC-MS.

Isolation and Separation of Volatiles. The isolation and identification of the sex pheromone followed the protocol in Figure 1. Mullein bugs were collected from natural stands of common mullein, *V. thapsus* L. Females were crushed in double-distilled pentane at −78°C, and the extracts were stored at −20°C in screw-cap vials with Teflon-lined lids. The concentration of extracts was expressed as bug equivalents (beq) (one crushed female bug or any undiluted fraction thereof = 1 beq). A micro-steam distillation–continuous extrac-

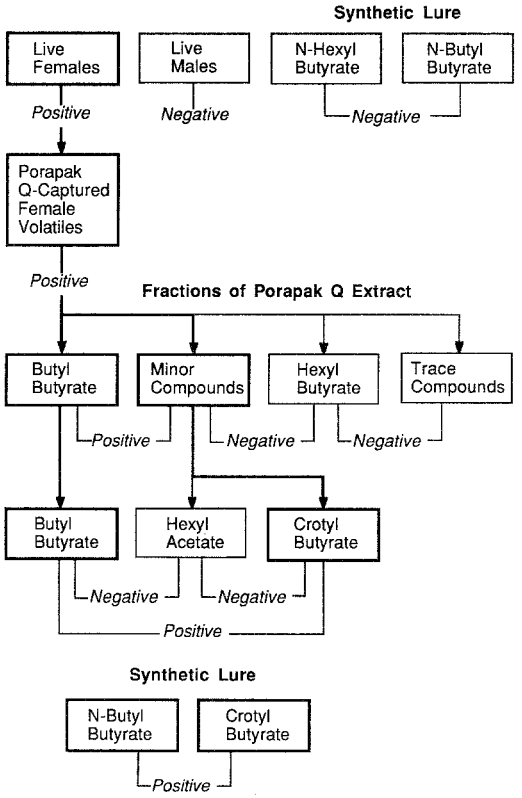

FIG. 1. Flow chart depicting sequence of experiments culminating in identification of the sex pheromone of *C. verbasci*. Live males as well as hexyl butyrate and butyl butyrate were tested by Thistlewood et al. (1989b).

tion apparatus (Godefroot et al., 1981) was employed for the isolation of volatiles from the pentane extracts of crushed bugs.

Volatiles from live *C. verbasci* females were collected in Porapak Q (50–80 mesh, Applied Science Laboratories Inc.) using methods described by Pierce et al. (1984). Air was drawn at 1.9 liters/min through a glass aeration chamber (15 cm OD × 30 cm) containing females on mullein stalks. At approx. 48-hr intervals, the aeration chamber was cleaned and fresh plant material and female bugs were added. Captured volatiles were expressed as bug-hours (bh) (1 bh = volatiles produced by 1 female for 1 hr). Volatiles from female bugs feeding on mullein were recovered by overnight extraction of the Porapak Q in a Soxhlet extractor with pentane. The solution was concentrated to approx. 10 ml by distilling off the pentane through a 30-cm Dufton column.

A Varian 1200 gas chromatograph fitted with a stainless-steel column (3.05 m × 3.18 mm OD) packed with 10% SP-1000 on Supelcoport (100/120), 10:1 effluent splitter, and thermal gradient collector (Brownlee and Silverstein, 1968) was used for micropreparative separation of steam-distilled or Porapak Q-trapped female volatiles. Before separation, a portion of the solution containing the volatiles was set aside for field tests. The remainder of the sample was concentrated under a stream of nitrogen at −10 to 0°C to approx. 30 μl before injection into the chromatograph. Fractions were rinsed from the collection tubes into 1 ml volumetric tubes containing ca. 200 μl of hexane or pentane, which were made up to volume with hexane. Aliquots from these were transferred to screw-cap vials for later release in field traps.

Field Bioassays. Bioassay experiments were used to monitor the isolation and identification of the sex pheromone (Figure 1). Five experiments were done at the Agriculture Canada Research Station, Summerland, British Columbia. Unless stated otherwise, all treatments were replicated four times in a completely randomized design. A 2-liter ice-cream carton trap with a sticky liner insert (Thistlewood et al., 1989b) was used in all experiments and set at a height of 1.5 m in both orchard and mullein field test sites. Those in an orchard were placed 0.5 m from the outer canopy edge. All bait receptacles were suspended inside the center of the trap. Data were transformed to $\sqrt{(n + 0.5)}$ prior to statistical analysis (ANOVA), and Tukey's pairwise comparison of the means (SAS Institute, 1985).

In experiment 1, fractions of the steam-distilled volatiles from crushed bugs (250 beq) or unfractionated extract (100 beq) were dissolved in 2 ml of pentane and held in a 5-ml glass vial. The screw cap for each vial was drilled to give a 2-mm vent. Traps were deployed in a mixed planting of Red Delicious and Golden Delicious apples for four days commencing August 29, 1986. Treatments were separated by at least 6 m, and replicates by 8 m.

Porapak Q-collected female volatiles or fractions thereof were tested in experiment 2 to establish a dose–response relationship. Concentrated extract in

a diethyl ether–pentane solvent was transferred by syringe into a 2-ml centrifuge tube and released through a 2-mm hole in the cap. Treatments were doses of 29,400, 9800, and 2900 bh, solvent control (ether–pentane), and a caged-female control (five per trap). The caged females were replicated three times; all other treatments had four replicates. This experiment was conducted over a six-day period commencing September 6, 1987.

In experiment 3, fractions of Porapak Q-trapped volatiles were placed into 2-ml centrifuge tubes through a 2-mm diam. hole in the cap. Fractions were tested at a strength of 8000 bh. Control stimuli were five caged females and solvent. Tests ran for 11 days commencing September 21, 1987. The objective was to verify the activity initially defined by the fractions from the crude insect crushes. This experiment was set up in an apple orchard; live-caged females had three replicates, all others had four. A fourth experiment using 10,000 bh was undertaken in the same orchard to resolve whether butyl butyrate alone had any attractiveness.

The fifth and final experiment involving 7000 bh was conducted to determine the identity of the minor component that interacts in combination with butyl butyrate. It was set up August 1988, in a field of mullein planted a 2 × 2-m grid. There were 4 m between treatments and 8 m between replicates.

Experiments with Synthetic Pheromone. Synthetic *n*-butyl butyrate and (*E*)-crotyl butyrate (16:1, w/w) were tested in a three-replicate dosage–response experiment in a Bartlett pear orchard in September 1988. Persistence of the lure was enhanced by mixing the butyrates with light paraffin oil. Treatments were 4 ml oil in an open 6-ml glass vial containing a mixture of butyl and crotyl butyrate at 2.0, 1.0, 0.1, and 0.01%, compared with paraffin oil and caged-female controls. Release rate of the butyrates was determined by the Porapak Q-collection method (Pierce et al., 1984). Numbers of males captured were transformed to $\sqrt{(n + 0.5)}$, prior to ANOVA and pairwise comparison of the means using the least significant difference test (SAS Institute, 1985).

Synthetic butyl butyrate and (*E*)-crotyl butyrate (16:1, w/w) also were tested in three release devices and compared as baits to five live-caged females. Dispensers were: (1) capillary tubes 1.18 ± 0.03 mm ID × 40 mm, (2) coagulation tubes 0.91 ± 0.03 mm ID × 40 mm, and (3) 20-ml glass vials. Four microliters of the butyrate mixture was transferred by syringe into the tubes, while 0.04 ml of the 16:1 synthetic pheromone blend was mixed in 4 ml light paraffin oil in the 20-ml vials.

Release rates of 5 μl synthetic lure from coagulation and capillary tubes ($N = 7$) were determined in the laboratory at 25 ± 1°C by measurement of miniscus regression.

All dispensers were suspended from the center of a 2-liter carton trap, hung at 1.5 m in an orchard block of Red Delicious in September 1988. Traps were set in a completely randomized design with each treatment having three repli-

cates. Data were transformed to $\sqrt{(n + 0.5)}$, prior to ANOVA and least significant difference test, $P < 0.05$ (SAS Institute, 1985).

RESULTS AND DISCUSSION

Pheromone Identification. Pheromone activity was centered in fraction 2 of the steam-distilled bug volatiles (Figure 2A), which contained butyl butyrate and minor compounds eluting after it and before hexyl butyrate (Table 1, experiment 1).

Porapak Q-captured female volatiles were as active at 29,400 bh as five females (Table 1, experiment 2). Attraction was less at 9800 or 2900 bh, but still higher than the solvent control. The capture rates in comparison to that of live females may be misleading, because the longevity of the extracts was <4 days (unpublished data) and attraction must have declined rapidly once they were placed in the traps.

The Porapak Q-trapped volatiles and a combination of fractions 1 and 2 thereof (Figure 1B) achieved captures approaching those of caged females (Table 1, experiments 3 and 4), verifying the response to fraction 2 of the female steam-distilled extract (Table 1, experiment 1). Hexyl butyrate (fraction 3) did not influence male captures alone, in combination with butyl butyrate (Smith, 1989; Thistlewood et al., 1989b), or in combination with fraction 2 (Table 1, experiment 3) and was eliminated as a candidate phermone. Butyl butyrate alone (Figure 1B, fraction 1) was inactive (Table 1, experiment 4), yet attraction was achieved when it was combined with the minor compounds in fraction 2, which were inert when tested alone (Table 1, experiment 3).

The minor components were separated into three fractions. Of these, only the combination of butyl butyrate and the fraction containing peak CB (Figure 2B) was as active as the unfractionated female volatiles (Table 1, experiment 5). Thus, the sex pheromone of the mullein bug was identified as the synergistic combination of butyl butyrate and compound CB.

Structures of Minor Compounds. The mass spectrum of peak CB (Figure 1A and B) exhibited a base peak at *m/z* 71, a parent ion at *m/z* 142, and a weak peak at *m/z* 89 ($C_4H_9O_2^+$), a strong peak in the spectrum of butyl butyrate (mol wt = 144). Since females of several *Lygus* spp. contain and emit hexyl and (*E*)-hexenyl butyrate (Aldrich, 1988), peak CB was hypothesized to be an unsaturated analog of butyl butyrate, i.e., (*E*)-crotyl butyrate [(*E*)-2-butenyl butanoate]. Comparison of the mass spectrum and retention time of the unknown to those of the synthetic sample confirmed this hypothesis. Present in both male and female volatiles were hexyl acetate and 1-hexanol (Figure 1A and C). These compounds were identified by GC-MS and search of reference spectra. The assignments were confirmed by comparison of their mass spectra and retention times to authentic samples.

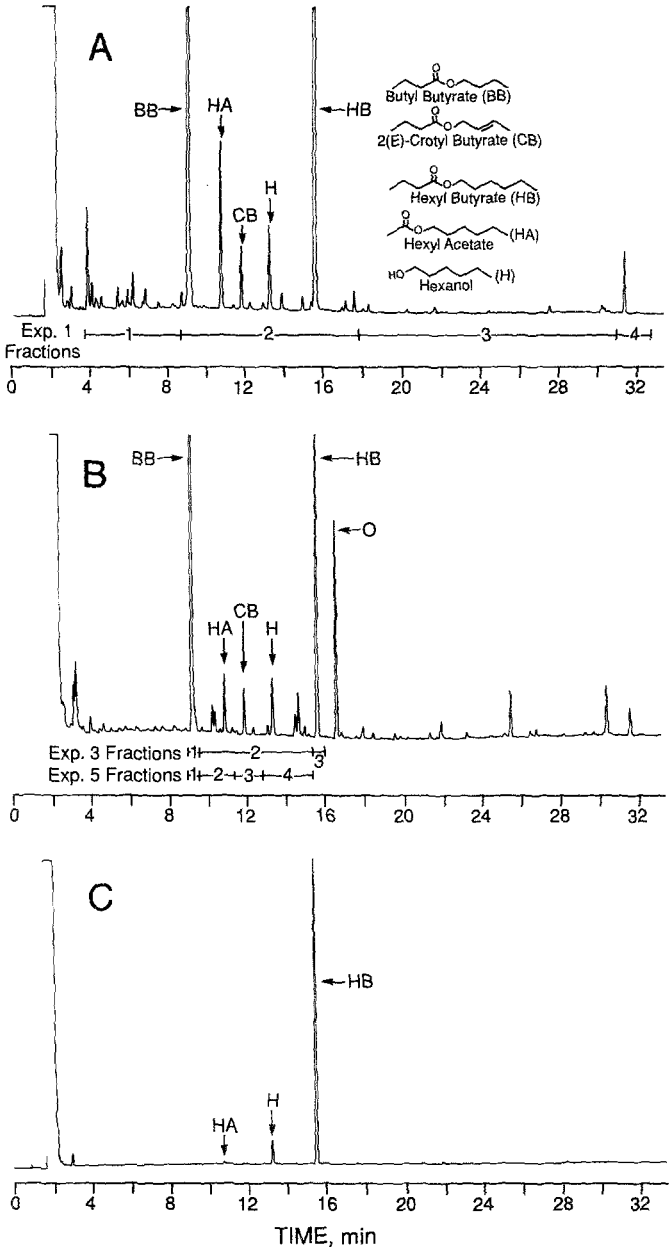

FIG. 2. Gas chromatograms of *C. verbasci* volatiles: (A) steam-distilled volatiles from females; (B) Porapak Q-trapped volatiles from females feeding on mullein; and (C) steam-distilled volatiles from males. BB = butyl butyrate, HA = hexyl acetate, CB = (*E*)-crotyl butyrate, H = 1-hexanol, HB = hexyl butyrate, and O = 1-octen-3 ol (from mold growing on mullein).

			4	
	Hexane	5ml	4	1.1 ± 0.5c

[a] Fraction numbers correspond to those on gas chromatograms of female extracts or Porapak Q-captured female volatiles (Figure 2).

[b] Means within an experiment followed by a common letter are not significantly different, $P < 0.05$, Tukey's pairwise comparison test (SAS Institute, 1985).

[c] Zero means excluded from analysis.

Response to Synthetic Pheromone. More male *C. verbasci* were trapped using synthetic lure at 1.0% and 2.0% concentration in paraffin oil than at lower dosages (Table 2). A concentration as low as 0.1% induced a significant response. Attraction to the synthetic pheromone released from two devices equalled that of live females (Table 3).

On the basis of these results, we conclude that the two-component sex pheromone in *C. verbasci* is comprised of butyl butyrate and (*E*)-crotyl butyrate acting synergistically, and that these components occur naturally in a ratio of

TABLE 2. MEAN NUMBER OF MALE *C. verbasci* CAPTURED IN CONCENTRATION RESPONSE EXPERIMENT TO BUTYL AND CROTYL BUTYRATE (16:1) IN 4 ML PARAFFIN OIL[a]

Synthetic lure concentration	Males caught ($X \pm$ SE)[b]

Abstract—The effects of parameters associated with a Delta sticky trap on the sex pheromone-mediated responses of male *Epiphyas postvittana* (Walker) were tested in a wind tunnel. Males flying to a pheromone source landed closer to the source when other males were stuck on the base, suggesting the importance of visual cues in the landing behavior of males of this species. With an increase in time (numerical order of the male in the experiment), males became stuck on the base farther from the source whether or not other males were stuck on the base. The alignment of the trap to the wind or the location of the pheromone source within the trap did not significantly affect the percentages of males that entered the trap, but both significantly affected the position at which males entered the trap. When these data were corrected for the probability of catching males, a treatment with the source to the side of the trap was predicted to catch more moths than the other treatments tested, although this difference was not significant. However, in a field-trapping experiment the treatment with the source to the side caught significantly more moths than treatments with the source either in the middle or near the top of the trap. This latter result is probably due to the greater efficiency of the trap when the source is in this position, as indicated in the wind-tunnel experiment, rather than an increase in the number of males entering the trap. Finally, the pheromone-mediated responses of male *Planotortrix octo* were tested to the various trap alignments. As the angle of the trap to the wind increased, significantly fewer *P. octo* males entered the trap, due principally to both fewer males orienting to the source and proceeding to enter the trap after having landed on it. This difference between the responses of *P. octo* and *E. postvittana* males is, we believe, due to the breakdown in plume structure

*To whom correspondence should be addressed.

0098-0331/91/0700-1449$06.50/0

from the source as the trap angle to the wind increases and to a greater sensitivity of *P. octo* males to a more structured pheromone plume. This accounts, at least to some extent, for the consistently greater field catches of *E. postvittana* over *P. octo* (and possibly other New Zealand leafroller moths) in many locations throughout New Zealand.

Key Words—Sex pheromone, traps, wind tunnel, behavior, *Epiphyas postvittana*, *Planotortrix octo*, Lepidoptera, Tortricidae.

INTRODUCTION

Field-trapping is one of the most commonly used techniques in sex pheromone studies. Generally, it is used to bioassay chemicals in order to develop a newly identified pheromone blend or to improve the efficacy of an already identified pheromone blend of a particular species. In addition to its use in identification studies, field-trapping using sex pheromones is extensively used for monitoring pest populations. The empirical determination of a threshold catch allows decisions to be made concerning the application of insecticide (or other) treatments for the control of a pest. By this technique, the number of insecticide treatments applied to a crop can be reduced or the efficacy of the treatments improved.

Although the catches of insects in traps are used by researchers to infer behavioral effects mediated by chemicals, these catches are the result of a sequence of behavioral events exhibited by a number of individuals (see Kennedy, 1977). In its natural environment, a male moth exhibits a number of behavioral responses when locating a female releasing sex pheromone (Baker, 1989). However, the surrounding of a pheromone source by a trap alters the environment that the male experiences and probably results in the modification of his behavioral responses, particularly at close range, used in locating the source. Consequently, the probability that the male may find the pheromone source may differ from the natural situation.

The effects of parameters associated with a trap on the ability of a male to locate the pheromone source inside the trap has long been recognized. In particular, studies examining the location (particularly height), design, and color of traps with respect to the number of insects caught in the trap are common (see, for example, Robacker et al., 1990). The actual effects of these factors on male behavior are usually inferred from the number of insects caught in the trap and presumed to relate to how the insect normally responds in its natural environment (see for example, Bakke and Riege, 1982). Despite the probable importance of a number of parameters associated with traps in modifying behavioral responses of insects, and hence influencing trap catches, there is little understanding of which behavioral responses these parameters actually modify.

In New Zealand, a group of endemic and introduced tortricid species forms a serious pest complex of many fruit crops (Wearing et al., 1991). The intro-

duced Australian species, the light-brown apple moth, *Epiphyas postvittana* (Walker), is one of the most economically important of these pests. Its sex pheromone has been identified as a mixture of (*E*)-11-tetradecenyl acetate (*E*11–14:OAc) and (*E,E*)-9,11-tetradecadienyl acetate (*E,E*-9,11–14:OAc) (Bellas et al., 1983), and, when used in sticky traps, is highly efficacious for catching male *E. postvittana* (Suckling et al., 1988). Compared to the large numbers of male *E. postvittana* caught in most parts of New Zealand, the numbers of the endemic New Zealand leafroller moth species caught are generally smaller in a given location (Suckling et al., 1988). While this may relate to the respective distributions and population sizes of the species, the consistency of the difference in trap catch suggests that there may be an innate behavioral or ecological difference between these species that contributes to the different trap catches. Under standard wind-tunnel conditions, similar percentages of males of *E. postvittana* (Muggleston and Foster, 1989) and various New Zealand species (Foster et al., 1990; J.R. Clearwater and S.P. Foster, unpublished) appear to respond to their respective synthetic sex pheromone blends, suggesting that the efficacy of the synthetic blend, under controlled conditions, does not account for this difference.

In order to investigate how some of the parameters associated with a sticky trap influence male behavior, we have studied the sex pheromone-mediated responses of male *E. postvittana* to changes in these parameters. To ascertain whether differences in behavioral responses to these parameters could account for the lower trap catches of the endemic New Zealand leafroller moth species, the responses of male *Planotortrix octo* (Dugdale) to changes in one of these parameters also have been studied.

METHODS AND MATERIALS

Insects. *E. postvittana* and *P. octo* are maintained as laboratory cultures at D.S.I.R. Plant Protection. For the experiments reported here, insects of both species were handled similarly. Larvae of both species were reared on synthetic diet (Singh, 1974). Male pupae were sorted and placed in an incubator at 18°C and a 16:8 light–dark photoperiod. Male moths were collected within 24 hr of emergence and placed in a 2-liter plastic container with moist vermiculite on the bottom, along with a 10% honey solution for food.

Chemicals. *E*11–14:OAc was purchased from Sigma Chemical Company (St. Louis, Missouri) and was greater than 99% isomerically pure as determined by capillary gas chromatography (GC). Tetradecyl acetate (14:OAc) was purchased from Bedoukian Fine Chemicals (Danbury, Connecticut); GC analysis showed no tetradecenyl acetates as impurities in this chemical. The (*Z*)-8-tetradecenyl acetate (*Z*8–14:OAc) and *E,E*-9,11–14:OAc used in this work were

gifts from Shin Etsu Chemical Company (Tokyo, Japan); they were greater than 97% and 94% isomerically pure, respectively. The chemicals were dissolved in pentane and applied to rubber septa (A.H. Thomas Co., Philadelphia, Pennsylvania) for use in the wind-tunnel and field-trapping trials. For *E. postvittana*, the blend used in the wind-tunnel and field trials was *E*11–14:OAc (100 μg) and *E,E*-9,11–14:OAc (10 μg) (Muggleston and Foster, 1989). A septum loaded with *Z*8–14:OAc (100 μg) and 14:OAc (100 μg) (Galbreath et al., 1985) was used in the wind-tunnel experiment involving *P. octo*. When not in use, the septa were stored in 4-ml glass vials at −15°C.

Wind-Tunnel Protocol. A 1.4-m-long wind tunnel based on the design of Miller and Roelofs (1978) was used for the experiments. Individual male moths, 3–6 days old, were placed individually in wire mesh cylinders (with a plastic lid at one end) and allowed to acclimate to the temperature (19 ± 1°C) and light conditions (0.5 lux) of the tunnel at least 1.5 hr before the start of an experiment. Individual males were introduced into the tunnel between the second and fourth hours of the scotophase as described (Muggleston and Foster, 1989).

The following experiments were conducted in the wind tunnel:

1. A corrugated plastic sheet (18 × 18 cm), coated with a thin layer of sticky glue (Product No. 633, Davis Gelatin Ltd., Christchurch), was rested (sticky side up) on a small, 12.5-cm-high wire table in the center of the tunnel, with one edge 5 cm from the farthest point upwind in the tunnel. The plastic sheet was divided into a grid of 9 × 9 (2-cm) squares. The pheromone source was placed in the middle of the grid. Individual *E. postvittana* males were released into the tunnel, and their initial point of contact on the grid and final position on the grid (i.e., where they stuck) were recorded. Males were allowed 2 min from the time of release within which to become stuck to the base, otherwise they were removed from the tunnel and not included in the data set for initial and final positions on the grid. Three hundred twenty males were flown over four days.

2. This was essentially a repeat of experiment 1 except that after males had become stuck to the sheet, they were removed from the base. Fifty males were tested.

3. A white Delta-shaped trap (see Figure 1) was used in this and other experiments. The trap, without a sticky base, was placed on the wire table in the tunnel. The trap was placed with the long axis parallel, 45°, or 90° to the direction of the wind. *E. postvittana* males were released into the tunnel and scored for the following four behavioral categories: (1) activation and ability to fly, (2) orientation upwind and initiation of upwind pheromone-mediated flight, (3) flight to the midpoint of the tunnel, and (4) position of landing on and entry into the trap. Four different landing and entry positions were distinguished (Figure 1): males landed directly on the base (base, "a" in Figure 1); males landed

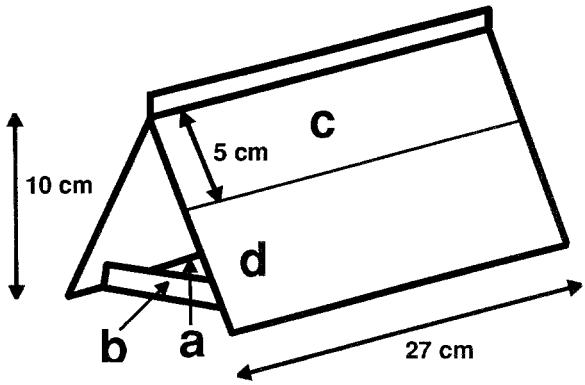

FIG. 1. The Delta trap used in the experiments. The letters indicate the various defined positions that insects landed on and subsequently entered the trap from (refer also to the text): a = base, b = flap, c = top, d = side.

on the outside of the flap ("b" in Figure 1), and walked over the flap to enter the trap (flap); males landed on and entered the trap within 5 cm of the top ("c" in Figure 1) of the trap (top); males landed on and entered the trap below 5 cm from the top ("d" in Figure 1) of the trap (side). Included in this experiment was a treatment consisting only of a base (without glue) and source. The behavioral responses of 60 males to each of the treatments were recorded.

4. This experiment, testing the effect of the location of the pheromone source within the trap on male *E. postvittana* behavioral responses, was conducted similarly to that for the effect of trap alignment. For the different treatments, the trap was aligned with the wind and the source placed inside the trap at four different locations: in the center of the base, with the large cavity of the septum pointing downwind (0°); in the center of the base with the large cavity upwind (180°); pinned to the middle of the trap, approximately 2 cm from the apex, with the large cavity pointing downwind (top); and placed on the base halfway along the long axis of the trap and 2 cm from one side, with the large cavity of the septum pointing downwind (side). The responses of 56 males to each of these treatments was recorded using the same design as for experiment 3.

5. In order to determine the efficacy of the various trap and source alignments used in the two preceding experiments for catching male *E. postvittana*, the percentages of males that entered the trap at each of the four defined positions (i.e., base, top, side, and flap) and stuck on the base were recorded. For each of the positions, 25 males were observed entering the trap and scored for (1) sticking on or (2) escaping from the trap.

6. Thirty-nine *P. octo* males were flown to each of the four trap align-

ments tested for *E. postvittana*, and their responses determined as in experiment 3.

Field-Trapping. The field trial for *E. postvittana* was run at Kumeu Research Orchard (near Auckland). The Delta traps were placed on various shelter (poplar and pine) trees, approximately 1.5 m from the ground. Traps within a replicate series were placed at least 10 m apart; replicates were placed at least 50 m apart. The numbers of moths caught in the traps were counted, the moths removed, and the traps rerandomized, weekly. The trial tested the effect of source location within the trap on catches of males. The different locations of the source within the trap were as in wind-tunnel experiment 5, except the 0° and 180° positions were equivalent in the field due to changing wind directions.

Statistical Analyses. The initial landing and final resting positions of the moths in experiments 1 and 2 were compared using regression analysis. The initial landings were analyzed using the computer program PLUM, a method for analysis of ordered categorical data (McCullagh, 1980). The model fitted was: $Y = C + a + bt$, where Y is the distance from the source, C is a constant, and b is the rate of increase in distance from the source with time t (i.e., the number of moths that have already landed). Distributions of the moths on the surface with regard to upwind or downwind location were compared using chi-squared tests.

For wind-tunnel experiments 3, 4, and 5, distributions were compared using chi-squared tests. A chi-squared test for each species was used to test for the difference in numbers entering the trap in the comparison of experiments 6 and 3. Additionally, in the comparison of these two experiments, the individual behaviors were classified as none; orient only; orient and land but did not enter; and orient, land, and enter, and were analyzed as ordered categorical data using the PLUM program (McCullagh, 1980).

Data from the field trial were transformed to $\sqrt{(X + 0.5)}$ values and analyzed by a two-way ANOVA followed by a comparison of means using Fisher's protected least significant differences test.

Observation of Plume Structure. The structure of the plumes emerging from the Delta trap, aligned at different positions to the wind, were visualized using a small incense stick, emitting smoke, placed at the center of the base.

RESULTS

Landing and Sticking Positions (Wind-Tunnel Experiments 1 and 2). After initially contacting the base, *E. postvittana* males moved a great deal over the surface of the base, either by walking or flying, often towards the pheromone source. Males were also frequently observed to fly away from the base and

return. Of the 320 male *E. postvittana* (28.4%) tested in experiment 1, 91 stuck on the base (Figure 2). A reasonably constant catch, of approximately 35%, was recorded for the first 240 males flown. However, subsequent to this only 7.5% (6) of the next 80 males flown stuck to the base. A higher proportion (50.0%) of males tested was caught on the base when males previously flown to the source were removed from the base (experiment 2).

Statistical comparison of the initial landing positions of male *E. postvittana* between experiments 1 (previous males not removed from the base) and 2 (previous males removed from the base) gave a significant landing parameter (Figure 3A and B). Thus with an increase in time (i.e., numerical sequence), males landed significantly closer to the pheromone source in experiment 1 than in experiment 2. This effect was due predominantly to the significantly (chi-squared test, $P = 0.99$) higher proportion of males that first landed in the grid position containing the pheromone source in experiment 1 (34.1%) compared to experiment 2 (4.0%). In experiment 1, landing at the grid position containing the pheromone source occurred relatively infrequently (one in seven males that landed) over the first 28 males that landed on the base; however, subsequent to this it occurred at a frequency of just under one in 2.5 males. In both experiments, a high proportion of males landed at the downwind edge of the base (53.8% and 72.0% of males landed at grid positions on this edge in experiments 1 and 2, respectively).

The final positions of the males (i.e., where they stuck) in both experiments (Figure 3 C and D) bore little or no apparent relationship to the initial

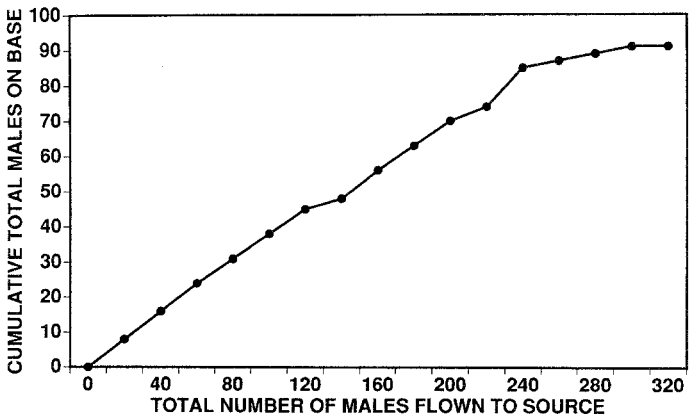

FIG. 2. Number of male *Epiphyas postvittana* caught on a sticky base, out of the total number of males flown to the pheromone source; the data are divided into sequential groups of 20 males flown.

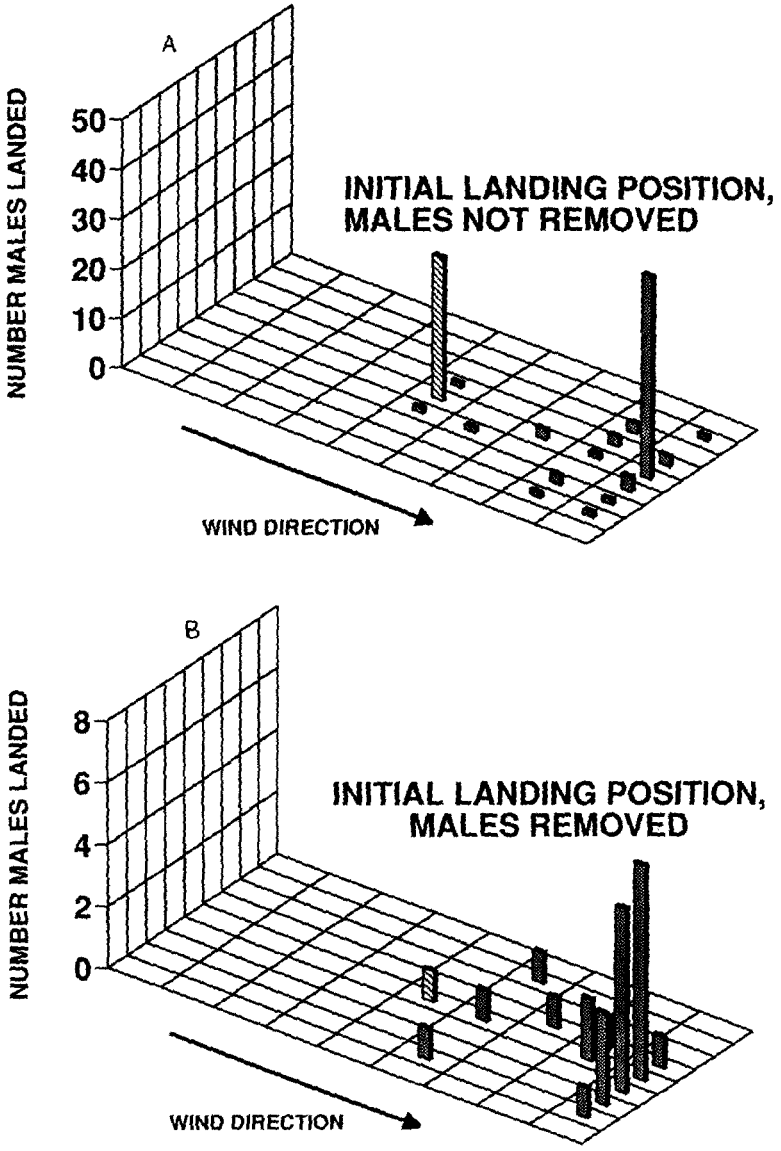

FIG. 3. Position and frequency of male *Epiphyas postvittana* landing or sticking on a base containing a pheromone source (from experiments 1 and 2); (A) initial landing position when other males were left on the base; (B) initial landing position, when other males were removed from the base; (C) final resting position (i.e., where males stuck), when other males were left on the base; (D) final resting position when other males were removed from the base. The location of the pheromone source on the base is shown by the bar with the diagonal stripe.

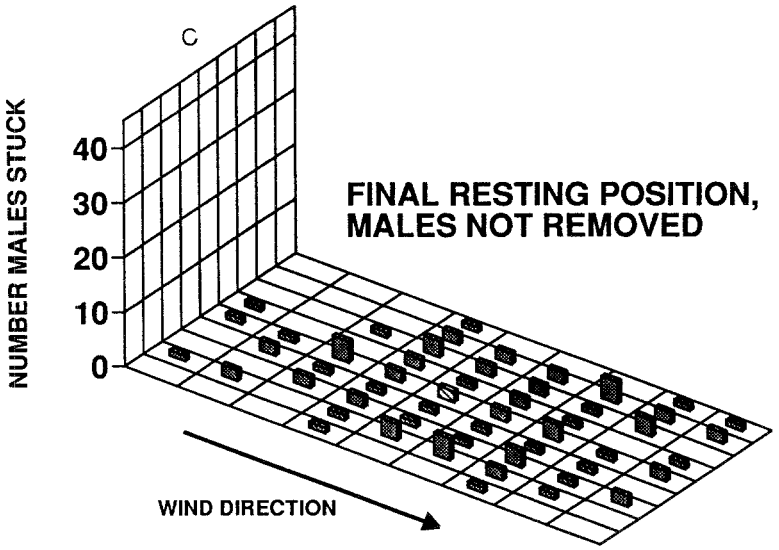

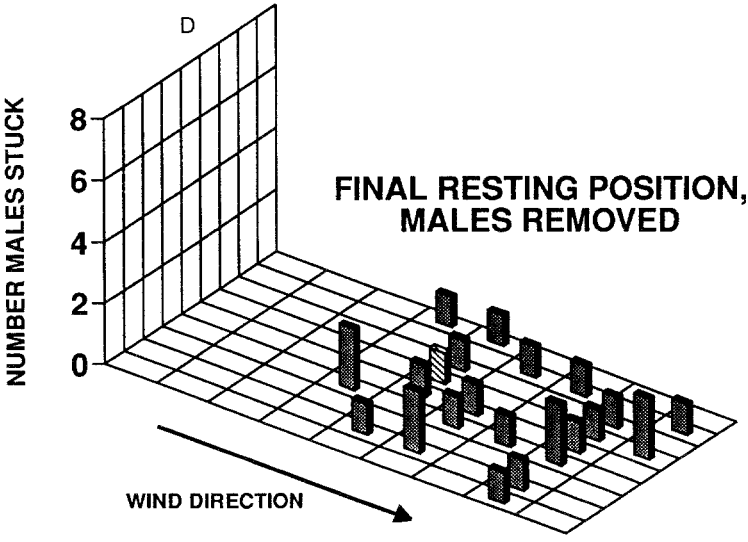

FIG 3. Continued

landing position. There was no significant difference in the distance that males became stuck from the source between experiments 1 and 2. However, there was a significant ($P < 0.05$) difference between the two experiments in the distributions of males stuck on the base. Overall, a significantly higher proportion of males became stuck downwind of the source in experiment 2 (males removed) than in experiment 1. However, there was no significant difference in the distributions of the first 25 males stuck on the base between these experiments, indicating that males became stuck upwind of the source mainly after the downwind positions largely were occupied. The final position of males in both experiments tended to increase in distance from the source with time.

Effect of Trap Alignment on Response and Catch (Wind-Tunnel Experiments 3 and 5). In experiment 3, 82% of the male *E. postvittana* tested to the base and source (without trap), contacted the base (Figure 4). Very high proportions of males entered the trap, whether it was aligned at 0°, 45°, or 90° to the wind. Although there was a slight tendency for the proportion of males

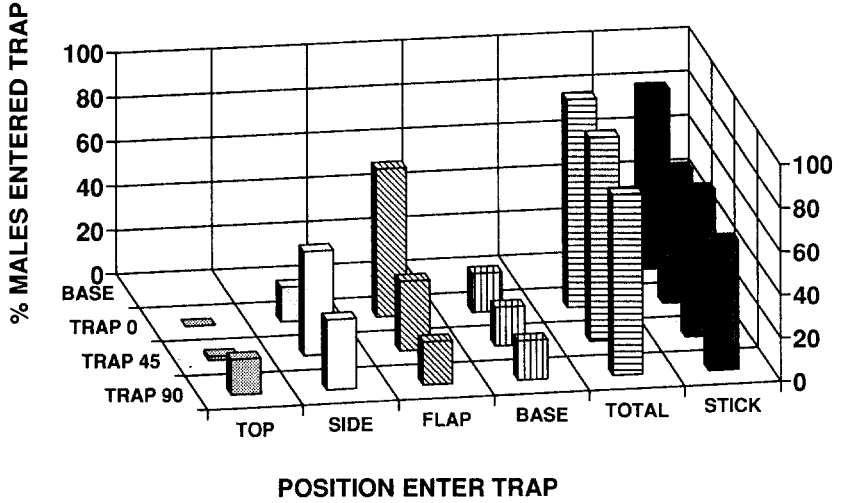

FIG. 4. The proportions of male *E. postvittana* that landed on and entered the trap at different positions for different alignments of the trap to the wind. TOP = males landed on and entered the trap within 5 cm of the top of the trap; SIDE = males landed on and entered the trap below 5 cm from the top of the trap; FLAP = males landed on and entered the trap through the entrance flap of the trap; BASE = males landed on and entered the trap directly on the base; TOTAL = sum of the individual percentages. These total percentages were corrected for probability of capture of males in the trap and these data are shown as STICK. Trap 0, 45 and 90 are the three trap alignments (in degrees), while BASE is a sticky base only.

entering the trap to decrease as the angle of the trap to the wind direction increased, there were no significant differences ($P > 0.05$) between these three treatments. However, there were differences in the proportions of males that entered the trap at the different positions, between the treatments (Figure 4). Thus, with a trap alignment of 0°, a significantly ($P < 0.01$) higher proportion of males landed and entered the trap at the flap position (66.7%) of all males entering the trap) than was observed for the other treatments. The remaining males that entered the trap aligned 0° to the wind landed and entered at either the bottom or side positions in approximately equal proportions. However, with the trap aligned 45° to the wind, the greatest single percentage of males that landed and entered (48.2%) did so at the side. The proportion of the males entering the trap at this position was significantly ($P < 0.05$) greater for this treatment than for the other two trap alignments. Quite a large proportion (32.1%) of the males flown to this treatment (45°) entered the trap at the flap position. When the trap was aligned 90° to the wind direction, males landed and entered the trap in more similar percentages for all four positions. The most significant ($P < 0.01$) difference in male response between this alignment and the other alignments was the relatively high proportion (18.0%) of males that landed and entered the trap near the top (0.0% and 1.8% of the males entered at this position when the trap was aligned 0° and 45°, respectively).

In experiment 5, the percentages of males that stuck to the base after entering the trap at the four different positions were determined as 100.0%, 52.0%, 76.0%, and 52.0% for the base, flap, side, and top positions, respectively (not significantly different, $P > 0.05$). If the data from experiment 3 are corrected for capture of the male (by sticking) by multiplying the percentages of males that landed and entered the trap at the different positions by the probability of a male sticking to the base after entering the trap at these positions (i.e., the proportions that were experimentally observed to stick), then the percentages of trap capture can be calculated for the different trap alignments; these corrected values are shown in Figure 4 along with the uncorrected (percentage of males entering trap) data. No significant differences ($P > 0.05$) in trap capture between the different alignments were detected.

Effect of Source Location on Response and Catch (Wind-Tunnel Experiment 4). There were no significant differences ($P > 0.05$) in the percentages of males that landed on and entered the trap between treatments that tested each of the four locations of the source (Figure 5).However, as in experiment 3, there were significant differences in the proportions of males that landed on and entered the trap at the different positions for the four treatments. As observed in experiment 3, a very high proportion of the males that landed on and entered the trap with the source at 0° did so at the flap position (87.8%). The pattern with the source at 180° was similar to this, although overall slightly fewer males entered the trap. Significantly greater ($P < 0.01$) percentages of males entered

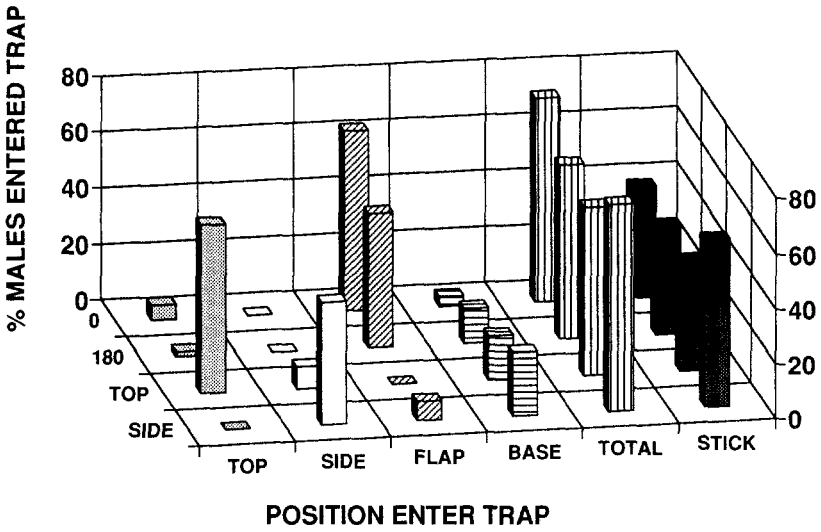

FIG. 5. The proportions of male *E. postvittana* that landed on and entered the trap at different positions for the different source locations. 0 = source placed in center of base with the large cavity facing downwind; 180 = source placed in center of base with the large cavity facing upwind; TOP = source placed in middle, 2.5 cm from the apex, of the trap; SIDE = source placed on base, halfway along the long axis and 2 cm from the side of the trap. Data corrected for probability of capture of males in the trap (STICK) are also shown. Acronyms are as in Figure 4.

the trap at this position (flap) for these two source locations, than for the other two source locations tested. In contrast to this, a large proportion (67.6%) of males landed on and entered the trap near the top for the treatment with the source near the top of the trap, significantly greater ($P < 0.01$) than for all the other treatments. For the treatment with the source located near the side of the trap, a significantly greater ($P < 0.01$) percentage of males (59.5%) entered the trap at the side position than for all the other treatments tested.

If these data are corrected for catch, as for experiment 3, then the treatment with the source placed to the side would be expected to give the highest percentage of males caught (61.0% of males tested), compared to the other treatments, which would be expected to catch approximately 40% of the males tested (Figure 5). Although suggestive, this difference was not significant at $P = 0.05$.

Comparative Responses of Male P. octo *and* E. postvittana *to Different Trap Alignments (Wind-Tunnel Experiments 6 and 3).* Male *P. octo* were flown to the three trap alignments (plus a base) as for *E. postvittana* in experiment 3. The data are shown in Figure 6A along with the comparative data for *E. postvittana* (Figure 6B). Virtually the same percentages of *P. octo* and *E. postvit-*

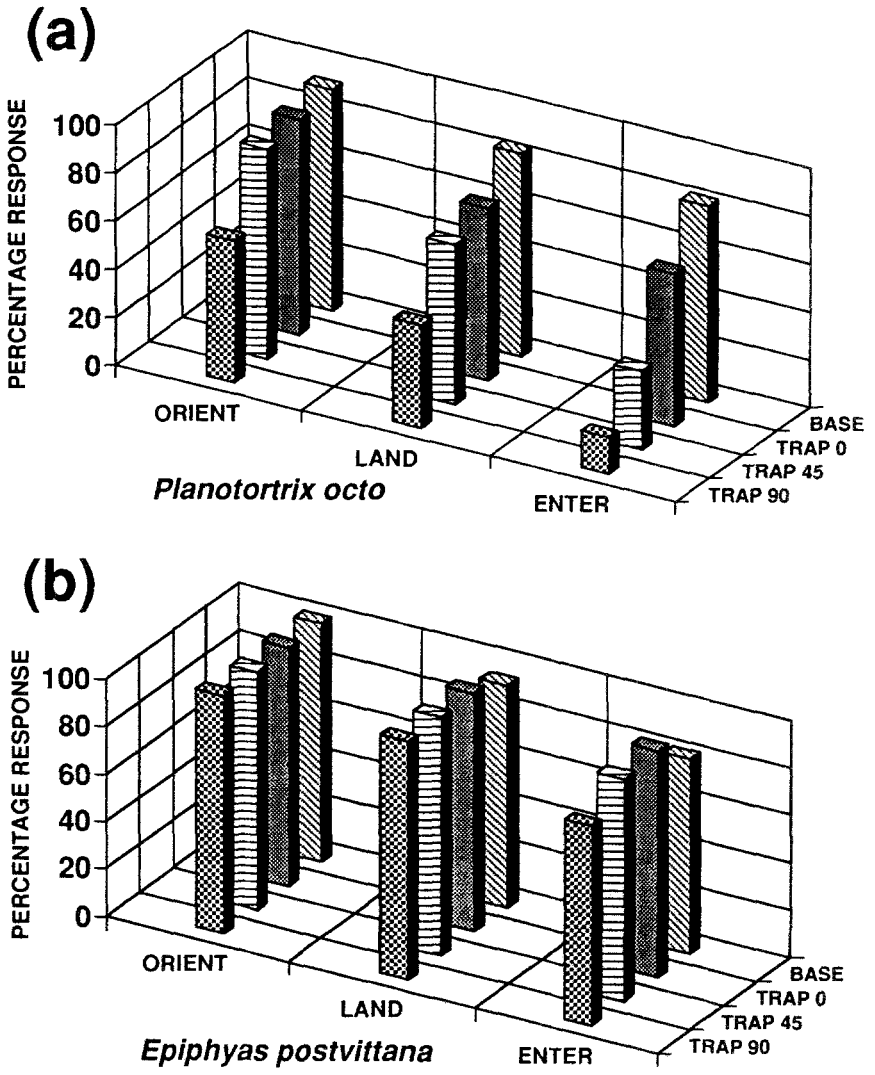

FIG. 6. The percentages of males that oriented to the source and flew upwind (ORIENT), landed on the trap (LAND), and entered a trap (ENTER) aligned at different directions to the wind (other acronyms as in Figure 4) of (A) *Planotortrix octo*, and (B) *Epiphyas postvittana*.

tana males touched the pheromone source (82.1% and 81.7%, respectively) when it was presented on the base alone. However, with the inclusion of the trap, significant differences in the percentages of the two species entering the trap were apparent. With the trap aligned 0° to the wind, a significantly smaller ($P < 0.01$) percentage of *P. octo* males (64.1%) entered the trap than did *E. postvittana* males (95.0%). This difference was due to the compounding effects of a slightly smaller percentage of *P. octo* males (89.7%) orienting upwind than did *E. postvittana* males (100.0%), and a greater proportion of *P. octo* males arresting upwind flight prior to landing on the trap. The differences between the responses of the two species were more apparent when the trap was aligned 45° to the wind. Thus, in contrast to the high percentage of *E. postvittana* males that entered the trap (93.3%), only 33.3% (significantly less, $P < 0.01$) of the *P. octo* males tested actually entered the trap. This decrease in males entering the trap over that observed when the trap was aligned at 0° was due in very large part to the high proportion of the *P. octo* males that landed on, but did not enter, the trap. Only 50% of the males that landed on the trap proceeded to enter it, compared with 89% when the trap was aligned at 0°; in comparison, 93.3% of the *E. postvittana* males entered the trap when it was aligned 45° to the wind. The difference in response between the two species was emphasized further when the trap was aligned 90° to the wind; only 15.4% of *P. octo* males entered the trap compared to 83.3% of *E. postvittana* males. Again this difference was due largely to the relative proportions of males that landed on, but did not enter, the trap (35.3% of *P. octo* males compared with 83.3% of *E. postvittana* males), although another important factor was the smaller percentage of *P. octo* males that oriented upwind relative to that of *E. postvittana* (59.0% compared to 100.0%). Overall, *P. octo* males were less likely to exhibit the more advanced behaviors as the trap alignment with respect to the wind increased, than were *E. postvittana* males.

Field-Trapping. Results from the field trial testing the effect of source location within the trap on the number of *E. postvittana* males caught in the trap are shown in Table 1. Of the three treatments tested, the greatest number of males ($P < 0.05$) were caught in the trap with the source located to the side. The other two treatments (i.e., top and 0°) caught approximately equal numbers of moths.

Observations of Smoke Plume. Compared to the relatively tight smoke plume released from the base alone, the plume from the trap aligned 0° to the wind was more turbulent and diffuse. With the trap aligned 45° to the wind direction, the turbulent and diffuse structure of the plume was even more enhanced. The plume exiting the trap aligned 90° to the wind was highly diffuse, with the diameter at the trap mouth exceeding the width of the trap (Figure 7); the filamentous structure of the plume was barely discernible.

DISCUSSION

In New Zealand, the greatest use of synthetic sex pheromones is in the monitoring of phenologies of leafroller moth pests using sticky traps (Suckling et al., 1988). We have investigated several parameters associated with a particular type of trap (Delta) and have found that they influence aspects of the pheromone-mediated behavior of male *E. postvittana*.

A comparison of the initial landing positions on a sticky base when males previously flown to the pheromone source were left on the base and when these males were removed from the base showed a significant difference between the two treatments; incoming males tended to land closer to the pheromone source on the base in the former treatment. Overall, on the base containing males, the initial landing positions were much more focused than they were on the base with no males, with some 79% of the males landing at just two positions on the grid (see Figure 3). The most notable difference in landing position between the two treatments was the much greater proportion of males that landed at the grid position containing the source, on the base containing males.

In addition to the female sex pheromone, there are conceivably three other sensory inputs that could influence the landing position of the males: chemical, tactile, or visual. Male *E. postvittana* are not known to have any scent organs that mediate behavior in other males or females, such as those reported in other species of moths (see for example *Grapholita molesta*; Baker and Cardé, 1979a). Therefore, it appears unlikely that the males already on the trap are releasing chemicals that influence the landing position of the incoming male. Another possibility is the presence of an increased number of male scales in the air, around the base containing the males, influencing male landing behavior. Moth scales, in combination with visual stimuli, have been shown to influence copulatory attempts (and hence close-range behavior) by male *Adoxophyes sp.* (Shimizu and Tamaki, 1980).

Perhaps the cues most likely to influence the landing behavior of males, however, are visual ones. After alighting, Oriental fruit moth males, in the presence of female sex pheromone, are influenced by visual inputs at close range to the pheromone source (Baker and Cardé, 1979b). In the presence of pheromone, males of this species exhibit a complex series of courtship behaviors. These behaviors are exhibited more frequently when a visual stimulus is associated with the pheromone source than when the two factors are separated (Baker and Cardé, 1979b). Although this postalighting visual aspect has been studied, as have the optomotor responses that male moths use in the control of their groundspeed during flight (Baker, 1989), little is known about the importance of visual cues that trigger landing responses of male moths under pheromone-mediated flight. Visual inputs, such as front-to-back motion over the eye

and size and contrast of the visual input, are thought to trigger the landing behavior of the housefly, *Musca domestica* (Borst, 1989).

E. postvittana males do not exhibit such a complex sequence of courtship behaviors as do male Oriental fruit moths. Rather, males tend to land on the surface a few centimeters away from the pheromone source and rapidly approach the source fanning their wings before attempting copulation (Muggleston and Foster, unpublished). The data presented in these experiments show that the presence of other males on the trap base influenced incoming males to bypass landing at the edge of the base more frequently and land on, or very close to, the pheromone source. This effect could be the result of either or both of two visual inputs. First, the males on the base presented a lesser degree of contrast between the downwind edge of the base and the floor of the tunnel, compared to that of a white base without males; hence males were not induced to land until they were extremely close to the pheromone source. Second, the contrast of the pheromone source (a red septum) against the white base was not as great when other males were on the base, and therefore males were unable to visually detect the pheromone source, and consequently land, until they were extremely close to it. Whether males in this situation were ultimately induced to land by visual or olfactory cues, these data suggest that *E. postvittana* males are able to distinguish the spatial position of an olfactory source in a field of similar visual inputs.

The differences in the final positions of the males between the two experiments (i.e., a greater proportion of males sticking downwind of the source in experiment 1 over experiment 2) was probably a consequence of the surface of the base becoming less sticky downwind of the source, due to the deposition of male bodies and/or scales on the surface of the glue and hence males eventually become stuck on a sticky (upwind) surface. This explanation is further supported by the observation of the final position of the male tending to increase in distance from the source with time. These data also show that the sticky surface of the base becomes less efficient at catching male *E. postvittana* after approximately 86 males are caught on the base. Although this figure would probably vary according to the sizes of males caught on the base, as well as factors such as the effect of the trap to constrain movement of a male on the base, this figure probably represents a useful guideline for the saturation point of the trap for this species.

The alignment of the trap, with respect to the wind direction, appears to have little or no effect on the number of male *E. postvittana* entering, or even being caught in, the trap. However, it does have a significant effect on the responses of the males; males land on and enter the trap at different positions, in different proportions, according to the alignment of the trap. In contrast to these results for *E. postvittana*, the alignment of the trap to the wind does drastically affect the number of *P. octo* males that land on and enter the trap. Thus,

as the alignment of the trap to the wind was changed from 0° to 45° to 90°, the percentages of males that entered the trap decreased from 64.1% to 33.3% to 15.4%, respectively. This decrease was predominantly due to the larger proportions of the *P. octo* males that landed on but did not enter the trap, as the alignment of the trap to the wind direction increased. A further contributing factor was the decrease in the percentages of males that oriented to the wind and exhibited upwind flight as the angle between the trap and the wind direction increased. This latter factor became more significant at an angle of 90°.

This decrease in the number of *P. octo* males that actually entered the trap correlates with the change in the plume structure of the pheromone released from the trap (see Figure 7). The structure of the chemical plume is an important factor in pheromone-mediated flight (Baker, 1989). Lewis and Macaulay (1976) demonstrated a correlation between the shape of the chemical plume given off by traps and the number of male *Cydia nigricana* caught in the traps; trap designs releasing broader and less structured plumes caught fewer moths. Likewise as the angle of the Delta trap increased with respect to the wind direction, the plume released from the trap became broader and less structured, and, in the case of *P. octo*, fewer males oriented and ultimately entered the trap. As noted, this effect was not observed for *E. postvittana* males, suggesting that the two species have different responses to the changes in plume structure, i.e., *P. octo* males are more sensitive to loss of plume structure.

The different responses of males of the two species to the alignment of the trap is probably a significant factor in the relatively smaller catches of *P. octo* (and possibly other species in this genus and the genus *Ctenopseustis*), compared to *E. postvittana* males, that are observed in field-trapping experiments (Suckling et al., 1988). Under controlled conditions in the wind tunnel, similar percentages of *P. octo* and *E. postvittana* males responded to their respective synthetic blends, suggesting that the differences in field catches are probably not due to the relative efficacies of the isolated synthetic blends to elicit upwind flight of the respective males. In the field, traps for these species are usually placed with little or no regard for the wind direction, which is assumed to be a random effect on replicated trap catches. However, a trap will probably spend only a relatively small proportion of its time aligned to the wind. Given equal population sizes of *P. octo* and *E. postvittana* in a particular location, then catches of *P. octo* should be lower, as is observed. It should be noted, however, that although this effect is probably a major contributor to the lower relative trap catches of *P. octo*, the relative sizes of the populations of the two species in particular locations may also be important.

The location of the pheromone source within the trap also can have a significant effect on the behavioral responses of males. Although the location of the source within the trap had only a small effect on the numbers of males entering the trap, it significantly affected where males landed and entered the

trap. This wind-tunnel experiment indicated that placing the pheromone source to the side of the trap (as opposed to the other source locations) resulted in more efficient capture of the males entering the trap. The data from the field trial testing the trap captures resulting from the various source locations were consistent with the wind-tunnel data. These experiments show that the effects of certain parameters associated with field-trapping can be tested under controlled conditions, and, if promising, can be validated or invalidated in the field. In practical terms, these particular experiments have shown that the catch by the Delta trap can be improved for trapping *E. postvittana* (and possibly other species) by placing the pheromone source at the side rather than in the normal center position. This improvement probably is due to an increased probability that males are caught in the trap after entering it, rather than more males actually entering the trap.

This approach of studying pheromone trapping in a wind tunnel has allowed us to improve trap efficiency for *E. postvittana* as well as to understand how some of the parameters associated with pheromone trapping affect the behavior of male *E. postvittana* and *P. octo* in response to a pheromone source within the trap. Such controlled studies may allow researchers to open the "black box" of field trapping for different species and allow field-trapping techniques and data to be improved.

Acknowledgments—We thank Mr. D. Rogers and Ms. A. Barrington for supplying the insects, and Dr. M.O. Harris for comments on an earlier version of the manuscript.

Abstract—A number of studies concerning the analysis of axillary odors have assumed that the characteristic odor produced in the axillae is due to volatile steroids and isovaleric acid. Organoleptic evaluation of chromatographic eluants from axillary extracts was employed to isolate the region in the chromatogram where the characteristic odor eluted. The odor of the dissolved eluant was eliminated when it was treated with base, suggesting that acids make up the characteristic axillary odor. Subsequent extraction of the pH-adjusted axillary extract in conjunction with organoleptic evaluation of the chromatographic eluant, preparative gas chromatography, and analysis by GC-MS as well as GC-FTIR showed the presence of a number of C_6 to C_{11} straight-chain, branched, and unsaturated acids as important contributors to the axillary odor. The major odor component is (*E*)-3-methyl-2-hexenoic acid. Three homologous series of minor components are also important odor contributors; these consist of the terminally unsaturated acids, the 2-methyl-C_6 to -C_{10} acids and the 4-ethyl-C_5 to -C_{11} acids. These types of acids have not been reported previously as components of the human axillary secretions and have not been proposed previously as part of the principal odor components in this area.

Key Words—Axillary odors, (*E*)-3-methyl-2-hexenoic acid, androstenone, human axillary secretions, malodors, 7-octenoic acid.

INTRODUCTION

The human axillary region is a body area with unique odor-producing characteristics. In the axillae, apocrine, sebaceous, eccrine, as well as the recently described apoeccrine, glands (Sato et al., 1987), provide an excellent environment for a large permanent population of microorganisms (Leyden et al., 1981). These microorganisms are believed to generate a variety of odoriferous compounds that characterize our underarm region (Labows et al., 1982). Previous analyses of both the apocrine secretion and the total axillary sweat have shown the presence of a variety of both volatile and nonvolatile steroids (Brooksbank, 1970; Brooksbank et al., 1974; Claus and Alsing, 1976; Labows et al., 1979b; Bird and Gower, 1980).

The apocrine secretion when freshly collected at the skin surface is odorless. (Hurley and Shelly, 1960; Shehadeh and Kligman, 1963). However, incubation with the resident bacteria results in the production of a characteristic odor, which appears to be unique to the organism used (Leyden et al., 1981). The micrococci bacteria present in the axillae impart an acidic odor to the secretion. The headspace above apocrine secretion incubated with micrococci has been reported to contain isovaleric acid (Labows, 1979; Labows et al., 1982). The diphtheroid bacteria give similar chromatographic headspace profiles with isovaleric acid being present. However, the odor is more distinct and pungent, suggesting the presence of other unidentified volatiles (Labows et al., 1982).

Analysis of freshly collected apocrine secretions in our laboratory have demonstrated the presence of two androgen steroid sulfates: 17-oxo-5α-androstan-3α-yl sulfate (androsterone sulfate) and 17-oxo-5α-androsten-3β-yl sulfate (dehydroepiandrosterone sulfate) (Labows et al., 1979b). Both dehydroepiandrosterone sulfate and androsterone sulfate are present in high concentrations (Labows et al., 1979b; Preti et al., 1987) and may serve as precursors for more volatile, odoriferous steroids.

Studies recently completed in our laboratories employed axillary extracts obtained from men and women to influence the menstrual cycle length and timing (Preti et al., 1986; Cutler et al., 1986). Another report from our laboratory discussed the analysis of the extracts and the levels of several steroids present in them. The extracts also contained a series of aliphatic acids ranging from two to 18 carbons (Preti et al., 1987).

Investigators have collected the volatiles in the axillary area for chromatographic analysis and evaluation of individual peaks for malodor (Dravnieks et al., 1975). However, no structure elucidation was performed in these studies.

Two recent reviews (Labows, 1988; Gower, 1989), have suggested, but not proven, that the characteristic odor in the axillae is due to the presence of volatile steroids and isovaleric acid. The volatile steroids suggested as contributing to the axillary odor are 5α-androst-16-en-3α-ol (androstenol), 5α-androst-16-en-3-one (androstenone), and 4,16-androstadien-3-one (androstadienone). These steroids are formed, in part, by the action of cutaneous microorganisms (Labows, 1988) and have low olfactory threshold (Amoore et al., 1977); however, there is approximately a 40–50% anosmia to androstenone in the adult United States population (Labows and Wysocki, 1984), which implies that this odor is not recognized by half the population.

Since axillary secretion extracts contain a complex mixture of compounds that are not well characterized, it is possible that secretion components (other than those noted above) are important for both mediating the odor character and physiological activity. We report here the isolation and identification of compounds from a combined male axillary secretion extract that contains the characteristic odors present in the axillae.

METHODS AND MATERIALS

General. [^{1}H]NMR spectra for the (*E*)-3-methyl-2-hexenoic acid collected by preparative gas chromatography from the axillary extract were recorded on a Bruker AM-500 spectrometer, employing $CDCl_3$ as solvent with $CHCl_3$ as reference; 21,000 scans were used to obtain sufficient data for structural determination. For the synthetic samples, [^{1}H]NMR spectra were recorded on a Bruker AM-400 spectrometer, employing $CDCl_3$ as solvent with TMS as reference.

Gas Chromatography–Mass Spectrometry (GC-MS) Analysis. A Finnigan 4510 GC-MS data system equipped with a split–splitless injector, a fused silica capillary column, and capabilities for operation in both electron impact and chemical ionization modes was used for analysis. The columns employed were a 30-m × 0.32-mm-ID fused silica column with a 0.25-μm coating of Stabilwax (cross-bonded polyethylene glycol), or a 30-m × 0.32-mm-ID fused silica RTX-1 column with a 0.25-μm coating of cross-bonded methyl silicon (Restek, Port Matilda, Pennsylvania). Analysis conditions for each column were as follows: Stabilwax, 60°C (4 min hold) to 220°C, at 3°C/min, hold for 45 min; RTX-1, 60°C (4 min hold) to 300°C, at 4°C/min, hold for 15 min. The mass spectrometer is interfaced to a Nova 4X computer, which utilizes the Super Incos software for data acquisition, analysis, and quantitation. The mass range employed during these analyses was *m/z* 40–450. This mass range was scanned once each second and a typical run included 4000 scans. The data system also included the NBS library of 42,000 compounds.

Identifications were based on interpretation of unknown spectra and their

comparison with both the NBS library and mass spectra generated from synthetic and/or commercially available standard compounds. In addition, the relative chromatographic retention times of unknowns and known standards were compared. A mixture of fatty acid ethyl esters was used to determine the relative retention times (van den Dool and Kratz, 1963) and generate an ethyl ester unit for each compound.

Gas Chromatography–High-Resolution Mass Spectrometry (GC-HRMS) This was performed using a Carlo Erba Fractovap 4160 series gas chromatograph interfaced to a Kratos MS-50. High-resolution spectra of the eluting components were obtained using a scan time of 5 sec for the decade 20–200 daltons, an ionizing voltage of 70 eV, and an ionizing chamber temperature of 150°C. Data were acquired, reduced, and exact masses calculated using the Kratos DS-55 software.

Gas Chromatography–Fourier Transform Infrared Spectra. These were obtained using a Hewlett-Packard 5890 gas chromatograph interfaced to a Hewlett-Packard 5965A infrared detector. Samples were analyzed using either a 30-m × 0.32-mm-ID fused silica column with a bonded 0.5-μm coating of Supelco Wax (60°C for 4 min then programmed to 220°C at 3°C/min) or a Hewlett-Packard 50-m × 0.32-mm-ID column with 0.5-μm bonded coating of methyl silicone. Spectra were obtained at 4 wave number resolution with 1.6 scan/sec or 8 wave number with 3 scans/sec.

Collection of Axillary Secretions. The axillary secretions used in this investigation were collected from six healthy male volunteer donors (ages 25–40). Each donor had large numbers of lipophilic diphtheroids in his axillary region. These microorganisms have been associated with production of the strongest axillary odors (Labows et al., 1982; Leyden et al., 1981). The protocol followed by donors and the methods used for the collection were described previously (Cutler et al., 1986; Preti et al., 1987).

Preparation of Axillary Secretion Extract. Extracts were prepared by extracting 12 pads at a time with doubly distilled ethanol, as previously described (Cutler et al., 1986; Preti et al., 1987). The ethanol-soaked pads were subsequently soaked with a mixture of 85 : 15 chloroform–methanol for 1 hr and then squeezed (Nanograde Solvents from Mallinkrodt, St. Louis, Missouri; these solvents contain little or no impurities by GC-MS analysis when 100–200 ml are concentrated to ≤ 50 μl) (15 ml/pad). Approximately 95% of the chloroform–methanol was recovered. The two extracts were combined, then concentrated to a volume of 50–100 μl by a rotary evaporator, and subsequently stored at −60°C until analysis. Through the use of standards in model experiments, we determined that 59% of the 3-methyl-2-hexenoic acids and 85% of the C_7–C_9 acids were recovered from the pads.

Preparative Gas Chromatographic (PGC) Fractionation and Collection of Axillary Secretion Extracts. PGC fractionation of axillary secretion extracts was

performed on a Perkin-Elmer 990 gas chromatograph equipped with hydrogen flame-ionization detector, linear temperature programmer, and modified with a capillary effluent splitter with a 10:1 split ratio as well as a thermal gradient collector (Brownlee and Silverstein, 1968). Fractions were collected in 40-cm × 1.8-mm-OD glass capillary tubes. Retrieval of the collected fraction was accomplished by breaking the end of the tube, drawing one end to a point, and rinsing the tube with small aliquots (about 20–30 μl) of desired solvent. The column used for separation was 30 m × 0.52 mm ID coated with Stabilwax; the analysis conditions used for the separation were as follows: 60°C for 4 min and then 3°C/min to 220°C with a hold for 48 min at the final temperature.

Isolation of Acidic Components From Axillary Secretion Extract. The concentrated axillary secretion extract (100 μl) was put into a centrifuge tube and then cooled to 0°C. Saturated aqueous sodium bicarbonate (2 ml) was added into the tube. After shaking, the mixture was extracted with $CHCl_3$ (1 ml × 2). The resulting two layers were separated by centrifugation for 5 min. The bottom organic layer, containing the basic and neutral components, was transferred to a 5-ml pear-shaped flask by using a thinly drawn pipet. This was stored at −10°C until analysis.

The aqueous layer remaining in the centrifuge tube was cooled to 0°C, and acidified with 0.5 M HCl to a pH of 2. The mixture was extracted with $CHCl_3$ (1 ml × 2). The organic layer was again separated as described above and concentrated to 20 μl.

A second procedure was performed for the isolation of acidic components. This involved treatment of the cooled (0°C), concentrated (without adding $NaHCO_3$, as above) axillary secretion extract with 0.5 M HCl, and extraction with $CHCl_3$. The two layers formed were separated by the same procedures as above. The organic layer was treated with saturated aqueous sodium bicarbonate and separated. The basic aqueous layer produced from the last step was acidified and extracted with $CHCl_3$. After separation of the two layers, the organic layer that contains the acidic components was concentrated and analyzed. The procedure yielded the same array of compounds as was found when the extract was first exposed to bicarbonate.

Synthesis of 7-Octenoic Acid. To a stirred mixture of 1,6-heptadiene (3.57 g, 0.039 mol) and toluene (5 ml), 8.2 ml (1/3 mol eq) of $Al(i\text{-butyl})_2H$ was added while maintaining the temperature below 40°C. This mixture was then stirred for 3 hr at 50–60°C. After cooling this mixture to room temperature, 7.7 ml (1/3 mol eq) of *n*-butyl lithium was added. We then bubbled CO_2 gas into the mixture (at room temperature) and followed the formation of 7-octenoic acid by gas chromatography. The addition of CO_2 was ceased when no further acid was found. The mixture was subsequently poured into a 10% HCl solution and extracted with 3 × 30 ml of ether. The ether layer then was extracted with 3 × 3 ml of 10% NaOH solution and the NaOH solution subsequently acidified

with 2 M HCl and extracted with 3 × 30 ml of diethylether. The ether layer was dried and concentrated to give 2.5 g (45%) of an oil which contained 77% of 7-octenoic acid. Pure quantities of the acid for subsequent experiments were obtained by preparative gas chromatography as described above.

Preparation of Trimethylsilyl Derivatives. In order to form trimethylsilyl (TMS) esters and/or ethers, 5 μl of the concentrated acid fraction was reacted at 70°C for 30 min with 10 μl *N,O*-bistrimethylsilyltrifluoroacetamide (BSTFA) and 2 μl trimethylsilyl chloride. The resulting reaction mixture was analyzed by GC-MS using the non-polar RTX-1 column described above.

Organoleptic Evaluation of Chromatographically Separated Components (Smell Chromatography). To determine which of the chromatographic eluants had odors resembling the axillary extract, a panel of two to four judges were assembled to perform the smell chromatography. Each panel member was able to perceive the "urinous" odor of androstenone and the "musky" odor of androstenol (Amoore et al., 1977; Labows et al., 1982). Prior to smell chromatography, the entire mixture to be analyzed was evaluated after placing a small (1–5 μl) aliquot on a filter paper strip and allowing the solvent to dry. The odor of the entire mixture then was evaluated by the panel. The sample was left in a fumehood within easy access should it be needed for reference. Olfactory sampling began approximately 3 min after injection. Each judge sampled the chromatographic eluate every 30–40 sec on a rotating basis. They were asked to record which portions of the eluate most resembled the original "bouquet" in terms of quality and intensity. Panelists were instructed not to communicate with each other during judging and to make sure that other panelists could not see their records. Smell chromatography was performed with the flame ionization detector off and olfactory sampling of the chromatographic eluent occurring at each 30-sec interval by two or more observers. The analyses were performed using the following conditions: Sil-8, 60°C (4 min) to 300°C at 4°C/min; Stabilwax, 60°C (4-min hold) to 220°C at 3°C/min. The carrier gas (He) flow rate in each analysis was 2 ml/min.

Hydrogenation of Collected Peak K. Into a 0.4 ml V-shaped reaction vial were placed 10 mg of 10% palladium on charcoal catalyst, 50 μl nanograde methanol, and collected compound [K] (≤ 0.2 μg in 10 μl of $CHCl_3$). A small stream of hydrogen was introduced into the mixture at room temperature. After 5 min, the mixture was transferred to a 1-ml centrifuge tube and centrifuged at top speed for 5 min. The clear reaction mixture was withdrawn into a small pear-shaped vial and concentrated to about 5 μl using a Savant Speed Vac Concentrator (model SVC-100H) prior to analysis by GC-MS.

Structural Data for Synthetic (E)- *and* (Z)-*Methyl-2-Hexenoic Acids.* The 3-methyl-2-hexenoic acids were synthesized using the procedure of Wadsworth and Emmons (1961) to condense triethylphosphonoacetate with 2-pentanone. This procedure gives a 1:3 mixture of the *Z* and *E* isomers.

The NMR spectrum for the *E* isomer has been previously reported using a 100-MHz instrument (Smith et al., 1969). However, FT-IR data for the *E* as well as 500-MHz NMR, FT-IR, and MS data for the *Z* compound are given below:

(E)-*3-Methyl-2-Hexenoic Acid.* IR max (vapor) cm^{-1} 3581, 2971, 1751, 1651, 1391, 1270, 1198, 1106, 858. Ethyl ester unit = 13.49.

(Z)-*3-Methyl-2-Hexenoic Acid.* [^{1}H]NMR ($CDCl_3$) 0.95 (3H, triplet, J = 7.3, C—6H), 1.15 (2H, sextuplet, J = 7.5, C—5H), 1.91 (3H, doublet, J = 1.3, C—7H), 2.62 (2H, triplet, J = 7.7, C—4H), 5.69 (1H, singlet, C—2H); IR max (vapor) cm^{-1} 3580, 2973, 1750, 1649, 1385, 1271, 1186, 1112, 1009, 860. Mass Spectrum: *m/z* (rel. int.) M^+ 128 (71), 113 (81), 111 (21), 100 (50), 95 (72), 87 (32), 83 (25), 82 (59), 72 (13), 71 (42), 69 (100), 67 (85), 57 (24), 56 (13), 55 (73), 53 (37), 45 (25), 43 (88), 42 (27), 41 (93); ethyl ester unit = 13.05.

RESULTS

The suggestion that volatile steroids might be involved in the characteristic axillary malodors initially prompted us to perform organoleptic evaluation of the chromatographic eluant (henceforth, smell chromatography) with the concentrated axillary extracts using a nonpolar, methyl silicon column. We previously had established reliable retention times for the volatile steroids using this type of column (Preti et al., 1987). The results of this experiment are illustrated in Figure 1 (top). This shows that within the first 15 min of the analysis, a strong, characteristic axillary odor eluted. The urinous, musky odors characteristic of the volatile steroids (such as androstenol, androstenone, 3,5-androstadienone, and the pyrolysis products of dehydroepiandrosterone sulfate and androsterone sulfate) elute in the area shown at about 40–45 min. The identical extract injected onto the more polar, Carbowax-type phase (Figure 1, bottom), shows the characteristic axillary odor eluting at a retention time of 38–53 min. This is preceded by the sharp, acidic smells of short-chain aliphatic acids (such as butyric and isovaleric acids). On this column, the volatile steroids eluted after 65–70 min. These results suggested that a yet unidentified group of compounds was responsible for the characteristic axillary odor.

Collection of the area where the characteristic axillary odors elute was performed using preparative gas chromatography. The collected eluant was dissolved in methylene chloride, divided in two, and treated with two aqueous base solutions: (1) $NaHCO_3$ (pH 9.9); and (2) $Na_2B_4O_7$ (pH 10.8). Both treatments resulted in an elimination of the characteristic axillary odor. This experiment suggested to us that acidic components with C_6 or greater carbons (based on chromatographic retention times) carried the characteristic underarm odor.

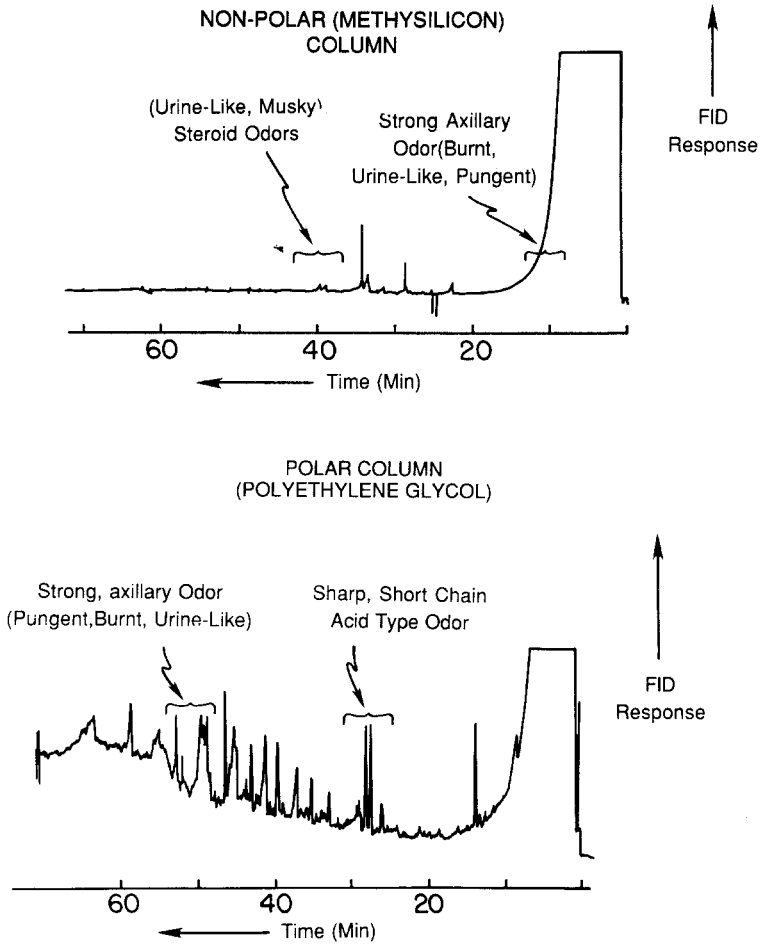

FIG. 1. Top: Flame ionization detector (FID) response and organoleptic evaluation of compounds in the axillary secretion extract eluting from the bonded methyl silicone column. Strong, characteristic axillary type odors elute with the first 10–18 min. The odor of the volatile steroids (such as androstenone and androstenol) as well as the pyrolysis products of the steroid sulfates are found in the time frame shown. Bottom: Results of the organoleptic evaluation of compounds in the axillary secretion extract eluting from the bonded Carbowax-like (Stabilwax) column. The characteristic axillary odors elute in the time frame shown. Steroids such as androstenone and androstenol have long retention times on this column (>65 min).

We subsequently isolated the acidic components from a combined (six male donors) concentrated male axillary extract. The extract containing the acid components was concentrated to 20 μl by rotary evaporation. This acidic concentrate had a characteristic axillary malodor—identical to that of the entire extract. The neutral and basic part of the extract had little or no odor. A second procedure employing initial acidification of the extract gave identical results (see Methods and Materials).

Smell chromatography of the acidic fraction using the polar (Stabilwax column), showed a series of components with burnt, urinous, and axillary-like qualities eluting from times 37–54 min. Therefore, a number of the compounds eluting in this time frame carried a significant portion of the axillary odor. However, the major component, found at ethyl ester unit (EEU) of approximately 13.50 (peak K in Figure 3) appeared to be a major contributor to the axillary odor.

The reconstructed ion chromatogram (RIC) obtained from separation and analysis of the combined acid fraction from the male donors is shown in Figure 2. The area outlined in Figure 2 is expanded in Figure 3 (bottom). The shaded areas indicate where important odors elute. Correlation of the data from smell chromatography with the GC-MS data is carried out by matching the relative retention times (based on ethyl ester indices; van den Dool and Kratz, 1963) on both the chromatograph where the smell chromatography was performed and on the GC-MS system.

Figure 3 also shows a plot (mass chromatogram, top) of m/z 60. This "McLafferty rearrangement" ion is characteristic of aliphatic acids (with an available γ-hydrogen and an unsubstituted α-carbon) (Budzikiewicz et al., 1967). In this figure, m/z 60 is particularly large for the normal, straight-chain acids.

In addition to the mass spectral and relative retention time data, further analysis of the acidic extract was performed by combined gas chromatography–Fourier transform-infrared spectroscopy (GC-FTIR). All of the compounds identified in this mixture are listed with their corresponding ethyl ester units in Table 1. Those compounds thought to be important contributors to the odor are marked with an asterisk.

Characterization of (E)- *and* (Z)-*3-Methyl-2-Hexenoic Acid.* Mass spectra obtained by combined GC-MS using both polar and nonpolar columns showed that the major component (peak K) had the mass spectrum shown in Figure 4. A molecular ion at m/z 128, as well as losses of 15, 17, and 28 from the molecular ion are seen. Also noted was a small component eluting at approximately 13.00 EEU (peak G in Figure 3), which had an identical mass spectrum, suggesting the presence of a stereoisomer. A high-resolution mass spectrum of peak K showed its molecular ion to have an elemental composition of $C_7H_{12}O_2$ (exact mass = 128.0837; found = 128.0820).

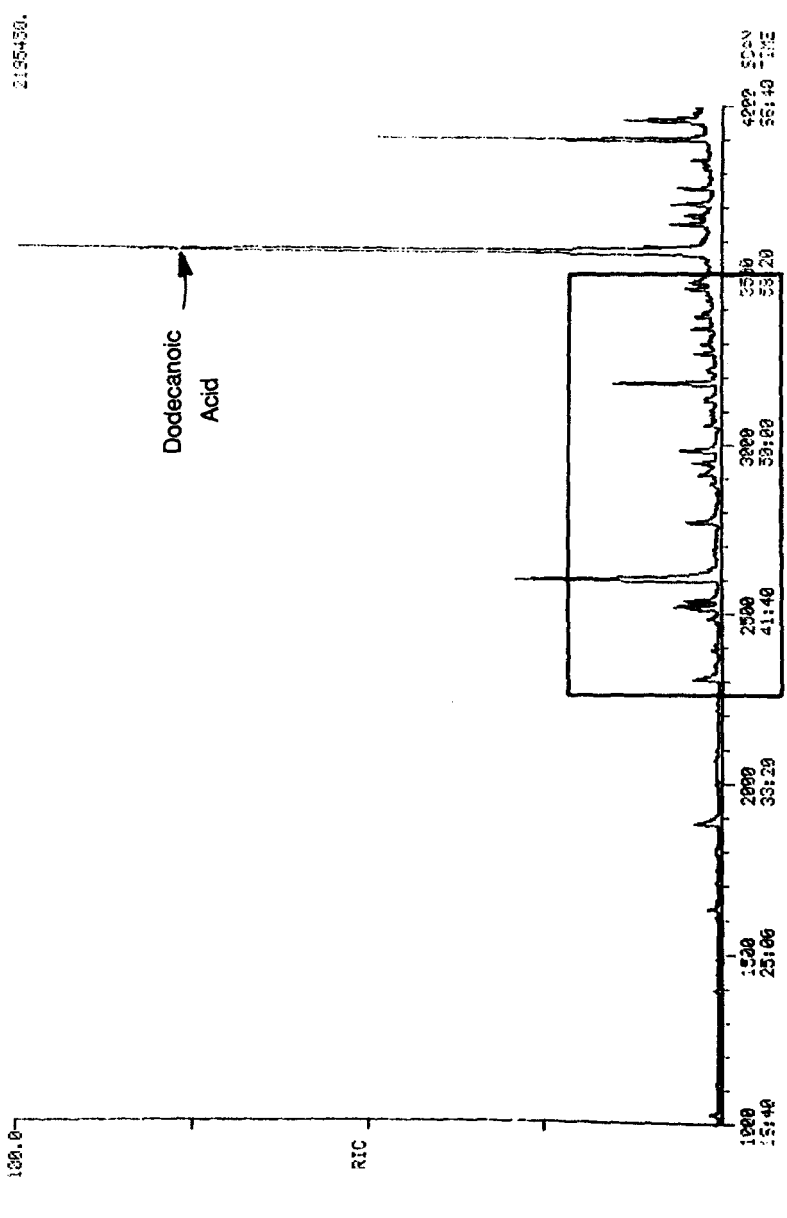

FIG. 2. The computer reconstructed chromatogram generated by the analysis of the total acid portion of the axillary extract. The outlined area is the part of the chromatogram where the characteristic axillary odors are found, as shown in Figure 3. The major component seen at approximately 3590 scans is nonodorous normal dodecanoic acid.

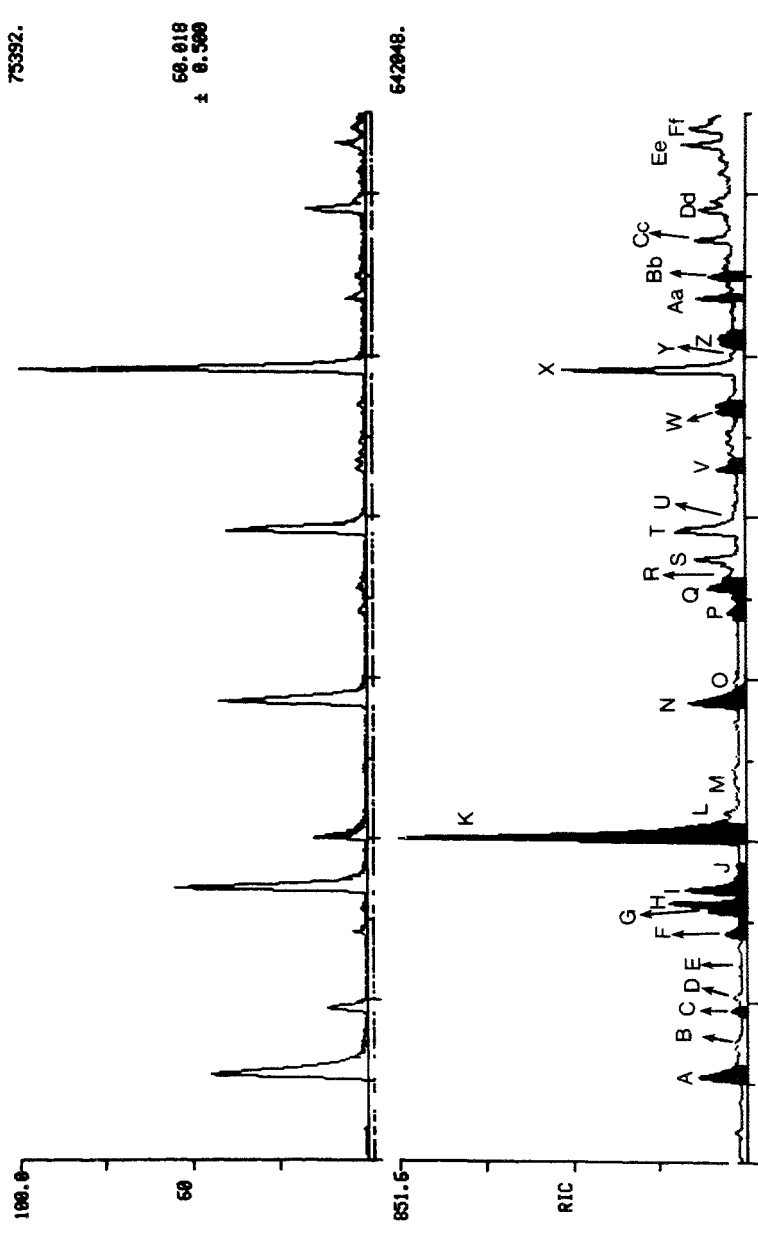

FIG. 3. The outlined portion of the chromatogram from Figure 2 is expanded here. In addition the top part of the figure shows a plot of *m/z* 60 ("mass chromatogram") in this region. This ion is characteristic of aliphatic acids with an available α-carbon as discussed in the text. This ion is particularly large for the normal, straight-chain acids. The shaded areas represent portions of the chromatogram where characteristic axillary-type odors eluted. The identity of all the labeled peaks in the chromatogram may be found in Table 1. Those compounds in the shaded areas are marked with an asterisk in Table 1.

TABLE 1.[a]

Peak		Molecular weight	Retention time (ethyl ester unit)
A	*n*-hexanoic acid[C,G]	116	12.20*
B	2-methylhexanoic acid[G]	130	12.39

[a]The following symbols are used in this table: T = tentatively assigned by mass spectral data. C = FTIR spectrum corresponds to assigned structure; G = correspondence of mass spectrum and relative chromatographic retention times with commercially available or synthetic sample. *Indicates compound thought to be a contributor to axillary odor. ^ C_5–C_7 γ-lactones also present,

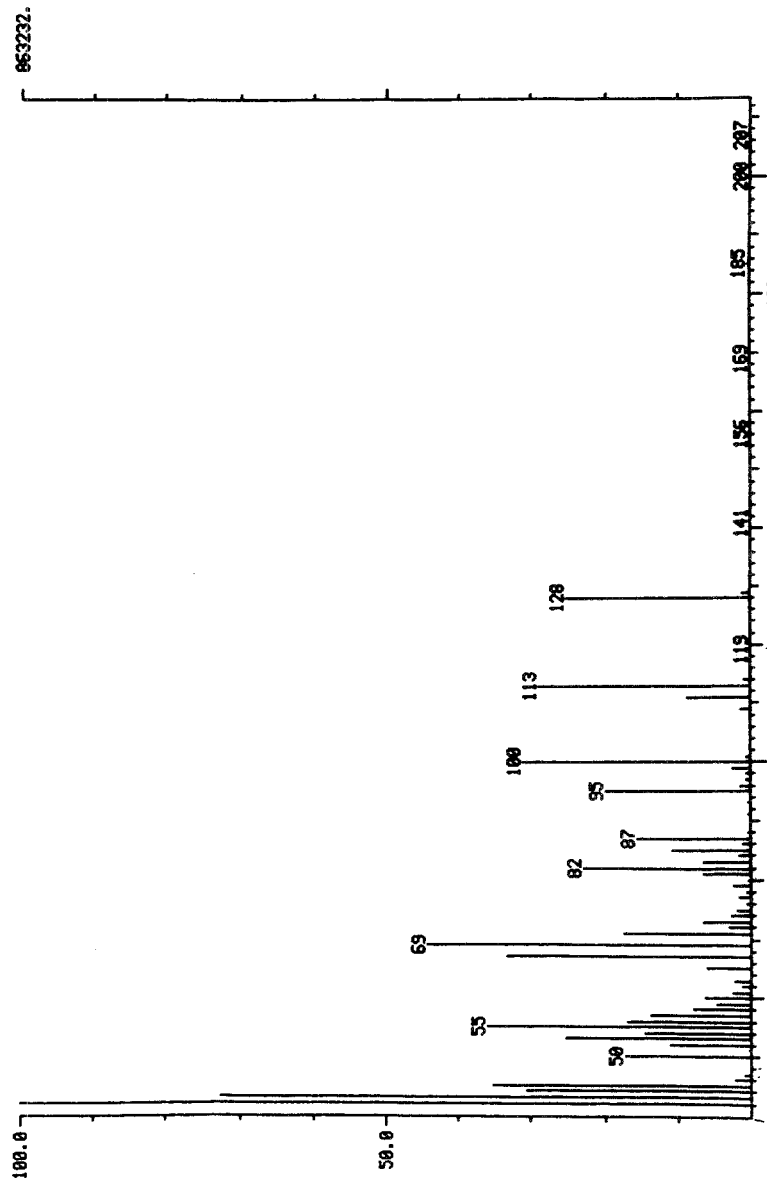

FIG. 4. Mass spectrum obtained from peak K in Figure 3, subsequently characterized as (*E*)-3-methyl-2-hexenoic acid.

Two analyses of the acid mixture were performed using GC-FTIR. The compound of interest showed identical vapor phase IR spectra on both polar and nonpolar columns (Figure 5). A search of a compilation of IR vapor-phase spectra suggested an α,β-unsaturated acid (personal communication from Mr. Michael Boruta, Sadtler Research Laboratories, after searching unknown spectra against Sadtler's IR-Vapor Phase Data Base). In addition, the EEU of peak K and the MS data also suggested a branched, unsaturated C_7 acid. We isolated a small amount (≤ 0.2 μg) of the unknown acid and performed a microhydrogenation. GC-MS analysis of the resultant reaction mixture showed a mass spectrum that was consistent with the structure of 3-methylhexanoic acid.

From the above data, the most probable structure was postulated to be 3-methyl-2-hexenoic acid. This compound was synthesized using the procedure of Wadsworth and Emmons (1961) to condense triethyl phosphonoacetate with 2-pentanone. This procedure gave a 1:3 mixture of the *Z*- and *E* isomers; each was isolated using PGC. The MS, EEU, FTIR and [^{1}H]NMR spectra for each isomer were obtained, allowing assignment of the *E* structure to peak K; the *Z* isomer was the minor component, peak G.

As further confirmation of our structural assignments, PGC using a wide-bore (0.53 mm) bonded capillary column was employed to collect sufficient amounts of the proposed *E* isomer from a concentrated extract. This extract was obtained from a collection of 20 pads worn by one donor (with the strongest axillary extract odor) across a 20-day period. Approximately 4.6 μg of the proposed *E* isomer were collected and used to obtain the FT-[^{1}H]NMR spectrum. This quantity yielded sufficient data to confirm that the collected compound was the (*E*)-3-methyl-2-hexenoic acid.

Characterization of Other Axillary Odor Compounds. Figure 6 shows the FTIR spectra of peaks A, N, T, and X, which correspond to the C_6, C_8, C_9, and C_{10} straight-chain acids. In contrast to solution-phase IR spectra, the vapor-phase spectra show very sharp absorption at 3577 cm^{-1} for the carboxyl OH stretching.

In addition to the (*Z*)- and (*E*)-3-methyl-2-hexenoic acids, several other unsaturated compounds appear to be present, including compounds with terminal double bonds. The C_8 unsaturated acid, 7-octenoic acid, is a minor component of the mixture but appears to have a high odor impact. The mass spectrum of 7-octenoic acid as well as that of a synthetic sample are shown in Figure 7. In addition to the correspondence of the mass spectra, the relative retention times of the naturally occurring and synthetic 7-octenoic acids are identical. Several other terminally unsaturated compounds are also present (Table 1). Since retention times and mass spectra suggested these compounds might be homologous to 7-octenoic acid, we obtained 8-nonenoic acid from Takasago International Corp. (Tokyo, Japan), 9-decenoic acid from Tokyo Kasei Kogyo Co., Ltd. and 10-undecenoic acid from Sigma Chemical Co. Although both the EEU

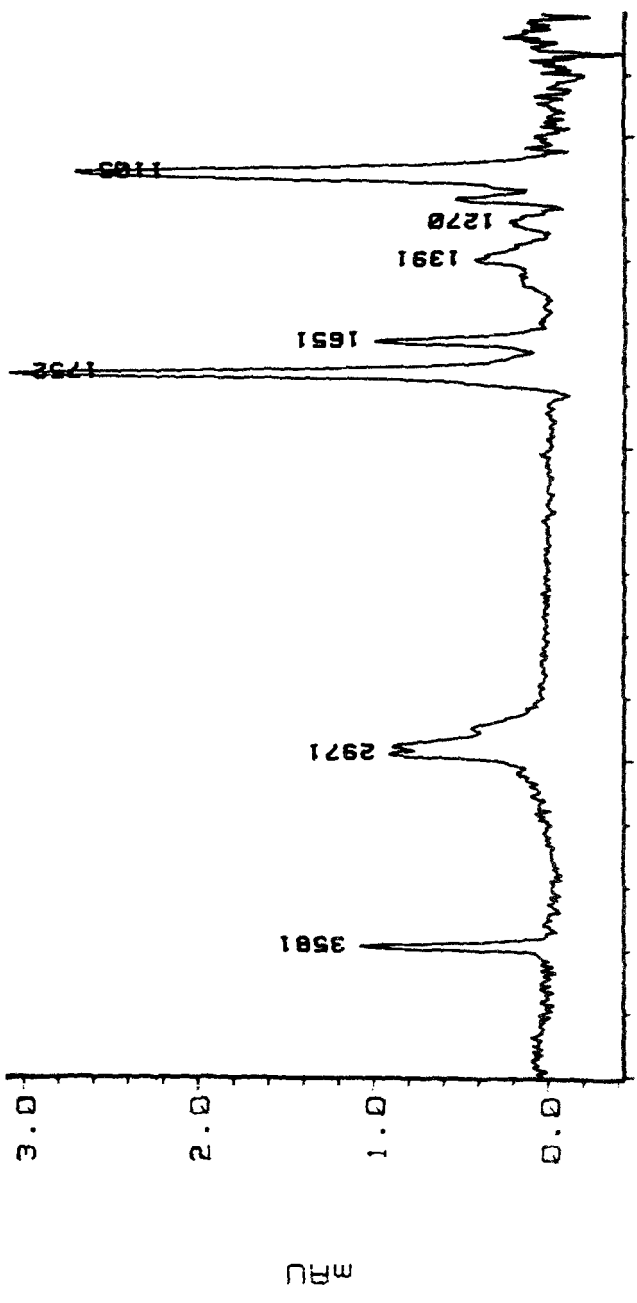

FIG. 5. Vapor-phase IR spectrum obtained from peak K in Figure 3. Note the sharp absorption at 3581 cm^{-1} due to the carboxyl-OH function, in contrast to the broad absorption seen in solution-phase IR spectra of acids.

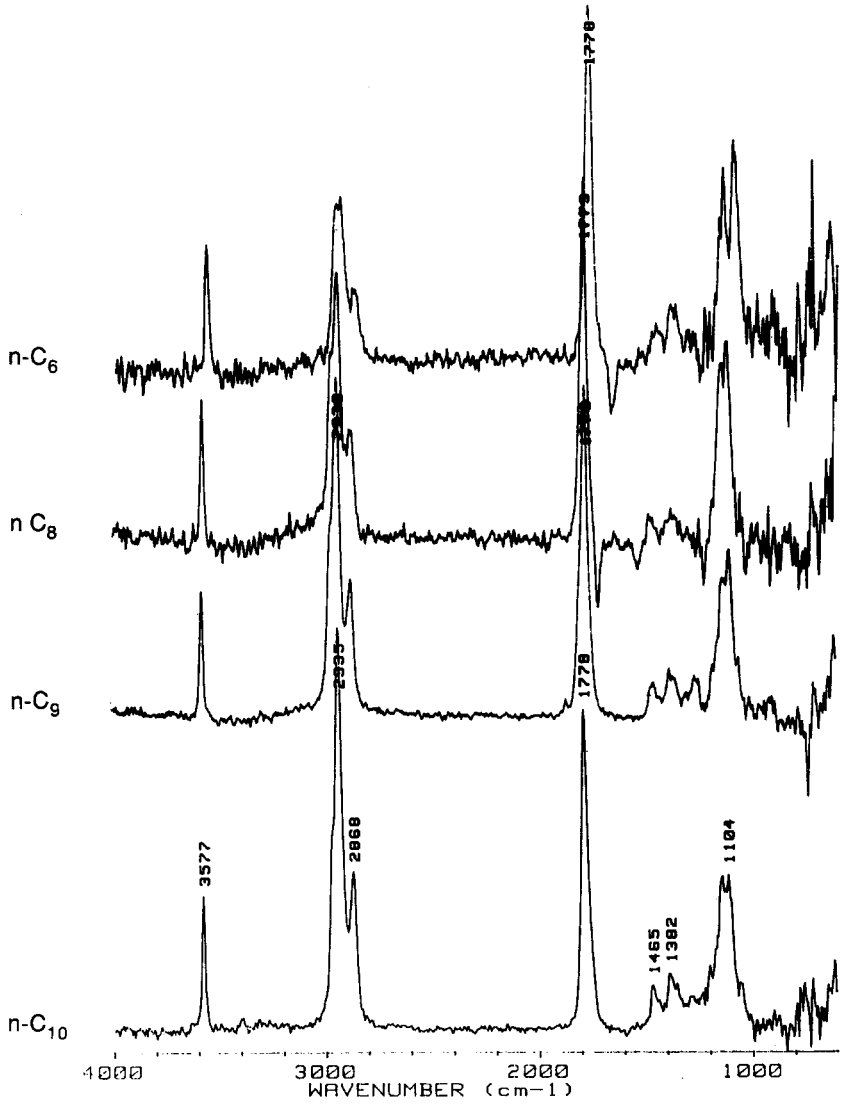

FIG. 6. Shows four overlapping FTIR spectra from normal hexanoic, octanoic, nonanoic, and decanoic acids. Note the sharp adsorption at 3577 cm^{-1} for the carboxyl OH stretching.

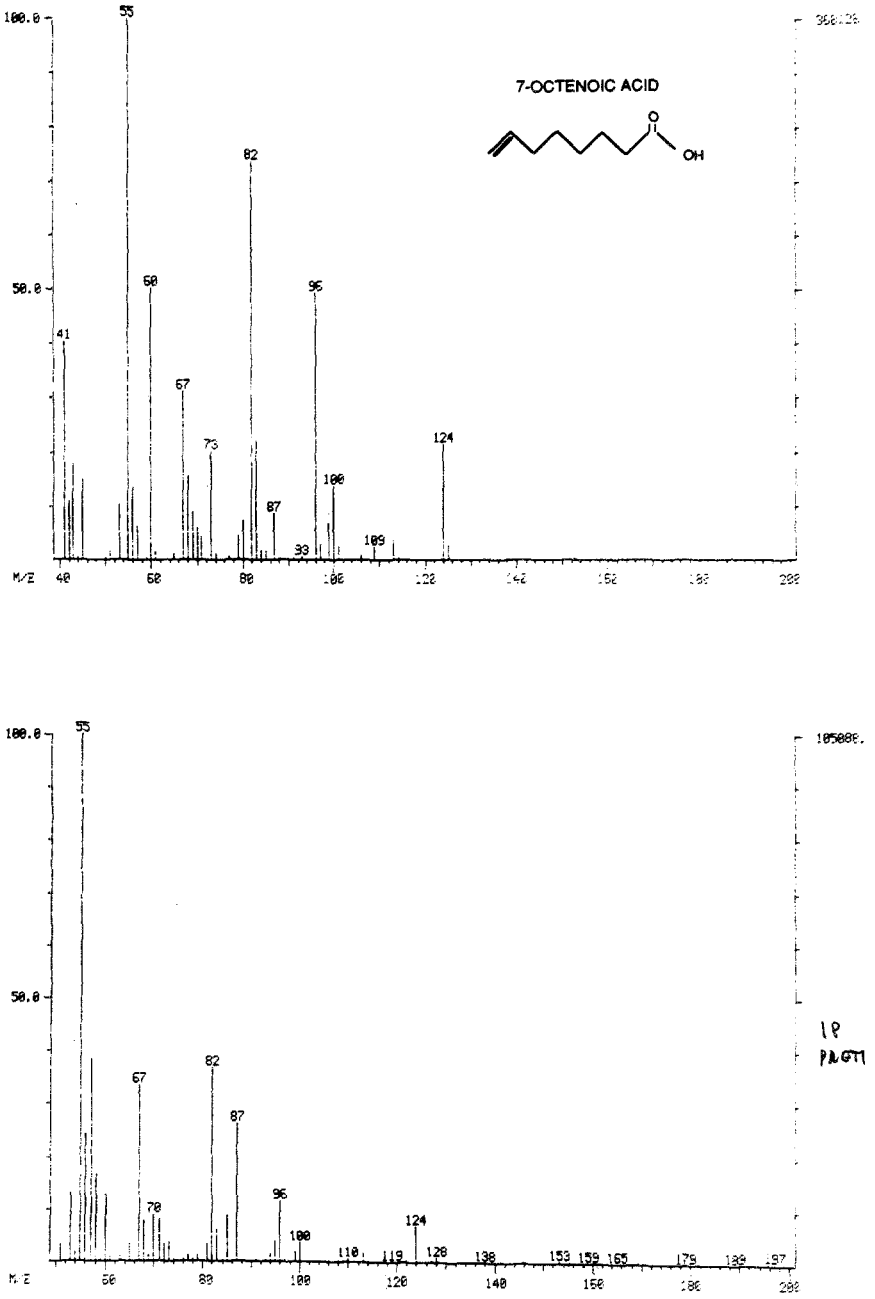

FIG. 7. Mass spectrum of synthetic 7-octenoic acid (top) compared with that of the proposed 7-octenoic acid found in the axillary extract centered at scan 2915 (bottom).

and mass spectra of 9-decenoic acid were identical to that of the unknown in the extract, the 8-nonenoic had an EEU of 15.86 (unknown = 16.04, Table 1). In addition, the mass spectrum of the unknown showed a larger proposed molecular ion and a different overall fragmentation pattern than that of the standard sample. The EEU of standard 10-undecenoic acid was 17.84 (unknown = 17.76); however, the mass spectrum of the unknown appeared to be "mixed," since it appears to elute with another compound. Consequently, it is difficult to conclude if 10-undecenoic acid is present since the mass spectra could not be compared directly in this sample.

Branched-Chain, Saturated Acids. The GC-MS data also showed two series of branched-chain acids. One homologous series consisted of 2-methyl acids beginning with 2-methyl hexanoic acid (peaks B, J, O, U, and Y). The mass spectra of the 2-methyl acids are characterized by ions at both *m/z* 74 ("McLafferty rearrangement" ion in α-methyl substituted acids), and *m/z* 87. Although these are the same ions that are present in the low mass end of methyl ester mass spectra, neither their relative retention times nor the molecular ion regions of their mass spectra correspond to methyl esters.

A second homologous series of acids possessed an ethyl group on the 4-position in the chain (peaks F, P, V, Aa, and Ee in Figure 3). The 4-ethyl-octanoic acid in the series (peak V) has a "goatlike" smell and has been previously isolated from sebaceous gland secretions of mature male goats (Sugiyama et al., 1981). In addition, this compound has been studied because of its low odor threshold (Boelens et al., 1983). This series of acids appears to be characterized by ions at M^+-29 and M^+-59, which in 4-ethyloctanoic acid ("goat acid") are seen at *m/z* 143 and 113, respectively (Figure 8).

γ-Lactones. Trace quantities of a series of C_5—C_{10} γ-lactones were found from scan numbers 1500–3000 by examining the mass chromatogram of *m/z* 85 (Labows et al., 1979a). Except for C_5 γ-lactone, all the other γ-lactones show a base peak at *m/z* 85, which is the characteristic peak of γ-lactone. This series of compounds has been reported previously to be formed by *Pityospirum ovale* isolated from the scalp (Labows et al., 1979a).

Analysis Using a Nonpolar Column. To further examine the axillary odor components, we chromatographed the mixture on a nonpolar column with and without derivatization. The analysis without derivatization did not reveal any new components but did show that (*Z*)- and (*E*)-3-methyl-2-hexenoic acids as well as many of the other C_6—C_{11} acids shown in Table 1 elute within the first 15–18 min. This would explain the presence of the strong axillary odors shown eluting in the smell chromatogram of the nonpolar column in Figure 1 (top). In addition, this analysis also showed the presence of both the volatile steroids (androstenone and androstenol) and the pyrolysis products of the two steroid sulfates (androsterone sulfate and dehydroepiandrosterone sulfate) described in

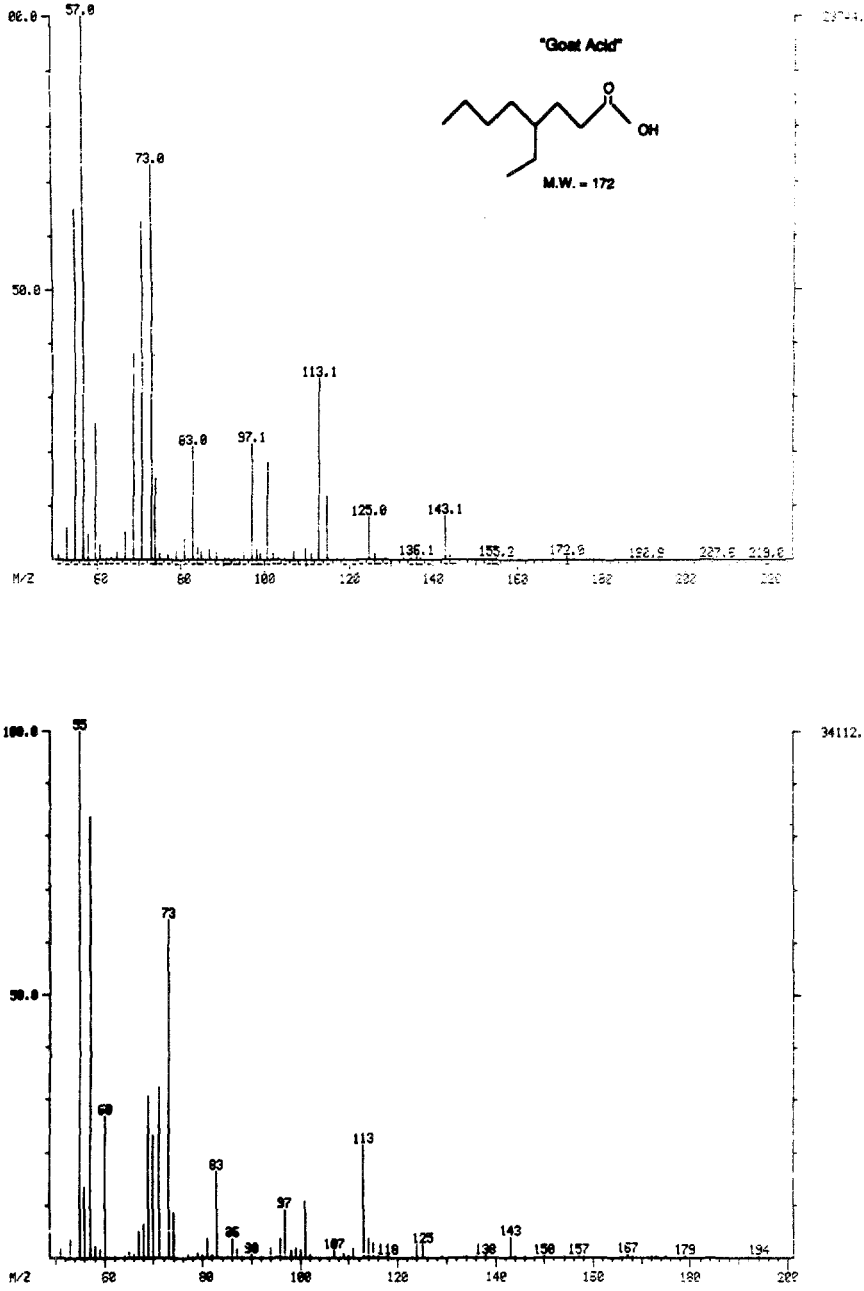

FIG. 8. Mass spectrum of commercially available 4-ethyloctanoic acid ("goat acid"; top) compared with that of the proposed 4-ethyloctanoic acid found in the axillary extract centered at scan 3062 (bottom).

previous studies from our laboratory (Labows et al., 1979b). These eluted at the predicted retention times, as shown in Figure 1.

Analysis of the trimethylsilyl derivatives revealed a variety of components not seen in the earlier analysis; however, a majority of the compounds are not contributors to the odors since they are higher-molecular-weight (C_{12}—C_{18}), straight-chain saturated, branched, and unsaturated acids. Several aromatic acidic compounds were identified including benzoic, phenylacetic, *o*-methylbenzoic and phenylpropanoic acids, and *p*-hydroxybenzaldehyde. The largest of these components appears to be *p*-hydroxybenzaldehyde; however, it is relatively odorless and only phenylacetic acid appears to lend some odor quality to the axillary odor.

DISCUSSION

The results obtained from this study suggest that volatile C_6—C_{11} straight-chain, branched, and unsaturated acids are the major contributors to underarm odor. Previous investigations of axillary secretions have not reported such a complex mixture of acids nor have these compounds been suggested as important axillary odorants (Labows, 1988; Gower, 1989). Those compounds with branching or unsaturation seem to have a high odor impact. A major contributor to the axillary odor is (*E*)-3-methyl-2-hexenoic acid; it is both unsaturated and branched. The *Z* isomer, which is present at one-tenth the concentration of the *E* isomer, also has a high odor impact. However, its odor quality is more like aliphatic acid.

(*E*)-3-Methyl-2-hexenoic acid was once thought to be the odor that characterized patients suffering from schizophrenia (Smith et al., 1969). Further studies later showed the compound to be present in normal patients also (Gordon et al., 1973). These previous studies employed whole-body sweat collected from patients placed in plastic bags between two electric blankets; consequently, the specific body site(s) for production of this malodorous compound could not have been correctly determined. Further, the *Z* isomer was not reported in these past studies of whole body sweat.

Mass spectrometric evidence for the presence of the volatile steroids in the acidic fraction was seen using the nonpolar methyl silicone column. However, in view of the relatively large odor impact of the acids (smell chromatography experiment), the high prevalence of a specific anosmia to one of the steroids (androstenone) and the relatively (to the steroids) high concentration of the acid compounds, we do not feel that the steroids are important malodor contributors. Further, their retention times, as noted above, do not suggest that they elute at the time when the strongest axillary odors elute.

Labows (1988) recently suggested that organoleptic descriptions of the

axillary odors implied the presence of not only isovaleric acid but also medium-chain acids, such as 4-ethyloctanoic acid. The latter is present (see Table 1) in the acidic axillary extract and has a very low olfactory threshold (Boelens et al., 1983). No data are available concerning the olfactory threshold for (*E*)-3-methyl-2-hexenoic acid or many of the other acids identified in our study.

As noted in the results, the neutral and basic fractions possessed very little odor. An organoleptic panel (four persons) that evaluated the concentrated extract as well as its acid, base, and neutral fractions found that all the characteristic axillary odor was in the acid fraction.

Recent applications of the technique of smell chromatography to malodor problems in the food industry (Sevenants and Sanders, 1984; McGorrin et al., 1987) and odor threshold measurements (Marin et al., 1988) suggested it would be an ideal way to pursue the chromatographic retention times of the characteristic axillary odors. This proved to be correct. Its application here showed that several of the compounds present at relatively low concentrations (such as the terminally unsaturated acids) were important contributors to the odor. Since the smell chromatography experiment suggested that the region where 7-octenoic acid eluted contained an important odor, we carefully investigated each of the minor chromatographic components in the area to determine which might possess an axillary-like odor. The result was the identification of 7-octenoic acid and subsequently the other terminally unsaturated homologs noted in Table 1.

We noted that one of us (H.J.L.) could not perceive either of the 3-methyl-2-hexenoic acids. Consequently, we are currently examining how extensive this specific anosmia might be. When asked to describe the odor, people tested who can smell these acids gave as their most frequent replies: urinous, sweaty, burnt, woody, acrid, musty, and musky. Many of these descriptors also have been attached to the odor of volatile steroids (Ohloff et al., 1983).

In the study reported here, the axillary secretion extracts were combined from six male donors. We are currently collecting and evaluating data from individuals. It is believed that there will be quantitative differences in the composition of axillary from each donor. Therefore, a different group of the combined male donor axillary secretion extracts may give a different ratio of the characteristic odor components.

The low levels of γ-lactones seen in the analyses (Table 1) may be due to the metabolism of *Pityrosporum ovale*. These yeast organisms are found on human skin areas that contain large numbers of sebaceous glands and may be part of the normal resident axillary flora. These yeasts previously have been shown to produce γ-lactones in the presence of human sebum. The lactones have a pleasant odor (Labows et al., 1979a).

The research of Hurley and Shelly (1960) as well as Shehadeh and Kligman (1963) demonstrated that freshly produced apocrine secretion is odorless and

that the axillary odor arises from the action of cutaneous microorganisms upon apocrine secretion. Consequently, the precursors for the odor are contained within the apocrine secretion. Previous analyses of the secretion have shown that it contains steroid sulfates, cholesterol, lipids, and about 10% protein (Labows et al., 1979b, 1982). In addition, considerable speculation has focused on the formation of the volatile steroids from apocrine secretion precursors (Labows, 1988; Gower, 1989). However, since the compounds reported here were not known to be important malodor constituents, no speculation has appeared concerning their precursors. The structure of the characteristic odors suggests that the precursors for these compounds would almost certainly not be amino acid-like in composition due to the chain length and branching of the acids involved. In addition, since the odor is formed very quickly in both in vivo and in vitro experiments, it would suggest a simple bond cleavage to form the odor and not a complex bacterial catabolism from higher molecular components. Consequently, the apocrine secretion may contain the characteristic odor compounds esterified to higher-molecular-weight lipid components or perhaps even bound to the proteins in some fashion.

Acknowledgments—The authors wish to acknowledge the help of Mr. Steve Huhn of Nabisco Brands, Inc. (Schaeberle Technology Center, East Hanover, New Jersey) and Mr. Walter O. Ledig of International Flavors and Fragrances (Union Beach, New Jersey) for obtaining the FTIR spectra. We also thank: Mr. Michael Boruta of Sadtler Research Laboratories (a division of Bio-Rad Laboratories) for employing their PC-IR Search Software to compare our FTIR data to their IR-Vapor Phase Data Base; Mr. Ken McGinley of the Duhring Laboratories, Department of Dermatology, University of Pennsylvania, for screening axillary secretion donors for the correct microflora and odor production; and Mrs. Janice Blescia for typing this manuscript. NMR spectra of the chromatographically collected compounds were obtained with the help of Dr. George Furst, Director of the Analytical NMR Facility in the Department of Chemistry, University of Pennsylvania. This work was supported in part by a postdoctoral fellowship awarded to the Monell Chemical Senses Center by Takasago International Corporation.

Book Review

Phytochemical Ecology: Allelochemicals, Mycotoxins, and Insect Pheromones and Allomones. Chang-Hung Chou and George R. Waller (eds.). Taipei: Institute of Botany, Academia Sinica, 1989. 504 pp.

This book is the proceedings of the meeting on Phytochemical Ecology: Allelochemicals, Mycotoxins and Insect Pheromones and Allomones held in Taipei and Kenting, Taiwan, December 13–20, 1988. The order of the papers follows the sequence at the meeting, and all papers are included. The topics covered were allelopathy, plant–animal interactions, mycotoxins, and insect pheromones and allomones. This was an extremely broad range of subjects to be covered by 35 papers. The papers supposedly were arranged under eight major headings according to the contents. These included Frontiers of Phytochemical Ecology, Allelopathy in Natural and Agricultural Ecosystems, Biochemical and Physiological Basis of Allelochemicals, Allelochemicals in Soils and Rhizosphere, Allelochemical Actions of Fungal Metabolites, Allelochemicals in Weed Control, Mycotoxins, and Pheromones. Three to six papers were listed under each of the headings and the relationships between several of the papers and the headings were not clear. The inclusion of mycotoxins with the other topics seemed rather illogical, even though the subject is a very important one.

The wide range of topics does appear reasonable when one considers the overall goal of the symposium. That goal was to stimulate cooperative research projects in phytochemical ecology between scientists in Taiwan and other participating countries. Unfortunately, this resulted in a proceedings that has a very narrow treatment of most topics and decreased its value as a reference for scientists in specialized areas. In spite of these limitations, most of the papers are of excellent quality and many of them were presented by some of the top scientists in the world in the areas of presentation.

This reviewer finds it very difficult to summarize the papers presented in this book, because it cannot be done accurately by the major headings listed in the contents. Five chapters dealt primarily with the allelopathic potentials of selected plant species, chiefly in Taiwan, Korea, Australia, Mexico, and Florida in the United States. One chapter concerned interactive effects of allelochemicals and environmental stress, one involved allelopathy and agricultural sustainability, five covered the topic of allelochemicals in weed control, three dealt with the fate of allelochemicals in soils, one chapter concerned the use of *Pseudomonas cepacia* (K413) as a potential biofungicide, and four chapters

0098-0331/91/0700-1493$06.50/0

dealt primarily with the identifications of new and old allelochemicals. The 20 chapters listed to this point were obviously concerned primarily with allelopathy.

One chapter dealt in part with allelopathic interactions of algae and in part with the production by algae of chemicals toxic to fish, humans, and other animals. Six chapters were concerned with mycotoxins, six chapters with pheromones, one chapter with the control of insects by allelochemicals, and one with the abiotic synthesis of humic polymers in soil.

In addition to the technical chapters, the proceedings includes a preface, four opening addresses, an introduction, conclusions and recommendations, summary remarks, an author index and a subject index.

Book Review

CRS Handbook of Insect Pheromones and Sex Attractants. M.S. Mayer and J.R. McLaughlin. Boca Raton, Florida: CRC Press, 1991. 1083 pp. $295 (outside the U.S., $345).

The arrival of the *Handbook of Insect Pheromones and Sex Attractants* in our laboratory was akin to a mail delivery in Antarctica. Our minds were already fully occupied, but when the book arrived, we were immediately tempted to explore this informative compendium. With enthusiasm, and in considerable awe of this work, we set about to evaluate it. It soon became evident that this handbook is an invaluable research tool.

The handbook is divided into two parts. Part I, the major section, is entitled Insect Sex Pheromones, and begins with a list of Genera by Order and Family followed by a List of Species. The bulk of the informative text is comprised of many Entries in Order of Genera. Part I ends with three indexes, one to Footnoted Species, for which taxonomic clarification is given, the second to Common Names, and the third to Chemicals .

The smaller Part II deals with pheromone chemistry. It begins with a Pheromone Synthesis Table of Contents in which pertinent references are listed alphabetically under the IUPAC name of each compound. The book ends with two independent lists, in which alphabetically ordered references are grouped under two headings, General Analytical Methods and General Synthetic Methods.

Because most of the text of part I is arranged alphabetically by genera, readers who know the scientific names of the species on which they seek information will easily thumb through the pages until they find them. If one were interested, for example, in the genus *Phyllonorycter*, he or she would find on pages 705–708 entries for nine species, from *P. blancardella* to *P. watanabei*. Exploring *P. blancardella* further, one would find the generic synonym (*Lithocolletis*), the species author [(Fabricius)], the common name (spotted tentiform leafminer), and the order and family (Lepidoptera: Gracillariidae). Three headings follow the above taxonomic information: Field Attractant, indicating biological activity, but no proven function as a pheromone component for the one compound listed by IUPAC name below the heading; Biological Assay, under which there is a concise and useful description of field and electrophysiological assays done on this species; and References, under which are listed five pertinent publications.

0098-0331/91/0700-1495$06.50/0

For other species, the headings are justifiably different, yet descriptive, and the information is greater in extent. Thus, the headings for *Heliothis zea* are: Female Sex Pheromone Components, Isolation and Identification, Biological Assay, and References, and the text and references cover two full pages.

Despite the authors' obvious concern for accuracy, there are several errors or omissions with regard to taxonomy, spelling, and chemical accuracy. More seriously, many readers will be confused about the content of the book. While the title reads in part, Insect Pheromones, the preface indicates that the scope of the book is restricted to chemicals that have "sex pheromonal" or "mating" activity, including aggregants linked to reproduction. Yet the text includes questionable assignments, e.g., as Female Sex Pheromone Components for two multifunctional compounds produced by honeybee queens. The book would be even more useful if it had included all pheromones, avoiding difficult and arbitrary decisions as to whether a given compound was truly involved in reproduction. As it stands now, there are huge omissions; e.g., there is a single entry for the Formicidae, an obscure reference to one species being attracted to citronellol. Expansion to embrace a wider spectrum of behavioral activity is recommended for future editions, which it is hoped are being contemplated even now. It would also be helpful if there were an index to species, giving the pages on which they appeared. Finally, and unavoidably, the book refers only to literature published before 1988 and is thus already out of date.

Nevertheless, this volume will be an essential resident in all laboratories that conduct serious research on insect pheromones and should be acquired by all university and other libraries that have a scientific clientele. At a somewhat daunting price of $295 (U.S.) or $348 (U.S.) outside of the United States, one cannot expect too many individuals to purchase it. However, if I were about to graduate in insect chemical ecology, or if I had not received a review copy, I might already be strongly hinting that it would make a nice graduation or Christmas present.

ANNOUNCEMENT

SYMPOSIUM ON INSECT–PLANT RELATIONSHIPS

The 8th International symposium on Insect–Plant Relationships will be held on March 9–13, 1992, at Wageningen, The Netherlands.

Topics to be discussed will include host-plant selection, insect–plant communities, plant defenses, multitrophic interactions, genetics and evolution, and plant resistance.

In addition to invited papers, the program will include submitted oral and poster presentations. Proceedings of the meeting will be published before the end of the year.

First circular and organizational matters:

(Received November 26, 1990; accepted March 25, 1991)

Abstract—A field study of the food eaten by solitary desert locusts was carried out in a winter breeding area in Mauritania. The food eaten, determined by the plant epidermis found in fecal pellets, was compared to the plant's availability in the habitat. *Schouwia purpurea*, well represented in the diets, was dominant at the study site. Adults had a preference for *Tribulus terrester*. Growth and feeding on these two plants were compared. The high water content of *S. purpurea* leaves limited the dry matter eaten and slowed down growth. Glucosinolates were separated and quantified by gas chromatography. There are 132 μmol/g dry matter in green leaves. In multiple choice tests, with paper disks, glucosinolate extracts were phagostimulant at a low concentration (21 μmol/g dry matter) and repulsive at a higher one (214 μmol/g dry matter). Biting behavior on *S. purpurea* was recorded and analyzed on video. The importance of *Schouwia purpurea* in desert locust habitats and its defenses is discussed.

INTRODUCTION

Schouwia purpurea is a typical Saharian crucifer that grows in few places, although it is sometimes found with a dense and impressive vegetative development in large areas. Most of the surveys on the desert locust report the presence of this crucifer in its habitats (Roffey and Popov, 1968). In spite of its importance, very few studies have been devoted to *S. purpurea* (Boulet, 1966; Hemming and Symmons, 1969). It is found mainly in Talak, Aïr, and Tibesti. It is also found in Egypt and Arabia and has been introduced recently in India (Bhaumik, 1983). In Mauritania *S. purpurea* grows only in Aftout Faïe and the southern part of Adrar.

Cruciferae contain secondary plant compounds such as glucosinolates. Since some are toxic for nonhost insects, they could be defensive substances (Erickson and Feeny, 1974). Glucosinolates are found in all species of the Cruciferae family and are present in seeds, roots, and leaves. Their types and concentrations are taxon specific (Josefsson, 1972; Cole, 1976). Glucosinolates biosynthesis depends on the environment and can be enhanced by physiological stress such as low temperatures (MacLeod, 1976).

Selective feeders on Cruciferae have evolved detoxifying ability (Slansky and Feeny, 1977). The desert locust, known to be a generalist, does not refuse *S. purpurea* and is currently reared on cabbage. Therefore, is *Schistocerca gregaria* adapted to *S. purpurea?*

During its migrations throughout the Sahara, the desert locust, although very mobile, has to find patches of vegetation to feed on. At the same time, successful reproduction depends on locating the right food plants in the right place for oviposition. While there are many data on desert locust flight and swarm displacements, studies on solitary populations are rare. Information is still needed in the field on what makes reproduction a success in Saharian habitats.

Food plant quality is an important feature, and the following studies analyze what occurs with the most conspicuous annual forb encountered by the desert locust in its winter breeding area in Mauritania.

Study Site. The investigations lasted two successive years (October–December 1987 and August–December 1988) in Aftout Faïe, 250 km from Nouakchott (18°50N, 13°55W) (Ghaout, 1990). The El Gourarya site is a wadi, 3 km long, which is flooded during the rainy season. The bottom part of the valley is obstructed by live sand dunes, where water accumulates. Humidity persists for many months. Wells 0.5–3 m deep contained water for three months during the 1987 winter. The soil is an alluvial clay with gravel on the surface.

This wadi was a pasture of annual forbs of about 100 hectares in 1987 and was reduced to 3 hectares in 1988. The extent of the pasture depends on seasonal rains, but vegetation is always scanty with a sparse ground cover. *Schouwia purpurea*, *Tribulus terrester*, *Boerhavia repens*, and *Colocynthis vulgaris* form a plant community typical of desert locust habitat (Table 1) (Ozenda, 1983; Popov et al., 1984).

Schouwia purpurea–Desert Locust Association. In West Africa, *Schistocerca gregaria* populations move north from the Sahelian zone to the Sahara at the same time Inter-Tropical Convergence Zone (ITCZ) is retreating south. Breeding in *Schouwia* and *Tribulus* biotopes occurs in September, and the larvae develop in these habitats during the winter season. They are known to be selectively chosen by locusts to breed and are monitored by locust-control organizations (Popov et al., 1984).

S. purpurea is the only annual in the Sahara that remains green for more than four months and even up to seven months during a rainy winter. *S. purpurea* requires large quantities of water and needs a clay soil. This explains the

very limited areas where *S. purpurea* can grow (Hemming and Symmons, 1969). It is worth noting that the eggs of the desert locust, which are also very demanding of water, develop well in such a soil.

T. terrester grows more quickly than *S. purpurea* and requires sandy soil. It flowers one month after rain and provides food and shelter to young larvae early in the breeding season. This annual plant does not last long, however.

These two plants are often associated, each colonizing a different part of the soil. Typically, *T. terrester* is found on live sand at the surface of the clay, and *S. purpurea* has its roots growing in cracks. We studied a site where *S. purpurea* was dominant, but *T. terrester* was dominant in other places in the Aftout Faïe area.

METHODS AND MATERIALS

Field Work

Feeding preferences of solitary hoppers and adults were determined from the leaf epidermis remaining in the feces. In November and December, once a week about 10 hoppers and adults were caught at the study site, between 11 AM and noon. Each individual was kept without food in a clear plastic box until the next morning to collect feces, and returned to the study site. Fecal pellets were dried and stored in a bag until they could be brought back to the laboratory for examination. The method used gave the locusts enough time to complete their meal after an overnight rest; therefore the probability of obtaining individuals with a full alimentary tract was higher. The feces collected were what the insects had eaten in the morning. Determining diet from epidermis remaining in feces is not destructive, and a small number of solitary locusts could be followed in the same place from hatching to adulthood. The feces of 52 hoppers and 74 adults were individually examined between October and December 1987.

The remaining fragments found in the whole feces (10–20 pellets) of each individual were hydrated for 24 hr in water with a few drops of a detergent (Teepol). The plant material was shredded and the epidermis separated and treated for 30 sec in hypochlorite (15%). The epidermis was rinsed and dehydrated in ethanol. Seven mounted slides were made for each individual and examined with a microscope. A collection of epidermis was prepared for identification purposes by giving locusts known plants to feed on. Rejected plants and tree leaves were prepared from collection samples. In this particular case, the epidermis had to be loosened in boiling water. *Colocynthis vulgaris* is one of the plants that the desert locust refused to eat.

Diet determination and feeding preferences were studied where the hoppers hatched: that is, in a limited part of the site (1 hectare) narrowed by sand dunes. On November 1, the plant cover was estimated in this part of the study site

from a strip transect 1 m wide and 100 m long. Rare plants were sought for throughout the site (Table 1). Since plants were sparse and covered less than 10% of the ground, the length and width of each plant had to be measured to calculate the approximate area. Availability percentage give some indication of the probability for a locust to be in contact with a particular plant species. During November, the diet of the 24 hoppers and 36 adults caught was compared to the availability of various plant species.

The nutritive value of food plants was determined from rearings conducted in the field, under a tent roof protecting the insects from direct insolation. The air temperature and humidity conditions were measured in the shade. The mean temperature varied from 33.6°C in October to 25°C in December. First-instar hoppers caught at the study site had the typical green color of the solitary phase. Contacts were prevented by rearing the hoppers in individual transparent plastic boxes 21 × 15 × 8 cm. Experiments were limited to five males and five females, due to the scarcity of solitary hoppers at the study site. They received a monospecific diet of *S. purpurea* or *T. terrester* leaves renewed every day. All rearing began on the same day in order to compare development. The length of the hopper period was calculated from the day of second instar molt to imaginal molt. Food consumption and growth were calculated, starting on the day following the molt, for seven days during the fifth instar and 10 days during adulthood. Food consumption and ECI Waldbauer's indices were used in order to compare the nutritional value of *S. purpurea* and *T. terrester*.

$$\text{Efficiency of conversion of ingested food (ECI)} = \frac{\text{weight gained}}{\text{weight ingested}} \times 100$$

In these field experiments, the dry weights were obtained by an infrared thermocontrol balance which desiccated the plant material at 90°C until its weight was stable.

Preparation of Plants for Chemical Analysis. S. purpurea and *T. terrester* were harvested by hand on October 10, 1988. Senescent *S. purpurea* leaves were harvested specifically in early December to establish a comparison with the green leaves collected in October. Plant material was air dried in a shady place, at a maximum air temperature of 43°C, and stored in plastic bags. Brought back to the laboratory in January 1989, they were freeze-dried, milled, and stored in plastic bags at −40°C until analyzed. Feces collected from experimental locusts fed with one food plant were dried, milled, and stored in the same way.

Laboratory Work

Extraction and Chemical Analysis of Nutrients. Kjeldahl nitrogen determination was used for the nitrogen content of leaves and feces (six replicates each). It was measured on a photocolorimeter with a Nessler reagent according

to Strauch's protocol (1965). Cellulose was extracted from plant material (two replicates) with NaOH, HCl, sodium hypochlorite, and hydrogen peroxide as an oxidizing agent according to Jenkins (1930). In the feces, uric acid and allantoic acid were determined apart (four replicates) in order to quantify excreted nitrogen (Mainguet and Le Berre, 1973). The assimilated part of nitrogen was measured as the difference between nitrogen ingested and nitrogen rejected minus nitrogen excreted. The enzymatic breakdown of uric acid by uricase was determined on a photocolorimeter and that of allantoic acid according to the Schryver-Fosse phenylhydrazine method (Fosse and Brunel, 1929; Razet, 1961).

Extraction and Analysis of Mustard Oil Glucosides. Glucosinolates tested for their antifeedant properties were isolated from 100 g of dried green *S. purpurea* leaves, following Nayar and Thorsteinson's (1963) method. Mustard oil glucosides were extracted with 70% ethanol in a Soxhlet apparatus for 24 hr. The brownish syrupy concentrate was chromatographed on a neutral alumina column, then on a cellulose column to purify the extract.

Glucosinolate analyses were performed on the leaves and seeds of *S. purpurea* and also on feces. Paper filter disks prepared for multiple choice tests, with the purified extract, were analyzed in order to determine the quantity of glucosinolates deposited. All these analyses were performed at the INRA laboratory of Le Rheu. Individual glucosinolates were separated and quantified by gas chromatography. Sinigrin (allyl glucosinolate) was used as an internal standard. Derivatization with silylating reagents [N-methyl-N-trimethylsilylheptafluorobutyramide (MSHFBA) and trimethylchlorosilane (TMCS)] was carried out according to Thies (1976, 1977, 1979) and Heaney and Fenwick (1980). The volatilized glycosides were separated using a capillary column (25 m × 0.32 mm ID), packed with 1% OV-1 on 100% methyl. The oven temperature was increased by 10°C/min from 185°C to 280°C. The injection port temperature was 280°C and the detector temperature was 290°C. Hydrogen was used as a carrier gas.

Behavioral Tests. Some mustard oil glucoside extracts from *S. purpurea* leaves were tested in the laboratory for their antifeedant effects on 3-day-old fifth-instar nymphs. Paper filter disks impregnated or not with glucosinolates were given in a multiple choice test, to six females starved for 3–5 hr. The test was run in a clear plastic box (11 liters) kept at 33°C, heated and lighted by electric bulbs. Disks (5.5 cm diameter) impregnated or not with the extract were presented pinned on a cork. The test ended when half a disk had been eaten. The remaining area of each disk was measured with an electronic area measurer and the amount eaten calculated. Three concentrations of mustard oil glucosides were tested and replicated three times each.

Biting behavior on fresh *S. purpurea* leaves was recorded in the laboratory with a Hitachi video camera fixed on a stereomicroscope. Three-day-old, fifth-

instar nymphs, ready to feed if given suitable food (a fresh cabbage leaf), were tested and their biting recorded for 1 min, then *S. purpurea* was given and biting recorded for 1 min. Finally a cabbage leaf was given again to confirm readiness. The biting sequences of 16 individuals were analyzed on a videotape recorder.

Statistics

The effect of the food plant treatment on the locusts' growth was determined by the statistical analysis ANOVA for three-factor designs and complete blocks. We used the statistical computer package SX STATISTIX.

RESULTS

Feeding Preferences of the Solitary Phase. Gut content analysis, from the feces collected, showed that the hoppers had rarely eaten more than one plant (12.5%), but 31.1% of the adults had eaten two plants and 8.1% had eaten three. The adults' diet is more diversified (8 plants eaten to 10 recorded) than that of hoppers (4/10) but it decreased in diversity from October to December (Table 2).

The frequency of plant species found in the feces was compared to their frequency on the strip transect. Since plant cover was determined on November 1, the comparison was limited to locusts caught during November. The hoppers' diet was not different from what was available on the strip transect. *S. purpurea* and *Boerhavia repens* (dominant) were found in feces in the same proportions (Figure 1).

On examination of adult feces, *T. terrester* was found more frequently than expected. This plant was recorded twice on the strip transect (Table 1) and 12 times in feces. Chi-square test comparing *T. terrester* frequencies on a 2×2 contingency table is highly significant $\chi_1^2 = 28.4$. *Colocynthis vulgaris*, although a little more abundant than *T. terrester*, was never present in feces (Table 1, Figure 1). In fact *C. vulgaris* was definitely rejected by desert locusts when given to feed in rearings.

Nutritional Value. The water content (88% fresh weight), and nitrogen were higher in *S. purpurea* than in *T. terrester*, but the cellulose content was lower (15% dry weight) (Table 3). Senescent, fallen leaves were conserved to be eaten by locusts. They contained less secondary substances than green leaves but also less nitrogen (Tables 3 and 4).

At the end of larval development the hoppers, reared since their second instar on fresh *S. purpurea* leaves, were about three days late compared to those reared on *T. terrester*. The mean length of each instar, male and female, was regularly a little bit longer on *S. purpurea* than on *T. terrester;* the Wilcoxon

				F	0.03	50.21	17.01	14.73
				P	0.86	0.006	0.05	0.002

[a]Mean weights (mg/day). F( ) = number of females, M( ) = number of males. FWE = mean fresh weight eaten. DWE = mean dry weight eaten. DWG = mean dry weight gain. ECI = efficiency of conversion of food ingested. ANOVA for plant, age, sex, and complete blocks.

the dry matter eaten on *S. purpurea* was about half that eaten on a *T. terrester* diet. This difference is highly significant ($F = 50.21$, $P < 0.01$). Daily weight increase was different for the two diets; hoppers and adults grew more on *T. terrester* than on *S. purpurea* ($F = 17.01$, $P = 0.05$), but the dry weight gain/dry weight consumed ratio (ECI) was better on *S. purpurea* ($F = 14.73$, $P < 0.01$). The effect of age was highly significant in ECI analysis ($F = 37.78$, $P < 0.01$). This supports earlier results (Hoekstra and Beenakkers, 1976).

These results indicate that *S. purpurea* food was digestible due to a low cellulose content, but it is difficult to discuss food assimilation; AD and ECD indices are more subject to unacceptable errors than ECI (Schmidt and Reese, 1986). There was no difference concerning the fresh weight of *S. purpurea* or *T. terrester* consumed ($F = 0.03$, $P > 0.80$, Table 6). This result, which is different from that of dry weight consumption, can be explained by the high water content of *S. purpurea* leaves.

Secondary Substances in S. purpurea. Gas chromatography indicated that six glucosinolates were present in *S. purpurea* leaves (Table 4). Four components were identified: gluconapin, glucobrassicanapin, progoitrin, and 4-OH-glucobrassicin. Two peaks (A and B) had nearly the same gas chromatographic retention times as indole glucosinolates. Analysis, without the internal standard, confirmed that sinigrin was present as traces in leaves. Senescent leaves have less glucosinolates, especially gluconapine, than green leaves. Seasonal variation of the glucosinolate contents in the different crucifer parts have been described by Feeny and Rosenberry (1982); there was always a marked decrease with age, sometimes associated with flowering (Rodman and Louda, 1984). The total glucosinolate content in green leaves (132 μmol/g dry matter) (Table 4) was very high compared to cultivated crucifers. In *Brassica napus*, a food well accepted by *S. gregaria* in laboratory experiments, it varied from 18 μmol/g dry matter in the leaf to 40 μmol/g dry matter in the stem (Bradshaw et al., 1984). In *S. purpurea* seeds, glucosinolates were not very important (90 μmol/g dry matter) compared to what was found in *B. napus* seeds, the highest content being 160–180 μmol/g for the Jet Neuf cultivar and the least about 10 μmol/g in the selected cultivar (Tapis d'or cv.). The presence of only trace amounts of glucosinolates in the feces could indicate that they were being either absorbed or extensively degraded. Derivatives such as isothiocyanates were not investigated.

Behavioral Tests. Locusts feeding on a plant cut off pieces of the leaf blade and chewed them with regular biting movements. On accepted food, this rhythm sometimes lasted for over 1 min without interruption. If there were any unacceptable portions, the mandibular movements stopped and another biting site was tried. A shortening of the biting sequences showed that an antifeedant had been detected. Tests on fifth-instar nymphs, ready to feed on a cabbage leaf

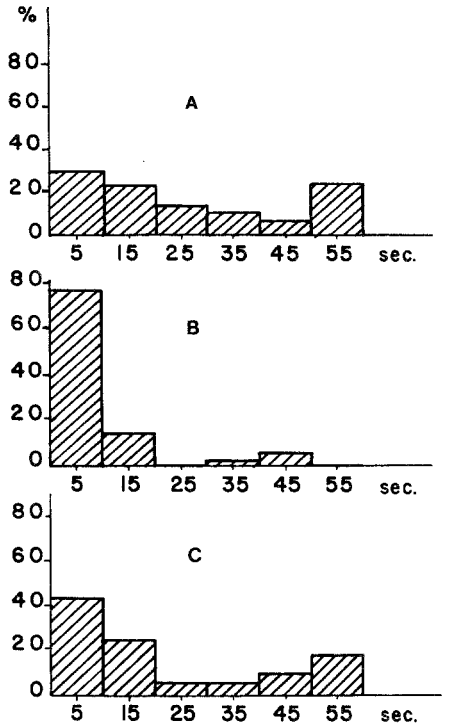

FIG. 2. Histogram of the mean durations of continuous biting on a 1-min feeding video record. Fifth-instar nymphs were successively given (A) cabbage leaf; (B) *Schouwia purpurea* leaf; (C) cabbage leaf.

showed that the biting sequences had various lengths; 50% were over 20 sec (Figure 2). If the same individual was given a *S. purpurea* leaf immediately after, biting sequences were then shortened, 80% being 10 sec or less.

In order to test if the glucosinolates contained in the leaves should be considered as antifeedants, a multiple-choice test on paper filter disks impregnated with a glucosinolate extract was compared to sucrose and paper controls (Table 7). The extract was obtained from *S. purpurea* green leaves collected in the field. The concentration of glucosinolates had an effect on the percentage of disks eaten. ANOVA analysis was significant on paper disks impregnated with the extract and on paper disks impregnated with the extract plus sucrose. At a low concentration (2 μmol/g dry matter), glucosinolates were phagostimulants, but at a higher level (214 μmol/g dry matter) they were dissuadants and consumption shifted to the control disks. This concentration was only twice that found in *S. purpurea* leaves.

TABLE 7. MEAN PERCENTAGES OF PAPER FILTER DISKS EATEN IN MULTIPLE-CHOICE TEST[a]

Disks impregnated	Doses			F	P
	A	B	C		
Extract alone	31.9	10.8	5.8	7.90	0.021
Extract + sucrose 10%	30.6	61.9	7.7	11.52	0.009
Sucrose 10%	23.7	18.0	66.3	6.38	0.033
Paper filter alone	13.9	9.2	20.2	0.81	0.49

[a]Three replicates for each concentration of glucosinolates. B = initial extract, 21.4 μmol glucosinolates/g paper filter. A = initial extract diluted ten times. C = initial extract concentrated ten times. One-way ANOVA analysis on arcsin transformation of percentages.

DISCUSSION

Desert locusts have no true preference for *Schouwia purpurea*. Since solitary hoppers are less active than adults, they usually feed mainly on plants used for shelter. Field observations indicate that young hoppers were effectively standing on *S. purpurea* leaves. Solitary hoppers are less active than gregarious ones, especially in dense cover (Uvarov, 1977). They rest for long periods on vegetation, basking or sheltering, and are more likely to feed where they stay. In the diet observed, *S. purpurea* represents no more than 70% of the plants eaten, and adults complete their diet with various dicotyledons. Adults fly easily, and it is impossible to determine that they have eaten their meal where they were captured; this is shown by the rare plants eaten and not recorded on the transect. *T. terrester* was rare all over the study site, and this plant was consumed more than it should be. There is certainly a preference for it.

For locusts reared on one plant with no choice, *S. purpurea* is not the best food, compared to *T. terrester*. Positive nutritional factors, such as a high nitrogen content and not too much cellulose are counterbalanced by factors that reduce consumption such as a high water content. Too much water is known to be unfavorable to the desert locust (Lewis and Bernays, 1985), and the amount of water ingested with fresh *S. purpurea* leaves probably limits the volume of food intake in the foregut by proprioceptive feedback control.

In the field, during the 1988 campaign, gregarious adults were observed eating dried *S. purpurea* leaves, although green ones were plentiful. This could be a way of regulating water intake and enhancing growth. Laboratory observations on the feeding behavior of the desert locust (Lewis and Bernays, 1985) indicate a preference for food with various water contents. Growth is better if the locust can regulate the proportion of water and dry matter intake.

A preference for food with a low concentration of glucosinolates, especially gluconapine and progoitrine, that decrease in senescent leaves could be the reason why adults were seen eating dead fallen *S. purpurea* leaves. *Melanoplus sanguinipes* reduces feeding when glucosinolate extracts, which contain progoitrine and gluconapine, are added to its diet (Pawlowski et al., 1968). Our tests showed that glucosinolates were phagostimulant at low concentrations but deterrent at high ones, even given with sucrose in multiple-choice tests. In our laboratory experiments, the desert locust had short biting sequences on green *S. purpurea* leaves. The enzymatic hydrolysis of glucosinolates when leaves are crushed yields glucose, sulfate, and mustard oils, which are volatile allyl and butenyl isothiocyanates, responsible for the strong-smelling odors; this could induce a chemical barrier when present in high concentrations, as in *S. purpurea*.

The four glucosinolates found are known to be toxic constituents for vertebrates since they are degraded by myrosinase. They do not seem to be toxic for locusts since they can be fed throughout their development.

A commercially available cabbage glucoside, sinigrin, is a phagostimulant for the desert locust (Le Berre and Tira, 1977) but sinigrin has been found to be nearly absent in *Schouwia purpurea*, the native crucifer, and therefore probably does not play a significant part in the insect–plant relationship.

Our results indicate that *S. gregaria* is relatively well adapted to its host plant but that *S. purpurea* is mainly interesting for its water content and the shelter it provides when the locust is able to diversify its diet with various other food plants. Under desert conditions, the persistence of vegetation is important to maintain the locust for several months in its habitat long enough to allow reproduction. Popov et al. (1984), describing *S. gregaria* biotopes in Tamesna, indicated that the mixed vegetation *S. purpurea–T. terrester* is more likely to provide food and shelter, in the long run, than a monospecific vegetation. The complementarity of these two plants is also suggested in our results and should be more specifically investigated.

(Received January 9, 1991; accepted March 25, 1991)

Abstract—Ipsenol was identified from the frass of male, but not female, *Ips latidens* from British Columbia, feeding in phloem tissue of lodgepole pine, *Pinus contorta* var. *latifolia*. The responses of *I. latidens* to sources of ipsenol and *cis*-verbenol were determined with multiple-funnel traps in stands of lodgepole pine in British Columbia. Ipsenol attracted both male and female *I. latidens*, verifying that it is a pheromone for this species. Male *I. latidens* showed a slight preference for (*S*)-(−)-ipsenol. *cis*-Verbenol was not produced by beetles of either sex and, in contrast to an earlier report, both enantiomers inhibited attraction to ipsenol-baited traps. The predators, *Enoclerus sphegeus* and *Thanasimus undatulus* (Cleridae), were attracted to traps baited with *cis*-verbenol and ipsenol.

Key Words—Pheromone, ipsenol, *cis*-verbenol, chirality, *Ips latidens*, Coleoptera, Scolytidae, predator, kairomone, *Enoclerus sphegeus*, *Thanasimus undatulus*, Cleridae.

INTRODUCTION

In British Columbia, the bark beetle, *Ips latidens* (LeConte) (Coleoptera: Scolytidae), feeds and breeds in the phloem tissue of lodgepole and ponderosa pines, *Pinus contorta* var. *latifolia* Engelmann and *P. ponderosa* Douglas ex Lawson

*To whom correspondence should be addressed at: Phero Tech Inc., 7572 Progress Way, RR #5, Delta, British Columbia, Canada V4G 1E9.

0098-0331/91/0800-1517$06.50/0

and Lawson, respectively (Bright, 1976; Furniss and Carolin, 1980; Wood, 1982). Like many other bark beetles, *I. latidens* has the potential to be a significant pest in stands of lodgepole pine, particularly in association with the mountain pine beetle, *Dendroctonus ponderosae* Hopkins (Scolytidae), or during periods of chronic drought (Furniss and Carolin, 1980; Miller and Borden, 1985).

Ipsenol (2-methyl-6-methylene-7-octen-4-ol) has been implicated as a pheromone for *I. latidens* in California. *Ips latidens* were caught, albeit in low numbers, on traps baited with either ipsenol or a mixture of ipsenol and *cis*-verbenol (*cis*-4,6,6-trimethylbicyclo[3.1.1]hept-3-en-2-ol) (Wood et al., 1967). In Idaho, *I. latidens* were attracted to sources of racemic ipsenol; alone and in combination with bolts of ponderosa pine (Furniss and Livingston, 1979). However, the question of whether ipsenol is a pheromone for *I. latidens* is still unresolved since the production of ipsenol by *I. latidens* has not yet been determined.

Our objective was to determine the identity of pheromone(s) used by *I. latidens* in stands of lodgepole pine in British Columbia. Various scolytid species show behavioral responses to different enantiomers of ipsenol and the related chiral alcohol, ipsdienol (2-methyl-6-methylene-2,7-octadien-4-ol) (Borden, 1982). Therefore, we tested the three following hypotheses: (1) one or both sexes of *I. latidens* would produce one or both enantiomers of ipsenol and/or one or both enantiomers of *cis*-verbenol; (2) *I. latidens* would be attracted to chiral ipsenol; and (3) *cis*-verbenol would act synergistically in increasing attraction of *I. latidens* to chiral ipsenol. Concurrent research by Seybold et al. (1991) tested similar hypotheses for *I. latidens* in California, breeding in ponderosa pine.

METHODS AND MATERIALS

In 1984, adult *I. latidens* were obtained from a 2-year-old colony that originated near the east gate of Manning Park, British Columbia. Using the gelatin-pill-capsule technique (Borden, 1967), 16 adult males and five adult females were restrained, individually, on noninfested bolts of lodgepole pine, collected near Princeton, British Columbia. Beetles were allowed to bore into the bark and feed for 24 hr. The frass of each individual was crushed in 150 μl of pentane. These extracts were analyzed by splitless capillary gas chromatography (Hewlett Packard HP 5890 using a 30-m $\times$ 0.25-mm-ID fused silica column). The identities and integrities of ipsenol and *cis*-verbenol were verified by mass spectrometry using splitless capillary gas chromatography (Hewlett Packard HP 5985B).

Racemic ipsenol (chemical purity, 98%) was obtained from Bedoukian

Research Inc. (Danbury, Connecticut). B.J. Johnston (Department of Chemistry, Simon Fraser University, Burnaby, British Columbia) supplied chiral ipsenols (optical purities, 96% (*S*)-(−) and 94% (*R*)-(+), respectively; chemical purities, 98%). (−)-β-Phellandrene was obtained from the SCM Corporation (Jacksonville, Florida).

Phero Tech Inc. (Vancouver, British Columbia) supplied polyethylene, bubble-cap devices containing the following chemicals: (1) racemic ipsenol (chemical purity, 98%) in solution with 1,3-butanediol; (2) 1,3-butanediol (chemical purity, >98%); (3) ethanol (chemical purity, 99%); and (4) chiral *cis*-verbenols (optical purities, 84% (*S*)-(−) and 94% (*R*)-(+), respectively; chemical purities, 98%).

β-Phellandrene was released from closed, polyethylene, microcentrifuge tubes (1.8 ml) (Evergreen Scientific, Los Angeles, California). The release rate was approximately 8 mg/day at 27–30°C (determined by weight loss). Ipsenol release devices consisted of either 10-cm lengths of C-flex tubing (ID = 1.6 mm; OD = 2.4 mm) (Concept Inc., Clearwater, Florida) filled with a solution of ipsenol in ethanol, or polyethylene, bubble-cap devices filled with a solution of ipsenol in 1,3-butanediol, and heat-pressure sealed. The release rates of ipsenol from these devices were approximately 0.6 and 0.2–0.3 mg/day, respectively, at 24°C (determined by collection of volatiles on Porapak-Q). 1,3-Butanediol was not released from either C-flex or bubble-cap lures. Ethanol release devices consisted of either 10-cm lengths of C-flex tubing or polyethylene bubble-caps, each filled with ethanol and heat-pressure sealed. The release rates of ethanol from these devices were approximately 10 and 6 mg/day, respectively, at 24°C (determined by weight loss). *cis*-Verbenol was released from polyethylene, bubble-cap devices at a rate of 3–6 mg/day at 27–30°C (determined by weight loss).

In all experiments, eight-unit, multiple-funnel traps (Lindgren, 1983) (Phero Tech) were set in mature stands of lodgepole pine near Princeton, British Columbia. Each trap was suspended such that the top funnel of each trap was 1.3–1.5 m above ground. No trap was within 2 m of any tree. Treatments were assigned randomly within replicates. Sexes of *I. latidens* captured in experiment 1 were determined by dissection and examination of genitalia. Sexes of *I. latidens* captured in other experiments were not determined due to insufficient numbers for most of the treatments. Sexes of other beetles caught in traps were not determined.

In experiments 1–3, replicate grids were placed at least 100 m apart, and traps were spaced 10–15 m apart within each replicate. The effect of chiral ipsenol was tested in experiment 1. Eleven replicates of six traps per replicate, were set in grids of 2 × 3, from May 23 to July 2, 1987. The treatments, using C-flex devices, were as follows: (1) blank control; (2) ethanol control; (3) racemic ipsenol (0.6 mg/day); (4) racemic ipsenol (1.2 mg/day); (5) (*S*)-(−)-

ipsenol (0.6 mg/day); and (6) (*R*)-(+)-ipsenol (0.6 mg/day). All ipsenol devices contained ethanol.

Experiment 2 tested the effects of ethanol and the interaction between ipsenol and ethanol. Seven replicates of four traps per replicate were set in grids of 2 × 2, from August 6 to 31, 1989. The treatments, using bubble-cap devices, were as follows: (1) 1,3-butanediol; (2) ethanol and 1,3-butanediol (as two separate devices); (3) racemic ipsenol; and (4) racemic ipsenol and ethanol (as two separate devices). All ipsenol devices contained 1,3-butanediol.

Experiment 3 tested for interaction between (*S*)-(−)-*cis*-verbenol and the combination of ipsenol and β-phellandrene. β-Phellandrene is used as a kairomone by *I. latidens* (Miller and Borden, 1990). Nine replicates of four traps per replicate were set in grids of 2 × 2, from May 21 to June 23, 1988. The treatments, using C-flex devices, were as follows: (1) ethanol control; (2) racemic ipsenol and β-phellandrene (as two separate devices); (3) (*S*)-(−)-*cis*-verbenol; and (4) the combination of racemic ipsenol, β-phellandrene, and (*S*)-(−)-*cis*-verbenol (as three separate devices). All ipsenol devices contained ethanol.

Experiment 4 tested for interaction between (*R*)-(+)-*cis*-verbenol and ipsenol. β-Phellandrene was not used due to lack of availability. Traps were placed 50 m apart in a single, large grid pattern measuring 200 × 400 m. Ten replicate blocks of four linearly consecutive traps per block were set along parallel trap lines, spaced 50 m apart, from June 21 to July 10, 1989. The treatments, using bubble-cap lures, were as follows: (1) 1,3-butanediol; (2) racemic ipsenol; (3) (*R*)-(+)-*cis*-verbenol; and (4) racemic ipsenol and (*R*)-(+)-*cis*-verbenol (as two separate devices). All ipsenol devices contained 1,3-butanediol.

The data were analyzed using the SAS statistical package version 5.0 (SAS Institute Inc., Cary, North Carolina). Trap catches of all species were transformed by $\ln(Y + 1)$ to remove heteroscedasticity. Sex ratio data for *I. latidens* were normalized by an arcsin transformation. Homoscedastic data were subjected to either one-, two-, or three-way analysis of variance (ANOVA). Evidence of synergy in the attraction of beetles, due to the interaction of multiple components, was determined by the interaction term in ANOVA. Two multiple contrasts were performed in experiment 1. Ryan-Einot-Gabriel-Welsch (REGW) multiple-range tests were used in experiments 2–4 when $P < 0.05$.

RESULTS AND DISCUSSION

Ipsenol is a pheromone for *Ips latidens*. It was found in the frass of 10 of 16 male *I. latidens* (estimated range, 10 ng to 1 mg), but not in the frass of any female. The chirality of ipsenol was not determined because we were unable to separate the acetyl lactate diastereomers (Slessor et al., 1985) of synthetic

racemic ipsenol by gas chromatography. *cis*-Verbenol was not found in any samples. Similar results were found by Seybold et al. (1991) for Californian *I. latidens*. The major monoterpene in the frass was β-phellandrene. β-Phellandrene is the major monoterpene in the phloem tissue of lodgepole pine (Mirov, 1961; Shrimpton, 1972, 1973) and is a kairomone for *I. latidens* (Miller and Borden, 1990).

In experiments 1 and 2, *I. latidens* were significantly attracted to ipsenol, with a slight preference for (*S*)-(−)-ipsenol (Figures 1A and 2). The results in

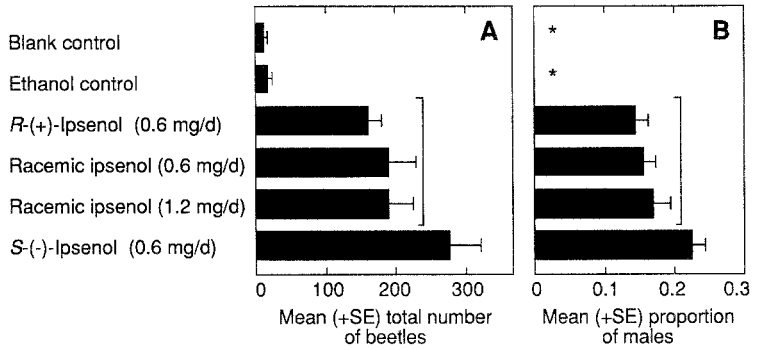

FIG. 1. The effect of chiral ipsenol on the number (A) and sex ratio (B) of *Ips latidens* responding to multiple-funnel traps near Princeton, British Columbia, in experiment 1 from May 23 to July 2, 1987 ($N = 11$). Mean numbers grouped by a line are significantly different from the blank and ethanol controls as well as (*S*)-(−)-ipsenol [multiple contrasts, $F(1,49)$, $P < 0.001$ and $P = 0.025$, respectively, on data transformed by $\ln(Y + 1)$]. Mean proportions of males grouped by a line are significantly different from (*S*)-(−)-ipsenol [multiple contrast, $F(1,30)$, $P = 0.008$, on data transformed by $\arcsin(Y)$]. Some treatments (*) had insufficient numbers for determinations of sex ratios.

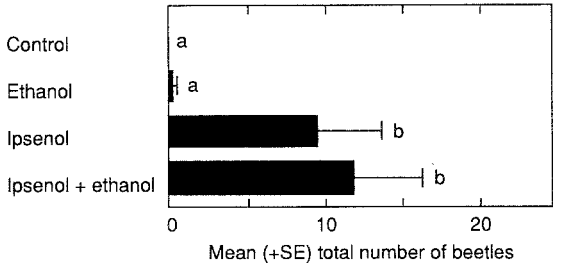

FIG. 2. The effect of ethanol and ipsenol on the attraction of *Ips latidens* to multiple-funnel traps near Princeton, British Columbia, in experiment 2 from August 6 to September 2, 1989 ($N = 7$). Means followed by the same letter are not significantly different at $P = 0.05$ [REGW multiple range test on data transformed by $\ln(Y + 1)$].

experiment 1 can be attributed solely to ipsenol, since ethanol alone was not attractive and there was no significant interaction between ethanol and ipsenol in experiment 2 [ANOVA, $F(1,24)$, $P = 0.441$ and $P = 0.989$, respectively]. The sex ratios of *I. latidens* captured in experiment 1 were affected by chirality [ANOVA, $F(3,30)$, $P = 0.048$]. Proportionally more males responded to (*S*)-(−)-ipsenol than to either racemic or (*R*)-(+)-ipsenol (Figure 1B). Our results agree with the field data of Wood et al. (1967) and Furniss and Livingston (1979) and recent laboratory data of Seybold et al. (1991).

In contrast to results from California (Wood et al., 1967), both enantiomers of *cis*-verbenol inhibited the response of *I. latidens* to sources of ipsenol (Figures 3 and 4). *cis*-Verbenol was not produced by male *I. latidens*. *cis*-Verbenol is produced by sympatric species of bark beetles such as *D. ponderosae* (Pierce et al., 1987; Libbey et al., 1985) and may act as a synomone

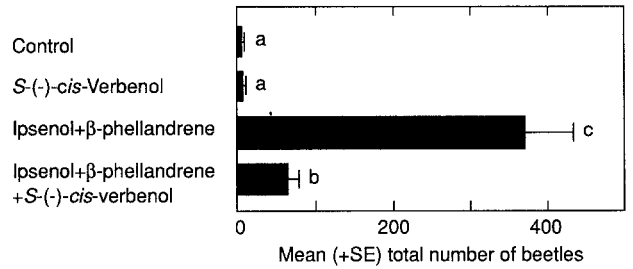

FIG. 3. The effect of (*S*)-(−)-*cis*-verbenol and the combination of ipsenol and β-phellandrene on the attraction of *Ips latidens* to multiple-funnel traps near Princeton, British Columbia, in experiment 3 from June 8 to 23, 1988 ($N = 9$). All treatments contained ethanol. Means followed by the same letter are not significantly different at $P = 0.05$ [REGW multiple range test on data transformed by $\ln(Y + 1)$].

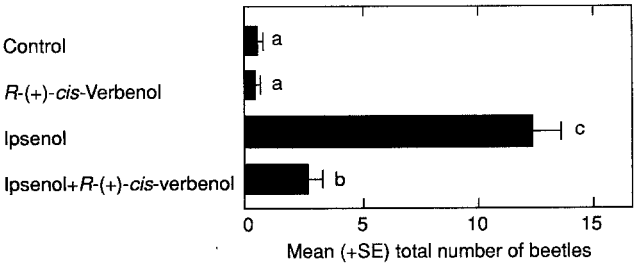

FIG. 4. The effect of (*R*)-(+)-*cis*-verbenol and ipsenol on the attraction of *Ips latidens* to multiple-funnel traps near Princeton, British Columbia, in experiment 4 from June 21 to July 10, 1989 ($N = 10$). Means followed by the same letter are not significantly different at $P = 0.05$ [REGW multiple range test on data transformed by $\ln(Y + 1)$].

(Nordlund and Lewis, 1976), facilitating resource partitioning and minimizing interspecific competition for phloem tissue. The role of synomones in cross-attraction and host partitioning has been demonstrated in bark beetle communities such as the loblolly pine, *P. taeda* L., community of southern pine beetles in the southern United States (Hedden et al., 1976; Vité et al., 1978; Dixon and Payne, 1979; Birch et al., 1980; Svihra et al., 1980; Paine et al., 1981; Watterson et al., 1982).

Sources of ipsenol and/or *cis*-verbenol and/or ethanol also were attractive to other species of bark beetles. In experiment 1, *Ips mexicanus* (Hopkins) preferred traps baited with ipsenol, regardless of chirality or release rate (Table 1). The treatment with the highest release rates of ipsenol and ethanol were preferred by *Hylurgops porosus* (LeConte) and a *Pityophthorus* Eichhoff species. Unlike the *Pityophthorus* species, *H. porosus* was attracted to ipsenol alone. *Hylastes longicollis* Swaine did not exhibit any preferences in experiment 1. However, in experiment 3, ipsenol with β-phellandrene was the preferred treatment for *H. longicollis* as well as for *I. mexicanus* and a *Pityophthorus* species (Table 2). *Hylurgops porosus* showed equal preference for the combinations of ipsenol and β-phellandrene, and ipsenol with β-phellandrene and (*S*)-(−)-*cis*-verbenol.

TABLE 1. EFFECTS OF CHIRAL IPSENOL ON ATTRACTION OF *Ips mexicanus, Hylastes longicollis, Hylurgops porosus*, AND A *Pityophthorus* sp. (SCOLYTIDAE) TO MULTIPLE-FUNNEL TRAPS NEAR PRINCETON, BRITISH COLUMBIA, IN EXPERIMENT 1, MAY 23 TO JULY 2, 1987 ($N = 11$)

Treatment	Mean (±SE) total number of beetles[a]			
	Ips mexicanus	*Hylastes longicollis*[b]	*Hylurgops porosus*	*Pityophthorus* species
Blank control	0.1 ± 0.1 a	6.3 ± 1.4	12.9 ± 4.2 a	5.7 ± 3.1 a
Ethanol	0.1 ± 0.1 a	8.7 ± 1.8	23.0 ± 5.3 bc	4.0 ± 1.9 a
Ethanol + (*R*)-(+)-ipsenol (0.6 mg/day)	2.8 ± 1.1 b	7.9 ± 1.2	25.3 ± 4.6 bc	7.4 ± 2.1 ab
Ethanol + racemic ipsenol (0.6 mg/day)	2.5 ± 0.7 b	6.3 ± 1.3	22.8 ± 5.1 bc	7.8 ± 1.8 ab
Ethanol + racemic ipsenol (1.2 mg/day)	2.4 ± 0.9 b	9.0 ± 1.7	31.7 ± 4.9 c	13.3 ± 3.7 b
Ethanol + (*S*)-(−)-ipsenol (0.6 mg/day)	2.5 ± 0.9 b	5.8 ± 1.4	19.2 ± 4.0 b	3.3 ± 0.8 a

[a] Means within a column followed by different letters are significantly different at $P = 0.05$ [REGW multiple range test on data transformed by $\ln(Y + 1)$].
[b] No significant differences among means [ANOVA, $F(5, 49)$, $P = 0.232$].

TABLE 2. EFFECTS OF (*S*)-(−)-*cis*-VERBENOL AND COMBINATION OF RACEMIC IPSENOL AND β-PHELLANDRENE ON ATTRACTION OF *Ips mexicanus, I. perturbatus, Hylastes longicolis, Hylurgops porosus,* A *Pityphthorus* SPECIES (SCOLYTIDAE), AND *Enoclerus sphegeus* (CLERIDAE), TO MULTIPLE-FUNNEL TRAPS NEAR PRINCETON, BRITISH COLUMBIA, IN EXPERIMENT 3, JUNE 8–23, 1988 ($N = 7$)

Teatment	Mean (± SE) total number of beetles[a]					
	Ips mexicanus	*Ips perturbatus*	*Hylastes longicollis*	*Hylurgops porosus*	*Pityophthorus* species	*Enoclerus sphegeus*
Ethanol	0.2 ± 0.2 a	0.8 ± 0.5 a	3.8 ± 0.6 a	9.0 ± 3.5 a	0.8 ± 0.3 a	0.7 ± 0.7 a
Ethanol + (*S*)-(−)-*cis*-verbenol	2.0 ± 0.6 b	1.4 ± 0.9 a	5.1 ± 1.8 a	8.6 ± 1.7 a	1.3 ± 0.4 a	5.3 ± 1.6 bc

Ethanol + ipsenol + β-phellandrene + (*S*)-(−)-*cis*-verbenol	3.3 ± 0.5 b	1.9 ± 3.7 b	3.9 ± 1.2 a	14.6 ± 3.9 ab	2.1 ± 1.2 a	15.0 ± 5.1 c

[a]Means within a column followed by different letter are significantly different at $P = 0.05$ [REGW multiple-range tests on data transformed by $\ln(Y + 1)$].

Explanations for significant treatment differences in these species must be viewed as speculative. Responses by bark beetles suggest that ipsenol and/or *cis*-verbenol are used as either pheromones or synomones (Tables 1 and 2). However, there are no data on the phenology of pheromone production by any of these species. The low numbers caught in traps, relative to *I. latidens*, may be a consequence of four factors: (1) low population numbers; (2) missing pheromones; (3) other semiochemical functions; or (4) random chance.

The experimental areas were selected for abundance of *I. latidens*. We have no data on the abundance of the other species. However, *I. pini* (Say) and *Pityogenes knechteli* Swaine were very abundant in both years but neither was trapped. Ipsenol inhibits the response of *I. pini* to suitable hosts and to its own pheromone, ipsdienol (Birch and Light, 1977; Birch et al., 1977; Furniss and Livingston, 1979). It seems reasonable to hypothesize that ipsenol and/or *cis*-verbenol are also inhibitory to *P. knechteli*, or have no effect.

The preferred treatment for the clerid (Coleoptera), *Enoclerus sphegeus* F., in experiment 3 was the combination of ipsenol with ethanol, β-phellandrene and (*S*)-(−)-*cis*-verbenol (Table 2). The interaction between treatments had an additive, not synergistic, effect on the attraction of *E. sphegeus* [ANOVA, $F(1,24)$, $P = 0.822$]. In experiment 4, both *E. sphegeus* and *Thanasimus undatulus* Say (Cleridae) preferred the combination of ipsenol and (*R*)-(+)-*cis*-verbenol over all other treatments (Table 3). The interaction between ipsenol and (*R*)-(+)-*cis*-verbenol had a synergistic effect on the attraction of *E. sphegeus* [ANOVA, $F(1,36)$, $P = 0.001$] but an additive effect on the attraction of *T. undatulus* [ANOVA, $F(1,36)$, $P = 0.560$].

TABLE 3. EFFECTS OF (*R*)-(+)-*cis*-VERBENOL AND RACEMIC IPSENOL ON ATTRACTION OF *Enoclerus sphegeus* AND *Thanasimus undatulus* (CLERIDAE) TO MULTIPLE-FUNNEL TRAPS NEAR PRINCETON, BRITISH COLUMBIA, IN EXPERIMENT 4, JUNE 21 TO JULY 10, 1989 ($N = 10$)

Treatment	Mean (± SE) total number of beetles[a]	
	Enoclerus sphegeus	*Thanasimus undatulus*
Blank control	0.1 ± 0.1 a	0.1 ± 0.1 a
(*R*)-(+)-*cis*-Verbenol	0.2 ± 0.1 a	2.5 ± 1.0 b
Ipsenol	1.2 ± 0.3 b	2.3 ± 0.5 b
Ipsenol + (*R*)-(+)-*cis*-verbenol	5.9 ± 0.9 c	6.0 ± 1.1 c

[a]Means within a column followed by different letters are significantly different at $P = 0.05$ [REGW multiple range tests on data transformed by $\ln(Y + 1)$].

Responses by the clerids, *E. sphegeus* and *T. undatulus*, to sources of *cis*-verbenol and the combination of ipsenol and *cis*-verbenol (Tables 2 and 3) are consistent with other studies demonstrating the use of bark beetle pheromones as kairomones by predators (Borden, 1982; Dahlsten, 1982). The lack of specificity in prey of *E. sphegeus* is exemplified by its capacity to respond to pheromones of other species such as *exo*-brevicomin produced by *Dendroctonus* and *Dryocoetes* species (Borden et al., 1987).

Acknowledgments—We thank D.L. Wood and S.J. Seybold for their encouragement, collaboration, and reviews of the manuscript. Additional comments were received from two anonymous reviewers. D.E. Bright and E. Rickey kindly verified the identifications of Scolytidae and Cleridae, respectively. Voucher specimens have been deposited with the Entomology Museum at Simon Fraser University. G. Owen provided assistance with gas chromatography and spectral analyses, and B.J. Johnston resolved both enantiomers of ipsenol. L. Wheeler, T. Richerson, and C. Matteau assisted in processing captured beetles. Assistance in the manufacture of ipsenol release devices was provided by Phero Tech Inc. This research was supported in part by an H.R. MacMillan Family Fund Fellowship and a Simon Fraser University Graduate Research Fellowship to D.R.M., the Natural Sciences and Engineering Research Council of Canada (Operating Grant A3881 and Strategic Grant G1611),and the Science Council of British Columbia [Grant 1 (RC 14-16)].

ENANTIOSPECIFIC SYNTHESIS OF (*R*)-1,7-DIOXASPIRO [5.5]UNDECANE [MAJOR COMPONENT OF OLIVE FRUIT FLY (*Dacus Oleae*) SEX PHEROMONE] FROM D-FRUCTOSE[1]

ISIDORO IZQUIERDO CUBERO,* MARIA T. PLAZA LÓPEZ-ESPINOSA, and RAFAEL ACUÑA CASTILLO

Department of Organic Chemistry, Faculty of Pharmacy, University of Granada, 18071 Granada (Spain).

(Received November 28, 1990; accepted March 26, 1991)

Abstract—The synthesis of the title compound **13** has been carried out through the preparation of its precursor, (3*R*,4*R*,5*S*,6*R*)-3,4,5-trihydroxy-1,7-dioxaspiro[5.5]undecane (**6**), obtained from D-fructose using Wittig's methodology, reduction, and spiroketalation. Compound **6** was transformed into **13** by a Barton deoxygenation at C-5 followed by a Corey dideoxygenation at C-3,4 of the appropriately protected derivatives.

Key Words—Enantiospecific, synthesis, spiroacetal, pheromone, olive fruit fly, D-Fructose, *Dacus oleae*, Diptera, Tephritidae.

INTRODUCTION

Since Baker et al. (1980) isolated and identified the major component of the sex pheromone of the olive fruit fly as 1,7-dioxaspiro [5.5]undecane (**13**), several racemic (Ley and Lygo, 1984; Brinker et al., 1985; DeShong et al., 1988) and three enantiospecific (Redlich and Francke, 1984; Mori et al., 1985; Iwata et al., 1985) syntheses of this compound have been reported. Retrosynthetic analysis of **13** (Scheme 1) indicated that it could be synthesized via a double cyclization of a δ, δ'-dihydroxyketone. Since the δ-hydroxyketone moiety is present in a hexulose, synthesis from this source would only necessitate an elongation

0098-0331/91/0800-1529$06.50/0

of the sugar chain at C-1 (Wittig methodology) with the appropriately functionalized synthon.

We report here an enantiospecific synthesis of (*R*)-1,7-dioxaspiro[5.5]undecane (**13**) using D-fructose as the chiral precursor, with the chirality of the spiranic center assured by a double anomeric effect (Deslongchamps et al., 1981; Chan et al., 1985; Aamlid et al., 1987).

METHODS AND MATERIALS

General Methods. Melting points were determined with an electrothermal melting point apparatus and are uncorrected. Solutions were dried over $MgSO_4$ before concentration under diminished pressure. [^{13}C]-(75.4 MHz) and [^{1}H]NMR spectra (300 MHz, internal Me_4Si) were recorded with a Bruker AM-300 spectrometer of solutions in $CDCl_3$. The assignment of resonances for **13** was assisted by ^{13}C–^{1}H COSY spectra (Figure 1). Infrared spectra were recorded with a Perkin-Elmer 782 spectrophotometer and mass spectra with a Hewlett-Packard HP-5988-A spectrometer. Optical rotations were measured on solutions in chloroform (1-dm tube) with a Perkin-Elmer 141 polarimeter. Gas–liquid chromatography (GLC) was performed on a Perkin-Elmer 8410 gas chromatograph equipped with a flame-ionization detector and a steel column (2 × 0.125 in. id) packed with 5% OV-17 on Chromosorb W (100–120 mesh) at 250° (A) and 115° (B). The N_2 carrier gas flow rate was 30 ml/min, the injection port temperature was 290° (A) and 200° (B), and the detector zone temperature was 290° (A) and 200° (B). Thin-layer chromatography (TLC) was performed on silica gel G (Merck) (0.25 mm) with detection by charring with sulfuric acid. Column chromatography was done with silica gel Merck (7734). Tetrahydrofuran (THF) was distilled from sodium-benzophenone ketyl and stored over 4-Å molecular sieves prior to use.

The noncrystalline compounds for which elemental analyses were not obtained were shown to be homogeneus by chromatography and characterized by NMR and mass spectrometry.

(3-Benzoxypropyl)triphenylphosphonium Bromide (1). A solution of 25.8 g (98.6 mmol) of triphenyl phosphine and 22.6 g (98.6 mmol) of 3-benzoxypropane bromide (Smith and Sprung, 1943) in 220 ml of dry toluene was heated under reflux for three days. During this time **1** (49 g , quantitative) precipitated as a white crystalline solid, which was collected by filtration, washed with ether–hexane (1 : 1), and dried; mp 158–160°; ν^{KBr} 3049, 3006 (C—H, aromatic), 2991, 2893, 2865 (C—H), 1438 (benzyl), 1184, 1115, 1101, 1064, 1017, 995, and 888 (C—O—C), 753 and 736 cm^{-1} (aromatic). [^{1}H]NMR (80 MHz): δ 8.00–7.50 (m, 15H, 3 Ph), 7.11 (s, 5H, $\underline{Ph}CH_2$), 4.45 (s, 2H, $PhC\underline{H}_2$), 4.10–3.60 (m, 4H, H-1,1′,3,3′), 2.20–1.62 (m, 2H, H-2,2′).

Analysis: Calc. for $C_{28}H_{28}BrOP$: C, 68.43; H, 5.74. Found: C, 68.28; H, 5.74.

(Z)-1-O-Benzyl-2,3,4-trideoxy-5,6:7,8-di-O-isopropylidene-β-D-arabino-non-3-ene-5-ulo-5,9-pyranose (3). To a stirred solution of potassium *tert*-butylate (0.6 g, 5 mmol) in anhydrous tetrahydrofuran (THF) (10 ml) under N_2, **1** (2.45 g, 5 mmol) was added at room temperature. The mixture was stirred for 30 min to yield an orange solution of the ylide. A solution of 2,3:4,5-di-*O*-isopropylidene-β-D-*arabino*-hexos-2-ulo-2,6-pyranose **2** (Izquierdo and Plaza, 1990) (1.29 g, 5 mmol) in dry THF (5 ml) was added dropwise. The reaction was left at room temperature for 1 hr. TLC (ether–hexane, 3:2) revealed the presence of a new compound and the absence of **2**. The mixture was poured into ice-water, extracted with ether (3 × 100 ml), and the combined extracts washed with brine. Concentration of the solvent gave a residue that was chromatographed on silica gel (ether–hexane, 1:3) to yield **3** as a syrup (2.91 g, 64%), retention time 12.01 min (A), $[\alpha]_D = -11.2°$ (*c* 1); ν^{film} 3067 and 3032 (C—H, aromatic), 2991, 2938 and 2906 (C—H), 1664 (C=C), 1455 (benzyl), 1383 and 1373 (CMe_2), 1253, 1212, 1171, 1102, 1071, 987 and 898 (C—O—C and 1,3-dioxolane ring), 738, and 698 cm^{-1} (aromatic).[^{1}H]NMR: δ 7.35–7.20 (m, 5H, $CH_2\underline{Ph}$), 5.63 (dt, 1H, $J_{2,3}$ 7, $J_{3,4}$ 11.7 Hz, H-3), 5.53 (dd, 1H, $J_{2,4}$ 1.4 Hz, H-4), 4.58 (dd, 1H, $J_{6,7}$ 2.4, $J_{7,8}$ 8 Hz, H-7), 4.50 (s, 2H, $\underline{CH_2}Ph$), 4.20 (dm, 1H, H-8), 4.18 (d, 1H, H-6), 3.84 (dd, 1H, $J_{8,9a}$ 2, $J_{9a,9e}$ 13 Hz, H-9*a*), 3.72 (d, 1H, H-9*e*), 3.58–3.46 (m, 2H, H-1,1′), 2.88–2.68 (m, 2H, H-2,2′), 1.52, 1.46, 1.33, and 1.32 (4 s, 12H, 2 CMe_2). For the [^{13}C]NMR, see Table 1. Mass spectrum: *m/z* 375 (1.9, M^+-Me), 267 (2.1), 229 [1.8, $M^+-CH=CH-(CH_2)_2OBn$], 209 (1.8), 184 (5.2), 171 (6.9), 170 (6.5), 160 (7.9), 143 (40.1), 126 (10.4), 105 (44.2), 101 (15.3), 99 (13.4), 91 (100, $C_7H_7^+$), 83 (33.7), and 43 (30.8, Ac^+).

2,3,4-Trideoxy-5,6:7,8-di-O-Isopropylidene-β-D-arabino-5-ulo-5,9-pyranose (5) and its 1-O-benzyl derivative (4). Compound **3** (8.07 g, 20.7 mmol) in methanol (100 ml) was hydrogenated at 4 atm over Raney nickel (7 g). GLC after 6 hr, revealed that **3** had disappeared and that two new compounds [retention times 11.94 and 1.47 min (A)] were present. The catalyst was removed by filtration, washed with methanol, and the filtrate concentrated to a residue that was chromatographed (ether–hexane, 1:2 to 2:1) to yield first syrup **4** (2.18 g, 27%), $[\alpha]_D = -8.6°$, $[\alpha]_{365} = -21.7°$ (*c* 1.1); ν^{film} 3091 and 3068 (C—H, aromatic), 2991, 2939 and 2871 (C—H), 1455 (benzyl) 1383 and 1373 (CMe_2), 1253, 1213, 1107, 1066 and 899 (C—O—C and 1,3-dioxolane ring), 736, and 698 cm^{-1} (aromatic). [^{1}H]NMR (80 MHz): δ 7.30 (s, 5H, $CH_2\underline{Ph}$), 4.54 (dd, 1H, $J_{6,7}$ 2.5, $J_{7,8}$ 8 Hz, H-7), 4.48 (s, 2H, $\underline{CH_2}Ph$), 4.18 (dm, 1H, H-8), 4.06 (d, 1H, H-6), 3.88 (dd, 1H, $J_{8,9a}$ 1.5, $J_{9a,9e}$ 12.5 Hz, H-9*a*), 3.65 (dd, 1H, $J_{8,9e}$ 1 Hz, H-9*e*), 3.46 (bt, 2H, H-1,1), 1.88–1.50 (m, 6H, H-2,2′,3,3′,4,4′), 1.48, 1.43, and 1.30 (3 s, 12H, relative intensity 1:1:2, 2 CMe_2). For the

[a]Assignment uncertain within each pair marked with the same letter.

[^{13}C]NMR, see Table 1. Mass spectrum: *m/z* 394 (0.3, M^++2), 393 (1.9, M^++1), 392 (7.7, M^+), 377 (5.3, M^+−Me), 334 (1.3, M^+−Me_2CO), 319 (0.4, M^+−Me−Me_2CO), 317 (0.2, M^+−Me−AcOH), 301 (1.3, M^+−C_7H_7), 262 (1.5), 259 (1.1, M^+−Me−AcOH−Me_2CO), 241 (2.4), 229 [1.4, M^+−$(CH_2)_4$OBn], 191 (2.1), 185 (4.4), 171 [3.9, M^+−$(CH_2)_4$OBn−Me_2CO], 143 (13.9), 101 (10.8), 91 (100, $C_7H_7^+$), and 43 (67.5, Ac^+).

Eluted second was syrup **5** (4.21 g, 67.4%), $[\alpha]_D = -15°$ (*c* 1.13); ν^{film} 3450 (OH), 2992, 2939 and 2877 (C−H), 1383 and 1374 (CMe_2), 1253, 1212, 1189, 1085, and 1067 cm^{-1} (C−O−C and 1,3-dioxolane ring). [^{1}H]NMR: δ 4.51 (dd, 1H, $J_{6,7}$ 2.5, $J_{7,8}$ 8 Hz, H-7), 4.16 (dd, 1H, H-8), 4.04 (d, 1H, H-6), 3.80 (dd, 1H, $J_{9a,9e}$ 13, $J_{8,9a}$ 1.9 Hz, H-9*a*), 3.66 (d, 1H, H-9*e*), 3.58 (bt, 2H, H-1,1), 1.92 (bs, 1H, OH-1), 1.89–1.49 (m, 6H, H-2,2′,3,3′,4,4′), 1.46, 1.43, and 1.29 (3 s, 12H, relative intensity 1:1:2, 2 CMe_2). For the [^{13}C]NMR, see Table 1. Mass spectrum: *m/z* 302 (0.3, M^+), 287 (74.8, M^+−Me), 244 (2.1, M^+−Me_2CO), 229 [12.9, M^+−Me−Me_2CO or M^+−$(CH_2)_4$OH], 227 (16.6, M^+−Me−AcOH), 211 (21.3), 184 (17.9), 171 [15.7, M^+−Me-$(CH_2)_4$OH −Me_2CO], 169 (35.4, M^+−Me −AcOH−Me_2CO), 157 (24.0), 151 (53.0), 143 (46.5), 126 (23.2), 101 (100, $C_5H_9O_2^+$), 86 (22.6), and 43 (60.3, Ac^+).

When **3** (12.4 g, 31.8 mmol) was hydrogenated over Raney nickel (13 g) in methanol (150 ml) at 1.5 atm for 48 hr, only **5** (8.86 g, 92.3%) was obtained.

(3R,4R,5S,6R)-3,4,5-Trihydroxy-1,7-dioxaspiro[5.5]undecane (6). A solution of **5** (8.86 g, 29.3 mmol) in 70% aqueous trifluoroacetic acid (45 ml) was kept at room temperature for 20 hr. TLC (chloroform–methanol, 5:1) revealed the absence of **5** and the presence of a new compound of lower mobility. Concentration of the mixture and repeated codistillation with water and then with dichloromethane gave a residue that was purified by column chromatography (chloroform–methanol, 15:1) to yield **6** (6.47 g, quantitative), as a colorless syrup, $[\alpha]_D = -116.5°$ (*c* 1); ν^{film} 3416 (OH), 2948 and 2876 (C−H), 1265, 1223, 1122, 1072, 989, and 919 cm^{-1} (C−O−C). [^{1}H]NMR (80 MHz): δ 4.40–3.40 (bm, 10H) and 2.10–1.30 (bm, 6H). For the [^{13}C]NMR, see Table 2. Mass spectrum: *m/z* 205 (0.1, M^++1), 204 (0.4, M^+), 178 (0.9), 143 (0.5), 132 (1.2), 114 (9.4), 101 (100, $C_5H_9O_2^+$), 83 (23.2), 60 (27.9), 55 (25.1), and 43 (12.7, Ac^+).

(3R,4R,5S,6R)-5-Hydroxy-3,4-isopropyldioxy-1,7-dioxaspiro[5.5]undecane (7). To a stirred solution of **6** (2.9 g, 14.2 mmol) in dry acetone (25 ml) was added anhydrous copper sulfate (5 g) and *p*-toluene-sulfonic acid (0.5 g). The reaction mixture was kept at room temperature for 24 hr. TLC (ether) revealed the presence of a new compound of higher mobility. The reaction mixture was neutralized (K_2CO_3), filtered, and concentrated. Column chromatography (ether–hexane, 1:2 to 2:1) of the residue, yielded crystalline **7** (2.95 g, 85.3%), mp 136–138° (from hexane), $[\alpha]_D = -173°$ (*c* 1);

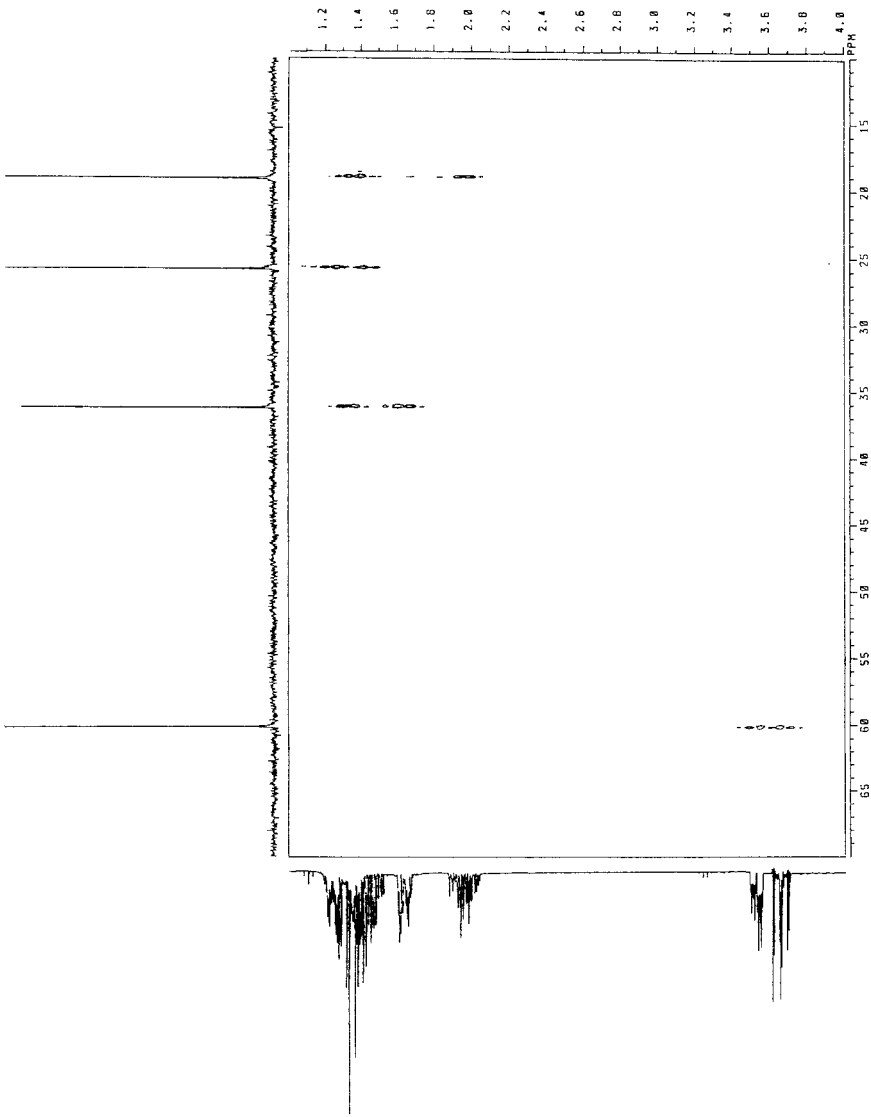

FIG. 1. Two-dimensional $^{13}C-^{1}H$ heteronuclear shift-correlation spectrum of **13**, at a ^{1}H frequency of 300 MHz. To clarify the spectrum, [^{1}H]- and [^{13}C]NMR spectra have been included along the axes of the two-dimensional spectrum.

ν^{KBr} 3476 (OH), 2970, 2947 and 2904 (C—H), 1383 and 1374 (CMe_2), 1249, 1226, 1216, 1174, 1113, 1071, and 991 cm^{-1} (C—O—C and 1,3-dioxolane ring). [^{1}H]NMR: δ 4.17 (dd, 1H, H-3), 4.07 (dd, 1H, $J_{3,4}$ 5.7, $J_{4,5}$ 7.3 Hz, H-4), 3.96 (d, 1H, $J_{2a,2e}$ 13.4 Hz, H-2*a*), 3.81 (dd, 1H, $J_{2e,3}$ 2.7 Hz, H-2*e*), 3.67 (m, 1H, H-8*e*), 3.56 (dt, 1H, $J_{8a,8e} = J_{8a,9a} = 11$, $J_{8a,9e}$ 3.3 Hz, H-8*a*), 3.34 (bt, 1H, H-5), 2.32 (d, 1H, $J_{HO,5}$ 8.1 Hz, HO-5), 1.92 (dt, 1H, $J_{10a,11a} = J_{11a,11e} = 13$, $J_{10e,11a}$ 4.6 Hz, H-11*a*), 1.79 (tq, 1H, $J_{10a,10e} = J_{9a,10a} = 13$, $J_{9e,10a} = J_{10a,11e} = 4$ Hz, H-10*a*), 1.64 – 1.43 (m, 4H, H-9*a*,9*e*,10*e*,11*e*), 1.49, and 1.33 (2 s, 6H, CMe_2). For the [^{13}C]NMR, see Table 2. Mass spectrum: *m/z* 244 (0.8, M^+), 229 (3.4, M^+-Me), 169 (0.4, $M^+-Me-AcOH$), 159 (2.1), 157 (2.1), 130 (2.6), 114 (10.0), 101 (100, $C_5H_8O_2^+$), 85 (58.0, $C_5H_8O_2^+-Me$), 83 (29.9), 59 (25.5, Me_2COH^+), and 43 (41.8, Ac^+).

Analysis: Calc. For $C_{12}H_{20}O_5$: 58.99; H, 8.25. Found: C, 58.56; H, 8.37.

(3R,4R,5S,6R)-3,4-Isopropyldioxy-5-[(thiomethyl)thiocarbonyloxy]-1,7-dioxaspiro[5.5]undecane (8). A solution of **7** (5.06 g, 21 mmol) in anhydrous THF (60 ml) was added to a stirred solution of sodium hydride (2.3 g, 96 mmol) (80% oil dispersion) in the same solvent (40 ml) and imidazole (100 mg) under N_2 at room temperature. The mixture was refluxed for 30 min, cooled, and carbon disulfide (2.9 ml, 47.4 mmol) was added dropwise. The reaction was refluxed again for 30 min, cooled, and methyl iodide (2.4 ml, 38 mmol) was added slowly, and the mixture was heated under reflux for 1 hr. TLC (ether–hexane, 3:2) revealed the absence of **7** and the presence of a new more mobile product. The excess hydride was destroyed by cautious addition of ether saturated with water (50 ml) and water (15 ml). The organic phase was separated and the aqueous phase extracted with ether (2 × 15 ml). The combined extracts were washed with brine and water, concentrated, and the residue chromatographed (ether–hexane, 1:2) to yield crystalline **8** (6.8 g, quantitative), mp 143–146° (from hexane), $[\alpha]_D = -154°$ (*c* 1); ν^{KBr} 2984, 2964, 2950 and 2875 (C—H), 1384 and 1375 (CMe_2), 1264, 1241, 1223, 1206 (C=S), 1172, 1117, 1084, 1069, 1030 and 985 cm^{-1} (C—O—C, C—S, and 1,3-dioxolane ring). [^{1}H]NMR: δ 5.83 (d, 1H, $J_{4,5}$ 8 Hz, H-5), 4.42 (dd, 1H, $J_{3,4}$ 5.4 Hz, H-4), 4.28 (dd, 1H, H-3), 4.05 (d, 1H, $J_{2a,2e}$ 13.4 Hz, H-2*a*), 3.88 (dd, 1H, $J_{2e,3}$ 2.8 Hz, H-2*e*), 3.75–3.65 (dm, 1H, H-8*e*), 3.59 (dt, 1H, $J_{8a,8e} = J_{8a,9a} = 11$, $J_{8a,9e}$ 3.5 Hz, H-8*a*), 2.59 (s, 3H, S—Me), 1.83–1.70 (m, 1H), 1.63–1.42 (m, 5H), 1.55 and 1.33 (2 s, 6H, CMe_2). For the [^{13}C]NMR, see Table 2. Mass spectrum: *m/z* 319 (1.2, M^+-Me), 259 (3.9, $M^+-Me-AcOH$), 227 (18.9, $M^+-OCS-MeSH$), 196 (46.3), 168 (68.1, $M^+-OCS-MeSH-Me_2CO$), 151 (17.6), 143 (23.0), 125 (27.7), 91 (78.7, $MeSCS^+$), 85 (50.6, $C_4H_5O_2^+$), 54 (82.5) and 43 (100, Ac^+).

Analysis: Calc. for $C_{14}H_{22}O_5S_2$: C, 50.27; H, 6.63. Found: C, 48.67; H, 6.28.

(3R,4S,6R)-3,4-Isopropyldioxy-1,7-dioxaspiro[5.5]undecane (9). A solu-

tion of **8** (3.7 g, 10.7 mmol) and azobisisobutyronitrile (50 mg) in dry toluene (40 ml) was added dropwise to a stirred solution of refluxing tri-*n*-butyltin hydride (4 ml, 14 mmol) in the same solvent (20 ml) under N_2. Refluxing was continued overnight. TLC (ether–hexane, 1:2) revealed that **8** had disappeared and that a new compound of lower mobility was present. Concentration of the solvent, followed by column chromatography (ether–hexane, 1:4) of the residue afforded crystalline **9** (2.65 g, quantitative), mp 58–60° (from hexane), $[\alpha]_D = -151.3°$ (*c* 1); ν^{KBr} 2992, 2960, and 2945 (C—H), 1373 (CMe_2), 1275, 1246, 1220, 1156, 1080, 1067, 1034, and 989 cm^{-1} (C—O—C and 1,3-dioxolane ring). [^{1}H]NMR: δ 4.35 (dt, 1H, $J_{3,4} = J_{4,5e} = 6.1$, $J_{4,5a}$ 8.3 Hz, H-4), 4.02 (bdd, 1H, H-3), 3.91 (d, 1H, $J_{2a,2e}$ 13.2 Hz, H-2*a*), 3.77 (dd, 1H, $J_{2e,3}$ 2.6 Hz, H-2*e*), 3.59 (dt, 1H, $J_{8a,8e} = J_{8a,9a} = 11.2$, $J_{8a,9e}$ 3.4 Hz, H-8*a*), 3.51 (dm, 1H, H-8*e*), 1.84 (dd, 1H, $J_{5a,5e}$ 13.7 Hz, H-5*e*), 1.86–1.69 (m, 2H), 1.61 (dd, 1H, H-5*a*), 1.56–1.45 (m, 3H), 1.39 (dt, 1H, $J_{10a,11a} = J_{11a,11e} = 13.2$, $J_{10e,11a}$ 4.2 Hz, H-11*a*), 1.45, and 1.29 (2 s, 6H, CMe_2). For the [^{13}C]NMR, see Table 2. *(3R,4S,6R)-3,4-Dihydroxy-1,7-dioxaspiro[5.5]undecane (**10**).* A solution of **9** (2.5 g, 11 mmol) in 60% aqueous acetic acid (20 ml) was heated at 50° for 30 min. TLC (ethyl acetate) revealed the presence of a new compound of lower mobility. The reaction mixture was concentrated and the residue coevaporated repeatly with toluene in order to remove the remaining acetic acid. Column chromatography (ethyl acetate) of the residue afforded **10** (2.36 g, quantitative) as a colorless syrup, $[\alpha]_D = -94°$ (*c* 1.4); ν^{film} 3414 (OH), 2945 and 2876 (C—H), 1224, 1094, 1072, 1002, and 986 cm^{-1} (C—O—C). [^{1}H]NMR (80 MHz): δ 4.25–3.40 (m, 6H), 3.00 (bs, 2H, HO-3,4), and 2.00–1.25 (m, 8H). For the [^{13}C]NMR, see Table 2. Mass spectrum: *m/z* 188 (5, M^+), 171 (3, M^+-OH), 157 (19), 145 (27), 133 (33), 112 (23), 101 (79, $C_5H_9O_2^+$), 99 (60), 83 (35) and 43 (100, Ac^+).

*(3R,4S,6R)-3,4-Thiocarbonyldioxy-1,7-dioxaspiro[5.5]undecane (**11**).* To a stirred solution of **10** (1 g, 5.32 mmol) and 4-dimethylaminopyridine (1.6 g, 13 mmol) in dry dichloromethane (25 ml) at 0° under N_2 was added 90% thiophosgene (0.6 ml) in the same solvent (5 ml). The reaction mixture was stirred for 45 min at 0° and then 12 hr at room temperature. TLC (ethyl acetate) showed the presence of a new faster running compound. The mixture was filtered, the filtrate concentrated, and the residue chromatographed (ether–hexane, 1:1) to yield crystalline **11** (0.73 g, 63%), mp 136–139° (from hexane), $[\alpha]_D = -77.5°$ (*c* 1); ν^{KBr} 2964, 2948, and 2880 (C—H), 1364, 1354, 1344, 1272, 1211 (C=S), 1181, 1098, 1068, and 996 cm^{-1} (C—O—C). [^{1}H]NMR: δ 5.14 (dt,

1H, $J_{3,4} = J_{4,5e} = 5.9$, $J_{4,5a}$ 7 Hz, H-4), 4.82 (bdd, 1H, H-3), 4.06 (d, 1H, $J_{2a,2e}$ 14 Hz, H-2*a*), 3.84 (dd, 1H, $J_{2e,3}$ 2.4 Hz, H-2*e*), 3.62 (dt, 1H, $J_{8a,9e}$ 3.6, $J_{8a,8e} = J_{8a,9a} = 11$ Hz, H-8*a*), 3.60–3.52 (m, 1H, H-8*e*), 2.03 (dd, 1H, $J_{5a,5e}$ 14.7 Hz, H-5*e*), 1.89 (dd, 1H, H-5*a*), 1.85–1.72, and 1.62–1.40 (2 m, 6H, H-9,9′,10,10′,11,11′). For the [^{13}C]NMR, see Table 2. Mass spectrum: *m/z* 232 (4, $M^+ + 2$), 231 (9, $M^+ + 1$), 230 (70, M^+), 174 (20), 152 (15), 127 (15), 101 (63, $C_5H_9O_2^+$), 99 (56), 86 (30), 84 (51), 83 (44), and 55 (100, $C_4H_7^+$ or $C_3H_4O^+$).

Analysis: Calc. for $C_{10}H_{14}O_4S$: C, 52.15; H, 6.13. Found: C, 52.11; H, 6.20.

(R)-*1,7-Dioxaspiro[5.5]undec-3-ene (12).* A solution of **11** (0.46 g, 2 mmol) in trimethylphosphite (1.5 ml) was heated under reflux for 48 hr. TLC (ether–hexane, 2:1) revealed the presence of a new faster running compound. Aqueous 20% sodium hydroxide (5 ml) was added with stirring and the mixture kept at room temperature for 4 hr, then extracted with ether (3 × 15 ml), and the combined extracts washed with water and concentrated to give a residue that was chromatographed (ether–hexane, 1:2) to afford **12** (0.26 g, 83%), retention time 6.1 min (B), $[\alpha]_D = -51°$ (*c* 2). [^{1}H]NMR: δ 5.74 (dm, 1H, H-3), 5.66 (ddt, 1H, $J_{3,4}$ 10.4, $J_{4,5}$ 6.7, $J_{2,4} = J_{4,5'} = 1.8$ Hz, H-4), 4.16 (dddd, 1H, $J_{2,2'}$ 16, $J_{2,3}$ 5.5, $J_{2,4}$ 3.5, $J_{2,5}$ 2 Hz, H-2), 4.03 (dddd, 1H, $J_{2',3}$ 4.5, $J_{2',4}$ 3, $J_{2',5}$ 1.5 Hz, H-2′), 3.75 (dt, 1H, $J_{8a,8e} = J_{8a,9a} = 11.3$, $J_{8a,9e}$ 3.1 Hz, H-8*a*), 3.66 (dm, 1H, H-8*e*), 2.16 (ddt, 1H, $J_{5,5'}$ 17.8, $J_{2,5} = J_{3,5} =$ 2.5 Hz, H-5), 2.03 (dm, 1H, H-5′), 1.87 (tq, 1H, $J_{9a,10a} = J_{10a,10e} = J_{10a,11a} = 13.4$, $J_{9e,10a} = J_{10a,11e} = 4.2$ Hz, H-10*a*), 1.73–1.45 (m, 5H, H-9*a*,9*e*,10*e*,11*a*,11*e*). For the [^{13}C]NMR, see Table 2.

(R)-*1,7-Dioxaspiro[5.5]undecane (13).* A solution of **12** (100 mg, 0.65 mmol) in anhydrous ether (8 ml) was hydrogenated over Raney Nickel (60 mg) at 1.5 atm for five days. Monitoring the reaction by GLC indicated the transformation of the peak with retention time 6.1 min into a faster running compound (retention time 4.41 min) (B). Removal of the catalyst by filtration and concentration of the filtrate, gave a residue that was chromatographed (ether–*n*-pentane, 1:4) to afford **13** (70 mg, 70%) as a colorless volatile oil, $[\alpha]_D = -119°$ (*c* 1.5, pentane), [lit (Redlich and Francke, 1984) $[\alpha]_D = -122.8°$ (*c* 3.2, pentane); lit. RESULTS AND DISCUSSION

Reaction of the ylid from (3-benzoxypropyl)triphenylphosphonium bromide (**1**) with 2,3:4,5-di-*O*-isopropylidene-β-D-arabino-hexos-2-ulo-2,6-pyranose (**2**) (Izquierdo and Plaza, 1990) in dry tetrahydrofuran gave only (*Z*)-1-*O*-benzyl-2,3,4-trideoxy-5,6:7,8-di-*O*-isopropylidene-β-D-*arabino*-non-3-en-5-ulo-5,9-pyranose (**3**). The *Z* configuration at C-3 was assigned on the basis of the $J_{3,4}$ value (11.7 Hz). The high stereoselectivity found was attributed to the use of a non-lithium-containing base to generate the ylide.

Hydrogenation of **3** over Raney nickel for short or long periods produced the saturated benzyl derivative (**4**) or the corresponding de-*O*-benzylated compound **5**, respectively.

Treatment of **5** with 70% aqueous trifluoroacetic acid for 20 hr resulted in deacetonation and cyclization to afford (3*R*,4*R*,5*S*,6*R*) -3,4,5-trihydroxy-1,7-dioxaspiro[5.5]undecane (**6**).[2] The structure of **6** was established from its [^{13}C]NMR spectrum where the chemical shift value of the spiranic carbon (δ 99.52) was in good agreement with those previously reported.

Conventional acetonation of **6** gave the corresponding 3,4-isopropyldioxy derivative **7**, which was deoxygenated at C-5, via its 5-xanthate derivative (**8**), by reduction (Barton and McCombie, 1975) to yield **9**.

Controlled hydrolysis of **9** in acid medium gave its deacetonated compound **10**, which was dideoxygenated by Corey and Winter's (1963) method via its 3,4-thiocarbonyldioxy derivative **11**, to produce (*R*)-1,7-dioxaspiro[5.5]undec-3-ene (**12**), which was subsequently hydrogenated to yield (*R*)-1,7-dioxaspiro[5.5]undecane (**13**), whose physical and spectroscopic data were in good accordance with those found in the literature (Redlich and Francke, 1984; Mori et al., 1985; Iwata et al., 1985). We have included the assignment of the [^{1}H]- and [^{13}C]NMR data.

DEVELOPMENTAL PROFILE OF SINALBIN (*p*-HYDROXYBENZYL GLUCOSINOLATE) IN MUSTARD SEEDLINGS, *Sinapis alba* L., AND ITS RELATIONSHIP TO INSECT RESISTANCE

ROBERT P. BODNARYK

Section on Germplasm Development and Biotechnology
Agriculture Canada, Research Station
195 Dafoe Road
Winnipeg, Manitoba, Canada R3T 2M9

(Received December 18, 1990; accepted March 1, 1991)

Abstract—Sinalbin was identified as a chemical component of insect antixenosis and antibiosis resistance mechanisms in seedlings of *Sinapis alba* by DEAE-Sephadex chromatography, HPLC, treatment with sulfatase and myrosinase, various feeding tests using artificial and natural substrates, and by measuring sinalbin concentrations in cotyledons and leaves during seedling development. The effects of sinalbin on feeding were dependent upon the insect species and upon the rapidly changing profile of sinalbin concentrations in the developing seedling. The high concentrations of sinalbin found in young cotyledons (up to 20 mM) and leaves (up to 10 mM) deterred the feeding of the flea beetle, *Phyllotreta cruciferae* Goeze and larvae of the bertha armyworm, *Mamestra configurata* Walker. The protection that sinalbin confers upon the vulnerable, newly emerged seedling (and upon tiny, young leaves) appears critical for the first few days of survival of *S. alba* under feeding pressure from flea beetles in the field. The lower concentrations of sinalbin found in older cotyledons and leaves (2–3 mM) offer little or no protection against *P. cruciferae* and may actually stimulate the feeding of this crucifer specialist. These concentrations of sinalbin, however, are still effective in reducing the level of feeding by larvae of the more generalist feeder *M. configurata*.

Key Words—Sinalbin, glucosinolate, resistance, *Sinapis alba*, *Brassica napus*, *Phyllotreta cruciferae*, Coleoptera, Chrysomelidae, *Mamestra configurata*, Lepidoptera, Noctuidae.

INTRODUCTION

The mustard, *Sinapis alba* L., shows a high level of resistance in the field to damage from adults of the crucifer flea beetle, *Phyllotreta* spp. (Putnam, 1977; Lamb, 1984). Antixenosis (nonpreference) and tolerance have been identified as two mechanisms in seedlings of *S. alba* that likely account for flea beetle resistance in this species (Bodnaryk and Lamb, 1991). Although flea beetle resistance is inherently valuable in growing *S. alba*, the question of utilizing its resistant traits in other more extensively grown crucifer crops, such as the oilseed rapes *Brassica napus* L., and *B. campestris* L., has not been addressed. Recent hybridization of *S. alba* and *B. napus* via embryo rescue (Ripley and Arnison, 1990) indicates that transfer of useful traits of *S. alba* to *B. napus* may not be as formidable a task as once imagined.

Chemically based resistance must be compatible with the end use of the crop for which the resistance is intended. The chemical basis of resistance in *S. alba* to pest insects is currently unknown and the potential that this resistance may have for transfer to other crops is therefore also unknown. The purpose of this research is to identify chemical factors that contribute to resistance in *S. alba* using two insect pests, namely the flea beetle *P. cruciferae* (a crucifer specialist) and the bertha armyworm, *M. configurata*, a more generalist feeder (Beirne, 1971). The research also examines the developmental profile of an identified resistance factor in *S. alba* and its relationship to insect resistance during early seedling growth.

METHODS AND MATERIALS

Insects. Flea beetles, *Phyllotreta* sp., were collected in May from allyl isothiocyanate baited traps in the field (Burgess and Wiens, 1980) and maintained in the laboratory in screened cages 0.5 × 0.5 × 0.5 m on cabbage leaves, *B. oleracea* L. obtained from a supermarket. Water was provided through a dental wick held in a flask. Prior to tests, *P. cruciferae* were selected and transferred by aspiration to a holding cage for one day with water only. The bertha armyworm, *M. configurata*, was reared on an artificial diet at 20°C and 60–70% relative humidity under an 18-hr light:6-hr dark cycle (Bucher and Bracken, 1976).

Plants. Uniform, large seeds from registered cultivars of mustard, *S. alba* cv. Ochre, and canola, *B. napus* cv. Westar, were selected by eye for individual planting in vermiculite in 175-ml styrofoam coffee cups having a 0.5-cm-diam. hole punched in the bottom. The cups were subirrigated with Hoagland's nutrient solution and held under wide-spectrum (Gro-Lux) artificial lighting in the laboratory at 20 ± 1°C, 50–60% relative humidity, and 18-hr light:6-hr dark

cycle. Plants were kept 8–10 cm from the lights and received about 200 μE/sec/m^2 of photosynthetically active radiation as determined using a LI-COR LI-190SB quantum sensor (LI-COR Inc., Lincoln, Nebraska).

Chemicals. Sinalbin was isolated from 200 g of seeds of *S. alba* as described by Hanley et al. (1983).

Extraction and Quantitation of Sinalbin. Cotyledons and first true leaves of *S. alba* were extracted in boiling 80% methanol as described by Bodnaryk and Palaniswamy (1990). Sinalbin was estimated as its desulfo derivative by HPLC as described by Minchinton et al. (1982).

Preparation of a Glucosinolate Fraction from Cotyledons. Cotyledons (5 g wet weight) from 4-day-old *S. alba* or 5-day-old *B. napus* seedlings were held for 5 min in 80 ml of boiling 80% methanol contained in the stainless steel cup of a Sorval homogenizer. The methanol–cotyledon mixture was then homogenized for 1 min at maximum speed and the homogenate centrifuged at 12,000*g*. The pellet was rehomogenized and further extracted with 80 ml of hot 80% methanol, centrifuged as above,and the extracts combined. Methanol was removed from the combined extract on a rotary evaporator at 40°C and the concentrated aqueous extract was adjusted to contain 0.05 M barium–lead acetate in a final volume of 80 ml. The mixture was stirred for 1 hr at ambient temperature and then centrifuged at 12,000*g* for 10 min to remove precipitated material. The clear supernatant was applied to a column of DEAE–Sephadex A-25 (0.2 g dry weight) that had been treated with 0.5 M pyridine–acetate and equilibrated with water. The column was washed with 20 ml of distilled water (discarded) and then with 3 ml of 0.1 M pyridine–acetate, 10 ml of 0.5 M pyridine–acetate and 10 ml of 1.0 M pyridine–acetate. The pyridine–acetate fractions were dried thoroughly on a rotary evaporator and reconstituted in 1.0 ml of distilled water for incorporation into feeding assays and for glucosinolate analysis.

Enzymatic Treatments: Sulfatase. Cotyledons (5 g wet wt) from 4-day-old *S. alba* were extracted as above and the extract bound to the top of a DEAE–Sephadex A-25 column (0.2 g dry wt). The extract was exposed "on column" to sulfatase (EC 3.1.6.1, Sigma Chemical Co., St. Louis, Missouri) for 24 hr as described by Minchinton et al. (1982). Desulfo glucosinolates were eluted with 2 ml of water, lyophilized, and reconstituted in 1 ml of distilled water for incorporation into feeding assays and for HPLC. The column was further eluted to produce 0.1, 0.5, and 1.0 M pyridine–acetate fractions for feeding assays and HPLC as described above.

Enzymatic Treatments: Myrosinase. Cotyledons (5 g wet wt) from 4-day-old *S. alba* or 5-day-old *B. napus* seedlings were homogenized in 60 ml of distilled water and held at 20 to 22°C for 3 hr to expose glucosinolates to endogenous myrosinase (β-thioglucosidase, E.C.3.2.3.1) (Bones, 1990). After

3 hr the mixture was adjusted to contain 80% methanol, boiled for 5 min, and processed as above to produce 0.1, 0.5, and 1.0 M pyridine–acetate fractions for feeding assays and HPLC.

Feeding Assays Using a Gelatin Substrate. Plant glucosinolate fractions or sinalbin were incorporated into gelatin for analysis of feeding inhibition or stimulation. The gelatin medium was prepared by adding 5 g of gelatin (type B from bovine skin, approx. 60 bloom) slowly to 50 ml of vigorously stirred distilled water at 20–22°C. The suspension was then heated at 100°C for 10 min with occasional swirling to dissolve the gelatin and then kept at 37°C for use throughout the day. Glucosinolate fractions or sinalbin contained in 0.5 ml distilled water were added to 2.0 ml of gelatin solution in 15 × 85-mm test tubes at 37°C. The tubes were capped with Parafilm and the contents mixed by inversion. Controls received 0.5 ml distilled water. An aliquot (100 μl) of the test mixture was pipetted onto the bottom of each of 20 polystyrene Petri dishes using an Eppendorf pipetter fitted with a disposable tip whose end had been enlarged to about 2 mm internal diameter for easy pipetting. An aliquot (100 μl) of the control mixture was pipetted adjacent to the test mixture leaving a space of about 2 cm. The tops of the Petri dishes were put in place, using care not to disturb the gelatin, and metal trays containing ice were placed over the dishes for about 20 min for gelling. "Seal tight" Petri dishes (9 × 50 mm, Fisher Scientific) were most convenient to use, but disposable Petri dishes (15 × 100 mm) with loose-fitting lids were also suitable if kept at high relative humidity throughout the feeding assay.

The feeding assay was begun by adding five adult flea beetles or one bertha armyworm larva to the Petri dishes and allowed to run for 24 hr. After 24 hr, lids and insects were removed and the gelatin allowed to dry at ambient temperature for 48 hr. The amount of feeding on the control and test disks was estimated gravimetrically in the case of bertha armyworm larvae, which consumed a significant proportion of the disks. The amount of gelatin consumed by flea beetles in the feeding assays was only a tiny proportion of the total, so that weighing did not give an accurate estimate of the amount eaten. Therefore, flea beetle feeding was estimated as surface area consumed. Feeding "spots" on the thin, transparent gelatin disks were visualized as their shadows cast on the white stage of a Wild M8 dissecting microscope by oblique (45°) lighting. The area of the discrete, well-defined dark "spots" was obtained using an optical grid fitted to an eyepiece of the microscope.

Feeding Assays Using Uptake by Excised Seedlings. Sinalbin was assayed for feeding inhibition or stimulation after uptake through the cut stem of seedlings of *B. napus*. This species contains no sinalbin (Bodnaryk and Palaniswamy, 1990) and is palatable to flea beetles and bertha armyworm larvae. The stems of 40 13-day-old seedlings were cut with a pair of fine, sharp scissors under distilled water and placed in 10-ml glass vials containing either distilled

water (controls, 20 plants) or 2 mM sinalbin (20 plants). The plants were held 8 cm under wide spectrum artificial lighting for 18 hr. Ten pairs of plants held in distilled water or 2 mM sinalbin were offered to flea beetles or bertha armyworm larvae in individual screened cages measuring 30 × 30 × 30 cm. In the case of the bertha armyworm feeding tests, each pair of vials containing the seedlings was put in an aluminum pan, which was then filled with vermiculite to reach the top of the vials. The vermiculite was moistened with distilled water and provided a convenient substrate for the bertha armyworm larvae which were introduced into the feeding test by placing them on the vermiculite in the middle of the space separating the two vials. After 6–24 hr the insects were removed from the plants, and the area eaten from cotyledons and first true leaves was estimated using an optical grid. The remaining plants not used in the feeding tests were analyzed for sinalbin levels in their cotyledons and first true leaves.

Paired Feeding Tests with S. alba *and* B. napus. Styrofoam coffee cups containing vermiculite were planted with *S. alba* and *B. napus* seeds in alternating order. Two experiments were conducted. In the first, 4-day-old seedlings of *S. alba* and 5-day-old seedlings of *B. napus* (two of each per cup; six cups per test; three replicates) were offered to *P. cruciferae* (five beetles per seedling) or *M. configurata* (one larva per seedling) for 24 hr. In the second, 13-day-old seedlings of *S. alba* and 14-day-old seedlings of *B. napus* (one of each per cup; six cups per test; three replicates) were offered to *P. cruciferae* (10 beetles per seedling or *M. configurata* (two larvae per seedling) for 24 hr. For the experiments with older seedlings, cotyledons were removed with sharp scissors 1 hr before the start of the experiment to permit a paired feeding test of first true leaves only. At the end of all feeding tests, the insects were removed and the amount eaten was determined by weighing cotyledons or leaves in the case of experiments with *M. configurata* or by estimating the area consumed with an optical grid in the case of *P. cruciferae*.

Growth and Development of M. configurata *Fed* S. alba *or* B. napus. Two experiments were conducted. In the first, 10 first-instar larvae were placed in each of six cages as above containing 72 4-day-old seedlings of *S. alba* or 72 5-day-old seedlings of *B. napus*. Seedlings were replaced daily. Since growing larvae of *M. configurata* are voracious feeders, it became necessary to add larger and larger quantities of seedlings as the larvae grew, effectively limiting the number of larvae that could be reared to maturity with the available facilities.

In the second experiment, egg masses containing 80–100 eggs from a single female were divided in half. The number of chorionated (fertile) eggs in each half was counted one or two days before hatch. Each half then was placed on an 18- to 25-day-old plant of *S. alba* or *B. napus* from which cotyledons had been removed by scissors. A minimum of four replicates were obtained for each plant species.

For both experiments, records of survival and body weight were obtained

on day 10, day 21, and at pupation. Survival to eclosion and the diapause-nondiapause state of the pupae also were recorded. Nondiapausing pupae were identified by the appearance of adult structures seen through the pupal cuticle. Diapausing pupae were dissected at the end of the study to confirm that no adult development had taken place.

RESULTS

Effect of DEAE-Sephadex A-25 Fractions of Extracted Cotyledons on Feeding. Incorporation into gelatin of the thoroughly dried 0.5 M pyridine-acetate DEAE-Sephadex A-25 fraction of cotyledons of *S. alba* that had been extracted in boiling 80% methanol deterred the feeding of flea beetles, *P. cruciferae*, and the bertha armyworm, *M. configurata* (Table 1, experiment 1). The deterrent effect was strongest for *M. configurata*, where consumption of the test gelatin containing the 0.5 M pyridine-acetate fraction was less than 5% of total feeding (Table 1, experiment 1). The 0.1 and 1.0 M pyridine-acetate fractions from *S. alba* (Table 1, experiment 1) and the 0.1, 0.5,and 1.0 M fractions from *B. napus* cotyledons had relatively little or no effect on feeding (Table 1, experiment 2).

Incorporation into gelatin of the 0.5 M pyridine-acetate fraction of cotyledons of *S. alba* that were extracted in water at 20–22°C and allowed to stand for 3 hr before boiling in 80% methanol had little effect on feeding (Table 1, experiment 3).

Investigation by HPLC of the 0.5 M pyridine-acetate fraction of cotyledons of *S. alba* extracted in boiling 80% methanol revealed a high concentration of *p*-hydroxybenzyl glucosinolate (sinalbin), the predominant glucosinolate of this mustard. Other glucosinolates were not detected in this fraction. When cotyledons of *S. alba* were extracted in water at 20–22°C and allowed to stand for 3 hr before boiling in 80% methanol, the 0.5 M pyridine-acetate fraction contained only a trace (0.24%) of sinalbin, an observation consistent with the destruction of this glucosinolate by endogenous myrosinase (Bones, 1990).

Incorporation into gelatin of the water and the 0.1, 0.5, and 1.0 M pyridine-acetate fractions of cotyledons of *S. alba* that were extracted in boiling 80% methanol, then treated on-column with sulfatase had little or no effect on feeding by *P. cruciferae* or *M. configurata* (Table 1, experiment 4). Investigation of the water fraction by HPLC revealed a high concentration of desulfosinalbin (not shown), which the feeding experiments in Table 1, experiment 4, demonstrated to be without deterrent effect. Investigation of the 0.1, 0.5, and 1.0 M pyridine-acetate fractions by HPLC revealed only a trace of sinalbin in the 0.5 M fraction, attesting to the efficient action of the sulfatase (not shown).

Effect of Sinalbin on Feeding. Sinalbin, when incorporated into gelatin,

altered the feeding response of *P. cruciferae* (Figure 1). Sinalbin concentrations of 0.5 to 2 mM appeared to stimulate feeding slightly while higher concentrations deterred feeding. Sinalbin strongly deterred feeding of *M. configurata* in a dose-dependent manner (Figure 1). At 20 mM, the highest concentration tested, feeding was partially deterred in *P. cruciferae* and completely deterred in *M. configurata* (Figure 1).

Uptake of Sinalbin by Excised B. napus *Seedlings and its Effect on Feeding.* Two-week-old seedlings of *B. napus* cv. Westar took up sinalbin through their cut stems and concentrated it in the cotyledons and leaves (Table 2, A). The concentration of sinalbin in excised seedlings held in a 2 mM sinalbin

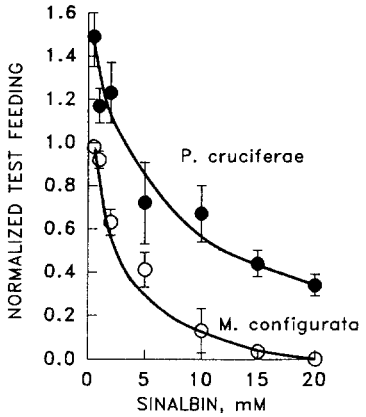

FIG. 1. Effect of sinalbin (*p*-hydroxybenzyl glucosinolate) on the feeding of flea beetles, *P. cruciferae*, and the bertha armyworm, *M. configurata*. Sinalbin was incorporated into gelatin for paired feeding tests of equal amounts of a test gelatin containing sinalbin and a control gelatin containing only water. Twenty paired tests each having five flea beetles or one armyworm were done for each concentration of sinalbin. Values for the amount eaten by the insects were normalized (control = 1). Normalized test feeding values > 1 indicate feeding stimulation by sinalbin; values < 1 indicate feeding inhibition.

solution of 18 hr was about 7 mM in cotyledons and 15 mM in leaves (Table 2, A).

P. cruciferae and *M. configurata* readily discriminated between excised seedlings of *B. napus* incubated in water or 2 mM sinalbin and fed less on the sinalbin-containing cotyledons and leaves (Table 2, A). The deterrent effect was greater in the leaves that had sinalbin concentrations approximately double those found in the cotyledons.

Paired Feeding Tests with Seedlings of B. napus *and* S. alba. There were remarkable between-plant and between-insect differences in the paired feeding tests described in Table 2, B. When the cotyledons of young seedlings were compared, both insects preferred to eat *B. napus*, by about 2 to 1 for *P. cruciferae* and by almost 7 to 1 for *M. configurata*. The concentration of sinalbin in the cotyledons of *S. alba* was about 10 mM and undetected in *B. napus* (Table 2, B, experiment 1). When the first true leaves of older plants were compared, *P. cruciferae* now preferred *S. alba* by nearly 9 to 1, a complete reversal in the feeding preference observed at the cotyledon stage. *M. configurata* continued to prefer *B. napus*, but now by only about 3 to 1. The concentration of sinalbin in the leaves of *S. alba* was 2.8 mM and undetected in *B. napus*.

Growth and Survival of M. configurata *fed* S. alba *or* B. napus. Larvae of *M. configurata* fed young seedlings of *S. alba* performed poorly compared to

cohorts fed young seedlings of *B. napus* or older plants of both species (Table 3). Survival of larvae was lower, survival to the pupal stage and to eclosion were lower, body weights were usually less, and the percentage of nondiapause pupae was abnormally low (Table 3).

M. configurata grew best on the cotyledons of *B. napus* (Table 3). Survival and body weights on older plants of *B. napus* cv. Westar (Table 3) were similar to those reported for larvae fed the detached leaves of another cultivar, *B. napus* cv. Regent (Turnock, 1985).

Developmental Profile of Sinalbin in S. alba *Seedlings.* Newly emerged seedlings of *S. alba* had high concentrations (>20 mM, Figure 2A) of sinalbin in their cotyledons. The concentration fell rapidly during the first few days of growth and tended to level off at about 2 mM. The amount of sinalbin in the cotyledons, however, remained almost unchanged during the same period (Figure 2B), indicating that the precipitous decline in the concentration of sinalbin

was due simply to "dilution" by the rapidly increasing biomass of the cotyledons.

Young leaves of *S. alba* also had a high concentration of sinalbin, which in 8-day-old seedlings exceeded 10 mM. The concentration fell to about 3 mM during the next six days of growth (Figure 2A). During the same period, the amount of sinalbin per leaf increased by more than threefold (Figure 2B), but whether this increased amount was derived from de novo synthesis or translocation was not investigated. Undoubtedly, the fall in the concentration of sinalbin in growing leaves would have been much greater if the amount of sinalbin per leaf had remained unchanged. In spite of apparently different mechanisms, the concentration of sinalbin in older cotyledons and leaves was maintained at about 2 mM, a value close to that reported earlier for 4- to 6-week-old leaves of *S. alba* (1.68 mol/g fresh weight) (Reed et al., 1989).

DISCUSSION

This research has established that the high concentrations of *p*-hydroxybenzyl glucosinolate (sinalbin) found in the cotyledons of young seedlings and

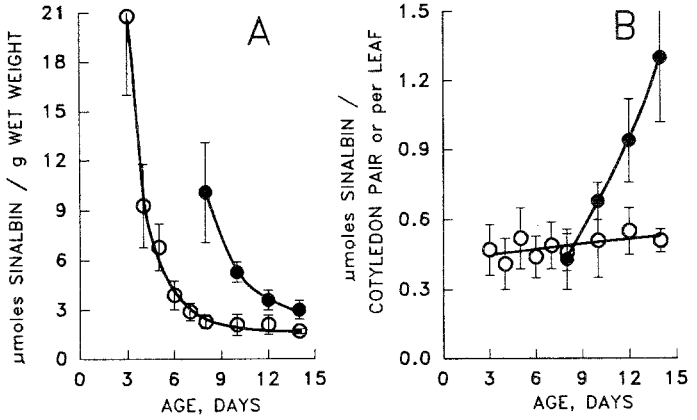

FIG. 2. Changes in the level of sinalbin in *S. alba* cv. Ochre during seedling growth. (A) changes in the concentration of sinalbin; (B) changes in the amount of sinalbin per cotyledon pair or per leaf. Open circles, cotyledons; closed circles, first true leaf. Each point represents the mean of the sinalbin level in four to eight samples that each contained 10 cotyledon pairs or 4–10 first true leaves. Vertical bars, standard deviation.

in young leaves of *S. alba* deter the feeding of flea beetles, *P. cruciferae*, and the bertha armyworm, *M. configurata*. The evidence in support of this finding was obtained from several diverse experiments. First, a glucosinolate fraction from cotyledons of *S. alba* obtained by DEAE–Sephadex A-25 chromatography deterred the feeding of *P. cruciferae* and *M. configurata* when incorporated into gelatin. A similar fraction prepared from the cotyledons of *B. napus*, which contains no sinalbin, did not deter feeding. Treatment of the glucosinolate fraction from cotyledons of *S. alba* with myrosinase and sulfatase, enzymes that are known to destroy glucosinolates, abolished the feeding deterrent activity. HPLC chromatography of the deterrent glucosinolate fraction revealed the presence of a high concentration of sinalbin and no other glucosinolates. Secondly, incorporation of known concentrations of sinalbin into gelatin altered the feeding response of both insects in a dose-dependent manner. Thirdly, uptake of sinalbin through the cut stems of seedlings of *B. napus*, a species normally palatable to *P. cruciferae* and *M. configurata*, reduced the feeding response of both insects. Finally, a study of sinalbin concentrations in developing seedlings of *S. alba* verified that the concentration of sinalbin shown to deter feeding in the artificial studies actually occurs in young cotyledons and leaves. Sinalbin, therefore, is a chemical component of the antixenosis (nonpreference) resistance mechanism described earlier for the cotyledons of *S. alba* (Bodnaryk and Lamb, 1991). The possibility that there are other as yet unidentified factors that contribute to the resistance of *S. alba* has not been ruled out by this study.

The effectiveness of sinalbin in deterring insect feeding needs careful evaluation in terms of both insect species and the rapidly changing profile of sinalbin concentration in the developing seedling. The high concentration of sinalbin found in young cotyledons (up to 20 mM) and young leaves (up to 10 mM) deterred the feeding of both *P. cruciferae* and *M. configurata*. The protection that sinalbin confers upon the vulnerable, newly emerged seedling appears to be critical for the first few days of survival under feeding pressure from flea beetles. Young seedlings of *B. napus*, which contain no sinalbin and no other feeding deterrent, are most susceptible to flea beetle feeding and are heavily damaged or killed in the field unless protected for two to three weeks by an insecticide (Lamb, 1984; Bodnaryk and Lamb, 1991). Tiny young leaves of *S. alba* may also be protected by their high concentration of sinalbin. These deterrent levels, however, are transitory, and the concentration of sinalbin in the cotyledons and leaves rapidly declines in the developing plant, largely due to simple "dilution" by the increasing tissue biomass. The lower concentrations of sinalbin found in the older *S. alba* plant (2–3 mM) offer little or no protection against *P. cruciferae* and may actually stimulate the feeding of this crucifer specialist. The less severe consequences of flea beetle feeding on the old, large leaves of a well-established plant may make the economics of maintaining a high concentration of sinalbin throughout a large tissue mass not worthwhile. The concentrations of sinalbin in the leaves of older plants are still effective in reducing the level of feeding by larvae of the more generalist feeder *M. configurata*, perhaps indicating an interesting compromise in *S. alba* between the costs of insect herbivory and the metabolic cost of protection.

In addition to its role in antixenosis, sinalbin also contributed to a second resistance mechanism identified in plants by Painter (1951), namely antibiosis. Like antixenosis, antibiosis caused by sinalbin is concentration dependent. Larvae of *M. configurata* fed young seedlings of *S. alba* in which the concentration of sinalbin in the cotyledons exceeded 20 mM had reduced levels of fitness as measured by their low survival, low body weights, and abnormal diapause compared to cohorts fed older plants of *S. alba* or *B. napus*. Although some of these effects may be due to partial starvation, it seems likely that sinalbin at low concentrations is antixenotic and at high concentrations antixenotic and antibiotic for larvae of *M. configurata*.

Glucosinolates in Brassicaceae comprise a group of some 80 thioglucosides with side chains of varying structure (reviewed in Larsen, 1981; Rodman, 1981) and having a variety of effects upon organisms that come in contact with them or their breakdown products (reviewed in Chew, 1988). There is a need for caution in interpreting the putative effects of glucosinolates on insect feeding. In some modern brassicas, glucosinolates do not determine the feeding rate of the flea beetle, *P. cruciferae* (Bodnaryk and Palaniswamy, 1990). As shown in this study, the effect of the glucosinolate sinalbin on insect feeding depends on

the stage of host plant development, the concentration of sinalbin, and the insect species being considered. The significance of glucosinolates as determinants of host-plant interaction must therefore be assessed on a case-by-case basis (Chew, 1988).

Sinalbin is a unique product of the mustard plant that has been highly selected for a specialized commercial use. Sinalbin also deters the feeding of important insect pests at critical times during the development of *S. alba*, making insect resistance in this plant the envy of crop protection entomologists. It seems clear, however, that the components of insect resistance in *S. alba* (antixenosis, antibiosis) that have sinalbin as their chemical basis would not be useful for transfer to the oilseed rapes or to other commercial crucifers because the presence of this glucosinolate usually would be incompatible with their end uses. It is possible to increase the level of insect resistance in the cotyledons and leaves of oilseed rape as shown by the experiments in which sinalbin was artificially introduced into *B. napus*. Incorporation of sinalbin into *B. napus* might be achieved by transfer of genes for sinalbin biosynthesis but would be acceptable only if the genes were not expressed to any significant degree in the seed pod. Unlike many other glucosinolates, trace amounts of sinalbin would be unlikely to pose significant human or animal toxicological problems since this product has been an accepted part of the human diet for centuries.

S. alba has other insect-resistance mechanisms apparently absent from the oilseed rapes, notably tolerance (Bodnaryk and Lamb, 1991) and wound-induced resistance (Palaniswamy and Bodnaryk, unpublished) that may not involve sinalbin. The utility of these traits for the oilseed rapes awaits laboratory and field evaluation of *S. alba* × *B. napus* hybrids (Ripley and Arnison, 1990) for insect resistance and canola quality.

Acknowledgments—I thank Lubomir Kudryk for skilled technical assistance and Drs. R.J. Lamb and P. Palaniswamy for helpful advice and discussion. This paper is dedicated to Dr. Tom Atkinson on the occasion of his retirement as Director of the Winnipeg Research Station.

(Received December 26, 1990; accepted March 1, 1991)

Abstract—The quinolizidine alkaloids (QA) of golden rain, *Laburnum anagyroides*, and those of phytophagous insects associated with the plant, as well as of parasitoids of the latter, were analyzed by capillary GLC and GLC-MS. The alkaloid content in samples of vegetative plant parts was high at the beginning of the season, then decreased, while that of reproductive organs was high throughout flowering, pod formation, and maturation. The analyses showed that the QA of the plant passed through two higher trophic levels (herbivorous insects and their parasitoids) and that the alkaloid pattern changed little during the passage. The alkaloids were present in two phytophagous insect species associated with golden rain: the predispersal seed predator, *Bruchidius villosus* [5–13 μg/g fresh weight (fw)], and *Aphis cytisorum* (182–1012 μg/g fw), an aphid that feeds on shoots, leaves, and inflorescences. Braconid and chalcidoid parasitoids emerging from the bruchid host also contained alkaloids (1.3–3 μg/g fw), as did three foraging ant species, *Lasius niger*, *Formica rufibarbis*, and *F. cunicularia* (45 μg/g fw), that visited the aphid colonies or honeydew-covered leaves of aphid-infested plants. The hypothesis that developing bruchid larvae and/or the plant "manipulate" QA supply to infested seeds was not supported, because QA content of leftover endosperm in seeds after bruchid development was similar to that of uninfested seeds. The frass of developing bruchid larvae was rich in QA (31 mg/g dry weight). While aphids sequestered, the bruchid larvae took up and eliminated QA with the frass without chemical transformation.

INTRODUCTION

Evidence is accumulating that interactions at three trophic levels can be mediated and/or influenced by chemicals originating from only one member of the food web, the plant (Price et al., 1980). For example, the development time of the parasitoid *Hyposoter exiguae* was prolonged in its host, *Heliothis zea*, and the percentage of adult survivorship decreased, if α-tomatine, the naturally occurring steroid glycoside in tomatoes, was present in the host's diet to the extent of 0.3–0.5% (Campbell and Duffey 1979, 1981). Similarly, the percentage of emerging *Apanteles congregatus* parasitoids from the host *Manduca sexta* was significantly lower in comparison with the control when they developed in a host reared on a diet containing a higher level of nicotine (Thurston and Fox, 1972). Benn et al. (1979) found that pyrrolizidine alkaloids were present in the parasitoid *Microplitis* emerging from the insect host *Nyctemera* living on *Senecio spathulatus* plants. However, the insect hosts were not affected by the chemicals in the above studies.

Quinolizidine alkaloids (QA) are characteristic secondary metabolites of the phylogenetically primitive tribes of the family Leguminosae (Kinghorn and Balandrin, 1984) and are especially abundant in the members of the tribe Genisteae (Waller and Nowacki, 1978). They are assumed to play an important role in plant defense against nonadapted phytophages (Waller and Nowacki, 1978; Wink, 1984c, 1985, 1988), but also constitute a nitrogen source for the plant seedlings (Nowotnowna, 1928, cited in Waller and Nowacki, 1978; Wink, 1985; Wink and Witte, 1985a). Phytophagous insects, such as aphids, acquire defense against generalist predators by sequestering QA (Wink and Römer, 1986). QA also have bacterio-and fungistatic properties (Wink, 1984a; Tyski et al., 1988) besides being highly toxic to most vertebrates and inhibitory for the development of other plant species (Pöhm, 1966; Waller and Nowacki, 1978; Wink, 1983).

The primary aim of the present paper wa⁻ to follow the fate of QA, both qualitatively and quantitatively, through a complex multispecies food web from the primary producer (*Laburnum anagyroides*) to the first (herbivorous) and second (carnivorous) consumer levels, as well as to scavengers (aphid-visiting ant species). For this purpose, we sampled and analyzed plant parts, and insect herbivores and organisms associated with them (parasitoids and ant species). We also were interested in the question of whether QA taken up by the bruchid seed predator would be found changed in a quantitative and compositional fashion when eliminated.

For some time it also has been known that some legume species are able to selectively abort seeds and/or pods containing seed predator larvae. Such and other "manipulations" by the plant can affect transport of nutrients and non-nutrients into the seeds (Stephenson, 1981). As, in the present plant seed predator system, egg-laying by bruchid females occurs on green pods and larvae develop in the ovules, the plant, by means of active defense, may alter the chemical environment within the seeds. Therefore, we also examined whether infested seeds contained a higher level of QA than uninfested ones.

METHODS AND MATERIALS

Host Plant. Laburnum anagyroides Medik (Leguminosae) is an endemic plant species in central and southern Europe (Soó, 1966). The tree is also widely grown as an ornamental in parks and gardens throughout Europe. Yellow flowers bloom within inflorescences through May and June. Pods containing one to nine seeds appear in June, grow to 2–8 cm in length, and harden by the end of August. Pods are dehiscent and remain on the plant. Many pods open in late September; however, most of them open only during the next spring. Some seeds fall out of the pod during the following spring, but many remain in the pod for a year or longer. Seeds are dark brown and 2–4 mm long.

Insect Herbivores. Aphis cytisorum Hart. (Homoptera: Aphididae) is a dark grey aphid with a waxy coating covering the body. Aphids hatch from overwintering eggs placed on the plant's trunk close to the soil surface. They move up the plant and form colonies on distal parts of new shoots, inflorescence axes, and leaves' lower surfaces. Individual aphid colonies are distinct; however, if the level of infestation is high, they later coalesce. Honeydew is produced in large amounts and is collected by several ant species.

The adults of the predispersal seed predator, *Bruchidius villosus* Fabr. (Coleoptera: Bruchidae), emerge from seeds of *L. anagyroides* and probably other overwintering sites such as under tree bark, although this is not well established. Females lay eggs on the surface of immature pods. Larvae enter through the pod wall and feed on developing seeds. By mid-August, larvae complete development and pupate, and adults emerge from open pods at the end of August or overwinter within seeds of closed pods on the plant.

Parasitoids. B. villosus is parasitized by chalcidoid and braconid species that emerge either in August–September or overwinter as larvae or adults inside the seeds and emerge the following May–June. (See more details in the Results section.)

Sampling Sites and Preparation of Plant and Insect Material for Chemical Analysis. Because *L. anagyroides* generally occurs as sporadically scattered individual trees and only rarely forms larger, homogeneous stands, both insect

and plant materials came from several collection sites in Hungary. Individual trees of (1) 2–3 m height and max. 10-cm trunk diameter, for which the local climatic and soil conditions varied greatly; and (2) one homogeneous stand (ca. 20 trees approx. 10–15 years old, growing on a long-abandoned damp area, on clay soil) were sampled for green plant parts, aphids, and ant species during 1987 (see Table 1 for dates of sampling).

For alkaloid analyses of green plant parts, lyophilized samples were used. One 6- to 60-g fresh weight sample of living plant parts, pooled from one to two trees for each sampling date and plant part (as indicated in Table 1) were removed and immediately put into a cool box, transferred to the laboratory, and stored at −60°C until further processing. The deep-frozen samples were crushed in a mortar filled with liquid N_2, put into a lyophilizer (Edwards, Great Britain, model EF 03), freeze-dried, ground, placed in vials, and finally placed back into the lyophilizer for sealing under vacuum. The samples were 2–9 g dry weight (dw) after lyophilization. In addition to the above, dry pods (without seeds), and whole mature seeds (4–5 g each sample; one from 1987 and several from 1989), testa (516 mg), and endosperm (1 g) of mature, dry intact seeds, as well as testa (184 mg) and leftover endosperm of seeds (447 mg) in which the predispersal seed predator bruchid had completed development, were collected and analyzed.

Aphids were collected from infested trees by brushing them into a container, and ants from aphid colonies and honeydew-covered leaves were collected with an aspirator. There were three samples of *A. cytisorum* collected at three points of time in 1987 (see Table 2), each containing approximately 4900, 7500 and 14,000 aphids, and two samples of ants, one a mixed sample of *Formica rufibarbis* F. and *F. cunicularia* Latr. and the other a homogeneous sample of 444 *Lasius niger* L. (Hymenoptera: Formicidae).

On September 2, 1987, a large sample of pods, with even mature pods still closed, were collected for obtaining bruchid adults and parasitoids for chemical analysis. The seeds from one batch of pods were removed and placed, at 25–26°C, under a photoperiod of 20:4 hr (light–dark). The containers were covered with linen cloth and humidified with wet cotton until both bruchids and parasitoids emerged from the seeds.

Emerging insects were collected daily and stored at −20°C in 70% EtOH. For alkaloid analysis, the following were used: (1) two samples of *B. villosus* containing 357 and 520 beetles, respectively; (2) three samples of parasitoids, one of 43 braconids, one of 64 pteromalids, and a third of 82 specimens of about three species of parasitoids. Parasitoids emerged from the same seed samples from which the bruchids originated.

Following the emergence of bruchids and parasitoids, one sample of empty cocoons (94 mg) of the braconid parasitoid, and one sample of bruchid larval frass together with pupation chambers of larvae lined with cemented fecal material (134 mg) were collected from infested seeds and used for analysis.

Chemical Analysis of Plant and Insect Material. Plant samples (500 mg) were homogenized in 15 ml 0.5 M HCl and left standing for 1 hr. The homogenates were made alkaline by adding 6 N NaOH and applied to standard Chem-Elute columns for solid-phase extraction. After elution with methylene chloride, the solvent was evaporated in vacuo.

TABLE 2. QUANTITATIVE AND QUALITATIVE QA COMPOSITION OF INSECTS ASSOCIATED WITH *L. anagyroides*

[a] Measured on a fresh weight basis.
[b] 1 = *N*-Methylcytisine; 2 = cytisine; 3 = 5,6-dehydrolupanine; 4 = anagyrine.
[c] Measured on a dry weight basis.
[d] Due to the lack of data on body weights, alkaloid contents per gram body weight could not be calculated; however, the samples contained 76 and 5 μg alkaloids, respectively.
[e] Pure sample of one pteromalid species.
[f] Mixed sample of a minimum of three eulophid and pteromalid species.

Alkaloid extracts were analyzed by TLC (cyclohexane–diethylamine, 7 : 3) and capillary GLC: Perkin Elmer GLC 8500 or Chrompack CP438A; DB-1 column (30 m × 0.3 mm); oven: 150°C, 2 min isothermal, to 320°C with 20°C/min; injector: 250°C; detector: 320°C; carrier gas: helium, 92 kPa. Quantification was carried out with cytisine as an external standard using a nitrogen-specific detector. GLC-MS measurements were performed as described in Wink et al. (1983). Alkaloids were identified according to their specific

Kovats retention indices and mass spectra and by using alkaloid standards (for details see Wink et al., 1983).

The QA contents in plant materials were determined on a dry weight (dw) basis, those of insects on a fresh weight (fw) basis. The QA contents of bruchid adults, measured on a fresh weight basis, were converted into dry weight to compare with QA content of larval feces that was measured on a dry weight basis. For the conversion we assumed that QA content was 10 times as high in dry materials.

RESULTS

Parasitoids. There was one braconid species, *Triaspis thoracicus* Curt. (Hymenoptera), present in the samples. Among the chalcidoid species, pteromalids, eulophids, and eupelmids were represented, and the presence of a *Tetrastichus* sp. (Hymenoptera: Eulophidae) was confirmed. In case of a *L. anagyroides* seed sample (containing approximately 5000 seeds), pteromalids and braconids emerged from ca. 18% of the bruchid-infested seeds.

Ants. At least three ant species (*Lasius niger*, *Formica rufibarbis*, and *F. cunicularia*, roughly in a 15 : 1 : 2 ratio) regularly visited the aphid colonies or, in the case of high aphid infestation, only the twigs and the leaves that were covered with honeydew.

Alkaloid Analysis: Qualitative Aspects. QA were detected in all components of food chain examined. Both the plant and insect samples showed similar alkaloid patterns (Tables 1 and 2). There were four quinolizidine alkaloids identified by TLC, capillary GLC, and GLC-MS: cytisine, *N*-methylcytisine, 5,6-dehydrolupanine, and anagyrine (Figure 1).

As for seasonal change in alkaloid composition, cytisine remained the major component in almost all plant samples. There was not much change in minor (5,6-dehydrolupanine and anagyrine) alkaloids either. The only substantial variation was shown in *N*-methylcytisine. An unusual pattern was detected in mature seeds and pod walls (without seeds) collected in 1987. Here, the cytisine content was very low, while the level of 5,6-dehydrolupanine was high. In the 1989 seed samples, cytisine was the main alkaloid (95.5 $\pm$ 1.3%, mean $\pm$ SD, $N = 4$), and *N*-methylcytisine was present in 3.1 $\pm$ 1.3% ($N = 4$). In comparison with alkaloids in the endosperm of seeds, *N*-methylcytisine made up a smaller percentage of two alkaloids found in the frass of *B. villosus* (Tables 1 and 2).

Bruchidius villosus beetles, *T. thoracicus*, and one pteromalid parasitoid sample contained predominantly cytisine; the other alkaloids were not present or occurred at levels too low to detect. In parasitoid sample II (Table 2), however, in addition to cytisine, a substantial proportion of *N*-methylcytisine was

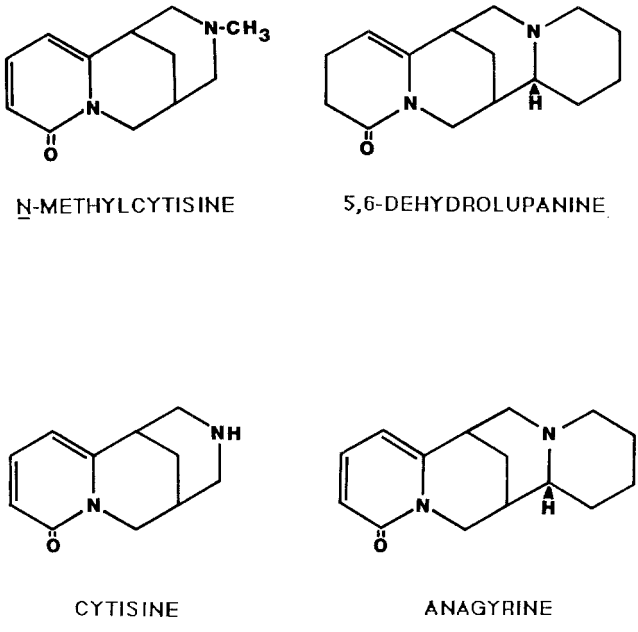

FIG. 1. Structural formulas of the quinolizidine alkaloids found in the samples.

present also. Larval feces of the bruchid and the cocoons of the braconid parasitoid were low in *N*-methylcytisine and rich in cytisine (Table 2).

Quantitative Aspects. Individual plant parts (on a microgram per gram dry weight basis) showed a seasonal trend in total alkaloid contents (Figure 2). In May, much of the alkaloid content was found in the reproductive organs, specifically in inflorescence axes and individual flower pedicels. Since flowering and pod formation is continuous within a given inflorescence and within a time period, the very young pods already present at peak flowering also contained a relatively very high amount of QA. Gradually, stems, leaves, and inflorescence axis and/or flower pedicels lost their QA contents by September, while developing pods maintained some (ca. 1 mg total QA/g dry plant material) until ripening. Mature seeds were especially rich in QA (Figure 2). In four samples of such seeds (collected at four different localities in 1989), QA content ranged from 9.075 to 23.161 mg/g dw. Of the seed parts (on a microgram per gram dry weight basis), endosperm often contained four to five times as much QA as seed testa (Figure 3).

Alkaloid contents of bruchids (determined on a fresh weight basis) were much lower than either those in fully grown green pods, mature dry seeds, or endosperm (Table 2, Figure 3). On the other hand, in the aphids, the alkaloid levels were higher than in the plant (Table 2) and were in accordance with the

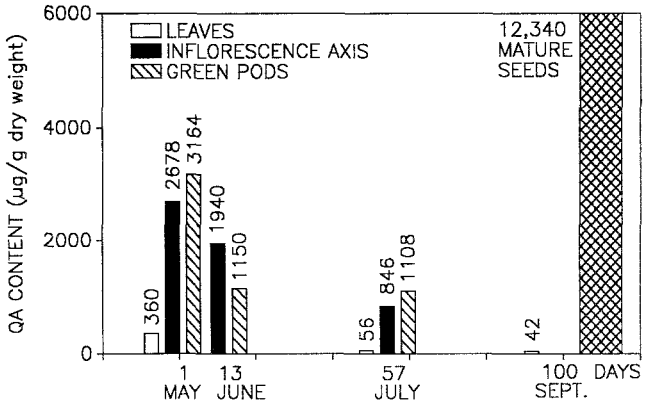

FIG. 2. QA content of various parts of *L. anagyroides* between May 27 and September 2.

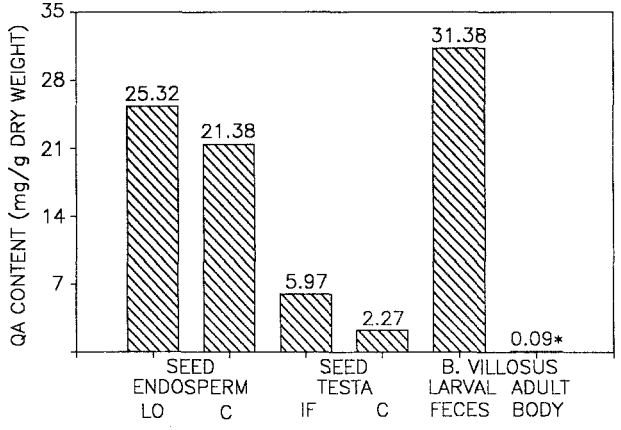

FIG. 3. QA contents of control and seed predator-infested *L. anagyroides* seed parts, as well as larval feces and bruchid adults. LO = leftover (i.e., bruchid-infested) endosperms, IF = infested, C = control. Asterisk denotes that the QA contents of adult bruchids were measured on a fresh weight basis, but were converted into dry weight values (see Methods and Materials for details).

seasonal change in the plant's QA content. Although the contents of QA in aphids were measured on a fresh weight basis, a cautious estimate on a dry weight basis (see Methods and Materials) would yield values 10 times as high as those found in the corresponding plant tissues. The most frequently visiting ant species, *L. niger*, weighed ca. 2 mg fw/individual and contained ca. 0.1

μg/ant of alkaloids. Alkaloid contents of parasitoids were much lower than those either in plant parts or in the host, but still detectable (Table 2).

QA content of endosperm of bruchid-infested and uninfested seeds were in the same range. The larval frass had a very high QA content (Figure 3 and Table 2). The peak oviposition period of bruchids (July; Szentesi, unpublished observation) coincided with a relatively low alkaloid content in the pod (a third to half of that present at early pod development).

DISCUSSION

Analysis of the quinolizidine alkaloid content of *L. anagyroides* and of associated insects showed that this major group of secondary plant metabolites passed through several trophic levels almost unchanged in terms of composition. One or more of the plant alkaloids appeared in two herbivores (an aphid and a bruchid), in various parasitoids, and in three ant species. This is remarkable if one considers the diversity and host specificity of participating organisms (see a more detailed discussion of this later).

Typical components of the QA group are cytisine (found in more than 79 plant species), *N*-methylcytisine, and anagyrine (Figure 1), constituting from trace quantities to 98% of total alkaloid content of a plant species (Mears and Mabry, 1971). Main sites of accumulation are the epidermal layers (Wink et al., 1984) and the reproductive organs, e.g., fruits and/or seeds (Wink, 1987; and present study).

Host Plant. In *L. anagyroides*, fresh leaves and stems contain about 150 μg/g fw cytisine (Wink, 1984c), and in both seeds and pods cytisine is the major alkaloid (Wink, 1984d). The QA level changed in different plant parts during the season. First young shoots, then inflorescences, and finally developing and mature pods and/or seeds contained the highest amount of QA (Figure 2). As reported also for other leguminous species (Waller and Nowacki, 1978; Wink and Hartmann, 1981), we found that *L. anagyroides* mobilized QA out of leaves and into seeds by the end of the season, showing that such compounds were not simply waste products. These findings are in agreement with the results of Greinwald et al. (1990) on *L. watereri* (Kirchn.) Dipp., a hybrid of *L. alpinum* and *L. anagyroides*. However, there were unusually high 5,6-dehydrolupanine and low cytisine levels in the 1987 pod wall and mature seed samples. The cause of these lower levels is unclear.

Insect Herbivores. Both *A. cytisorum* and *B. villosus* took up QA from *L. anagyroides*. The quantity present in the body, however, differed considerably between the two species (Table 2). *A. cytisorum* accumulated alkaloids against a concentration gradient. On two other legume species, *Petteria ramentacea* (Wink and Witte, 1985b) and *Cytisus scoparius* (Wink et al., 1982), *A. cyti-*

sorum also showed a higher level of QA content in the body than found in particular plant parts. The quantities of QA determined in aphid samples taken at three different points of time (Table 2) showed a seasonal change similar to that found in the plant. One of the reasons for this is that the aphids followed fresh tissue growth from shoot to flower axis to pod. Like many aphid species, *A. cytisorum* also taps the phloem sap, where the QA are reported to be transported in *Cytisus* and *Lupinus* plant species (Wink and Witte, 1984).

In the case of the bruchid species, the only stage feeding on the plant is the larva. Therefore, the QA uptake and quantity refer to this stage, although these were determined in the adults. The alkaloids present in the larvae eventually pass through the pupal stage to reach the adults. We think that the amount of QA taken up by a bruchid larva at any time during its development must have been in the range (ca. 1 mg/g dw) found in the plant tissue in which it developed in July. (In contrast, by the time the larvae completed development and adults emerged, there was a 10-fold increase of QA content in mature seeds in comparison with that in green pods.)

There was a high amount of QA continuously excreted by the bruchid larval feces: ca. 30 times as high as the quantity found in pods, and 200–600 times as high as the amount found in beetles (the latter was measured by a fresh weight basis and converted to dry weight). This reveals a very effective QA-eliminating process in the larvae. We assumed that they either continuously and quickly excreted the QA taken up while feeding, or the QA were degraded metabolically. The first mechanism seemed to be operating, although some changes in the qualitative QA pattern did occur. The fact that the feces were enriched in QA was the result of nutrients removal, and not the consequence of increasing QA content in the plant. We assume that, through *N*-demethylation reaction in the gut, some metabolic transformations also occur in the bruchid larva.

In connection with the described quantitative relationships, we believe that the possibility of "manipulating" QA content in the bruchid-infested seeds of *L. anagyroides* could exist both on the plant's and the seed predator's side. Janzen (1976) and Stephenson (1981) listed cases when fruits with bruchid larvae inside were subsequently aborted, although no proximal causes of this were known. In the case of *Laburnum/Bruchidius*, we considered the following possibilities: (1) The plant responded to the presence of bruchid larvae by delaying or hindering the maturation of seeds by not transporting all the nutrients, but increasing transport of the QA into the seeds. (2) Similarly, bruchid larvae could have avoided much of the QA transported to the seeds by either (a) influencing the transport itself or (b) completing development by the time of peak QA build-up (early to mid-August). The first hypothesis could be rejected with the present bruchid–plant relationship because infested and control seed endosperms contained the same quantities of QA (Figure 3); that is, the plant did not "manip-

ulate'' seed development. If abortion of bruchid-infested seeds occurred at all with *Laburnum*, it must have taken place at an earlier phase of seed development. As for the second hypothesis, assumption ''a'' is a possibility; however, we do not have evidence for it. Assumption ''b'' seems to be a realistic one, although it also implies that a high QA content is not preferred by the bruchid larvae.

As for the qualitative composition: the composition found in the aphids was similar to that demonstrated by the chemical analyses in the hostplant *L. anagyroides* (Tables 1 and 2). In other studies, the similarity was only partial. For example, although the most abundant alkaloid in *C. scoparius* is sparteine, 17-oxosparteine (derived from sparteine) was the most abundant alkaloid in aphids feeding on this plant (Wink et al., 1982). In *A. cytisorum* feeding on *Petteria ramentacea*, there was only one alkaloid, cytisine, found in the aphid, out of six occurring in the plant (Wink and Witte, 1985b).

The green *Laburnum* fruit varies more in QA composition during the time of bruchid larval development than does the mature seed or the bruchid adult. Although three components of the QA assemblage were present in fully grown pods, only two of them were found in larval frass, and one (cytisine) in the adult bruchid (Tables 1 and 2). Obviously, the plant gives the base for changes in the proportion of chemicals found in the herbivore feeding on it. For instance, more recently, Greinwald et al. (1990) identified 17 different QA from pods of *L. watereri*, of which 15 were not present in seeds.

We assume that both the aphid and the bruchid are likely to face much inter- and intraspecific chemical diversity in plant hosts. Besides the host plant, *L. anagyroides*, known to us, both insect species are reported from six other QA-containing plant species, and from a species, *Robinia pseudacacia*, devoid of QA (Krécsy, 1886; Kiss, 1895; Vadas, 1911; Escherich, 1923; Wahl, 1925; Zacher, 1936; Fischer, 1938; Hoffmann, 1945; Börner, 1952; F.P. Müller, personal communication). The main constituents of the latter are flavonoids and the nonprotein amino acid, canavanine (Bell, 1971). With some exceptions (see Wink, 1984b; Wink and Witte, 1984; Greinwald et al., 1990), few quantitative data are available on the seasonal, diurnal, or within-plant distribution of QA.

Herbivore infestation level and QA content of the host plant may be convergent. For example, the feeding sites of the legume-specialist aphid, *Acyrthosiphon spartii*, on the plant *Sarothamnus scoparius* were correlated with the highest concentration of the major alkaloid, sparteine (Smith, 1966). In contrast, the population density of a generalist aphid, *Macrosiphum euphorbiae*, decreased with increasing alkaloid level in *L. angustifolius* and *Cytisus scoparius*, respectively (Brusse, 1962; Wink et al., 1982). Possibly the within-plant density of a generalist insect species is inversely proportional, while that of an adapted specialist is directly proportional, to the alkaloid content of the plant.

Parasitoids. There was a decrease in QA content at the third trophic level

(Table 2), suggesting a limited, but still significant, passage of alkaloids. Similar passage of plant allelochemicals to parasitoids through an insect herbivore have been demonstrated under experimental conditions by Thurston and Fox (1972), Campbell and Duffey (1979, 1981), Thorpe and Barbosa (1986), and Barbosa et al. (1986). Benn et al. (1979) found about 300 μg alkaloid/larva in the lepidopterous host *Nyctemera* collected on *Senecio* plants in the field and stated that the alkaloids were present in the braconid parasitoids too, although no data were given. Despite the low level of QA detected in parasitoids in the present study, it is noteworthy that a substantial amount of cytisine was passed also to the pupal chamber wall, i.e., the cocoon, spun by the braconid parasitoid larvae (Table 2). The composition of QA found in the parasitoid samples corresponded to that present in adult bruchids with one exception (parasitoid sample II, Table 2) where *N*-methylcytisine occurred in large amounts.

Among the species found, *Tetrastichus* is reported both as a primary parasitoid (on the herbivore, *B. villosus*) and a secondary one (on the braconid, *T. thoracicus*), that is a (hyper)parasitoid (Medvedeva, 1978), or "metaparasite" sensu Steffan (1981), which may further complicate the possible routes of passage of alkaloids throughout the foodweb.

The parasitoid species we studied live in various bruchid species; e.g., *T. thoracicus* parasitizes a number of other unrelated bruchid species (*Bruchus atomarius*, *B. lentis*, and *B. rufimanus*) (Luca, 1970, 1977). These species, in turn, inhabit phytochemically diverse host plants.

Ants. The alkaloid analyses demonstrated (Table 2) that ants gather a substantial amount of QA from honeydew, both directly from tending aphids and from leaf surfaces. We think that in the latter case, UV radiation may decrease the compounds' stability. QA and/or the breakdown products are probably taken back to the nests where their fate is not known.

QA Along the Food Web. It is believed that peak QA quantities in plant parts throughout the season serve plant defense purposes (Waller and Nowacki, 1978; Wink, 1984c, 1985; Wink and Hartmann, 1981). Indeed, QA have important effects on the behavior and physiology of nonadapted herbivores. Their feeding-deterrent activity was demonstrated on the tortricid *Choristoneura fumiferana* (Bentley et al., 1984), on the pea aphid *Acyrthosiphon pisum* (Dreyer et al., 1985), and even on mollusks (Wink, 1984c).

The QA found in *L. anagyroides* have been sequestered by the aphids and excreted without much change by other members of the food web investigated. This suggests that QA might not play a primary role in the lives of the latter species. We do not know whether *A. cytisorum* on *L. anagyroides* enjoys any protection from specialized parasitoids or predators. However, evidence indicates that QA-containing aphids can gain protection from generalist predators. Wink and Römer (1986) and Gruppe and Römer (1988) demonstrated that two predators, *Carabus problematicus* and first-instar larvae of *Coccinella septem-*

punctata, were narcotized (temporarily immobilized) and killed, respectively, after feeding on *Macrosiphum albifrons* colonies grown (and containing 1.3 mg/g fw alkaloids) on a "bitter" *Lupinus* variety, whereas they preferentially consumed the aphids developing on a "sweet," i.e., alkaloid-free, lupine without exhibiting adverse symptoms.

In summary, all trophic levels studied tolerated the presence or absence of QA. This ability may prove to be a good strategy in a varying environment, variability meaning that both within- and among-plant species show chemical diversity.

Acknowledgments—An earlier version of the manuscript profited much from the careful reading and suggestions of Dr. Marion O. Harris (U.S.A.). We are also grateful to Drs. C.B. Montllor (U.S.A.), T. Jermy (Hungary), and E.A. Vogt (U.S.A.) for critical remarks; to Drs. L. Gallé, L. Szalay-Marzsó, C. Erdélyi, J. Papp (Hungary), L. Borowiec (Poland), Prof. F.P. Müller, Dr. H. Wendt (Germany), and Mr. A. Podlussány (Hungary) for species identification and comments; and to Mr. L. Tibai and Miss K. Ferencz (Hungary) for technical assistance. Special thanks are due to Dr. L. Witte (Germany) for carrying out the GLC-MS measurements.

(Received January 24, 1991; accepted March 1, 1991)

Abstract—*Acinetobacter calcoaceticus*, a gram-negative bacterium isolated from field soil, was found to be responsible for the biotransformation of 2(3H)-benzoxazolinone (BOA) to 2,2′-oxo-1,1′-azobenzene (AZOB). Experiments were conducted to evaluate the transformation of BOA to AZOB by this microbe in sterile and nonsterile soil. Transformation studies with soils inoculated with *A. calcoaceticus* indicated that the production of AZOB increased linearly with the concentration of BOA in sterile soil and showed a quadratic trend in nonsterile soils. This also indicated that all soil types studied for the transformation experiments might contain *A. calcoaceticus* capable of the conversion of benzoxazolinones.

Key Words—Allelopathy, 2,4-dihydroxy-1,4(2H)-benzoxazine-3-one, 2(3H)-benzoxazolinone, 2,2′-oxo-1,1′-azobenzene, *Acinetobacter calcoaceticus*.

INTRODUCTION

Rye is considered an important cover crop in Michigan, other parts of the United States, and around the world (Smeda and Weller, 1986; Smeda and Putnam,

*To whom correspondence should be addressed.
[1] Present address: 49823 Gallatin Road, Gallatin Gateway, Montana 59730.
[2] Present address: Microbiology Laboratory, Krug International, 1290 Hercules Drive, Houston, Texas 77058.

0098-0331/91/0800-1575$06.50/0

1988). Numerous allelochemicals with apparent weed control activity have been isolated and identified from rye (*Secale cereale* L.) herbage and found to inhibit lettuce (*Lactuca sativa* L.), redroot pigweed (*Amaranthus retroflexus* L.), and common lambsquarters (*Chenopodium album* L.) seed germination and root growth (Chou and Patrick, 1976; Patrick, 1955; Shilling et al., 1985). Barnes and Putnam (1986, 1987) and Barnes et al. (1987) isolated two hydroxamic acids, 2,4-dihydroxy-1,4(2H)-benzoxazin-3-one (DIBOA) and 2(3H)-benzoxazoline (BOA), from rye residues, compared their toxicity to phenyllactic acid and hydroxybutyric acid, the allelochemicals reported earlier from rye (Patrick, 1955; Shilling et al., 1985), and found that the hydroxamic acids, DIBOA and BOA, were the most toxic to both monocots and dicots. The benzoxazinones are thought to occur in plants as glucosides. Upon injury, they are released as DIBOA by glucosidase enzymes (Hofman and Hofmanova, 1968; Zungica et al., 1983). The quantities of these compounds in plants vary with the species, age, and the plant part used (Almeida, 1985; Barnes and Putnam, 1986; Tang et al., 1975; Virtanen et al., 1957). Recently, Nair et al. (1990) reported the production of an azoperoxide, 2,2′-oxo-1,1′-azobenzene (AZOB) in field soils incubated with BOA. The benzoxazinones produced by rye, DIBOA and BOA, were rapidly converted to AZOB in nonsterile bins over heat-sterilized soil, suggesting a microbial basis for the reaction. This new transformed allelochemical was more toxic to plants than its precursors, BOA or DIBOA (Hietala and Virtanen, 1960; Nair et al., 1990).

Allelochemicals can be released into the environment by processes such as volatilization, root exudation, leaching, microbial transformation, and release of toxins from decomposition of plant residues (Chapman and Lynch, 1983; Rice, 1984). The microorganisms either release or produce phytotoxins directly from residues or use the residues as substrate in the production of bioactive compounds (Atlas and Bartha, 1987; Patrick, 1955; Proebsting and Gilmore, 1941). For example, the contribution of microorganisms in the production of toxins from peach root bark was investigated, and several soil-born microorganisms were found to degrade amygdalin, an allelochemical from the peach tree, to HCN and benzaldehyde (Patrick, 1955; Proebsting and Gilmore, 1941). These degradation products were shown to be the toxic allelochemicals present in the soil containing decayed peach tree roots. This paper describes the isolation and identification of a soil microbe capable of transforming benzoxazinone to the more toxic AZOB and the rate of transformation of BOA to AZOB by this microbe in some Michigan field soils.

METHODS AND MATERIALS

General Experimental. Ultraviolet (UV) and visible absorption spectral analysis were performed on a Gilford Response II spectrophotometer. BOA was obtained commercially from the Aldrich Chemical company, Milwaukee, Wis-

consin, and was uniformly mixed with soil using a mortar and pestle, before addition of water and vortexing (1 min). Column chromatography was performed using a J.T. Baker Flash Column (20 × 2.7 cm, 250 ml). The silica column used was Analtech (35–75 μm particle size, 60 Å pore size), and the flow rate was 3 ml/min, unless otherwise specified. All analytical TLC (250 μm) and preparative TLC (1500 μm) were done on Uniplates (Analtech, Inc., Newark, Delaware). Homogenization of microbial colonies was done in a Brinkman Polytron (CH-6010) blender for 5 min. Soil was sterilized by autoclaving (1 hr, 15 atm, 120°C) for four successive days, and distilled water and media used were autoclaved for 20 min.

Soil Collection. All soil collection sites were in the State of Michigan. Spinks loamy sand soil (Psammentic, Hapludalfs, sandy, mixed, mesic) was collected (November, 1987) from the Horticulture Teaching and Research Center field, located on Jolly Road in East Lansing, Michigan. Soil was passed through an aluminum sieve (2 × 12 mm opening) and stored in a cubic yard bin at room temperature (15–22°C) for one year prior to use. Three other soils, Kalamazoo sandy loam (Typic Hapludalfs, fine-loamy, mixed, mesic), Metea loam (Arenic Hapludalfs, loamy, mixed, mesic) and Oshtemo sandy loam (Typic Hapludalfs, coarse-loamy, mixed, mesic) were collected in October and November of 1988 and stored under the same conditions. The Kalamazoo Sandy loam soil was collected at the Clarksville Research Station located in Clarksville, the Oshtemo sandy loam was from the Sodus Horticulture Research Farm located in Sodus, and the Metea loam was collected from the Moore Seed Farm located in Elsie.

Preparation of Media. Yeast maltose glucose (YMG) agar (yeast extract, 4 g; maltose, 10 g; glucose, 4 g; bacto-agar 18 g/liter), potato dextrose agar (PDA, Difco) (39 g/liter), and Nz-Amine agar (Nz-Amine, ICN Biomedicals Inc., 3 g/liter, bacto-agar 18 g/liter) were used for growth and identification of soil microbes. Antibacterial plates were prepared by adding chloramphenicol to a final concentration of 100 μg/ml. Antifungal Nz-Amine agar plates were prepared by adding nystatin and cycloheximide at concentrations of 30 μg and 500 μg/ml, respectively.

Isolation of Soil Microbes. Spinks loamy sand soil (1 g) was suspended in sterile physiological saline (9 ml) (0.85% NaCl in distilled water, w/v), vortexed (15 min), and allowed to settle (1 hr). This soil extract was tested for in vitro transformation of BOA to AZOB by incubating BOA (10 mg) with sterile soil (100 g), according to the procedure published earlier (Nair et al., 1990). Cultures were allowed to incubate in the dark at 26°C (96 hr), and extracted with MeOH (50 ml × 3). Biotransformation of BOA to AZOB by the soil extract containing microbes (1 ml) was verified by TLC comparison with the standard AZOB and by UV–visible spectroscopy.

Separation of Total Soil Microbes into Bacteria and Fungi. Serial 10-fold dilutions of the supernatant–soil extract was prepared in sterile distilled water.

Soil extracts (1 ml each) were pipetted into 10 different autoclaved test tubes, diluted to 10 ml each by sterile distilled water, and mixed well. Solutions from each tube (10 ul) were spread onto individual YMG plates. Plates at dilution of 10^{-6} showed the best separation of fungal and bacterial colonies. A total of nine individual colonies was further transferred onto YMG plates separately and assayed with BOA for the production of AZOB. Colonies found to be positive for transformation of BOA to AZOB were transferred to Nz-Amine agar and PDA plates enriched with antibacterial or antifungal compounds, respectively, and incubated (72 hr). Two fungi and one bacterium thus obtained were assayed for the transformation of BOA to AZOB.

Identification of Microbe. The bacterium that converted BOA to AZOB was further purified on antifungal Nz-Amine plates. Morphological and biochemical properties of the bacterium were determined with a Vitek Auto Microbic System using Vitek GNT gram-negative identification cards.

Spray Reagents for TLC Detection. DIBOA was detected on thin-layer plates with ferric chloride ($FeCl_3$) spray reagent consisting of 5% $FeCl_3$ in 95% ethanol, acidified with concentrated HCl. A spray reagent consisting of 1% ceric sulfate ($CeSO_4$) in concentrated H_2SO_4 was used to detect BOA.

Production and Extraction of AZOB from Soil. A commercial sample of BOA (4 g) was mixed thoroughly with Spinks loamy sand (4 kg) and distilled water (400 ml) and incubated (26°C, 96 hr) in four 2-liter Erlenmeyer flasks, as published earlier (Long et al., 1974). The soil was extracted with methanol (8 × 500 ml) and filtered through a Buchner funnel, using filter paper (Whatman No. 1). The extract was further filtered through a sintered glass filter (fine, 4–5 μm), and the solvent was removed by rotary evaporation. A preliminary TLC (toluene–ethylacetate, 5:4) of the crude extract indicated the presence of AZOB and unreacted BOA. Separation of BOA from AZOB was achieved by flash column chromatography (260 g, toluene–ethylacetate, 5:4). The orange band eluted was collected and dried in vacuo to produce dark brown crystals of AZOB (1.18 g).

Quantification of BOA and AZOB in Soil Extract. The samples were analyzed spectrophotometrically for BOA and AZOB. Standard curves for BOA and AZOB were prepared using known quantities of BOA (from 0.748 to 286.0 μg/100 ml in MeOH) and AZOB (from 1.51 to 96.402 μg/100 ml in MeOH) and by recording the absorbance at 273 and 432 nm, respectively. Standard solutions of each of the dried soil extracts stored at −20°C were prepared by dissolving the extract in MeOH in a 100-ml volumetric flask. The absorbance was recorded for each solution. Concentrations of BOA and AZOB in a given sample were obtained from the standard curve.

In Vitro Transformation Studies with Pure Cultures of A. calcoaceticus. Cultures of *A. calcoaceticus* were used from the stock cultures grown on YMG plates, and transformation of BOA to AZOB was carried out as reported earlier

(Nair et al., 1990). All treatments were incubated (26°C) in the dark for 1, 2, 4, 6, 12, and 24 days and extracted with MeOH (3 × 150 ml) and quantified for BOA and AZOB by UV spectroscopic procedure. Microbial populations were estimated by monitoring the colony-forming units (CFU) of the stock solution and were calculated to be 5.3×10^{10}.

Production of AZOB in Liquid Media. Baffle-bottomed Erlenmeyer flasks (500 ml) containing distilled water (100 ml) were autoclaved and cooled to room temperature. BOA (80 mg) and freshly homogenized colonies of *A. calcoaceticus* (5.3×10^{10} CFU, 1 ml) were added to the water and incubated (26°C) under shake conditions. The fermentation broth (96 hr old) was extracted with EtOAc (3 × 75 ml). Shake and nonshake flasks were extracted with EtOAc separately. The EtOAc layer from shake flasks was dried over anhydrous $MgSO_4$ and evaporated *in vacuo* (four days). Purification of AZOB from BOA by TLC (toluene–ethylacetate, 5:4) gave an orange band, free from BOA, and was eluted with $CHCl_3$–MeOH (1:1) and dried *in vacuo* affording pure crystals of AZOB (46 mg).

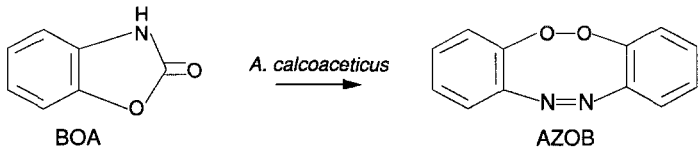
Microbial Transformation of BOA to AZOB. Experiments were conducted to study the rate of BOA transformation by the naturally occurring microbial population of *A. calcoaceticus* in field soil. BOA (30 mg each) was mixed with Spinks loamy sand (10 g each) containing distilled water (3.5 ml) in culture tubes (2.5 × 15.0 cm). Sterile foam plugs were used to cap the tubes, which were then wrapped with aluminum foil for the duration of the experiment. Culture tubes were placed in the dark and incubated (26°C) for periods of 1, 2, 4, 6, 12, and 24 days. At the end of the incubation period, the soil was extracted with MeOH (3 × 150 ml). The extracts were dried over anhydrous $MgSO_4$ and the solvent was removed *in vacuo*. All dried samples were stored at −20°C.

Statistical Methods. Data obtained in duplicated transformation studies were subjected to analysis of variance and means were compared with the least significant difference (LSD) test.

RESULTS AND DISCUSSION

Initial purification of soil extracts containing total microbial isolates were positive for the conversion of BOA to AZOB. Partial purification of the total isolates into bacteria and fungi afforded one bacterium and two fungi positive for the transformation of BOA to AZOB (Scheme 1). However, final purification of the fungi on bactericidal plates did not show transformation of BOA, and hence they were not investigated further.

The microbe capable of transforming BOA to AZOB in field soil was identified as a gram-negative rod-shaped bacterium with a tendency to form coccoid bodies. The organism grew well in a medium containing 0.4% peptone and



SCHEME 1. Transformation of BOA to AZOB in field soils using *A. calcoaceticus*.

0.02% tryptophan, under aerobic conditions, and was capable of using malonate as the sole source of carbon. Decarboxylase tests of the bacterium were negative with lysine, ornithine,and arginine. Glucose was not fermented in the presence of specific inhibitors, DP300 and *p*-coumaric, and the microbe did not produce acid with raffinose, sorbitol, sucrose, inositol, adonitol, rhamnose, arabinose, or glucose. Moreover, the microbe did not hydrolyze esculin or *o*-nitrophenyl-β-D-galactopyranoside. Under aerobic conditions, this organism did not produce acid with glucose, lactose, maltose, mannitol, or xylose. Tests for the production of H_2S, urease, and plant indican were negative. The aforementioned properties are in conformity with those of *A. calcoaceticus* described in *Bergey's Manual of Systematic Bacteriology* (Krieg and Holt, 1984).

Although analytical methods for benzoxazolines were reported earlier (Long et al., 1974; Nair et al., 1990; Virtanen et al., 1957), these methods are not convenient or quantitative for the determination of BOA and AZOB in soil extracts. Since BOA and AZOB gave characteristic UV–visible absorption maxima (Barnes et al., 1987; Nair et al., 1990), it is easy to calculate the concentrations of these compounds from their mixtures by monitoring the optical density (OD). This was confirmed from the concentration curves obtained for BOA and AZOB where OD was 273 and 432 nm, respectively. Standard curves were prepared separately by plotting each compound's concentration against its OD. Concentrations of AZOB and unreacted BOA in the various soil extracts were obtained directly from the standard curves.

The percentages of AZOB isolated from *in vitro* transformation experiments was greater than previously reported (Nair et al., 1990). The modified extraction procedure of AZOB from soil gave yields three times greater (29.8% vs. 9.1%) than previously reported values (Nair et al., 1990). This could be attributed to the new solvent system employed for the separation of AZOB from BOA. In the reported procedure (Nair et al., 1990), HCOOH and NH_4OH were used as part of the developing solvent system, and these may have degraded a portion of the AZOB isolated. The rate of production of AZOB in field soil was investigated under environmentally controlled conditions over a period of 24 days using sterile and nonsterile soils. In both cases, *A. calcoaceticus* cultures were added (5.3×10^{10}) to the soils previously incorporated with BOA. The quantities of AZOB production was proportional to the quantity of BOA avail-

able in the soil (Table 1). At the end of day 12, only 7% AZOB was detected with a loss of 12% BOA. However, the 0.1 mg of BOA/g soil (nonsterile) experiment showed the highest production of AZOB at day 3 (Table 1). The maximum yield of AZOB (9.7%) was observed during the incubation period of days 2–4 with an 85% decrease in BOA concentration. This yield is similar to the 9.1% reported by Nair et al. (1990).

The recovery of unreacted BOA from the treated soil was 33% of the total amount incubated. The remainder of the BOA already could have converted to AZOB or a portion could have decomposed to products that are not yet characterized. Furthermore, BOA might have decomposed to other products under mechanisms that are not yet known. However, a possible mechanism for the production of AZOB from BOA, monomethoxy AZOB (MAZOB) from MBOA and dimethoxy AZOB (DIMAZOB) from MBOA was described earlier by Nair et al. (1990). When the concentration of BOA in field soil was raised to 1.0 mg/g soil, the AZOB production increased linearly to the concentration of BOA. This indicated that the excess BOA might have functioned as an antimicrobial agent on the total microflora in the soil and prevented the soil microbes from utilizing BOA as a carbon or nitrogen source. Usually, microbial populations present in the soil are low in numbers but explode quickly when a suitable substrate becomes available (Atlas and Bartha, 1987). Therefore, having observed different trends for the BOA transformation in nonsterile field soil, it would seem logical that, given the appropriate time interval, a quadratic trend could be expected at both rates of BOA (early lag phase followed by linear phase). Rapid AZOB production detected in the different Michigan soils studied

TABLE 1. QUANTITIES OF BOA AND AZOB ISOLATED FROM STERILE SOIL INOCULATED WITH *A. calcoaceticus* AND NONSTERILE SOIL, BOTH INCUBATED WITH 0.1 mg OF BOA/g SOIL

	Days					
Compounds	1	2	4	6	12	24
Sterile soil						
BOA (μg)	331.9	279.2	229.9	253.5	193.7	191.7
AZOB (μg)	10.4	28.9	51.1	89.3	72.5	99.3
Nonsterile soil						
BOA (μg)	118.6	97.6	47.0	33.0	18.2	[a]
AZOB (μg)	11.2	32.6	33.8	13.5	3.1	[a]

[a] Not detectable levels.

suggested the presence of *A. calcoaceticus* capable of the conversion of BOA to AZOB (Figure 1 and 2).

AZOB was produced in large quantities in aqueous shake cultures for bioassay experiments. This method was convenient, cost effective, and less time-consuming. Extraction of AZOB and BOA by EtOAc from aqueous media was easily performed, and the rate of production of AZOB under shake conditions appeared greater. Since the production of AZOB occurred readily in liquid cultures, it is not necessary to use soil for the transformation of BOA.

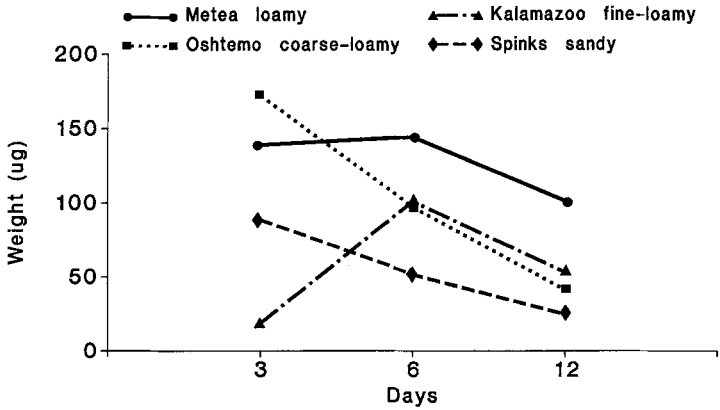


FIG. 1. Concentration of unreacted BOA present in the four Michigan soils used for transformation studies.

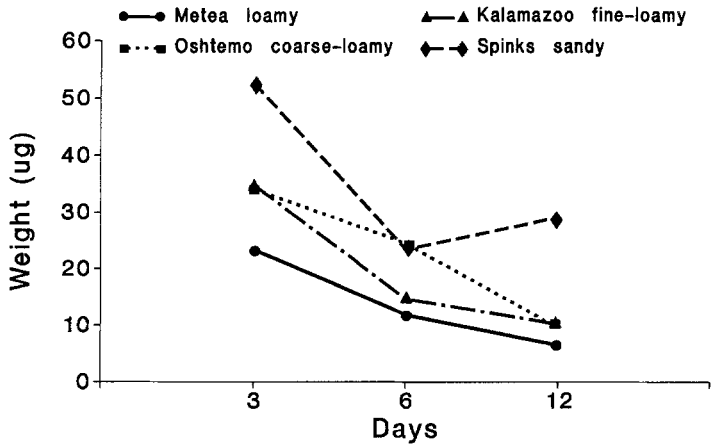

FIG. 2. Concentration of AZOB in four Michigan soils incubated with 0.1 mg of BOA per g of soil.

Even with a lower yield from the liquid medium (24%), when compared to the soil (30.8%), water was a more attractive transformation medium for large scale *in vitro* production of AZOB. The experiments with BOA in nonsterile soil also indicated that the AZOB produced might have been used by other soil microbe(s) as a substrate, thus explaining the quadratic trend observed (Table 1). These data support the difficulty encountered in the detection of AZOB from the soil incubated with rye tissue. The concentration of AZOB started to decline in the experiment with nonsterile soil (Table 1) by the end of day 4. Similar situations in the field can be envisioned where BOA leached from the rye residues is undergoing rapid transformation to AZOB. This experiment also suggested that the accumulation of AZOB will be difficult to detect in field soils with or without rye residues.

(Received January 28, 1991; accepted March 3, 1991)

Abstract—Hesperetin 7-rutinoside (Hesperidin) and taxifolin 3-arabinoside were detected in the soils associated with the rapidly spreading perennial weed, *Pluchea lanceolata*. In the present investigations, inhibitory potential of the aqueous extracts of the two compounds was established and confirmed through growth experiments pertaining to seed germination and seedling growth of radish, mustard, and tomato, with 10^{-4} M solutions of the authentic samples. The significance of the water-soluble compounds present in the rhizosphere zones of the weed and its interference potential is commented upon.

Key Words—Allelopathy, growth experiments, hesperidin, interference, *Pluchea lanceolata*, taxifolin 3-arabinoside.

INTRODUCTION

Previously, Inderjit and Dakshini (1990) reported that *Pluchea lanceolata* (DC) C.B. Clarke (Asteraceae) achieves its interference potential by releasing and inhibiting seed germination and seedling growth of different plant species through phytochemicals synthesized by the weed. These studies necessitated the identification of phytochemical compounds in the soils associated with the weed. Since a large number of phenolic compounds have been shown to possess

*To whom correspondence should be addressed.

0098-0331/91/0800-1585$06.50/0

allelopathic potential (Rice, 1984), isolation and characterization of only this category of compounds have been undertaken. This analysis resulted in the detection of the flavonone, hesperetin 7-rutinoside (hesperidin), and a dihydroflavonol, taxifolin 3-arabinoside, from the soils associated with the weed. Since the occurrence of these compounds in the soil has not been reported earlier, investigations on their effects on germination and growth of some plant species have been undertaken and data pertaining to these are reported here.

METHODS AND MATERIALS

The soils associated with and without (as controls) the weed, *Pluchea lanceolata*, were collected from the fields around the metropolitan city of Delhi. These samples were air-dried and stored in paper bags, to be used later for extraction of compounds.

Extraction, Purification, and Identification of Phenolic Constituents. The soil extracts (5 : 1, v/w) were prepared by shaking the soil samples with double distilled water (DDW) for 1 hr at room temperature. The extracts were filtered, dried in vacuum, and the residue extracted with 10 ml of methanol. These extracts were loaded on Whatman No. 3 (46 × 57 cm) chromatographic paper and developed by descending chromatography using the butanol–acetic acid–water (BAW, 4 : 1 : 5, upper phase) (Harborne, 1973). Chromatograms were dried and scanned bands were marked under UV ($-NH_3$) and UV($+NH_3$). Six bands appeared on the chromatogram with extracts from weed-associated soil, whereas only two bands were detected on the chromatogram with control soil extracts. Each band was eluted in methanol, loaded again separately, washed repeatedly with DDW, and finally extracted with methanol. To confirm the purity of these compounds, each compound was loaded on Whatman No. 1 chromatographic paper and run in four solvent systems: BAW, DDW, 15% acetic acid, and forestal (conc. HCl–acetic acid–water, 3 : 30 : 10). After confirming the purity of these compounds, each was again loaded on Whatman No. 3 chromatographic paper and washed repeatedly with DDW through descending chromatography. The compounds from chromatograms were finally eluted with methanol, and the eluates then were taken for spectral analysis and shifts (NaOH, $AlCl_3$, $AlCl_3$/HCl, NaOAc, and NaOAc/H_3BO_3), if any, of the parent as well as the hydrolyzed fractions. These purified compounds, after loading separately on Whatman No. 1 chromatographic paper, were developed through descending chromatography and the fluorescence (UV and UV+NH_3) and R_f (×100) values were recorded in the four solvent systems mentioned above. The DDW residue of the hydrolyzed parent compound was used for the characterization of sugar moiety, if any, following Harborne (1973). Further, the glycoside and aglycone forms were cochromatographed with the authentic samples and compared with data given by Mabry et al. (1970). The two compounds

common to both (control and weed-associated soil) were not considered for further study. Of the remaining four, two were phenolic acids and the others a flavonone and a dihydroflavonol. Since the former class of compounds has been reported earlier (Rice, 1984) in many allelopathic studies, only the last two compounds were subjected to further analysis.

Seed Germination and Growth Experiments. To investigate the allelopathic potential of the identified compounds, germination and growth experiments were performed. Since the synthetic glycoside of taxifolin (taxifolin 3-arabinoside) was not available, the synthetic aglycone (taxifolin) was used for germination studies. It could be argued that with such a step the comparison of results of two compounds may not be fully justifiable. However, in view of the observations of Rice and Pancholy (1974) that sugars are easily split from the glycoside fraction by microbial action and they tested aglycones for inhibitory activity, the results obtained in the present investigations can be compared.

The compounds hesperidin and taxifolin were dissolved initially in methanol, dried in vacuum, and dissolved in DDW to a final concentration of 10^{-4} M. In general, this low concentration of phytotoxins has been shown to be inhibitory to germination and seedling growth (McCahon et al., 1973; Williams and Hoagland, 1982). The seeds of commonly grown crops in the region, e.g., radish (*Raphanus sativus* var. pusa desi), mustard (*Brassica juncea* cv. PR 45), and tomato (*Lycopersicon esculentum* var. pusa ruby) were selected to study the allelopathic potential of the compounds. For germination studies, 50 seeds of these plants were sown on filter paper moistened with DDW (served as control) or compounds, each in equal volume, and placed in 15-cm-diam. Petri plates. To maintain uniform moisture status in the Petri plates, a cotton pad soaked in DDW or compounds was placed below the filter paper. Root and shoot lengths were recorded every 24 hr for seven days. Each treatment was replicated three times. During the period of experimentation, the temperature regime of 30 $\pm$ 5°C and diurnal regime of light condition were maintained. After seven days, fresh weight of three sets of five seedlings each was recorded. To get a better evaluation of the inhibitory effect, relative germination (RG) index was calculated as follows:

$$\text{RG index} = \frac{\text{number of seeds germinated at 48 hr} \times 100}{\text{number of seeds germinated at 168 hr}}$$

Comparison of the various parameters was made using one way analysis of variance.

RESULTS AND DISCUSSION

A flavonone, hesperidin, and a dihydroflavonol, taxifolin 3-arabinoside, were identified in the aqueous extracts of the soils associated with the weed, *Pluchea lanceolata* (Tables 1 and 2). Compared to taxifolin, hesperidin was a

stronger inhibitor of the seed germination of the three crop species (Table 3). Hesperidin also inhibited significantly ($P < 0.05$) the growth of roots and shoots of all seedlings. Similarly, taxifolin brought about reduction in roots and shoots of the seedlings ($P < 0.05$), excepting shoot growth of mustard and root growth of tomato (Table 3). However, on a relative basis, hesperidin inhibited the shoot growth more; taxifolin, on the other hand, suppressed the root growth more effectively except in tomato, where hesperidin was more inhibitory. Similarly, both compounds reduced the fresh weight of the seedlings of all species ($0.01 < P < 0.08$) except mustard seedlings grown with hesperidin. Like shoot growth, fresh weight of seedlings was affected more by hesperidin than taxifolin. Furthermore, tomato seeds were found to be more sensitive to the compounds than the other two crop species (except grown with taxifolin). It may be noted that the effect of these two compounds varied with seeds tested. Even though the reason for this variation can not be explained, it is likely that, as opined by Williams and Hoagland (1982), this may be due to differences in seed size, seed coat permeability, differential uptake, and metabolism. However, any inference in this regard requires further investigation.

Additionally, seedlings grown with either of the compounds showed browning of the root tip and root–shoot (hypocotyl) zones. Whether this resulted from increased reduction of ascorbic acid in the xylem vessels, as thought by Rice (1984), or from simple oxidation of phenolic compounds needs further study. In spite of earlier suggestions regarding the probable effects of flavanoids on different physiological parameters (Koeppe and Miller, 1974; Lang and Racker, 1974), mechanisms leading to suppression of seedling growth are not clear. However, the present study has shown that two compounds are potent allelochemics associated with the rhizosphere in soils of the weed. Furthermore, their role in interference of seed germination and seedling growth of crop spe-

PALATABILITY OF APOSEMATIC QUEEN BUTTERFLIES (*Danaus gilippus*) FEEDING ON *Sarcostemma clausum* (ASCLEPIADACEAE) IN FLORIDA

DAVID B. RITLAND

Department of Zoology
University of Florida
Gainesville, Florida 32611

(Received December 17, 1990; accepted March 4, 1991)

Abstract—Queen butterflies (*Danaus gilippus*) are generally considered unpalatable to predators because they sequester and store toxic cardenolides from their larval food plants. However, a major queen food plant in Florida, the asclepiadaceous vine *Sarcostemma clausum*, is shown here to be a very poor cardenolide source, and queens reared on this plant contain no detectable cardenolide. A direct evaluation of queen palatability using red-winged blackbirds indicates that *S. clausum*-reared butterflies are essentially palatable to these predators (85% of abdomens entirely eaten), indicating little protection from either cardenolides, other sequestered phytochemicals, or de novo defensive compounds. Wild-caught queens that presumably fed as larvae upon *S. clausum* and also had access to adult-obtained chemicals, such as pyrrolizidine alkaloids (PAs), were relatively palatable as well (77% of abdomens eaten); they did not differ significantly in palatability from the lab-reared butterflies. Together, these findings suggest that: (1) *S. clausum*-fed queens are poorly defended against some avian predators, and (2) for the particular queen sample examined, PAs do not contribute substantially to unpalatability. The discovery that *S. clausum*-feeding queens are essentially palatable is of additional significance because it compels a reassessment of the classic mimicry relationship between queen and viceroy butterflies. Viceroys have been shown recently to be moderately unpalatable; therefore, the established roles of model and mimic may be reversed in some cases.

Key Words—Chemical defense, mimicry, cardenolides, pyrrolizidine alkaloids, Asclepiadaceae, Lepidoptera, Danainae, *Danaus gilippus*, *Limenitis archippus*, *Sarcostemma*.

INTRODUCTION

Unpalatability and chemical defense are recurring themes in the study of arthropod antipredator strategies. Insects whose unpalatability is due solely to food-

0098-0331/91/0800-1593$06.50/0

plant-derived chemicals may possess a labile defense; species, populations, or individuals feeding on food plants that lack sufficient quantities of essential chemicals will themselves be relatively undefended (e.g., Brower et al., 1967; Brower, 1969; Bowers, 1980). Food-plant-related variation in chemical defense must significantly affect the ecology and evolution of not only the species in question, but also its predators and any mimics.

Milkweed butterflies (Nymphalidae: Danainae) are traditionally viewed as chemically defended and unpalatable, in part because their primary larval food plants (Asclepiadaceae and Apocynaceae) contain toxic and bitter cardenolides, which some danaines sequester and store for their own defense (Parsons, 1965; Reichstein et al., 1968; reviews: Ackery and Vane-Wright, 1984, and Brower, 1984). However, generalizations concerning danaine unpalatability may not be valid, because (1) species differ in their ability to sequester and store cardenolides (e.g., Brower et al., 1975; Rothschild et al., 1975), and (2) many danaine genera feed on host plants that reportedly lack cardenolides (Ackery and Vane-Wright, 1984). On the other hand, inferring that a danaine is palatable because it feeds on a cardenolide-free food plant may be spurious as well, because the butterfly could sequester other phytochemicals (as either a larva or an adult) or synthesize its own chemical deterrents. Therefore, direct investigations of palatability using relevant predators are necessary to elucidate the ecology and evolution of palatability-mediated predator–prey and model–mimic interactions.

This paper describes an investigation into the palatability of Florida queen butterflies, *Danaus gilippus berenice* (Cramer). The queen, like its better-studied congener, the monarch [*Danaus plexippus* (L.)], stores cardenolides sequestered from some of its larval food plants (e.g., Brower et al., 1975; Cohen, 1985; Ritland, 1991c). Queen larvae in Florida feed on several milkweeds (*Asclepias* spp.) with variable cardenolide contents (Roeske et al., 1976; Cohen, 1983). In addition, in central and southern Florida (where queens are most abundant), they commonly feed on asclepiadaceous vines, especially *Sarcostemma clausum* (Jacq.) Roem. & Schult. (personal observation). The cardenolide content of *S. clausum* has not been investigated, but some asclepiadaceous vines reportedly lack cardenolides (*Cynanchum*: Abisch and Reichstein, 1962; Hegnauer, 1964; *Gonolobus*: Brower et al., 1967), raising the possibility that queens feeding on *Sarcostemma* in Florida might be poorly defended.

However, as noted above, inferring the palatability of *S. clausum*-feeding queens from the cardenolide content of other asclepiadaceous vines is risky. *Sarcostemma clausum* may in fact be cardenolide-rich, or it might possess other phytochemicals (e.g., bitter polyhydroxysteroids; Hegnauer, 1964, and references within), which queens could sequester and store as distasteful deterrents. Moreover, even if *Sarcostemma*-feeding queens do not acquire defensive compounds as larvae, they may compensate via adult-obtained chemicals. Adult

queens store pyrrolizidine alkaloids (PAs) obtained from the nectar or sap of certain plants; metabolites of these PAs are crucial components of courtship pheromones (e.g., Brower et al., 1965; Pliske and Eisner, 1969; Pliske, 1975; Edgar et al., 1979). Several workers (e.g., Rothschild and Marsh, 1978; Eisner, 1980; Conner et al., 1981) have suggested an additional defensive role for these bitter-tasting and toxic (Bull et al., 1968) PAs. The effectiveness of PAs against vertebrate predators has not yet been established (Glendinning et al., 1990), but PAs do deter spider predators (e.g., Brown, 1984; Masters, 1990), and a PA-based defense in queens could potentially compensate for meager cardenolide concentrations.

Quantifying queen palatability is important from the standpoint of understanding queen–predator interactions, but it is important also because of the queen's mimicry relationship with the viceroy butterfly [*Limenitis archippus* (Cramer)] (Brower, 1958b). The viceroy has traditionally been considered a palatable mimic of the distasteful queen and an exemplar of temperate-zone Batesian mimicry (e.g., Scudder, 1870; Opler and Krizek, 1984). Recently, however, I have shown that viceroys are unpalatable to at least one avian predator (Ritland, 1991a; Ritland and Brower, 1991); therefore, if *Sarcostemma*-feeding queens possess an inadequate chemical defense, the established roles of model and mimic (in an ecological sense) may be reversed.

To clarify the palatability of queens feeding on *Sarcostemma*, I investigated (1) cardenolide content of *S. clausum*, (2) cardenolide content of queens reared on *S. clausum*, (3) palatability of *S. clausum*-reared queens to avian predators, and (4) palatability of queens from a natural population that had presumably fed as larvae upon *S. clausum* but that also had access to adult-obtained chemicals such as PAs.

METHODS AND MATERIALS

Quantitative Cardenolide Assay of Sarcostemma clausum

Sarcostemma R. Br. comprises some 22 New World species; only *S. clausum* is indigenous to Florida (see Holm, 1950, and Rosatti, 1989, for distributional data and nomenclatural history). In addition to being a primary queen food plant in southern Florida (personal observation; M.C. Minno, personal communication), *S. clausum* is a potentially important food plant for danaines in Central and South America and the Greater Antilles (Holm, 1950; Brown and Heineman, 1972).

I assayed 16 plants collected in southern Florida; four plants were sampled from each of four sites (Figure 1; voucher specimens in University of Florida Herbarium). Leaf material (~ 10 g) collected from each plant was immediately frozen in the field (on Dry Ice) to prevent enzymatic degradation of chemical

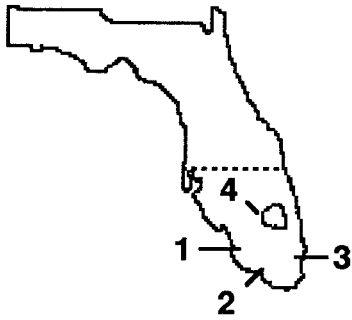

FIG. 1. Florida collection sites of *Sarcostemma clausum* for cardenolide spectroassay. Latitude and longitude data from U.S. Geological Survey maps. Dotted line represents approximate northern distributional limit of *S. clausum* (determined from University of Florida, University of South Florida Herbarium data). **1:** Lee Co., Hwy. 82, 16 km E of Fort Myers. 26° 34′ N, 81° 41′ W. **2:** Collier Co., jct. Hwy. 41 & 29. 25° 56′ N, 81° 22′ W. **3:** Dade Co., Hwy. 27 at Miami Canal. 25° 56′ N, 80° 26′ W. **4:** Glades Co., Hwy. 78, 9 km N of Hwy. 27. 26° 56′ N, 81° 7′ W.

constituents. After drying for 16 hr at 60°C, leaves from each plant were ground separately, and samples of ~0.4 g ground leaf material were extracted individually (in 10 ml 95% ethanol) in a shaker bath for 1 hr at 75–78°C. The standard spectroassay protocol (as modified by Malcolm et al., 1989) was employed to quantify cardenolide content (as digitoxin equivalents) of each sample.

Butterfly Rearing

Forty-four *S. clausum* plants were propagated from cuttings and root stock taken from ~25 plants in Collier and Glades Counties, Florida in May and October 1988 (sites 2 and 4, Figure 1). Several of these plants were propagated from the same wild plants sampled for cardenolide spectroassay. Plants were grown in pots under ambient conditions in Gainesville, Florida; I assumed that their chemical constitution approximated that of plants growing naturally. Progeny of six female queens (*ex* Collier/Glades Counties, October–November 1988) were randomly distributed among *S. clausum* plants. Plants were arranged so that larvae could move between plants and choose which leaves to eat, as they do in nature (personal observation). Thus, this study does not attempt to maintain a chemical connection between individual plants and butterflies, but rather assesses palatability of an artificial butterfly population feeding on a population of plants. Larvae were reared under ambient laboratory conditions in Gainesville, Florida, and were transferred to new plants before old ones were severely defoliated (to reduce the possibility of induced chemical defenses in the plants; e.g., Wratten et al., 1988). Butterflies were frozen one day after emergence and

stored with care to avoid desiccation (Ritland, 1991c). Red-winged blackbirds treat freshly killed and previously frozen queens in like manner, suggesting that the queen's chemical defenses are not degraded by freezing (Ritland, 1991c).

Quantitative Cardenolide Assay of S. clausum*-Reared Queens*

I assayed 12 butterflies reared on *S. clausum* to determine whether they concentrated cardenolides to higher levels than those found in the plants. Previously frozen butterflies were dried for 16 hr at 60°C, ground in petroleum ether using a tissue homogenizer, and then extracted in a shaker bath with petroleum ether for 30 min at 35–37°C to remove lipid. Lipid extraction reportedly removes negligible cardenolide (Nishio, 1980; Nelson and Brower, unpublished data). The ground butterflies were then individually extracted in 10 ml 95% ethanol in a shaker bath for 1 hr at 75–78°C, and each butterfly was individually assayed using standard spectrophotometric techniques (methods of Brower et al., 1972; modified by Brower et al., 1975, and Malcolm et al., 1991).

Palatability of S. clausum*-Reared Queens*

The role of cardenolides in danaine defense is well documented, and Brower et al. (1967, 1968, 1972), employing a combination of bioassays and spectroassays of butterflies from natural populations, demonstrated the existence of a cardenolide-based palatability spectrum in monarch butterflies. However, the possibility of de novo defensive chemicals or storage of other phytochemicals precludes reliable inference of butterfly palatability from food plant cardenolide content. Therefore, I directly assessed the palatability of *S. clausum*-reared queens (compared to palatable control butterflies) by presenting them to generalist avian predators: wild-caught male red-winged blackbirds, *Agelaius phoeniceus* (L.), Icteridae. Ritland and Brower (1991) discuss the ecological relevance of these predators.

I employed a rigorous new bioassay protocol that successfully evaluates palatability while eliminating several potential confounding factors: predators' previous experience with butterflies, aversions learned during the experiment, neophobia (fear of novel prey), and presentation order effects (Ritland, 1991c). Methodological details are presented elsewhere (Ritland, 1991c), but a key feature of my protocol was that I presented only butterfly abdomens to the birds. Birds were therefore likely to accept or reject butterflies based on postattack (gustatory) cues, rather than on visual (wing pattern) cues that they might have previously been conditioned to accept or reject in the wild. (The suitability of abdomens as estimators of whole-butterfly palatability is considered below).

Bird capture, acclimation, and training are detailed by Ritland (1991c). I conducted the experiments in specialized cages (see Coppinger, 1970) equipped with (1) a rotating "lazy-susan" device containing 12 feeding cups for butterfly

presentation and (2) one-way glass to facilitate observation. On each of two consecutive days, each bird received three *S. clausum*-reared queen abdomens randomly interspersed with three abdomens of palatable control butterflies (for a total of six queens and six controls per bird). Controls were species known to be palatable to red-wings (Ritland, 1991b): *Anartia jatrophe* (Johansson), *Phoebis sennae* (L.), *Urbanus proteus* (L.), *Papilio palamedes* Drury, and *P. glaucus* (L.). Abdomens were presented individually in the rotating feeding dishes for 12 sec at 10-min intervals.

Palatability Indices. When an abdomen was presented, I scored the bird's response as: 0 = not touched (sight-rejected), 1 = pecked once (taste-rejected), 1.5 = pecked repeatedly but not eaten, 2 = partly eaten, or 3 = entirely eaten. Thus, higher response scores indicate more vigorous attacks. If the bird ate the abdomen entirely, I recorded manipulation time (from initiation of attack to swallowing). Finally, I recorded the incidence of distress behavior (head-shaking, feather-ruffling, and vigorous bill-wiping) exhibited by each bird in response to controls and queens. Such reactions are commonly observed when birds encounter distasteful prey (e.g., Bowers, 1981; Schlee, 1986).

Each bird's responses to queens and controls were individually summarized by calculating mean response score, mean manipulation time, and percentage of trials eliciting distress behavior. I compared queens to controls via paired-sample t tests (corrected for unequal variance if necessary). In all comparisons, I tested a null hypothesis of no difference, and all probability values reported are two-tailed.

Controlling for Potential Differences in Bird Taste Sensitivity. To ensure that these particular birds were capable of tasting and rejecting defensive chemicals in butterflies, I assessed their reactions to two reference species: viceroys reared on *Salix caroliniana* Michx. and monarchs reared on *Asclepias curassavica* L. In earlier experiments, other red-wings treated viceroys as moderately unpalatable (40% eaten) and *A. curassavica*-reared monarchs as very unpalatable (6% eaten). Each bird in the current experiment received two viceroy and two monarch abdomens (in that order) at the end of the experiment, and their responses were compared to those of the red-wings used in previous feeding experiments.

Palatability of Wild-Caught Adult Queens

Adult queens were collected in Glades County, Florida (Figure 1, site 4) in November 1988. Extensive searching in the area yielded only *S. clausum* as a potential larval host plant. I therefore assumed that these butterflies fed as larvae upon *S. clausum*, and that they differed from my lab-reared queens primarily in having had local access to adult-obtained compounds such as PAs. Potential PA sources in the area at the time of queen collection included *Cro-*

talaria spectabilis Roth. and *C. retusa* L. (Fabaceae), senescent *Senecio glabellus* Poir. (Asteraceae), and *Eupatorium* spp. (Asteraceae). No queens were directly observed visiting these plants, but queens sampled from this site earlier in the year did contain variable PA concentrations (Ritland, 1991c).

I assessed the palatability of wild-caught queens in an experiment employing the same protocol outlined above; I used eight new red-wings, each of which received (over two consecutive days) six wild-caught queen abdomens randomly interspersed with six abdomens of the previously listed palatable control species. Palatability indices and statistical comparisons were as in the reared-queen experiment. These birds also received abdomens of *A. curassavica*-reared monarchs and *S. caroliniana*-reared viceroys at the end of the experiment to assess their taste sensitivity.

RESULTS

Sarcostemma clausum *Cardenolide Content*

Spectroassays revealed that seven (44%) of the 16 plants sampled contained no detectable cardenolide in their leaves (Table 1). The remaining nine plants registered peak absorbances of only 0.018–0.049, indicating very low cardenolide concentrations ranging from 2.2 to 12.5 μg (digitoxin equivalents) per 0.1 g dry leaf material. The mean cardenolide concentration of all 16 plants was only 3.8 μg/0.1 g dry weight (dw) (SD = 4.3), or 0.004%; mean concentration of the nine nonzero plants was 6.8 μg/0.1 g dw (SD = 3.4). Even these low concentrations may be overestimates, because of potential interference from coextracted phytochemicals (see also Cohen, 1983). Unless queen larvae are extremely efficient at concentrating cardenolides from their food plant, it seems unlikely that such low levels could contribute significantly to a butterfly's chemical defense (see palatability data, below). No significant difference in cardenolide concentration existed among plants from the four sites (Kruskal-Wallis one-way analysis, $H = 1.68$, $df = 3$, $P > 0.5$; but sample sizes are small). It is possible that elsewhere in its broad geographic range, *S. clausum* contains higher cardenolide levels or that cardenolide content varies seasonally as in *Asclepias* species (e.g., Nelson et al., 1981). Nonetheless, the southern Florida populations represented by these samples are evidently poor cardenolide sources for danaines.

Butterfly Cardenolide Content

Queens reared on *S. clausum* contained no detectable cardenolide; all 12 butterflies sampled registered absorbances of 0 (Table 1). They apparently were unable to concentrate the meager cardenolides of their host plant to an effective

level, similar to the situation with monarch butterflies reared on the cardenolide-free asclepiadaceous vine *Gonolobus rostratus* (Vahl) Roem. & Schult. (Brower et al., 1972).

Palatability of Lab-Reared Queens

Abdomens of the reared queens did not significantly differ from the palatable control abdomens in percentage eaten (paired-sample $t = 0.94$, $P = 0.62$) or response score ($t = 1.19$, $P = 0.27$) (Table 2, Figure 2). Six birds (75%) ate every queen abdomen offered, and only one bird was hesitant to eat the *S. clausum*-reared queens (perhaps due to previous experience or unusual sensitivity to low-level chemical defenses). Over 85% of the reared queens were entirely eaten, while 10% were dropped after a single peck (apparently taste-rejected).

[e] Percentage of trials that elicited "distress behavior" (head-shaking, etc.); see Methods and Materials for details.

Manipulation times of *S. clausum*-reared queen abdomens were significantly longer than those of control abdomens (mean time = 12.9 vs. 5.0 sec; $t = -3.2$, $P = 0.015$) (Table 2, Figure 2); this indicates that birds delayed between attacking and swallowing queen abdomens, perhaps due to low-level chemical defenses produced by the butterfly or sequestered from the larval host plant. An alternative hypothesis, that queens were manipulated longer due to their toughness, was explicitly eliminated by including two tough-textured control species (*Urbanus proteus*, *Phoebis sennae*); both of these were readily devoured without delay (mean times = 5.8 and 4.4 sec, respectively). The suggestion that the reared queens possess a low-level chemical deterrent gains support from the observation that 12.5% of queen presentations elicited distress behavior (compared to 2.1% of control presentations) (Figure 2). This level of distress behavior, while significantly greater than that observed with control abdomens ($t = 2.38$, $P = 0.048$), is considerably lower than that observed with

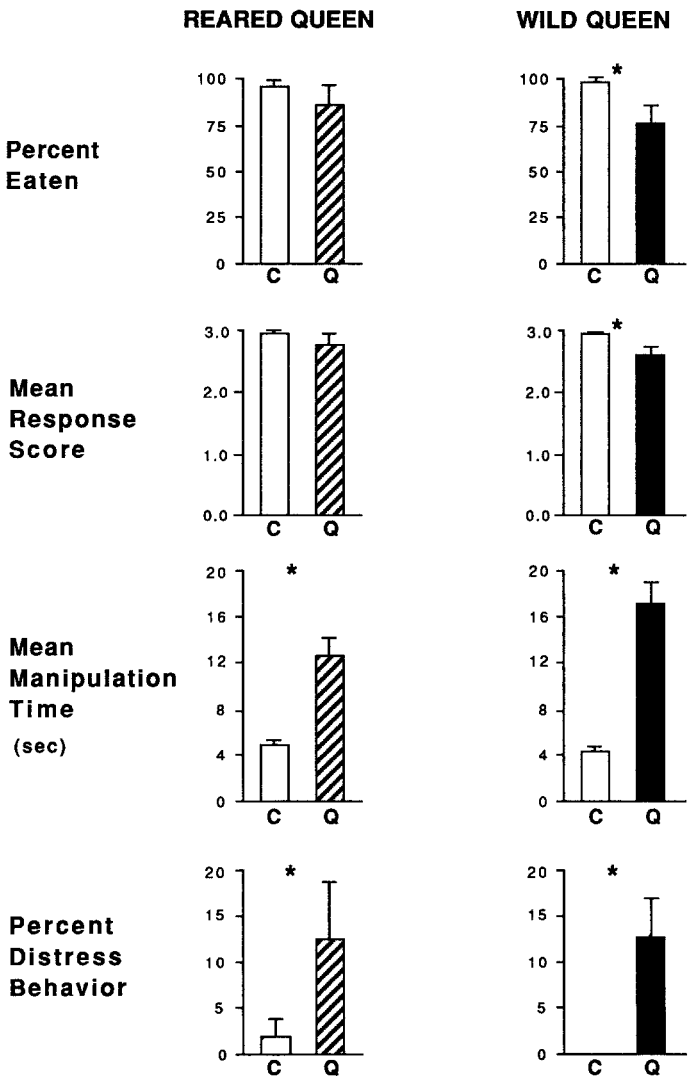

FIG. 2. Left column: Comparative palatability to eight red-winged blackbirds of control abdomens vs. abdomens of queens (*Danaus gilippus*) reared in the laboratory on *Sarcostemma clausum*. $N = 6$ controls and 6 queens per bird. See text for details on response score, manipulation time, and distress behavior. Right column: Comparative palatability to eight red-wings of control abdomens vs. abdomens of wild-caught queens that presumably fed as larvae on *S. clausum* and had access to adult-obtained defensive chemicals. $N = 6$ controls and 6 queens per bird. * indicates significant difference between queen and control (paired-sample t tests, $\alpha = 0.05$).

several other chemically defended butterflies (Brower, 1958a; Bowers, 1980; Ritland, 1991c).

Male and female queens did not differ in cardenolide content (paired-sample $t = 0.0$), percentage eaten ($t = 1.43$, $P = 0.20$), or response score ($t = 0.42$, $P = 0.68$) (Ritland, 1991c).

It is possible that *S. clausum*-reared queens were accepted because these particular red-wings were insensitive to butterfly chemical defenses in general; this explanation is eliminated by examining the treatment of *Salix caroliniana*-reared viceroys and *Asclepias curassavica*-reared monarchs offered at the conclusion of the experiment. The eight birds ate only 44% of viceroys (similar to the 40% eaten by 23 birds in an earlier study: $t = 0.23$, $P = 0.82$; Ritland, 1991b), and they ate only 12.5% of *A. curassavica*-reared monarch abdomens (similar to the 6% eaten by eight red-wings in a pilot experiment: $t = 0.61$, $P = 0.55$; Ritland, 1991c). Clearly, birds in the current experiment were capable of detecting and rejecting chemically defended butterflies.

Palatability of Wild-Caught Adult Queens

Overall, the eight red-wings ate significantly fewer wild-caught queen abdomens than control abdomens (paired-sample $t = 2.38$, $P = 0.048$), but half the birds ate every wild-collected queen abdomen offered. Seventeen percent of wild queens were taste-rejected after a single peck, and queens therefore elicited significantly lower response scores than control abdomens ($t = 2.5$, $P = 0.04$) (Table 3, Figure 2). As in the reared-queen experiment, manipulation times for wild queen abdomens were significantly longer than times for control abdomens (paired-sample $t = -4.6$, $P = 0.003$), and wild queens elicited a low but statistically significant ($t = -3.0$, $P = 0.02$) level of distress behavior (12.5%). This again suggests that a low-level chemical defense exists in the wild-caught queens. No significant difference existed between male and female wild-caught queens in percentage eaten (paired-sample $t = -1.5$, $P = 0.18$) or response score ($t = -0.8$, $P = 0.46$) (Ritland, 1991c).

As in the reared-butterfly experiment, the red-wings treated abdomens of *Salix caroliniana*-reared viceroys as moderately unpalatable; 50% were entirely eaten (similar to the 40% eaten by 23 red-wings in a previous experiment: $t = 0.67$, $P = 0.51$; Ritland, 1991b). *A. curassavica*-reared monarchs were treated as very unpalatable; 6% were entirely eaten, equaling the 6% eaten by eight red-wings in a pilot study ($t = 0.0$; $P = 1.0$; Ritland, 1991c). Therefore, the possibility that these particular birds were simply insensitive to defensive chemicals is eliminated.

Comparison of Reared and Wild-Caught Queens

My prediction that wild-caught queens (with access to pyrrolizidine alkaloids) would be substantially more distasteful than lab-reared queens was not upheld. While trends in this direction are apparent, no statistically significant difference existed between the two groups (Figure 2): (1) birds entirely ate 77% of wild queen abdomens (vs. 85% of reared queens eaten by the previous eight birds; $t = 0.60$, $P = 0.57$); (2) mean response score for wild queens was 2.60 (vs. 2.75 for reared; $t = 0.62$, $P = 0.55$); (3) mean manipulation time for wild queens was 17.6 sec (vs. 12.9 sec for reared; $t = 1.26$, $P = 0.22$); and (4) incidence of distress behavior was 12.5% in both cases ($t = 0.0$, $P = 1.0$).

Assessment of Experimental Procedure

The experimental protocol was designed to eliminate several factors that could confound assessment of palatability (see Ritland, 1991c), and it appears to have been successful: (1) No neophobia was evident; birds readily attacked and ate the unfamiliar and variously colored control abdomens. (2) No preexisting aversions were evident; every bird readily attacked the first queen abdomen it was offered, and abdomens were not rejected until after birds had tasted one or more of them. (3) Spearman rank correlation analysis indicates that no bird demonstrated a significant increase or decrease in response score over the course of its six queen presentations (Ritland, 1991c). This suggests that birds treated individual abdomens independently and did not learn to recognize them and accept or reject them based on visual cues. Therefore, I conclude that this experiment succeeded in measuring the birds' responses to palatability per se without the confounding influences of mimicry, previous experience, or learned aversions. (4) Extrapolating from palatability of abdomens in the laboratory to palatability of intact butterflies in the wild must be done cautiously. However, previous laboratory experiments comparing treatment of abdomens vs. intact butterflies reveal that the percentage of queen abdomens entirely eaten by birds approximates the percentage of intact queens at least partially eaten, i.e., killed (Ritland, 1991b). Therefore, in this system, measurements of abdomen palatability allow estimates of the relative palatabilities of intact butterflies and lend insight into the probability of a butterfly surviving an attack by a predator in the wild. (5) This paper considers the responses of a single predator species; since others may differ in sensitivity to the queen's defensive chemicals, future investigations must include other members of the predator community known or believed to exploit queen populations as prey (cf., Malcolm, 1990).

DISCUSSION

The spectroassays suggest that sampled *S. clausum* plants from southern Florida are very poor cardenolide sources, and the palatability trials indicate that queens reared on this food plant gain very little chemical defense against red-winged blackbird predators. (The possibility that these particular birds were simply insensitive to butterfly chemical defenses was eliminated by examining their treatment of viceroys and monarchs.) The observed palatability of *S. clausum*-reared queens parallels the findings of Brower et al. (1967), who showed that 100% of monarchs reared on a cardenolide-free vine, *Gonolobus rostratus*, were eaten by blue jay predators (*Cyanocitta cristata bromia* Oberholser).

The laboratory-reared queens contained no detectable cardenolide, and if

they stored other phytochemicals from their larval food plant, those apparently conferred little protection. I also found little evidence that queens synthesize their own defensive compounds in effective quantities (although significantly longer queen manipulation times and a low incidence of distress behavior suggest that perhaps they did possess low levels of distasteful noncardenolide compounds). I estimate that if these had been living butterflies, 90% of them would not have survived a bird attack (assuming that repeated pecks are fatal and discounting behavioral defenses). Previous workers have raised questions concerning the queen's cardenolide-based defense (Brower et al., 1975; Cohen, 1985), but the level of queen palatability revealed in the current experiment was surprising.

Wild-collected queens that presumably fed as larvae upon *S. clausum* and also had access to adult-obtained compounds such as pyrrolizidine alkaloids (PAs) were significantly less palatable than control butterflies, but the differences were not of great magnitude (Table 2, Figure 2). I estimate that had they been alive, 83% would not have survived their encounter with a bird (discounting behavioral defenses). Differences in palatability between wild-caught butterflies and reared ones were not statistically significant, but trends exist, and further investigation is required to determine whether wild-caught butterflies are less palatable. The comparison presented here suggests that at the point in time and space represented by the wild queen sample, PAs or other adult-obtained compounds were not a major component of chemical defense. The possibility remains, however, that PAs make substantial contributions to queen distastefulness in other areas or other seasons in which PA sources are more abundant or comprise a different array of species. Even within a single locale, seasonal changes in the flora (e.g., from *Senecio*-dominated in spring to *Crotalaria*- and *Eupatorium*-dominated in autumn) may result in quantitative and qualitative differences in the PAs available to queens. Studies of geographically and seasonally representative queen samples are needed to clarify the purported defensive value of PAs against vertebrate predators (cf. Glendinning et al., 1990; Ritland, 1991c).

Future investigations must also address the possibility that *S. clausum* varies geographically in cardenolide content or that queens vary geographically in ability to sequester defensive chemicals from it. Nonetheless, the finding that the sampled *S. clausum*-fed queens are poorly defended (chemically) against a generalist avian predator is of some significance, because *S. clausum* is a primary larval food plant throughout central and southern Florida and is probably utilized by queens in much of tropical America. Unless their unpalatability is bolstered by PAs or other adult-obtained substances, these conspicuously colored *S. clausum*-feeding queens are essentially "sheep in wolves' clothing" (Rothschild, 1972). It is unlikely that they are unpalatable enough to elicit con-

ditioned aversions in avian predators (see also Ritland, 1991c), and their conspicuous "warning" coloration may therefore be a liability rather than an advantage.

However, *S. clausum*-fed queens may not be completely vulnerable; they may gain some protection from predators via automimicry. An automimic is a palatable individual that is avoided by conditioned predators because of its resemblance to distasteful conspecifics (Brower et al., 1967). If palatable *S. clausum*-feeding individuals coexist with more distasteful queens (e.g., ones that fed on a high-cardenolide larval food plant such as *Asclepias curassavica*), and if predators have been conditioned previously to avoid the more distasteful queens, then *S. clausum*-fed queens may enjoy an automimetic advantage. The potential for automimicry in different natural populations and its possible consequences will be considered elsewhere.

The findings of this experiment are of additional significance because of the queen's mimicry relationship with viceroy butterflies. Viceroys are traditionally viewed as palatable (Batesian) mimics of queens, which have historically been considered unpalatable. However, as this experiment demonstrates, some queens are relatively palatable. Furthermore, recent studies (Ritland, 1991b; Ritland and Brower, 1991) reveal that Florida viceroys are themselves distasteful (40% of abdomens eaten in feeding experiments similar to this one); in fact, they are significantly more distasteful than the queens in the current experiment (viceroy vs. reared queen: $t = 3.2$, $P = 0.003$; viceroy vs. wild-caught queen: $t = 2.7$, $P = 0.01$). Hence, in areas where *S. clausum* is the primary food plant, queens essentially must be Batesian or very weak Müllerian mimics of relatively strong viceroy models. This postulated reversal of traditionally accepted roles suggests that some viceroy and queen populations are evolving in a very different selective milieu than previously believed; viceroys, rather than benefiting from their resemblance to queens, may suffer an elevated predation rate if palatable queens interfere with predators' aversive conditioning. Thus, the results of these experiments compel a comprehensive reanalysis of viceroy–queen mimicry dynamics. In addition, these findings prompt an investigation into the palatability of soldier butterflies, *Danaus eresimus* (Cramer), which also feed on *S. clausum* (personal observation) and which may be involved in a mimicry relationship with viceroys in Mexico (Chermock, 1947).

Acknowledgments—Lincoln Brower, Deane Bowers, and Ted Sargent provided very helpful comments on the manuscript; Robin Ritland assisted in obtaining plants, queens, and control butterflies; and Alfonso Alonso and Tonya Van Hook instructed me in spectroassay procedures. To all I am grateful. Spectroassays and palatability experiments were conducted in L.P. Brower's laboratory. Funding for travel and rearing equipment was provided by the National Geographic Society (grant 3417-86 to L.P. Brower) and a Sigma Xi grant-in-aid of research.

EXPOSURE TO ODORS FROM STRESSED CONSPECIFICS INCREASES PREFERENCE FOR HIGHER AMBIENT TEMPERATURES IN C57BL/6J MICE

DEL THIESSEN,* CHANA AKINS, and CARLOS ZALAQUETT

Department of Psychology
University of Texas
Austin, Texas 78712

(Received January 28, 1991; accepted March 8, 1991)

Abstract—Exposure to odors from stressed conspecifics increases preference for higher ambient temperatures in C57BL/6J mice. C57BL/6J male mice were individually allowed preferences on a thermal gradient ranging in temperature from 22°C to 42°C. Group 1 ($N = 10$) was exposed to odors from triads of foot-shocked conspecifics during the first 2-hr temperature preference trial. Group 2 ($N = 10$) was exposed to odors from triads of nonstressed conspecifics during similar testing. Body temperature (T_B) variations were measured in three animals of each group. Thermal preference was significantly higher for animals exposed to odors from stressed conspecifics than for animals exposed to odors from nonstressed animals (32.0°C vs. 29.0°C). T_B changes on the heated gradient were significantly higher for animals exposed to odors from stressed animals (+1.5°C) than for animals exposed to odors from nonstressed animals (−0.33°C). Additional animals on a nonheated thermogradient were tested for T_B when exposed to odors from stressed or from nonstressed animals ($N = 3$ per condition). There was no difference in T_B between these two groups. Increases in T_B on the heated gradient are apparently due to the higher ambient temperature choices and not due to the odor per se.

Key Words—Stress, odors, body temperature, ambient temperature, C57BL/6J mice, *Mus musculus*.

INTRODUCTION

Odors from animals under stress often signal injury, distress, or the presence of predators. The conspecific response to these signals is avoidance, dispersal,

*To whom correspondence should be addressed.

0098-0331/91/0800-1611$06.50/0

or increased activity (Muller-Velten, 1966; Carr et al., 1970; Rottman and Snowdon, 1972; Zalaquett and Thiessen, 1991). Observations of the gerbil, *Meriones unguiculatus*, and the mouse, *Mus musculus*, suggest a relationship between conspecific odors, physiological changes, and behavior (Cocke and Thiessen, 1986; Thiessen and Cocke, 1990). When gerbils are exposed to odor from stressed conspecifics, body temperatures are elevated about 0.38°C within 20 min. This effect is consistent with other findings that many forms of stress elevate body temperatures (Long et al., 1990). The gerbil becomes inactive when confined with the odor and will avoid the odor if given the opportunity. We have noted similar behavioral effects with BALB/cJ and C57BL/6J mice (Zalaquett and Thiessen, 1991; Zalaquett, unpublished observations). In addition, in mitogen assays of BALB/cJ mice, continuous exposure to odors from stressed mice for 24 hr results in immunological suppression of T-cell proliferation (Thiessen and Cocke, 1990).

These observations led us to speculate that animals may benefit from increased body temperatures. This appears true for animals exposed to pathogens and may also be the case for exposure to stressful stimuli. When a pathogen invades the body, the initial response often observed among most mammals is an increase in body temperature (Jampal et al., 1983). The febrile response is adaptive in that the spread of the infection is retarded and longevity is increased (Covert and Reynolds, 1977; Hart, 1988; Kluger et al., 1975; Kluger and Vaughn, 1978). Benefits are gained by the reduction of blood levels of iron and zinc, which are necessary for the proliferation of pathogens (Hart, 1988, 1990; Kluger, 1989). Increased body temperature also facilitates T-cell activity and interferon synthesis, and thus brings the force of the immune system into play at an early stage of infection (Downing et al., 1988; Duff and Durum, 1982).

Recent studies in this laboratory show that C57BL/6J mice seek out a higher ambient temperature when exposed to lipopolysaccharide (LPS) or to the odors from animals made ill with LPS (Akins et al., 1991; Akins and Thiessen, 1990). The similarity of reactions suggests that animals exposed to odors from stressed animals may also cause the recipients to seek higher ambient temperatures, a reaction that may facilitate immune responses.

This study tests the possibility that C57BL/6J mice subjected to body odors from stressed conspecifics will increase their temperature preferences and hence their body temperatures.

METHODS AND MATERIALS

Subjects. Fifty male C57BL/6J mice, approximately 60 days of age at the beginning of the study, were obtained from the Animal Resources Center at The University of Texas at Austin. Mice were housed in colony cages mea-

suring 16 × 16 × 13.5 cm at 26°C ambient temperature and 40% relative humidity, with ad libitum food and water under a 12:12 hr light–dark cycle. Twenty-four of these mice were assigned randomly to form four triads of stress odor (SO) donors and four triads of control odor (CO) donors. The remaining 26 animals were divided randomly into four groups housed individually and assigned one of the following conditions:

Group 1 ($N = 10$): stress odor recipients placed on the preheated temperature gradient. Body temperature was measured in three of these recipients (see Procedure below).

Group 2 ($N = 10$): control odor recipients placed on the preheated temperature gradient. Body temperature was measured in three of these recipients.

Group 3 ($N = 3$): stress odor recipients placed on the nonheated temperature gradient, measured for body temperature.

Group 4 ($N = 3$): control odor recipients placed on the nonheated temperature gradient, measured for body temperature.

Thus, animals were tested for temperature reactions to the stress and control odors and for changes in body temperature due to odor exposure or to temperature gradient exposure.

Test Apparatus. A schematic of the temperature gradient apparatus as described by Thiessen et al. (1970) is shown in Figure 1. The gradient was constructed of metal, measuring 147.3 cm in length and 11.4 cm in width. A tube attached to the bottom of the gradient carried water at room temperature one fourth the length of the gradient. Metal heating tapes were placed along the bottom adjacent to the water conduit and were spaced so that the temperature of the gradient ranged from 22°C to 42°C when heated. The heating tapes were regulated with a rheostat, and the gradient runway was enclosed with a removable Plexiglas hood.

The odor donor chambers (enclosed in a cabinet that precluded any visual or auditory contact between donors or experimental subjects) measured 50.6 × 30.8 × 30.8 cm and were sealed with weatherstripping. Colony cages, provided with wood shavings and Purina Lab Chow, were placed inside the donor chambers. The donor chambers were connected to the temperature gradient with Tygon tubing. Airflow from the donor chambers entered at the runway and was vacuumed out at a rate of 7–8 liters/min. The apparatus was housed in the test room adjacent to the colony room. The test room was maintained at room temperature (26°C).

An RCA video camera attached to an RCA video recorder monitored the behavior of animals on the temperature gradient. A Bailey type T probe needle (model BAT-12) was used to measure preferred ambient temperature along the length of the gradient.

Body Temperature Measurements. Biotelemetry devices (Mini-mitter thermistors model M) were used to measure mouse body temperature (T_B) (Thiessen

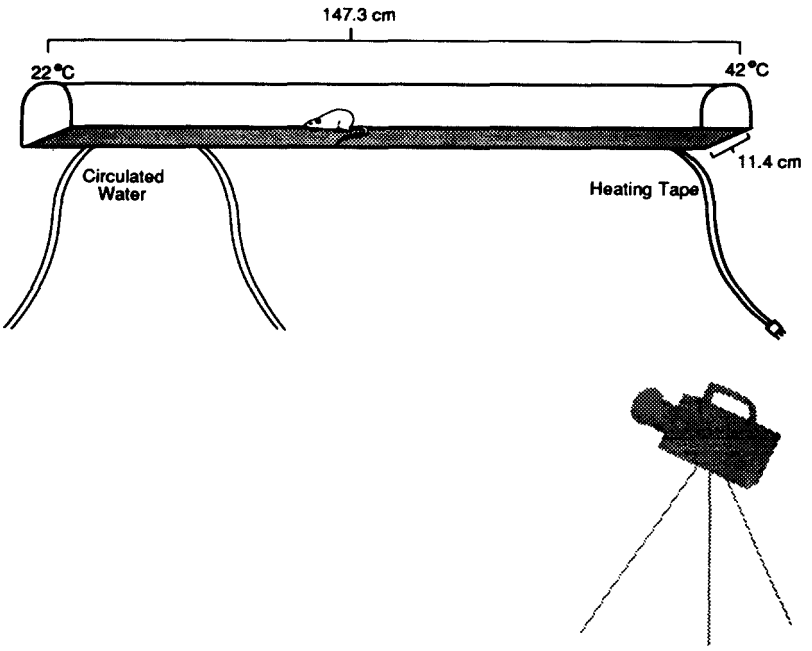

FIG. 1. Schematic diagram of the temperature gradient apparatus.

and Kittrell, 1980). Mini-mitters were reduced in size to accommodate mice by removing the plastic capping and coating the transmitter and battery with candle wax. These thermistors then were calibrated individually over a range of 11°C to 41°C in three steps. The interval between audible beats, which is temperature sensitive, was counted in milliseconds using a receiver and standard AM radio during testing and converted to body temperature using calibration data. As the termistor increases in temperature, the interval between beats decreases.

Mini-mitters were surgically implanted under anesthesia five days prior to testing. A calibrated thermistor was inserted into the interperitoneal cavity through a small incision on the right abdominal surface. The wound was sutured and mice were allowed to recover.

Shock Apparatus. The foot-shock apparatus was constructed of stainless steel with Plexiglas walls. The apparatus measured 24 × 24 × 35 cm with 0.2-cm stainless-steel grid bars spaced 0.4 cm apart forming the floor. Scrambled foot shock was supplied to the floor of the chamber by the Lafayette foot-shock apparatus (model 82404/5 SS). Shock parameters for the individual animals were three successive, 7-sec scrambled electric shocks, separated by a 60-sec rest interval (0.5 mA, 600 V).

Procedure. On the day of testing, mice were transferred from the colony

room to the test room. The temperature gradient apparatus was either preheated for 2 hr prior to testing or left at room temperature (nonheated) during the test period. Each triad of the control odor donors was habituated in the donor chamber with the active airstream 1 hr prior to testing. Each recipient mouse was placed individually on the gradient for 2 hr and received either odor from stressed donors or odor from control donors. Odors were introduced into either end of the gradient (warm or cool) in a random order to eliminate any possible position bias. Temperature preference was defined as that temperature where the mouse first rested for at least 5 min. Body temperature was recorded preceding each trial and immediately after each trial. The two groups were equated for original body temperature.

RESULTS

A *t* test for independent samples was used to test for differences in preferred ambient temperature between SO and CO recipients. These data are seen in Figure 2. Animals that received the odor from stressed conspecifics preferred

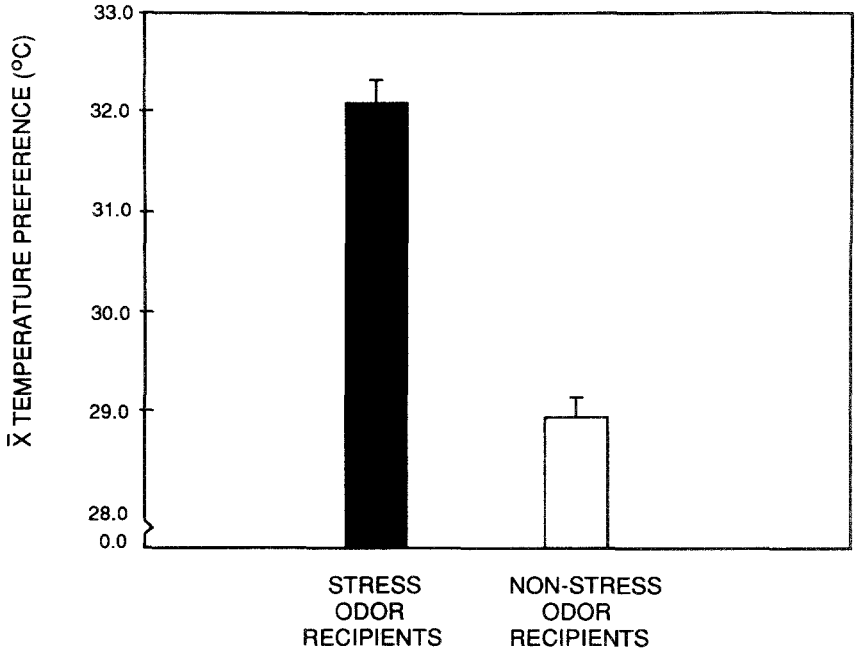

FIG. 2. Preferred ambient temperature (°C) of mice exposed to stress odors or control odors from conspecifics.

a significantly higher mean ambient temperature (32.0 ± 0.17°C) than those that received the nonstressed odors of conspecifics (29.0 ± 0.16°C), ($t = 15.53$, $df = 18$, $P < 0.005$). The difference in initial body temperature and the body temperature after each trial (2 × 2 ANOVA) was compared with SO and CO mice placed on a heated gradient and with SO and CO mice placed on a nonheated gradient. The variations in T_B between the four groups were significant ($F = 10.96$, $df = 3, 8$, $P < 0.005$). Stress odor recipients on a heated gradient had a significantly greater mean T_B increase (+1.5°C) than CO recipients on the heated gradient (−0.33°C). In addition, these SO recipients placed on the heated gradient had a greater mean T_B increase than SO recipients on the nonheated gradient (−0.33°C) and CO recipients on the nonheated gradient (−0.17°C). These data are seen in Figure 3. Among animals exposed to a heated temperature gradient (SO and CO combined), there was a significant relationship between temperature preference and T_B ($r = 0.89$, $df = 3, 8$, $P < 0.005$).

Thus, animals exposed to odors from stressed conspecifics chose a higher temperature preference on the gradient, and as a result of this preference, showed a higher body temperature.

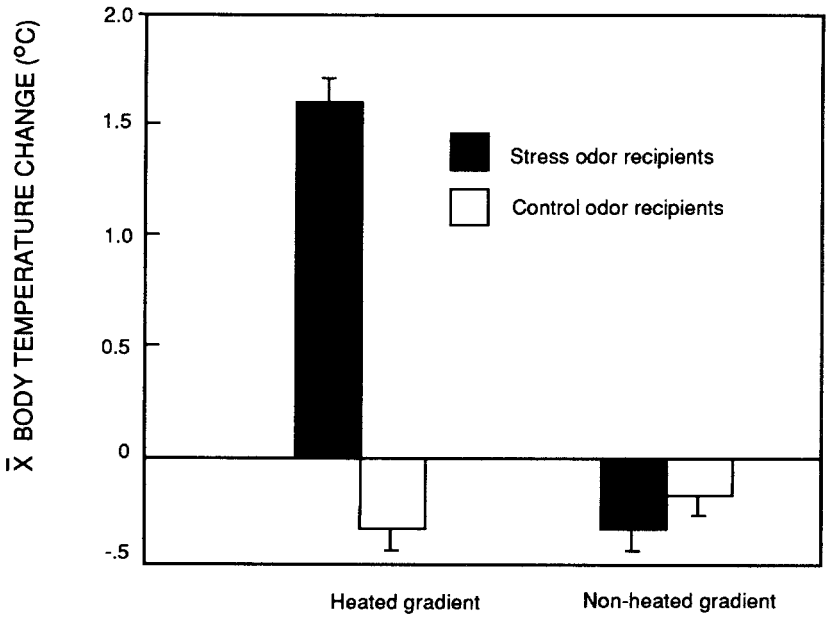

FIG. 3. Difference between initial and posttrial body temperature (°C) of stress odor and control odor recipients on a heated gradient or nonheated gradient for 2 hr.

DISCUSSION

C57BL/6J mice prefer a higher ambient temperature when subjected to the odors of stressed conspecifics. The consequence of the choice is an elevation in body temperature.

The behavioral choice of a higher ambient temperature may be adaptive. Many forms of stress are known to elevate body temperature (Long et al., 1990). In the case of odors from the stressed mice, the intensity of the stress may not be sufficient to evoke an increase in body temperature. The recipient animal may, however, gravitate toward a warmer environment, thus accomplishing the same effect.

The self-induced elevation of body temperature may indicate that the reaction to an odor from a stressed conspecific is a reflection of a more general process. Mice made ill with lipopolysaccharide, or those subjected to the odors from these individuals, also seek out a higher ambient temperature (Akins et al., 1991; Akins and Thiessen, 1990). The elevation of body temperatures that accompanies this behavior may be beneficial. Increased body temperature can, for example, limit the devastating effects of invasive organisms (Hart, 1988, 1990), and it also can facilitate T-cell activity and the synthesis of interferon (Downing et al., 1988; Duff and Durum, 1982). Hart (1988) makes the important point that animals may elevate their body temperature prophylactically when threatened with pathogen invasions.

Our observations suggest that mice react prophylactically to the possible consequences of a stress odor. Perhaps the self-induced elevation in temperature protects the mice from damage that might occur directly from the odor or from the consequences of immune depression. Animals subjected to stress are more vulnerable to disease (Hart, 1990; Khansari et al., 1990), and febrile temperatures can limit the spread of pathogens and stimulate the immune system (Hart, 1988, 1990; Downing et al., 1988; Duff and Durum, 1982).

Stress effects and consequences of pathogenic invasion often seem similar. Both cause an initial depression of T-cell and B-cell activities; both involve the activity of the pituitary–adrenal system; both elevate body temperature; and both trigger events that eventually facilitate immunoreactivity (Khansari et al., 1990; Hart, 1988).

From this perspective, what the animals appear to be doing is reacting to stress as if it were a pathogenic attack, or as if such an attack were imminent. Since disease often follows stress, it would be adaptive if the organism made no distinctions between stress and pathogenic invasion. Elevation of body temperature, either by systematic or behavioral means, could be an important initial response.

For this hypothesis to survive, it must be demonstrated that animals stressed by an odor have an advantage when they choose a higher ambient temperature.

Either their resistance to a disease must increase or their ability to cope with disease must be improved.

EFFECT OF OVIPOSITION DETERRENTS FROM ELDERBERRY ON BEHAVIORAL RESPONSES BY *Heliothis virescens* TO HOST-PLANT VOLATILES IN FLIGHT TUNNEL[1]

F.C. TINGLE* and E.R. MITCHELL

(Received January 11, 1991; accepted April 15, 1991)

Abstract—In flight-tunnel assays, mated female *Heliothis virescens* (F.) moths responded by positive anemotaxis to volatiles from extracts of two host plants (cotton and tobacco), but they did not fly to an extract from elderberry (*Sambucus simpsonii* Rehd.), a nonhost that contains an oviposition deterrent for *H. virescens*. When the elderberry extract was mixed with extract from either cotton or tobacco, the flight response by moths to volatiles emanating from the extract blends was reduced significantly at most doses when compared to the positive response to extracts from either host alone. The number of landings (including brief contacts) and landings that resulted in oviposition on the substrates treated with extract blends also were reduced significantly in most tests.

Key Words—Plant attractant, plant–insect interaction, plant extracts, cotton, tobacco, elderberry, *Heliothis virescens*, Lepidoptera, Noctuidae.

INTRODUCTION

Recent studies in environmentally controlled systems have demonstrated that mated *Heliothis virescens* (F.) and *H. subflexa* (Gn.) females respond to allelochemicals from cultivated and wild host plants for host-finding and oviposition. Tingle et al. (1989) demonstrated in flight-tunnel assays that *H. subflexa*

*To whom correspondence should be addressed.

[1] This article reports the results of research only. Mention of a proprietary product does not constitute an endorsement or the recommendation of its use by USDA.

females showed positive anemotaxis (i.e., upwind flight) toward the odor source in the presence of volatiles from an extract of leaves from their only known host, *Physalis* spp. (groundcherry). Then Tingle et al. (1990) showed in dual-choice tests that *H. subflexa* females demonstrated a significant preference for volatiles from extracts of groundcherry and that *H. virescens*, a polyphagous species, responded positively by anemotaxis to extracts from susceptible tobacco, cotton, *Desmodium tortuosum* (Swartz) de Candolle (host plants), and groundcherry (nonhost). When given a choice between volatiles from extracts of leaves from a susceptible tobacco cultivar and from a resistant cultivar, the *H. virescens* females did not fly to volatiles emanating from the resistant tobacco cultivar. Furthermore, Mitchell et al. (1991) showed in no-choice tests that *H. virescens* females responded positively via upwind flight in laboratory assays to volatiles emitted from methylene chloride washes of leaves from cotton, tobacco, and *D. tortuosum*, a weed species. They found that, except for *D. tortuosum*, the response was positive and linear with dose.

Earlier, Jackson et al. (1984) reported that whole-leaf cuticular washes from green leaves of a flue-cured tobacco stimulated oviposition by *H. virescens* when sprayed onto leaves of a resistant tobacco strain. Mitchell and Heath (1987) demonstrated that methanol extracts of washes from whole leaves of groundcherry increased egg deposition by *H. subflexa* on treated tobacco plants (a nonhost) 8.5-fold over untreated controls. These results were consistent whether the extract was evaluated on plants in greenhouse-cage tests or on broadcloth as the substrate in an olfactometer that they developed for oviposition behavioral studies. Using this olfactometer, Mitchell et al. (1990) found that extracts prepared with methylene chloride washes of cotton squares (flower buds) and leaves from cotton, tobacco, *D. tortuosum* (host plants), and groundcherry (nonhost), stimulated oviposition by *H. virescens*. The *H. subflexa* moths were stimulated to oviposit by groundcherry extract, its normal host, and extract from cotton squares, a nonhost.

In contrast to the studies with the chemicals that attract *H. virescens* and *H. subflexa* to their host or stimulate oviposition upon arrival, Tingle and Mitchell (1984, 1986) reported that extracts from various indigenous plants, including elderberry (*Sambucus simpsonii* Rehd.), acted as oviposition deterrents for *H. virescens*. They found that extracts prepared from homogenized elderberry leaves with either acetone, distilled water, ethanol, hexane, methanol, or methylene chloride deterred oviposition by *H. virescens* on treated substrates in laboratory choice tests. In field-cage bioassays, moths laid significantly fewer eggs on tobacco leaves treated with elderberry leaf–water extract than on untreated leaves on the same plant.

Thiery and Visser (1986) found that blending of odors from nonhost species, namely wild tomatoes, *Lycopersicon hirsutum* f. *glabratum* C.H. Mull, or cabbage, *Brassica oleracea* L. var. *gemmifera* D.C., with the attractive plant

odor of potato plants, *Solanum tuberosum* L., blocked the release of upwind responses by female Colorado potato beetles, *Leptinotarsa decemlineata* Say. They reported that the neutralization of the beetle's orientation response was obtained without repellency. Renwick and Radke (1987) discussed how acceptance or rejection of a plant by gravid cabbage butterflies, *Pieris rapae* L., may depend on the balance of positive and negative chemical stimuli, if both are present, within the plant. The present study was undertaken to determine if blending of the volatiles from a nonhost (elderberry), which contains an oviposition deterrent (Tingle and Mitchell, 1984, 1986), with attractant volatiles from host plants (cotton or tobacco) affects the olfactory orientation or other behavioral responses by mated *H. virescens* in the flight tunnel.

METHODS AND MATERIALS

A 60 × 60 × 195-cm Plexiglas flight tunnel (Tingle et al., 1989) was used to observe the effect of an oviposition deterrent from elderberry (Tingle and Mitchell, 1984, 1986) on the flight response of mated *H. virescens* females to volatiles from crude extracts of host plants (Tingle et al., 1990; Mitchell et al., 1991). Extracts were prepared from elderberry (native), cotton (variety McNair 220), and tobacco (NC 2326) by washing ca. 400 g of fresh plant material for 30 sec in 1 liter of methylene chloride, which was filtered and stored in 1-liter glass containers at 0°C until needed (Mitchell and Heath, 1987). Collections of plant material were made from cotton and tobacco plants that were located in cultivated field plots and from natural stands of elderberry. The cotton and elderberry plants were in the flowering stage, and tobacco was in the prebloom stage. The flowering stage of host plants has been shown as the most preferred phenological state by *Helicoverpa zea* (Boddie) (Johnson et al., 1975) and *H. armigera* (Hübner) (Roome, 1975).

Methylene chloride was used as the solvent for removing components from cotton squares (flower buds) and whole leaves of tobacco and elderberry (Mitchell et al., 1990, 1991; Tingle et al., 1990). Before testing, the extracts were concentrated in a rotary evaporator to 1-g equivalent (1 gE) per 200 μl solvent.

All test insects were reared in our laboratory colony on modified pinto bean diet using the methods described by Guy et al. (1985) and Mitchell et al. (1988). This *H. virescens* colony was started in 1987 (Mitchell et al., unpublished data) from field-collected insects; new genetic material from the field has been added each year since then. For testing, the adults were confined upon eclosion for mating (21 pairs) in 5.5-liter plastic cages with screened tops and held under a reversed 14 : 10 hr light–dark cycle in a holding room that was maintained at 25–26°C and 60–70% relative humidity.

On the day of testing, the moths were sexed by gently squeezing the abdo-

men to extrude the genitalia. The females were then confined in a 25 × 25 × 25-cm Plexiglas holding cage and placed in the flight tunnel room (3 × 2.6 × 2.1 m) ca. 1 hr before scotophase. An intake vent in the wall allowed a continuous flow of fresh unfiltered air from the outside into the room, which was maintained at the same environmental conditions as the holding room. An electric timer was used to control overhead fluorescent lights (two banks of two 40-W bulbs). Three 25-W red light bulbs that were equally spaced above the tunnel remained on continuously and provided a light level of 2.4 lux inside the tunnel. Air was pulled through the tunnel at ca. 0.4 m/sec and exhausted ca. 3 m above the roof covering the flight tunnel room via a 30-cm-diam. flexible pipe.

A test was begun by introducing into the tunnel 1 gE of extract from either cotton, tobacco, or elderberry alone, or 1 gE cotton or tobacco in combination with 1, 2, or 3 gE of elderberry extract, on an evaporator substrate (white muslin) that covered the end of a glass cylinder dispenser with a 3.5-cm opening. When a combination of two extracts was applied to the substrate, they were mixed together just prior to application. After waiting 5 min for the solvent to evaporate, the dispenser was placed at the upwind end of the tunnel. Air was blown through the cylinder with an aquarium pump at the rate of 1 liter/min. to provide a continuous flow (plume) of the extract odor through the tunnel. The location and form of the plume was verified previously by introducing smoke into the dispenser system and observing the smoke trail.

Each moth was removed from the holding cage and placed into a cylindrical 4 × 6.5-cm plastic cage with screened ends. After placement of the release cage into the downwind end of the flight tunnel, the moth was released immediately and observed for 2 min. Behavioral responses, including random and oriented flight, contacts and landings, and oviposition on extract-treated substrates, were recorded. Six replicates of six or eight (mean = 7.2) *H. virescens* females per replicate were tested individually in each treatment. One replicate of the three treatments in one or more tests was completed daily. Tests with untreated controls were conducted periodically to ensure that response to the dispenser substrate (white muslin) was negligible when treated with solvent only and that contamination of the bioassay system had not occurred. A limited supply of test insects prevented daily bioassays with untreated controls.

The following treatments with the indicated doses of elderberry extract were conducted to determine the effect of oviposition deterrents from elderberry (Tingle and Mitchell, 1984, 1986) on the flight response by mated *H. virescens* females to volatiles from extracts of cotton (1 gE) in tests 1–3 and tobacco (1 gE) in tests 4–6:

Test 1. Extracts: cotton, elderberry (1 gE), and cotton–elderberry (1 gE) mixture.

Test 2. Extracts: cotton, elderberry (2 gE), and cotton–elderberry (2 gE) mixture.

Test 3. Extracts: cotton, elderberry (3 gE), and cotton–elderberry (3 gE) mixture.

Test 4. Extracts: tobacco, elderberry (1 gE), and tobacco–elderberry (1 gE) mixture.

Test 5. Extracts: tobacco, elderberry (2 gE), and tobacco–elderberry (2 gE) mixture.

Test 6. Extracts: tobacco, elderberry (3 gE), and tobacco–elderberry (3 gE) mixture.

The data from the three treatments in each test were converted to arcsine $\sqrt{x}$ and analyzed using ANOVA (Steel and Torrie, 1960). Treatment means were separated using Duncan's multiple-range test (Duncan, 1955).

After a deterrent effect by volatiles from elderberry extract on the positive response by *H. virescens* to host-plant extracts in the flight tunnel was detected, the percent reduction in flight response was calculated as follows (HPE = host plant extract; EBE = elderberry extract):

$$\frac{\%\text{ response to HPE} - \%\text{ response to HPE with EBE}}{\%\text{ response to HPE}} \times 100$$

These data were analyzed for significance between responses to substrates treated with host-plant extracts and host-plant extracts combined with elderberry extract, using Student's paired t test (Steel and Torrie, 1960).

RESULTS AND DISCUSSION

The mated *H. virescens* females demonstrated a significant flight response by positive anemotaxis to host-plant volatiles in tests 1–6 (Figures 1 and 2) as expected. However, the moths showed no significant flight response to volatiles from elderberry at the three dosages tested. Moreover, when either 2 gE (test 2) or 3 gE (test 3) of elderberry extract was combined with 1 gE of cotton extract, significantly fewer moths flew to the extract mixture than the 47–67% that flew to the cotton extract alone (Figure 1). This resulted in reductions of 43% and 49%, respectively, in flight response to the cotton extract when 2 or 3 gE of the elderberry extract were combined with 1 gE of the extract from cotton (Table 1). No significant reduction in flight response was observed when 1 gE of the elderberry extract (test 1) was used in combination with 1 gE of cotton extract.

When extract from tobacco was used as the attractant (tests 4–6), 50–60% of the *H. virescens* females showed a positive flight response to the tobacco

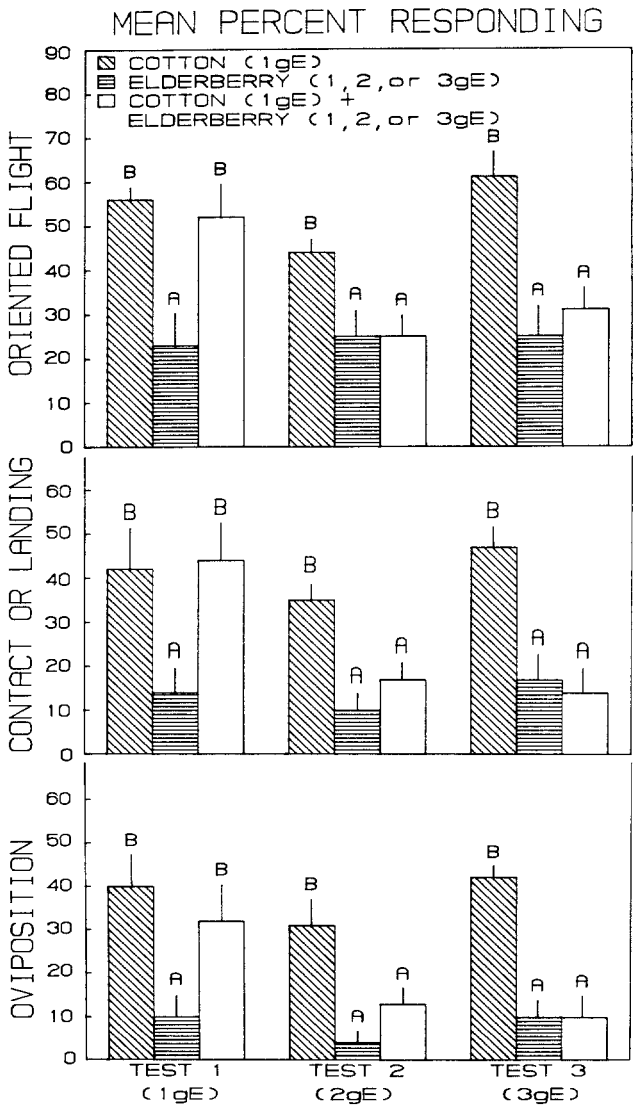

FIG. 1. Mean percentages of *Heliothis virescens* females responding to plant extracts in no-choice tests. Cotton extract (1 gE) was used as the attractant and 1, 2, or 3 gE of elderberry extract was used alone or in combination with cotton extract (1 gE) in tests 1, 2, and 3. Means within each test with the same letter are not significantly different, $P < 0.05$ [ANOVA, Steel and Torrie (1960); Duncan's multiple-range test (Duncan 1955)]. Vertical lines indicate standard error of means.

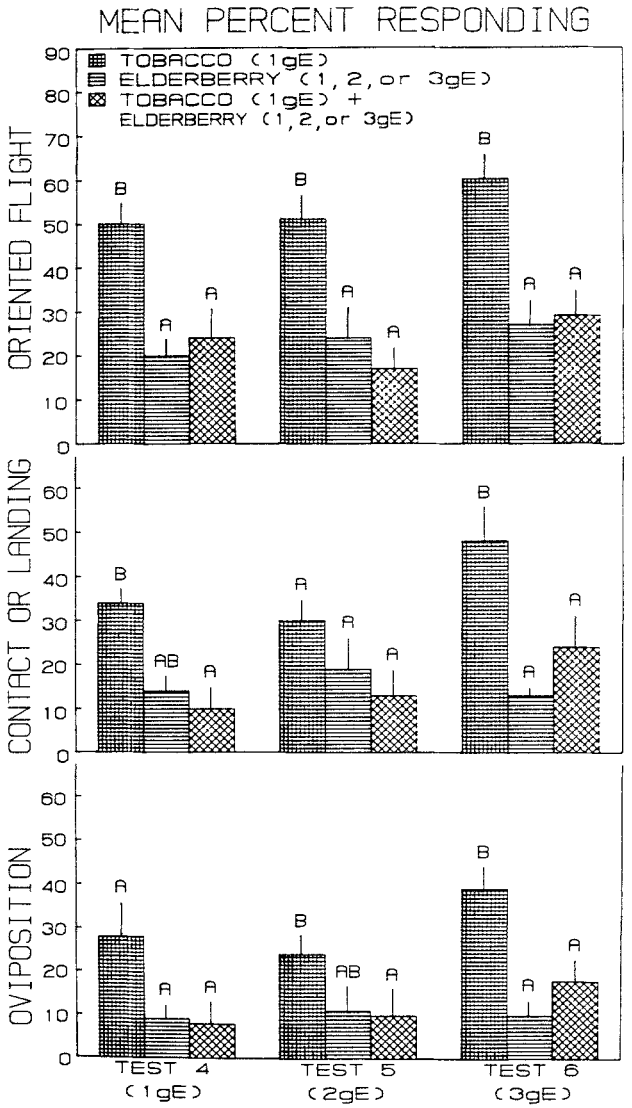

FIG. 2. Mean percentages of *Heliothis virescens* females responding to plant extracts in no-choice tests. Tobacco extract (1 gE) was used as the attractant and 1, 2, or 3 gE of elderberry extract was used alone or in combination with cotton extract (1 gE) in tests 1, 2, and 3. Means within each test with the same letter are not significantly different, $P < 0.05$ [ANOVA, Steel and Torrie (1960); Duncan's multiple-range test (Duncan 1955)]. Vertical lines indicate standard error of means.

extract alone (Figure 2). However, significant reductions of 51–66% in flight response to 1 gE of tobacco extract occurred when 1, 2, or 3 gE of the extract from elderberry were combined with the tobacco extract (Table 1). Moths that did not respond to the extracts flew in a random fashion or landed on the tunnel wall.

Reductions in the number of moths that either contacted or landed on the extract-treated substrates were similar to the flight response data when 1, 2, or 3 gE of the elderberry extract were combined with 1 gE of extract from either cotton or tobacco. More than 85% of the contacts resulted in landings on the substrates. Except when 1 gE of elderberry extract was combined with 1 gE of the cotton extract in test 1, the number of contacts and landings were significantly reduced by 53–71% (Table 1). When the substrates in tests 2 and 3 were treated with 1 gE of cotton extract combined with either 2 or 3 gE, respectively,

TABLE 1. PERCENT REDUCTION IN FLIGHT RESPONSE BY *H. virescens* FEMALES TO EXTRACTS FROM HOST PLANTS IN FLIGHT TUNNEL WHEN EXTRACT FROM ELDERBERRY LEAVES WAS ADDED TO EXTRACT FROM COTTON SQUARES (FLOWER BUDS) OR TOBACCO LEAVES

Elderberry extract dosage (gram equivalents)	Host plant extract (1 gE)			
	Cotton		Tobacco	
	Reduction (%)	*t*-value[a]	Reduction (%)	*t*-value[a]
Oriented flight to extracts[b]				
1 gE	6.3(1)	0.309NS	51.4(4)	2.571*
2 gE	42.8(2)	3.384*	66.1(5)	5.004**
3 gE	48.8(3)	3.682*	51.3(6)	3.535*
Contact or landing on extract substrates				
1 gE	0	0.194NS	69.4	3.552*
2 gE	52.8	2.572*	58.2	2.628*

Oviposition on substrates				
1 gE	19.4	0.786NS	70.1	2.271NS
2 gE	60.1	2.572*	60.1	3.511*
3 gE	76.7	3.737*	53.9	3.271*

[a] Calculated by Student's unpaired *t* test from percentage of moths demonstrating a positive response to extract from either cotton or tobacco alone and in combination with extract from elderberry (six replications per dose): NS = nonsignificant, $P < 0.05$; * significant, $P < 0.05$; ** significant, $P < 0.01$.

[b] Test numbers shown in parentheses.

of elderberry extract, only 17% and 14%, respectively, of the moths contacted or landed on the substrates (Figure 1). However, 35% and 47% of the moths in test 2 and 3, respectively, contacted or landed on the substrates treated only with the extract from cotton.

When the extract from tobacco was used as the attractant in tests 4–6, significant reductions of 58–69% in the number of contacts and landing on the substrates treated with the tobacco–elderberry mixture at all three dosages were indicated when the two treatments, tobacco and tobacco–elderberry mixture, were compared by the unpaired *t* test (Table 1). However, when data from all three treatments (tobacco, elderberry, and tobacco–elderberry mixture) were analyzed by ANOVA, significant reductions in the number of contacts and landings were evident only when 1 gE or 3 gE of elderberry extract were combined with 1 gE of the tobacco extract in tests 4 and 6 (Figure 2).

There was no significant reduction in the number of landings that resulted with oviposition on the extract-treated substrates when 1 gE of elderberry extract was combined with 1 gE of extract from either cotton (test 1) or tobacco (test 4) (Table 1, Figures 1 and 2). An increase in the amount of elderberry extract from 1 gE to 2 or 3 gE significantly reduced the number of landings with oviposition on substrates treated with the elderberry–host-plant mixture.

Although untreated controls with only the solvent (methylene chloride) on the substrate were conducted periodically in the flight tunnel, six replicates were conducted on the same days that behavioral responses by *H. virescens* females to both elderberry and host-plant extracts were monitored (Table 2). Significantly more moths demonstrated a positive flight response to the substrates treated with extracts from either cotton (three replicates) or tobacco (three rep-

[b] Cotton (three replicates) or tobacco (three replicates); responses to these two extracts were almost identical.

licates) than flew to either the elderberry- or methylene chloride-treated substrates. There were significantly more contacts, landings, and landings resulting in oviposition on the substrates treated with host-plant extracts. The responses by the females to the elderberry extract and to the solvent (methylene chloride) alone were statistically equal.

The effectiveness of extract from elderberry leaves began to deteriorate four to five months after the extract was prepared with methylene chloride and stored at 0°C. When 1 gE of 5- to 6-month-old elderberry extract was combined with 1 gE of tobacco extract, it did not inhibit the flight response of moths to the tobacco extract as 1 gE of <1-month-old elderberry extract did in test 4. Even when 3 gE of the aged elderberry extract were combined with 1 gE cotton extract, there was no significant effect on the positive response of *H. virescens* females to cotton extract.

Although the extract from elderberry apparently deteriorated after being stored for four to five months at 0°C, we have not detected a significant deterioration of either cotton or tobacco extract as an attractant for *H. virescens* in the flight tunnel, even when the extracts had been stored at 0°C for at least one year (unpublished data). Mitchell and Heath (1987) reported that crude extracts from whole-leaf washes of groundcherry in methanol could be stored for more than one year at 0°C without significant loss in oviposition stimulant activity for *H. subflexa*. The cotton extract used in this study was >9 months old, and the tobacco extract was >20 months old. Both extracts were still effective as attractants for *H. virescens* in the flight tunnel.

The inhibitory effect of the elderberry volatiles on the behavioral responses of *H. virescens* to attractive volatiles from host plants in our laboratory assays is evident. However, understanding the interaction of volatiles from diverse plant species, or even from various plants of a single species in varying growth stages, and how they affect insect behavior in field situations is difficult and poorly understood. Environmental conditions, including wind turbulence that blends the volatiles, must be considered. In addition to volatiles, phytophagous insects also use other plant stimuli (e.g., color, shape, size) in host selection. Elucidation of the chemistry of phytochemicals that govern plant selection and associated behaviors by insects offers opportunities to render them less attractive to specific insect species.

(Received January 10, 1991; accepted April 22, 1991)

Abstract—The Dufour glands of workers of *Dorylus (Anomma) molestus* contain chiefly linear alkenes and alkanes, with (*Z*)-9-tricosene and tricosane representing over 70%. The glands are relatively small with some indication of very small (nanogram or less) amounts of dihydrofarnesol. Minima, medium, and major workers of *Dorylus (Anomma) nigricans* contain a similar spectrum of compounds.

Key Words—Exocrine secretion, Dufour gland, *Dorylus (Anomma) molestus*, *Dorylus (Anomma) nigricans*, Dorylinae, Formicidae, Hymenoptera.

INTRODUCTION

The variation in the forms of organization of social insects is overwhelming. This can be illustrated by the variety of systems evolved within the Formicidae, which includes vegetarian seed-harvesting species and ferocious predators, strictly arboreal species and others that are entirely hypogaeic, while colony size ranges from as few as nine individuals in *Pachycondyla sublaevis* (Peeters,

1990) up to several millions. The Old World army ants, which constitute the subfamily Dorylinae, undoubtedly represent one of the most fascinating groups among the Formicinae. They comprise the Aenictini, the majority of which are found in tropical Asia and Northeastern Australia, and the Dorylini, which are mainly distributed in Africa. The New World army ants form the separate subfamily Ecitoninae.

The African Dorylini hold the record, by a wide margin, for size of colony in a monogynous ant, with approximately 22 million individuals in a colony of *Dorylus (Anomma) wilverthi* (Raignier and van Boven, 1955). Doryline ants do not have a permanent nest, and in their nomadic progress only occupy temporary bivouacs in between massive raiding bouts. In spite of their enormous colony size, their considerable impact upon the environment, and their unusual habits, Dorylinae have not received as much attention as other more amenable subfamilies of ants. The available papers deal mainly with their general biology and taxonomic aspects (reviewed by Raignier and van Boven, 1955, and Gotwald, 1982). A few reports have been published on the morphology of the exocrine glands of dorylines (Hölldobler and Engel, 1978; Billen, 1985). Nothing, however is known as yet on the ethological function or the chemical composition of the glandular secretions. This lack of information is more understandable when considering, on the one hand, the impossibility of keeping these nestless ants alive in the laboratory, and on the other, the practical problems of having sophisticated research equipment close to their African habitat.

Using the solid sampling technique of Morgan and Wadhams (1972), however, the site and time of collection of the material and the laboratory where it is chemically examined become independant of each other (cf., Billen et al., 1987). Using this technique we have been able to carry out the first chemical examination of the Dufour glands of the workers of *Dorylus (Anomma) molestus* (Gerstaecker) as part of a comparative taxonomic survey of this gland in various subfamilies of the Formicidae (Morgan, 1990a; Attygalle and Morgan, 1984). We report here this first chemical examination of a member of the subfamily Dorylinae, together with a preliminary examination of the Dufour glands of *Dorylus (Anomma) nigricans* Illiger carried out several years earlier and not yet fully reported.

METHODS AND MATERIALS

Live ants were collected near Nairobi, Kenya, and immediately flown to Leuven, Belgium, where they were dissected and the glands sealed in glass capillaries and sent by mail to Keele. Worker ants were immobilized by cooling over liquid nitrogen. Dissection was carried out in water under a binocular

microscope as described by Morgan (1990b). The dissected glands were dried and sealed in glass capillaries and kept in a refrigerator until ready for chemical analysis by combined gas chromatography–mass spectrometry.

Gas chromatography was carried out on a Hewlett Packard model 5890 gas chromatograph using helium (1 ml/min) as carrier gas on a fused silica capillary (12 m × 0.35 mm) coated with a 0.33-μm film of immobilized dimethylsilicone fluid (equivalent to OV-1) (Cambridge Capillaries, Cambridge, U.K.). The injector was set at 150°C, and the detector at 300°C. The column oven was programmed from 30°C to 250°C at 8°C/min and then held isothermally. Injection was splitless. The analytical column was linked to the Hewlett Packard 5970B mass selective detector through a deactivated, uncoated fused silica capillary (10 × 0.35 mm). The mass spectrometer was set to scan m/z 40–350 using 70 eV ionization with a scan time of about 1 scan/1.5 sec. Data were collected and processed by a Hewlett Packard ChemStation, model HP 59970C.

Formation of dimethylthioethers from alkenes for the location of double bonds was carried out on a nanogram scale as described by Billen et al. (1986) and Attygalle and Morgan (1988). A capillary containing 3, 5, or 10 Dufour glands was crushed under hexane, and to this was added dimethyl disulfide (50 μl) and a solution of iodine in ether (2 μl, 60 mg/ml). The mixture was placed in a Keele Microreactor (Attygalle and Morgan, 1986) sealed with a screw cap and heated overnight at 100°C. The reaction was halted by adding aqueous sodium thiosulfate (50 μl). For the linked gas chromatography–mass spectrometry of the reaction products, the injector was set at 280°C and the column programmed from 200°C to 320°C at 3°C/min.

The analyses of the Dufour glands of *Dorylus (Anomma) nigricans* were carried out by the same solid sampling technique of single dissected glands, but were performed some years earlier on the technology available then, i.e., packed gas chromatography column of polyethylene glycol (PEG 20M) operated at 210°C isothermally and without the benefit of mass spectrometry. The identifications of the alkanes and tricosene were based upon identity of retention times. The technique was as described in papers of that time (e.g., Billen et al. 1986).

RESULTS

The Dufour glands of *Dorylus (Anomma) molestus* are filled with linear alkanes and alkenes with (*Z*)-9-tricosene and tricosane together providing over 70% of the total (Table 1). No terpenes or oxygenated compounds were observed among the major components. A typical gas chromatogram is shown in Figure 1. The position of the double bonds in the alkenes was determined by conversion to the α,β-dimethylthioethers with dimethyl disulfide. The position of the

double bonds were easily located in tricosene and pentacosene from the mass spectral fragmentation of the dimethylthioethers. The geometry of tricosene was shown by comparison of the retention time of the derivative with that of an authentic specimen of (*Z*)-9-tricosene to be *Z*. That of the *E* isomer has a different retention time. Samples containing 3, 5, and 10 glands were each used for the formation of the dimethylthioethers, but there was insufficient material in each of them to locate the position of the double bond in heptadecene or nonadecene.

The only evidence of nonlinear compounds was in one sample that showed a peak eluting immediately after heptadecene, which had the mass spectrum and retention time of an authentic sample of (*Z*)-dihydrofarnesol made by the method of Dawson et al. (1988). In the remaining samples, this was too weak to be clearly seen.

The preliminary examination of *Dorylus (Anomma) nigricans* also showed that tricosane and probably tricosene were the major compounds present and that the general pattern of compounds was similar, but lack of identification of some of the other substances makes full comparison impossible. Five individual minima workers, one medium, and two major workers were examined. The major component in all of them was that tentatively identified as tricosene (mean value of 30 ng), followed by tricosane (27 ng); the third component eluting near docosane was unidentified.

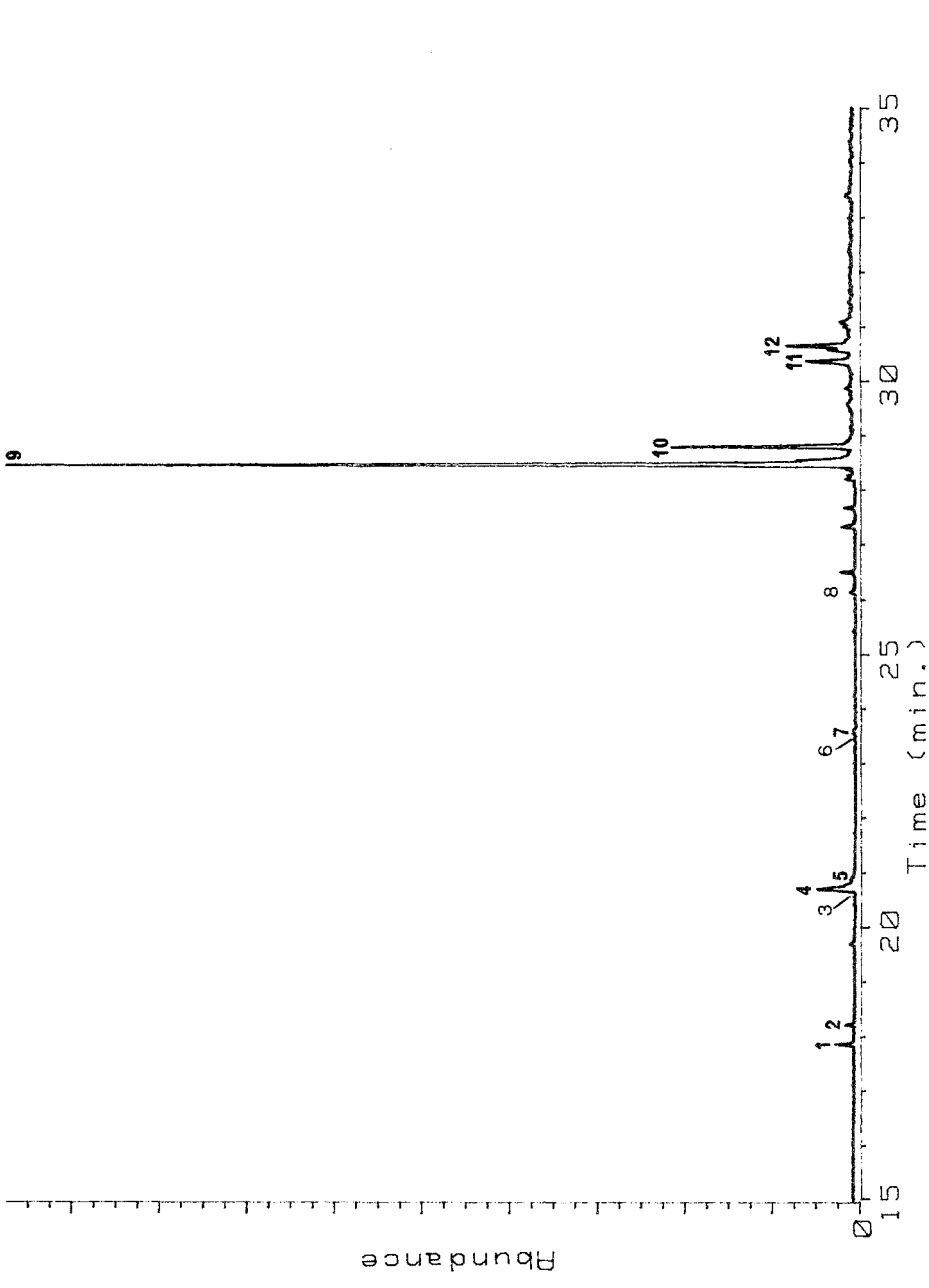

FIG. 1. Gas chromatogram of a single Dufour gland of a worker of *Dorylus (Anomma) molestus* on a capillary column. Labeled peaks are listed in Table 1.

DISCUSSION

Examination of Dufour glands of two species of *Dorylus* show that tricosene and tricosane are by far the major components in the glands of these members of the Dorylinae. Only seven single specimens of *D. molestus* were available, one of which showed a relatively high proportion of minor components, which included one terpenoid substance identified as dihydrofarnesol (Table 1) and one specimen in which the proportions of pentacosadiene and pentacosene were comparable with those of tricosene and tricosane. The result is relatively large standard deviations in the percentages in Table 1 for this small sample. The glands are comparatively small for ants, with this sample giving an average of 200 ng of secretion per gland.

The main points of interest are, first, the relatively high molecular mass (C_{23} and C_{25}) of the principal components. This we have noted previously (Attygalle et al., 1990) is characteristic of species living in a tropical climate, compared with species from a temperate climate, where C_{11}-C_{17} compounds usually predominate. Secondly, the tricosene is the same one encountered in *Atta* (Evershed and Morgan, 1981) and frequently elsewhere in insect cuticular hydrocarbons. Thirdly, although tricosane (mp 47.6°C) is a solid, tricosene is a liquid at room temperature, and the mixture of many alkenes will keep the tricosane in solution and keep the mixture liquid. Fourthly, the meager evidence for a sesquiterpene compound, dihydrofarnesol, already identified in a ecitonine ant (Morgan et al., in preparation) and now in its Old World counterpart, is interesting, although otherwise the chemistry of ecitonines and dorylines is very different.

The data on *D. nigricans* indicate that this species is not greatly different from *D. molestus*. The amount in the gland varied from 50 to 150 ng, rising with increasing size of the workers, but overall these glands are relatively small among ant Dufour glands. We may expect other species of *Dorylus* will give similar but not identical patterns of hydrocarbons in their Dufour gland.

At our present level of knowledge, there is nothing distinctive about this glandular secretion that correlates with the unusual nomadic existence of doryline ants.

Acknowledgments—We thank E.E. Martens (University of Nairobi, Kenya) for collecting *D. molestus* and J.K.A. van Boven for the *D. nigricans* and for identifying both species. J.P.J.B. and A.G.B. both thank the British Council for travel grants to visit Keele; A.G.B. thanks the Centre National de la Recherche Scientifique (CNRS/DRCI) for financial support; E.D.M. thanks the SERC for a grant for the purchase of GC-MS equipment. We thank S.J. Keegans for helpful discussion and advice.

Abstract—The cuticular hydrocarbons of *Formica selysi* (Formicinae) and *Manica rubida* (Myrmicinae) reared in single species and in mixed species colonies were determined using gas chromatography (GC) and GC-mass spectrometry. In colonies containing both species, each species modified its species-specific recognition odor. This odor is composed, at least partly, of cuticular hydrocarbons. The cuticular hydrocarbons of *M. rubida* consist only of saturated alkanes (*n*-alkanes and branched alkanes). In *F. selysi* the mixture also contains unsaturated compounds (monoenes and dienes). In heterospecific colonies, a new chemical signature developed. This signature resulted from qualitative and quantitative changes in the spectrum of hydrocarbons produced by each species and permitted the two species to inhabit the same nest without displaying interspecific aggression. The readjustment seemed to be more an active synthesis or an active transfer than simply a passive transfer from one species to the other. This may imply that the ants synthesized some components of the hydrocarbon signature of the other species. These synthesizing processes may be activated under particular social environmental conditions.

Key Words—Formicinae, mimicry, artificial mixed colonies, cuticular

hydrocarbons, colony recognition, ants, Hymenoptera, Formicidae, *Formica selysi*, *Manica rubida*.

INTRODUCTION

A fundamental feature of social insect colonies (bees, ants, and termites) is the fact that they are usually closed. Individuals of the same species from outside the colony are prevented from entering the nest and are repulsed, attacked, and often killed (Wilson, 1971).

There are, however, examples of mixed colonies of ants of different species coexisting in the same nest. The existence of natural associations of this kind prompted Fielde (1903) to create artificial mixed colonies of two or more species that never form such associations in nature. Using this heterospecific rearing technique, Fielde demonstrated that discrimination between nestmates and foreign individuals was based on a set of chemicals that together produced a colony-specific odor. More recently Hölldobler and Michener (1980) suggested that colony odor derives partly from chemicals produced by the colony members themselves. Analyses of these chemical recognition signals suggest that they are incorporated into the insect cuticle in termites and ants (Howard et al., 1980; Howard and Blomquist, 1982; Vander Meer et al., 1985). By transferring cuticular hydrocarbons from *Camponotus vagus* ants of one colony to those of another, Bonavita-Cougourdan et al. (1987) caused foreign ants to be treated like nestmates and so proved that hydrocarbons acted at least as one colony recognition odor. These findings have been confirmed by the results of studies on other ant species, *Camponotus floridanus* (Morel and Vander Meer, 1988) and *Cataglyphis cursor* (Nowbahari et al., 1989). Hydrocarbons also appear to act as species and colony recognition cues among termites (Howard et al., 1982; Clément et al., 1985; Bagnères et al., 1988; Haverty et al., 1988). Cuticular hydrocarbons also play an important role in the interactions between termitophilous and myrmecophilous taxa, or ant social parasites and their hosts (Howard et al., 1980; Vander Meer and Wojcik, 1982; Lemaire et al., 1986).

Larval transfers from one ant society to another have shown that the chemical signature (consisting mainly of cuticular hydrocarbons) changes in response to social environment (Bonavita-Cougourdan et al., 1989).

We have used heterospecific ant colonies as a system in which to study the mechanisms of species colonial recognition (Jaisson, 1980; Errard and Jaisson, 1985). Earlier work with heterospecific colonies concentrated on the means of producing an association of *Formica selysi* (Formicinae) and *Manica rubida* (Myrmicinae). These associations are made possible by the transient existence of a tolerance period occurring during the few days after imaginal eclosion (Errard, 1986, 1987). We also have shown that a mixture of unidentified chem-

icals, probably hydrocarbons, changed when the two species were reared in heterospecific colonies (Errard and Jallon, 1987).

Foragers from homospecific colonies were highly aggressive when forced into heterospecific confrontations in the laboratory. The resulting combats usually ended in one or both individuals being killed. Young workers of *M. rubida* and *F. selysi* put together to form heterospecific colonies showed no aggressive behavior, however. The behavior of each species rapidly adapted to the presence of allospecifics. We have shown, however, that in colonies where the two species coexist without aggression most of the individual interactions are preferentially directed towards ants of the same species. Furthermore, the two species retain their own spatial organization (Corbara and Errard, 1989, 1991).

Among the wide range of natural associations, the artificial heterospecific colonies of *F. selysi* and *M. rubida* are just an apparent myrmecobiosis (Stumper, 1950) because in these associations the ants of both species coexist in fairly close proximity but rear their own brood separately.

In the present study, we have identified the hydrocarbons extracted from the cuticle, and we also have examined the changes in composition and abundance of the cuticular hydrocarbons that occur when *F. selysi* and *M. rubida* are reared heterospecifically. We put forward hypotheses to explain the mutual tolerance that was concomitant with the chemical changes observed.

METHODS AND MATERIALS

Rearing. The species used in the present study, *Manica rubida* (Myrmicinae) and *Formica selysi* (Formicinae) were collected from the same biotope (French Alps, altitude 700 m) in July 1987, October 1988, and April 1989, at three different sites (Morillon, Fer à Cheval, Salvagny), where the two species are sympatric. Parent colonies from these three sites were reared in the laboratory (with queen) under the following conditions: natural photoperiod, temperature range 22 $\pm$ 2°C, diet consisting of honey, apple, flies, and mealworms. Two types of enclosures (open boxes containing food and water) were set up: those containing *F. selysi* cocoons and workers, and those containing *M. rubida* pupae and workers. Young workers of each species were removed within 24 hr of their emergence and used to form two kinds of colonies: control colonies (homospecific) and artificial mixed colonies (heterospecific). Each control colony contained 40–42 young workers, in addition to brood (consisting of 20 pupae in the case of *M. rubida* colonies, and 20 cocoons in the case of *F. selysi* colonies). The artificial mixed colonies consisted of 25 young workers of each species, less than 24 hr old, in addition to brood (10 pupae and 10 cocoons). None of these colonies contained any queens.

Sampling and Chemical Analysis of Cuticular Aliphatic Hydrocarbons.

Individual ants from 11 control colonies (coming from the different sites) and two heterospecific colonies were killed by freezing, and then weighed immediately, when about six months old. Each ant was then extracted with 2 ml pentane in a Wheaton tube. After 5 min, the total pentane extract was drawn off and evaporated under nitrogen. Eicosane (n-C_{20}) was added to each sample as an internal standard.

Extracts from 21 individuals of each species from homospecific colonies and 11 extracts of 11 individuals from heterospecific colonies (six *F. selysi* and five *M. rubida*) were mathematically analyzed. In our colonies, no distinction was made between individuals that emerged before or after the artificial colonies (control and mixed) had been set up. Saturated and unsaturated hydrocarbon fractions were separated on silica plates impregnated with 10% silver nitrate developed with benzene–hexane (8:92) (Howard et al., 1978). Capillary gas chromatography (GC) was carried out using a Chrompak CP Sil 5 WCOT column (25 m × 0.25 mm ID). The GC is a Delsi Girdel series 300 machine with a flame ionization detector (FID) coupled to an Enica series 10 integrator. Coefficients depending on the Delsi FID were calculated for each peak in relation to an internal standard (here n-C_{20}), using a mixture of synthetic n-alkanes (n-C_{16} to n-C_{38}) for each hydrocarbon at various concentrations, and a further coefficient of 0.8 for unsaturated alkanes was calculated also with synthetic alkenes at various concentrations. The injector was of the split-splitless type and the injection was performed for 15 sec in splitless mode. The carrying gas was helium at 1 bar and the temperature was programmed at 5°C/min from 100 to 320°C (10 min isothermal).

Mass spectra (MS) were produced with a Nermag R-1010 C linked to an IBM PC AT3 using the Spectral 30 software. Electron impact (EI) spectra were obtained at 70 eV, chemical ionization (CI) at 100 eV, and methane at 0.05 torr. The position of double bonds was determined by methyl thioether formation (Francis, 1981; Francis and Veland, 1981; Carlson et al., 1989). After determinations, a complementary GC-MS analysis (selected ion monitoring) was carried out to check whether any of the hydrocarbons' diagnostic ions, which were found to be absent from either species, might in fact be present in trace quantities. The threshold of the GC-MS was then increased by two.

Mathematical Analysis. Hydrocarbon species present in quantities greater than 0.5 ng/insect were included in the analysis using Lotus 1-2-3 software (version 2.01). A total of 32 peaks were recorded from *F. selysi* individuals reared homospecifically, and 26 from *M. rubida* reared homospecifically, and for each peak the surface was readjusted with the coefficient. Forty-two peaks were recorded on ants of both species reared in mixed colonies. The basic statistics (mean, variance, standard deviation, etc.) were calculated on both the proportional and absolute quantities of each hydrocarbon. Mean quantities were tested using Student's t test setting the significance level at $\alpha < 0.05$. Multi-

variate principal component analysis (MANOVA) and an analysis of correlation were carried out on the data using Statgraphic Inc. software. Principal component analysis was used to separate individual ants or individual hydrocarbon species along the principal canonical axes (i.e., those capable of absorbing the greatest proportion of the sample variance). Where the quantities of hydrocarbon species were highly correlated, they were removed from the analysis. The MANOVA therefore was carried out on a restricted set of 26 of the hydrocarbons after this correlation analysis.

RESULTS

Chemistry. The hydrocarbons extracted from homospecifically reared *M. rubida* consisted entirely of alkanes. Among these, 39.2% were *n*-alkanes, 41% monomethyl-alkanes, 15.2% dimethyl-alkanes, and 4.6% were undetermined saturated molecules. The cuticular mixture from *F. selysi* control colonies was characterized by the presence of numerous unsaturated molecular species (53.3%). Among these alkenes 40% were monenes and 17.3% dienes. Numerous alkane molecules also were observed (40%), 24.3% of which were *n*-alkanes, 7.2% monomethyl-alkanes, 8.5% dimethyl-alkanes; 2.7% of molecules are unknown. Heterospecifically reared ants of both species had intermediate hydrocarbon profiles between the profiles of single species *F. selysi* and *M. rubida* colonies (Figure 1). The hydrocarbon mixture from heterospecifically reared ants contained both alkanes and alkenes. The proportions of *n*-alkanes, monomethyls, dimethyls, monoenes, and dienes were 20.8, 15.4, 15.4, 16.1, and 4.7%, respectively, in *F. selysi*, and 24.6, 35.1, 15.7, 15.7, and 7.1% in *M. rubida*. Undetermined products amounted to 6.2% and 6.6% of the totals in *F. selysi* and *M. rubida*, respectively. The hydrocarbon MS peaks were identified (Table 1) and their diagnostic ions (using EI, CI and for EI after methyl thioether formation presented together with the numerical abbreviations of the hydrocarbons). The outcome of the search for diagnostic ions, such as the unsaturated products from *F. selysi* that were not found to be present in *M. rubida* (monoenes: *m/z* 322, 350, 378, 392, 406, 434; dienes: *m/z* 404, 432, 460) was negative. The proportions and absolute quantities (in nanograms per milligram of insect) of the compounds from each category of ants were tabulated (Table 2).

Mathematical Analysis. After principal component analysis of the relative proportion of the cuticular hydrocarbons, the first and second principal components accounted for 38.4% and 17.1% of the total sample variance. A further 9.5, 6.4, and 5.9% of the variance was explained by components 3, 4, and 5. With the first and third principal components alone, it was possible to separate the four categories of ants: homospecifically reared *F. selysi* and *M. rubida*,

[a] Standard deviation in parenthesis. Student t test: NS = not significant, $*P < 0.05$, $**P < 0.01$, $***P < 0.001$. *F. selysi* (control $N = 21$), *M. rubida* (control $N = 22$), *F. selysi* (mixed $N = 6$), *M. rubida* (mixed $N = 5$).

and *F. selysi* and *M. rubida* from heterospecific colonies (Figure 2A). The second component accounted for the variance between individuals within species. The four groups (*F. selysi* from control colonies, heterospecifically reared ants of both species, and *M. rubida* from control colonies) separated out along the first principal component axis (Figure 2A). Control colony *F. selysi* were most clearly characterized by the alkenes 9-$C_{27:1}$ (e20) and 9-$C_{25:1}$ (e11), and the dienes *n*32 and *n*38 of 29- and 31-carbon atoms. The *M. rubida* from control

(B) Component weight map, plotted for the 26 different hydrocarbons selected (a: *n*-alkane, m: monomethyl-alkanes, d: dimethyl-alkanes, e: monoene, n: diene).

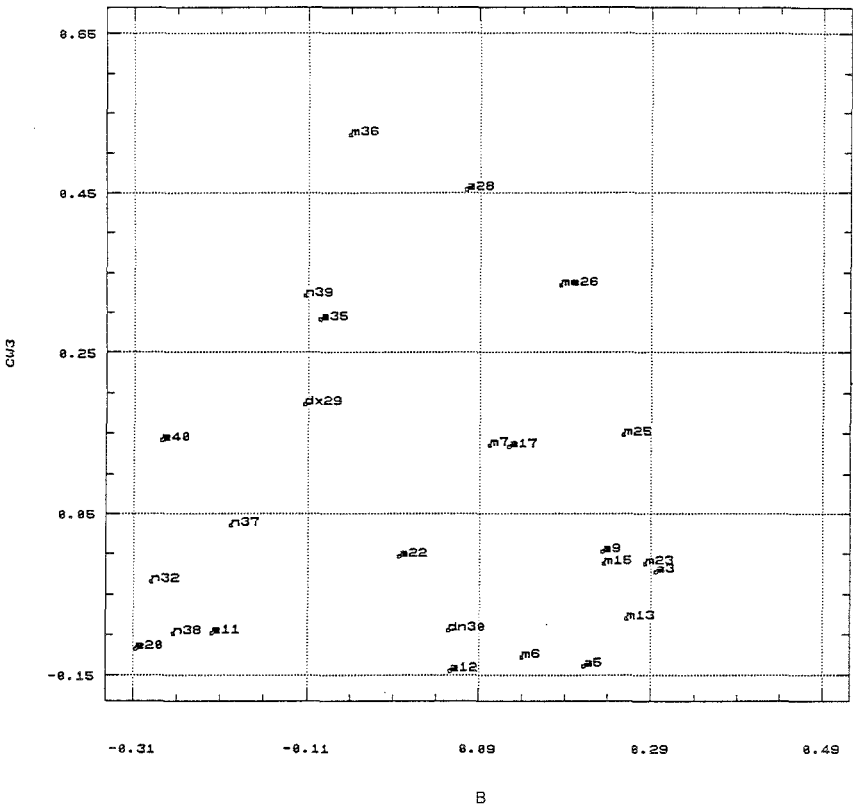

FIG. 2. Continued

colonies were characterized, however, by the alkanes n-C_{22} (a3), 13 + 11 + 9Me-C_{25} (m13) and 13 + 11 + 9Me-C_{27} (m23) (Figure 2B).

The interspecifically reared individuals clustered at the center of the first axis separated out along the third axis (Figure 2A). Four of the five heterospecifically reared *M. rubida* and a few individuals from control colonies occurred in the positive upper section of the plot. The negative lower section contained five of the six heterospecifically reared *F. selysi* and the most of individuals from control colonies.

Our analysis brought to light three categories of hydrocarbons (Table 2). One group contained cuticular hydrocarbons specific to *F. selysi* and comprised 13 peaks. A second group, with eight peaks, contained products species-specific to *M. rubida*. The third group (16 peaks) included the hydrocarbons shared by both species. The hydrocarbons that were common to both species (when reared homospecifically) formed 38.9% of those extracted from the cuticle of individ-

uals from *F. selysi* control colonies. The remainder, 58.5% were more specific to *F. selysi*; whereas the hydrocarbons common to both species amounted to 47.2% of the load from *F. selysi* reared heterospecifically. Products specific to *F. selysi* amounted to 22.3% and the remaining 24.3% were hydrocarbons specific to *M. rubida*. Control colonies of *M. rubida* carried 26.1% species-specific products and 69.3% of these were common to both species. The hydrocarbons carried by *M. rubida* from interspecific colonies, however, were 20.7% species-specific and 49.1% common to both species. The remaining 23.3% were specific to *F. selysi*. The proportion of species-specific hydrocarbons from heterospecifically reared ants of both species was conspicuously lower than in conspecific controls. Here the difference was greater (36%) in *F. selysi* than in *M. rubida* (6%). The proportion of shared hydrocarbons was 10% greater in heterospecific than in homospecific *F. selysi*. Heterospecifically reared *M. rubida*, however, had 20% less shared hydrocarbons than the conspecific controls.

As a result of these changes, the proportion of shared hydrocarbons carried by ants reared interspecifically converged towards 48% in both species. In addition, ants in heterospecific colonies possessed two or even three times as much cuticular hydrocarbons as those reared homospecifically (Table 2). The mean individual load of *F. selysi* was 1170 ng/mg of insect in control and 3251 ng/mg of insect in heterospecific colonies. Likewise in *M. rubida*, the mean individual load was 1130 ng/mg of insect among ants from homospecific colonies and was 2910 ng/mg of insect among ants from heterospecific colonies. All the categories of hydrocarbons increased by similar amounts and contributed equally to the increase in the proportions on interspecifically reared ants. The mean individual loads of some common hydrocarbons [including *n*-C_{25} (a12), *n*-C_{29} (a35), 9Me + 11Me-C_{23} (m6), 5Me-C_{23} (m7), 9Me + 11Me-C_{25} (m13) and the *x*,*y*-dimethyl-C_{28} (dx29)] were, for example, 20 ng/mg in controls and 100 ng/mg in heterospecifically reared ants (Table 2) .

With 11 of the 16 shared hydrocarbons, the increases in the amounts produced by ants from heterospecific colonies were greater in the species that produced the lower proportions of these hydrocarbons when reared in control colonies. The proportion of the mixture of 9- and 11-methyl pentacosane (m13) in *F. selysi* increased from 1.4% in control colonies to 7.5% in heterospecific ones. In *M. rubida* the proportions of this mixture decreased from 7.7% in control to 4.9% in interspecific colonies. Some *F. selysi*-specific hydrocarbons were more abundant however on *F. selysi* and *M. rubida* reared heterospecifically. These included *n*-C_{31} (a41), 11Me + 13Me-C_{29} (m36), 9-$C_{23:1}$ (e4) and nonacosadienes (*n*30, *n*31) (Figure 3). These products, which are absent in *M. rubida* reared alone, were three to four times more abundant on *M. rubida* reared heterospecifically than on *F. selysi* (which naturally synthesized these hydrocarbons) in control and mixed colonies. The loads carried by heterospecifically reared *F. selysi* were twice as much as those carried by conspecifics

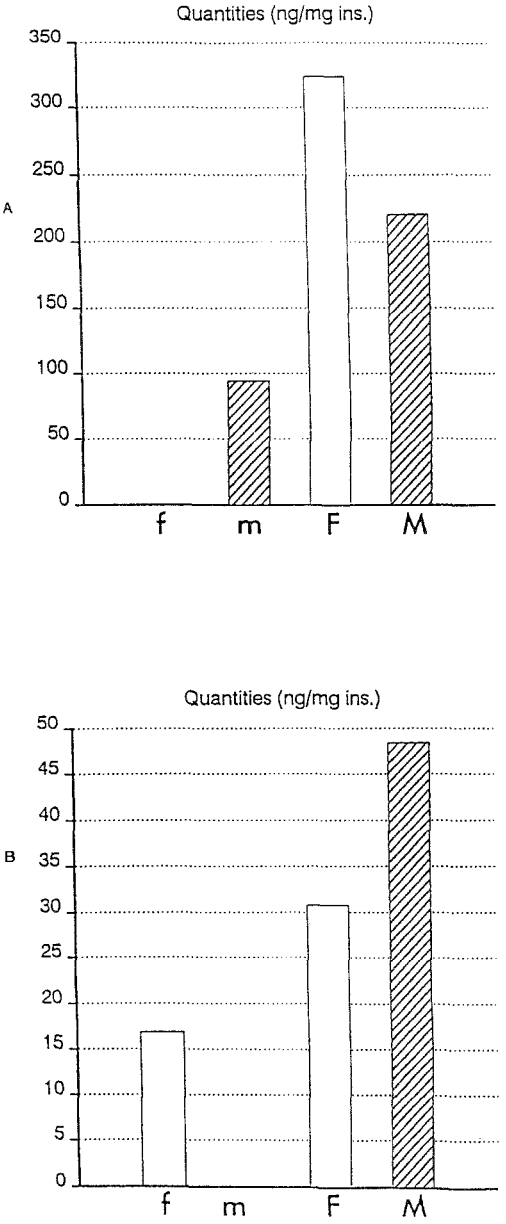

FIG. 3. Histograms of quantities in nanograms per milligram insect of two specific hydrocarbons (A: 5,17-diMe-C_{27}; B: 9-tricosene). f: homospecific reared *Formica selysi;* m: homospecific reared *Manica rubida;* F: heterospecific reared *Formica selysi;* M: heterospecific reared *Manica rubida*.

from control colonies. A similar pattern was observed in the case of 5,17-diMe-C_{27} (d27) and 3Me-C_{23} (m8) and other hydrocarbons specific to *M. rubida* (Figure 3). The proportions of *F. selysi*-specific hydrocarbons recorded from heterospecifically reared *F. selysi* were significantly different from the proportions recorded in heterospecifically reared *M. rubida* (chi-squared test, $\chi^2 = 70.01$, $df = 12$, $\alpha < 0.01$). This difference was largely attributable to six of 13 hydrocarbons *n*-C_{31} (a41), the mixture 11Me + 13Me-C_{29} (m3), 9-pentacosene (e11), 9-heptacosene (e20), 9–21 nonacosadiene (*n*31) and 9–23 hentriacontadiene (*n*39). Comparisons of *M. rubida*-specific hydrocarbons showed the existence of no significant differences between the proportions extracted from heterospecifically reared *M. rubida* and *F. selysi* (chi-squared test, $\sigma^2 = 3.47$, $df = 7$, $\alpha < 0.90$).

The two species appear to have reacted differently to heterospecific rearing. The quantities of cuticular hydrocarbons increased much more (80.6%) in *F. selysi* than in *M. rubida*, suggesting that *F. selysi* is more sensitive to the altered social environment produced by heterospecific rearing or has a different physiological development or a different nutritional behavior.

DISCUSSION

Our results demonstrate that there exists a close link between the species-specific cuticular signature—the particular spectrum of cuticular hydrocarbons—of *F. selysi* and *M. rubida*, and the tolerance between these species. This confirms similar findings in other social insects including both termites (Howard et al., 1982; Clément et al., 1985) and ants (Bonavita-Cougourdan et al., 1987; Morel and Vander Meer, 1988; Nowbahari et al., 1989). Mature adults from control colonies of the two species, when forced to occupy the same nest, are able to distinguish allospecifics on the basis of their species-specific chemical signature. Agonistic behavior occurs as soon as foreign ants are introduced into the nest and most of the foreign ants are killed in the resulting combat. By contrast, young ants reared heterospecifically show modified hydrocarbon profiles. By modifying their spectra, the two species become chemically more closely related. Individuals reared in heterospecific colonies are therefore tolerant of their allospecific nestmates and show no aggressive behavior (Corbara and Errard, 1991).

The individual hydrocarbon loads (in nanograms per milligram) carried by heterospecifically reared ants of both species were twice those of the control ants. Several processes contribute to this increase: (1) *M. rubida* "acquires" molecules species-specific to *F. selysi*, sometimes producing greater quantities of hydrocarbons than *F. selysi* from control colonies. In addition *F. selysi* reared heterospecifically greatly increase production of their own species-specific

hydrocarbons. The same phenomena occur with *F. selysi*. (2) Heterospecifically reared ants produce the hydrocarbons common to both species in much greater quantities than either species when reared alone. Despite these changes, each species retains a species-specific chemical signature. At the same time individuals of both species acquire a similar chemical signature that is specific to the colony.

What are the mechanisms mediating these phenomena that are so strongly influenced by the ants' social environment? Some authors have suggested that the queen plays an important role as a source of the chemicals that form the colony odor (Carlin and Hölldobler, 1986, 1987). In our experiments, however, there were no queens in either the heterospecific or homospecific colonies. The presence of allospecific workers alone produced all the changes observed in the hydrocarbon spectra of heterospecifically reared ants. A similar phenomenon has been observed in *Camponotus vagus* larvae (Bonavita-Cougourdan et al., 1989). The chemical and behavioral plasticity exhibited by *F. selysi* and *M. rubida* has been found to exist in many myrmecophile and termitophile species. Two hypotheses have been advanced to explain the phenomenon. Vander Meer and Wojcik (1982) suggested that cuticular hydrocarbons are merely transferred passively from the host to the myrmecophile. Howard et al. (1980, 1990), however, proposed that new chemicals are actively synthesized. In their larval transfers from one society to another, Bonavita-Cougourdan et al. (1989) gave three hypotheses to explain the changes in the chemical signature in response to social environment, in addition to its transfer from workers to larvae: (1) genetically controlled regulatory mechanisms in response to environmental stimuli; (2) workers providing larvae with entire synthesized hydrocarbons by feeding; (3) or with precursors of the hydrocarbons.

The synthesis and regulation of cuticular hydrocarbons, and likewise of venoms, appear to be controlled by Mendelian genes (Vander Meer et al., 1985; Ross et al., 1987). Passive transfer of hydrocarbons does not explain the increases in hydrocarbon loads we observed in both species reared heterospecifically. An ant receiving chemicals by passive transfer would be expected to pick up a smaller quantity of chemical than the amount carried by the donor ant. Even if the transfer of cuticular hydrocarbons was complete, the average quantities received would be equal to, but never more than, the quantities carried by the donor. This objection is particularly valid with molecules that are not normally synthesized by the receiving homospecifically reared ants. The hydrocarbon loads of heterospecifically reared *F. selysi* and *M. rubida* contained different proportions of the various species-specific and common molecular species (Figure 3). This fact implies that, even if the various hydrocarbons were transferred from one species to another, they were not exchanged all at once nor at the same rates.

It is unlikely that any "selection" of particular hydrocarbons may occur

during passive transfer because the cuticular products are chemically and physically very similar, as mathematical analysis has shown. A possible mechanism of the "transfer" type would involve the exchange of precursor molecules by trophallaxis rather than the exchange of fully synthesized hydrocarbons by cuticular contacts. This hypothesis can be rejected, however, because in our experiments there was very little trophallaxis between the two species.

Transfer of cuticular hydrocarbons also seems to be unlikely because it requires numerous interactions between the species. The molecules involved are not very volatile and would have to be deposited on the cuticle of allospecific ants during trophallaxis or mutual grooming, but interspecific behavior is uncommon in heterospecific ant colonies (Corbara and Errard, 1991). An active transfer mechanism of a different kind, however, may account for our data, one where the contents, or part of the contents, of the postpharyngeal gland are transferred during the brief interspecies contacts that occur in mixed colonies. We established previously that in both of these two species, this gland contains the same specific mixture as the cuticule (Bagnères and Morgan, 1991).

Since it is difficult to imagine a passive transfer mechanism that fits with our data, it is necessary to examine the alternative hypothesis that new hydrocarbons may be synthesized by heterospecifically reared ants of both species, quite apart from the possibility involving an active transfer of substances from the postpharyngeal gland (Bagnères and Morgan, 1991). Genetically controlled regulating mechanism may modify the synthesis of cuticular hydrocarbons and their precursor molecules in response to environmental stimuli. This mechanism also implies that there exist synthetic pathways that are activated only under certain environmental conditions or that nonspecific enzymes are involved in the synthesis of new molecules using new precursor molecules selected by unknown mechanisms.

In heterospecific colonies, therefore, a dynamic equilibrium exists. Each species synthesizes some components of the hydrocarbon signature of the other species. The differences between the species that exist when they are homospecifically reared are thus largely deleted in heterospecific colonies. This mechanism enables individual ants to escape interspecific aggression. In addition, our results show that the redistribution of hydrocarbons is such that each species retains a species-specific signature while acquiring a new odor that is specific to the colony.

We intend to carry out biochemical studies to determine whether, in fact, *F. selysi* and *M. rubida* are actually capable of synthesizing molecules that they do not normally produce.

Acknowledgments—The authors wish to thank Professor E.O. Wilson for his helpful comments on the present paper, Professor E.D. Morgan for revising the manuscript, D. Agosti for carrying out the determination of the species *Formica selysi*, and A. Davis and J. Blanc for the English translation of our manuscript.

VOLATILES MEDIATING PLANT–HERBIVORE–NATURAL ENEMY INTERACTIONS: ELECTROANTENNOGRAM RESPONSES OF SOYBEAN LOOPER, *Pseudoplusia includens*, AND A PARASITOID, *Microplitis demolitor*, TO GREEN LEAF VOLATILES

R. RAMACHANDRAN and D.M. NORRIS*

(Received February 19, 1991; accepted April 22, 1991)

Abstract—Electroantennograms were recorded from an herbivore, *Pseudoplusia includens* (Walker) (Lepidoptera: Noctuidae), and a parasitoid, *Microplitis demolitor* (Wilkinson) (Hymenoptera: Braconidae), exposed to 5- through 12-carbon aliphatic compounds of several chemical classes. The response of the herbivore was higher for the 6- and/or 7-carbon hydrocarbons, alcohols, aldehydes, esters, and ketones. The response of the parasitoid was higher for the 7- and 8-carbon hydrocarbons, aldehydes, and ketones. Responses of the herbivore and the parasitoid to alcohols were similar. Both the herbivore and the parasitoid were most sensitive to aldehydes and ketones, and least sensitive to alcohols and hydrocarbons. Responses of the parasitoid to hydrocarbons, aldehydes, and ketones were numerically higher than those of the herbivore. The adaptive significance of differential olfactory sensitivity between the herbivore and the natural enemy is discussed in relation to tritrophic interactions among plants, herbivores, and natural enemies.

Key Words—Herbivores, *Pseudoplusia includens*, Lepidoptera, Noctuidae, natural enemies, *Microplitis demolitor*, Hymenoptera, Braconidae, EAG responses, green leaf volatiles.

INTRODUCTION

Volatile phytochemicals apparently serve as important messengers in the interactions between plants and other organisms. However, knowledge of the specific roles of such phytochemicals in such interactions remains limited (Buttery et al., 1984; Buttery and Ling, 1985; Visser, 1986; Khan et al., 1987; Liu et

*To whom correspondence should be addressed.

0098-0331/91/0800-1665$06.50/0

al., 1989) as compared to that for less volatile, e.g., "tastant," compounds (Schoonhoven, 1968; Staedler, 1976; Visser et al., 1979; Norris, 1986). A few earlier workers (Jermy, 1966, 1976; Gilbert et al., 1967; Gilbert and Norris, 1968) not only elucidated an importance of volatile phytochemicals in the interactions between plants and herbivores, but also demonstrated specifically that allomonic volatiles are important means by which some plants are antixenosic towards potential guests. However, most published information emphasizes the attractiveness of plant volatiles to herbivores (Visser and Thiery, 1985; Metcalf, 1986; Landolt, 1989) and natural enemies (Eller et al., 1988; Navasero and Elzen, 1989; Sheehan and Shelton, 1989; Martin et al., 1990; Turlings et al., 1990). The responses of natural enemies of herbivores to such informational volatile phytochemistry also have been discussed as dimensions of tritrophic systems (Price et al., 1980; Price, 1986). Further investigations probably will yield evidence of polytrophic communications based especially on phytochemicals.

Results of more recent studies emphasize that the odor of a plant is typically composed of tens and hundreds of chemicals. Some are unique to a plant, while others are extremely common among them (van Straten and Marse, 1983; Visser et al., 1979). As an example of the latter point, green leaf volatile chemicals contribute variously to the smell of numerous plants (Visser, 1979; Hamilton-Kemp et al., 1988, 1989; Liu et al., 1989; Hernandez et al., 1989; Lwande et al., 1989; Connick et al., 1989; Dicke et al., 1990). Electrophysiological studies indicate that chemosensory neurons of adult phytophagous insects are highly sensitive to green leaf volatiles (Visser, 1979; Guerin and Visser, 1980; Dickens, 1984; Dickens and Boldt, 1985; Light and Jang, 1987; Ramachandran et al., 1990). Such chemicals also may be important in host–habitat location by several natural enemies (Baericke et al., 1989; Whitman and Eller, 1990; Turlings et al., 1990). In spite of this apparent importance of green leaf volatiles in tritrophic communications involving plants, herbivores, and their natural enemies, specific studies focusing on how these chemicals are perceived by phytophagous insects and their natural enemies are lacking. We therefore used an electroantennogram technique (Schneider, 1957) to analyze the olfactory sensitivities of both an herbivore, *Pseudoplusia includens* (Walker) (Lepidoptera: Noctuidae), and a parasitoid, *Microplitis demolitor* (Wilkinson) (Hymenoptera: Braconidae), to green leaf volatile chemicals. *Microplitis demolitor* is an introduced parasitoid (Shepard et al., 1983a) that develops successfully in *P. includens* (Shepard et al., 1983b).

METHODS AND MATERIALS

Insects. The colony of *P. includens* was maintained on a pinto bean-based diet (Shorey and Hale, 1965) at 27 ± 2°C and 50 ± 10% relative humidity

with a photoperiod of 14:10 hr light–dark. *M. demolitor* were reared on *P. includens* larvae following the methods of Herard et al. (1988). Adults of *P. includens* were maintained in cages with 10% sucrose solution, and those of *M. demolitor* were maintained with honey and water until used in experiments. Experiments utilized 4-day-old females and 2-day-old males.

Antennal Preparation. A moth was immobilized in a disposable 5-ml polypropylene pipet tip with paraffin wax. The insect's head and a part of the prothorax protruded from the narrow end of the pipet (the end had been cut to the appropriate dimension). Each parasitoid was immobilized in a similar manner in a pipet tip (1017-01-1, Robbins Scientific Corp., Mountain View, California 94043) with a small quantity of modeller's clay (Permoplast, American Art Clay Co., Inc., Indianapolis, Indiana). A wad of cotton, dipped in distilled water, was inserted in the wider end of the pipet to prevent rapid desiccation of the insect. The right antenna of each insect was removed to permit easy access for the indifferent electrode to the base of the recording left antenna. Insects were allowed to recover for 15 min before initiation of an experiment.

The distal end of the recording antenna was inserted into the tip of a glass pipet (20 μm diam) containing a chlorinated silver wire (Ag–AgCl) electrode (recording electrode) filled with a saline solution (NaCl, 3.75 g; $CaCl_2$, 0.105 g; KCl, 0.175 g; $NaHCO_3$, 0.100 g; H_2O, 500 ml) (Roelofs, 1984) containing 10% (v/v) of polyvinylpyrolidone (Aldrich Chemical Co., Milwaukee, Wisconsin). The base of the antenna was connected to a similar saline filled electrode. The Ag–AgCl electrode was connected through a Molex Soldercon IC terminal (Digi-Key part No. 1938-4) to a differential input probe (model HIP 16) of an amplifier (model P16 AC/DC microelectrode amplifier, Grass Instruments, Quincy, Massachusetts). The analog electroantennogram (EAG) signal, amplified 100 times, was converted to digital form through an analog–digital interface (Metrabyte DAS-8-PGA-analog-digital interface; Metrabyte Corporation, Taunton, Massachusetts). The digital signals were either viewed directly on a Compaq PC or imported into a spreadsheet program, Lotus 1-2-3 (Lotus Development Corporation, Massachusetts), using Labtech Notebook, Version-4, software (Laboratory Technologies Incorporation, Wilmington, Massachusetts). An EAG signal was monitored at the rate of 100 signals per second. Maximal EAG depolarizations were read from *xy* plots of time (msec) versus signal (v).

An experimental antenna was continuously bathed in a stream of calcium chloride-dried, activated charcoal-filtered air (40 ml/sec), which was rehumidified by bubbling it through an Erlenmeyer flask (2 liters) containing distilled water. The prepared air was introduced to the experimental site through the base of a modified Bunsen burner (Bjostad, 1988). The upper part of the Bunsen burner was replaced with a 10-cm-long glass delivery tube that had a 2-cm ID for the *P. includens* antenna and an 0.8-cm ID for the *M. demolitor* antenna.

The delivery tube had a 3-mm hole in its side wall to allow the tip of a disposable Pasteur pipet to be inserted into the airstream. The distal tip of the delivery tube was positioned 2 cm from the antennal preparation. Stimuli were applied into the airstream using a disposable Pasteur pipet (5.75 in. long). The tip of the pipet was introduced into the hole in the side wall of the delivery tube. Air (ca. 2 ml) was quickly puffed (ca. 30 msec) from a 5-ml syringe through the disposable pipet into the airstream. The modified Bunsen burner air delivery and the syringe were permanently mounted in front of a microscope stage that held the antennal preparation. A glass funnel (10 cm diam.), connected to a vacuum line, was positioned 10 cm behind the antennal preparation to evacuate chemicals continuously from the experimental area. The antenna was stimulated at 4-min intervals. A standardized series of stimulations with five test chemicals was preceded and followed by both the standard chemical (100 μg of *cis*-3-hexen-1-ol) and the control (1 μl of hexane) stimulations (Light and Jang, 1987). The *P. includens* antennal preparation remained in experimentally stable condition for 5–6 hr. *M. demolitor* antennal preparations were dependably utilized experimentally for 2 hr. Preparations were maintained in a room at 25 $\pm$ 2°C and 70% relative humidity.

Chemicals. The studied volatile phytochemicals, their source and purity are presented in Table 1. Each chemical was dissolved in HPLC-grade hexane (Aldrich Chemical Company) to yield 100 mg/ml solutions. Involved vials were numbered serially; during an experiment, each chemical was known and referenced only by its assigned number. Experimental hydrocarbons were used without a carrier solvent. For an experiment, the quantity of hydrocarbons was 10 μl for *P. includens* and 1 μl for *M. demolitor*.

Experimental Protocol. A hexane-washed, oven-dried, filter-paper strip (3 $\times$ 1 cm) was inserted into an otherwise prepared Pasteur pipet. One microliter of a test solution then was applied on the filter paper. Such a stimulus-containing Pasteur pipet was prepared prior to experimental stimulation in a room different from the one housing the EAG preparation. EAGs were recorded from three males and three females of *P. includens*, and four males and four females of *M. demolitor*.

Each EAG was analyzed by measuring the maximal millivolt (−mV) amplitude of depolarization elicited by a given stimulus. Each millivolt response was converted to a percentage value of the mV response to the accompanying standard (100 μg *cis*-3-hexen-1-ol). This analysis has been utilized in other EAG studies on insect olfaction (Guerin and Visser, 1980; Dickens, 1984; Dickens and Boldt, 1985; Light and Jang, 1987).

Statistical Analysis. The relative EAG responses to compounds within a chemical group (e.g., hydrocarbons, alcohols) were analyzed by ANOVA to distinguish the effects of sex and compounds. Multiple comparisons were performed with the mean responses of both sexes to individual compounds in a

group (when the effect of compounds was significant) or the mean responses of each sex to all compounds in a group (when the effect of sex was significant). Means were separated by Tukey's honestly significant difference test (Zar, 1984). When the interaction between the effect of sex and chemical was significant, differences in the responses of the two sexes to individual compounds

were evaluated by Student's t test (Zar, 1984). Responses of *P. includens* and *M. demolitor* were compared only in magnitude.

RESULTS

Electroantennogram Response

The typical electroantennogram responses of *P. includens* and *M. demolitor* were similar (Figure 1). This response was characterized by a fast depolarization followed by a slow return to the baseline. The recording technique permitted real-time analysis of the characteristics of a response. The fast depolarization phase of the *P. includens* response occurred between 0.2299 and 0.5299 sec (mean $\pm$ standard deviation = 0.41819 ± 0.078, $N = 18$). There was a significant positive linear relationship between the maximum amplitude of depolarization and the time for maximum depolarization (Figure 2, Student's t statistics = 2.69 $P < 0.05$). The recovery to baseline occurred between 1.5 and 4.3 sec (mean $\pm$ standard deviation = 2.926 ± 0.8835, $N = 18$) and also was related linearly to the amplitude of EAG response (Figure 2, Student t statistic = 2.23, $P < 0.05$).

Response to Standard

The absolute EAG amplitude elicited from male versus female *P. includens* or *M. demolitor* in response to stimulation with the standard (*cis*-3-hexen-1-ol) did not differ statistically (Table 2). EAG responses of female *M. demolitor* and female *P. includens* were similar (Mann-Whitney U test, $P < 0.4$), but male *P. includens* response was higher than that of male *M. demolitor* ($P < 0.006$).

TABLE 2. ELECTROANTENNOGRAM RESPONSES OF *P. includens* AND *M. demolitor* TO 100 μg OF *cis*-3-HEXEN-1-OL

Sex	EAG responses (mV)[a]	
	P. includens	*M. demolitor*
Female	3.67 ± 0.6ax	3.02 ± 0.3ax
Male	3.61 ± 0.2ax	2.34 ± 0.3ay

[a] Values in columns followed by the same letter are not significantly different, $P < 0.05$, Student's t test. Values in rows followed by the same letters are not significantly different, Mann-Whitney U test, $P < 0.05$.

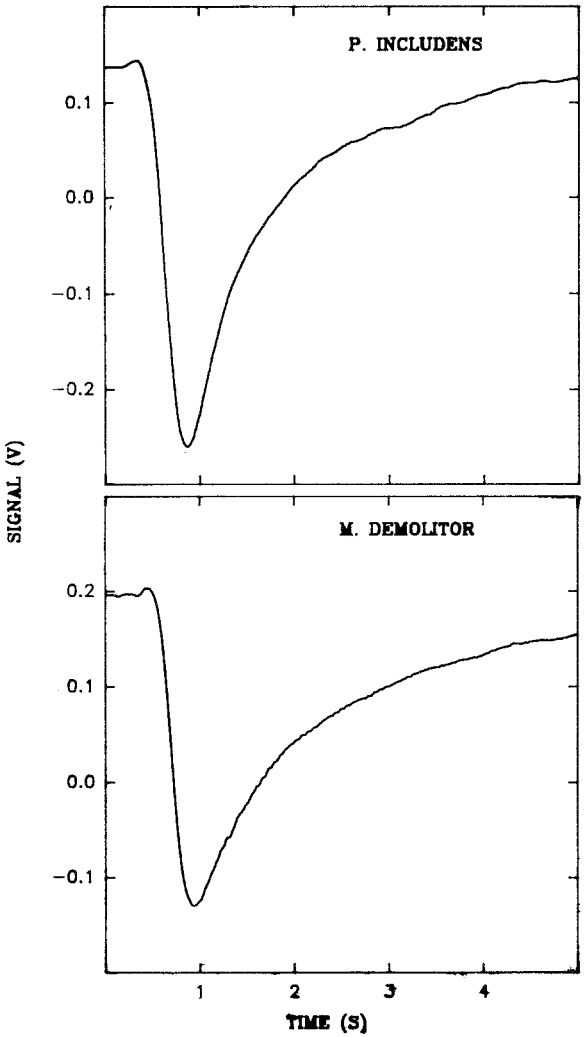

FIG. 1. Typical electroantennogram responses of *P. includens* and *M. demolitor* to stimulation with 100 μg of *cis*-3-hexen-1-ol.

Response to Hydrocarbons

Responses of male versus female *P. includens* to stimulation with hydrocarbons did not differ significantly ($F^{1,26} = 0.35$, $P < 0.350$). In both sexes, responses to all hydrocarbons differed significantly from the filter-paper control (Figure 3). Responses to compounds of different carbon-chain lengths were not

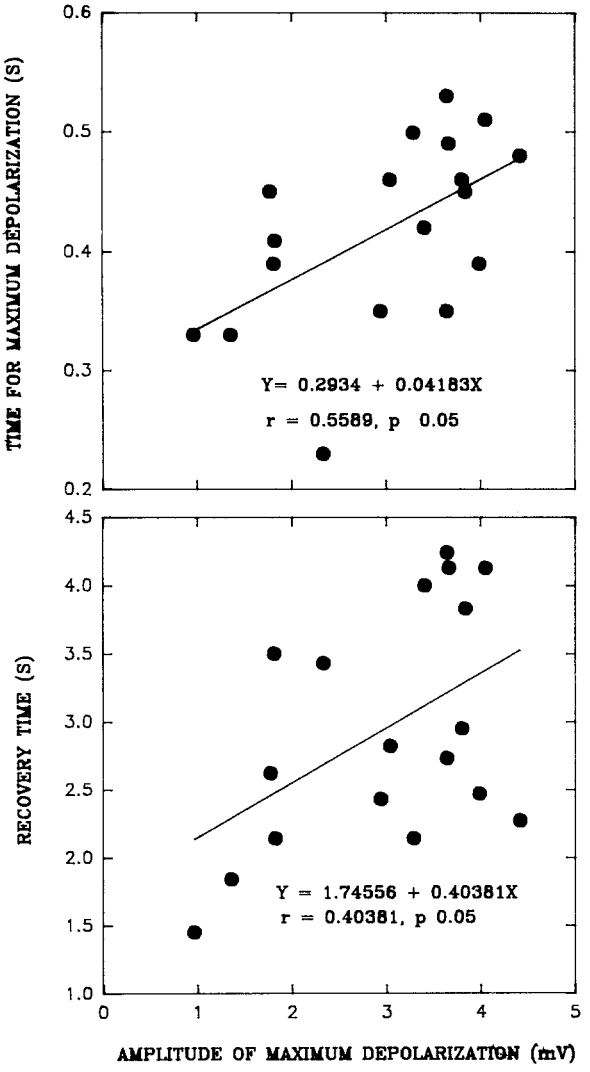

FIG. 2. Relationships between the amplitude of the EAG responses of *P. includens* and the times for depolarization and recovery.

statistically different. The recorded numerical responses, however, peaked at six carbons and decreased gradually at longer carbon-chain lengths (Figure 3).

The responses of male and female *M. demolitor* to hydrocarbons were similar ($F^{1,39} = 0.05$, $P < 0.8212$). Response to each hydrocarbon was significantly different from that to filter-paper control (Figure 3). Response to 7-, 8-,

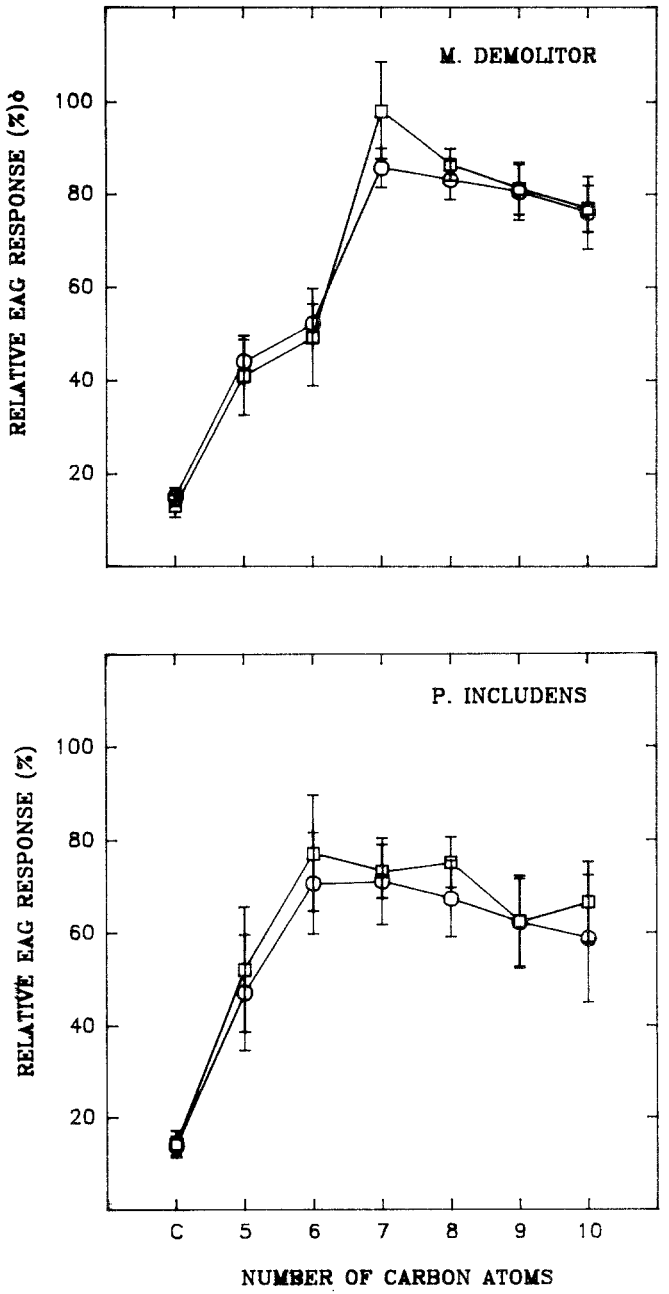

FIG. 3. EAG responses of *M. demolitor* and *P. includens* to saturated hydrocarbons. C = control (1 μl of hexane). Circles = females, squares = males.

9-, and 10-carbon compounds was significantly higher than that to 5- and 6-carbon compounds (Figure 3). More specifically the numerical response to hydrocarbons of different carbon-chain lengths peaked at 7 carbons and then decreased gradually at greater lengths (Figure 3). The response of *M. demolitor* to hydrocarbons was numerically higher than that of *P. includens*, although the quantity of stimulant was ten times lower.

Response to Aliphatic Aldehydes

Saturated Aldehydes. The magnitude (84%) of response of male *P. includens* to saturated aldehydes was higher than that (74%) of the females ($F^{1,30} = 5.71$, $P < 0.02$). Responses to 6-, 7-, 8-, and 9-carbon compounds were significantly higher than to a 10-carbon compound. Responses to 12- and 14-carbon compounds did not differ from that of the control (Figure 4). Responses peaked between the 6- and 8-carbon chain lengths.

Responses of male *M. demolitor* were higher than those of females (137.8 and 117.6% for male and female responses, respectively; $F^{1,33} = 14.51$, $P < 0.006$). Responses to 7-, 8-, and 9-carbon aldehydes were significantly higher than that to 6- and 10-carbon compounds (Figure 4). Responses of *M. demolitor* peaked at the 8-carbon chain length.

Unsaturated Aldehydes. There was a significant interaction between sex and carbon chain length regarding the responses of *P. includens* to compounds ($F^{5,22} = 3.29$, $P < 0.02$). Male responses to 6-, 7-, and 8-carbon compounds were higher than those of the females (Figure 5). Responses of both sexes to 6-, 7-, and 8-carbon compounds were significantly higher than those to 5- and 9-carbon compounds (Figure 5). Responses numerically peaked between the 6- and 7-carbon chain lengths.

Male *M. demolitor* elicited a higher EAG response (119.8%) to unsaturated aldehydes than did females (106.3%) ($F^{1,39} = 19.71$, $P < 0.05$). Responses to 7- and 8-carbon compounds were significantly higher than to all other compounds. Responses peaked between the 7- and 8-carbon chain lengths (Figure 5). Peak responses of *M. demolitor* were higher than those of *P. includens*.

Aliphatic Alcohols

Saturated Alcohols. Responses of male *P. includens* to 6- and 7-carbon alcohols were significantly higher than that of females. Highest responses were recorded for 5-, 6-, and 7-carbon compounds (Figure 6). Responses dropped ca. 40% as the carbon chain length increased beyond 7 carbons. Response to 9-, 10-, 12-, and 14-carbon compounds did not differ significantly from that to the solvent control.

Female *M. demolitor* response (79.61%) was higher than that of the males

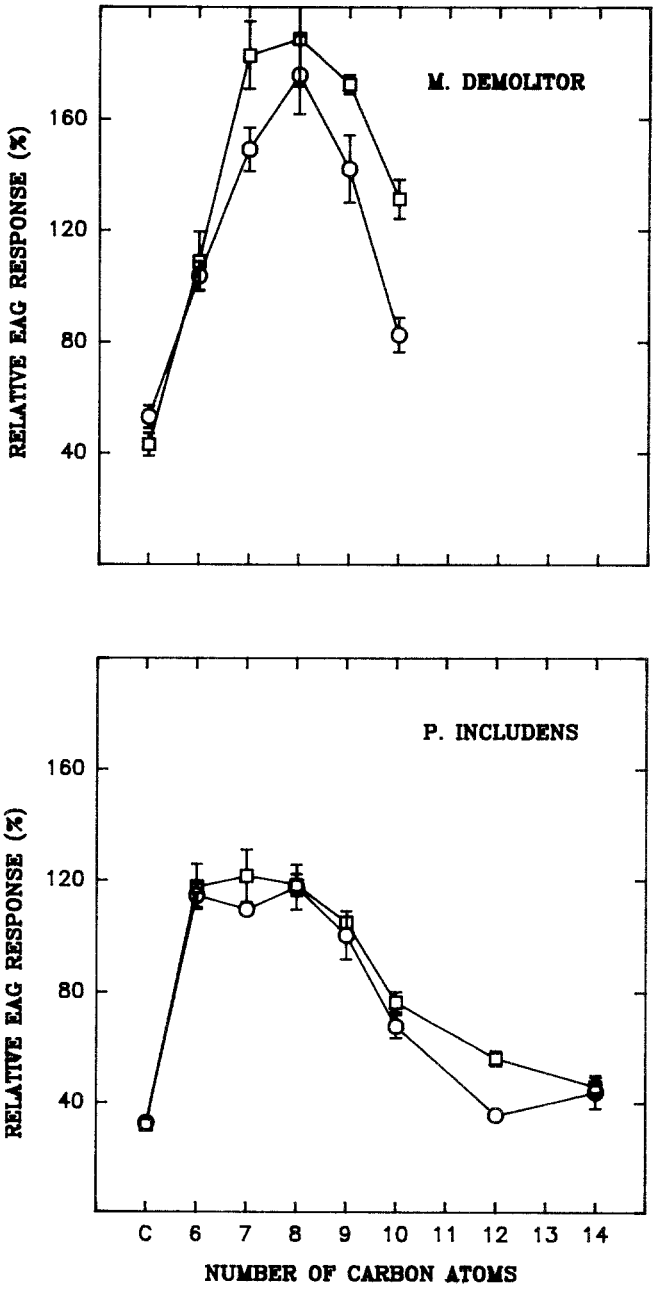

FIG. 4. EAG responses of *M. demolitor* and *P. includens* to saturated aldehydes. C = control (1 μl of hexane). Circles = females, squares = males.

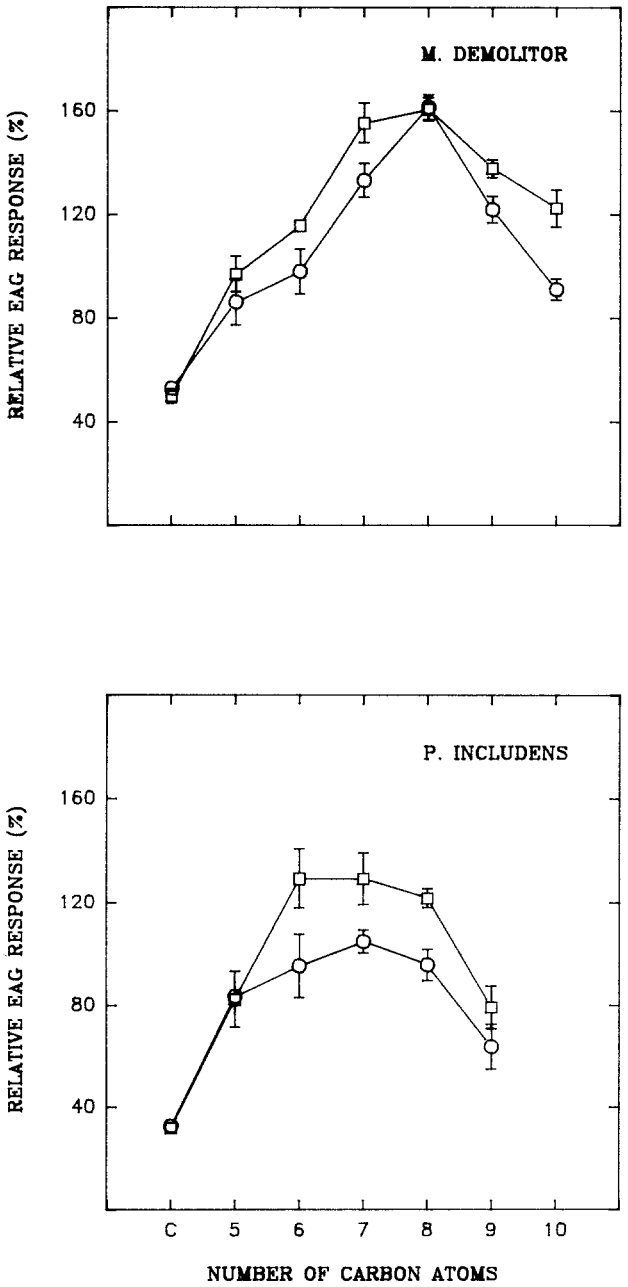

FIG. 5. EAG responses of *M. demolitor* and *P. includens* to unsaturated aldehydes. C = control (1 μl of hexane). Circles = females, squares = males.

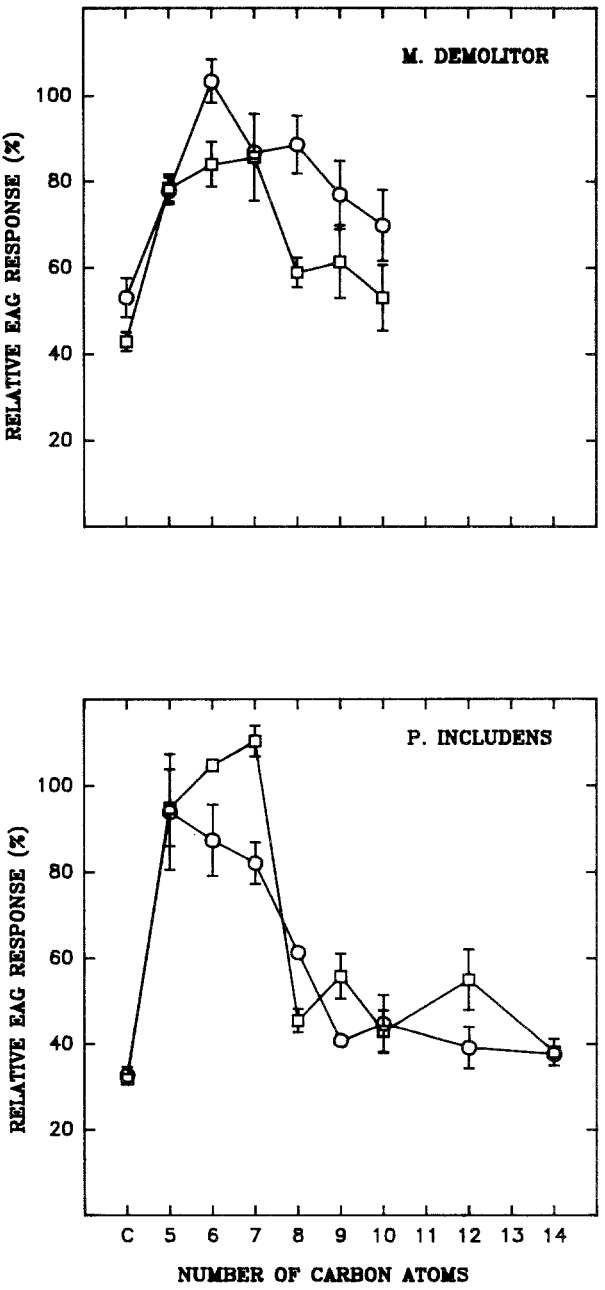

FIG. 6. EAG responses of *M. demolitor* and *P. includens* to saturated alcohols. C = control (1 μl of hexane). Circles = females, squares = males.

(67.51%) ($F^{1,37} = 15.21$, $P < 0.004$). The highest numerical response was recorded for the 6-carbon compound, although this response was not statistically different from that for 5-, 7-, and 8-carbon compounds (Figure 6). The response profiles of *M. demolitor* and *P. includens* were similar (Figure 6).

Unsaturated Alcohols. Responses of male versus female *P. includens* to unsaturated alcohols were similar ($F^{1,22} = 2.88$, $P < 0.1036$). The two optical isomers of a 6-carbon alcohol (*cis*- and *trans*-hexen-1-ol) and an 8-carbon unsaturated alcohol elicited higher responses in this chemical class (Figure 7). The responses to 9-, 10-, 12-, and 14-carbon compounds were lower than to the above alcohols but significantly higher than that to the solvent control. Responses of *M. demolitor* to these unsaturated alcohols were not studied.

Aliphatic Ketones

Male and female responses of *P. includens* were similar among the studied compounds of this chemical class ($F^{1,26} = 0.13$, $P < 0.7252$). Response to the 8-carbon ketone was statistically similar to that for the 7-carbon compound (Figure 8). Responses to the other studied ketones were lower. Aliphatic ketones elicited similar responses from male and female *M. demolitor* ($F^{1,26} = 0.81$, $P < 0.3772$). The responses could be categorized into two homogenous groups: (1) responses to 7-, 8-, and 9-carbon compounds, which were high and significantly different from that to the solvent control; and (2) responses to 5-, 6-, and 10-carbon compounds, which did not differ from those to the solvent control. Peak response was observed at the 8-carbon chain length (Figure 8). Peak response of *M. demolitor* was numerically higher than that of *P. includens*.

Esters

Responses of both sexes of *P. includens* were similar. Response to all compounds was significantly higher than that to the solvent control (Figure 9). Comparison of means indicates that the compounds could be divided into three distinct groups: the highest response, recorded with the 6-carbon compound; the intermediate, recorded with 7- and 8-carbon compounds; and the lowest responses, recorded with 9- and 10-carbon esters. Responses of *M. demolitor* to esters were not studied.

Response to Functional Groups

To determine how the chemical functional group affected the EAG response, that reaction to 6-, 7-, and 8-carbon compounds with different functional groups was analyzed by ANOVA. *P. includens* adults proved more sensitive to aldehydes (saturated or unsaturated) and ketones (Figure 10). Hydrocarbons were the least stimulatory.

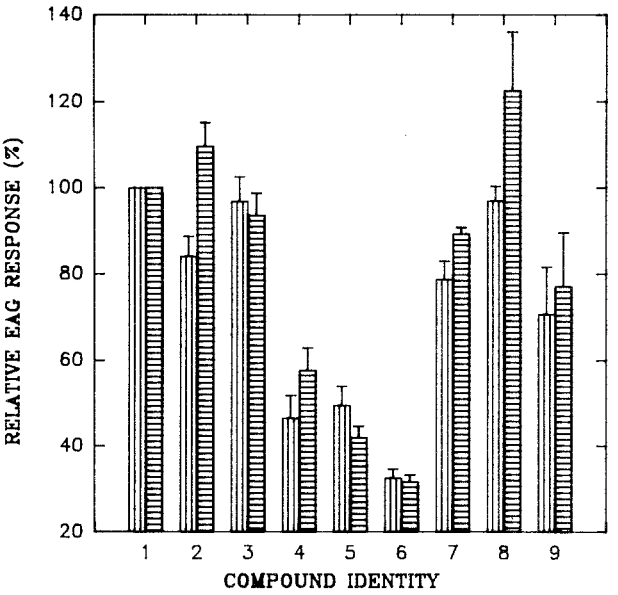

FIG. 7. EAG responses of *P. includens* to unsaturated alcohols. (1) *cis*-3-hexen-1-ol, (2) *trans*-3-hexen-1-ol, (3) 1-octen-3-ol, (4) *cis*-3-nonen-1-ol, (5) *trans*-5-decen-1-ol, (6) control (1 μl of hexane), (7) *cis*-7-tetradecen-1-ol, (8) *cis*-7-dodecen-1-ol, (9) control (10 μl of hexane). C1 = 1 μl of hexane as control, C2 = 10 μl of hexane as control. One microliter of 100 mg/ml solutions was used as stimuli for compounds 1, 2, 3, 4, and 5. Ten microliters of 10 mg/ml solutions were used for compound numbers 7 and 8. Hence these results are to be compared with their respective solvent controls (i.e., 1 or 10 μl of hexane). Columns with vertical lines = females, with horizontal lines = males.

For *M. demolitor*, saturated aliphatic aldehydes were the most stimulatory, and unsaturated aldehydes and ketones were next (Figure 10). Responses to alcohols and hydrocarbons were lower, but similar (Figure 10).

DISCUSSION

Characteristics of EAG Responses. A typical EAG response has at least three measurable parameters: (1) the amplitude of depolarization, (2) the time required for depolarization, and (3) the time required to return to the baseline after depolarization. Most studies use the amplitude of depolarization as the parameter to measure the sensitivity of insects to olfactory stimulants (Blust and Hopkins, 1987; Light and Jang, 1987; Whitehead, 1986). A few investigations have also utilized the recovery time, or half time to recovery, to the baseline

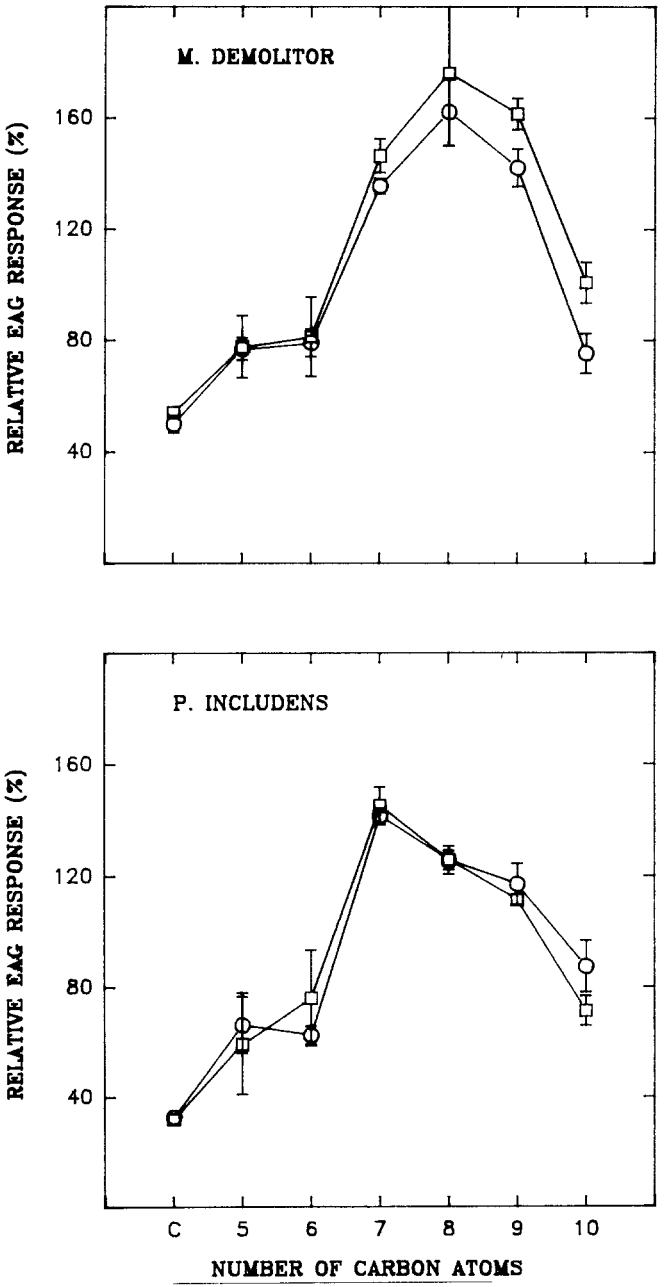

FIG. 8. EAG responses of *M. demolitor* and *P. includens* to aliphatic ketones. C = control (1 μl of hexane). Circles = females, squares = males.

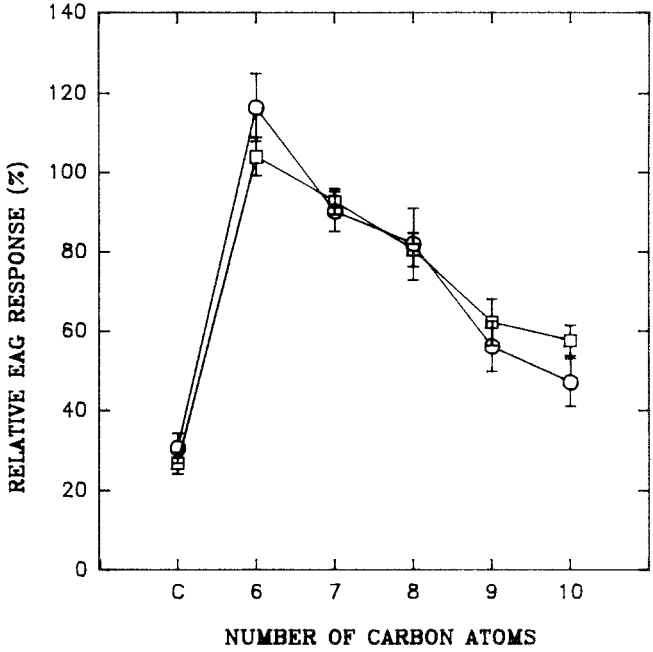

FIG. 9. EAG responses of *P. includens* to esters. C = control (1 μl of hexane). Circles = females, squares = males.

as an index of EAG response (Visser, 1979). Compounds with high biological activity are reported to have slow recovery to the baseline (Roelofs, 1986). However, relationships among the above three parameters are not well documented. Our EAGs were recorded in real time to an accuracy of 1/100th of a second. Our results indicate that both the time for depolarization and the recovery time are significantly related linearly to the amplitude of depolarization. However, only a small portion of the variability in these two parameters was accounted for (r^2 = 0.3124 and 0.1631 for depolarization and recovery time, respectively; Figure 2) by their dependence on the amplitude of depolarization.

Female adults of the herbivore, *P. includens*, and the natural enemy, *M. demolitor*, elicited similar absolute EAG responses to the standard, *cis*-3-hexen-1-ol. Since the magnitude of the EAG response to a given stimulus is directly related to the number of receptors reacting (Payne, 1975) and the length of the herbivore antenna (9.6 ± 0.5 mm) is about three times longer than that of the parasitoid (3.3 ± 0.2 mm for female antenna), then the similarity in the responses suggests a higher density of receptors per unit of antennal length on the natural enemy.

Sexual Differences. Males of both the parasitoid and the herbivore are more

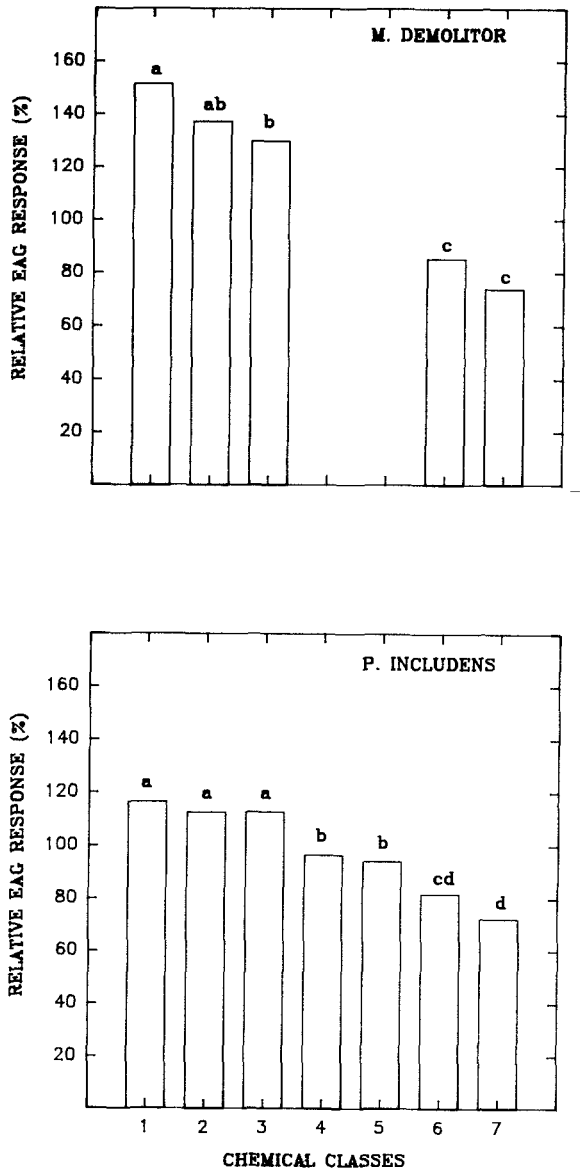

FIG. 10. Responses of *M. demolitor* and *P. includens* to compounds with different functional groups. Each bar is the mean response of male and female moths, or parasitoids, to 6-, 7-, and 8-carbon compounds; (1) saturated aldehydes, (2) unsaturated aldehydes, (3) ketones, (4) unsaturated alcohols, (5) esters, (6) alcohols, (7) hydrocarbons. Bars not bearing the same letters are statistically significant, Tukey's honestly significant difference test, $P < 0.05$.

sensitive than the female to saturated and unsaturated aldehydes. Adult males of several phytophagous insects have given a higher response than their conspecific females to some plant volatiles (Guerin and Visser, 1980; Dickens, 1984; Honda et al., 1986; Blust and Hopkins, 1987; Hansson et al., 1989; Ramachandran et al., 1990). The higher sensitivity of males to some plant volatile compounds may be explained partially on the basis that some of these compounds may also stimulate pheromone receptors and thus produce a larger EAG response through additive or synergistic effects. The observed sensitivity of male antennae to plant volatiles has led to the postulation that the perception of plant volatiles by male antennal receptors evolved before their function in pheromone detection. It has been further theorized that a primitive mate-finding system could be based on both sexes gathering around suitable food plants (Lanne et al., 1987; Hansson et al., 1989). Synergism of bark beetle and cotton boll weevil sex pheromones by plant volatiles (Bedard et al., 1969, 1980; Dickens, 1989) and the attraction of male cabbage looper moths to cabbage plants in a wind tunnel (Landolt, 1989; Landolt and Heath, 1990) support the suggestion that such resource-based mating strategies occur in insects.

Males of the parasitoids, *Diadromus pulchellus* Wesmeal and *D. collaris* Gravenhorst, are also known to perceive plant volatiles (Lecomte and Pouzat, 1985). Mate location by male *Campoletis sonorensis* (Cameron) was reported to be mediated partly by volatiles of cotton (McAuslane et al., 1990). However, other studies have reported that male parasitoids do not respond to volatiles from the host habitat (Elzen et al., 1986; Eller et al., 1988; Whitman and Eller, 1990) or that their response to such volatiles was lower than that of conspecific females (Martin et al., 1990). The EAG responses of male *M. demolitor* were comparable to those of the females for hydrocarbons and ketones, higher for saturated aldehydes, and lower for alcohols. It seems likely that both the low concentration and the unnaturalness of the stimulus source, and the physiological condition of the males, may have influenced their response in studies where male parasitoids did not orient to plant volatiles (McAuslane et al., 1990).

Carbon Chain Length Effects. Phylogenetically diverse phytophagous insects have been reported to be selectively responsive to 6- and 7-carbon alcohols and aldehydes (Visser, 1986; Light and Jang, 1987). The EAG responses of *P. includens* similarly were higher for 6- and 7-carbon hydrocarbons, saturated and unsaturated aldehydes, saturated and unsaturated alcohols, and esters. The response to ketones clearly peaked at 7 carbons. This latter significant difference may possibly be explained by the fact that the functional group in ketones is located on the second carbon, whereas it is on the first carbon in the other classes of chemical compounds tested. This difference thus might make a 7-carbon ketone the reactive equivalent of a 6-carbon compound in the other chemical classes.

With the natural enemy, *M. demolitor*, the responses were higher for the

7- and 8-carbon hydrocarbons, saturated aldehydes, unsaturated aldehydes, and ketones. In all chemical classes tested, except alcohols, there was a 1-carbon shift in the peak response by the parasitoid as compared to the herbivore. A similar higher EAG response to heptanal than hexanal was recorded for *C. sonorensis* (Baehrecke et al., 1989). Our results, along with those of Baehrecke et al. (1989), thus suggest a difference in the olfactory-response profile of a herbivore and its parasitic hymenopteran to plant volatiles. Six-carbon alcohols, aldehydes, and their derived esters are found in several plants (van Straten and Maarse, 1983; Visser et al., 1979; Visser, 1986). Consequently, higher responses of herbivores to 6-carbon compounds could be of adaptive significance. However, several plants reportedly contain a full range of ca. C_2–C_{12} aliphatic compounds (van Straten and Maarse, 1983; Connick et al., 1989; Liu et al., 1989). In view of our limited understanding of which plant volatiles parasitoids utilize to locate their host habitat (Whitman, 1988a,b), the biological significance of the observed heightened sensitivity of some parasitoids to 7-carbon compounds remains unknown. The searching behavior of the parasitic wasp, *Orgilus lepidus* (Hymenoptera: Braconidae), however, was elicited by heptanoic acid, which is present in the frass of its host, the larvae of the potato tuber moth (Hendry et al., 1973). It is well known that volatiles from the frass of host larvae play important roles in the behavior of several parasitoids (Vinson, 1984; Nordlund et al., 1988; Whitman, 1988a,b; Lewis and Tumlinson, 1988). When the above caterpillars ingest and metabolize host tissues, 7-carbon aliphatic compounds may be uniquely abundant volatile metabolites in their frass. The observed high responses of some parasitoids to 7-carbon compounds thus might be adaptive.

Several studies also have demonstrated an increase in parasitoid responses to plants damaged by herbivorous insects (Whitman and Eller, 1990; Turlings et al., 1990). Herbivore damage certainly increases the quantity of volatile compounds emanating from the plant (Whitman and Eller, 1990; Turlings et al., 1990). Whether herbivore damage produces a significant shift from 6-carbon to 7-carbon compounds in the volatile profiles of a plant is not known.

Chemical Class Effects. EAG amplitudes for phytophagous insects have been selectively greater for either aldehydes (Dickens, 1984; Dickens and Boldt, 1985; Ramachandran, 1990) or alcohols (Guerin and Staedler, 1982; Visser, 1979; Kozlowski and Visser, 1981; Van der Pers, 1981). In *P. includens*, responses to saturated and unsaturated aldehydes and ketones were higher than to other tested chemical classes. The *P. includens* response profile was similar to that of *Anthonomas grandis* (Dickens, 1984) and *Trirhabda bracharides* (Dickens and Boldt, 1985). The hierarchy of responses by the parasitoid, *M. demolitor*, and the herbivore, *P. includens*, to compounds in the tested chemical groups was remarkably similar (Figure 10). However, the response of the parasitoid to tested aldehydes, ketones, and hydrocarbons was greater than that of the herbivore. The higher responses of the parasitoid to hydrocarbons was of

particular interest because the quantity of stimulus was 10 times lower. Various studies have shown that parasitic Hymenoptera are stimulated by kairomones originating from the host's body and scales (Vinson, 1984; Nordlund et al., 1988; Whitman, 1988a,b). Since the host body and scales contain cuticular hydrocarbons, a higher response by a parasitoid to hydrocarbons may be adaptive.

Green Leaf Volatiles and Tritrophic Interactions among Plants, Herbivores, and Natural Enemies. Several authors have suggested that plant volatiles have evolved to serve tritrophic communicative roles (Whitman, 1988b, 1990; Dicke and Sabelis, 1989; Dicke et al., 1990). Based on the evidence that the release of green leaf volatiles is increased after an herbivore attack (Wallbank and Wheatley, 1976; Tollsten and Bergström, 1988; Dicke et al., 1990; Whitman and Eller, 1990) and that several parasitoids and predators are much more attracted to damaged plants than to undamaged plants (Sato, 1979; Elzen et al., 1983; Loke et al., 1983; Odell and Godwin, 1984; Nadel and van Alphen, 1987; Dicke and Sabelis, 1988; Whitman, 1988b; Whitman and Eller, 1990), it has been proposed that such release of volatiles might represent an act of "screaming for help" by the plants (Whitman and Eller, 1990). Our results, which indicate that the parasitoid antenna is much more sensitive to several plant volatiles than that of the herbivore, support the hypothesis that a higher release of such volatiles after herbivore attack is adaptive to the plant. Whether the differences in the electrophysiological responses of the herbivore and parasitoid correlate with differing behavioral responses remains to be determined. Our observed increased sensitivity of the parasitoid antenna to 7-carbon versus 6-carbon compounds suggests that the 7-carbon volatiles may be more important in parasitoid host-seeking behavior. We hypothesize that herbivore frass may be the major source of such 7-carbon volatiles. When some herbivores ingest and metabolize host tissues, 7-carbon aliphatic compounds may be uniquely abundant in their frass. Identification of heptanoic acid in the frass of the potato tuber moth as the kairomone for its parasitoid supports our contention (Hendry et al., 1973). Although emphasis currently is placed on plants as the most important source of volatile cues for parasitoid orientation (Whitman and Eller, 1990; Turlings et al., 1990), we suggest that the contribution of volatiles in herbivore frass may be more important. An alternative explanation for the observed heightened sensitivity of the parasitoid antenna to 7-carbon compounds could be that after herbivore damage there is a shift from 6- to 7-carbon volatiles being released by a plant. There is, however, no experimental evidence to support this. Our current research is examining these possibilities.

Acknowledgments—A Robert S. McNamara Fellowship from the Economic Development Institute of the World Bank to R.R. made these studies possible. (Received March 8, 1991; accepted April 22, 1991)

Abstract—Neonate *Plutella xylostella* moved more rapidly, spent more time walking, and engaged in searching behaviors more often on leaves of NY 8329, a resistant cabbage with glossy leaves, than on Round-Up, a susceptible variety with normal wax bloom. The neonates also spent significantly more time palpating and more time biting and spinning silk on the susceptible cabbage (although the latter two differences were not significant). Very similar differences in neonate behavior occurred on leaf surface wax extracts (hexane and dichloromethane) of the two cabbage genotypes. Leaf surface waxes are thus strongly implicated in eliciting reduced acceptance of the glossy cabbage by neonate *P. xylostella*. The chemical compositions of the leaf wax extracts were markedly different. Several compounds, including the triterpenols α- and β-amyrin, were found only in the glossy waxes. The percentages of some major wax constituents differed between wax extracts of the two cabbage types. These differences in wax composition may condition the plant resistance in glossy types.

Key Words—*Plutella xylostella*, Lepidoptera, Plutellidae, *Brassica oleracea*, plant epicuticular lipids, leaf surface waxes, insect movement, insect behavior, host-plant resistance.

INTRODUCTION

The diamondback moth, *Plutella xylostella* (L.), a serious pest of crucifer crops, is extremely difficult to control because of resistance to insecticides in many populations (Talekar and Griggs, 1986; Shelton et al., 1991). Among the alternatives to pesticides are insect-resistant crop genotypes derived from the glossy-leafed cauliflower PI 234599 (Lin et al., 1983, 1984; Eigenbrode et al., 1990; Dickson et al., 1990). These genotypes have a glossy leaf surface wax, which differs from the normal whitish wax bloom (normal bloom) of cultivated *Brassica* (Eigenbrode and Shelton, 1990).

Larval survival on some glossy genotypes of cabbage is $< 1\%$ of survival on normal bloom susceptible cabbages, and first instars are most strongly affected (Lin et al., 1983; Eigenbrode et al., 1990). Neonates move several times faster, establish fewer feeding sites, and have much higher mortality on resistant glossy-leafed plants than on susceptible plants with normal bloom. Disruption or removal of the leaf waxes of NY 8329, a resistant glossy cabbage descended from PI 234599, eliminated differences in (Dickson et al., 1984) *P. xylostella* neonate movement rates between this line and Round-Up, a susceptible cabbage variety with normal bloom (Eigenbrode and Shelton, 1990). These results suggested that glossy leaf surface waxes conditioned resistance to *P. xylostella* by eliciting reduced acceptance of the plants by neonates.

In this paper we report quantitative descriptions of the behaviors of *P. xylostella* neonates on glossy-leafed resistant NY 8329 and normal bloom susceptible Round-Up, in order to define better the host acceptance behaviors of the larvae. The role of leaf waxes in host acceptance was examined by quantifying behaviors on leaf surface wax extracts of these two cabbage genotypes. The composition of the leaf wax extracts used in these assays was determined by GC-MS analysis and chemical differences examined as the possible basis of behavioral discrimination by the larvae.

METHODS AND MATERIALS

Plants and Insects. Seeds of glossy cabbage NY 8329 were provided by M.H. Dickson (Department of Horticulture, New York State Agricultural Experiment Station) and those of a susceptible hybrid cabbage, Round-Up, were obtained from Seedway (Hall, New York). Seedlings were started in the greenhouse on April 15, 1989, and transplanted to field plots on June 16, 1989. Bioassays and extractions were performed using plants six weeks after transplant. Neonate *P. xylostella* were obtained from a laboratory colony, established in the autumn preceding the bioassay studies and maintained through the winter in the laboratory. These insects were reared on the same meridic diet used to rear larvae used in determining resistance levels of the plants.

Bioassay. Before being used in bioassays, neonate larvae were subjected to a two-stage screening procedure to reduce variability in their level of activity. Batches of approximately 1000 eggs freshly laid on cabbage extract-treated aluminum foil sheets were incubated at 28°C. Soon after the larvae hatched, they descended from the foil sheet on a silken thread. The first stage of the screening accepted only those larvae descending 3 cm to 6 cm from the sheet in a 5-min period. This group then was placed in the center of a 10-cm circle on glass, and those larvae reaching the perimeter of the circle in an additional 5 min were used in the bioassays. Thus the larvae used were neonates that had not yet fed, were < 1 hr old, and were similar in activity levels.

Larvae were placed on the test substrate (plant material or wax extract) and their movement and behaviors were quantified for 5 min. Larval movement rates, orientation, and degrees of turn per centimeter of track, as well as time and number of occurrences of specific behaviors were recorded using a computer-assisted monitoring device (Eigenbrode et al., 1989). This device permits simultaneous recording of larval location and specific behaviors observed at 30 $\times$ magnification with a dissecting microscope. Larvae were confined for observation in a 3 $\times$ 5-cm arena by a barrier of silicone grease (Dow-Corning, Corning, New York). If a larva left the arena or became entrapped in the silicone grease barrier, the observation was terminated.

Average speed was defined as the average distance traveled per minute during the entire 5-min observation. Average speed is therefore determined by the speed of walking and amount of time spent walking. This variable is identical with movement rate reported in previous studies of *P. xylostella* on resistant plants (Eigenbrode and Shelton, 1990; Eigenbrode et al., 1991). Walking speed was defined as the average distance traveled per minute, calculated only while the insect was walking. The direction of travel was calculated every 0.25 cm of path. The change in the direction of travel from the previous determination (degrees of turn) then was calculated. The accumulated degrees of turn during a 5-min observation were divided by the total path length of that observation to determine the average degrees of turn per centimeter of path (turning). The specific behaviors recorded were biting, palpating, searching, spinning silk, and walking. Biting was defined as contraction of the mandibular muscles, visible through the larva's cuticle, while the mouthparts were in contact with the substrate. Palpating was defined as touching the mouthparts repeatedly to the substrate but not biting. Searching was defined as raising the front half of the body from the substrate and moving it from side to side. Spinning silk was defined as the deliberate side to side movement of the head while spinning a silken strand and anchoring the strand at the extremes of this movement. Walking was defined as forward movement by the larva.

Test Substrates. Tests were performed on fresh leaves or on leaf surface wax extracts deposited on glass. Leaves were cut from plants in the field and

the petioles were immediately placed in water-filled tubes. The leaves were brought to the lab within 15 min, and observations were made on the underside of the leaves [the leaf surface preferred by larvae in the field (personal observations; Salinas, 1984)]. Leaves selected for study were the sixth to eighth fully expanded leaves on the plant. Each leaf was used for recording for no more than 1 hr (approximately five larvae could be recorded during this time period).

Waxes were removed from the leaf surfaces by washing the leaves in either hexane or dichloromethane. Approximately 30 leaves (sixth to eighth fully expanded) of each of the two genotypes were washed for 10 sec in three consecutive baths of the respective solvent. The three washings were combined, dried over sodium sulfite, and filtered. The amount of wax in each pooled extract was determined by evaporating the samples and weighing the residues. The amount of wax/cm^2 of leaf surface of each cabbage genotype was calculated, using the combined area of the leaves used to prepare the extract. Volumes of extract were applied to clean glass slides and evaporated so that a film of waxes was deposited on the slide. The amount of extract applied was adjusted to produce a wax deposit of approximately 60 μg/cm^2, which is the wax load on the susceptible cultivar, Round-Up. Preliminary studies with different wax loads indicated that this was the best procedure to detect larval discrimination. Leaf waxes deposited on slides did not differ substantially between the two genotypes in morphology, as determined by SEM, unlike the waxes on intact leaves, which have extremely different crystal structures (Eigenbrode et al., 1991). The assays thus detect differences in larval response to wax qualities, independent of amount or morphology of wax on the leaves of the two cabbage genotypes. The wax coated slides were held at -20°C until they were used in the bioassays. Barriers were constructed and larval behaviors were recorded as on intact leaves.

Design of Tests and Analysis. For the fresh leaf tests, 10 leaves of NY 8329 and Round-Up were used and a total of 45 and 52 larvae were recorded on each of the two lines. The recordings took place over a four-day period using larvae from two consecutive cohorts of larvae. The cabbage genotype was alternated hourly during the recording.

The test design was similar on deposited wax extracts. For each solvent $\times$ genotype combination, 30 larvae were observed, five on each of six replicate slides. The treatments were alternated and the replicate slides were used in rotation during recording. The tests for each solvent were conducted and analyzed as separate experiments comparing cabbage varieties, and each experiment used larvae from a single cohort and was conducted over a three-day period.

The behavioral data described above were determined for each larva in the tests. Differences in the mean values of each behavior or category on the leaves or waxes of the two cabbage genotypes were evaluated with Student's t test.

GC-MS Analysis. Extracts were treated with *N,O*-bis(trimethylsilyl)-

acetamide at 110°C for 10 min. Samples were dried under a stream of N_2 and resuspended in hexane. Aliquots were analyzed by combined gas chromatography–mass spectrometry (Hewlett Packard 5890A/5970). The capillary column (25-m cross-linked methyl silicone) was held at 55°C for 3 min after injection (splitless), and the oven temperature was then raised to 305°C at a rate of 15°C/min and held at this temperature for 20 min. Individual peaks were identified by their mass spectra (Holloway et al., 1976; Heupel, 1985; Espelie and Bernays, 1989), which were recorded at 70 eV at intervals of 0.8 sec. Quantitation was based upon the integration of total ion chromatograms.

The trimethylsilyl ether derivatives of standard samples of α-amyrin (K&K Chemicals) and β-amyrin (Pfaltz & Bauer) were found to have retention times and mass spectra identical to those of the components recovered from NY 8329 cabbage leaves, and the mass spectra were matched by computer search with the National Bureau of Standards Mass Spectral Library.

RESULTS

Behaviors of neonate *P. xylostella* differed on fresh leaves of the two cabbage genotypes (Table 1). The larvae spent significantly more time walking, walked more frequently, and walked significantly faster on leaves of NY 8329 than on leaves of susceptible Round-Up. As a result, average speed and walking speed were both significantly greater on the glossy genotype. Neonates also accumulated more degrees of turn per centimeter of path length on Round-Up than on NY 8329, and this difference was marginally significant. The larvae searched significantly more often on resistant leaves and spent more time searching (although the latter difference is not significant at $\alpha = 0.05$). The larvae also spent less time palpating resistant leaves and palpated them less often than susceptible leaves (although the latter difference is not significant at $\alpha = 0.05$). Larvae spent less time biting and spinning and engaged in these two behaviors less often on the resistant leaves than on susceptible leaves (although these differences are also not significant at $\alpha = 0.05$).

Larval behaviors also differed on the extracted leaf surface waxes of the two cabbage genotypes (Table 1). Relative responses of the larvae to waxes of the two genotypes were very similar to the responses to intact leaves from these genotypes. The cabbage genotype eliciting the greater response (occurrences or time) in the intact leaf bioassay almost always also elicited a greater response in the bioassay on the wax extracts. Exceptions were palpations (on both wax extracts) and searching (on hexane extracts), in which there were no differences between the two genotypes. However, the size of the behavioral differences and statistical separations were not as great on leaf wax extracts as on fresh leaves. Statistical separation was greatest on leaves, less on hexane-extracted waxes,

and least on dichloromethane-extracted waxes, both in the number of differences significant at $\alpha = 0.05$ (6 vs. 4 vs. 3) and the size of the P values in general. One exception to this trend was biting; on hexane extracts, biting was much greater on Round-Up relative to NY 8329 than on whole plants.

Average speed, but not walking speed, was significantly greater on waxes from resistant NY 8329 than on waxes from susceptible Round-Up. Average speed and walking speed are both more than four times greater on waxes than on leaves of both genotypes (average speed = 3.47 cm/min on waxes vs. 0.82 on leaves; walking speed = 5.46 cm/min on waxes vs. 1.19 on leaves). It is possible that this difference is due to the differences in the larval cohorts used in these experiments. This is unlikely, however, since variation between cohorts in other behaviors is minimal. The mean values for all other behavioral statistics are comparable on fresh leaves and wax extracts.

The wax extracts from the two genotypes were shown by GC-MS to be very different chemically (Table 2). The epicuticular lipids recovered from leaves of Round-Up were dominated by a few components: *n*-nonacosane, 14- and 15-nonacosanol, 15-nonacosanone, and *n*-hentriacontane. These compounds comprised 91% of the surface lipids in the dichloromethane extract of Round-Up leaves, but only 13% of the surface lipids in the dichloromethane extract of NY 8329 leaves (Figure 1). Primary fatty alcohols were the major components (37% in the dichloromethane extract and 45% in the hexane extract) of the NY 8329 leaf wax, with hexacosanol the dominant homolog (Table 3). The NY 8329 leaves had a much lower proportion of *n*-alkanes than did the Round-Up leaves, and within this class of compounds the NY 8329 surface lipids had a shorter average chain length (more C_{25} and C_{27}; no detectable C_{31}). The secondary alcohols, 13- and 14-heptacosanol, were found only in the extracts of NY 8329 leaves, while the secondary diol, 14,15-nonacosandiol, was more prominent in the Round-Up leaf wax extracts (Table 2). The triterpenols, α- and β-amyrin, were detected only in the surface lipids of the NY 8329 leaves.

The hexane and dichloromethane extracts of Round-Up leaves were similar in chemical composition. There were greater differences between the two extracts of NY 8329 leaves. The dichloromethane extracts had a larger proportion of fatty acids (10%) than did the hexane extracts (2%) and hexacosanoic acid was found only in the dichloromethane extract (Table 2). There was also a greater amount of triterpenols in the dichloromethane extract (9%) of NY 8329 leaves than in the hexane extract (3%).

DISCUSSION

The differences in neonate *P. xylostella* behavior on intact leaves of resistant glossy NY 8329 and susceptible normal bloom Round-Up cabbage support the hypothesis that larvae reject the resistant glossy plants. Increased larval

movement rates, which had been interpreted as indicators of larval nonacceptance of glossy resistant *Brassica oleracea* (Eigenbrode and Shelton, 1990; Eigenbrode et al., 1991), are shown here to be associated with increased searching and reduced biting and silk spinning on these plants, as compared with the susceptible normal bloom type.

The epicuticular lipid composition found for the leaves of Round-Up was similar to that previously reported for *Brassica oleracea* (Netting et al., 1972; Baker, 1974). In each class of components, C_{29} was consistently the dominant homolog. NY 8329 lipids were not dominated by the C_{29} homologs and had a more diverse composition. The higher percentage of free fatty acids and primary alcohols and lower percentage in alkanes, secondary alcohols, and ketones in

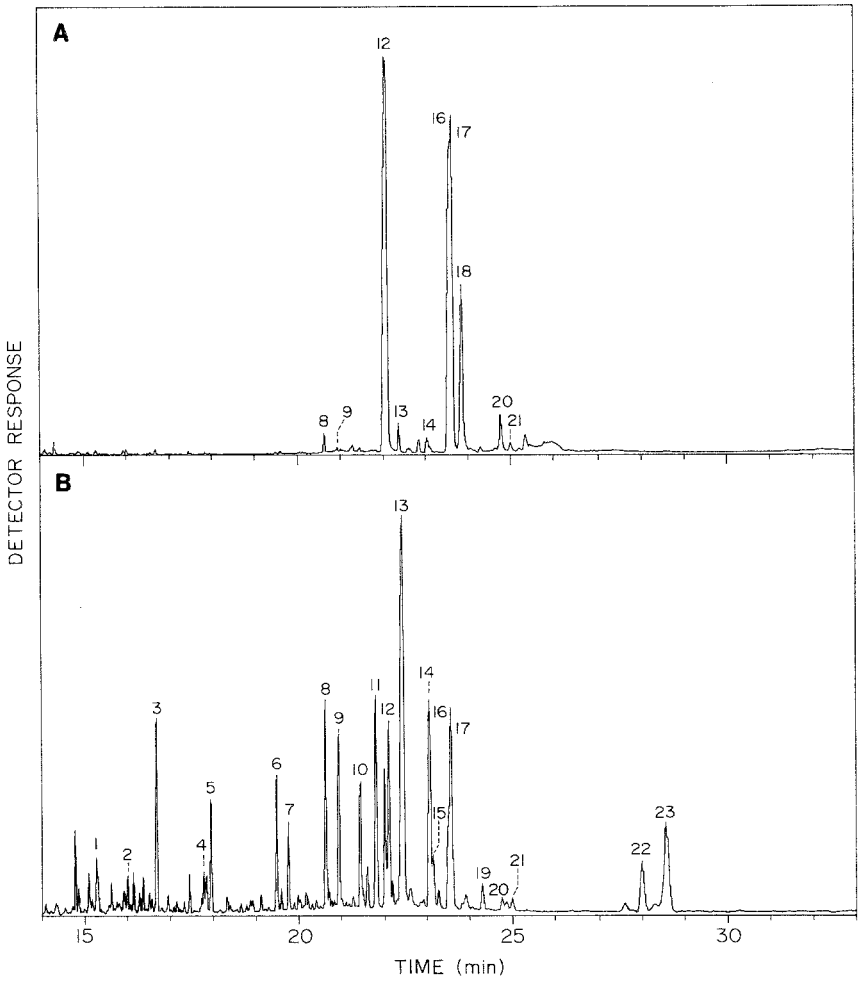

FIG. 1. Total ion chromatograms of the derivitized lipids recovered from the leaves of Round-Up (A) and NY 8329 (B) cabbage by dichloromethane extraction. Numbered peaks are identified in Table 2.

NY 8329 epicuticular lipids, as compared with the lipids of normal genotypes, resembles previously studied glossy mutants of *Brassica oleracea* (Baker, 1974).

The similarity of neonate *P. xylostella* behaviors on leaf wax extracts and intact leaves of NY 8329 and Round-Up implicate the leaf surface waxes in eliciting reduced acceptance of intact glossy plants. The substantial chemical differences between the wax extracts evidently produced the observed behavioral differences. It appears likely that discrimination by the larvae is a response

TABLE 3. CUTICULAR LIPID COMPOSITION (%) OF ROUNDUP AND NY 8329 CABBAGE LEAVES

to a combination of stimulants and deterrents. Waxes from resistant and susceptible plants stimulate more biting and spinning than untreated glass or paraffin-treated glass substrates (unpublished data). In the experiments we report here, all larvae did some biting or spinning on resistant waxes and some searching on susceptible waxes. Those compounds comprising a lower percentage of the epicuticular waxes of NY 8329 than of Round-Up (Table 2, peaks 12, 16, 17, 20, and 21) are candidates as feeding stimulants or arrestants. This group contains the C_{29} *n*-alkane, alcohols, ketone, and a diol, as well as the C_{30} alcohol. Those components that comprise a higher percentage of (or are only present in) NY 8329 waxes (Table 2, peaks 1–11, 13–15, 22, and 23) may be deterrents. This group contains the free fatty acids, all the *n*-alkanes and fatty alcohols with C number <29, and α- and β-amyrin. Of particular interest are α- and β-amyrin, which together comprise 9% of the cuticular lipids of the NY 8329 leaves (Table 2) and had been found previously in the leaf wax of *Brassica napus* (Holloway et al., 1977). The triterpenols comprised only 0.4% of the total cuticular lipids in *B. napus*, but the α- and β-amyrin were found in the same ratio (2.5 : 1) as they were in the leaves of NY 8329. The palmitate ester of α-amyrin has been shown to inhibit growth of several lepidopteran species (Shankaranarayana et al., 1980). The structural similarity of α- and β-amyrin (which have the ursane and oleanane ring skeletons, respectively) to sterols may cause them to be toxic to some phytogphagous insects, and the presence of these compounds in the cuticle of NY 8329 leaves may play a role in the observed resistance to diamondback moth.

Hexane extracts of the cabbage leaves elicited greater behavioral differences with better statistical separation than did the dichloromethane extracts. Discrimination on the basis of biting was more clear between hexane extracts than intact plants. This suggests that the nonpolar constituents of the leaf waxes,

which are more dominant in the hexane extract, may be important in eliciting the behavioral differences. Those possible deterrents in higher relative concentrations in hexane extracts than in dichloromethane extracts (Table 2, peaks 1, 9, 10, and 13; tetradecanoic acid, tetracosanol, pentacosanol, and hexacosanol) and those possible stimulants in lower relative concentrations in hexane extracts (Table 2, peaks 16, 17, 20, 21; 14- and 15-nonacosanol, 15-nonacosanone, 14,15-nonacosandiol, and triacontanol) could be important allelochemics in the leaf waxes.

Although the physiological mechanisms by which insects detect nonpolar compounds with low volatility remain obscure, there is sufficient evidence that leaf surface wax components act as allelochemics. Plant surface wax extracts (Blaney and Chapman, 1970; Bernays et al., 1976, 1985; Albert and Parisella, 1983; Woodhead, 1983, 1987; Maloney et al., 1988; Woodhead and Padgham, 1988; Varela and Bernays, 1988; Chapman and Bernays, 1989), and specific compounds typically found in leaf waxes, including long chain alkanes (Klingauf et al., 1971, 1978), alcohols (Nayar and Fraenkel, 1962; Mori, 1982) esters (Woodhead, 1983; McKibben et al., 1985), and carboxylic acids (Greenway et al., 1978), can act as allelochemics affecting insect herbivore behavior. Thus, it is not unreasonable to conclude that specific compounds in *Brassica* waxes influence *P. xylostella* larval behaviors. Additional bioassays with chromatographic fractions of the crude wax extracts and with pure samples of the specific compounds listed above should determine the most active components.

The ability of *P. xylostella* larvae to discriminate between host-plant genotypes and leaf waxes is innate; the animals in these tests were neonates with no experience with potential food sources. In only a few other cases has innate discrimination on the basis of leaf surface lipids been demonstrated (Mori, 1982; Bernays et al., 1985; Varela and Bernays, 1988). In certain ecological settings, innate neonate discrimination at the leaf surface may permit larvae to locate the most suitable host plants, or host-plant tissues, before beginning to feed. Discrimination by neonates therefore can be adaptive and possibly occurs in many herbivores. However, increased searching and walking and reduced feeding behaviors on glossy cabbages in an agricultural monoculture apparently prevent timely establishment by *P. xylostella* larvae and result in the observed higher mortality on these plants.

The differences between neonate behaviors on the surface wax extracts of NY 8329 and Round-Up in this study were less distinct statistically than those on intact leaves of the resistant and susceptible cabbages. On intact leaves, the larvae apparently respond to other factors in addition to leaf wax composition. Our previous work has indicated that physical characteristics of the leaf surface waxes affect larval behavior and survival. Intact leaves of glossy resistant plants have reduced densities of wax crystallites and reduced amounts of wax/cm^2 (wax load) on their leaf surfaces, as compared with susceptible *Brassica* geno-

types (Eigenbrode et al., 1991). Crystallite density and wax load explained 69% of the variation in larval survival on a collection of 18 *Brassica* genotypes.

This statistical relationship between *P. xylostella* survival and movement and leaf wax physical characteristics may, however, only indicate a behavioral response to wax chemistry. This is possible because the morphology of leaf surface waxes on *Brassica* is largely determined by leaf wax chemistry (Jeffree et al., 1975; Holloway et al., 1977; Jeffree, 1986). Our data suggest, however, that chemical and physical attributes of leaf waxes act together, possibly with other leaf characteristics, to influence neonate *P. xylostella* behaviors. Differences in larval behavior occurred on pure wax extracts with identical morphology but were more pronounced on leaves with morphologically intact waxes. The much higher movement rates of larvae on wax extracts than on intact leaves, and the smaller differences in walking speed on extracts as compared with intact leaves (Table 1), suggest that wax morphology has particularly strong effects on larval locomotion.

This system represents one of the best examples of surface wax-mediated host-plant suitability, since survival of *P. xylostella* on glossy cabbages descended from PI 234599 is so much less than survival on normal bloom genotypes ($< 1\%$). It is therefore important to elucidate the mechanisms of this interaction. Better understanding of reduced acceptance and survival of *P. xylostella* on glossy resistant *Brassica* also will improve screening procedures for the development of cultivars resistant to this important pest.

Acknowledgments—We thank Wendy C. Kain for assistance with behavioral monitoring, and Glen W. Chapman from the Richard B. Russell Research Center for generous assistance in this project. We also thank John T. Trumble and Gregory P. Walker for critical reviews of drafts of the manuscript. This research was partly supported by the New York State Cabbage Growers Association, the Cornell Biotechnology Program, and by HATCH project No. 610 allocated to the Georgia Agricultural Experiment Station.

(Received August 17, 1990, accepted October 29, 1990)

Abstract—The bark beetle *Ips pini* (Say) displays variation in its response to and production of enantiomeric blends of its pheromone ipsdienol. One of the principal predators of *Ips pini* is *Thanasimus dubius* (F.), which uses ipsdienol as a kairomone for prey location. During 1988 and 1989, in Wisconsin and Michigan, the response of both species to a range of enantiomeric blends of ipsdienol was investigated. Blends tested had the following ratios of the (*S*)-(+) to (*R*)-(−) enantiomers: 3%:97%, 25%:75%, 50%:50%, 75%:25%, and 97%:3%. Either 75% (+):25% (−) or 50% (+):50% (−) ipsdienol captured the most *Ips pini* in both years at both sites. The 25% (+):75% (−) blend also caught more *Ips pini* than the control during both years at both sites. All blends tested were attractive to *Thanasimus dubius* in both years at both locations. Blend preferences of both species were variable and labile at both sites. Response patterns of both species in Wisconsin were different from those in Michigan each year. Furthermore, response patterns of both species to the ipsdienol blends changed from 1988 to 1989 at both locations. A genetic component to this variation would permit predator-prey coevolution, as well as the development of resistance by *Ips pini* to management strategies based on mass-trapping with single blends.

INTRODUCTION

Bark beetles (Coleoptera: Scolytidae) are the most destructive insect pests of North American forests. The pine engraver, *Ips pini* (Say), colonizes pine and spruce throughout much of North America (Lanier et al., 1972; Birch et al., 1980; Wood, 1982) and is the most common bark beetle in the Great Lakes region (Schenk and Benjamin, 1969). Adults and larvae feed on the phloem of weakened and recently killed trees. Upon colonization of a suitable host, adult males emit a pheromone containing primarily ipsdienol (2-methyl-6-methylene-2,7-octadien-4-ol), which attracts other males and females to the tree (Vité et al., 1972; Birch, 1978; Birch et al., 1980; Borden, 1982; Miller et al., 1989).

Ipsdienol occurs as (*R*)-(−) and (*S*)-(+) enantiomers, the relative proportion of which determines response specificity in *Ips pini*. There is geographic variation among North American populations of *Ips pini* in their response to and production of pheromones (Lanier et al., 1972; Birch, 1978; Miller et al., 1989). Western North American populations respond to 97% (−)-and are inhibited by (+)-ipsdienol (Birch et al., 1980). New York populations respond preferentially to a racemic mixture, i.e., 50% (+):50% (−) (Lanier et al., 1980). In Wisconsin, traps baited with 75% (+):25% (−) or 50% (+):50% (−)-ipsdienol caught significantly more beetles than 100% (−), 25% (+), or 100% (+) (Raffa and Klepzig, 1989). The 75% (+)-ipsdienol caught more than three times the number of beetles than did the racemic mixture during a two-week test, but differences were not significant.

Thanasimus dubius (F.) (Coleoptera: Cleridae) is a principal predator of *Ips pini* in the Great Lakes region (Schenk and Benjamin, 1969). *Thanasimus dubius* and other *Thanasimus* species use bark beetle pheromones as kairomones for prey location (Vité and Williamson, 1970; Bakke and Kvamme, 1980; Mizell et al., 1982; Hansen, 1983; Payne et al., 1984; Raffa and Klepzig, 1989). Enantiomeric specificity in their responses (Hansen, 1983; Payne et al., 1984; Raffa and Klepzig, 1989) is considered evidence that clerid predators have coevolved with their scolytid prey (Payne et al., 1984; Raffa and Klepzig, 1989). For example, predation may select for changes in the pheromone system of *Ips pini*, allowing temporary escape from its natural enemy. *Thanasimus dubius* then could be under strong selection to track these changes, permitting location of its primary prey (e.g., Price, 1981). Coevolution, however, requires heritable variation in the selected traits within populations of both species (Janzen, 1980). Miller et al. (1989) concluded that intrapopulation variation in the pro-

duction of ipsdienol enantiomeric blends by *Ips pini* most likely had a genetic basis; however, this variation has not been shown to be heritable. Kairomonal response preferences by *Thanasimus dubius* to *Ips* and *Dendroctonus* pheromones have been observed to vary from year to year, depending on the relative abundances of the different species of prey (Billings and Cameron, 1984).

Bark beetle suppression through mass-trapping, using aggregation pheromones as bait, is receiving much attention, but requires detailed knowledge of the pheromone preferences of target populations (Bakke, 1982, 1989). A high level of genetic variation within populations of *Ips pini* would create the potential for rapid development of "resistance" to pheromone-based programs that rely on only one pheromone blend (Lanier et al., 1972; Slessor et al., 1985; Borden et al., 1986; Miller et al., 1989).

The objectives of this study were: (1) to further characterize the preferences of *Ips pini* and *Thanasimus dubius* to enantiomeric blends of ipsdienol in the Great Lakes region, (2) to determine the degree of intrapopulational variation in the response of both species to the ipsdienol mixtures, and (3) to compare preferences between populations of the two species within the Great Lakes Region.

METHODS AND MATERIALS

Blend Preferences. The response of *Ips pini* and *Thanasimus dubius* populations to enantiomeric mixtures of ipsdienol was monitored in the field during 1988 and 1989, near Colfax, Wisconsin, and in Midland, Michigan. The Wisconsin study was conducted in an even-aged, 18-ha, pure stand of red pine (*Pinus resinosa* Ait.) planted in 1958. The Michigan study was conducted in a mature (ca. 75-year-old), naturally regenerated, 8-ha, mixed stand of red pine and eastern white pine (*Pinus strobus* L.), with a deciduous understory.

Populations were sampled using eight-unit Lindgren funnel traps (Lindgren, 1983) baited with 8-mg, C-flex, ipsdienol dispensers provided by Phero Tech, Inc., Delta, British Columbia. The lures had a pheromone release rate of 0.2 mg/day, and were replaced every four weeks. The following enantiomeric blends of ipsdienol were tested during 1989 in Wisconsin and both years in Michigan: 3% (+):97% (−), 25% (+):75% (−), 50% (+):50% (−), 75% (+):25% (−), 97% (+):3% (−), and a blank control. Only the 25% (+):75% (−), 50% (+):50% (−), and 75% (+):25% (−) mixtures were tested in Wisconsin in 1988.

In Wisconsin during 1988, and in Michigan during both years, each treatment was randomly assigned to one trap. Traps were separated by 15–25 m. Captured insects were removed and counted weekly. Traps remained in place throughout the season, but the locations of the pheromone baits were rerandom-

ized weekly to guard against spurious effects due to position. Thus, the experimental design was a randomized complete block, with blocks replicated in time. The 1989 Wisconsin experiment was designed as the previously described experiments but with traps deployed in three spatially separated blocks. Within each block, traps were separated by 15–25 m, and each treatment was represented once. The three blocks were equally spaced throughout the stand.

In Wisconsin, sampling was conducted from June 5 until October 16, during 1988, and April 9 until October 22, during 1989. In Michigan, sampling was conducted from April 13 until October 20, in 1988, and March 13 until November 20, in 1989.

Statistical Analysis. Data were analyzed separately by year and site using analysis of variance (PROC GLM; SAS Institute, 1988). Because variances were proportional to means, data were square-root transformed before analysis. Means were separated using the protected LSD test. Weeks with less than two insect captures were excluded from analyses.

Chi-square analyses were used to test for changes in pheromone preference between years. (PROC CATMOD, log-linear model; SAS Institute, 1988). Only the 25% (+), 50% (+), and 75% (+) blends were used in the chi-square analysis of the Wisconsin and Michigan *Ips* data, and the Wisconsin *Thanasimus* data. The other blends were not tested in Wisconsin in 1988. In Michigan, they did not capture enough *Ips* to affect the analysis. All blends were used in the chi-square analysis of Michigan *Thanasimus* data.

RESULTS

Ips pini *in Wisconsin.* There were differences in the 1988 blend preferences of *Ips pini* in Wisconsin ($F = 4.2$; $df = 2,36$; $P = 0.022$). The racemic blend tended to capture more insects than the 75% (+):25% (−) blend, but differences were not significant (Table 1). Both mixtures captured significantly more insects than did 25% (+):75% (−) ipsdienol (Table 1).

There were also differences in the number of *Ips* beetles captured by the ipsdienol blends in 1989. The analysis of variance indicated that a much greater proportion of the total variance was due to the pheromone blends than effects due to site, date, or any interactions ($F = 321.1$ for blend compared to $F = 19.7$ for date and $F \leq 4.4$ for all other effects) (Table 2). The significant blend × date interaction was due to a reduction in the absolute difference between blends in weeks when few beetles were captured. The relative proportion of beetles captured by the different blends tended to remain constant across the season. The 75% (+):25% (−)-ipsdienol captured significantly more *Ips* beetles than all other blends, followed by 50% (+):50% (−) and 25% (+):75% (−)-ipsdienol, respectively (Table 1). The 97% (+):3% (−) and 3% (+):97%

[a] Means within a column followed by the same letter are not significantly different ($P > 0.05$; protected LSD test applied to square-root transformed data).

(−) blends caught significantly more *Ips* than the control traps, but far fewer than the preferred blends.

Patterns of response by *Ips pini* to ipsdienol enantiomers changed from 1988 to 1989. The proportion of total beetles captured by 50% (+)-ipsdienol dropped from 52% in 1988 to 32% in 1989, while the proportion captured by the 75% (+) blend increased from 36% in 1988 to 56% in 1989 (Table 3). There was little change in the proportion of insects captured by 25% (+)-ipsdienol.

Ips pini *in Michigan.* Pheromone blends differed in *Ips* capture rates in 1988 ($F = 15.4$, $df = 5,105$; $P < 0.001$) and 1989 ($F = 10.3$; $df = 5,105$; $P < 0.001$). During both years, 75% (+)-ipsdienol captured more *Ips* than the

[a]Trap weeks = the number of weeks in which insects were captured × the number of traps baited with each pheromone blend.

racemic mixture, although not significantly more; the 25% (+) mixture captured significantly fewer insects than the two preferred blends, but significantly more than the controls (Table 1). This response pattern differed from that observed for *Ips pini* in Wisconsin during the same two years.

In Michigan, the response pattern of *Ips pini* to ipsdienol enantiomers also changed significantly from 1988 to 1989 (Table 4). However, the magnitude of change was less than that observed in Wisconsin. The proportion of the total number of beetles captured by 75% (+)-ipsdienol dropped from 60% in 1988 to 50% in 1989, while the proportion captured by 50% (+)-ipsdienol increased from 31% in 1988 to 37% in 1989. There was little change in the proportion of *Ips* captured by the other pheromone blends (Table 3).

Thanasimus dubius *in Wisconsin.* In 1988, there also were apparent differences in the numbers of *Thanasimus* captured by different ipsdienol blends ($F = 3.0$; $df = 2,16$; $P = 0.079$). The racemic mixture captured more insects than the other two blends tested (Table 1).

There were highly significant differences among ipsdienol mixtures in numbers of *Thanasimus* beetles captured in Wisconsin in 1989 (Table 1). As with *Ips pini*, the variation accounted for by date, site, and all interactions was small compared with the variation due to pheromone blend (Table 2). The 75% (+)- and 97% (+)-ipsdienol blends were the most preferred; the racemic mixture captured significantly more *Thanasimus* than did 25% (+)-ipsdienol, which in turn was preferred over the 3% (+) blend (Table 1).

In Wisconsin, the pattern of response by *Thanasimus dubius* to ipsdienol enantiomers also changed significantly from 1988 to 1989 (Table 4), with the pattern of change similar to that of *Ips pini* at the same location. During 1988, the racemic mixture captured 54% of the total number of *Thanasimus*, compared to 24% and 22% for 75% (+)- and 25% (+)-ipsdienol, respectively. In

TABLE 4. CONTINGENCY ANALYSES COMPARING RESPONSE PATTERNS OF *Ips pini* AND *Thanasimus dubius* TO IPSDIENOL ENANTIOMERIC BLENDS FOR 1988 AND 1989 NEAR COLFAX, WISCONSIN, AND MIDLAND, MICHIGAN[a]

Species	Location	*df*	chi-square	*P*
Ips pini[b]	Wisconsin	2	453.1	<0.001
Ips pini[b]	Michigan	2	11.9	0.003
Thanasimus dubius[b]	Wisconsin	2	20.3	<0.001
Thanasimus dubius[c]	Michigan	4	49.1	<0.001

[a] The null hypothesis tested was that relative attractiveness of ipsdienol blends did not differ between years.
[b] Compares 25%, 50%, and 75% (+)-ipsdienol.
[c] Compares 3%, 25%, 50%, 75%, and 97% (+)-ipsdienol.

1989, however, the racemic mixture captured only 21% of the total *Thanasimus*, while the proportion captured by 75% (+)-ipsdienol increased to 31%. The 97% (+) blend, which was not tested in 1988, captured 27% of the total number of insects in 1989.

Thanasimus dubius *in Michigan.* In Michigan, all ipsdienol blends captured significantly more *Thanasimus* than the control during 1988 ($F = 8.2$; $df = 5,70$; $P < 0.001$) and 1989 ($F = 6.5$; $df = 5,60$; $P < 0.001$). The racemic blend captured significantly more *Thanasimus* than 3% (+)-ipsdienol, but there were no significant differences among the other blends (Table 1). In 1989, however, 97% (+)-ipsdienol was favored over all other blends with no differences observed among the remaining blends (Table 1).

As with the other three populations studied, the response pattern of *Thanasimus dubius* in Michigan changed significantly from 1988 to 1989 (Table 4). The proportion of the total number of *Thanasimus dubius* captured by 97% (+)-ipsdienol increased from 21% in 1988 to 52% in 1989; all other blends captured a greater proportion of the total number of *Thanasimus* beetles in 1988 than in 1989 (Table 3).

DISCUSSION

Ips pini population in Wisconsin and Michigan responded most strongly to 75% (+)- or 50% (+)-ipsdienol during both years, which agrees with an earlier report from Wisconsin (Raffa and Klepzig, 1989). This preference is more similar to New York populations, which respond preferentially to 50% (+)-ipsdienol (Lanier et al., 1980), than to western North American populations, which respond preferentially to the 97% (−) enantiomer (Birch et al., 1980). However, our experiment found substantial variation in response to ipsdienol within *Ips pini* populations from both Michigan and Wisconsin. Miller et al. (1989) demonstrated variation in the production of ipsdienol enantiomers among individual *Ips pini* within New York, California, and British Columbia populations. This indicates that variation exists among individuals in both the response and production components of the pheromone system of *Ips pini*. We also found substantial intrapopulation variation in the response of the clerid predator *Thanasimus dubius* to ipsdienol in both Michigan and Wisconsin.

The pheromone preferences within *Ips pini* and *Thanasimus dubius* populations in Wisconsin and Michigan were labile, changing from 1988 to 1989. Furthermore, these species exhibited geographic variation in their response to ipsdienol on a relatively local scale. The pattern of response by the Michigan *Ips pini* population to ipsdienol was different than that of the Wisconsin population both years. The same was true of the *Thanasimus dubius* populations. In fact, our 1988 data for *Thanasimus dubius* in Wisconsin differed from that collected by Raffa and Klepzig (1989) during the same year only 150 km away.

It is unknown to what degree, if any, intrapopulation variation in the response of *Thanasimus dubius* or *Ips pini* to ipsdienol is heritable. However, hybridization studies with *Ips pini* indicate a genetic basis to the interpopulation variation in response to ipsdienol (Piston and Lanier, 1974; Lanier et al., 1980). The spatial and temporal variation that we observed suggests a possible genetic component to the intrapopulation variation as well. High genetic variation within both predator and prey species would provide the potential for coevolutionary change. *Thanasimus dubius* may select for changes in the pheromone system of *Ips pini*, resulting in reduced predation (Raffa and Klepzig, 1989). The high variation observed in the response of *Thanasimus dubius* to ipsdienol may facilitate rapid counter adaptation to changes in *Ips pini* populations.

The potential capacity of *Ips pini* for evolutionary change in its pheromone system has important implications for pest management strategies. In particular, *Ips pini* may develop resistance to mass-trapping programs, adapting to ipsdienol blends other than those used as bait (Lanier et al., 1972; Slessor et al., 1985; Borden et al., 1986; Miller et al., 1989). Variation within populations of *Ips pini* may require that blend preferences of local populations be well characterized before and monitored during the course of mass-trapping programs. Several blends may have to be used simultaneously and/or rotated as part of a resistance management program.

Acknowledgments—We thank Herbert H. Dow for allowing us to conduct the Michigan experiments on his property. We are grateful to Matt Ayres for his substantial contributions to the analysis and interpretation of the data. Dave Petty and Tom Young assisted with field collections in Michigan. Cathy Infante and Dave Petty counted the insects. Earlier versions of the manuscript were criticized and improved by Matt Ayres, Ronald P. Billings, Kelly S. Johnson, Daniel R. Miller, James R. Miller, David G. Nielsen, James K. Nitao, Kenneth F. Raffa, and Stephen Teale. This study was conducted in cooperation with the Department of Entomology and Pesticide Research Center, Michigan State University.

Davis, California 95616

(Received March 12, 1991; accepted April 25, 1991)

Abstract—Catalase activity was detected in the midgut tissues and regurgitate of several lepidopteran pests of the tomato plant. Greatest activity in the midgut was detected in larval *Helicoverpa zea*, followed by *Spodoptera exigua, Manduca sexta*, and *Heliothis virescens*. We present evidence that catalase, in addition to removing toxic hydrogen peroxide, may inhibit the oxidation of plant phenolics mediated by plant peroxidases. Small amounts of larval regurgitate significantly inhibited foliar peroxidase activity via removal of hydrogen peroxide. Treatment of foliage with purified catalase nearly eliminated peroxidase activity and was superior as a larval food source compared to untreated foliage. Tomato foliar peroxidases oxidize an array of endogenous compounds including caffeic acid, chlorogenic acid, rutin, coumaric acid, cinnamic acid, and guaiacol. The oxidized forms of these compounds are potent alkylators of dietary and/or cellular nucleophiles (e.g., thiol and amino functions of proteins, peptides, and amines). When tomato foliar protein was pretreated with peroxidase and chlorogenic acid and incorporated in artificial diet, larval growth was reduced compared to larvae fed untreated protein. Thus, the diminution of peroxidase activity and removal of hydrogen peroxide by catalase may represent an important adaptation to leaf-feeding. The secretion of catalase in salivary fluid during insect feeding is also suggested to be a potential mechanism for reducing hydrogen peroxide formation as an elicitor of inducible plant defenses.

INTRODUCTION

The presence of hydrogen peroxide in plant tissues may pose a significant impediment to the growth and survival of herbivores. Hydrogen peroxide is a powerful oxidant (Cadenas, 1989; Fridovich, 1989). The utilization and/or function of proteins, enzymes, and glutathione may be impaired due to oxidation of thiols and decarboxylation of amino acids by hydrogen peroxide (H_2O_2) (Slump and Schreuder, 1973; Berlett et al., 1990). In the presence of catalytic amounts of ferrous or manganese ions, H_2O_2 can degrade to form the hydroxy radical ($HO\cdot$), the most powerful oxidant known (Fridovich, 1989; Cadenas, 1989; Yim et al., 1990). This radical can then react with DNA, membrane lipids, and other essential cellular components (Halliwell and Gutteridge, 1984; Fridovich, 1989).

In conjunction with plant peroxidases (POD), H_2O_2 catalyzes the oxidation of diphenols to *o*-quinones. The quinones are susceptible to attack by nucleophilic amino and thiol groups of proteins (Matheis and Whitaker, 1984a, 1987). The enzymatic oxidation of the diphenol chlorogenic acid to chlorogenoquinone by polyphenol oxidase has been shown to impair the growth of *Helicoverpa* (=*Heliothis*) *zea* and *Spodoptera exigua* (Felton et al., 1989).

Peroxidase with H_2O_2 can directly oxidize tyrosine residues of proteins, causing substantial cross-linking (Matheis and Whitaker, 1984b). Plant peroxidases have multiple oxidative activities with broad substrate specificity; an array of phytochemicals including simple monophenols (e.g., coumaric acid), alcohols (e.g., coniferyl alcohol), coumarins (e.g., esculetin), and dihydroxyphenols (e.g., chlorogenic acid) may be oxidized by peroxidase (Gaspar et al., 1982).

Furthermore, H_2O_2 and POD are known to catalyze the cross-linking of hydroxyproline-rich glycoproteins in cell walls that stabilize cell walls against pathogen invasion (van Huystee, 1987). Moreover, POD and H_2O_2 are involved in the formation of lignin (van Huystee, 1987). The role of these cell-wall strengthening reactions in impeding utilization of plant tissues by insect herbivores is largely unknown (Stamopoulos, 1988; Wainhouse et al., 1990). POD may also be involved in lipid peroxidation and the formation of reactive molecules such as linoleic hydroperoxide (Garner, 1984; Keppler and Novacky, 1987). Both the primary oxidative products, fatty acid hydroperoxides, and the secondary products, such as malondialdehyde, form addition products with nucleophilic groups of protein (Garner, 1984). These lipid oxidation products have been implicated as defense mechanisms against herbivores (Shukle and

Murdock, 1983; Hildebrand et al., 1986, 1989; Duffey and Felton, 1989; Mohri et al., 1990).

Plants produce H_2O_2 by a variety of processes. Hydrogen peroxide may be formed from the reduction of oxygen directly by two-electron transfer reactions catalyzed by flavoproteins or via an initial one-electron step to O_2^- followed by dismutation (Cadenas, 1989). Hydrogen peroxide is a by-product of photosynthesis and several oxidative enzymes including glycollate oxidase, diamine oxidases, uricase, glucose oxidase, etc. (Choudhuri, 1988).

A number of plant compounds, implicated in defense against herbivores, may provide a source of H_2O_2, including photodynamically activated furanocoumarins, thiophenes, polyacetylenes, and extended quinones (Joshi and Pathak, 1983; Downum and Rodriguez, 1986). Moreover, ubiquitous dihydroxyphenolic compounds such as caffeic acid and chlorogenic acid autoxidize under basic conditions to form H_2O_2 (Hanham et al., 1983; Cilliers and Singleton, 1989; Tulyathan et al., 1989; Cheynier et al., 1989). Because the midgut pH of many lepidopteran larvae is basic, H_2O_2 may be formed from the autoxidation of phenolics in the digestive system of these species.

The tomato plant *Lycopersicon esculentum* contains substantial levels of the diphenols, rutin, and chlorogenic acid, that are sources of H_2O_2 in basic environments (Felton et al., 1989). Tomato is attacked by several lepidopteran larvae including *H. zea, Heliothis virescens, S. exigua, Trichoplusia ni*, and *Manduca sexta*. The midgut pH of these species, in all instances, is alkaline and ranges from 8.0 to 11.3 (Dow, 1984; Martin et al., 1987; Felton et al., 1989). Thus, the formation of H_2O_2 in the midguts of these species is likely and may adversely affect larval growth and survival. Consequently, the avoidance or removal of exogenous H_2O_2 is desirable.

The first line of defense against H_2O_2 toxicity is via enzymatic removal by catalase or glutathione peroxidase. Catalase has been well characterized recently in a number of lepidopteran larvae (Ahmad et al., 1987, 1988a,b; Pritsos et al., 1988a,b). In this investigation, we report on the presence of high levels of catalase in the midgut tissues and digestive fluid of several common lepidopteran herbivores of the tomato plant. Evidence for the particular advantages of possessing catalase activity in the digestive systems of these herbivores is presented.

METHODS AND MATERIALS

Insects. Eggs of *Helicoverpa zea, Heliothis virescens*, and *Spodoptera exigua* were obtained from the USDA Laboratory, Stoneville, Mississippi. Eggs of *Manduca sexta* were obtained from Dr. Bruce Hammock, University of California, Davis. In order to exclude differences in larval enzyme activity asso-

ciated with feeding on varying artificial diets, larvae for all species were reared on the same artificial diet containing 5% casein (wet wt) following Chippendale (1970).

Enzyme Preparation. For detection of catalase activity in midgut tissue, groups of five midguts were dissected from actively feeding 2-day-old fifth-instar larvae. After removal of midgut contents, the midgut was washed in 1.15% KCl and homogenized in ice-cold sodium phosphate buffer, pH 7.0 for all assays. The homogenate was centrifuged at 15,000*g* for 15 min. The soluble fraction was used immediately as the enzyme source.

To assay catalase in digestive fluid, larvae were gently held behind the head with forceps, and regurgitate was collected in a tube on Dry Ice. Fluid from at least 50 larvae was collected for each species except *M. sexta*. Digestive fluid was mixed 1:1 with 0.9% NaCl and centrifuged at 15,000*g* for 15 min. Supernatant was used as enzyme source.

To assay tomato foliar catalase, chlorogenic acid oxidase, or peroxidase activity, ca. 2-g leaflets from field-grown *Lycopersicon esculentum* var. Ace were excised with a razor blade. Leaflets were homogenized in ice-cold sodium phosphate buffer, pH 7.0, containing 5% polyvinylpolypyrrolidone. Homogenate was centrifuged as above and used immediately for enzyme assay.

Assay and Characterization of Larval Catalase. Catalase activity was monitored by following the loss of hydrogen peroxide at 240 nm (Aebi, 1984). Enzyme activity was determined from the linear portion of the rate curve and one unit of catalase activity expressed as the decomposition of 1 μmol H_2O_2/min/mg protein. Protein concentration was determined following Bradford (1976) with bovine serum albumin as a standard.

To determine the effect of pH on midgut catalase activity from different insect species, assay was performed at a pH range of 4.7 to 10.0 for most species. Three replicates in duplicate were performed for each species at each pH level tested. The buffer used in all assays was 0.1 M sodium phosphate. The catalase activity of regurgitate was assayed at pH 5.5 and pH 6.5. The experiment was replicated three times.

To determine the Michaelis constant (K_m) and V_{max} of catalase and H_2O_2 for the different insect species, varying substrate concentrations were used. In all instances at least seven concentrations of H_2O_2 were used. The initial absorbance was kept constant at ca. 0.500 by adjusting the concentration of H_2O_2 in the reference and sample cuvettes. The K_m was determined by a regression curve of a Lineweaver-Burk plot, and in all instances the correlation coefficient exceeded 0.96. Three replicates were performed for each species, and 95% confidence limits were used to determine statistical significance.

Characterization of Foliar Catalase and Peroxidase. Catalase activity for foliage was assayed as described above for insect larvae. Tomato plants (var. Ace) were grown in the field, and foliage was excised at the flowering stage.

Enzyme was prepared as described above. Catalase activity of tomato foliage was assessed across the pH range of 5.5 to 10.0. Three replicates for each pH unit were performed. Protein concentration was determined following Jones et al. (1989).

Peroxidase activity was determined following Ryan et al. (1982) by recording the increase in absorbance at 470 nm. The following substrates were tested: chlorogenic acid, rutin, guaiacol, coumaric acid, ferulic acid, esculetin, caffeic acid, cinnamic acid, and 3,4-dimethoxybenzyl alcohol. Four replicates per test chemical were performed. Peroxidase activity was then calculated by subtracting the difference in mean activity between treatments with H_2O_2 and without H_2O_2.

The peroxidase activity of tomato foliage was measured using 3 mM guaiacol across the pH range of 5.5 to 10.0. Protein concentration was determined following Jones et al. (1989). Three replicates for each pH unit were performed.

Effect of Foliage-Feeding on Midgut Catalase Activity. To determine if the ingestion of tomato foliage affects larval midgut catalase activity in *H. zea*, newly molted fifth-instar larvae were either given freshly excised tomato leaflets or maintained on artificial diet. Leaflets were removed from field-grown *L. esculentum* var. Ace. After 48 hr of feeding on foliage or artificial diet, larvae were sacrificed for catalase assay. For each treatment, 12–80 μg of midgut protein was assayed for activity. Activity was assessed at the enzyme optima of pH 6.5 and at the midgut pH 8.5. Differences between treatments were compared by the regression plot of catalase activity against micrograms of midgut protein. Three replicates of five larvae per treatment were performed.

Effect of Larval Regurgitate on Foliar Peroxidase Activity. Leaflets were excised from greenhouse-grown tomato plants (var. Castlemart) at the six-leaf stage. One-gram aliquots of leaflets were homogenized in 20 ml ice-cold buffer. Homogenates were centrifuged for 15 min at 15,000*g*. Substrate for peroxidase activity was 2 mM guaiacol with 5 mM H_2O_2.

Regurgitate from fifth-instar *H. zea* was obtained as described above. Regurgitate was collected from individual larvae on preweighed parafilm, weighed to the nearest 0.1 mg, and immediately mixed with 1.5 ml enzyme substrate. A 20-μl aliquot of the foliar peroxidase was quickly added, and peroxidase activity was recorded as described. Twenty-one samples were tested with 0 to ca. 25 mg of regurgitate in each.

Effects of Hydrogen Peroxide, Peroxidase, and Chlorogenic Acid on Larval Growth. To determine if larval growth was affected by the presence of dietary peroxidase, H_2O_2, and/or chlorogenic acid, tomato foliar protein was treated with combinations of the above chemicals. Foliar protein was obtained from field-grown var. Castlemart plants at the mature fruit stage. Protein was extracted and semipurified following Broadway and Duffey (1988) and Felton et al. (1989), free from protease inhibitor contamination. A 35-ml aqueous solu-

tion of 500 mg tomato foliar protein was incubated with various combinations of 125 mg chlorogenic acid, 34 μl 30% H_2O_2, and/or 28 mg purified horseradish peroxidase (Sigma Chemical Co., St. Louis, Missouri). The treatments included H_2O_2; H_2O_2 and peroxidase; H_2O_2, peroxidase, and chlorogenic acid; chlorogenic acid alone; and a control with untreated protein. Solutions were adjusted to pH 8.0 with 2 N NaOH and mechanically stirred for 60 min at room temperature.

Following incubation, solutions were added to the remaining dry portion of an artificial diet (Broadway and Duffey, 1988). The diets were then prepared with hot aqueous agar solution to give final fresh weight concentrations of 0.5% foliar protein, 10 mM H_2O_2, 3.5 mM chlorogenic acid, and 180 units peroxidase activity per gram of diet. Peroxidase activity was determined using guaiacol and activity expressed as 1 unit = 0.001 change in absorbance/min. The levels of these chemicals are consistent with what occurs commonly in tomato foliage (Felton et al., 1989; unpublished data).

Bioassays with *H. zea* larvae were conducted following Broadway and Duffey (1986) with a 16:8 light–dark cycle at 27°C. Neonate larvae were placed on the diet treatments, and fresh diet was provided every 48 hr. Larvae were weighed to the nearest 0.1 mg after 16 days. A total of 50 larvae were tested for each treatment, and larval mortality or escape did not exceed 4% for any treatment.

Effects of Catalase Activity on Ability of Tomato Foliage To Support Larval Growth. To determine if catalase activity protects tomato foliage from oxidative damage, Ace variety tomato plants were grown in the field. At the immature fruit stage, foliage was excised with a razor blade. The foliage was equally divided into one of two treatments. In the first treatment, 100 g foliage was homogenized in 200 ml ice-cold 0.01 M sodium phosphate (adjusted to pH 8.0 with 2 N NaOH) with 40 mg heat-inactivated catalase (from horseradish, Sigma Chemical Co.) and then mechanically stirred for 1 hr at 25°. Homogenate was then frozen and lyophilized. An artificial diet was prepared with agar from the dried leaf powder (Felton et al., 1989).

In the second treatment, 100 g foliage was homogenized with 40 mg of purified, active catalase. Otherwise, foliage was treated identically and diet was prepared as described above. Twenty-five second-instar *H. zea* per treatment were placed on the respective diet following conditions described above. Larval weight was recorded daily for 12 days. The experiment was replicated three times.

Catalase activity of foliage for both treatments was determined from several aliquots of the homogenate immediately following homogenization. Oxidation of chlorogenic acid was also followed spectrophotometrically for each aliquot (Felton et al., 1989). The formation of the lipid oxidation product, malondialdehyde, was determined with thiobarbituric acid from aliquots of

extracts of dried leaf powder following the method of Stewart and Bewley (1980).

RESULTS

Characterization of Larval Midgut Catalase. pH 6.5 was optimum for larval midgut catalase from *M. sexta, S. exigua*, and *H. zea* (Figure 1). *H. virescens* had much lower activity than the other species with a peak at pH 6.5–8.0 (Figure 1). Activity for *H. virescens* was not significantly different between 6.5 and 8.0.

The highest V_{max} and K_m were found in *H. zea* larvae followed by *S. exigua* (Table 1). *H. virescens* had the lowest V_{max}, whereas *M. sexta* had the lowest K_m (Table 1).

Catalase Activity in Larval Regurgitate. The presence of catalase activity in larval regurgitate was detected in the three species examined: *S. exigua, H. zea*, and *H. virescens* (Table 2). The highest activity was detected in *S. exigua* followed by *H. virescens* and *H. zea*. The activity of catalase was determined at pH 6.5, the pH optimum for catalase from midgut tissue (Table 1), and at pH 5.5, the pH of crushed foliage. In all three species examined, regurgitated catalase was less active at pH 5.5 than at pH 6.5 (Table 2).

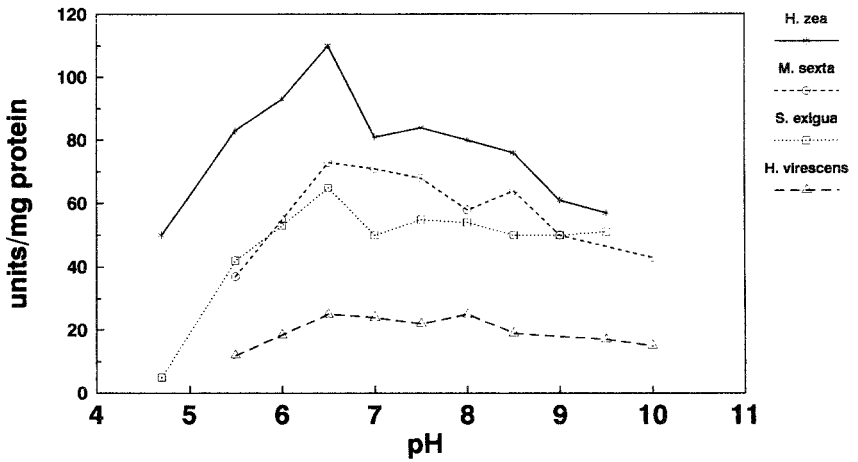

FIG. 1. Effect of pH on lepidopteran midgut catalase activity. Each point represents the mean of three replicates performed in duplicate. Activity for *H. virescens* was significantly lower ($P < 0.05$) than all other larvae at all pH levels tested. The activity of *H. zea* was significantly higher than other species for pH 4.7–8.0. Activities for *M. sexta* and *S. exigua* were not significantly different from each other except at pH 7.0. Significance is based on nonoverlap of 95% confidence limits.

TABLE 1. CHARACTERIZATION OF CATALASE ACTIVITY OF MIDGUT TISSUE OF SEVERAL LARVAL LEPIDOPTERAN HERBIVORES OF TOMATO PLANT[a]

Species	K_m constant (mM)	V_{max} (μmols/min/mg protein)
Helicoverpa zea	136.8a	291.7a
Heliothis virescens	37.7c	35.9c
Spodoptera exigua	71.9b	80.9b
Manduca sexta	22.3d	38.3c

TABLE 2. CATALASE ACTIVITY IN DIGESTIVE REGURGITATE OF SEVERAL LEPIDOPTERA LARVAE

Species	Activity (μmols/min/mg protein)[a]	
	pH 5.5	pH 6.5
Heliothis virescens	26.9b	15.8b
Spodoptera exigua	140.8a	97.5a
Helicoverpa zea	3.5c	3.1c

[a] Means in columns not followed by the same letter are significantly different at $p < 0.05$ following ANOVA and 95% confidence limits.

Characterization of Foliar Catalase and Peroxidase. Tomato foliar catalase was active across the range of pH 5.5–10.0 with a sharp peak of activity at pH 7.0 (Figure 2). The level of foliar catalase activity was substantially lower than that of any insect species with the exception of *H. virescens*.

Tomato foliar POD was also active from pH 5.5 to 10.0 but did not exhibit as sharp a peak as catalase (Figure 3). The optimum was at pH 5.5 with a secondary peak at pH 7.0.

Tomato POD oxidized a wide variety of phytochemicals known to occur in tomato foliage (Table 3). Greatest activity was towards caffeic acid followed by guaiacol, chlorogenic acid, esculetin, ferulic acid, coumaric acid, rutin, cinnamic acid, and 3,4-dimethoxybenzyl alcohol (Table 3). Relative activities are only approximations because the estimation of activities was based on the assumption that extinction coefficients of oxidative products were similar. Chlorogenic acid and caffeic acid were the only substrates oxidized by polyphenol

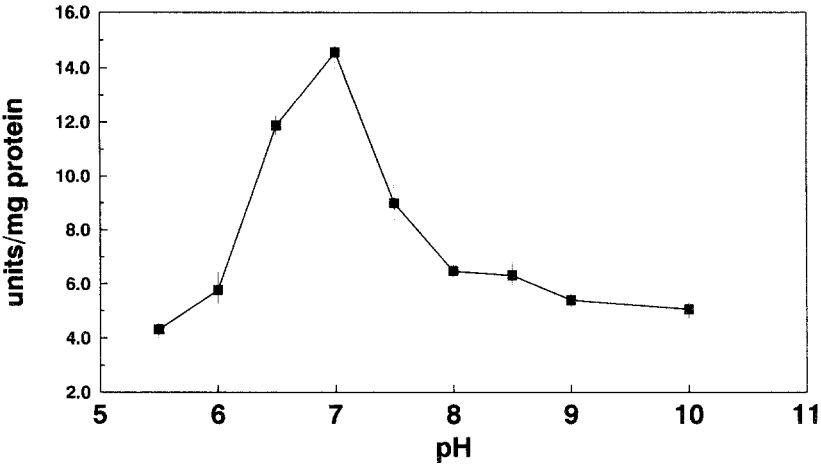

FIG. 2. Effect of pH on foliar catalase activity. Each point represents the mean of three replicates performed in duplicate. Bars represent standard error of the mean.

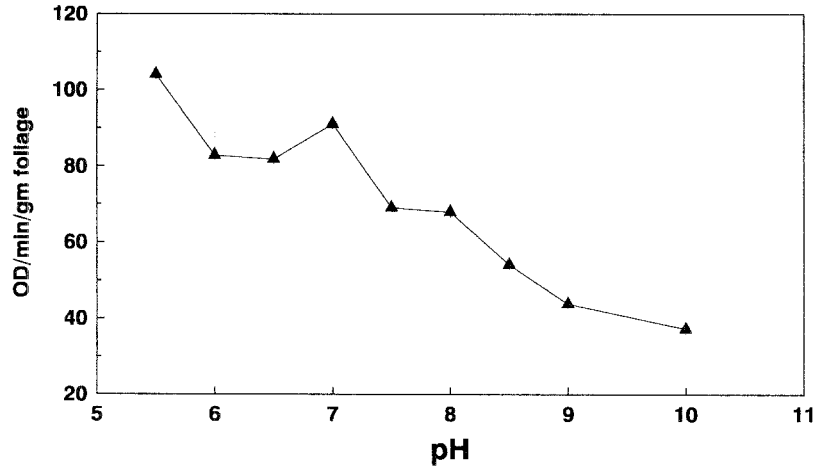

FIG. 3. Effect of pH on foliar peroxidase activity. Each point represents the mean of three replicates performed in duplicate. Bars represent standard error of the mean.

oxidase; peroxidase activity towards these substrates was five- to sixfold higher than polyphenol oxidase activity (data not shown).

Effect of Foliage-Feeding on Midgut Catalase Activity. The ingestion of tomato foliage had no significant effect on midgut catalase activity (Figures 4 and 5). Regression lines for data from larvae feeding on artificial diet or tomato foliage were parallel for both pH 6.5 (Figure 4) and pH 8.5 (Figure 5). The

[b] CAT = catalase activity expressed as units/min/g foliage.
[c] POD = peroxidase activity expressed as change in OD/min/g foliage.
[d] PPO = rate of total oxidation of chlorogenic acid catalyzed by peroxidase and polyphenol oxidase expressed as change in OD/min/g foliage.
[e] MAL = malondialdehyde equivalents expressed as μmol/g foliage wet weight.
[f] RGR = relative growth rate (mg/day/mg larva) based on weight gain for 12 days.

slopes between treatments were not significantly different ($P > 0.05$) for either pH level. Catalase activity was greater at pH 6.5 than at pH 8.5 for both treatments.

Effect of Larval Regurgitate on Foliar Peroxidase Activity. Larval regurgitate significantly reduced foliar peroxidase activity (Figure 6). The slope of the regression curve of POD activity vs. regurgitate was significantly less than zero ($P < 0.01$). The addition of relatively small amounts of regurgitate (e.g., 5–10 μl) to the enzyme preparation caused greater than 50% reduction in peroxidase activity.

Reduction in peroxidase activity is apparently due to the removal of H_2O_2 by catalase activity in the regurgitate. Addition of 75 μl 3% H_2O_2 restored most peroxidase activity in samples containing regurgitate. Typically at least 20 μl

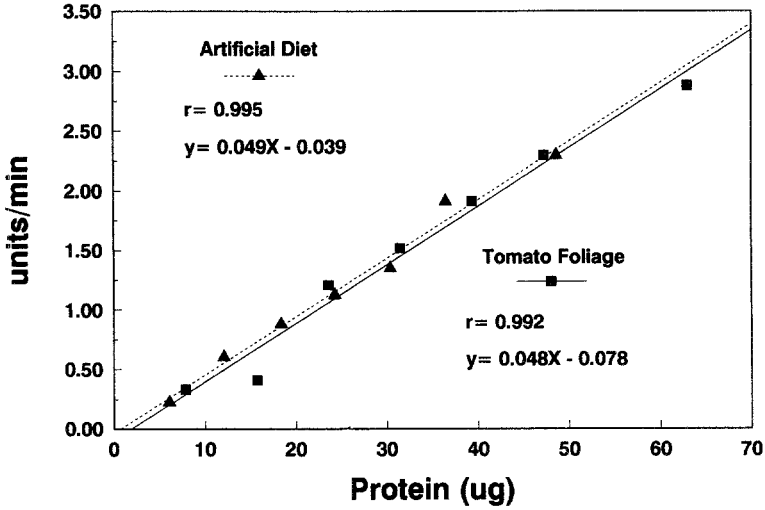

FIG. 4. Effect of foliar feeding on midgut catalase in *Helicoverpa zea* at pH 6.5. Each point represents the mean of three replicates performed in duplicate.

of regurgitate could be collected per larva with an average catalase activity of 3.50 μmol/min/mg protein. Regurgitate boiled in an equal volume of H_2O_2 and added to foliar enzyme preparation had no effect on peroxidase activity.

Effects of Hydrogen Peroxide, Peroxidase, and Chlorogenic Acid on Larval Growth. The growth of larvae was significantly reduced in all treatments relative to the control (Figure 7). The greatest growth reduction occurred with the peroxidase + chlorogenic acid + H_2O_2 treatment, with larvae weighing less than 28% of the control (Figure 7). In the control treatment, 60% of the larvae were in the fourth instar and 40% in the fifth instar. In the treatment with peroxidase + chlorogenic acid + H_2O_2, 26% were second instars, 65% third instars, and the remainder fourth instars. The presence of H_2O_2, chlorogenic acid, or peroxidase + H_2O_2 reduced larval growth by approximately 30–50% for each treatment. Preliminary experiments with heat-inactivated peroxidase added to diet showed that larval growth was not affected by the addition of the small amount of extra protein.

Effects of Catalase Activity on Ability of Tomato Foliage to Support Larval Growth. Supplementing the leaf homogenate with catalase effectively removed most of the foliar peroxidase activity (Table 4). Addition of purified catalase increased total catalase activity by over 300-fold (Table 4). Furthermore, the total rate of oxidation of chlorogenic acid was reduced when catalase was added to the homogenate (Table 4).

When first instar larvae were placed on the respective diets, greater than

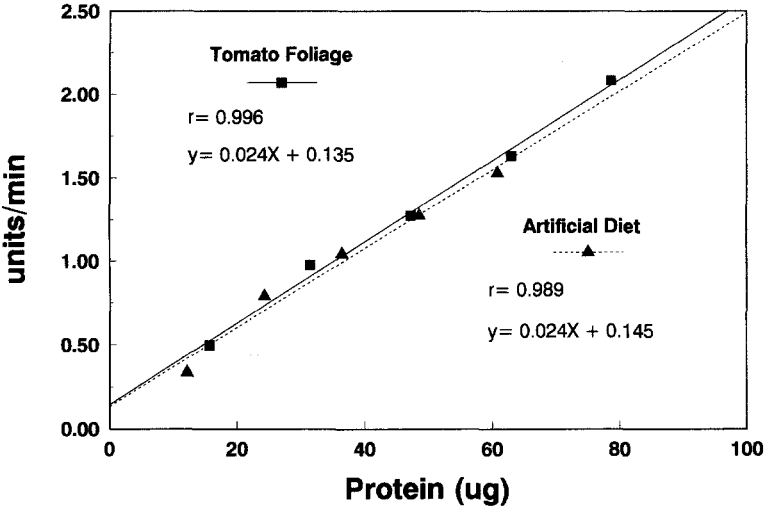

FIG. 5. Effect of foliar feeding on midgut catalase in *Helicoverpa zea* at pH 8.5. Each point represents the mean of three replicates performed in duplicate.

50% mortality occurred in both treatments. Subsequent bioassays used newly molted second-instar larvae that had fed on artificial diet for the first instar. Larvae that were fed on diet prepared from catalase-treated foliage grew significantly faster than those on diet prepared without catalase (Table 4). In addition to the alterations in foliar enzymes shown in Table 4, the presence of malonidialdehyde was reduced by the catalase treatment. These data suggest that foliar peroxidases contribute to lipid peroxidation.

DISCUSSION

Feeding on plant tissues, and tomato foliage in particular, may pose a significant barrier to herbivores not adapted to dietary H_2O_2. The potential adverse effects of H_2O_2 are many: (1) the utilization of amino acids may be directly impaired due to oxidative decarboxylation and oxidation of thiol groups by H_2O_2 (Slump and Schreuder, 1973; Berlett et al., 1990; Yim et al., 1990); (2) protein and enzyme function may be disrupted by H_2O_2 (Cadenas, 1989); (3) lipid peroxidation may be initiated (Garner, 1984); and (4) H_2O_2 is genotoxic and may induce cross-linking of DNA, base destruction, and single- and double-strand breaks in DNA (Hanham et al., 1983).

The combined action of H_2O_2 and peroxidases may: (1) cross-link proteins by formation of dityrosine bridges (Matheis and Whitaker, 1984b); (2) oxidize lignin precursors (e.g., coniferyl alcohol) that may bind to dietary protein

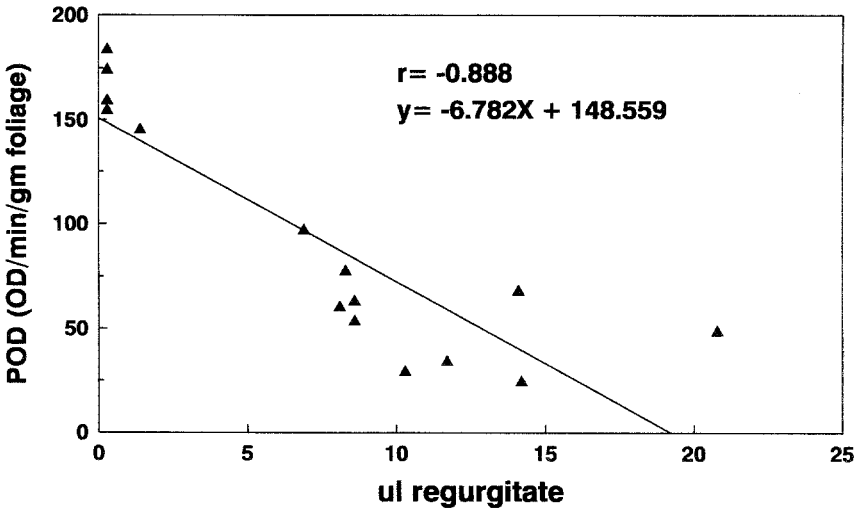

FIG. 6. Effect of *Helicoverpa zea* regurgitate on foliar peroxidase (POD) activity. Each point represents regurgitate collected from one larva feeding on artificial diet.

(Whitmore, 1982) or strengthen cell wall structures, impeding further attack by pathogens and herbivores; (3) oxidize diphenols to produce reactive *o*-quinones that covalently bind to dietary amino acids, peptides, and protein (Kalyanaraman et al., 1987; Duffey and Felton, 1989; Felton et al., 1989); (4) oxidize carotenoids and free fatty acids to form reactive lipid oxidation products (Garner, 1984); (5) oxidatively deaminate protein-bound lysine to form intermolecular cross-links between lysine residues (Stahmann et al., 1977); (6) oxidize ascorbic acid to dehydroascorbic acid (Gaspar et al., 1982); and (7) catalyze production of hydroxyproline-rich proteins that stabilize cell walls (van Huystee, 1987). Thus, the H_2O_2-dependent peroxidases have broad substrate specificity and, depending upon the substrate and cooxidant, may have monophenolase, diphenolase, tyrosinase, lipoxygenase, alcohol dehyrogenase, ascorbic acid oxidase, or lysyl oxidase activities. Considering the broad toxicological implications cited above, it is surprising that the defensive roles of plant peroxidases against insect herbivores have not been more widely studied.

The activity of peroxidases in foliage and in the insect digestive system will depend upon the balance between H_2O_2-generating and competing H_2O_2-degrading systems (i.e., catalase). The generation of H_2O_2 in foliage may result from: (1) photosynthetic reactions (Mehler reaction); (2) autooxidation of diphenols in alkaline fluids; and (3) a number of plant oxidative enzymes (e.g., uric acid oxidase, glycollate oxidase, glucose oxidase, diamine oxidase). Constitutive levels of H_2O_2 in plant tissues may be fairly high (e.g., ca. 15 mM;

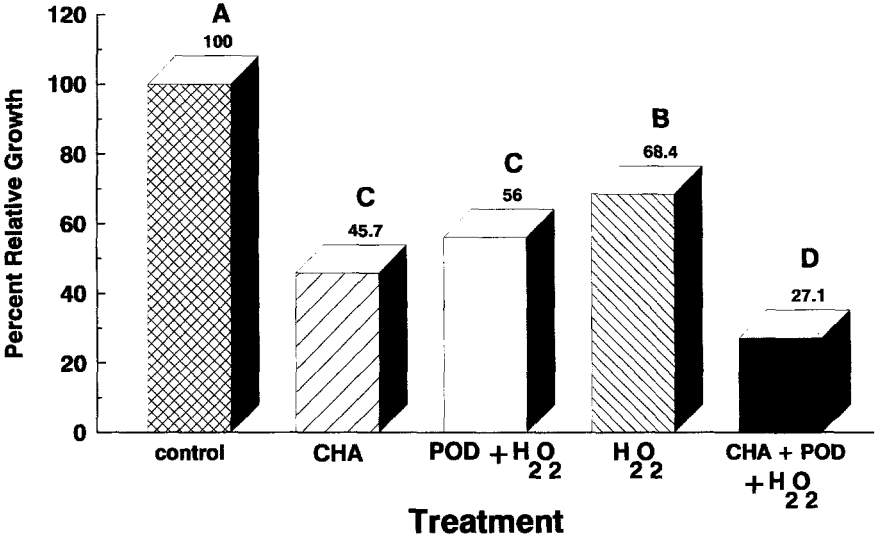

FIG. 7. Effect of peroxidase, hydrogen peroxide, and chlorogenic acid on growth of *Helicoverpa zea*. Means followed by the same letter are not significantly different at $P < 0.05$. CHA = chlorogenic acid; POD = peroxidase.

Choudhuri, 1988), and there is evidence that a rapid burst of H_2O_2 production occurs immediately upon wounding of plant tissues (Apostol et al., 1989). Our data with tomato foliage suggest that endogenous levels of H_2O_2 are sufficient for POD activity to contribute to reduced larval growth and development (Table 4).

Eukaryotic cells possess a variety of mechanisms to avoid H_2O_2 toxicity including: (1) catalase activity; (2) ascorbic acid at alkaline pH to reduce H_2O_2 to water; (3) ascorbate peroxidase; (4) glutathione peroxidase; and (5) peroxidases in the presence of hydrogen donors (Elstner, 1987). Catalase may be the most efficient mechanism because there is no requirement for glutathione or ascorbate; furthermore, there is no danger resulting from the formation of oxidized substrates by peroxidase (Figure 4).

Despite substantial catalase activity in the *H. zea* midgut, sufficient H_2O_2 for plant POD activity remains as indicated by the finding that approximately 25% of ingested rutin is oxidized and bound to excreted protein (J. Workman, G. Felton, and S. Duffey, unpublished data). Rutin is not a substrate for tomato foliar polyphenol oxidase. The presence of midgut POD activity may be a consequence of the great difference in apparent K_m values for H_2O_2 with catalase (i.e., millimolar range) vs POD (micromolar range, unpublished data), which would allow limited POD activity at low concentrations of H_2O_2. The potential

toxicity resulting from high levels of POD is apparently greater than that for polyphenol oxidase because of the wider array of POD substrates in tomato foliage including monophenols, diphenols, coumarins, ascorbates, and fatty acids (Table 3) (Garner, 1984). Whereas rutin is a substrate only for POD, chlorogenic acid is oxidized by both POD and polyphenol oxidase, and hence, a much greater percentage (ca. 45%) of ingested chlorogenic acid is bound to excreted protein (Felton et al., 1989).

Under certain conditions (e.g., low plant POD activity and/or low H_2O_2 concentration), the enzymatic oxidation of chlorogenic acid or rutin has minimal impact upon the nutritional quality of dietary protein (G. Felton, J. Workman, D. Sternberg, and S. Duffey, unpublished data). Hence, the presence of high catalase activity with resulting attenuated POD activity in the digestive system may be a desirable adaptation for overcoming dietary oxidative stresses. However, because of the large number of variables (e.g., substrates, reactants, competing enzymes), it is extremely difficult to meaningfully simulate conditions occurring at the plant–herbivore interface by artificial diet experiments. At best our bioassays represent only first order approximations of antibiosis.

It is worth noting that in certain herbivores, high levels of POD may be desirable because POD may function to simultaneously eliminate H_2O_2 and detoxify plant phenolics (Miles and Peng, 1989). We suggest that this may be limited to insects with an acidic pH in their digestive system (e.g., acridids) or those that form a salivary sheath while feeding on vascular tissues (e.g., aphidids). Under acidic conditions, oxidized plant phenolics do not bind covalently to amino acids but instead polymerize, forming nontoxic polymers (Felton et al., 1989; Duffey and Felton, 1989). Hence, damage to the nutritional quality of protein is avoided.

In addition to the diminution of H_2O_2 toxicity by catalase, this detoxicative enzyme may have other important functions. Recently, H_2O_2 has been implicated in transduction of defense signals in plants due to its exceedingly rapid production in cells following elicitor application and its ability to stimulate phytoalexin production (Apostol et al., 1989). Application of catalase to *Glycine max* plant cells significantly inhibited the formation of the phytoalexin glyceollin (Apostol et al., 1989). If these recent results prove to represent a generalized mechanism of defense signaling in plants, then the implications of our findings are more significant. If catalase is released in herbivore saliva during feeding, the transduction of certain defense signals in plant cells could be disrupted. Such disruption may offset, in part, the decline in leaf quality often observed following wounding by herbivores (e.g., Schultz and Baldwin, 1982).

In summary, the presence of catalase in the digestive system of herbivores may offer an extremely important protective mechanism against: (1) direct H_2O_2 toxicity; (2) the toxicity resulting from the formation of free radicals, quinones, and lipid oxidation products by peroxidases; (3) loss of nutrients such as amino

acids, linoleic acid, thiamine, and ascorbic acid; and (4) the induction of active plant defenses by interference with transduction of defense signals.

(Received December 18, 1990; accepted April 26, 1991)

Abstract—Mountain hares (*Lepus timidus* L.) commonly have high proportions of birch (*Betula* spp.) in their winter diets, whereas European hares (*Lepus europaeus*) do not. The effects of a birch extract added to laboratory diets offered to mountain hares and European hares on the digestibility and sodium balance were measured. The extract added contained total phenolics equivalent in amount to that occurring in diets containing 0, 40, 60 and 80% dry matter of birch twigs. Increasing dietary phenolic concentration led to reduced voluntary food intake and apparent protein digestibility in both hare species. No effects on apparent dry matter digestibility were observed. The highest concentration of birch extract caused severe sodium losses via the urine by European hares but not by mountain hares. The effects of the birch extract within the digestive system appear to be similar in the two hare species, whereas the mountain hare appears to be better adapted to the toxic effects that disrupted sodium balance in the European hare. These preliminary results suggest that detoxification rather than digestive ability *per se* may contribute to different mammalian herbivores' feeding strategies.

Key Words—*Lepus timidus, Lepus europaeus, Betula pendula*, hares, birch, phenolic, digestion, chemical defense, sodium balance.

INTRODUCTION

Secondary plant compounds were originally named because they had no known function within the plant. In recent years, many studies have shown that certain secondary compounds or groups of them can influence herbivores' food selection or intake (Bryant, 1981; Tahvanainen et al., 1985; Iason and Waterman, 1988; Sinclair et al., 1988a). However, the theory of antiherbivore plant chemistry assumes that a chemical's action as an antifeedant is associated with a negative effect on the herbivore, either toxicity or a reduction in the herbivore's digestive ability (Rhoades, 1979). Members of a common and diverse group of secondary compounds, the phenolics, which includes different types of tannins and glycosides, show a range of antiherbivore effects. Phenolic plant constituents not only reduce *in vivo* digestibility (Lindroth et al., 1986; Sinclair et al., 1988b; Robbins et al., 1987a) but can also reduce the efficiency of nutrient utilization (Mole et al., in preparation). Both low- and high-molecular-weight phenolics can reduce ruminant in vitro digestibility (Risenhoover et al., 1985; Palo, 1985; Sunnerheim et al., 1988) and have been implicated as causing sodium loss in mountain hares, rabbits, and mice (Freeland et al., 1985; Palo and Knutsson, 1987; Palo et al., 1983, 1989). It is paradoxical that despite this array of possible negative effects, many herbivores continue to ingest large amounts of forages which contain phenolics.

Mammalian herbivores may be classified along a continuum from concentrate selectors, many of which utilize woody plant tissue, the browsers, to a less selective grazing or bulk-feeding strategy (Van Soest, 1982; Hofmann, 1989). Browsers feeding on leaves, twigs, and buds of woody shrubs or trees ingest more phenolics than the grazers, which take more graminoids, few of which contain phenolics in their vegetative parts (Jung et al., 1979; Rhoades and Cates, 1976; Hagerman and Butler, 1989). The browsers are hypothesized to be able to counter any detrimental effects of phenolics, either by bearing the costs of the toxic effect, the detoxification process, or the reduction in digestibility. They may also possess counteradaptations to nullify such effects, e.g., by secretion of tannin-binding salivary proteins (Robbins et al., 1987b). The present study aims to compare the effects of phenolic extracts from one plant species, the silver birch (*Betula pendula*) on two mammalian herbivores with contrasting feeding strategies.

An appropriate pair of mammalian herbivores for the comparison are the mountain hare (*Lepus timidus*) and the European hare (*Lepus europaeus*). These species are congeneric and have a cecal fermentation digestive system. In the northern temperate latitudes where their distribution overlaps, they are of similar body size and life-history strategy (Flux, 1981; Swihart, 1984). However, their feeding strategies are quite different; the mountain hare is a summer grazer reverting to woody browse in the winter (Lindlöf et al., 1974; Iason and Water-

man, 1988). The European hare also eats graminoids and herbs in summer (Seiskari, 1963; Helminen et al., 1966) but continues to do so in winter (Hyytinen, 1974). In boreal and arctic ecosystems, including at the northern limit of the distribution of European hares in Fennoscandia (see Lindström et al., 1989), the birch is an important food source to mountain hares but not European hares (Hyytinen, 1974; Barikmo, 1976). The constituents of extracts of *Betula pendula* are well characterized both chemically (Palo, 1984; Sunnerheim et al., 1988) and in terms of their effects on lagomorphs in which they cause sodium imbalance (Palo et al., 1983; Palo and Knutsson, 1987). Birch extracts have also been shown to reduce the *in vivo* digestibility of dry matter and protein in snowshoe hares (Sinclair et al., 1988b). The specific aims of this study are to compare the effect of a phenolic birch extract on the digestion and sodium retention of mountain hares and European hares. This approach should permit the elucidation of differences in digestion and sodium metabolism between them and identification of possible adaptations of browsing hind-gut fermenters to phenolic rich diets.

METHODS AND MATERIALS

Twigs were collected between April 7 and April 28, 1987, from previously unbrowsed shoots of *Betula pendula* around the Grimsö research station in southern-central Sweden. This was milled to approximately 5-mm particles and 1 kg aliquots were soaked for 1–2 hr in 6 liters 96% ethanol, after which time it was homogenized for 2 × 10 min. The ethanolic extract was decanted and filtered through a No. 3 filter (Munktells Swedish). A volume of 96% ethanol equivalent to that originally decanted was added to the residue. This procedure was repeated and the extracts pooled. The solvent was evaporated in a rotary evaporator and the residue concentrated. The residue was then redissolved in ethanol and applied as a fine spray in an enclosed space to commercially available pelleted animal food (Gödför Nötför, Lantmännen, Örebro; Energy 13.2 MJ/kg dry matter; crude protein 15.8% dry matter; neutral detergent fiber 19.6% dry matter).

The concentration of the ethanol-diluted extract was quantitatively adjusted such that the amount of total phenolics added was equivalent to that predicted to be found in a diet consisting of 40, 60, or 80% dry matter of fine (1-mm-diameter) birch twigs. Total phenolics were defined as those measured by the Folin-Ciocalteau assay and the predicted concentration in 1-mm-diameter birch twigs was according to Palo (1985). Control pellets were prepared with an equivalent volume of 96% ethanol. All pellets were dried to constant weight in an air draft at 30°C.

Three adult mountain hares, one nonreproducing female and two males,

and two adult male European hares were individually housed in large cages equipped with a device for the immediate separation and collection of urine and feces. The experiment was conducted in July–August 1987. After two weeks of feeding on only untreated pellets, they were offered the pelleted diets treated with ethanol only or 40, 60, or 80% phenolics. Each diet was offered to each hare for three days. This period was considered long enough to observe measurable effects on sodium balance (Palo and Knutsson, 1987) and digestibility. Reichardt et al. (1984) began fecal collections on the third day of treatment. The intention of this study was to compare only the short-term effects of phenolics without confounding experimental results with long-term adaptation that may occur at different rates in the two species. Between each of these treatments, at least three days of only untreated pellets were given; hence the basal diet was consistent throughout the whole experiment and long-term adaptation to phenolics was prevented.

Water was freely available throughout the experiments. Total collections of urine and feces were made, and hares were weighed daily. The hares were not trained to use laboratory drinking bottles and two of the individuals persistently tipped over their water supply; hence urine volume produced could not be determined precisely for these hares. Feces and food samples were air dried at 40°C and milled to pass a 1-mm mesh. Nitrogen in food and feces was determined colorimetrically with a Technicon autoanalyzer and converted to protein concentration ($\times 6.25$). Sodium was determined in food, feces, and urine samples by flame photometry. Apparent digestibility of protein or dry matter was calculated on a daily basis as the difference between the amounts consumed and excreted in the feces, expressed as a percentage of the amount consumed.

For food intakes, digestibility, and sodium balance, each variable was analyzed using a three-way factorial analysis of variance (Winer, 1971) with species, phenolic treatment, and day of measurement as fixed factors; individuals were treated as replicates. Only measurements on the second and third days of each treatment were included, although the intake on all three days of the treatments was also analyzed and presented separately to investigate possible aversion to the new food types.

RESULTS

Food Intake. When phenolic extracts were added to the pellets at 40, 60, and 80% levels, there was a tendency, although not significant, for a lower intake on day 1 than days 2 and 3 of the treatments (day 1: 30.07 g/kg/day; day 2: 34.11 g/kg/day; day 3: 33.09 g/kg/day, $F = 2.92$, $df = 2,27$, $P < 0.1$). The aversion to the phenolic treated pellets was particularly marked for the 80% phenolic treated pellets (day 1: 22.91 g/kg/day; day 2: 31.29 g/kg/

day; day 3: 33.42 g/kg/day; $F = 4.76$, $df = 2,9$, $P < 0.05$); there was no significant variation in food intake between days of the control treatment ($F = 0.26$, $df = 2,9$, NS).

Food intake varied significantly between treatments ($F = 4.481$, $df = 3,24$, $P < 0.05$), decreasing progressively with increasing dietary phenolic concentration (Figure 1). Food intakes on 60% and 80% phenol treatments were significantly lower than the control diet ($P < 0.05$, Fisher's protected LSD). Intake did not differ between species (mountain hares: 36.29 g/kg/day; European hares: 37.18 g/kg/day; $F = 0.155$, $df = 1,24$,NS) or between days 2 and 3 ($F = 0.008$, $df = 1,24$, NS).

Apparent Digestibility. Although the second and third successive days of treatment were included separately in all statistical analyses of digestibility, there were no differences between days for any of the digestibility measurements; hence data for different days are pooled.

Mean digestibility of dry matter was reduced when the birch phenolic extract was added to the pellets as compared to the control pellets, with the exception of the 80% treatment for European hares (Figure 2A). However, the errors associated with these measurements were large and dry matter digesti-

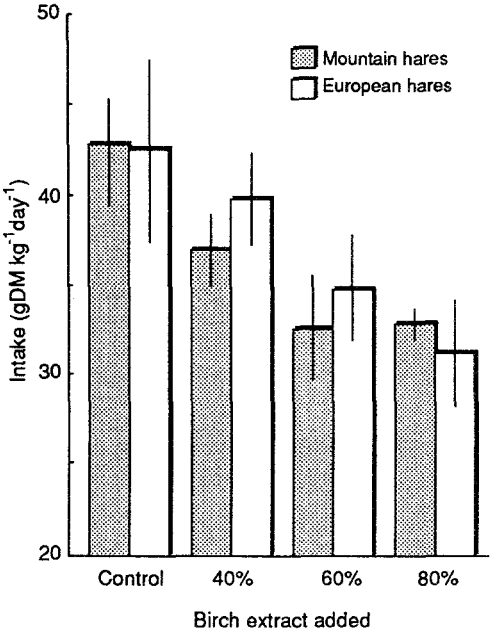

FIG. 1. The voluntary food intake by mountain hares and European hares offered control (solvent treated) commercial animal pelleted diet or the pellets treated with the phenolic birch extract equivalent to 40, 60, or 80% dry matter of birch (means ± SE).

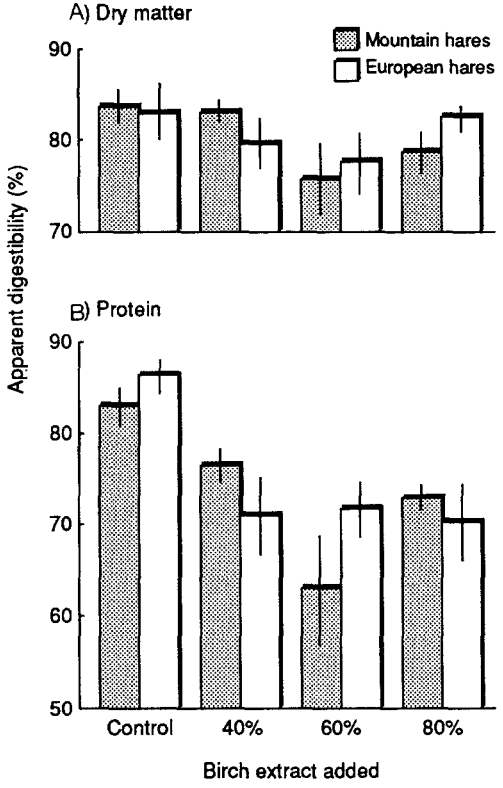

FIG. 2. The apparent digestibility of (A) dry matter and (B) protein of the artificial diet treated with increasing amounts of birch extract (mean ± SE).

bility did not vary significantly with phenolics added to the diet ($F = 1.79$, $df = 3,24$, NS); nor did it differ between species ($F = 0.03$, $df = 1,24$, NS).

Protein digestibility did not vary between species (mountain hares: 74.3%, European hares 75.2%, $F = 0.118$, $df = 1,24$, NS) but was significantly different between phenol treatments ($F = 6.266$, $df = 3,24$, $P < 0.01$); all levels of phenol treatment had lower protein digestibility than the control diet ($P < 0.05$, Fisher's protected LSD, Figure 2B).

Sodium Balance. Previous studies on domestic rabbits showed that phenolic-induced sodium imbalance occurred rapidly on the first day of treatment (Palo and Knutsson, 1987). A preliminary analysis of the data showed that this was also the case for European hares; on each of the three phenolic-treated diets, sodium balance on day 1 was negative. On days two and three this trend was reversed on the 40 and 60% phenol-treated diets, but it was reinforced, becoming even more strongly negative on days 2 and 3, when the 80% phenol-

treated diet was offered to European hares. The analyses reported here include only sodium balances on days 2 and 3 of treatments, which did not differ from each other ($F = 2.675$, $df = 1,24$, NS). The sodium balance of mountain hares was consistently positive regardless of treatment, whereas the European hares' sodium balance was around zero or was positive in all treatments except the 80% phenolic treatment when it was strongly negative (Figure 3). Although the species × treatment interaction was not significant ($F = 2.641$, $df = 3,24$, $P < 0.1$), the sodium balance was significantly different between treatments ($F = 3.726$, $df = 3,24$, $P < 0.05$) and overall was negative for European hares (−0.013 mmol/kg/day) but not mountain hares (1.233 mmol/kg/day) ($F = 9.828$, $df = 1,24$, $P < 0.01$). On average, only 1.7% of total sodium excreted was via the feces, 98.3% was excreted in the urine.

The mean weight changes of the hares were slight and not different between species (mountain hares: +0.3%/day; European hares: +0.5%/day, $F = 0.058$, $df = 1,24$, NS) or between treatments (control: −1.5%/day; 40% pheonlics: + 1.8%/day; 60% phenolics: −0.4%/day; 80% phenolics: +1.1%/day, $F = 2.726$, $df = 3,23$, NS). There was no correlation between weight change and sodium balance (mountain hares: $r = 0.16$, $df = 22$, NS; European hares: $r = 0.19$, $df = 14$, NS).

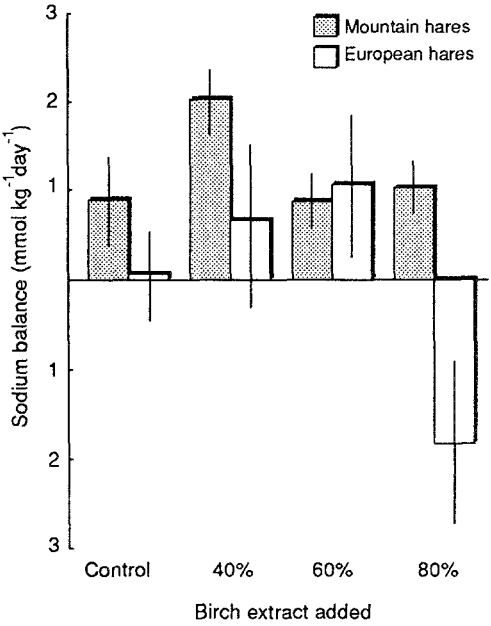

FIG. 3. The sodium balance of mountain and European hares fed with artificial diet treated with increasing amounts of birch extract (mean ± SE).

DISCUSSION

The theory of antiherbivore plant chemistry assumes the avoidance or reduced intake of a plant by a herbivore is due to the plant secondary compounds exerting some harmful effect on the animal (Rhoades, 1979). This study confirms others, which have shown that extracts of birch trees reduce the digestibility of food by hares (Sinclair et al., 1988b). Although phenolics have the property of complexation with both proteins and polysaccharides (Swain, 1979), the extract of birch used in this experiment inhibited only protein digestibility; total dry matter digestibility was unaffected. Some fractions of birch extracts have been shown to reduce organic matter digestibility in *in vitro* rumen systems (Palo et al., 1985; Sunnerheim et al., 1988). Sunnerheim et al. (1988) showed that polyphenolics had only a slight depressive effect on *in vitro* organic matter digestibility and that a low-molecular-weight fraction actually increased digestibility. Another *in vitro* study suggested that tannins may increase the digestibility of proteins (Mole and Waterman, 1985). However, the results here show that even at relatively low concentrations the *in vivo* effects of birch phenolics were to reduce the digestibility of proteins. The strength of this effect, combined with the absence of a reduction in *in vivo* dry matter digestibility suggests that in cecal fermenters the most significant antidigestive effect of birch phenolics is via their association with proteins. It suggests that interactions with plant cell wall constituents or any general antibiotic effect against the digestive system microorganisms are less important. Palo (1987) suggested that the type of digestive system of a herbivore, e.g., foregut or hindgut fermentation, will govern the pathway and action of certain plant secondary metabolites. In hindgut fermenters such as hares, it is more likely that low-molecular-weight compounds are rapidly absorbed prior to the site of microbial fermentation, whereas in foregut fermenters they might be transformed to a greater extent. Their action in the digestive tract would thus be relatively less.

The effect of high-molecular-weight plant chemical substances, such as tannins, on digestion might be expected to be similar in the two hare species, as a result of their similar digestive systems. However, differences in specific digestive physiological functions have been shown to exist between species with different feeding strategies but that have the same digestive system, e.g., qualitative differences of saliva produced by browsing and grazing ruminants that permit superior digestion of tannin-rich diets by the browsers (Robbins et al., 1987b). No differences were detected between the two hare species in the apparent digestibility of any of the dietary constituents measured. However, this does not preclude the possibility that differences in ability to digest different food components may develop given longer periods of exposure to the birch extract than permitted by this experiment. In contrast, there was a marked difference between the mountain and European hares in the effect of birch phenolics on

sodium balance. The sodium balance was strongly negative in European hares on the 80% phenol treatment, primarily due to a greatly increased urinary excretion, while no effect was observed in mountain hares. Sodium balance was not merely a correlate of weight loss, since there was no association between them in either species of hare. Previous studies of mountain hares and snowshoe hares (*Lepus americanus*) have found that a diet of pure narrow-clipped birch twigs, fed in winter, induces net sodium loss and loss of weight (Pehrson, 1983; Reichardt et al., 1984). This was not observed in mountain hares in this study, probably because the highest concentration of phenolics used was lower than that in a diet of pure birch twigs and, secondly, the basal diet was considerably more energy-rich than a twig diet. Furthermore, this experiment was conducted in summer with nonreproductive adults, circumstances that again may have led to a favorable energy balance that permitted any costs of detoxification to be met. Nevertheless, a significantly higher sodium excretion that increased with phenolic concentration of the diet was observed in European hares. This indicates a relatively lower tolerance of birch phenolics by this species as compared to mountain hares.

We conclude that although birch phenolics depressed apparent protein digestibility, they did so equally in both mountain and European hares. Apparent digestibility of dry matter was not significantly affected in either species. This experiment provides no support for the hypothesis that the reported differences in feeding strategy between the two species are associated with differences in the effects of phenolic secondary compounds on their digestive ability. We cannot, however, dismiss the possibility that longer-term adaptation may be different in the two species. In contrast, with only relatively short-term exposure to concentrations of birch phenolics equivalent to that in a diet of 80% birch, the sodium balance of European hares was severely impaired whereas that of mountain hares was unaffected. It is hypothesized that some component of the birch extract interfered with a systemic metabolic process or possibly kidney regulation of sodium balance, since most sodium is excreted via the urine. A parallel study showed that the extent and nature of biotransformation and urine excretion of catabolites of platyphylloside, a major birch phenolic constituent (Sunnherheim et al., 1988), also varied between the two hare species (Palo et al., 1989). The preliminary results reported here, lead to the hypothesis that metabolic differences and toxic effects, rather than differences solely in digestive function, may underlie the categorization of mammalian herbivores into those that commonly eat phenolic-rich foods (browsers) and those that do not (grazers).

METABOLICALLY BLOCKED ANALOGS OF HOUSEFLY SEX PHEROMONE: I. SYNTHESIS OF ALTERNATIVE SUBSTRATES FOR THE CUTICULAR MONOOXYGENASES

BACHIR LATLI and GLENN D. PRESTWICH*

Department of Chemistry
State University of New York
Stony Brook, New York 11794-3400

(Received January 15, 1991; accepted April 26, 1991)

Abstract—Cuticular monooxygenases in the cuticle of the female housefly *Musca domestica* oxidize (*Z*)-9-tricosene to *cis*-9,10-epoxytricosane and to (*Z*)-9-tricosen-14-one. One possible explanation for these two products is that a single monooxygenase accepts the alkene substrate in two different orientations. Eleven analogs of (*Z*)-9-tricosene bearing methyl substituents, cyclopropyl groups, fluorine substituents, deuterium substituents, and additional double bonds were synthesized to probe the substrate requirements of this monooxygenase system. In addition, the 11 corresponding epoxides were prepared to aid in identification of the metabolites of each modified alkene.

Key Words—*Musca domestica*, housefly, Diptera, Muscidae, monooxygenase, (*Z*)-9-tricosene analog, *cis*-9,10-epoxytricosane, (*Z*)-9-tricosen-14-one, synthesis, cyclopropyl, inhibition, isotope effect, fluorination, epoxidation.

INTRODUCTION

The sex pheromone of the housefly *Musca domestica* was first demonstrated by Rogoff et al. (1964) and was identified as (*Z*)-9-tricosene and called muscalure (Carlson et al., 1971). It was shown that this compound attracts males in an olfactometer at doses as low as 0.07 μg (Adams et al., 1984). In a study to determine the effects of structural variation of (*Z*)-9-tricosene on activity (Carlson et al., 1974), a variety of compounds with different double bond positions

*To whom correspondence should be addressed.

0098-0331/91/0900-1745$06.50/0

and geometry or even with a triple bond and with methyl branching at different points in the molecule or with different carbon chain and length of carbon chain linked to the unsaturated bond were synthesized and tested in an olfactometer and a pseudofly test. The structural requirements for activity were found to be not very stringent. *cis*-9,10-Epoxytricosane and (*Z*)-14-tricosen-10-one, along with a series of C_{28}–C_{30} methyl alkanes, are also components of the pheromone. Each of these components has a precise role; (*Z*)-9-tricosene increases male mating strike activity toward females and other males. The epoxide and ketone decrease the number of homosexual mating strikes, thus acting as a sex recognition factor. The methyl alkanes act as arrestants and increase the length of time that a male spends with a treated model (Adams and Holt, 1987).

Newly emerged males and females have similar cuticular lipid profiles; the major hydrocarbon components are (*Z*)-9-alkenes of 27 carbons and longer. From stages 4 through 8 (vitellogenic stages of the female), both the percentage of alkenes and the percentage of (*Z*)-9-heptacosene in the alkene fraction decrease while the percentage of (*Z*)-9-tricosene increases. Since (*Z*)-9-tricosene (I) is readily converted to both the epoxide (II) the ketone (III) (Figure 1) (Blomquist et al., 1984), the increase of (*Z*)-9-tricosene is mirrored by a concomitant increase in the C_{23} epoxide and ketone.

The cytochrome P-450 monooxygenases present in housefly cuticle have been found to be responsible for the conversion of (*Z*)-9-tricosene into 9,10-epoxide and to 14-keto metabolites (Ahmad et al., 1987). These reactions correspond to oxygen insertion into an alkene pi electron system and to oxygen insertion into an alkane C—H bond, respectively. Formation of the ketone requires a second oxidation of a carbinol C—H bond, presumably giving the hydrate of the ketone. An alternative is the existence of a specific alcohol dehydrogenase that rapidly converts all alcohol formed to the ketone (cf. Prestwich,

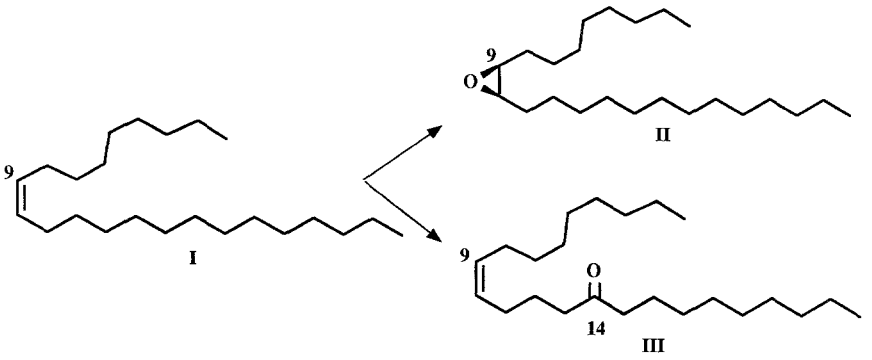

FIG. 1. Oxidation of (*Z*)-9-tricosene by cuticular polysubstrate monooxygenase of the housefly.

1987). It seems likely that both epoxide and ketone metabolite can arise by the action of a single monooxygenase; the different products would result from different orientations of the substrate in the active site (Figure 2).

To explore these possibilities, we synthesized a selection of compounds (and their expected metabolites) possessing modifications in the 14 position and in the alkyl chains of (*Z*)-9-tricosene (Figures 3 and 4). First, an additional alkene was introduced in the chain or as an *exo* methylene at C-14, providing an alternative site of epoxidation (compounds **1a, 2a**). Second, the C-14 position was blocked with only methyl to allow observation of the expected alcohol intermediate in ketone production (compounds **3a, 4a**). Third, the C-14 position was blocked with two methyl groups or with a spiro-fused cyclopropane ring, producing compounds resistant to oxidation at this site, yet still capable of 9,10-epoxidation (compounds **5a, 6a**). Fourth, the C-14 position was blocked with either one or two fluorine atoms, thereby altering the C—H oxidation (compounds **7a, 8a**). Fifth, one or two deuterium atoms were introduced at C-14 with the goal of retarding the second C—H oxidation and to permit measurement of kinetic isotope effect (compounds **9a, 10a**). Sixth, a perfluorooctyl chain was used to replace the octyl chain to probe the importance of hydrophobicity of the alkyl chain and of the nucleophilicity of the olefin on the epoxidation reaction (compound **11a**). Finally, the metabolism of these analogs in vivo was investigated and will be described in the following paper in this issue (Guo et al., 1991).

METHODS AND MATERIALS

General

Air-sensitive materials and reactions were employed using standard techniques. All glassware was dried in the oven or with a flame. The glassware and syringes were assembled hot and allowed to cool under nitrogen atmosphere. Reactions were carried out under nitrogen atmosphere unless otherwise indicated. Tetrahydrofuran (THF) and diethyl ether (Et_2O) were distilled from sodium benzophenone under nitrogen in a recirculating still, with a deep purple or blue color maintained in the distillation pot. Methylene chloride, HMPA, and triethylamine were distilled from calcium hydride (CaH_2). Benzene and toluene were dried by azeotropic distillation and stored over activated 3 Å molecular sieves. Ethyl acetate (EA) and hexane (H) were purchased from Fisher and distilled before use. Starting materials were obtained from commercial suppliers and were used without further purification, unless otherwise noted. All solvent transfers were accomplished using syringe or double-ended needle technique. "Isolated as usual" indicates that the organic extractions were combined, washed with aq. $NaHCO_3$, satd. NaCl, dried over $MgSO_4$, filtered, and concentrated in vacuo at room temperature (rt). Silica gel (SiO_2) chromatography was performed using 30 to 63-μm "flash" grade SiO_2 under nitrogen pressure.

Apparatus

Infrared (IR) spectra were obtained with a Perkin Elmer 1600 series FT-IR as neat liquid films or as solutions in carbon tetrachloride (CCl_4). UV spectra were recorded on a Perkin Elmer Lambda 5 UV/VIS spectrophotometer. Analytical gas chromatography (GC) was carried out on a Varian model 3700 chromatograph equipped with FID and using He as the carrier gas. The following columns were used: DB-5 (30 m $\times$ 0.25 mm) or DB-5 Megabore (15 m $\times$ 0.5 mm) (both J & W Scientific). The retention times were reported using the following program T_i = 50°C, T_f = 250°C, T_p = 10°C/min, with a delay at T_i for 2 min, unless otherwise indicated. Thin-layer chromatography (TLC) was performed with MN Polygram Sil G/UV 254 (4 $\times$ 8 cm). Visualization was accomplished by UV light, iodine, an ethanol–vanillin–H_2SO_4 solution, or an ethanol–phosphomolybdic acid solution, R_f = retention factor. Flash chromatographic purifications were carried out on Woelm Silica 32–63 μm or on alumina Woelm N-Super 1, using an ethyl acetate–hexane (EA/H) solution unless otherwise indicated. Fraction distillation or bulb to bulb Kugelrohr distillation at reduced pressure was also used for the purification of the crude products. Mass spectra (MS) were obtained at 70-eV ionization potential [^{1}H]NMR spectra were recorded at 300 MHz on a QE 300: s, singlet; d, doublet; dd,

doublet of doublets; t, triplet; q, quartet; m, multiplet; br, broadened. [^{13}C]NMR spectra were obtained at 75 MHz with off-resonance decoupling [^{19}F]NMR and [^{2}H]NMR spectra were recorded on an NT-300 using trichlorofluoromethane ($CFCl_3$) as an internal standard in C_6D_6 in case of [^{19}F]NMR and CCl_4 plus one drop of $CDCl_3$ for [^{2}H]NMR. Chemical shifts (ϕ) were expressed as parts per million (ppm) upfield from $CFCl_3$ (ϕ = 0 ppm) for fluorinated compounds. All other NMR samples were prepared in $CDCl_3$ or in $CDCl_3$ with 0.03% TMS, and shifts reported in ppm relative to δ ($CDCl_3$) = 7.259 ppm (^{1}H) or 77.00 ppm (^{13}C). Only diagnostic resonances are reported.

Synthesis of Alkenyl Ketone

*3-*n*-Nonyl-2-cyclohexenone (12).* A solution of 12.76 g (0.09 mol) of 3-ethoxy-2-cyclohexenone (Mori et al., 1977) and 23.3 g (0.11 mol) of freshly distilled *n*-nonylbromide was added dropwise to a stirred suspension of 6.26 g of lithium (25% wt dispersion in oil) in 40 ml of dry THF at 0°C under N_2 atmosphere (Figure 5). The mixture was stirred at rt for 2 hr, excess lithium was removed, and the solution was filtered by suction through a short pad of Celite. The filtrate was poured into 5% ice-diluted H_2SO_4, extracted with ether, and the product was isolated as usual. The pure product was isolated by fractional distillation at 0.6–0.8 mm Hg and 145–150°C as a colorless oil in 90% yield (17 g), which solidified upon refrigeration; R_f = 0.2 in 10% EA/H. FT-IR (neat): 2926, 2854, 1672, 1625, 1456, 1428, 1416 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 5.70 (s, 1H), 2.34 (t, J = 6.7 Hz, 2H), 2.27 (t, J = 5.8 Hz, 2H), 2.19 (t, J = 7.6 Hz, 2H), 1.97 (quintet, J = 6.3 Hz, 2H), 1.47 (quintet, J = 7.1 Hz, 2H); [^{13}C]NMR ($CDCl_3$); δ 199.74, 166.59, 125.49.

*3-*n*-Nonyl-2,3-Epoxycyclohexanone (13).* To a solution of 12 g of 3-*n*-nonyl-2-cyclohexenone (54 mmol) in 55 ml of MeOH, 26 ml of 30% H_2O_2 was added dropwise followed by 4.7 ml of 6 N NaOH during a 10-min period. After stirring at rt for 18 hr, the mixture was poured in 150 ml of water, extracted with ether, and purified (SiO_2) to give 12 g of a colorless oil in 93% yield, R_f = 0.40 in 10% EA/H. FT-IR (neat): 2929, 2854, 1715, 1458, 1401 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 2.90 (s, 1H), 1.50–2.40 (m, 6H); [^{13}C]NMR ($CDCl_3$): δ 206.74, 65.29, 61.08.

1-Pentadecyn-6-one (14). *p*-Tosylhydrazide (8.4 g, 43.7 mmol) was added in one portion to a stirred, ice-cold solution of 10.4 g (43.7 mmol) of the epoxide (13) in 50 ml of dry CH_2Cl_2 and 25 ml of acetic acid. The mixture was stirred for 3 hr at 0°C, 14 hr at rt, poured into water and extracted with hexane. The crude product was isolated as usual with hexane and purified (SiO_2) to give a colorless oil in 67% yield (6.6 g), R_f = 0.52 in 10% EA/H. FT-IR (neat): 3313, 2925, 2854, 1718, 1459, 1411 cm^{-1}; [^{1}H]NMR ($CDCl_3$); δ 2.55 (t, J = 7.2 Hz, 2H), 2.40 (t, J = 7.4 Hz, 2H), 2.22 (br t, 2H), 1.50–2.00 (m, 3H); [^{13}C]NMR ($CDCl_3$): δ 210.48, 83.56, 68.94.

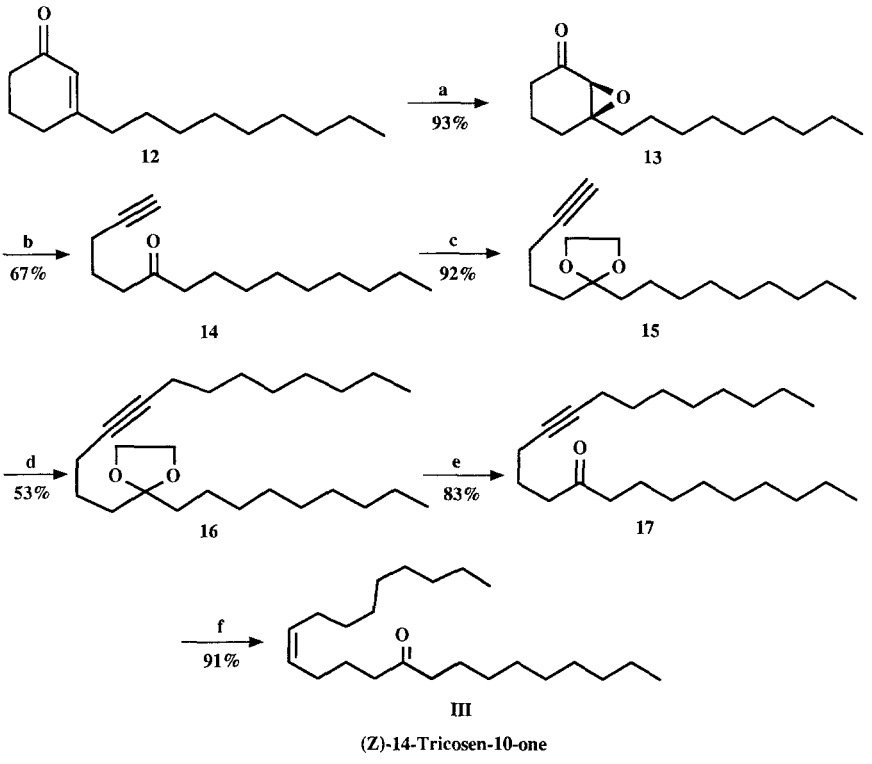

FIG. 5. Synthesis of (Z)-14-tricosen-10-one, a key precursor to several analogs: (a) H_2O_2, 6N NaOH, 25°C; (b) $TsNHNH_2$, CH_2Cl_2, AcOH, 0 to 25°C; (c) $HOCH_2CH_2OH$, $TsOH-H_2O$, C_6H_6, reflux; (d) *n*-BuLi, HMPA, *n*-$C_8H_{17}Br$, THF, −78°C; (e) 3N $HClO_4$, THF, 25°C; (f) H_2, 5% $Pd/BaSO_4$, EtOH, quinoline.

6-Ethylenedioxy-1-pentadecyne (15). A mixture of 1-pentadecyn-6-one (3 g, 13.5 mmol), an excess of ethylene glycol (20-fold molar excess), and 160 mg of *p*-toluenesulfonic acid monohydrate in 100 ml of benzene was heated under reflux with continuous removal of water for 3 hr. After cooling to rt, the mixture was washed with aq. $NaHCO_3$, the aqueous layer was extracted with hexane, and the product was isolated as usual. The crude product was chromatographed (SiO_2) to give 3.3 g of a colorless oil in 92% yield, R_f = 0.45 in 10% EA/H. FT-IR (neat): 3312, 2924, 2854, 1728, 1459 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 3.93 (s, 4H), 2.20 (t, 2H), 1.94 (s, 1H), 1.52–1.84 (m, 6H); [^{13}C]NMR ($CDCl_3$): δ 111.52, 77.43, 67.14, 64.90.

14-Ethylenedioxy-9-tricosyne (16). A solution of *n*-BuLi in hexane (5.6 ml, 2.5 M solution) was added dropwise to a solution of 2.66 g (10 mmol) of 6-ethylenedioxy-1-pentadecyne in 20 ml of dry THF stirred at −78°C under

N_2 atmosphere. The resulting yellow solution was stirred for 1 hr, 5 ml of dry HMPA was added, the red solution was stirred for an additional 30 min at −78°C, and then 1-bromooctane (2.2 g, 11 mmol) was added dropwise. The reaction solution was warmed to 0°C using an ice bath and stirred for 2 hr as the ice melted. The resulting clear solution was poured into water, extracted with hexane, and the product isolated as usual to give, after SiO_2 chromatography, 2 g of a colorless oil (53%), R_f = 0.57 in 10% EA/H. FT-IR (neat): 2925, 2854, 1466 cm^{-1}; ^1H NMR ($CDCl_3$): δ 3.88 (s, 4H), 2.00–2.20 (m, 4H), 1.40–1.98 (m, 4H); ^{13}C NMR ($CDCl_3$): δ 111.53, 81.12, 79.05, 64.90.

14-Tricosyn-10-one (17). A mixture of 1.5 g (4 mmol) of 14-ethylenedioxy-9-tricosyne in 15 ml of THF and excess of 3 N $HClO_4$ solution was stirred at rt for 24 hr, diluted with water, and the product isolated as usual. Purification of the product (SiO_2) gave 1.10 g in 83% yield, R_f = 0.51 in 10% EA/H. FT-IR (neat): 2955, 2927, 2855, 1716, 1466, 1411 cm^{-1}; ^1H NMR ($CDCl_3$): δ 2.51 (t, J = 7.3 Hz, 2H), 2.38 (t, J = 7.4 Hz, 2H), 2.16 (m, 4H), 1.72 (m, 2H); [^{13}C]NMR ($CDCl_3$): δ 210.91, 81.13, 79.04.

(Z)-14-Tricosen-10-one (III). A mixture of the above acetylenic ketone (0.80 g, 2.4 mmol), quinoline (0.80 ml of a solution of 100 mg : 1.0 ml, quinoline–hexane) and palladium on barium sulfate (5%, 100 mg) in absolute ethanol (15 mL) was stirred under hydrogen atmosphere. The progress of the reaction was monitored by GC. When no alkyne remained, the mixture was filtered through a short pad of Celite, washed with ether, concentrated in vacuo, and purified on SiO_2 by elution with 1–15% EA/H to give 732 mg of a colorless oil (91% yield), R_f = 0.65 in 10% EA/H. R_t = 14.74 (capillary GC, T_i = 140°C, 2 min; 7°C/min; T_f = 215°C). FT-IR (neat): 3004, 2924, 2853, 1716, 1465, 1409 cm^{-1}; ^1H NMR ($CDCl_3$): δ 5.34 (m, 2H), 2.37 (m, 4H), 2.01 (m, 4H); ^{13}C NMR ($CDCl_3$): δ 211.01, 130.82, 128.56; LR-EI-MS, m/z (rel. abund.): 337 (M^+-1, 0.9).

Synthesis of Diene Analogs

5-Tetradecyn-1-ol THP ether (18). To a solution of 5-hexyn-1-yl-tetrahydropyranyl ether (1.0 g, 5.5 mmol) in dry THF (12 ml), stirred at −78°C, was added dropwise 4 ml of *n*-BuLi (1.6 M solution in hexanes) (Figure 7). The resulting yellow solution was stirred at −78°C for 1 hr, 3 ml of dry HMPA was added, and the stirring was continued for another 30 min. A solution of *n*-bromooctane (1.0 ml, 5.5 mmol) in THF (5 ml) was added dropwise, the mixture was warmed gradually to rt, and the product isolated as usual. The crude product was purified (SiO_2) to give 1.45 g as a colorless oil (90%), R_f = 0.51 in 10% EA/H. FT-IR (neat): 2927, 2856, 1454, 1440 cm^{-1}; [^1H]NMR ($CDCl_3$): δ 4.57 (m, 1H), 3.85 (m, 1H), 3.72 (m, 1H), 3.50 (m, 1H), 3.40 (m, 1H), 2.12 (m, 4H); [^{13}C]NMR ($CDCl_3$): δ 98.67, 80.40, 79.70, 66.99, 62.14.

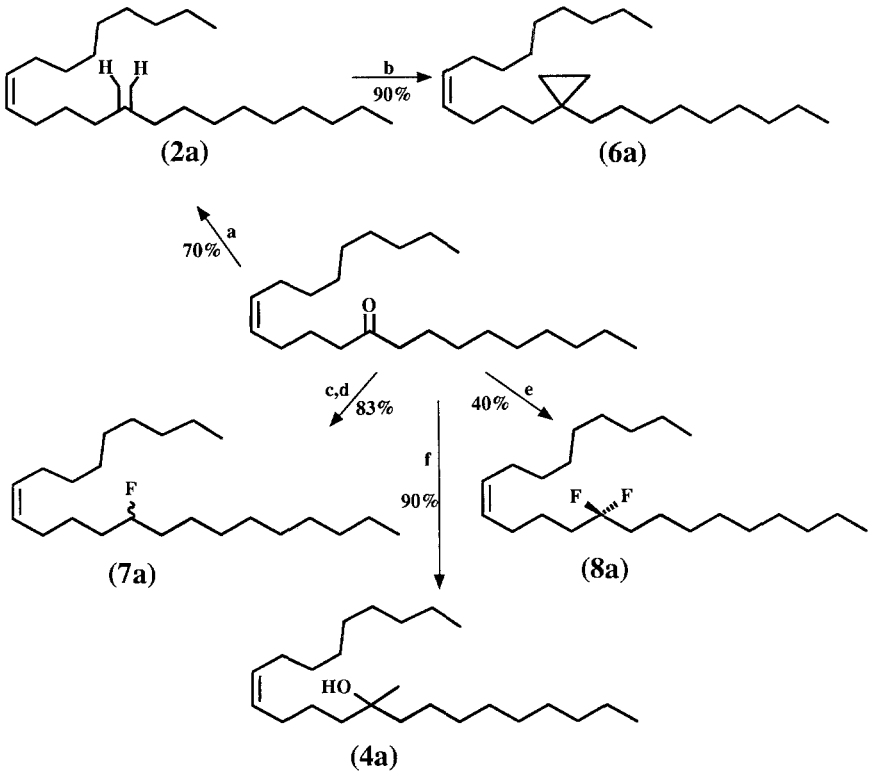

FIG. 6. Transformation of the enone **(III)** to the diene, cyclopropyl, tertiary alcohol, and mono and difluoro analogs: (a) $CH_3(C_6H_5)_3PBr$, *n*-BuLi, THF −78°C; (b) CH_2N_2, $Pd(OAc)_2$, Et_2O, 0°C; (c) $NaBH_4$, MeOH, 0°C; (d) DAST, CH_2Cl_2, −78°C; (e) DAST, CH_2Cl_2, 35°C; (f) CH_3MgBr, THF, 0°C.

(Z)-*5-Tetradecen-1-ol (19).* A solution of the alkynyl ether, **18** (0.70 g, 2.40 mmol), and PPTS (75 mg, 0.30 mmol) in ethanol (25 ml) was stirred at 55°C overnight, concentrated in vacuo, and purified (SiO_2) to give 0.64 g (92%) of a colorless oil, $R_f = 0.14$ in 10% EA/H. Next, a mixture of the alkynol (315 mg, 1.5 mmol), one drop of quinoline, and 20 mg of $Pd/BaSO_4$ (5%) in ethanol (10 ml) was stirred under a slight positive pressure of hydrogen. The mixture was filtered through Celite, concentrated *in vacuo*, and purified (SiO_2) to give 300 mg (94%) of a colorless oil, $R_f = 0.17$ in 10% EA/H. FT-IR (neat): 3329, 3004, 2925, 2854, 1459, 1404 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 5.36 (m, 2H), 3.64 (t, $J = 6.4$ Hz, 2H); [^{13}C]NMR ($CDCl_3$): δ (130.76, 129.70 8% *trans* impurity), 130.26, 129.23, 62.58.

(Z)-*5-Tetradecenal (20).* To a suspension of pyridinium chlorochromate

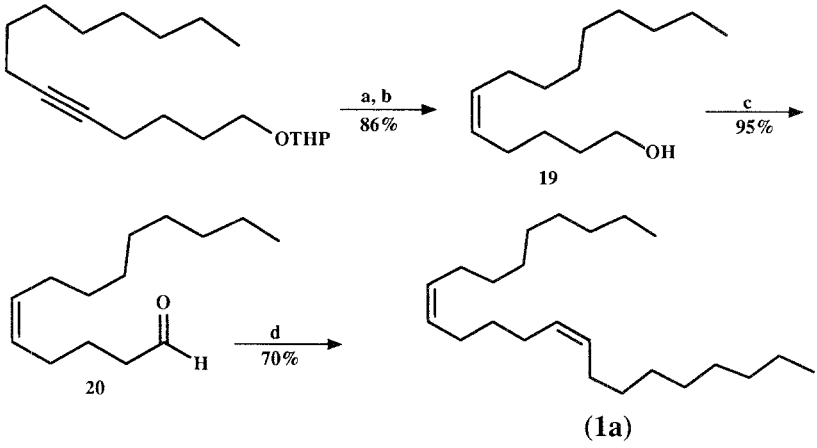

FIG. 7. Synthesis of the (Z,Z)-9,14-diene analog: (a) PPTS, EtOH, 60°C; (b) H_2, 5% $Pd/BaSO_4$, EtOH; (c) PDC, CH_2Cl_2; (d) n-$C_9H_{19}P(C_6H_5)_3Br$, n-BuLi, THF, −78°C.

(330 mg, 1.5 mmol) and sodium acetate (10 mg) in dry CH_2Cl_2 (10 ml) was added alcohol **19** (212 mg, 1 mmol) in dry CH_2Cl_2 (5 ml). After stirring the mixture for 2 hr at rt, it was diluted with ether, filtered through Florisil, concentrated, and purified (SiO_2) to give 200 mg of pure product as a colorless oil (95%), R_f = 0.5 in 10% EA/H. FT-IR (neat): 3004, 2925, 2854, 1728 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 9.77 (t, J = 1.7 Hz, 1H), 5.34 (m, 2H), 2.43 (dt, J = 1.6, 7.4 Hz, 2H); [^{13}C]NMR ($CDCl_3$): δ 202.50, 131.35, 128.11.

(Z,Z)-9,14-Tricosadiene (1a). To a solution of triphenylphosphine n-nonyl bromide, prepared from n-nonyl bromide and triphenylphosphine (470 mg, 1 mmol) in dry THF (5 ml) stirred at −78°C under nitrogen atmosphere, a solution of n-BuLi (0.5 ml, 1.6 M solution in hexanes) was added dropwise. The orange solution was stirred at −78°C for 1 hr, then (Z)-5-tetradecenal (105 mg, 0.5 mmol) in dry THF (2 ml) was added dropwise. After stirring 14 hr at rt, the product was isolated as usual with hexane and purified (SiO_2) to give 112 mg of a colorless oil (70%), R_f = 0.88 in 10% EA/H; R_t = 12.20 (T_i = 140°C, 2 min; 7°C/min; T_f = 220°C). FT-IR (neat): 3004, 2956, 2923, 2854, 1466 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 5.36 (m, 4H), 2.02 (m, 8H); [^{13}C]NMR ($CDCl_3$): δ 130.23, 129.51; EI-MS m/z 320 (M^+, 2.9).

cis,cis-9,10,14,15-Bisepoxy Tricosane (1b). To a solution of the above diene (5 mg, 15.6 mmol) in CH_2Cl_2 (1 ml) was added m-chloroperbenzoic acid (1 mg), stirred at 0°C for 1 hr, and the product isolated as usual from a hexane–water partition. Purification on SiO_2 afforded 5 mg (90%), R_f = 0.43 in 10% EA/H; R_t = 17.51 (T_i = 140°C, 2 min; 7°C/min; 250°C). [^{1}H]NMR ($CDCl_3$): δ 2.92 (m, 4H).

(Z)-2-(n-Nonyl)-1,6-pentadecadiene (2a). To a solution of methyltriphenyl-phosphonium bromide (107 mg, 0.30 mmol) in THF (5 ml), stirred at −78°C, was added *n*-BuLi (0.14 ml, 1.6 M solution in hexanes) dropwise. The red solution was stirred at −78°C for 1 hr, (Z)-14-tricosen-10-one (50 mg, 0.15 mmol) in THF (1 ml) was added, and the solution was stirred 1 hr as it warmed to rt. The mixture was poured into water, the product was isolated with hexane, and purified on SiO_2 to give 35 mg (70%) of a colorless oil, $R_f = 0.85$ in 10% EA/H; $R_t = 15.37$ ($T_i = 140$°C, 2 min; 7°C/min; $T_f = 250$°C). FT-IR (neat): 3071, 2957, 2925, 2855, 1644, 1466 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 5.36 (m, 2H), 4.69 (s, 2H); [^{13}C]NMR ($CDCl_3$): δ 150.10, 130.25, 129.48, 108.51.

2-n-Nonyl-1,2,9,10-bisepoxypentadecane (2b). The epoxide was prepared from 5 mg of diene, **2a**, in 91% yield as described above, $R_f = 0.43$ in 10% EA/H; $R_t = 19.78$ ($T_i = 140$°C, 2 min; 7°C/min; 250°C). [^{1}H]NMR ($CDCl_3$): δ 2.91 (m, 2H), 2.58 (s, 2H).

Synthesis of 14-methyl-(Z)-9-tricosene

5-Bromo-2-pentanone (21). A mixture of CuCl (1.0 g, 10 mmol), $PdCl_2$ (176 mg, 1 mmol), water (0.5 ml), dimethyl formamide (3.0 ml), and 5-bromo-1-pentene (1.5 g, 10 mmol) were stirred under an atmosphere of oxygen overnight at rt (Tsuji et al., 1976) (Figure 8). The dark mixture was poured into 3 N HCl and the product was isolated by extraction with CH_2Cl_2 followed by SiO_2 purification to give 1.0 g (60% yield) of pure product as a colorless oil that decomposes if left at rt, $R_f = 0.12$ in 10% EA/H. FT-IR (neat): 1715 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 3.35 (t, $J = 6.4$ Hz, 2H), 2.59 (t, $J = 7.0$ Hz, 2H),

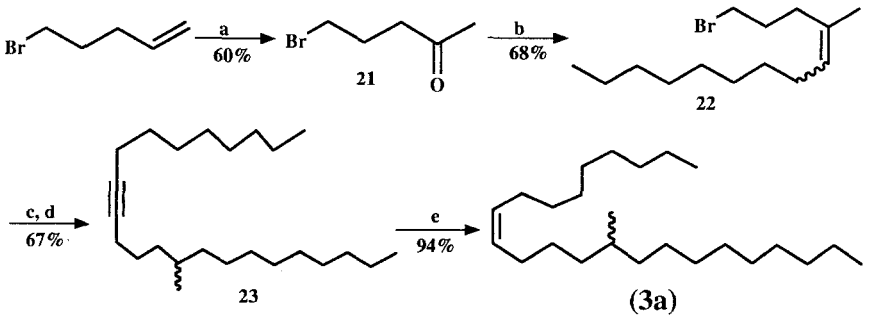

FIG. 8. Synthesis of 14-methyl-(Z)-9-tricosene: (a) $PdCl_2$, CuCl, DMF, H_2O, O_2; (b) n-$C_9H_{19}P(C_6H_5)_3Br$, n-BuLi, THF, −78°C; (c) H_2, 10% Pd/C, EtOH; (d) n-C_8H_{17}-C≡CH, n-BuLi, HMPA, THF, −78°C; (e) H_2, 5% $Pd/BaSO_4$, EtOH.

2.07 (s, 3H), 2.01 (dt; J = 6.7, 13.3 Hz, 2H); ^{13}C NMR ($CDCl_3$): δ 207.24, 41.31, 33.22, 31.77, 30.00, 26.25.

1-Bromo-4-methyl-4-tridecene (22). To a solution of *n*-nonyltriphenylphosphonium bromide (1.7 g, 3.6 mmol) in THF (10 ml), stirred at −78°C, was added dropwise *n*-BuLi (1.7 ml, 1.6 M in hexanes). The orange solution was stirred for 1 hr at −78°C, and then a solution of the above bromo ketone (300 mg, 1.8 mmol) in THF (5 ml) was added to give a colorless solution that was stirred at −78°C for 2 hr. The mixture was poured into water and the product isolated with hexane and purified (SiO_2) to give 340 mg (68% yield) of a 1:1 mixture (E:Z), R_f = 0.72 in 10% EA/H. FT-IR (neat): 2956, 2924, 2853, 1666, 1457 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 5.21 (br t, 1H); 3.39 (br t, 2H); 2.36 (m, 4H); 1.68 and 1.59 (s, s, 1:1 ratio, 3H); ^{13}C NMR ($CDCl_3$): δ 128.14 (127.08), 126.27 (125.24).

14-Methyl-9-tricosyne (23). To a solution of 1-decyne (50 mg, 0.30 mmol) in dry THF (4 ml) stirred at −78°C under nitrogen atmosphere was added *n*-BuLi (0.23 ml, 1.6 M solution in hexanes). After stirring for 1 hr, HMPA (1 ml) was added, the yellow solution was stirred for 30 min, a solution of 4-methyl-1-bromotridecane (70 mg, 0.25 mmol) (obtained by reducing the double bond in compound **22**) in THF (1 ml) was added, and the solution was stirred for 2 hr at −78°C. The reaction was poured into water and the product isolated with hexane and purified (SiO_2) to give 59 mg of a colorless oil (70%), R_f = 0.68 in 10% EA/H. FT-IR (neat): 3315, 2924, 2854, 1465 cm^{-1}; [^{1}H]NMR ($CDCl_3$): δ 2.14 (m, 4H); ^{13}C NMR ($CDCl_3$): δ 84.78, 80.25.

14-Methyl-(Z)-9-tricosene (3a). A mixture of 14-methyl-9-tricosyne (25 mg, 0.074 mmol), 5% Pd/$BaSO_4$ (5 mg), and one drop of quinoline in absolute ethanol was stirred under a slight positive pressure of hydrogen until no alkyne remained (GC). The mixture was filtered through Celite, concentrated, and purified on 20% $AgNO_3$–SiO_2 to give 25 mg (94%) of >98% *cis* alkene as a colorless oil, R_f = 0.80 in 10% EA/H; R_t = 14.48 (T_i = 140°C, 2 min; 7°C/min; T_f = 250°C). FT-IR (neat): 3004, 2955, 2923, 2853, 1652, 1465, 1403 cm^{-1}. [^{1}H]NMR ($CDCl_3$): δ 5.35 (m, 2H), 2.02 (m, 4H); [^{13}C]NMR ($CDCl_3$): δ 129.89.
