(Received March 28, 1990; accepted August 6, 1990)

Abstract—Four major chemotypes of *Cyperus rotundus* L. (purple nutsedge) have been reported based on the composition of essential oils in mature tubers. Distribution of the H, M, K, and O type in countries of the Pacific Rim and Basin was investigated. In general, the H type dominates on the islands of Japan, and the O type has the widest range of distribution. The O type also dominates the Pacific Basin islands except for Hawaii, where the K-type is dominant. Inhibitory activity of the essential oils from *C. rotundus* tubers against the seedling growth of lettuce and oats was in the order of H > M > K > O. Seven major sesquiterpenes were isolated from the oils and their inhibitory activities determined. Results suggest that *C. rotundus* of different chemotypes may have different allelopathic activity in the crop–weed interaction.

Key Words—*Cyperus rotundus*, purple nutsedge, weeds, allelopathy, chemotype, essential oil, sesquiterpene.

INTRODUCTION

The geographical variation of *Cyperus rotundus* L. (purple nutsedge) has been studied by Komai et al. (1977) based on the sesquiterpene composition of essential oils from the mature tubers. Three chemotypes, i.e., H, M, and O type

0098-0331/91/0100-0001$06.50/0

were found in Asia (Komai and Ueki, 1981). Recently, we reported the presence of the K type, a new chemotype in the Hawaiian Islands (Komai and Tang, 1989). Major sesquiterpenes in each essential oil (%) are as follows:

H type: α-cyperone (38.6); β-selinene (18.5), and cyperol (7.4)
M type: α-cyperone (30.7), cyperotundone (19.4), β-selinene (17.8), cyperene (7.2), and cyperol (5.6)
K type: cyperene (28.7), cyperotundone (8.8), petchoulenyl acetate (8.0), and sugeonyl acetate (6.9).
O type: cyprene (30.8), and cyperotundone (13.1)

To obtain a more complete picture of the geographical distribution of these four chemotypes, additional clones were collected from countries and islands of the Pacific Rim and Basin and their chemotypes determined according to the established method (Komai and Tang, 1989). Inhibitory activities of the four essential oils against lettuce and oat seedling growth were compared. Seven major sesquiterpenes were isolated and their inhibitory activities determined. Results suggest that *C. rotundus* of different chemotypes may have different allelopathic activity against crops. The significance of these findings is discussed.

METHODS AND MATERIALS

Sample Preparation. Mature tubers of *Cyperus rotundus* L. were collected from various regions in the Pacific region countries. A total of 254 clones were obtained (Table 1). Essential oils were prepared from each sample by *n*-hexane extraction as soon as the sample was obtained (Komai and Tang, 1989). Prior experiments showed that the sesquiterpene composition was consistent in essential oils of the tubers within a given chemotype (Komai et al., 1977; Komai and Tang, 1989).

Individual sesquiterpenes were prepared by repeated silica gel column chromatography from the K-type tubers collected from Oahu, Hawaii, and M type from the Miyazaki Prefecture in Japan. Seven compounds, including α-cyperone, cyperotundone, cyperol, β-selinene, cyperene, sugeonol acetate, and patchoulene acetate were isolated and purified for bioassay.

Instrumental Analyses. GC of the essential oils was performed on an SP-7100 Gas Chromatograph (Spectral Physics) equipped with a flame ionization detector and a 20-m × 0.25-mm-ID, DB-5 fused silica capillary column (J&W Scientific). The oven temperature was programmed from 90 to 250°C at 4°C/min. For GC-MS analysis an HP-5730 gas chromatograph–mass spectrometer was used. Conditions for GC of the GC-MS were similar to those of the GC analysis. For the MS, 70 eV and 300 mA electron energy were used. The ion-

source temperature was 200°C. Compounds were identified by comparison of GC retention times and mass spectra with those of the authentic compounds.

Inhibitory Activities. Inhibition of the lettuce (*Lactuca sativa* L. Anuenue) seedling growth was performed by transferring 20 pregerminated seeds to a Petri dish (diam. 6 cm) containing a Whatman No. 1 filter paper treated with the *n*-hexane extract of each chemotype (Table 2). For sesquiterpenes, 0.5, 1, or 5 mmol of the individual compound in hexane were applied (Table 3). Two milliliters of H_2O were added to moisten the filter paper after the solvent was evaporated. Hypocotyl and radicle length were measured four days after incu-

bation and the inhibitory activity was expressed as percent growth of those of the control (i.e., with H_2O alone).

Methods for determining inhibition of oat (*Avena sativa* L.) seedlings (Tables 4 and 5) were similar to those of the lettuce except a 9-cm Petri dish was used and 4 ml of H_2O were added to the essential-oil-treated filter paper instead. The lengths of leaf sheath and radicle were measured after four days. All experiments were performed in the dark at 23°C in covered Petri dishes.

RESULTS AND DISCUSSION

Distribution of Purple Nutsedge Chemotypes in Pacific Rim and Basin. Table 1 shows that of the 254 clones analyzed, the O type has the broadest distribution, ranging from the Asian to the American mainland. Although in most cases the sample size was too small to draw any conclusions, it nevertheless showed that the O type was the exclusive chemotype collected from Aus-

tralia, Indonesia, and other Pacific islands including Samoa, Saipan, Republic of Palau, Guam, Cook Island, and Tonga. The O type was also the only chemotype of clones collected from Arizona, Mississippi, and Alabama. The Hawaiian islands are an interesting exception, where the K type dominates the *C. rotundus* population. In addition, O-type clones found in Hawaii are higher in cyperotundone and lower cyperene content compared to those found elsewhere; it may be designated as the Hawaiian O type.

In a previous publication, we speculated that the K type might have evolved in the Hawaiian islands (Komai and Tang, 1989). In the present experiment, one K-type and four O-type clones were determined from a southern California collection, and the only clone collected from Medellin, Mexico, was also a K type. Thus, it is also possible that the K type has a central American origin. More data on clones from the American mainland are required to clarify this.

Of the eight clones collected from different locations in Indonesia, three had a GC profile unlike those of *C. rotundus*. A comparison of the GC profiles showed that they were *Cyperus tuberosus* (Komai, unpublished) and were misidentified as *C. rotundus*. This is hardly surprising since these two species are morphologically quite similar. The fact that GC profiles were able to differentiate the two suggests the usefulness of the present technique in the identification of *Cyperus* species, especially for those with little morphological distinction (Backer and Bakhuizen van der Brink, Jr., 1968).

The H type was found only in Japan in an earlier study (Komai and Ueki, 1981) and also represents ca. 2/3 of the Japanese *C. rotundus* population. The unexpected presence of the H type in the Black Sand Beach area on the island of Hawaii leads to the speculation that the localized distribution of H type in this tourist resort has been a recent introduction.

Inhibitory Activity of Essential Oils. The growth inhibitory activity on lettuce and oat seedlings by essential oils prepared from the four chemotypes of *C. rotundus* are shown in Table 2 and 4, respectively. The overall potency of inhibition was in the order of H > M > K > O type, although the difference between H and M type on oats was neglegible. At the lowest concentration tested (i.e., 250 ppm of essential oil in aqueous suspension), the growth of lettuce seedlings (radicle plus hypocotyl elongation) was reduced by 30, 23, and 11% of the control in H, M, and K type, correspondingly. The O type slightly enhanced lettuce seedling growth at 250 ppm, although it is not significantly different from the control at 5% level. At 500 and 1000 ppm, the O and K type were similar in inhibitory activities. Results on oat seedlings showed that at 250 ppm, the growth was reduced to 24, 28, and 5% by H, M, and K type, respectively. A slight enhancement was again observed in the O type at 250 ppm, and similar activities were recorded in the O and K type at 500 and 1000 ppm.

Inhibitory Activity of Individual Sesquiterpenes. Activities of the major

sesquiterpenes isolated from the nutsedge tubers on lettuce and oat seedling growth are shown in Table 3 and 5, respectively. Sesquiterpenes with ketone (i.e., α-cyperone and cyperotundone) or hydroxyl (i.e., cyperol) groups were more inhibitory than the acetates and hydrocarbons. For example, α-cyperone at the 5 mmol level was nearly twice as inhibitory as β-selinene, cyperene, sugeonol acetate, or pachoulene acetate in both lettuce and oats. Based on our previous findings (Komai and Tang, 1989), approximately half of the sesquiterpenes in the H and M type *C. rotundus* are ketones and alcohols, while the O and K type contain only ca. 10% ketones and no alcohols. These data correspond to the observed differences in inhibitory activities.

C. rotundus has been considered as the most serious weed in cultivated land in tropical and subtropical regions (Holm, 1971). In recent years, increasing evidence has supported the role of allelopathy in weed–crop interactions (Putnam and Tang, 1986). It is likely that in *C. rotundus*, with its relatively high sesquiterpene content, allelopathy also contributes to the interference on crop plants. Based on our results, it may be theorized that O and K type *C. rotundus* would be allelopathically less damaging to crop productivity than the H and M type.

While additional laboratory and field experiments are necessary to verify this concept, it is true that, by definition, the chemotype within species of a donor plant shall determine the chemical impact on its environment, which would lead to different levels of allelopathic activity. A recent study (Siriwardana, 1986) in Hawaii showed that the yield of six crops of fresh bean pods were not significantly reduced by *C. rotundus* infestation ranging from 390 to 1100 shoots/m^2 at three weeks. These results differ from those of William and Warren (1975), who reported an average of 41% yield reduction over two bean crops with similar *C. rotundus* densities. Both studies utilized similar row and plant spacing. It is possible that among many other variables in comparing two separate sets of experiments, chemotype played a role in the discrepancies observed.

(Received June 21, 1990; accepted August 9, 1990)

Abstract—Three allelochemicals from rye or its breakdown products were evaluated for activity on garden cress (*Lepidum sativum* L.), barnyardgrass [*Echinochloa crus-galli* (L.) Beauv.], cucumber (*Cucumis sativus* L.), and snap bean (*Phaseolus vulgaris* L.). 2,4-Dihydroxy-1,4(2H)-benzoxazin-3-one (DIBOA), 2(3H)-benzoxazolinone (BOA), and 2,2′-oxo-1,1′-azobenzene (AZOB) were all applied singly at 50, 100, and 200 ppm and in two- and three-way combinations each at 50 and 100 ppm. AZOB at 100 and 200 ppm produced 38–49% more inhibition than DIBOA, while combinations of BOA/DIBOA, which contained AZOB at 100 ppm had 54–90% more inhibition when compared to DIBOA/BOA combinations. All combinations were slightly antagonistic to barnyardgrass, while several combinations caused a synergistic response to garden cress germination and growth. Cucumbers and snap beans exhibited both types of responses, depending on the allelochemical combination and application rate. The plant-produced benzoxazinones were more inhibitory to crops than weeds. Therefore, improved herbicidal selectivity would be expected if there were rapid transformation of the benzoxazinones to the microbially produced AZOB.

Key Words—Allelopathy, 2,4-dihydroxy-1,4(2H)-benzoxazine-3-one, DIBOA, 2(3H)-benzoxazolinone, BOA, 2,2′-oxo-1,1′-azobenzene, AZOB, synergism, antagonism.

INTRODUCTION

Rye (*Secale cereale* L.) is an annual cereal grain that has shown potential as a cover crop in a variety of cropping systems (Putnam and Defrank, 1983; Barnes and Putnam, 1986) because it has been found to reduce weed biomass, improve soil aggregation, reduce soil erosion, and enhance water penetration and retention (Blevins et al., 1971; Young, 1982). With the renewed interest in lowering energy inputs, reduced-tillage systems employing cover crops will undoubtedly be an important tool of the future. Maintenance of residues on the soil surface will be inherent to these reduced-tillage systems. Residues can interact with weeds or crops to potentially reduce the growth of the plants. This interference can arise from competition for essential plant growth requirements such as light, water, and nutrients (Knavel et al., 1977; Teasdale and Frank, 1983; Mascianica et al., 1986; Skarphol et al., 1987; Glenn and Welker, 1989) or from allelopathic chemicals released into the environment from decaying plant residues (Shilling et al., 1985; Barnes et al., 1987; Nair et al., 1990).

Although there have been numerous studies on toxicity of rye residues (Kimber, 1973; Chou and Patrick, 1976; Putnam and Defrank, 1983; Shilling et al., 1985; Barnes and Putnam, 1986; Barnes et al., 1987), none has offered a complete explanation of interference reported by these plant residues. There have been several attempts to isolate and identify the many compounds within rye showing biological activity. Virtanen et al. (1957) isolated a cyclic hydroxamic acid, 2(3H)-benzoxazoline (BOA), from 4-day-old rye seedlings and reported BOA as being responsible for the chemical resistance of rye to *Fusarium* infection. Tang et al. (1975) further quantified BOA present in rye and found eight times more BOA in the shoots than in the roots. Chou and Patrick (1976) identified nine compounds from decaying rye tissue that were inhibitory to lettuce seed germination. Zungica et al. (1983) evaluated rye for two hydroxamic acids, 2,4-dihydroxy-1,4(2H)-benzoxazin-3-one (DIBOA) and BOA, and found them commonly occurring in both cultivated and wild accessions. Shilling et al. (1985) isolated phenyllactic acid (PLA) and hydroxybutyric acid (HBA) from field-grown rye and found each allelochemical inhibited redroot pigweed (*Amaranthus retroflexus* L.), common lambsquarters (*Chenopodium album* L.), and common ragweed (*Ambrosia artemisiifolia* L.) growth at concentrations of 2 mM. Barnes et al. (1987) compared the activity of four rye compounds, PLA, HBA, DIBOA, and BOA, and reported DIBOA and BOA to be the most toxic to large crabgrass [*Digitaria sanguinalis* (L.) Scop.], barnyardgrass [*Echinochloa crus-galli* (L.) Beauv.], proso millet (*Panicum miliaceum* L.), redroot pigweed, tomato (*Lycopersicon esculentum* Mill.), and lettuce (*Lactuca sativa* L.) root growth at concentrations of 67–250 ppm.

Nair et al. (1990) and Chase et al. (unpublished results) isolated a microbially produced 2,2′-oxo-1,1′-azobenzone (AZOB) from soil enriched with

BOA and showed that DIBOA, BOA, and AZOB were inhibitory to barnyardgrass and garden cress (*Lepidum sativum* L.) at concentrations of 67–250 ppm. In these tests, AZOB was more biologically active than BOA and DIBOA.

Although there have been numerous compounds isolated and identified from rye tissue, it is difficult to predict the active concentration of any one compound at any one time as it occurs in nature. It is possible that they might occur either alone or in numerous combinations under various environmental and plant conditions. Since the hydroxamic acids, BOA and DIBOA, and their AZOB breakdown product exhibited the most activity, the objective of this study was to evaluate these three known rye allelochemicals singly and in combinations for their activity on various weeds, cucumbers and snap beans.

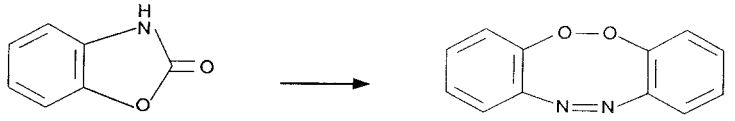
METHODS AND MATERIALS

Spray Reagents for TLC Detection. DIBOA (Figure 1) was detected on thin-layer plates with ferric chloride ($FeCl_3$) spray reactant consisting of 5% $FeCl_3$ in 95% ethanol, acidified with concentrated HCl. A spray reagent consisting of 1% ceric sulfate ($CeSO_4$) in concentrated H_2SO_4 was used to detect BOA (Figure 1).

Source of Allelochemicals. BOA was obtained from Aldrich Chemical company and AZOB was produced from BOA, using the procedure of Nair et al. (1990) (Scheme 1).

Extraction of DIBOA. Seedlings of rye (Wheeler, 11 days old, 2.2 kg) were homogenized in a Waring blender with distilled water (4.5 liters), and kept at room temperature (1 hr) to ensure enzymatic hydrolysis of the DIBOA glucoside to DIBOA. After filtering through cheesecloth, the filtrate was heated in a water bath until the temperature of the extract reached 70°C. It then was cooled immediately in an ice bath. Coagulated components were removed by vacuum filtration, using Whatman No. 1 filter paper. Filtrate was then lyophilized at 5°C and stored at −20°C until further separation.

Lyophilized rye extract (121.91 g) was stirred with HCl in MeOH (1.5 liters, pH 1.0) for 2 hr at room temperature. The mixture then was filtered through a sintered glass filter (fine, 4–5 Å) and the filtrate dried in vacuo. This crude residue was extracted with $CHCl_3$ (3 × 100 ml), and the organic extract



BOA AZOB

SCHEME 1. Transformation of benzoxazolinone to 2,2′-oxo-1,1′-azobenzene.

was evaporated to dryness. The oily residue (35.3 g) was redissolved in $CHCl_3$ and precipitated with hexane (500 ml) and filtered. This procedure was repeated twice and the combined $CHCl_3$–hexane extract was dried in vacuo (12.84 g). A TLC analysis of this crude product confirmed the presence of DIBOA.

Further purification of DIBOA from the above partially purified mixture was carried out by vacuum liquid chromatography. A slurry of column silica (40–60 mesh size, 260 g) in $CHCl_3$–MeOH (4 : 1) was packed under vacuum in a sintered glass filter (medium, 10–15 Å) and washed with $CHCl_3$–MeOH (4 : 1, 300 ml). The partially purified gum containing DIBOA (12.84 g) in $CHCl_3$–MeOH (4 : 1, 30 ml) was applied on the silica under vacuum and eluted with the same solvent system. Four fractions were collected in 250-ml portions and analyzed by TLC. Fractions 2 and 3, positive for DIBOA by $FeCl_3$ spray, were combined and evaporated to dryness (10.94 g). This was purified again by flash column chromatography (silica, $CHCl_3$–MeOH 4 : 1 v/v). The initial fraction (30 ml) was discarded and, upon TLC analysis, fractions 1–21 (each 5 ml) were found to be negative for DIBOA. Fractions 22–29 (each 10 ml), monitored by TLC with $FeCl_3$ spray, were found to contain the largest quantity of DIBOA. Removal of solvent at reduced pressure afforded a brown solid (2.43 g). Final purification of DIBOA was achieved by TLC (silica, $CHCl_3$–MeOH, 4 : 1) and the resulting product recrystallized from $CHCl_3$–MeOH mixtures, and gave pale yellow crystals of DIBOA (187 mg).

Bioassay. Activity of three known compounds associated with rye (DIBOA, BOA, and AZOB) were assayed on two weed indicators (garden cress and barnyardgrass) and two crops [cucumber (*Cucumus sativus* L.) and snap bean (*Phaseolus vulgarus* L.)]. Growth parameters recorded were seed germination and root and shoot lengths. All three compounds were applied alone at 50, 100, and 200 ppm and in two- and in three-way combinations, each applied at 50 and 100 ppm. The experimental design was a randomized complete block design with four replications.

Stock solutions (1 mg/ml methanol) of purified compounds were applied to filter paper (Whatman No. 1) that lined the Petri dishes. Pure methanol also was included as a control. After application of the compounds on the filter paper, the solvent was allowed to evaporate (2–3 hr) in the dark before seed placement. In the snap bean assays, the solvent was allowed to evaporate for an additional 6–8 hr prior to planting.

Weed seeds (15) were uniformly distributed on filter paper (4.25 cm) in Petri dishes (60 × 15 mm), after which distilled water (1.5 ml) was added. Garden cress and barnyardgrass seeds then were incubated for 72 and 96 hr, respectively. Flurry cucumber seeds (5) were uniformly distributed on filter paper (7 cm) in Petri dishes (100 × 15 mm), and then distilled water (2 ml) was added. Cucumbers then were incubated for 120 hr. Bush Blue Lake 47 snap bean seeds (4) were uniformly distributed on seed germination paper (5 ×

5 cm) in Magenta boxes (6 × 6 × 9 cm) after which distilled water (5 ml) was added. A cellulose sponge (3.0 × 3.8 × 6.2 cm) saturated with distilled water was suspended from the sides of the box before attaching the lids. Each container was individually sealed with parafilm (American Can Co.) and incubated for 216 hr.

Incubation of Bioassay. After placing the lids onto the containers, they were randomly placed on trays (36 × 57 cm) lined with damp brown paper toweling. Each tray held one to two blocks and was covered with a clear plastic bag before placement into the incubator at 26°C for the duration of the study.

Statistical Methods. Data obtained in bioassays were subjected to analyses of variance and means were compared with the least significant difference (LSD) test. Tables represent the means from duplicate experiments. Analyses for synergism or antagonism of combination treatments were conducted according to Colby's methods (1967).

RESULTS AND DISCUSSION

DIBOA Quantification. Since DIBOA was not available commercially, it was necessary to isolate it from field- or greenhouse-grown rye tissue. The modification of DIBOA extraction procedure gave a higher yield of DIBOA than previously reported (Nair et al., 1990). The major difference in the extraction step was the treatment of lyophilized extract with HCl in MeOH. Barnes and Putnam (1986) quantified hydroxamic acids by colorimetric methods and obtained a 27-fold increase of DIBOA in greenhouse-grown rye shoots over field grown. Our yields were lower than Barnes and Putnam (1987) but were fourfold higher than Nair et al. (1990). However, we did not process all the positive DIBOA-containing fractions. This DIBOA along with BOA and AZOB was used for evaluating allelopathic activity of these compounds under field and greenhouse conditions.

Relative Biological Activity of Allelochemicals. Of the three chemicals tested on barnyardgrass, AZOB was the most active, reducing both root and shoot growth at all three application rates (Table 1). Combinations of the compounds containing AZOB showed 41–67% more activity on roots and 20–33% more activity on shoots when compared to combinations of DIBOA/BOA at the same concentrations. The combinations showed slightly less activity when compared to expected values by Colby's methods. This would suggest that these compounds are antagonistic when they are applied together.

For garden cress, all parameters measured were inhibited by the application of AZOB (Tables 2 and 3). Germination was reduced by three- to fourfold by combinations containing AZOB/BOA each at 100 ppm. In addition, AZOB or BOA applied singly showed two- to fourfold more activity on both shoot and

root growth when compared to DIBOA. Shoot and root growth was severely inhibited with combinations of AZOB/BOA or AZOB alone at 100 ppm. In the above-mentioned combinations, the observed values were always less than the expected, suggesting synergism. The order of activity on garden cress was AZOB > BOA > DIBOA, which is in agreement with Nair et al. (1990).

[b] All combinations were each applied singly at the given rate.

For cucumbers, DIBOA was more inhibitory to both root and shoot growth than either BOA or AZOB when applied singly (Table 4). When applied singly at 50 ppm, none of the chemicals reduced root or shoot growth, but when concentrations were 100 ppm or greater, there were significant reductions in growth.

LSD (0.05)		17			32	

[a] ( ) = expected value calculated by $E = D^1 \times B^1/100$.
[b] All combinations were each applied singly at the given rate.

Again, DIBOA, BOA, and all combinations were more active with increasing concentrations. The DIBOA/BOA combinations were 14–44% more inhibitory than the combinations of BOA/AZOB and appeared to be synergistic, while the BOA/AZOB combinations appeared to have antagonistic effects. This suggested that the most toxic compounds to cucumbers were ones found in the rye herbage and not the microbially produced AZOB. If rapid conversion of these compounds did occur, one could expect improved cucumber crop safety in the presence of decomposing plant material.

In the snap bean assay, there was more variation, perhaps due to seed variability or more intricate experimental design. Overall, shoot growth appeared more sensitive than roots, with DIBOA and BOA showing a rate response with increasing concentrations (Table 5). For combinations with 50 ppm of each compound, only slight synergistic activity was seen, while at 100 ppm, antagonism was evident. Applications of BOA at 100 and 200 ppm and combinations of BOA/AZOB showed the greatest inhibition. Both large-seeded dicot crops were more affected by DIBOA/BOA and BOA/AZOB combinations. From previous work (Putnam and Defrank, 1983; Skarphol et al., 1987) both cucumber and snap beans have been shown to respond favorably to cover crop residues. A possible explanation is that the large-seeded crops are located too deeply to be influenced by the residues, or, alternately, the concentrations of these chemicals are too low to affect the emergence of the crops. The effect seen on small-seeded weeds such as cress and barnyardgrass could come from rapid degradation of the benzoxazinones from the injured plant material and the more active

microbially produced AZOB. Moreover, the smaller seeds are located closer to the soil surface where higher concentrations of these compounds might exist.

CONCLUSIONS

The benzoxazinones have been reported in cereal grains and corn plants (Virtanen et al., 1957). In addition, the recent isolation of the microbially produced AZOB may help to account for a portion of the 88% of inhibition by rye residues that Barnes and Putnam (1987) could not account for. These results show that both small-seeded species were strongly inhibited by AZOB, while garden cress was inhitited by BOA as well. These results agree with Barnes and Putnam (1987) and Nair et al. (1990), who reported BOA to be more active on dicot and small-seeded crop species. For monocots, there has been allelochemical activity reported with DIBOA. The finding that AZOB has herbicidal potential against several small-seeded species gives hope that microbially produced allelochemicals would be useful in weed control.

In general, when comparing the response of the different growth parameters, root and shoot inhibition were more sensitive indicators of allelopathic activity than germination inhibition. Only in the case of garden cress was germination a positive indicator of activity. Neither of the large-seeded crops nor barnyardgrass showed significant germination inhibition. This indicated that the

mode of action for barnyardgrass, cucumber, and snap bean was not on germination processes but rather on early plant development processes. This suggests the expected field response would be reduced plant growth rather than a reduction in number of plants.

Our results not only suggest that these compounds are selectively allelopathic, but indicate the relative quantities of these compounds are important in determining the expected outcome. Earlier bioassays with these compounds used only small-seeded species whereas ours compared larger-seeded crops. It appears that selectivity can be achieved based on seed size and seed placement. This same principle has allowed the selective use of synthetic herbicides for decades. However, the difficulty with allelochemicals is to predict or quantify what might be present at any particular time in the field.

COMPARISON OF FURANOCOUMARIN CONCENTRATIONS OF GREENHOUSE-GROWN *Ruta chalepensis* WITH OUTDOOR PLANTS LATER TRANSFERRED TO A GREENHOUSE

ALICJA M. ZOBEL

Department of Chemistry
Trent University
Peterborough, Ontario, Canada K9J 7B8

(Received February 26, 1990; accepted August 9, 1990)

Abstract—*Ruta chalepensis* contained concentrations of furanocoumarins 25–50% of those found in *R. graveolens* both in the whole leaf and on its surface. On the leaf surface of plants grown all year indoors in a greenhouse, they increased steadily between November 1 and December 14 on mature upper and lower leaves. New growth upper leaves on December 14 contained less than mature upper leaves. Plants transferred from outdoors to the greenhouse showed decreased concentrations after the first two weeks, followed by recovery both in the whole leaf and on the leaf surface. Proportions of xanthotoxin and bergapten to psoralen changed during the experiment. On the leaf surfaces and in the whole upper leaves of the indoor plants, the proportions were often similar, but in the transferred plants, in most cases, psoralen was less than bergapten or xanthotoxin in the upper leaves and markedly less in the lower leaves. Implications of these findings for possible effects of environmental changes on secondary plant metabolism are discussed.

Key Words—Furanocoumarins, *Ruta chalepensis*, photophytodermatitis, surface deposition, plant defense.

INTRODUCTION

Linear furanocoumarins, or psoralens, which are known to cause photophytodermatitis, are localized to some extent on the leaf surfaces of plants that elaborate them (Zobel and Brown, 1988b, 1989, 1990a,b). An outstanding example is *Ruta graveolens*, which has been noted since ancient times for inducing this dermatitis. We have found that, in extreme cases, over 55% of the total fur-

0098-0331/91/0100-0021$06.50/0

anocoumarins of the leaf, in micrograms per gram fresh weight, can be extracted from the surface (Zobel and Brown, 1989, 1990a).

Studies on *Heracleum lanatum* (Umbelliferae) have revealed significant changes during the growing season in the concentrations of the three predominant furanocoumarins in this species: psoralen, xanthotoxin, and bergapten, both on the leaf surface and in the whole leaves (Zobel and Brown, 1990b).

A hypothesis has been advanced that a function of these surface coumarins is to protect the plant against microbial attack, acting as a defense barrier (Zobel and Brown, 1989). Any such external barrier must be affected by changes in the plant's environment, as well as its developmental changes.

A number of workers have hypothesized about the role of these compounds in plants (Camm et al., 1976; Berenbaum, 1978; Berenbaum and Neal, 1985; Städler and Buser, 1984; Matern et al., 1988), and on their biological activity (Chakraborty et al., 1957; Murray et al., 1982; Towers, 1987; Nitao, 1988), especially under UV irradiation (Pathak and Fitzpatrick, 1959; Grekin and Epstein, 1981; Towers and Yamamoto, 1985; Towers, 1986). Some investigations have dealt with increased concentrations of furanocoumarins as a response to infection (Ashwood-Smith et al., 1985; Surico et al., 1987) and to other stresses (Beier and Oertli, 1983). Recently experiments have demonstrated changes in concentrations of furanocoumarins depending on the plant's developmental stage (Berenbaum and Zangerl, 1986) and on environmental and nutritional conditions (Zangerl and Berenbaum, 1987).

In order to ascertain to what extent such changes might occur in a plant in response to changes in its environment, I have examined *Ruta chalepensis*, comparing concentrations in plants grown outdoors that were subsequently transferred to a greenhouse with those of control plants grown in a greenhouse for the whole year.

METHODS AND MATERIALS

Four 2-year-old *R. chalepensis* subshrubs, each with about 20 long shoots each containing about 40 leaves, growing outdoors in the soil during the summer growing season (outdoor plants), were used. They were transferred to pots on October 1, 1988, before the autumn frosts, and allowed to remain outdoors for the rest of that month to let the plants recover from root damage. Four others grown throughout the year in a greenhouse (indoor plants) were used as controls. The first leaf samples for analysis were collected from both groups on October 1 as a control for how well the potted plants had recovered from transplanting, and the second at the beginning of the experiment on November 1 just before the outdoor plants were transferred to a greenhouse. The next three samples were collected at ca. two-week intervals (November 15 and 30, and

December 14). From each plant, four of the uppermost leaves of similar size, 2–4 cm long, were collected. These were not new growth, but small-sized, mature leaves. Separate samples of such leaves were collected for analysis from the indoor and outdoor plants, and, in each case, the lowest three undamaged green leaves were collected from the same plants for comparison purposes. In contrast to *R. graveolens*, there were no senescent yellowish leaves during the whole experiment.

The leaves of each sample were weighed and surface coumarins extracted by a previously described method (Zobel and Brown, 1988a, 1989). The furanocoumarins in the extracts were also purified and determined as described earlier (Thompson and Brown, 1984; Zobel and Brown, 1988a).

RESULTS

Transferring *R. chalepensis* plants to a greenhouse from outdoors resulted in changed concentrations of furanocoumarins both on the leaf surface and in the whole leaf, compared to the plants growing indoors throughout the year (Table 1).

The indoor plants exhibited physiological changes depending on the time of year and the photoperiod, without influence of other environmental condi-

tions such as wind and rain. The outdoor plants (brought into the greenhouse November 1), in contrast, were affected by the transfer indoors, in response to their new environment. All but the December 14 leaves were mature, differing only in size and location on the plant. On December 14, as the upper leaves of both groups of plants were then new growth, the experiment was terminated, because, as shown below, the results obtained suggested a different physiology from that of the mature leaves.

Table 1 compares the sum of the concentrations (Σ values) of psoralen, xanthotoxin, and bergapten (P + X + B). On November 1 the concentrations were similar to those of October 1 in the same group of plants, but the outdoor plants had higher concentrations in the whole leaf than the indoor plants, both in the upper leaves (difference 130 μg/g) and in the lower leaves (100 μg/g), and on the surface of the upper leaves (110 μg/g). On the lower leaves, the indoor group had over 40% more than the outdoor (difference of 130 μg/g). Upper leaves of both groups contained much more total furanocoumarins than the lower leaves, with a difference of ca. 400 μg/g, corresponding to more than half of the lower leaves' concentration.

The indoor plants showed a steady increase in surface concentrations of the furanocoumarins on the mature leaves. The total concentrations increased until November 15 in the upper leaves, and until November 30 in the lower, followed by a decrease.

The lower leaves of the indoor plants had a stable percentage of furanocoumarins on the surface (46–55%), whereas the outdoor plants began with a low percentage (23% of the total), increasing steadily to 50% at the conclusion. The surface concentrations in the lower leaves of the indoor plants paralleled those of the whole leaf, but the upper leaves did not always follow this pattern, i.e., the 30% increase in the whole leaf concentration on November 15 was unaccompanied by any increase in the surface concentration, which showed a marked increase only after two weeks.

Changes were observed after the plants had been transferred into the greenhouse. On November 1 the outdoor plants contained 10% more furanocoumarins in the whole upper leaves and 20% more on the surface than the indoor. The lower leaves contained much smaller concentrations than the upper, both in the whole leaf and on the surface, with the percentage on the surface little more than half that of the upper leaves (23% vs. 43%). On November 15, the upper leaves of the outdoor plants showed decreased concentrations in the whole leaves and on the surface. The lower leaves showed decreased concentration in the whole leaves, but it was unchanged on the surface. They recovered in the next two weeks and made up or even exceeded the difference; this recovery was especially visible on the surface. For mature leaves, the highest percentages on the surface were 54% and 50%.

Ratio of Psoralen to Xanthotoxin and Bergapten. Table 2 shows the pro-

portions of the three furanocoumarins in the whole leaf and on the leaf surface, with the value for psoralen taken as unity. Four distinct groups of ratios are evident: (1) the upper leaves of the indoor plants, with similar concentrations of the three furanocoumarins (except November 15); (2) their lower leaves, showing a drastic diminution of psoralen (7 to 25 times); (3) upper leaves of the outdoor plants, having bergapten and xanthotoxin concentrations 1.1–2.6 times that of psoralen (except November 15); and (4) lower leaves of the outdoor plants, with bergapten and xanthotoxin concentrations ca. 1.6–13.3 times those of the upper leaves.

DISCUSSION

These observations have demonstrated that, after transfer to the greenhouse, the plants responded by increasing furanocoumarin production and steadily increasing extrusion to the surface. As well, new growth after this recovery contained a higher percentage on the surface than new growth of the indoor plants (63% vs. 47%); this interesting phenomenon needs more investigation before conclusions can be drawn.

The findings of the present experiment, and unpublished data from this laboratory on *Ruta graveolens* showing similar trends in response, but with concentration values at least twice as high, suggest that there are two parallel

physiological processes influencing furanocoumarin concentrations in the whole leaf and on its surface. The first process, genetically dependent, governs the levels of these compounds and their proportions according to the period of the year and is typical of the species; the second is a physiological and biochemical response to changes in environmental conditions. Further experiments are needed to compare *R. chalepensis* and *R. graveolens* to other species with respect to these phenomena, because if, as seems probable, furanocoumarins play a defense role in plants, their levels in the whole leaf and especially on its surface should show changes with varying environmental conditions. Measurements taken over a complete vegetative period on leaves of *Heracleum lanatum* showed changes in concentrations on the surface and in the whole leaves depending on their developmental stage and on the time within the vegetation period (Zobel and Brown, 1990b). Investigations are now in progress with similar measurements for both *Ruta* species.

(Received June 19, 1990; accepted August 20, 1990)

Abstract—Cucumber seedlings growing in a 1 : 2 mixture of soil (Portsmouth B_1) and sand adjusted to pH 5.2 were treated every other day five times with 0, 0.0625, 0.125, 0.25, or 0.5 μmol/g soil of ferulic, caffeic, *p*-coumaric, *p*-hydroxybenzoic, protocatechuic, sinapic, syringic, or vanillic acids. Treatments began when seedlings were 8 days old. The effects on mean absolute rates of leaf expansion were used to estimate the relative potencies of these phenolic acids to ferulic acid. Based on the results of this experiment, ferulic, *p*-coumaric, *p*-hydroxybenzoic, and vanillic acids were chosen for further study. Materials and procedures were identical in the second study, but treatments consisted of mixtures of the four phenolic acids at concentration combinations designed to achieve 40% or 60% inhibition of absolute rates of leaf expansion. Using joint action analysis, a model describing the action of the phenolic acid mixtures was developed. A model involving only two factor terms was sufficient to describe the observed responses of cucumber leaf area to the phenolic acid mixtures. The action of *p*-hydroxybenzoic acid on absolute rates of leaf expansion was inhibited by the presence of the other three phenolic acids. No other antagonisms or synergisms existed among the four compounds.

Key Words—Allelopathy, phenolic acid mixtures, similar joint action analysis, mean absolute rates of leaf expansion, *Cucumis sativus*.

INTRODUCTION

Soils contain complex mixtures of phenolic acids (Whitehead, 1964; Guenzi and McCalla, 1966; Whitehead et al., 1981, 1983; Kuiters and Denneman, 1987; Kuiters et al., 1987). Many of these phenolic acids, either individually or in mixtures, have been shown to have allelopathic activity in numerous bioassays (see for example Rice, 1984; Einhellig, 1987).

Concentrations of phenolic acids in soils are determined primarily by the rate of input (i.e., leaf leachates, root exudates, or decomposition and leaching of plant debris), absorption and adsorption by seeds and roots, fixation by soil components, leaching, and microbial utilization (Skujins, 1967; Haider and Martin, 1975; Huang et al., 1977; Dalton et al., 1983; Rice, 1984; Shann and Blum, 1987). That the rates of these processes are differentially affected by the environment suggests that the qualitative and quantitative content of phenolic acids in soil solutions is constantly changing. Understanding how various mixtures of phenolic acids affect plant growth, thus, becomes essential to the identification of the role of allelopathic interactions in managed and natural communities.

Predicting how phenolic acid mixtures of varying composition (i.e., numbers and concentrations) affect seed germination and plant growth in soil, however, is not simple, since effects of individual phenolic acids in mixtures may be synergistic, additive, or antagonistic (Rasmussen and Einhellig, 1977; Blum et al., 1984, 1985, 1989; Einhellig, 1987). Recently, the authors characterized the action of phenolic acid pairs on plant growth by use of joint action analysis (Gerig et al., 1989; Blum et al., 1989). In the current work, we extend this analysis to mixtures of four phenolic acids.

METHODS AND MATERIALS

General Aspects. Cucumber seeds (*Cucumis sativus* cv. Early Green Cluster; Wyatt Quarles Seed Company, Raleigh, North Carolina) were germinated in the dark at 28–30°C in trays containing sterile vermiculite and Hoagland's solution (Hoagland and Arnon, 1950). After 24 hr, the trays containing the seedlings were transferred to a light bank and exposed in a 12-hr light period (140 μEisteins/m^2/sec), followed by a 12-hr dark period. Seedlings were planted in 155-ml cups (one per cup) containing 150 g of a soil–sand mixture (1 : 2 by weight). Portsmouth B_1-horizon soil material (fine loamy, mixed, thermic Typic Umbraquaalts) was obtained from the NCSU agricultural research farm in Plymouth, North Carolina, sieved, air-dried, and adjusted to pH 5.2 with calcium hydroxide. River sand was rinsed with deionized water and then air-dried. The cups, which did not have drainage holes, were inserted through holes in a plywood sheet that protected everything below the soil surface from direct irra-

diance of the light banks (Blum and Dalton, 1985). Seedlings were grown at room temperature (21–30°C) with a 12-hr light period. Seedlings were supplied with 7 ml double-strength Hoagland's solution every other day. Sufficient distilled water was added daily to bring the weight of a given cup (160 g for cup and soil) and its seedling to approximately 190 g. Cup plus seedling weight was maintained above 170 g. For further details of the cup system, see Blum et al. (1987). Length and width measurements were taken for each leaf (excluding cotyledons) on day 8, first day of phenolic acid treatments, and day 18, the last day of the experiment.

Phenolic Acid Treatments. In the first study, seedlings were treated every other day (maximum of five treatments) with 0, 0.0625, 0.125, 0.25 or 0.5 μmol/g soil of ferulic (FER), caffeic (CAF), *p*-coumaric (PCO), *p*-hydroxybenzoic (POH), protocatechuic (PRO), sinapic (SIN), syringic (SYR), or vanillic (VAN) acid. Phenolic acid treatments were alternated with nutrient solution application. The pH of each solution was adjusted to pH 5.2 with NaOH.

Seedlings in the second study were treated every other day (five treatments, maximum) with all possible combinations of FER, PCO, POH or VAN. Concentration levels for individual phenolic acids and each phenolic acid in the two-, three-, or four-way mixtures were determined in the first study. The concentrations of individual phenolic acids and the phenolic acid mixtures were adjusted so that each provided approximately 40% or 60% inhibition. Concentrations ranged from 0.05 to 0.37 μmol/g for FER, 0.06–0.41 for PCO, 0.17–0.72 for POH, and 0.04–0.35 for VAN.

Experimental Design. The experimental designs for the seedling bioassays were as follows. In study 1, eight individual phenolic acids were each tested at five concentrations. In study 2, 31 combinations of phenolic acids were tested. In both studies, all treatments were replicated three times in complete blocks, with a complete set of treatments being randomly arranged under each of three light banks.

Data Analyses. Leaf areas were determined from length and width measurements of leaves and the following equation:

$$\text{Leaf area} = -1.457 + 0.00769LW$$

($P = 0.0001$, $R^2 = 0.98$, $N = 121$), where leaf area is in cm^2 and length (L) and width (W) values are in mm (Blum and Dalton, 1985). Mean absolute rates of leaf expansion (AGR) were calculated for each seedling by the equation (Radford, 1967):

$$\text{AGR} = \text{leaf area of seedling on day 18} - \text{leaf area of seedling on day 8}$$

Data were analyzed by nonlinear regression (Gallant, 1975) and joint action analysis (Gerig et al., 1989).

RESULTS AND DISCUSSION

Study 1: Effects of Individual Phenolic Acids. Data from the first study were analyzed to determine the potencies (on an equimolar basis) with respect to growth inhibition on cucumber seedlings of each of eight phenolic acids. FER was found to be the most potent and was used as the reference compound. The data were analyzed through use of a model closely related to the joint action model which predicted AGR by the function:

$$f(Z; \beta) = \begin{cases} \beta_1/(1 + \exp\{\beta_3[\ln(Z) - \beta_2]\}), & Z > 0 \\ \beta_1, & Z = 0 \end{cases} \quad (1)$$

where β is the vector of unknown parameters, Z, the effective concentration of the mixture, is defined by

$$Z = \text{cFER} + \beta_4\text{cCAF} + \beta_5\text{cPCO} + \beta_6\text{cPOH} + \beta_7\text{cPRO} + \beta_8\text{cSIN} + \beta_9\text{cSYR} + \beta_{10}\text{cVAN}$$

and where, for convenience, cFER, cCAF, $\cdots$, cVAN denote the concentration (μmol/g) of FER, CAF, $\cdots$, VAN acids in the mixture. In study 1, only one compound was present in a treatment. For that treatment, the other compounds had a concentration of zero.

The parameter β_1 measures the response under control conditions [i.e., $f(0; \beta) = \beta_1$]; β_2 is the value of ln (Z) required to achieve 50% inhibition, and β_3 controls the rate at which the curve descends as a function of Z.

The estimates of the parameters in the model, including β_4, β_5, $\cdots$, β_{10}, the potencies of each compound relative to FER, are shown in Table 1. Potencies are ordered from largest to smallest, and compounds that appear together in a grouping did not differ significantly at the 0.05 level of significance.

The compounds included in study 2 were selected from the eight used in the first. Compounds FER, PCO, VAN, and POH were chosen to include a range of potencies and phenolic acid types (i.e., corresponding benzoic and cinnamic acid derivatives). SIN was excluded because it reacted with the soil, turning it red.

To select concentrations for the constituents of each of the mixtures in study 2, combinations of the compounds FER, PCO, POH, and VAN were chosen so each would contribute the same amount to the effective concentration. Thus, from Table 1 we see, for combinations of PCO and POH (when cFER = cVAN = 0), that the effective concentration was:

$$Z = 0.67\text{cPCO} + 0.35\text{cPOH}$$

TABLE 1. PARAMETER ESTIMATES INCLUDING POTENCIES OF PHENOLIC ACIDS RELATIVE TO FERULIC ACID

Parameter	Estimated value	
β_1: Average of three control values (cm^2/11 days)	60.32	
β_2: Log(Z) for 50% inhibition	−1.089	
β_3: Rate parameter	1.108	
Phenolic acid	Relative potency	Compound groupings[a]
FER - ferulic acid - 4 hydroxy-3-methoxycinnamic	1.00	a
β_8: SIN - sinapic acid - 3,5 dimethoxy-4-hydroxycinnamic	0.70	a b
β_5: PCO - p-coumaric acid - p-hydroxycinnamic	0.67	b
β_{10}: VAN - vanillic acid - 4 hydroxy-3-methoxybenzoic	0.67	b
β_9: SYR - syringic acid - 3,5 dimethoxy-4-hydroxybenzoic	0.59	b c
β_4: CAF - caffeic acid - 3,4 dihydroxycinnamic	0.38	c d
β_6: POH - p-hydroxybenzoic acid - p-hydroxybenzoic	0.35	d
β_7: PRO - protocatechuic acid - 3,4 dihydroxybenzoic	0.13	e

[a] Potencies of compounds followed by the same letter do not differ at the 0.05 level of significance.

To obtain the approximate concentrations required to achieve 40% inhibition, we solved the equation:

$$f(Z; \hat{\beta}) = \hat{\beta}_1(1 - 0.4)$$

for Z, where $f(Z; \beta)$ is defined in (1) and is evaluated at the estimated parameter values, $\hat{\beta}$, given in Table 1. Thus, $Z = 0.485$ and the corresponding concentrations:

$$\text{cPCO} = (0.485/2)/0.67 = 0.36\ \mu\text{mol/g}$$

$$\text{cPOH} = (0.485/2)/0.35 = 0.69\ \mu\text{mol/g}$$

As expected, the realized inhibition rates for the mixtures differed from those predicted from study 1 since the model for the first ignored potential synergistic or antagonistic effects. Moreover, to increase ease of application, the actual concentrations used in study 2 differed slightly from those chosen by this process.

Study 2: Effects of Mixtures of Phenolic Acids. Joint action analysis was applied to the entire data set, allowing treatment combinations involving different concentrations of up to four phenolic acids. Table 2 lists AGR means and standard deviations by treatment group. The experimental design utilized a sequence of four nested models. The first, and most encompassing, included

[a] FER = ferulic acid, PCO = *p*-coumaric acid, POH = *p*-hydroxybenzoic acid, VAN = vanillic acid; concentrations in μmol/g soil; AGR = mean absolute rate leaf expansion, cm^2/11 days.

all possible terms, including those with one, two, three, and four factors, where, for example, each (of six) two-factor term involved the concentrations of a pair of compounds. The second and third models included terms with up to three and two factors, respectively. The fourth model, which allowed for no antagonism or synergism and which described similar joint action (Gerig et al., 1989), contained only single-factor terms. Based on the analysis of the data, the model allowing for up to two-factor terms was chosen.

This chosen two-factor model for describing the joint action of four compounds is a generalization of the two-factor, joint action analysis model (Gerig et al., 1989). The function $f(Z; \beta)$, as specified in (1), gives the AGR expected when seedlings have been treated with a given mixture, where Z is the effective concentration of the mixture. If cFER, cPCO, cPOH, and cVAN are the concentration in μmol/g of FER, PCO, POH, and VAN acids, respectively, then Z for the mixture is defined as

$$Z = \text{cFER} + \beta_4\text{cPCO} + \beta_5\text{cPOH} + \beta_6\text{cVAN} + 2\beta_7(\beta_4\text{cFERcPCO})^{1/2} + 2\beta_8(\beta_5\text{cFERcPOH})^{1/2} + 2\beta_9(\beta_6\text{cFERcVAN})^{1/2} + 2\beta_{10}(\beta_4\beta_5\text{cPCOcPOH})^{1/2} + 2\beta_{11}(\beta_4\beta_6\text{cPCOcVAN})^{1/2} + 2\beta_{12}(\beta_5\beta_6\text{cPOHcVAN})^{1/2}$$

Parameters β_4, β_5, and β_6 are potencies for compounds PCO, POH, and VAN relative to that of compound FER. Parameters β_7, β_8, $\cdots$, β_{12} are the associated (pairwise) coefficients of synergy. When a coefficient of synergy is positive (negative), the effect of the corresponding pair of phenolic acids is greater (smaller) than expected under the similar joint action model.

The data were used to fit the parameters by nonlinear regression using the SAS procedure PROC NLIN (SAS Institute Inc., 1988). A summary of the results is given in Table 3. Table 3 is organized with the most encompassing (four-term) model represented at the top, followed by successive simplifications of the model. As would be expected, models that included more terms had smaller error sums of squares, and as higher order terms were removed from the model, the sums of squares increased. F tests compared the model associated with a given row with that associated with the row below. The following demonstrates the calculation of the test statistic for comparing the model that includes up to four-factor terms with that which includes up to three-factor terms:

$$F = [(2603.2 - 2499.2)/(19 - 18)]/[2499.2/77] = 3.20$$

From the P value of 0.078, we see that the model with terms up to four factors does not fit the data significantly better than that with terms up to three factors, nor does the model with terms up to three factors fit the data significantly better ($P = 0.259$) than that with terms up to two factors. However, there is a significant ($P = 0.001$) deterioration for the fit in the model with only single-factor

TABLE 3. SUMMARY RESULTS FOR JOINT ACTION ANALYSIS

Terms included in the model, up to	Degrees of freedom		Error sums of squares	Tests that deleted terms are zero:		
	Model	Error		F	df	P value

One factor (SJA)	8	88	3628.3			

terms as compared to that with up to two-factor terms. The decision to adopt the two-factor model was based on this analysis.

The detailed analysis of the data using the two-factor model is presented in Table 4. From the table we see that the dose (in μmol/g) required to achieve 50% inhibition is 0.40, 0.50, 0.65, and 0.50 for FER, PCO, POH, and VAN, respectively. These reflect the differing potencies of the compounds, FER being the most potent. There is an interesting and suggestive pattern for the coefficients of synergy values. Significant antagonism is demonstrated between POH and FER, between POH and PCO, and, marginally, between POH and VAN. Two hypotheses concerning the joint action of the compounds are consistent with this pattern: (A) that POH inhibits the uptake of FER, PCO, and VAN, or (B) that each of FER, PCO, and VAN inhibit the uptake the POH. The following alternate definition of effective concentration models the first hypothesis (Model A):

$$Z = Z_1 \exp(-\beta_7\beta_5 \text{cPOH}) + \beta_5 \text{cPOH}$$

where Z_1 = cFER + β_4cPCO + β_6cVAN. When β_7 is positive and cPOH increases, the multiplicative factor, exp $(-\beta_7\beta_5$cPOH), will damp the magnitude of the contribution of FER, PCO, and VAN to the effective concentration. For this reason, β_7 is referred to as a damping parameter.

The following alternate definition of effective concentration models the second hypothesis (model B):

$$Z = Z_1 + \beta_5 \text{cPOH} \exp(-\beta_7 Z_1)$$

TABLE 4. PARAMETER ESTIMATES FOR TWO-FACTOR MODEL

Parameter	Estimated value		Compounds FER	PCO	POH	VAN
β_1: Average of three control values (cm^2/11 days)	53.57					
β_2: Log(Z) for 50% inhibition μmol/g	−0.925		0.40	0.50	0.65	0.50
β_3: Rate parameter	1.515[a]					
Potencies relative to FER			1.00	0.79	0.61[a]	0.79
Coefficients of synergy			FER	PCO	POH	VAN
		FER		0.06	−0.20[a]	−0.09
		PCO			−0.32[a]	−0.01
		POH				−0.19

[a] Significant at the 0.05 level.

where Z_1 = cFER + β_4cPCO + β_6cVAN. When β_7 is positive and as Z_1 increases, the multiplicative factor, exp $(-\beta_7 Z_1)$, will damp the magnitude of the contribution of POH to the effective concentration.

Using nonlinear regression, these models were fit yielding the analyses in Tables 5 and 6. Table 7 summarizes and compares the analyses for two- and one-factor models along with models A and B. It can be seen in Tables 5 and 6 that in each case the damping parameter, β_7, is significantly greater than zero and that the estimates of other parameters are similar in value to those for the two factor model as listed in Table 4. Table 7 shows that the data fit models A and B about as well as they fit the two-factor model. It should be noted that the two-factor model and models A and B are not nested, so the F tests are only approximate. Thus, on the basis of this analysis there is no way to choose between the models A and B.

CONCLUSIONS

Based on similar ring substitutions, the cinnamic and benzoic acids can be paired as follows: CAF and PRO, FER and VAN, PCO and POH, and SIN and SYR, respectively. Although it was not possible to identify the roles, if any, of the various substitutions on the benzene ring, the data clearly show that the cinnamic acid derivatives were more inhibitory to cucumber seedlings than their corresponding benzoic acid derivatives. This is identical to what has been observed for cucumber seedlings growing in nutrient culture (Blum et al., 1985). Whether this difference in inhibition is due to differences in toxicity of the compounds, differences in uptake, or differences in the ability of cucumber seedlings to detoxify these types of compounds is not known. Shann and Blum (1987), however, noted that FER uptake by cucumber seedlings was 50–75% higher than that of POH in nutrient culture.

The joint action of the four chosen phenolic acids on the absolute rates of leaf expansion of cucumber seedlings was surprisingly easy to characterize. Their action apparently did not depend on complicated interactions involving three or four compounds. Characterization of the interactions of all possible two-compound combinations was sufficient. Significant antagonistic effects were noted only for POH and FER, POH and POC, and, marginally, for POH and VAN. Shann and Blum (1987) noted, using ^{14}C-labeled FER and POH, that the uptake of FER by cucumber seedlings was unaffected by the presence of POH, but that the uptake of POH was reduced 30% in the presence of FER. This, in combination with our modeling efforts here, suggests that the uptake of POH by cucumber seedlings may be affected by other phenolic acids and that model B describes the joint action of the compounds.

That individual components in a mixture are antagonistic in their action does not, however, negate that mixtures may have a greater impact on growth unless, of course, the compounds are highly antagonistic. The effects of all combinations (two- and thee-way) that did not include POH were additive.

Clearly, the demonstrated joint action of phenolic acids on cucumber seedlings growth in the Portsmouth B_1 soil system suggests that concentrations of individual phenolic acids in a mixture required for a given growth inhibition decline as the number of phenolic acids in mixture increase. In this laboratory study, using only four phenolic acids (in nature mixtures are much more complex), 10, 10, 24, and 7 μg/g soil of FER, PCO, POH, and VAN, respectively, were required to inhibit growth of cucumber seedlings 15%. Such concentrations of phenolic acids, depending on extraction procedures, have been found in both forest and agricultural soils (Guenzi and McCalla, 1966; Shindo et al., 1978; Katase, 1981; Whitehead et al., 1982; Kuiters et al., 1987).

MECHANISMS OF RESISTANCE IN WILD RICE *Oryza brachyantha* TO RICE LEAFFOLDER *Cnaphalocrocis medinalis* (GUENÉE) (LEPIDOPTERA: PYRALIDAE)

R. RAMACHANDRAN[1,2,*] and Z.R. KHAN[1]

International Rice Research Institute (IRRI)
P.O. Box 933
Manila, Philippines

(Received June 6, 1990; accepted August 8, 1990)

Abstract—A wild rice, *Oryza brachyantha*, was rated as highly resistant to rice leaffolder, *Cnaphalocrocis medinalis* (Guenée), while its F_1 hybrid from a cross with a high-yielding, leaffolder-susceptible rice, IR31917-45-3-2, was rated resistant in a standard screening test. In comparison with IR31917-45-3-2, *O. brachyantha* and the F_1 hybrid were unsuitable for oviposition, survival, and growth of *C. medinalis*. However, growth and survival of larvae in artificial diets containing lyophilized leaf powder of IR31917-45-3-2 and *O. brachyantha* were comparable. Studies on the feeding and settling preference of the larval stages suggested that the mechanism of resistance of *O. brachyantha* is that of antixenosis type. Olfactometer tests with first-instar larvae and electroantennogram responses of adults indicated a lack or low levels of volatile attractants in *O. brachyantha* and the F_1 hybrid in comparison with IR31917-45-3-2. Bioassays of sequential solvent extracts of these plants indicated that larval preference for IR31917-45-3-2 and nonpreference for *O. brachyantha* and the F_1 hybrid were due partly to chemical factors present in hexane and methylene chloride extractables. Closer arrangement of silica cells in the epidermal layer of *O. brachyantha* and a higher mandibular wear in larvae reared on *O. brachyantha* suggested that physical resistance due to silica may be an additional cause of resistance. It was hypothesized that the high levels of resistance observed in *O. brachyantha* may be due to an additive or synergistic action of the absence of attractants or feeding stimulants, the presence of deterrents, and the physical resistance offered by silica. The significance of these results to a successful wide hybridization

program aimed at transferring resistance factors from wild rice to cultivated rice is discussed.

Key Words—Wild rice, *Oryza brachyantha*, rice, *Oryza sativa*, host plant resistance, antixenosis, attractants, deterrents, silica, rice leaffolder, *Cnaphalocrocis medinalis*, Lepidoptera Pyralidae.

INTRODUCTION

The rice leaffolder *Cnaphalocrocis medinalis* (Guenée) (Lepidoptera: Pyralidae) has emerged as a major pest of rice in tropical and subtropical Asia (Heinrichs et al., 1985a). The insect has increased in importance both in upland and lowland ricefields, particularly in areas where modern varieties are grown extensively (Mohandas, 1975; Litsinger et al., 1987). Several outbreaks of the pest have been reported in Bangladesh, China, Fiji, India, Japan, Korea, Malaysia, Nepal, Philippines, Sri Lanka, and Vietnam (Khan et al., 1988). Breeding for leaffolder resistance in rice is considered a practical and safe means of controlling this pest in Asia (Heinrichs et al., 1985a). However, the degree of resistance observed in cultivated rice is only of a moderate level.

Wild relatives of cultivated crop plants often possess disease and insect resistance. High levels of insect resistance have been recorded in wild relatives of tobacco (Heusing and Jones, 1988), potato (Boiteau and Singh, 1988), dry bean (Cardona et al., 1989), and rice (Heinrichs et al., 1985a,b). Several wild relatives of *Oryza sativa* also were found to be resistant to rice leaffolders (Heinrichs et al., 1985a; Khan et al., 1989), of which several accessions of *Oryza brachyantha* were identified as highly resistant (Heinrichs et al., 1985a; Medina and Tyron, 1986). Since *O. brachyantha* and *O. sativa* are of different genomes, conventional techniques cannot be adopted for breeding purposes. However, recent developments in breeding techniques (Brar and Khush, 1986) permit such hybridization and, at the International Rice Research Institute (IRRI), there is an active program aimed at introducing useful genes for insect and disease resistance through wide hybridization.

Resistance of crop plants to leaf-feeding insects has been correlated with physical factors (Coley, 1983; Feeny, 1970; Webster, 1975); the presence of feeding deterrents (Otieno et al., 1985; Reynolds et al., 1985) metabolic inhibitors (Smith, 1985), toxic chemicals (Lin et al., 1987), and volatile repellents (Khan et al., 1987; Liu et al., 1988); or the absence of kairomones (Rembold and Tober, 1985). Understanding the bases of resistance and the biological activity of allelochemicals involved can facilitate breeding programs aimed at transferring resistant factors to cultivated crops (Davis et al., 1989; Rembold and Tober, 1985). Such knowledge also will ensure that resistant varieties do not adversely affect other biological control agents regulating the pests (Kauff-

man and Kennedy, 1989). The present study was undertaken to understand the mechanisms and causes of leaffolder resistance in *O. brachyantha* (accession no. 100115) and an F_1 hybrid obtained by crossing *O. brachyantha* with a high-yielding rice parent, IR31917-45-3-2, using the embryo rescue technique (Jena and Khush, 1984).

METHODS AND MATERIALS

Plants and Insects. Thirty- to 40-day-old plants of *O. brachyantha* (IRRI accession no. 100115) and a high-yielding rice leaffolder-susceptible breeding line of *O. sativa*, IR31917-45-3-2, grown in an insect-proof screenhouse, were used in the study. An F_1 hybrid of *O. brachyantha* and IR31917-45-3-2 was propagated as clones from three plants. Forty-day-old IR36 and TKM6 plants were used as the standard susceptible and resistant checks, respectively, in some of the experiments. The rice leaffolder *C. medinalis* was reared on IR36 plants in a greenhouse following the rearing method developed at IRRI (Waldbauer and Marciano, 1979).

Evaluation of Resistance. To confirm their resistance, *O. brachyantha*, IR31917-45-3-2, and their F_1 hybrid, along with IR36 and TKM6 plants, were tested against *C. medinalis* following the procedure described by Khan et al. (1989). Forty-day-old test plants were infested at the rate of two first-instar larvae per tiller. The larvae were enclosed by Mylar cages (22 cm diam. and 60 cm high). Fifteen days after infestation, the cages were removed, and the extent of damage of each leaf was determined by the standard evaluation system (IRRI, 1988). Damage ratings were computed using the number of leaves in each damage grade, and damage ratings were computed. All entries were replicated six times.

Sequential Solvent Extraction of Plants. Lyophilized leaves of IR31917-45-3-2, *O. brachyantha*, and the F_1 hybrid were ground in a UDY mill with a 100-mesh screen. One hundred grams of powder from each test plant was extracted in series twice with 200 ml each of *n*-hexane, methylene chloride, methanol, and water at room temperature for 24 hr. Organic solvents in each extract were evaporated under reduced pressure and water extractables were lyophilized to dryness. All extractables were weighed and redissolved in their respective solvents at desired concentrations for bioassays.

Orientation of First-Instar Larvae. The orientational response of first-instar *C. medinalis* larvae to crushed leaves of *O. brachyantha*, IR31917-45-3-2, and the F_1 hybrid was studied in an olfactometer. The olfactometer consisted of a glass tube (1 cm diam. and 30 cm long) with a median hole (0.3 cm diam.). Two plungers (glass tubes of 0.7 cm diam. and 10 cm long) one holding the test material (0.5 g of crushed leaf or a 5 × 2.5-cm filter paper treated with

extracts of test plant) and the other holding a rolled paper towel of equal dimension (for tests with leaf) or a filter paper treated with solvent (for tests with extracts) were slid into either end of the tube and placed such that their ends were 3 cm away from the median hole. The whole arrangement rested on a Perspex box (30 × 30 × 5 cm) filled with water. The top of the Perspex box was covered with a filter paper of equal dimension. The Perspex box was fitted onto a lower box holding a red 25-W electric bulb. The experiment was conducted in a dark room with the red light from the bottom. The water in the Perspex box prevented the warming up of the surface of the box from the heat generated by the bulb below. The filter paper on the surface of the box ensured further diffusion of the red light.

Ten newly emerged first-instar larvae of *C. medinalis* were released into the tube with a camel's hair brush. Air was pushed through the plungers at the rate of 1 ml/min with a peristaltic pump (LKB Bromma 12000 Variaperpex). After 3 min of release, the distribution of the larvae on either side of the center was recorded. To facilitate the quantification of the distribution of the larvae, 0.5 cm on either side of the release hole was designated as the starting point. Larvae in this section were considered as not having oriented and were excluded from the analysis. The percentage of larvae on the side of the stimulus (crushed leaf or extract-treated filter paper) and on the control side (rolled paper towel or solvent-treated filter paper) were recorded. The experiment was replicated 10 times and treatments were randomized within each replication. All the replications used a new tube with the position of the control and stimulus plungers interchanged.

Orientation responses of first-instar larvae to 2.5 μl of 500, 1000, 2500, and 5000 ppm of hexane, and methylene chloride extractables of the test plants were studied. Methanol and water extractables were not used, as preliminary bioassays indicated the absence of any activity. After application of the extract to the filter paper, an evaporation time of 1 min was allowed before they were inserted into the arms of the olfactometer. No air was pushed through the plungers in experiments with plant extracts.

Settling Preference of First- and Third-Instar Larvae. First- and third-instar larvae of *C. medinalis* were provided a choice of leafcuts of two test plants. For first-instar larvae, one leafcut (3 cm long) of each of the two test plants was placed equidistant opposite the other in petri dishes lined with moist filter paper, with the adaxial surface up. Cut ends of the leaves were wrapped with moist cotton. Ten newly emerged larvae were released in the center of the Petri dish. The Petri dishes were covered with perforated aluminum foil and kept in darkness. After 5 hr, the number of larvae settled on leafcuts of each test plant was counted.

For third-instar larvae, 6-cm-long leafcuts from 40-day-old plants were presented for 6 hr to four larvae starved but water-satiated for 3 hr. Four leafcuts of two test plants were arranged alternately equidistant on a circle in 15-cm-diam. Petri dish arena, whose lid was lined with 12.5-cm-diam. wet filter paper disk. Larvae were released in each Petri dish, and after 5 hr the number of larvae that settled on the leafcuts of the test plants were counted. The area eaten on each leafcut also was measured. Experiments with the first and third instars were replicated 10 and six times, respectively.

Bioassays of the sequential solvent extracts consisted of leafcuts of IR36 plants treated with either hexane, methylene chloride, methanol, or water extractables (10 μl on a 3-cm leafcut for first instars or 20 μl on a 6-cm leafcut for third instar) and were presented with their respective solvent-treated control leafcuts to 10 first-instar larvae or four third-instar larvae as described above. Experiments with the first-instar larvae were conducted at 312, 625, 1250, 2500, and 5000 ppm of each extractable. For the third instars, hexane and methylene chloride extractables were tested at 500, 1000, 2500, and 5000 ppm and methanol and water extractables were tested at 2500 and 5000 ppm only. The number of first-instar larvae settled on the treated and control leafcuts 5 hr after infestation were counted. The difference in the percentage of larvae that settled on the treated and the control leafcuts were used as an index of settling preference of the first-instar larvae. The leaf area fed by the third-instar larvae on treated and control leafcuts was measured after 24 hr. The difference in the area fed between control and treated leaves at each extract concentration was used as an index of feeding preference of the third instars.

Dispersal of First-Instar Larvae. A 6-cm leafcut of *O. brachyantha*, IR31917-45-3-2, F_1 hybrid, and the resistant check TKM6 were placed individually inside a Petri dish (9 cm diam.) lined with a moist filter paper. Ten first-instar *C. medinalis* larvae were released on each leafcut. The Petri dishes were arranged in a randomized block design consisting of 10 replicates in the laboratory. At 10-min intervals, the number of larvae remaining on the leafcut was counted for 1 hr. Subsequently, similar observations were taken at hourly intervals up to 5 hr.

Solvent extracts were bioassayed using IR36 leafcuts treated with 20 μl (10 μl on the adaxial and abaxial surface of the leafcut) of 1000, 2500, and 5000 ppm of hexane and methylene chloride extact. Observations on the number of larvae that settled on the leafcuts were taken 1 and 5 hr after infestation.

Feeding and Growth on Excised Leaves. To determine the leaf area consumed and percent increase in body weight, *C. medinalis* larvae starved for 3 hr but water-satiated were weighed individually on a microbalance (Mettler, ME30) and then enclosed singly in a Petri dish (9 cm diam.) with two leafcuts

(6 cm long) of the test plants. After 24 hr, larvae were starved but water-satiated for 4 hr so that all the green matter was excreted out of the gut. Individual larval weights were recorded and the percent weight increase in 24 hr was calculated for each test plant. The leaf area consumed by an individual larva was recorded according to Khan et al., (1989). The experiment was replicated 10 times.

The antifeedant activity of sequential solvent extracts was determined by enclosing a single third-instar larva with two IR36 leafcuts (6 cm long) treated with 20 μl of 2500 or 5000 ppm of extractables for 24 hr. The experiment was replicated 10 times. The leaf area scraped by the larvae was measured at the end of the experiment.

Survival and Growth on Potted Plants and Artificial Diets. Potted plants of *O. brachyantha*, IR31917-45-3-2, F_1 hybrid, IR36 (susceptible check), and TKM6 (resistant check) covered with Mylar cages (60 cm high and 22 cm diam.) were arranged in a randomized complete block design and infested with first-instar larvae in batches of 20. Each pot had five plants consisting of 17–20 tillers. Each treatment had six replications. The number of larvae surviving was counted 15 days after infestation. Subsequently, the plants were checked every day for pupation. A growth index was calculated as the ratio of the percentage of larvae developing into pupae to the mean growth period in days. The higher the growth index, the more suitable the plant was for *C. medinalis* growth. One day after pupation, the pupae were sexed and weighed on a microbalance (Mettler, ME30).

To study the growth responses of larvae on artificial diet containing test plant material, intact leaves of IR31917-45-3-2 and *O. brachyantha* were lyophilized and ground in a UDY mill with a 100-mesh screen. The leafpowder was incorporated in the leaffolder artificial diet developed at IRRI (Khan, 1987) at a ratio of 90% diet and 10% leaf powder. No leaf powder was added to one set of diet (control). Ten grams of treated or control diet were placed in each plastic cup and covered with a snug-fitting lid. Five first-instar larvae were released into each cup, and the cups were kept inverted at 28°C and 60 $\pm$ 5% relative humidity. Fifty cups were maintained for each treatment and the control. Five days after infestation, the percent mortality in each cup was recorded and the density of larvae was reduced to two per cup. Fifteen days after infestation, 20 randomly selected larvae from each treatment were weighed individually. The remaining larvae were allowed to pupate, and their larval duration and pupal weights were recorded.

Oviposition. To determine the ovipositional preference of mated female moths, *O. brachyantha*, IR31917-45-3-2, and the F_1 hybrid were planted in a seed box (55 $\times$ 40 $\times$ 15 cm). The plants were spaced 25 cm from each other. The seed box was covered with a cage (55 $\times$ 40 $\times$ 80 cm) made of a wooden frame and nylon mesh. Five pairs of field-collected moths were released in the center of each cage. Cotton dipped in 25% honey solution was provided in the

center of the cage on a wooden stake. The experiment was conducted in an insectary at a mean temperature of 27 ± 4°C and was replicated 10 times. After 48 hr, the number of eggs laid on each plant was counted.

Moth ovipositional response was tested by releasing five pairs of 3-day-old mated females on individual potted plants of *O. brachyantha*, IR31917-45-3-2, and F_1 hybrid. The plants were covered by Mylar cages (22 cm diam. and 60 cm high). The experiment was replicated 10 times in an insectary at 27 ± 4°C. The number of eggs laid was counted 48 hr after release.

Electroantennogram Responses of Adults. Antennal preparation for measuring the EAG responses of moths was the same as that described by Ramachandran et al. (1990). The stimulus was applied from a Pasteur pipet containing 215 mg of crushed leaves of test plants. Electroantennogram responses of ten 4-day-old females and ten 2-day-old males to leaves of IR36, TKM6, IR31917-45-3-2, *O. brachyantha*, and the F_1 hybrid were recorded. Antennae were stimulated at 2-min intervals and stimulation with a test leaf was followed and preceded by purging with a standard (100 μg of 1-hexanol). Absolute EAG potentials were converted to relative responses to the standard following the method of Guerin and Visser (1980).

Mandible Wear Pattern of Larvae Reared on Test Plants. Ten first-instar larvae were caged on three 40-day-old potted plants of IR31917-45-3-2 and *O. brachyantha*. Larvae were collected from the plants after 7, 14, and 21 days and preserved in 70% ethanol. The mandibles of the larvae were dissected and mounted on slides. Measurements on the width (estimate of the absolute size of mandible) and length (measure of wear-related changes in the incisor length) (Raupp, 1985) were recorded under a microscope fitted with an ocular micrometer.

Since the size and stage of larvae reared for the same duration on IR31917-45-3-2 and *O. brachyantha* differed significantly at the three different sampling times, a comparison of mandible size across the different sampling times was not valid. The width and length of mandibles of different instars of the larvae may be linearly related. If width is an absolute measure of mandible size and length a measure of the wear on the mandibular incisors (Raupp, 1985), then the relationship between the width and length of larvae reared on the test plants would be different if wear on the mandibles due to feeding on these plants is different. We tested this hypothesis by examining the differences in the linear relationship between width and length of mandibles of larvae reared on IR31917-45-3-2 and *O. brachyantha*.

Silica Deposition Pattern and Content. Leaves of 40-day-old IR31917-45-3-2, *O. brachyantha*, and the F_1 hybrid plants were cut into 2-cm pieces and immersed in 70% ethanol for three days. The leaves were placed on glass slides with their adaxial surface facing down. With a razor blade, the tissue from the abaxial surface was scraped until only the dorsal epidermal layer remained. A

2-mm piece of leaf was removed and boiled for 1 min in 20 ml phenol containing five drops of 0.1% aqueous safranin. The leaf pieces then were mounted on glass slides using the safranin–phenol solution and examined under a microscope. A regular pattern of silicified cells was observed in all three tests plants. Rows of silica cells were arranged longitudinally on the epidermal layer. A set of three to five widely spaced single rows of silica cells (designated as single rows) was arranged in between two closely arranged rows (designated as double rows). The number of single rows in between double rows, the distance between two single rows, the distance between the two single rows in a double row, and the number of silicified cells in a microscopic field were counted from 10 randomly selected leaf pieces. Crude silica content was estimated from oven-dried leaf samples of the test plants by the gravimetric method described by Yoshida et al. (1976).

Statistical Analysis. All percentage values were transformed to arcsine/p before analysis. Back-transformed means and standard errors are presented. In other cases, nontransformed data were used for analysis. Details of the analysis are presented along with the tables or figures.

RESULTS

Plant Damage. After 15 days of infestation, the percentage of leaves damaged on the test plants was significantly different ($F_{4,25} = 47.69$, $P < 0.001$). The lowest damage was observed on *O. brachyantha*, followed by the F_1 hybrid. The percentage of damaged leaves in IR31917-45-3-2, IR36, and the standard resistant check TKM6 were not significantly different. Damage rating based on the number of leaves with each damage grade (IRRI, 1988) was also the lowest on *O. brachyantha* and the F_1 hybrid, followed by TKM6 (Table 1).

Sequential Solvent Extraction of Plants. Sequential solvent extractions of IR31917-45-3-2, *O. brachyantha*, and the F_1 hybrid yielded 1.3, 1.8, and 1.6% with hexane; 1.7, 2.1, and 2.3% with methylene chloride; 8.6, 9.5, and 11.6% with methanol; and 4.2, 4.2 and 4.7% with water.

Orientation of First-Instar Larvae. A significantly higher proportion of first-instar larvae oriented towards crushed leaves of IR31917-45-3-2 than to the control (paired t test, $P < 0.01$) (Table 2). However, no significant difference was observed in the number of larvae orienting to *O. brachyantha* or F_1 hybrid as compared to those orienting to the control (Table 2).

Hexane extractables of IR31917-45-3-2 attracted first-instar *C. medinalis* larvae at all concentrations tested (Table 3). A similar attraction to methylene chloride extractables of IR31917-45-3-2 was evident at 2500 and 5000 ppm. Attraction to hexane extractables of *O. brachyantha* was significant at 1000 ppm. At the same concentration, significant orientation of larvae away from the treated side was observed for those exposed to methylene chloride extractables.

TABLE 1. *C. medinalis* FEEDING DAMAGE TO IR31917-45-3-2, *O. brachyantha*, F_1 HYBRID OF IR31917-45-3-2 AND *O. brachyantha*, TKM6, AND IR36 RICE PLANTS[a]

Plant	Damaged leaves (%)	Damage rating
IR31917-45-3-2	87 ± 5a	8.7ab
O. brachyantha	16 ± 2c	0.3d
F_1 (IR31917-45-3-2 × *O. brachyantha*)	32 ± 6b	2.3c
TKM6 (resistant check)	68 ± 5a	7.3b
IR36 (susceptible check)	75 ± 4a	0.9a

[a] In a column, means followed by the same letter are not significantly different [$P = 0.05$; Duncan's (1951) multiple range test]. Average of six replications; each replication had 17–20, 40-day-old, tillers infested with 20 first-instar larvae. Damage rating was calculated following the standard evaluation system for rice (IRRI, 1988).

TABLE 2. ORIENTATION OF FIRST-INSTAR LARVAE OF *C. medinalis* TO CRUSHED LEAVES OF IR31917-45-3-2, *O. brachyantha*, AND THEIR F_1 HYBRID[a]

Plant	Percent larvae orienting to		Difference and its significance
	Crushed leaf	Control	
IR31917-45-3-2	71 ± 3.5	29 ± 3.5	42**
O. brachyantha	57 ± 3.7	43 ± 3.7	14ns
F_1 hybrid	58 ± 4	42 ± 4	16ns

[a] Mean of 10 replications. ns, not significant.
**, significant at $P < 0.01$. Paired t test (Zar, 1984).

Settling Preference of First- and Third-Instar Larvae. A significantly higher number of larvae settled on IR31917-45-3-2 and TKM6 leaves when these leaves were presented with *O. brachyantha* and F_1 hybrid leaves in two-choice tests. When a choice was given between *O. brachyantha* and the F_1 hybrid, a significantly higher proportion of larvae was recovered from the F_1 hybrid (Table 4).

Similarly, the number of third-instar larvae that settled on *O. brachyantha* was significantly lower when presented with IR31917-45-3-2, the F_1 hybrid, and TKM6 in two-choice test (Table 4). However, no significant difference was observed in the settling behavior of the third-instar larvae when the F_1 hybrid was presented with IR31917-45-3-2 or TKM6. Larval feeding was greater on IR31917-45-3-2, TKM6, and the F_1 hybrid when presented in a two-choice test with *O. brachyantha*, and was more on IR31917-45-3-2 when presented with

TABLE 3. ORIENTATION OF FIRST-INSTAR *C. medinalis* LARVAE TO HEXANE AND METHYLENE CHLORIDE EXTRACTABLES OF IR31917-45-3-2 AND *O. brachyantha*[a]

Concentration	% larvae orienting to IR31917-45-3-2	Control	Difference ± SEM and its significance	% larvae orienting to *O. brachyantha*	Control	Difference ± SEM and its significance
Hexane extractables						
5000	68	32	36 ± 7**	53	47	6 ± 3ns
2500	64	36	28 ± 6**	49	51	− 2 ± 9ns

500	64	36	28 ± 6**	54	46	9 ± 6ns
Methylene chloride extractables						
5000	69	31	38 ± 11*	54	46	9 ± 14ns
2500	69	31	38 ± 8*	46	54	− 8 ± 13ns
1000	56	44	12 ± 6ns	42	58	−16 ± 5*
500	52	48	4 ± 6ns	49	51	− 2 ± 6ns

[a]2.5 μl of the extractables were applied on a 5 × 2.5-cm filter paper and the solvent allowed to evaporate for 1 min before conducting the test. *$P < 0.05$, **$P < 0.01$, ns = not significant, paired *t* test (Zar, 1984).

the F_1 hybrid (Figure 1). However, there was no significant difference in the area fed on the test leafcuts when the choice was between the F_1 hybrid and TKM6 (Figure 1).

First-instar larvae preferred to settle on the control leafcuts when presented with leafcuts treated with either 5000 ppm hexane extractables or 1250, 2500 or 5000 ppm methylene chloride extractables of *O. brachyantha* and F_1 hybrid in a choice test (Figure 2, $P < 0.001$, paired *t* test). At lower concentrations, no significant preference for either control or treated leaves was observed. However, at 625 and 312 ppm of hexane extractables of IR31917-45-3-2, a significant preference for treated leaves was evident (Figure 2; differences were significant at $P < 0.05$, paired *t* test). Similarly, there was a significant preference for leafcuts treated with 5000 ppm of methanol extractables and 312 ppm of water extractables of IR31917-45-3-2.

Third instars fed significantly more on the control leaves when presented with leaves treated with 500, 1000, 2500, and 5000 ppm of hexane or methylene chloride extractables of *O. brachyantha* in a choice test (Figure 3) ($P < 0.001$, paired *t* test). No significant differences were evident in tests with hexane and methylene chloride extractables of IR31917-45-3-2. The methanol and water extractables of *O. brachyantha* and IR31917-45-3-2 did not affect the feeding preference of the third-instar larvae.

TABLE 4. SETTLING RESPONSE OF FIRST-INSTAR AND THIRD-INSTAR LARVAE OF *C. medinalis* ON LEAFCUTS OF *O. brachyantha*, IR31917-45-3-2, F_1 HYBRID OF *O. brachyantha* AND IR31917-45-3-2, AND TKM6 IN TWO-CHOICE TESTS[a]

	First instar		Third instar

[b] ns, not significant; *significant, $P < 0.05$; **$P < 0.01$, ns = not significant (paired t test, Zar, 1984).

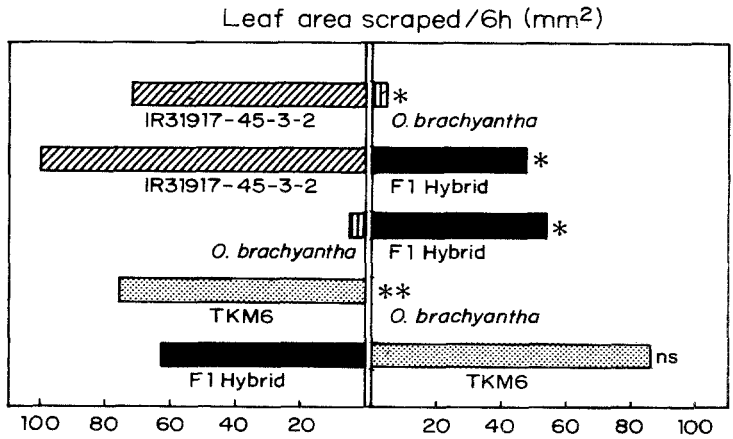

FIG. 1. Leaf area scraped (mm^2)/third instar *C. medinalis* larva/6 hr in choice tests. *Significant difference, paired t test, $P < 0.05$ (Zar, 1984).

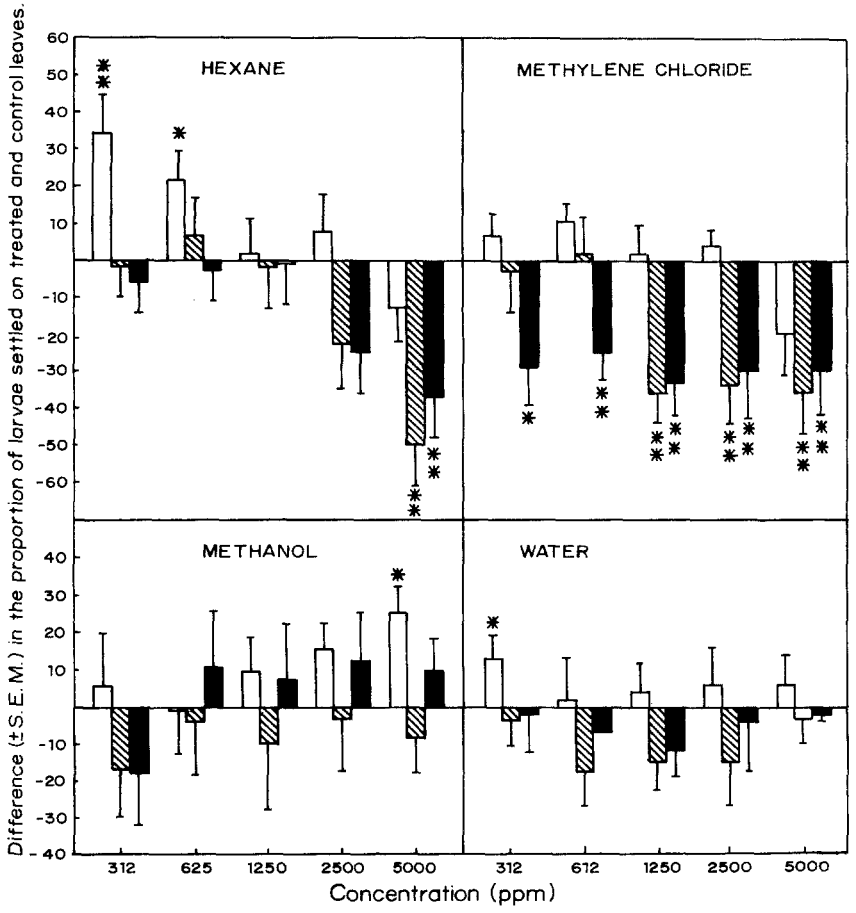

FIG. 2. Differences in the proportion of first-instar *C. medinalis* larvae settled on extract-treated and their respective solvent-treated control leafcuts [(number of larvae settled on treated leafcuts—number of larvae settled on control leafcuts/total number of larvae recovered) × 100]. Empty bars = extractables of IR31917-45-3-2; lined bars = extractables of *O. brachyantha*; filled bars = extractables of F_1 hybrid. Positive difference indicates a preference for treated leafcuts. *Significant at $P < 0.05$, **significant at $P < 0.001$, paired t test (Zar, 1984). Vertical lines indicate standard error of difference.

Dispersal of First-Instar Larvae. Ten minutes after release, significantly fewer larvae remained settled on *O. brachyantha* and the F_1 hybrid as compared with those on IR31917-45-3-2 and TKM6 (Figure 4). The rate of decrease in the number of larvae that remained settled on *O. brachyantha* and the F_1 hybrid leaves was higher than that for larvae on IR31917-45-3-2 and TKM6. At the

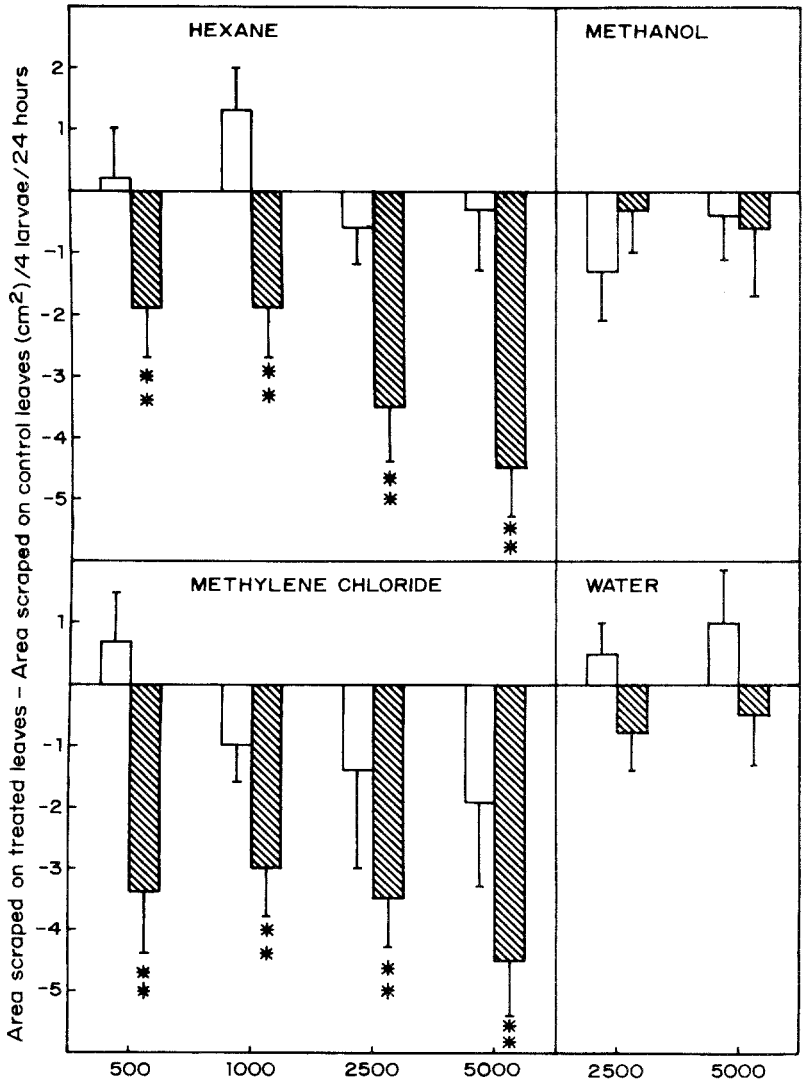

FIG. 3. Differences in the area scraped/4 third-instar *C. medinalis* larvae/24 hr between sequential solvent extractable-treated leafcuts and their respective solvent-treated leafcuts in choice tests. Empty bars = extractables of IR31917-45-3-2; lined bars = extractables of *O. brachyantha*. *Significant at $P < 0.05$, **significant at $P < 0.001$, paired t test, (Zar, 1984). Vertical bars indicate standard error of difference.

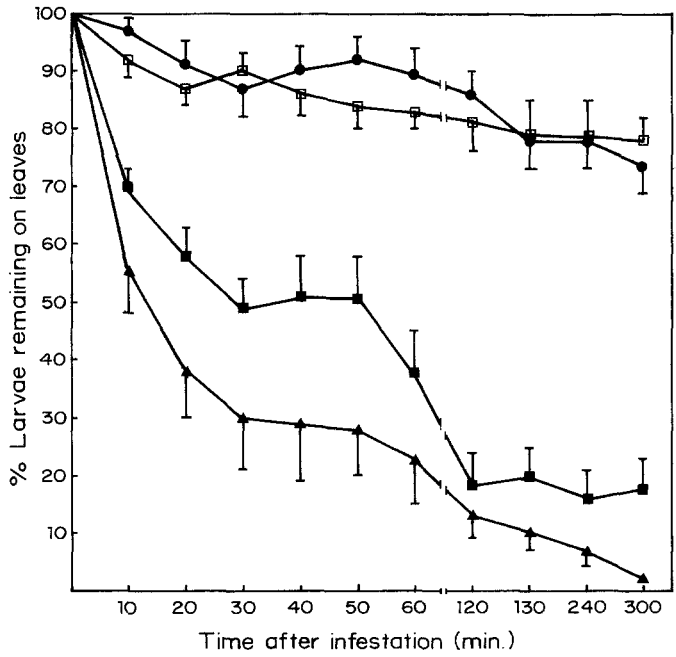

FIG. 4. Percentage of first-instar *C. medinalis* larvae settling on rice leaves (● = IR31917-45-3-2, □ = TKM6, ■ = F_1 hybrid, ▲ = *O. brachyantha*) from 0 to 300 min postinfestation. Vertical bars indicate standard error of means.

end of the experiment, only 15% and 1% of larvae remained settled on the F_1 hybrid and *O. brachyantha*, respectively.

In a similar bioassay with plant extracts, a significantly higher number of first-instar larvae remained settled on control leaves than on leaves treated with extractables of all three plants (Figure 5). A significantly higher proportion of larvae remained settled on leaves treated with hexane and methylene chloride extractables of IR31917-45-3-2 compared to leaves treated with the same solvent extractables of *O. brachyantha*. The proportion of larvae that remained settled on the leaves treated with extractables from the F_1 hybrid was intermediate to both its parents. Trends were similar at both 1-hr and 5-hr observation times (Figure 5).

Feeding and Growth on Excised Leaves. In no-choice tests, the area fed by the third-instar larvae in 24-hr was significantly lower on *O. brachyantha* than on other test plants ($F_{3,24} = 16.2$, $P < 0.01$) (Table 5). Larvae gained ca. 30% of their initial weight when fed for 24 hr on IR31917-45-3-2, IR36, or TKM6 leaves. Larval weight gain after feeding on the F_1 hybrid leaves was

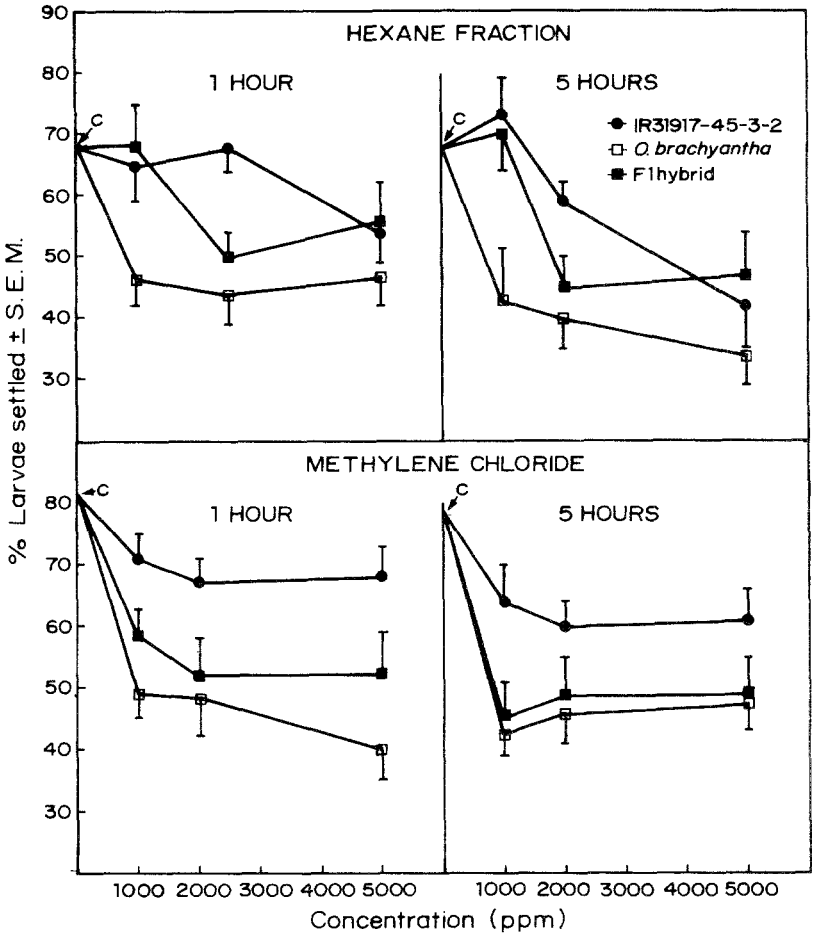

FIG. 5. Settling behavior of first-instar *C. medinalis* larvae to hexane and methylene chloride extractables of IR31917-45-3-2, *O. brachyantha*, and their F_1 hybrid in a no-choice test, c = solvent treated control.

significantly lower (21%). Weight gain was only 1% on *O. brachyantha* leaves (Table 5).

The area of leaf scraped in 24 hr by third-instar larvae on leaves treated with 5000 and 2500 ppm of hexane, methylene chloride, methanol, or water extracts of IR31917-45-3-2, *O. brachyantha*, and the F_1 hybrid did not differ significantly from that of their respective controls.

Survival and Growth on Potted Plants and Artificial Diets. Fifteen days after infestation, survival of larvae on IR31917-45-3-2, IR36, and TKM6 were

TABLE 5. PHYSIOLOGICAL RESPONSES OF *C. medinalis* LARVAE FED IR31917-45-3-2, *O. brachyantha*, F_1 HYBRID OF IR31917-45-3-2 AND *O. brachyantha*, IR36, AND TKM6 RICE PLANTS[a]

Plant	Leaf area scraped/larvae per 24 hr (cm^2)[b]	Weight gain/ larva per 24 hr[b] (%)	Larval survival 15 DAI[c]	Pupation (%)[c]	Larval period (days)[c]	Growth index[c,d]	Pupal weight (mg)[c]
IR31917-45-3-2	3.66 ± 0.9a	33.7 ± 6.4a	71 ± 3a	71 ± 3a	17.9 ± 0.8c	4.0a	20.9 ± 1.1a
O. brachyantha	0.54 ± 0.2b	1.3 ± 3.8b	12 ± 3c	0c			
F_1 (IR31917-45-3-2 × *O. brachyantha*)	2.84 ± 0.6a	21.1 ± 4ab	40 ± 6b	36 ± 5b	22.0 ± 0.9a	1.6b	14.8 ± 1.0c
TKM6 (resistant check)	3.74 ± 0.6a	34.8 ± 5.2a	62 ± 5a	62 ± 5a	22.0 ± 0.5a	2.8ab	17.6 ± 1.3b
IR26 (susceptible check)	3.8 ± 0.8a	36.4 ± 6.4a	70 ± 4a	70 ± 4a	19.4 ± 0.8b	3.6a	21.2 ± 1.1a

[a] In a column, means followed by the same letter are not significantly different [$P = 0.05$; Duncan's (1951) multiple range test].
[b] Average of ten replications.
[c] Average of six replications; each replication had 20 newly emerged larvae caged on 40-day-old plants.
[d] Growth index, percent larvae becoming pupae divided by mean development period.

similar and significantly higher than on *O. brachyantha* and the F_1 hybrid (Table 5). The larvae surviving on *O. brachyantha* were still in their second and third stadia, while those on IR31917-45-3-2, IR36, and TKM6 were already in their fourth and fifth stadia. All larvae that had survived up to 15 days pupated on IR31917-45-3-2, IR36, and TKM6, whereas no pupation occurred on *O. brachyantha* (Table 5). Heavier pupae were obtained from IR31917-45-3-2 and IR36 than from TKM6 and the F_1 hybrid. Larval duration was longer on TKM6 and the F_1 hybrid than on IR36 and IR31917-45-3-2 (Table 5).

Five days after infestation, the percentage of larvae that survived did not differ significantly between artificial diet without any leaf powder (control) and diet incorporated with leaf powder of IR31917-45-3-2 or *O. brachyantha* (Table 6). Subsequently, 96% of the larvae pupated in control diets while 77% and 69% pupated in IR31917-45-3-2 and *O. brachyantha* leaf powder-incorporated diets, respectively (Table 6). Incorporation of leaf powder significantly decreased the larval and pupal weights as compared with those on control diets (Table 6). Larval duration in the leaf powder-incorporated diets also was delayed significantly in comparison to larvae fed control diets. However, the performance of larvae in diets with IR31917-45-3-2 leaf powder was comparable to larvae fed diets with *O. brachyantha* leaf powder (Table 6).

Oviposition. Adult female *C. medinalis* preferred to oviposit on IR31917-45-3-2 plants in choice tests with *O. brachyantha* and the F_1 hybrid. Seventy-three percent of the eggs were laid on the IR31917-45-3-2, 24% on F_1 hybrid, and 5% on *O. brachyantha* (Table 7).

The ovipositional response of *C. medinalis* to the three test plants also differed significantly in a no-choice oviposition test ($F_{2,18} = 23.32$, $P < 0.01$).

TABLE 6. PERFORMANCE OF *C. medinalis* FED ARTIFICIAL DIET INCORPORATED WITH LEAF POWDER OF IR31917-45-3-2 AND *O. brachyantha*[a]

Parameter	Control	IR31917-45-3-2	*O. brachyantha*
Survival/cup after 5 days (%)[b]	50.7 ± 2.5a	50.6 ± 2.7a	51.4 ± 2.9a
Survival to pupation (%)[c]	96	76.5	69.10
Larval weight (mg)[d]	7.35 ± 0.98a	2.95 ± 0.96b	4.33 ± 1.0ab
Larval duration (days)	25 ± 0.7a	29.1 ± 0.8b	30.3 ± 0.7b
Pupal weights (mg)	22.9 ± 0.5a	20.7 ± 0.5b	19.2 ± 0.5b

[a] Freeze-dried leaf powder was incorporated in a leaffolder artificial diet (Khan, 1987). Means in a row not followed by the same letter are significantly different, Duncan's (1951) multiple range test, $P < 0.05$.

[b] On the sixth day, the density/cup was reduced to two.

[c] Survival to pupation was calculated on the basis of the proportion of all caterpillars that pupated after the sixth day.

[d] Weight of 22 randomly selected larvae, 15 days after infestation.

The number of eggs laid on IR31917-45-3-2 was significantly more than that laid on the F_1 hybrid and *O. brachyantha* (Table 7).

Electroantennogram Responses of Adults. The EAG responses of both the male and female moths of *C. medinalis* to crushed leaves of IR36, TKM6, and IR31917-45-3-2 were similar and significantly higher than the EAG response to leaves of *O. brachyantha* (Table 8). The response to leaves of the F_1 hybrid was intermediate to the responses to IR31917-45-3-2 and *O. brachyantha* (Table 8).

Mandible Wear Pattern of Larvae Reared on Test Plants. Within both rices tested, there was a significant linear relationship between mandible width and length when data for 7-, 14-, and 21-day sampling dates were combined (Figure 6; linear regression significant, $P < 0.01$). The elevation of the regression line for larvae reared on IR31917-45-3-2 was significantly higher than that for larvae reared on *O. brachyantha* (Figure 6, $F_{1,103} = 16.96$, $P < 0.001$). This indicates that, for a given width of mandible, the length was greater in larvae reared

TABLE 7. OVIPOSITION OF *C. medinalis* ON IR31917-45-32, *O. brachyantha*, AND THEIR F_1 HYBRID IN CHOICE AND NO-CHOICE TESTS[a]

	No-choice (No. of eggs/5 females/2 days)	Choice (% eggs laid)
IR31917-45-3-2	170 ± 20a	73 ± 5a
O. brachyantha	40 ± 4c	5 ± 2c
F_1 hybrid	83 ± 9b	22 ± 5b

[a] In a column, means followed by the same letter are not significantly different [$P < 0.05$, Duncan's (1951) multiple range test].

TABLE 8. EAG RESPONSES OF *C. medinalis* TO CRUSHED LEAVES[a] OF RICE PLANTS

Rice plant	Relative EAG responses[b] ± SEM	
	Female	Male
IR36	79.5 ± 4.0 a	83.8 ± 1.6 a
TKM6	80.3 ± 4.4 a	88.1 ± 8.7 a
IR31917-45-3-2	81.3 ± 4.3 a	94.6 ± 3.7 a
Oryza brachyantha	65.3 ± 3.6 b	69.6 ± 3.5 b
F_1 hybrid	70.2 ± 3.8 ab	80.5 ± 1.8 ab

[a] 215 mg of crushed rice leaves were used as a stimulus source. Means in a column not followed by the same letter are significantly different, Duncan's (1951) multiple range test, $P < 0.05$.
[b] Response relative to 10 μl of 10 mg/ml solution of 1-hexanol in heptane.

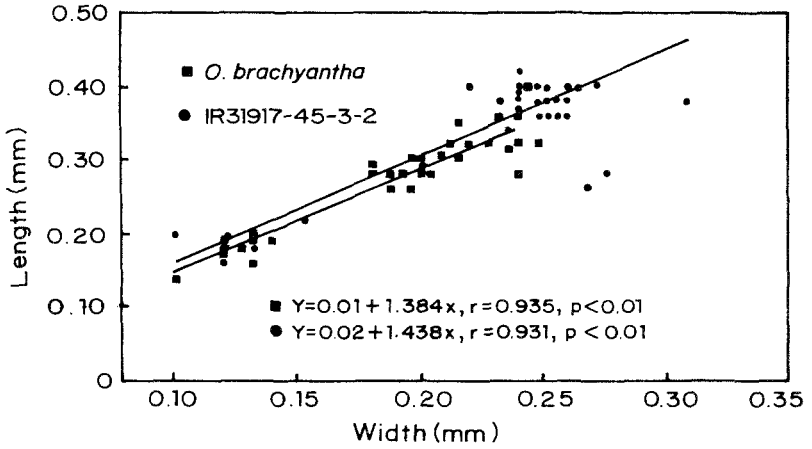

FIG. 6. Relationship between mandible width and mandible length of *C. medinalis* larvae reared on IR31917-45-3-2 and *O. brachyantha*.

on IR31917-45-3-2 than on *O. brachyantha*, suggesting a higher mandibular wear in larvae feeding on the latter plants.

Silica Deposition Pattern and Content. IR31917-45-3-2, *O. brachyantha*, and the F_1 hybrid did not differ significantly in the number of single rows of silica cells deposited between two double rows. The distance between two adjacent single rows of silica cells was smaller in *O. brachyantha* and the F_1 hybrid (Table 9) as compared with IR31917-45-3-2. The two rows in a double row of silica cells were more closely placed in *O. brachyantha* as compared with IR31917-45-3-2; in the F_1 hybrid, this value was intermediate. *O. brachyantha* leaves had a significantly higher number of silica cells per unit area than IR31917-45-3-2 or the F_1 hybrid (Table 9). The silica content of the leaves of the three test plants did not differ significantly.

DISCUSSION

The suitability of plants as hosts to insects is determined by an array of interactions between insect responses to various plant characteristics (Saxena, 1969). The main categories of behavioral and physiological responses during insect establishment on plants are orientation, settling, feeding, metabolism of ingested food, growth, adult survival, egg production, and oviposition (Saxena, 1969). A plant's resistance to insects could be due to the disruption of one or more of the physiological and behavioral responses of the insect to the plant characteristics (Khan and Saxena, 1985). Depending on whether the plant char-

TABLE 9. SILICA DEPOSITION PATTERN IN EPIDERMAL LAYER OF ADAXIAL SURFACE AND SILICA CONTENT OF IR31917-45-3-2, *O. brachyantha* AND THEIR F_1 HYBRID LEAVES[a]

Parameter	IR31917-45-3-2	*O. brachyantha*	F_1 hybrid
Number of single rows of silica cells in between double rows	4.1 ± 0.3a	4.6 ± 0.2a	4.2 ± 0.2a
Distance between adjacent rows of silica cells in double rows (mm)	0.0535 ± 0.005a	0.0412 ± 0.001b	0.0041 ± 0.003b
Distance between adjacent single rows	0.1718 ± 0.006a	0.1162 ± 0.005c	0.1426 ± 0.008b
Number of silica cells/unit area	72 ± 5.0a	86 ± 4b	70 ± 5a
Silica content (%)	4.73 ± 0.30a	4.48 ± 0.14a	5.21 ± 0.67a

[a] Means in a row followed by the same letter are significantly different. Duncan's (1951) multiple range test, $P < 0.05$.

acteristics affect the insect's behavior or physiology, the modalities of resistance of a plant could be classified as antixenosis or antibiosis (Painter, 1951; Wiseman, 1985).

Our results indicated that the resistance of *O. brachyantha* to *C. medinalis* is due to strong nonpreference. Nonpreference of adults was expressed in the lower number of eggs laid on *O. brachyantha* in both choice and no-choice tests. In the larval stages, nonpreference was expressed in the small proportion of first- and third-instar larvae settling on *O. brachyantha* when presented with the other test plants in choice tests. In no-choice experiments, a large proportion of larvae crawled off the leaves of *O. brachyantha*. A similar phenomenon was observed in larvae of the fall armyworm, *Spodoptera frugiperda* (J.E. Smith), which crawled off a resistant corn line Antigua 2D-118 (Wiseman et al., 1983). These effects against adult oviposition and first-instar settling also were observed in the F_1 hybrid but the magnitude was less than that in *O. brachyantha*.

The low survival and reduced growth rate of larvae on potted plants of *O. brachyantha* as compared with other rice plants may indicate high levels of antibiosis in this wild rice. However, the absence of significant differences in the growth and survival of larvae in artificial diets incorporated with the leaf powder of *O. brachyantha* and IR31917-45-3-2 suggests that mortality of larvae on the wild rice may have been due to reduced food intake and consequent starvation. Low levels of feeding by third-instar larvae on excised leaves of *O. brachyantha* as compared with those on the rice plants further support this conclusion. The growth responses of larval stages fed artificial diets containing

leafpowder of resistant plants have been considered an accurate indicator of antibiotic properties of resistant plants (Wilson et al., 1984; Wiseman, 1985). Incorporation of leaf powder of TKM6, a resistant rice variety, significantly reduced the growth and pupal weights of *C. medinalis* as compared with other test plants, suggesting that antibiosis is one of the mechanisms of resistance in this variety (Khan et al., 1989).

Our studies on the orientation of the first-instar *C. medinalis* larvae and electroantennogram responses of adult moths to leaves of the test plants suggested that susceptible IR31917-45-3-2 may contain volatile chemicals that are attractant to both larvae and adults. The neutral reaction of first-instar larvae and the lower EAG response of adult moths to volatiles from crushed leaves of *O. brachyantha* and the F_1 hybrid indicate either a lack or low levels of these chemicals in these plants. The presence of volatile chemicals that are attractant or repellent and their relative proportion in soybeans were attributed as one of the factors that confer resistance (Liu et al., 1988). Differential attraction of *Heliothis armigera* (Hubner) to resistant and susceptible pigeonpea cultivars has been related to differences in the relative concentation of volatile compounds in their aromagrams (Rembold and Tober, 1985). Headspace analysis of the volatile profiles of strawberry cultivars during periods of resistance and susceptibility to *Tetranychus urticae* Koch suggested that causes of resistance may be due to a buildup of volatile salicylates accompanied by accumulation of nonvolatile phenols (Hamilton-Kemp et al., 1988). The olfactory sensitivity of the rice leaffolders to several plant volatiles is known (Ramachandran et al., 1990). Identification of the volatile chemicals emanating from the plants in this study would enable us to determine empirically the exact role of these chemicals in the resistance of *O. brachyantha*.

The susceptibility of IR31917-45-3-2 and the resistance of *O. brachyantha* and the F_1 hybrid were due partly to allelochemicals, extractable with hexane and methylene chloride, as indicated by the results of bioassays with the solvent extracts of these plants. Results of olfactometer tests and settling preference assays with first-instar larvae suggested that one of the causes of susceptibility of IR31917-45-3-2 might be the presence of attractants or feeding stimulants in these fractions. The settling preference of first-instar larvae in choice and no-choice tests and the feeding preference of third instars in choice tests suggest the presence of deterrent chemicals in the hexane and methylene chloride extractables of *O. brachyantha* and the F_1 hybrid plants. However, these deterrents did not have any antifeedant effect on the third-instar larvae, probably because of the low biological activity of these deterrent chemicals.

Bernays and Chamberlain (1982) and Raubenheimer and Simpson (1990) found that deterrent effects of tannic acid to *Locusta migratoria* (L.) were observed only in a choice test and not in no-choice feeding trials. Raubenheimer and Simpson (1990) hypothesized that a feeding deterrent either raises the

threshold for initiation of insect feeding, so that feeding begins only when the inhibitory feedback from the gut and blood is lower, or lowers the threshold for meal termination so that the insect stops feeding at a lower gut volume. Both these mechanisms may result in reduced consumption by an insect. However, if the thresholds for initiation and termination of feeding are altered equally, then the patterns of feeding would be unaffected by the feeding deterrent, resulting in similar quantities of consumption in controls and treatments (Raubenheimer and Simpson, 1990). This also may explain why the feeding deterrents in the hexane and methylene chloride fractions of *O. brachyantha* did not show any antifeedant properties against the third-instar larvae of *C. medinalis*.

The loss of adverse effects of *O. brachyantha* on the biology of *C. medinalis* when *O. brachyantha* was incorporated into artificial diets and the absence of antifeedant effects of the sequential solvent extracts prompted us to examine the possibility of additional physical causes of resistance in *O. brachyantha*. The pattern of silica deposition on the epidermal layer of rice leaves and its wearing effect on the mandibles of the larval stages has been considered one of the factors that contributed to the rice plant's resistance to leaffolders (Hanifa et al., 1974). The difference in the elevation of regression lines between the width (a measure of the absolute size of the jaw) and the length (a measure of the wear on the incisor) of the mandibles of larvae reared on *O. brachyantha* and IR31917-45-3-2 suggests that mandible wear of larvae feeding on wild rice may have been higher. More closely placed rows of silica cells in the leaves of *O. brachyantha* as compared with those in IR31917-45-3-2 may have conferred some level of physical resistance to feeding by *C. medinalis* larvae on this wild rice.

The high degree of resistance of *O. brachyantha* to leaffolders appears to be the result of additive or synergistic action from a lack of volatile attractants, the absence of less volatile attractants and/or feeding stimulants, the presence of feeding deterrents, and physical resistance offered by the closer arrangement of silica cells. The probability of transferring leaffolder resistance to cultivated rice by wide hybridization with *O. brachyantha* seems fair, considering the multiplicity of resistance factors involved. However, the degree of resistance obtained may not be very high, if our hypothesis—that resistance in *O. brachyantha* is the result of joint action of the resistance factors involved—is correct. Wide hybridization to improve the degree of resistance in some cultivars (i.e., choosing a rice parent that already has one or more of the resistance factors) may be a more successful strategy.

FEEDING RESPONSES OF *Chilo partellus* (SWINHOE) (LEPIDOPTERA: PYRALIDAE) LARVAE TO SORGHUM PLANT PHENOLICS AND THEIR ANALOGS

BALDWYN TORTO,[1] AHMED HASSANALI,* KAILASH N. SAXENA, and SAGARY NOKOE

The International Centre of Insect Physiology and Ecology (ICIPE), P.O. Box 30772, Nairobi, Kenya

(Received May 9, 1990; accepted August 20, 1990)

Abstract—Phagostimulatory responses of third-instar larvae of *Chilo Partellus* to phenolic components identified in an ethyl acetate extract of the leaf whorls of 3-week-old plants of *Sorghum bicolor* cultivar IS 18363 were studied in no-choice bioassays. The major components in the extract were identified as 4-hydroxybenzaldehyde and 4-hydroxybenzoic acid, with 4-hydroxy-3-methoxycinnamic acid, 3,4-dihydroxycinnamic acid, and 4-hydroxycinnamic acid present in minor amounts. All but 4-hydroxycinnamic acid were stimulatory at the doses tested. 4-Hydroxybenzaldehyde was more stimulatory than other potential biogenetic analogs. Hydroxybenzoic acids generally elicited greater feeding response than cinnamic acids, and the pattern of oxygen substitution in the benzene ring was related to bioactivity.

Key Words—*Chilo partellus*, Lepidoptera, Pyralidae, sorghum, feeding response, phenolics, phagostimulant, 4-hydroxybenzaldehyde, 4-hydroxybenzoic acid, 4-hydroxy-3-methoxycinnamic acid, 3,4-dihydroxycinnamic acid, 4-hydroxycinnamic acid.

INTRODUCTION

The variation in palatabilty of different cultivars of a host plant to insect pests has been attributed in a number of studies to quantitative or qualitative differences in the content of their allelochemics (Sogawa and Pathak, 1970; Hedin

*To whom correspondence should be addressed.

0098-0331/91/0100-0067$06.50/0

et al., 1977; Robinson et al., 1978; Woodhead, 1982; Haskins and Gorz, 1985; Otieno et al., 1985). Previous studies on different cultivars of *Sorghum bicolor* have shown that qualitative differences in the chemical composition of surface wax play a significant role in determining the level of damage caused by the nymphs of *Locusta migratoria* (Woodhead, 1983). Specific surface wax chemicals also have been implicated in the differential establishment of young larvae of *Chilo partellus* on the leaf whorls of certain sorghum varieties (Woodhead and Taneja, 1987).

We have recently shown that feeding by third-instar *C. partellus* larvae on sorghum is mediated by surface and tissue chemicals of different polarities extractable sequentially with hexane, ethyl acetate, and methanol (Torto et al., 1990). As part of an attempt to identify the stimuli involved in the feeding process of this insect and to elucidate the allelochemical basis of the palatibility of different cultivars of host plants, we have carried out a detailed fractionation and analysis of an ethyl acetate extract of a preferred sorghum cultivar IS 18363, in order to identify the phagostimulatory constituents in the extract. In this paper, we report the effects of phenolic constituents identified in the extract and some of their analogs on the feeding of the third-instar larvae of the insect.

METHODS AND MATERIALS

Insects. Freshly molted third-instar larvae of *C. partellus* were obtained from stock cultures maintained on an artificial diet at the ICIPE insectary (Ochieng et al. 1985). Third-instar larvae feed first on the leaves of the host plant before gradually boring into the stem. This stage was selected for bioassay owing to the longer-term objective of elucidating the basis for the change in larval feeding sites.

Extraction and Fractionation. Freshly cut, undamaged whorls of 3-week-old sorghum plants were extracted by dipping them first in hexane (15 min) and then in ethyl acetate (15 min) followed by soaking in methanol (24 hr). All extracts were concentrated to dryness in vacuo.

A sample of the ethyl acetate concentrate was redissolved in ethyl acetate and extracted with water (Figure 1). The combined aqueous phase was freeze-dried and the organic phase concentrated to dryness in vacuo. In bioassays, both phases stimulated larval feeding. Preliminary HPLC analyses of the two partition phases showed that phenolic components in the extract were present predominantly in the organic phase, while the aqueous phase contained components in common with those in the methanol extract of the whorls (Figure 2). The two major phenolic components in the organic phase were separated by preparative HPLC on a Varian 5000 liquid chromatograph, equipped with a Varian MCH-10 reverse phase column, 50 cm $\times$ 8 mm. The column was eluted with

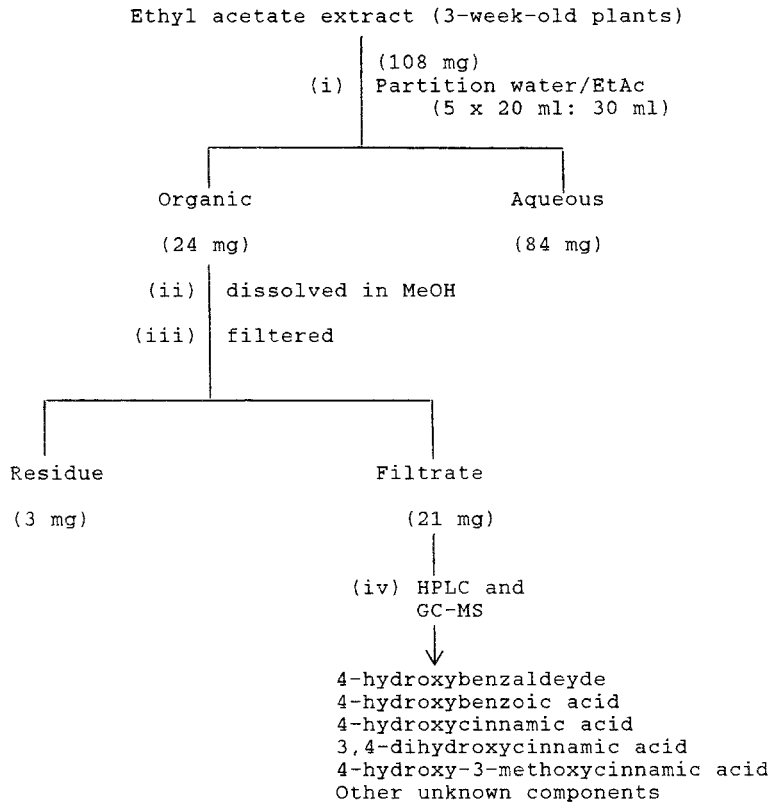

FIG. 1. Flow diagram for the isolation of *p*-hydroxybenzoic acid and *p*-hydroxybenzaldehyde from ethyl acetate extract of the leaf whorls of the 3-week-old plants of sorghum IS 18363.

20% aqueous methanol at a flow rate of 3.0 ml/min at 25°C and the eluate monitored at 240 nm. The fractions corresponding to the two major components were pooled, concentrated, and identified by mass spectrometry and coinjection with authentic samples.

Acetylation of Organic Phase. Since the preparative HPLC separation of the organic phase yielded only the two major phenolic components, the minor components present in this phase were identified as acetyl derivatives. Acetylation of the organic phase with acetic anhydride in dry pyridine at 0°C for 24 hr, gave a mixture of acetates that were identified by GC-MS.

Bioassays for Feeding Activity. The no-choice feeding tests were conducted in small glass vials (23 × 27 mm) with tight porous caps. A wad of moist cottonwool placed inside the cap maintained a high humidity. The cottonwool was covered with a fine-wire mesh that fitted tightly inside the cap.

TABLE 1. MEAN WEIGHT OF DISK CONSUMED (mg) BY THREE THIRD-INSTAR LARVAE ON CELLULOSE ACETATE DISKS TREATED WITH PHENOLIC CONSTITUENTS OF SORGHUM AND THEIR ANALOGS

Phenolic group	Compound	Mean wt (mg) consumed[a]
4-derivatives	4-hydroxybenzaldehyde	0.11099 a
	4-methoxybenzyl alcohol	0.09817 b
	4-hydroxybenzoic acid	0.06625 c
	4-methoxybenzoic acid	0.06603 c
	4-hydroxybenzyl alcohol	0.05540 d
	4-methoxybenzaldehyde	0.02537 e
	4-hydroxycinnamic acid	inactive
Dihydroxy derivatives	3,4-dihydroxybenzoic acid	0.15801 a
	3,4-dihydroxycinnamic acid	0.03630 b
Hydroxymethoxy derivatives	4-hydroxy-3-methoxybenzoic acid	0.09172 a
	4-hydroxy-3-methoxycinnamic acid	0.03409 b
Other compounds	chlorogenic acid	0.07342 a
	quinic acid	0.04092 b

[a] Means with the same letter in a phenolic group are not significantly different ($P < 0.05$) Duncan's multiple-range test.

Test samples in solvents were applied topically to both sides of cellulose acetate disks (12 mm diameter, 7.902 ± 0.348 mg, Cole-Parmer Co., Chicago, Illinois) and were dried in a stream of warm air (Doss and Shanks, 1986). Each test disk then was dampened with 15 μl of double-distilled water and placed in the vial. Control disks dipped into solvent and air dried were similarly treated with double-distilled water. Three third-instar larvae, starved for 24 hr prior to testing, were placed into each vial. All the feeding tests were conducted for 24 hr in the dark at 78 ± 2% relative humidity and 29 ± 2°C. Test and control disks were weighed several times to a constant weight before and after the assay on a Cahn 21 milligram balance to ±0.001 mg.

The following were assayed: (1) organic and aqueous partition phases of the ethyl acetate extract; (2) purified synthetic samples of 4-hydroxybenzoic acid and 4-hydroxybenzaldehyde, the two major phenolic components of the ethyl acetate extract; (3) purified samples of some selected analogs of the two compounds comprising 4-hydroxybenzyl alcohol, 4-methoxybenzaldehyde, 4-methoxybenzoic acid, and 4-methoxybenzyl alcohol; (4), purified synthetic samples of 4-hydroxycinnamic acid, 3,4-dihydroxycinnamic acid, and 4-hydroxy-3-methoxycinnamic acid, the three minor components of the ethyl acetate extract, and their analogs comprising 4-hydroxy-3-methoxybenzoic acid, 3,4-dihydroxybenzoic acid and 2, 5-dihydroxybenzoic acid; and (5) chlorogenic

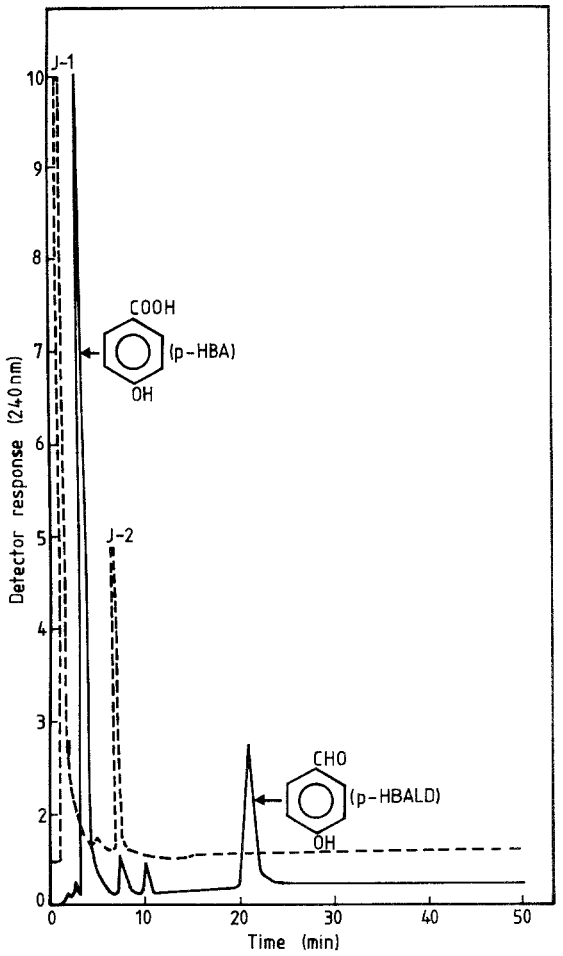

FIG. 2. Elution profiles of the organic (———) and aqueous (– – – –) partition phases of ethyl acetate extracts of leaf whorls of the 3-week-old plants of IS 18363 on a Zorbax C-18 column (25 × 4.6 mm).

acid, a relatively common constituent of plants (Sondheimer, 1964), and its degradative product, quinic acid. Compounds were obtained from Aldrich Chemical. Co. (Milwaukee, Wisconsin), purified by recrystallization, and the purity of each was checked by HPLC and/or GC. All compounds were tested at 10, 25, 50, 150, 250, 350, and 450 μg/disk. Each test was replicated 15 times.

The relative feeding response was calculated for each dose by dividing the mean weight of treated disks consumed by that of the control disks consumed.

The means were subjected to analysis of variance for differences due to phenolic compounds and doses. Overall means were separated using Duncan's multiple-range test. Dose–response plots for the phenolic compounds were derived from the equation: $y = ax^b c^x$ using the least-squares procedure on the logarithmic form: $\ln y = \ln a + x \ln c + b \ln x$, where y = relative feeding response, x = dose (μmol/disk), and a, b, and c are constants that determine the nature and slope of the plot.

Determination of Extent of Oxidation of 4-Hydroxybenzaldehyde during Bioassays. Since aldehydes are rapidly oxidized on exposure to air, an attempt was made to determine the extent of oxidation of 4-hydroxybenzaldehyde during the assay period. 4-Hydroxybenzaldehyde was dissolved in methanol to give 1 mg/ml solution. Ten cellulose acetate disks each were treated with 200 μg of 4-hydroxybenzaldehyde and then dried in a stream of warm air. Prior to the assay the disks were moistened with 15 μl of double-distilled water. Five of the disks were extracted immediately with 1 ml of methanol, and a 10-μl aliquot of each extract was analyzed by reverse-phase HPLC. The remaining five disks in assay containers were maintained at the conditions of the bioassay, i.e., 78 $\pm$ 2% relative humidity, temperature 29 $\pm$ 2°C for 24 hr. The disks then were extracted similarly with methanol and analyzed. The mean peak areas corresponding to 4-hydroxybenzaldehyde in the chromatograms after 0 and 24 hr of the assay were calculated and compared. Peaks representing the absorptions of 4-hydroxybenzioc acid also were checked for in the chromatograms.

RESULTS

Both the aqueous and organic partition phases of the ethyl acetate extract of IS 18363 elicited feeding responses from *C. partellus* larvae. The organic phase components were found to be mainly phenolic (Figure 3). The major compounds were 4-hydroxybenzaldehyde and 4-hydroxybenzoic acid, identified by mass spectral analysis of samples isolated from a micropreparative HPLC column. The minor components were 4-hydroxy-3-methoxycinnamic acid, 3, 4-dihydroxycinnamic acid, and 4-hydroxycinnamic acid, identified as their acetyl derivatives by comparison of their GC-MS data with those of authentic samples and also confirmed by coinjection with authentic samples on an HPLC reverse-phase column. Studies of the aqueous components will be reported elsewhere.

All the phenolic constituents, with the exception of 4-hydroxycinnamic acid, elicited feeding responses from third-instar *C. partellus* larvae (Figures 4 and 5; Table 1). The dose–response curves of the phenols followed roughly the same pattern, reaching an optimum and then dropping. Analyses of variance indicated significant differences in feeding responses due to the two sets of treat-

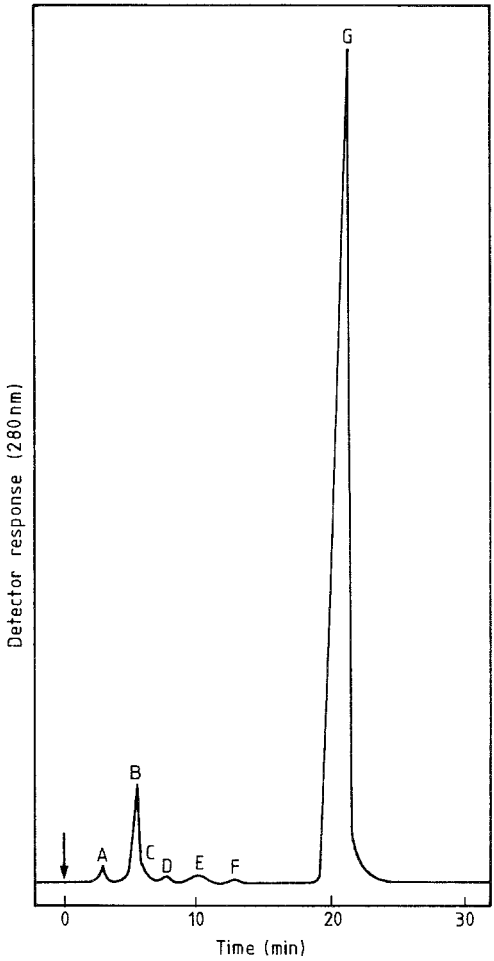

FIG. 3. Elution HPLC profile of the ethyl acetate extract of the leaf whorls of the 3-week-old plants of IS 18363 on a Zorbax C-18 column (25 cm × 4.6 mm). (A) unknown; (B) 4-hydroxybenzoic acid; (C) 3,4-dihydroxycinnamic acid; (D) unknown; (E) 4-hydroxy-cinnamic acid; (F) 4-hydroxy-3-methoxycinnamic acid; (G) 4-hydroxybenzaldehyde.

ment effects: dose ($F = 96.6$, $P < 0.0001$) and phenolic material ($F = 195$, $P < 0.0001$). There were also significant interactions between these effects, although Duncan's multiple-range procedure was able to separate the means computed from feeding rates over the whole dose range of the bioassays (Table 1).

4-Hydroxybenzaldehyde was the most stimulatory of the compounds. There

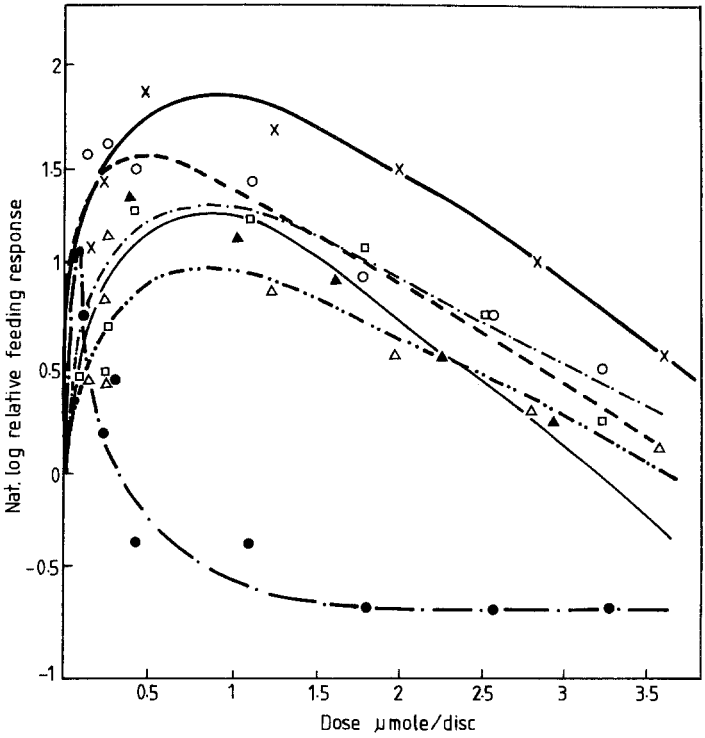

FIG. 4. Dose-response relationships for 4-hydroxybenzaldehyde, 4-hydroxybenzoic acid, and analogs. The relationships, derived by the least-squares procedure ($r^2 = 0.8405 - 0.9815$), represent plots of ln y versus x in the equation: $\ln y = \ln a + x \ln c + b \ln x$: ——— 4-hydroxybenzaldehyde (x); ----- 4-hydroxybenzoic acid (○); —··—·· 4-hydroxybenzyl alcohol (△); —·—·—· 4-methoxybenzyl alcohol (□); ——— 4-methoxybenzoic acid (▲); ——·——· 4-methoxybenzaldehyde (●).

was no significant oxidation of the aldehyde during the bioassay period; therefore the observed activity was essentially due to the aldehyde. Oxidation of the aldehyde to the corresponding acid and its reduction to the alcohol caused a significant drop in activity (Table 1). In contrast, a comparison of the activities of the methoxy derivatives of these compounds showed the opposite trend, the alcohol being most stimulatory and the aldehyde least.

For the cinnamic acids, 4-hydroxycinnamic acid was nonstimulatory at all the doses tested, but 4-hydroxy-3-methoxycinnamic acid and 3, 4-dihydroxycinnamic acid gave comparable feeding rates (Figure 5).

Comparison of hydroxybenzoic acid and its analogs with the cinnamic acids

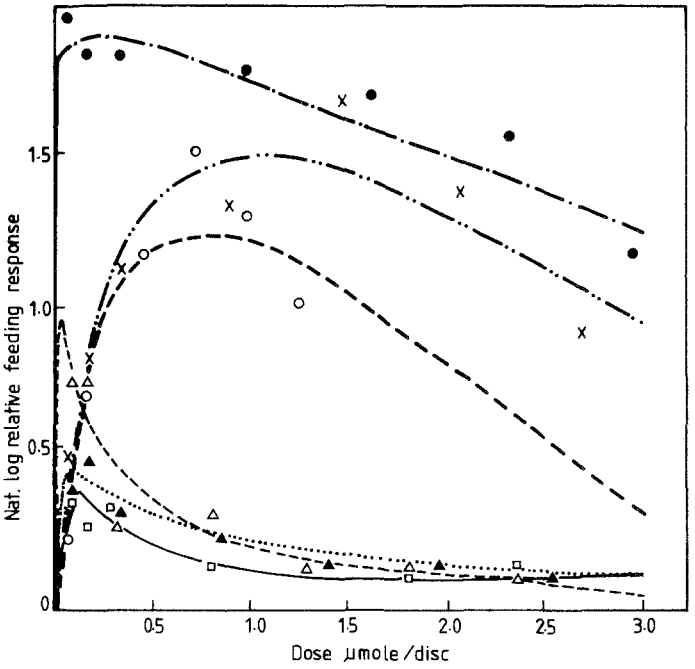

FIG. 5. Dose–response relationships for selected oxygenated benzoic and cinnamic acids and derivatives. The relationships, derived by the least-squares procedure ($r^2 = 0.8508 - 0.9069$), represents plots of ln y versus x in the equation: $\ln y = \ln a + x \ln c + b \ln x$; —·— 3,4-dihydroxybenzoic acid (●); —··— 4-hydroxy-3-methoxybenzoic acid (x); --- chlorogenic acid (○); ----- quinic acid (△); ····· 3,4-dihydroxycinnamic acid (▲); ——— 4-hydroxy-3-methoxycinnamic acid (□).

showed that the activities of the former differed significantly from those of the latter (Table 1). Hydroxybenzoic acids were generally more stimulatory than their corresponding cinnamic acids. Thus 4-hydroxy-3-methoxybenzoic acid was more stimulatory than 4-hydroxy-3-methoxycinnamic acid; 3,4-dihydroxybenzoic acid was more stimulatory than 3,4-dihydroxycinnamic acid; and whereas 4-hydroxybenzoic acid was a strong stimulant, 4-hydroxycinnamic acid was not stimulatory.

Of interest was the complete lack of response to 2,5-dihydroxybenzoic acid, a known phenolic constituent of sorghum seedlings (Woodhead and Cooper-Driver, 1979) but not encountered in the varieties studied in the present work. On the other hand, chlorogenic acid, which has not been reported as a

constituent of sorghum, and its degradative product, quinic acid, were both stimulatory.

DISCUSSION

Two groups of compounds are present in the ethyl acetate extracts of whole undamaged whorls of IS 18363, a cultivar of *S. bicolor* preferred by *C. partellus* larvae: phenolics and more polar, but not yet identified, components (Figure 2). The major phenolic feeding stimulants identified were 4-hydroxybenzaldehyde and 4-hydroxybenzoic acid. Interestingly, 4-hydroxybenzaldehyde has been shown previously to deter feeding by the locust *L. migratoria* and the aphid *Schizaphis graminum* (Woodhead and Bernays, 1978; Dreyer et al., 1981; Woodhead, 1982). On the other hand, Fisk (1990) found that a phenolic extract from sorghum was stimulatory to the homopteran *Peregrinus maidis*, and Baker et al. (1986) showed that 4-hydroxybenzaldehyde and some of its derivatives are strong feeding stimulants for the elm bark beetle *Scolytus multistriatus*. A range of allelochemics now has been demonstrated to play different and often opposite semiochemical roles in different insects (Janzen, 1979; Matsuda and Senbo, 1986; Norris, 1986; Whitman, 1988), reflecting differing evolutionary responses of these herbivores to defensive chemicals elaborated by plants.

The dose effect on the stimulatory activity of the phenolic compounds bioassayed in the present study is noteworthy. Of particular interest is the dose–response relationship of 4-methoxybenzaldehyde (Figure 4), which is stimulatory at very low doses but rapidly becomes a deterrent at higher doses. This pattern is probably replicated by some of the other compounds at sufficiently high doses and suggests that caution needs to be exercised in interpreting feeding response data based on a limited dose range that diverges appreciably from the concentrations of the allelochemics in natural systems.

Comparison of the stimulatory effects of benzoic and cinnamic acids shows that activity is dependent upon the nature and type of substitution in these compounds. Cinnamic acids were weaker feeding stimulants than the corresponding benzoic acids. The variation in the stimulatory activity of cinnamic acids suggests that the extra oxygen at the 3-position in the benzene ring may be crucial for the activity of this class of phenolic compounds. This would account for the significant stimulatory activity of 3,4-dihydroxycinnamic acid and 4-hydroxy-3-methoxycinnamic acid but lack of activity by 4-hydroxycinnamic acid. Conversely, all three corresponding hydroxybenzoic acids, including 4-hydroxybenzoic acid, demonstrated significant activities. The complete lack of feeding response to 2,5-dihydroxybenzoic acid indicates that the substitution patterns on the benzene ring for this class of compounds are important for their bioactivity to *C. partellus*.

Chlorogenic acid, a common plant constituent (Sondheimer, 1964), but so far not reported to be present in sorghum, previously has been found to play various roles in host plant selection by insects. Found in potato leaves, it is phagostimulatory to the Colorado potato beetle, *Leptinotarsa decemlineata* (Hsiao and Fraenkel, 1968). It also has been reported to be stimulatory to some leaf beetles such as *Gastrophysa atrocyanea* but deterrent to others such as *Lochmaeae capreae cibrata* (Matsuda and Senbo, 1986). Other workers have observed that the compound served as a growth factor for certain insects, e.g., silkworm larvae (*Bombyx mori*) (Kato and Yamada, 1968) and the potato aphid, *Macrosiphum euphorbiae* (Chawla et al., 1974). In the present study, it stimulated feeding by larval *C. partellus* and was a better stimulant than its degradative products, quinic and 3,4-dihydroxycinnamic acids (Figure 5; Table 1).

In summation, our results suggest that although structural requirements for activity within each phenolic group tested are relatively specific, the insect appears to perceive and respond to a relatively broad range of plant phenols, albeit to varying levels of sensitivity. The implications of these findings are not clear. At the chemoreception level, it may indicate the presence of several sets of receptors with different degrees of specialization for different structural types. Since larval *C. partellus* is an oligophagous insect that feeds on sorghum, maize, and some wild grasses, it is perhaps important that it should be able to recognize the different profiles of allelochemics it may encounter within its host range. Single-cell electrophysiological studies and identification and quantification of phenolic feeding allelochemics from different hosts might shed some light on these questions. In addition, the precise roles of these phenols in the feeding process and the way they interact with the polar and nonpolar groups of phagostimulatory compounds need detailed elucidation before a complete picture of factors governing host palatability to this insect can emerge.

(Received July 3, 1990; accepted August 20, 1990)

Abstract—The abilities of hatchling pine snakes (*Pituophis melanoleucus*) and king snakes (*Lampropeltis getulus*) to discriminate the chemical trails of pine and king snakes was investigated in Y-maze experiments. Pine snakes were housed for 17 days either with shavings impregnated with pine snake odor, king snake odor, or no odor to test for the effect of experience on choice. Both pine and king snake hatchlings entered the arm with the pine snake odor and did not enter the arm with the king snake odor. The data support the hypothesis that hatchlings of both species can distinguish conspecific odors from other odors and that our manipulation of previous experience was without effect for pine snake hatchlings.

Key Words—Chemical cues, pine snakes, king snakes, *Pituophis melanoleucus*, *Lampropeltis getulus*, experience.

INTRODUCTION

Following the trail of conspecifics or prey has been demonstrated in controlled laboratory experiments for snakes (Brown and Maclean, 1983; Chiszar et al., 1986; Ford, 1982; Ford and O'Bleness, 1986; Ford and Schofield, 1984; Gehl-

*To whom correspondence should be addressed.

bach et al., 1971; Heller and Halpern, 1981; Burger, 1989) and for lizards (Cooper and Vitt, 1986a). Reptiles respond to odors on applicators by increased activity or increased tongue flicks (Cooper and Vitt, 1984, 1985, 1986b; Cooper et al., 1986). These studies suggest the use of chemical-detecting abilities in several important contexts including recognition of prey (Burghardt, 1973; Chiszar et al., 1986), detection of conspecifics, (Cooper and Vitt, 1984), discrimination of male from female conspecifics (Cooper and Vitt, 1984), discrimination of conspecific and closely related syntopic congeners (Cooper and Vitt, 1986c), trailing conspecifics to find hibernacula (Brown and Maclean, 1983; Burger, 1989) or mates (Ford and O'Bleness, 1986), and differentiation of ophiophagous from nonophiophagous snakes (Weldon and Burghardt, 1979; Weldon, 1982; Cooper, 1990). For a further review, see Burghardt (1980) and Von Achen and Rakestraw (1984).

Snakes can distinguish conspecific from heterospecific odor trails (Ford and O'Bleness, 1986). Further, pine snake hatchlings avoid the odor trail of their predator, king snakes, and approach the odor trail of pine snakes (Burger, 1989). The influence of experience on scent-trailing by snakes has not been investigated. Since lizards or snakes are housed in cages, they have been exposed to odors of their own conspecifics for some time. Thus, previous experiments with chemoreception have not determined if the snakes were merely selecting a familiar odor and avoiding an unfamiliar one. In this paper we report experiments designed to examine discrimination by hatchling pine (*Pituophis m. melanoleucus*) and king (*Lampropeltis getulus*) snakes exposed to odors of adult pine and king snakes and to examine the role of previous experience on discrimination in pine snakes. King snakes prey on other species of snakes (Fitch, 1963; Ditmars, 1935); therefore, pine snakes should avoid the odor of king snakes and select the pine snake odor in Y-maze tests. King snake hatchlings may avoid the odor of conspecifics as they too may be eaten by adult king snakes. However, king snake odor would normally be the familiar odor for hatchling king snakes.

METHODS AND MATERIALS

Under appropriate state permits, pine snake eggs from 12 clutches were collected from the Pine Barrens of southern New Jersey (Ocean, Cumberland, and Monmouth counties). Eggs ($N = 78$) incubated at 28°C were hatched and maintained in the laboratory in 1988. Eggs ($N = 16$) from two female king snakes also were hatched in the laboratory. Snakes were maintained individually at 28°C in plastic cages (30 × 15 × 9 cm) containing pine shavings or paper. Snakes were given the opportunity to drink water. All snakes were tested when 17–20 days old, after they had shed but before they were fed. King snakes

were maintained in cages with paper not previously exposed to snake odors until testing.

Pine snake hatchlings from each clutch were divided randomly in three groups, and each group was assigned to one home cage shavings group. The three groups were: (1) shavings from a pine snake cage, (2) shavings from a king snake cage, and (3) clean shavings (control). Shavings for the experimental treatment groups were obtained by placing clean shavings 1.5 cm thick in the bottom of the cage of an adult pine or king snake and leaving them. Every five days the shavings in the adult pine (hereafter called pine snake shavings) and king (hereafter called king snake shavings) snake cages were changed, and the odorous shavings placed in zip-lock bags in a freezer. These shavings were then placed 1.5 cm thick in the bottom of the approximate pine snake hatchling cages from the time of hatching until testing.

There were four experiments: (1) pine snake hatchlings tested with a Y-maze choice of king snake versus pine shavings; (2) king snake hatchlings tested with a Y-maze choice of king snake versus pine snake shavings; (3) pine snake hatchlings tested with king snake and pine snake shavings from the freezer; and (4) pine snake hatchlings tested with king and pine snake shavings from the home cages of the pine snake hatchlings (after they had lived there for several days). This set of experiments was designed to test whether pine and king snakes distinguished odor from pine and king snake adults; whether previous experience affected pine snake hatchling choice; and whether pine snakes could distinguish (as measured by tongue flicks) the pine snake from king snake shavings and the used (in pine snake home cages) pine snake shavings from used king snake shavings.

To determine whether pine snakes could make directional responses to chemical trails, Y-maze experiments were conducted. The base arm of the Y maze was 1 m long and 15 cm wide, with 15 cm high wooden sides. At the end of the base arm were two side arms (experimental arms, 45° angle from the initial arm) having the same dimensions as the base arm. Clean shavings were placed in the base arm, and king snake shavings and pine snake shavings were each placed over paper in different experimental arms. The experimental shavings with the paper were changed after each trial, and the location of the adult-scented shavings was reversed between each trial.

In the Y-maze experiments each snake was introduced into the base arm facing the opening with its head at the entrance and allowed to move freely up the arm to the intersection, where it usually moved into one of the experimental arms. The trial ended when the snake left the Y maze through the experimental arms. The time each snake was in the base and experimental arm, time at the Y junction, and the number of tongue flicks when the snake was in each location were recorded. An assistant released the snake into the maze. Each snake was tested only once.

Following the Y-maze experiments, pine snakes were placed in a base arm of similar size containing either adult pine snake or adult king snake shavings, and we counted the number of tongue flicks per 15 sec when the snake was moving over the surface (after Cooper and Vitt, 1986d). The hatchling was first tested on the odor of one species and then on the other. The order of presentation was switched between each hatchling tested.

After this experiment, pine snakes were tested in the same apparatus using tongue flicks as a measure of response, but the shavings used were removed from all home cages and mixed by type (all pine snake shavings or all king snake shavings). These shavings, therefore, had been initially moved over by either an adult king snake or adult pine snake and subsequently moved over by pine snake hatchlings. This experiment was designed to determine if pine snake hatchlings were still able to distinguish the two adult odors on the shavings after several days of use by other hatchlings.

Chi-square tests were used to determine the significance of the response frequency in the Y-maze experiments, and Kruskal-Wallis tests were used to determine differences in central tendencies of time and tongue flicks in the experiments. Given are means $\pm$ one standard deviation in the text.

RESULTS

Most snakes moved rapidly in the base arm, remained motionless for a few seconds at the Y junction, explored the Y junction for a few more seconds, and then moved rapidly down one arm.

Pine snake hatchlings in the Y-maze experiment entered the side arm containing the pine snake shavings at significantly greater than chance frequency, regardless of the home cage shavings they had experienced (Table 1). Although more pine snakes that lived with king snake shavings entered the arm containing the king snake shavings than did those under the other rearing conditions, the differences were not significant. Six of the 10 snakes that entered the king snake arm backed up several times before moving to the end of the arm. Further, eight snakes that ultimately chose the pine snake side first started down the king snake side and backed up to the Y junction before going down the pine snake side.

Pine snake hatchlings behaved similarly in the base arm regardless of their ultimate choice (Table 2). Further, they behaved similarly at the Y junction, largely because, regardless of final choice, some snakes first started down both sides. However, hatchlings entering the king snake side moved more slowly and made significantly more tongue flicks than those entering the pine snake arm.

TABLE 1. RESPONSE OF PINE AND KING SNAKES IN Y-MAZE CHOICE TEST AND TONGUE FLICKS PER 15 SEC (MEAN ± 1 SD) FOR PINE SNAKES WHEN MOVING SLOWLY ON SHAVINGS

	Number of snakes	Arm entered: Pine snake shavings	Arm entered: King snake shavings	$\chi^2(P)$
Pine snake choice test				
Pine snake shavings	26	24	2	18.60 (0.001)
King snake shavings	26	20	6	7.52 (0.01)
No odor shavings	26	24	2	18.60 (0.001)
King snake choice test				
(no home cage shavings)	14	12	2	7.14 (0.01)
Pine snake tongue flicks				
Test shavings	78	18.2 ± 3.2	22.1 ± 3.9	5.96 (0.01)
Home cage shavings	27	19.3 ± 2.8	24.0 ± 2.1	4.35 (0.01)

King snake hatchlings in the Y-maze experiment also entered the arm containing the pine snake odor in a significantly greater number of trials than entered the arm containing the king snake odor (Table 1). Although sample sizes were small, king snakes emitted slightly more tongue flicks when in the king snake arm than when in the pine snake arm (Table 2), but sample sizes were too small to allow statistical evaluation.

Pine snake hatchlings emitted more tongue flicks per 15 sec in response to the king snake shavings than in response to the pine snake shavings (Table 1). In this experiment the shavings used were from the cages of adult king and adult pine snakes that were similar to those used in the Y-maze choice experiments. We then tested the hatchling pine snakes with shavings from the home cages of the hatchlings to detect whether there was still adult king and adult pine snake odor that the hatchlings could distinguish. These cage shavings had pine snake hatchlings moving on them for five days in addition to originally being in the cages of either an adult king or an adult pine snake. Pine snake hatchlings again gave significantly more tongue flicks to the king snake shavings compared to the pine snake shavings.

Previously it has been shown that pine snake hatchlings prefer to enter the arm with a conspecific when given a choice of conspecific versus no odor; they avoid king snake odor when given a choice of king snake versus no odor (Burger, 1989). This experiment was designed to test the effect of previous experience with the odors of king and pine snakes.

TABLE 2. TIME SPENT AND NUMBER OF TONGUE FLICKS EMITTED BY SNAKES IN Y MAZE WHEN GIVEN A CHOICE OF KING OR PINE SNAKE ODOR[a]

[a] Statistical test not performed because of small sample sizes. Given are means ± 1 SD for the choice they made. Tongue flicks are per 15 sec NS = not significiant.

DISCUSSION

This set of experiments, in conjunction with previous experiments (Burger, 1989), shows that: (1) Both pine and king snake hatchlings select the pine snake arm more frequently than the king snake arm. (2) Pine snake hatchlings prefer the pine snake shavings even when they are reared since hatching on shavings with a king snake odor. Thus, pine snakes are not merely responding to familiar

odors (in some cases, their own), but are responding to the specific odors. (3) Pine snake hatchlings distinguish between the odors by giving more tongue flicks to the king snake shavings compared to the pine snake shavings. (4) Pine snake hatchlings can distinguish king snake odor from pine snake odor even though the shavings have been in cages of hatchling pine snakes for several days. This is the first study to demonstrate differential selection of chemical odors that were over five days old, and it demonstrates a preference for pine snake odors regardless of previous experience.

Given the previous tests (Burger, 1989), the present experiment shows that hatchling pine and king snakes select and follow the shavings containing the chemical odor of an adult pine snake and avoid the shavings containing the chemical odor of an adult king snake. Pine and king snake hatchlings emerge from their nests in late August and early September and find hibernacula in the next few weeks (Burger et al., 1988). New Jersey pine snakes hibernate in underground burrows that they dig themselves, although elsewhere gopher snakes (*Pituophis m. deserticola*) hibernate in mammal burrows with other species of snakes (Brown et al., 1974; Parker and Brown, 1973; Burger et al., 1988).

Pine snakes in New Jersey hibernate in dens with up to 25 pine snakes and three king snakes (Burger et al., 1988), thus it would be adaptive for both species to be able to follow very weak trails of pine snake. A naive hatchling wandering about the pine barrens may come across chemical trails of only a few pine snakes. In the present Y-maze experiment the chemical odor on the shavings was five days old, yet both pine and king snakes chose the pine snake arm and avoided the king snake arm. Thus the odor was sufficiently strong to be assessed five days later. Further, both king and pine snake hatchlings distinguished five-day-old odors of adult pine and king snake as measured by tongue flick rates.

King snakes prey on other species of snakes (Fitch, 1963; Ditmars, 1935), including pine snakes in the pine barrens. Presumably, they would also prey on conspecifics. Indeed, after our experiments, one of the king snake hatchlings ate one of the other king snake hatchlings. Thus hatchlings of both species have an adaptive reason for avoiding king snake trails. Our results with tongue flicks of pine snake hatchlings corroborate findings of a greater tongue flicking response by squamates to potential predators. Naive garter snakes (*Thamnophis elegans*) (Weldon, 1982) and adult skinks (*Eumeces laticeps*) (Cooper, 1990) emitted significantly more tongue flicks to swabs rubbed against the skin of king snakes than to those from nonophiophagous snakes or blank swabs.

One objective of the study was to determine the role of prior experience in the choice experiments. Hatchling pine snakes caged for 17 days with shavings with odors of either pine or king snake showed similar responses to the choice test; all preferred the pine snake odor. Thus prior experience with a

familiar odor did not alter their choice. Moreover, we found that pine snake hatchlings were able to distinguish the pine snake from the king snake odor even though the shavings had been in cages of hatchling pine snakes for several days.

Acknowledgments—We thank R.T. Zappalorti for help while collecting the pine and king snake eggs.

Abstract—Matsunone, (2*E*,4*E*)-4,6,10,12-tetramethyl-2,4-tridecadien-7-one, is the primary sex pheromone of *Matsucoccus resinosae*, *M. thunbergianae*, and *M. matsumurae*. The synthetic compound was tested in the laboratory and in field tests with all three species, and significantly more males responded to synthetic matsuone than to controls. The attraction of synthetic matsuone to males in field tests was not significantly different from that of virgin females at the same matsuone release rate. An analog of matsuone previously shown to be biologically active was also tested in the laboratory with *M. resinosae* and *M. thunbergianae*, and field tested with *M. resinosae*. The active analog required a dose approximately 100 times greater than matsuone to yield maximum laboratory bioassay response, and in field tests, attraction was not significantly different from controls at doses at which matsuone was significantly attractive.

Key Words—*Matsucoccus resinosae*, *M. thunbergianae*, *M. matsumurae*, Coccoidea, Margarodidae, scale insects, pine bast scales, sex pheromone, (2*E*,4*E*)-4,6,10,12-tetramethyl-2,4-tridecadien-7-one, matsuone.

INTRODUCTION

Pine bast scales in the genus *Matsucoccus* Cockerell are major pests of pine in France (Carle, 1968, 1974), Israel (Mendel et al., 1988), Korea (Park, 1988), China (Li et al., 1980), and the United States (Bean and Godwin, 1955; McClure, 1976, 1983b). Studies on the chemical communication of these insects began with Doane's (1966) report of a female-produced sex attractant for *Matsucoccus resinosae* Bean and Godwin. Sex pheromones have since been documented in *M. matsumurae* (Kuwana) (Qi et al., 1983), *M. thunbergianae* Millar and Park (Park et al., 1986), *M. massonianae* Young et Hu (Young and Qi, 1983), and *M. josephi* Bodenheimer and Harpaz (Sternlicht et al., 1983). Although a taxonomic revision has not been formally proposed, *M. matsumurae* and *M. resinosae* are almost certainly the same species (McClure, 1983a; Young et al., 1984).

Park et al. (1986) reported the isolation of the sex pheromone of *M. resinosae* and the demonstration of its cross-attractiveness with *M. thunbergianae*. Spectral data available to Lanier et al. (1989) reduced the number of possible structures for this compound to four: **1, 2, 3** and **4** (Figure 1). On the basis of strong circumstantial evidence, Lanier et al. (1989) identified the pheromone of *M. resinosae*, *M. matsumurae*, and *M. thunbergianae* as (2*E*,4*E*)-4,6,10,12-tetramethyl-2,4-tridecadien-7-one (**1,** Figure 1), and gave it the trivial name matsuone. Although we were successful in synthesizing two analogs of this structure (**3** and **4,** Figure 1) and demonstrating biological activity with one of them (**3**), the compound we proposed as the true pheromone (**1**) in Lanier et al. (1989) was not available for testing. We recently synthesized matsuone (**1**) (see Figure 1) and its geometric isomer (2*E*,4*Z*)-4,6,11,12-tetramethyl-2,4-tridecadien-7-one (**2**) (Webster et al., 1990). We report here laboratory and field tests of three species of *Matsucoccus* pine bast scales with the two new synthetic compounds (**1** and **2**) and those analogs (**3** and **4**) tested by Lanier et al. (1989).

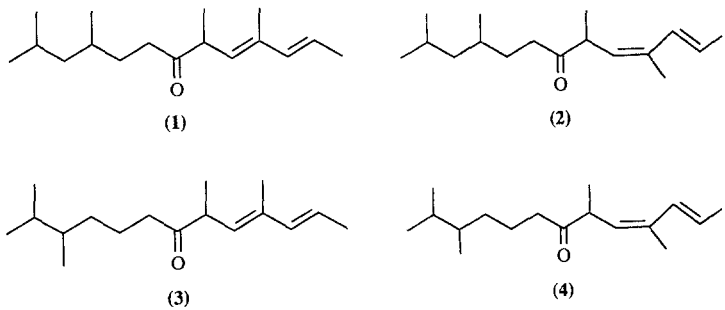

FIG. 1. Chemical structures of matsuone and the three analogs tested.

METHODS AND MATERIALS

Field Sites and Insect Sources. Field experiments were conducted in Dutchess County, New York, U.S.A., from June 7 to September 15, 1989; in Tonggang County, Chonnam Province, Korea, from April 5 to 7, 1989; and the suburbs of Wu Xi City, China, from April 25 to 27, 1989 for *M. resinosae*, *M. thunbergianae*, and *M. matsumurae*, respectively. Infested branches of *Pinus resinosa* Ait., *P. thunbergiana* Franco, and *P. tabulaeformis* Carr. containing cocoons of *M. resinosae*, *M. thunbergianae*, and *M. matsumurae*, respectively, were placed in emergence cages similar to those described by Lanier et al. (1989). Males emerging from the cocoons were tested in laboratory behavioral bioassays.

Laboratory Bioassays. The bioassay procedures used for *M. resinosae* and *M. thunbergianae* were those of Park et al. (1986) and Lanier et al. (1989). First, the test compound in 1 μl hexane in a micropipet was deposited just inside the tip of a medicine dropper. Excess hexane was expelled by depressing the bulb of the medicine dropper 20 times, and the dropper was positioned about 8 mm to one side of a pedestrian male. Puffs of air were delivered to the antennae of the pedestrian male by gently pressing the bulb at 1.5-sec intervals. Relative attraction was measured as the number of sides of a 4-cm-equilateral triangle along which a male would follow the retreating dropper tip. The highest response rating, three, indicated that the male followed the dropper for all three sides of the triangle, and the lowest response rating, zero, indicated no attraction. Incomplete following of the dropper along a side of the triangle was designated by the fraction of the side completed. For *M. thunbergianae*, males showing the response score of three to 2×10^{-3} female equivalents (see Lanier et al., 1989) were tested, while with *M. resinosae*, the positive control was a live virgin female placed in the dropper tip.

Bioassays with *M. matsumurae* in China used the method of Qi et al. (1983) and Lanier et al. (1989). Two filter paper disks of 1 cm diameter, each containing one of two materials or one material and a solvent blank, were placed into a 7-cm-diameter Petri dish. After the solvent had evaporated, 10 males were introduced and the Petri dish was covered. The behavior of males in the dish was observed, and the number of males on each of the disks was recorded after 10 min.

Field Experiments. In Korea, the field experiments were performed in a *P. thunbergiana* forest with trees approximately 8 m tall. White plastic cards (10 $\times$ 14 cm) coated with Tanglefoot were affixed to horizontal bamboo poles 0.5 and 1.5 m above the ground. Traps were set in open areas of 15–40 m diam. and 7–20 m away from the trees. Treatments were assigned randomly on the poles so that each pole contained one replicate with different treatments spaced 1 m apart on the pole. Unbaited traps were placed in the field at 6 pm, April

5, 1989. Treatments of 222 μg matsuone in 60 μl benzene on rubber GC septa (Supelco Inc., Bellefonte, Pennsylvania), 60 μl benzene on rubber GC septa, and 20 newly emerging females in a 2 × 2 × 0.5-cm fine net cage were replicated 10 times: five each at 0.5 and 1.5 m above the ground. Emerging females used as baits were collected between 8:00 and 9:30 AM, April 6. Baits were attached with pins to the lower portion of the sticky traps between 9:30 and 10:00 AM, April 6. Those males that were caught on untreated traps in the early morning were removed as the baits were set. Counts of these traps were then made between 12:00 and 1:00 PM on both April 6 and 7 by removing the males from the traps during counting.

In China, the field trapping experiments were conducted in a suburban forest of *P. tabulaeformis*. Three replications of the following six treatments were tested: 1, 10, and 40 μg matsuone on filter paper, one and five newly emerged females, and a benzene control. The trap, a piece of sticky cardboard (28 × 23 cm) folded in the middle at a 60° angle, was similar to that described by Lanier et al. (1989). Three 1-cm-diam. holes were cut into each flap, and a roll of filter paper (5 × 0.8 cm) that served as the pheromone dispenser was hung inside the trap. Traps were hung from pine branches at heights between 1.5 and 2 m. Distance between traps was greater than 20 m.

In New York, traps placed 2.44 m high were positioned between 1 and 2 m from the nearest branches and were at least 1.5 m from each other within a small planting of *P. resinosae*. Most of the trees were widely spaced, so that the crown was visible to the ground. Since *M. resinosae* usually occurs in the crowns, this site was ideal for setting traps at reasonable heights. Tree height at the site ranged from 1.5 m to 20 m. Dewill elm bark beetle traps (Dewill Inc., Elmhurst, Illinois) were cut into thirds (sticky surface of 20 × 48 cm), formed into cylinders 15 cm in diameter with the sticky surface facing outward, and stapled around a vertical pole 2.44 m in height. The baits were protected from the sun by fastening them with wire approximately 2 cm within inverted plastic film canisters (3 cm diam. × 4.8 cm). The bait apparatus then was stapled to the pole so that it was situated inside the sticky cylinder. Trials with live females as a treatment were set up between 8:00 and 9:30 AM, and results were recorded after 1:00 PM. Trials without live females were set up between 1:30 and 5:30 PM, and results were recorded after several days.

The first field experiment in New York tested the relative attraction of 25 μg matsuone (**1**), 250 μg matsuone, 25 μg **2**, 250 μg **2**, and a hexane control. Rubber GC septa served as the pheromone dispenser. Five replications of this experiment were set up on June 8 and dismantled on June 15. Ten more replications were set up on June 20 and dismantled on June 25.

We next compared known quantities of matsuone with attraction to live adult females. Six replicates of 20 live females each (collected between 6:30 and 8:30 AM on August 15, 1989) were placed in fine netting and added to the

traps along with baits by 9:30 AM. Four doses of matsuone were chosen and replicated 10 times: 10, 50, 100, and 250 μg. Trap catch was recorded between 1:00 and 2:00 PM the same day. The pheromone dispenser for this experiment was a cotton dental wick (Healthco International, Boston, Massachusetts). The last experiment reported herein tested 200 μg each of matsuone (**1**), a hexane control, and **2, 3,** and **4** on rubber GC septa. The experiment was set up September 15 and dismantled September 25.

Release Rate Determination. The relative release rates of matsuone from rubber septa, dental cotton wicks, and filter paper were determined in the laboratory. Matsuone was added to the dispensers, and they were immediately placed in a 250-ml Erlenmeyer flask that was protected from UV radiation with aluminum foil. Each of the dispensers was tested with 250 μg of matsuone, and filter paper was also tested at 40 μg because this dose was effective for trapping males in China. There were four replicates of each dispenser at each dose tested. House vacuum pulled room air through activated carbon (6–14 mesh), past the dispensers, and through 0.6 g Porapak Q, on which matsuone was collected. Flow through the flask was held constant at 100 ml/min. Temperature was held constant at 20 $\pm$ 2°C. Volatiles were recovered from the Porapak with 4 ml of pentane. Extractions were made after 24, 48, and 72 hr for each dispenser, and also at 168 hr for rubber septa. The concentration of matsuone in the samples was determined with an HP 5890 gas chromatograph fitted with a 50-m methyl silicon capillary column (DB-1, Supelco, Inc., Bellefonte, Pennsylvania) with 1 ng/μl *n*-octadecane as an internal standard.

Statistical Analysis. The statistical package SAS (SAS Institute, 1985) was used for data analysis. All field data were analyzed with one-way or two-way analysis of variance (ANOVA), then by Duncan's (1955) multiple-range test when significant F values were found in the ANOVA. The trap-catch data were subject to log $(X + 1)$ or square root $(X + 0.5)$ transformations as needed to meet the assumption of equal variance (Winer, 1971). Nonparametric procedures were required for analysis of laboratory bioassays with *M. resinosae* and *M. thunbergianae*. A rank transformation followed by the procedures above served this purpose (Conover and Iman, 1981; SAS Institute, 1985, p. 19).

RESULTS

Laboratory Bioassays. In bioassays with *M. thunbergianae* in Korea, responses of pedestrian males to all doses of matsuone tested except the lowest dose, 0.04 pg, were significantly higher ($P < 0.05$) than the control (Table 1). Maximum responses to matsuone were elicited by doses of 4.0 pg to 0.40 ng, while the dose required for maximum response to **3** was about 0.50 ng. Differences in attraction between the highest dose of **3** (0.50 ng) and doses of mat-

TABLE 1. MEAN RESPONSES IN LABORATORY BIOASSAYS OF *Matsucoccus thunbergianae* MALES TO DILUTIONS OF MATSUONE AND ANALOG **3**[a]

Material	Quantity (pg)	No. tested	Mean response ± SE
Hexane		24	0.06 ± 0.03 E
Matsuone	4.0×10^{-2}	24	0.21 ± 0.07 DE
	4.0×10^{-1}	24	1.08 ± 0.23 C
	4.0×10^{0}	24	2.88 ± 0.09 A
	4.0×10^{1}	24	2.73 ± 0.15 A
	4.0×10^{2}	24	2.79 ± 0.11 A
	4.0×10^{3}	24	2.04 ± 0.24 B
Analog **3**	5.0×10^{-1}	24	0.15 ± 0.05 E
	5.0×10^{0}	24	0.42 ± 0.10 D
	5.0×10^{1}	24	1.98 ± 0.22 B
	5.0×10^{2}	24	2.69 ± 0.15 A

suone from 4.00 pg to 0.40 ng were not significant.

In bioassays with *M. resinosae* in the United States, responses to doses between 50.0 pg to 5.0 ng of matsuone, and between 5.0 ng and 50.0 ng of **3** were not significantly different from the positive control of a live female (Table 2). All doses of **2** and **4** elicited lower ($P < 0.05$) responses than a live female. All doses of matsuone and doses of 50.0 pg, 5.0 ng, and 50.0 ng of **2** gave greater responses than the hexane control. No dosage of **4** gave response significantly greater ($P < 0.05$) than the hexane control. For **2** and **3,** responses to all doses from 50.0 pg to 50.0 ng were higher ($P < 0.05$) than to the hexane control.

Laboratory bioassays in China utilizing the Petri dish bioassay indicate that *M. matsumurae* are significantly attracted to matsuone (Table 3). At all doses tested except the lowest dose (10 ng), more ($P < 0.01$) males were attracted to filter paper disks containing matsuone than to disks with benzene alone. Increasing the dosage of matsuone increased the number of males on the matsuone disk. In a choice test comparing 0.20 μg matsuone with 5 female equivalents (see Lanier et al., 1989) of crude extract, there was no significant difference between the number of males on the two filter paper disks. When comparing 0.20 μg matsuone in choice tests with 8.0 μg **3,** significantly more males were found on the filter paper disk with 0.2 μg of matsuone.

Field Tests. In field tests with *M. thunbergianae* in Korea, significantly more males were caught in traps baited with 222 μg matsuone 0.5 m from the ground than all other traps (Figure 2). Traps baited with 20 live females placed

at 0.5 m also caught more ($P < 0.05$) males than controls, but there was no significant difference between any treatments placed at 1.5 m.

In China, traps baited with 10 and 40 μg of matsuone caught significantly more male *M. matsumurae* than control traps, traps with 1 female, and traps with 1 μg of matsuone (Figure 3). Differences between traps with 10 and 40 μg of matsuone and traps with five females were not significant, nor were differences between traps with 1 μg of matsuone and control traps. Traps with one or five females caught significantly more males than control traps.

In the United States, significantly more ($P < 0.05$) male *M. resinosae* were caught on traps baited with 250 μg of matsuone than those baited with 25

* = significantly different from zero ($P < 0.01$).

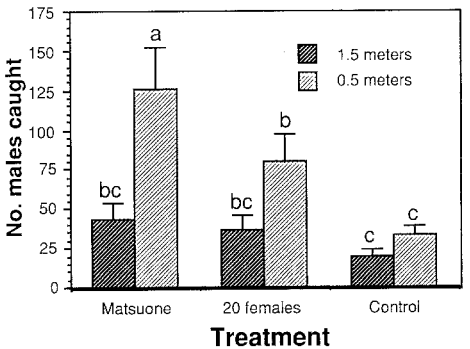

FIG. 2. Number of male *M. thunbergianae* caught in traps baited with 222 μg matsuone on rubber septa, 20 live females, and a solvent control. Although raw data are shown, statistical analysis was performed on log $(X + 1)$ -transformed data. Bars topped by different lowercase letters are significantly different ($P < 0.05$) as indicated by Duncan's (1955) numerical multiple-range test. Standard error bars are indicated.

μg matsuone, 25 μg **2**, 250 μg **2**, or a hexane control (Figure 4); no other significant differences were found. In dose–response tests using cotton dental wicks as the pheromone dispenser, there was no significant difference between traps baited with 100 and 250 μg matsuone, and there was no difference between control traps and traps with 20 live females (we cannot explain this last result).

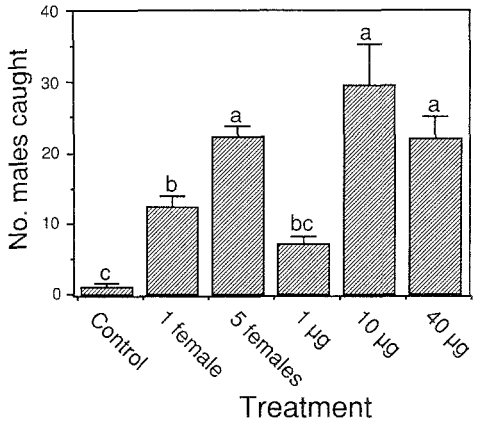

FIG. 3. Number of male *M. matsumurae* caught in traps baited with matsuone on filter paper or live females. Bars topped by different lowercase letters are significantly different ($P < 0.05$) as indicated by Duncan's (1955) numerical multiple-range test. Standard error bars are indicated.

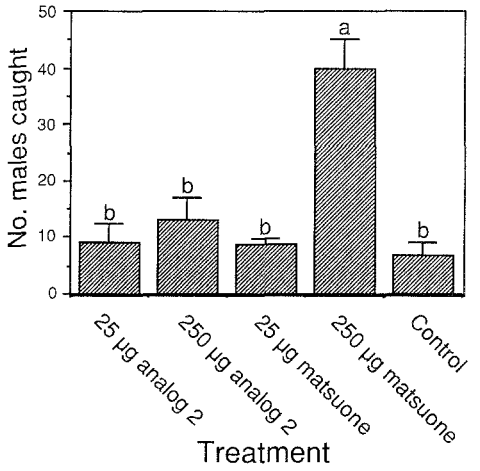

FIG. 4. Number of male *M. resinosae* caught in traps baited with matsuone, **2**, or solvent on rubber septa. Although raw data are shown, statistical analysis was performed on square root ($X + 0.5$) -transformed data. Bars topped by different lowercase letters are significantly different ($P < 0.05$) as indicated by Duncan's (1955) numerical multiple-range test. Standard error bars are indicated.

All other differences were significant (Figure 5), including the difference between male catches on traps baited with 10 μg matsuone and control traps. A regression of the dose-response curve was significant ($P < 0.05$) with an R^2 of 50.9%. In a similar experiment in which all analogs were tested, more males ($P < 0.05$) were caught on traps baited with matsuone than traps baited with any analog. There was no significant difference between catches on traps baited with **2, 3, 4,** and the hexane control (Figure 6).

Release Rates. The release rate of matsuone from filter paper rolls and dental cotton wicks was significantly greater than that from rubber GC septa (Supelco, Inc., Bellefonte, Pennsylvania) for each of the first three days (Table 4). Significantly more matsuone was released from cotton wicks than filter paper on day 2, but there was no significant difference on days 1 or 3. The release rate of 40 μg matsuone from filter paper was higher than that of 250 μg matsuone from rubber septa on day 1, but this difference was not significant on day 2 or day 3. The average release rate from rubber septa from days 4–7 was equivalent to that released from rubber septa on day 2.

DISCUSSION

Park (1988) placed newly emerged *M. thunbergianae* females in a device designed to collect the female sex pheromone on filter paper. The filter paper was extracted with hexane, and 5×10^{-3} female hour equivalents (FHE) yielded

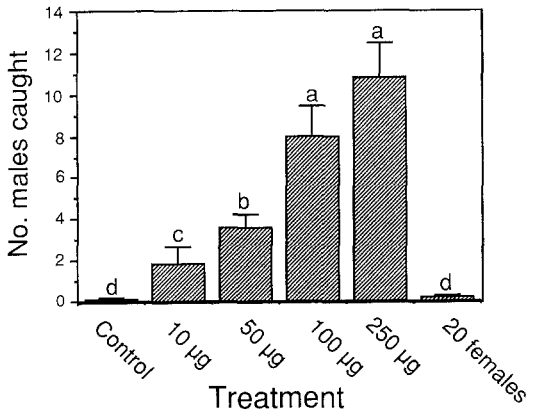

FIG. 5. Number of male *M. resinosae* caught in traps baited with live females or different doses of matsuone on cotton dental wicks. Although raw data are shown, statistical analysis was performed on log $(X + 1)$ -transformed data. Bars topped by different lowercase letters are significantly different ($P < 0.05$) as indicated by Duncan's (1955) numerical multiple-range test. Standard error bars are indicated.

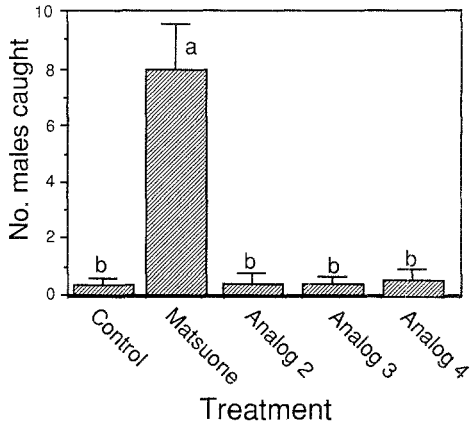

FIG. 6. Number of male *M. resinosae* caught in traps baited with 200 μg of matsuone and three analogs on rubber septa. Although raw data are shown, statistical analysis was performed on log $(X + 1)$ data. Bars topped by different lowercase letters are significantly different $(P < 0.05)$ as indicated by Duncan's (1955) numerical multiple-range test. Standard error bars are indicated.

TABLE 4. RELEASE RATE OF MATSUONE FROM PHEROMONE DISPENSERS AS MEASURED IN THE LABORATORY

Dispenser type	Load rate (μg)	Release rate (μg/day ± SE)			
		Day 1	Day 2	Day 3	Days 4–7
Rubber septa	250	1.50 ± 0.60ef	0.41 ± 0.03fg	0.12 ± 0.02g	0.41 ± 0.09e
Cotton wick	250	12.52 ± 2.84ab	8.93 ± 0.29bc	1.98 ± 0.29e	
Filter paper	250	17.03 ± 1.68a	3.95 ± 0.80d	1.06 ± 0.19ef	
Filter paper	40	6.15 ± 0.96d	1.09 ± 0.90ef	0.25 ± 0.10fg	

an average response of 2.2 in the same bioassay as used in the present study (5×10^{-2} FHE gave an average of 3.0). This response is equivalent to the response of *M. thunbergianae* males to 4.0 pg of matsuone and *M. resinosae* males to 50.0 pg matsuone reported herein. If we assume that all of the sex pheromone was collected on the filter paper in Park (1988) and that matsuone is the only active compound, we can estimate the production of matsuone (based on the level of response) to be in the range of 0.8 ng/hr for *M. thunbergianae* and 10 ng/hr for *M. matsumurae* and *M. resinosae*.

Because we determined the release rate of matsuone from the dispensers utilized in the present study (Table 4), we can compare the field trap catch of

synthetic matsuone to that of natural matsuone. The field tests in China were conducted for three days, so if we use the release rate of 40 μg matsuone from filter paper from day 2 as an average, approximately 54 ng/hr of synthetic matsuone were released (Table 4). *M. matsumurae* females produce approximately 10 ng/hr, so the five females tested would have produced approximately 50 ng/hr of natural matsuone (a conservative estimate given our assumptions). The number of male *M. matsumurae* caught on traps baited with five females and those baited with 40 μg matsuone on filter paper were not significantly different. In experiments in Korea with *M. thunbergianae*, septa were loaded with matsuone the afternoon before being applied to the traps, and the experiments were set up for two days, so it is again appropriate to use the release rate data from day 2. The release rate of matsuone from rubber GC septa on day 2 was approximately 17 ng/hr (Table 4), while the calculated release rate of 20 female *M. thunbergianae* would be approximately 16 ng/hr. Both traps baited with 20 females and traps baited with 222 μg synthetic matsuone on rubber GC septa caught significantly more males than control traps at 0.5 m in height. Traps baited with synthetic matsuone also caught significantly more males than traps baited with 20 females at 0.5 m (Figure 2), but this difference in trap catch was not significant when data from both heights (0.5 and 1.5 m) are pooled. If our calculation of the release rate of matsuone from these *Matsucoccus* spp. is correct, it appears that matsuone can account for all of the attraction to female-baited traps.

Demonstrating biological activity of the synthetic compound is crucial to verifying the identification of a pheromone. We have shown that synthetic matsuone is significantly attractive to three species of pine bast scales in laboratory and field tests, and we have shown that matsuone can account for all of the attraction of live females in the field. We have corroborated the conclusion of Lanier et al. (1989) that (2*E*,4*E*)-4,6,10,12-tetramethyl-2,4-tridecadien-7-one is the major sex pheromone of *M. resinosae*, *M. thunbergianae*, and *M. matsumurae*. Lanier et al. (1989) were correct in their prediction that matsuone would show much higher activity than its analogs. In laboratory bioassays with both *M. resinosae* and *M. thunbergianae*, the dose of **2** (the most active analog) required to produce a full response was approximately 100 times greater than that required for matsuone. In field trials with *M. resinosae* with 200 μg of all analogs present on rubber septa, only traps baited with matsuone caught significantly more males than the control.

The final identification step is also the first step in the utilization of semiochemicals in integrated pest management. Synthetic pheromones have been produced for a number of other Coccoidea and have been successfully incorporated into management programs (for detection and monitoring) for the citrus mealybug, *Planococcus citri* (Risso) (Ortu and Delrio, 1982); the citrophilous mealybug, *P. calceolariae* Mask. (Rotundo et al., 1979); the San Jose scale,

Quadraspidiotus perniciosus (Comstock) (Angerilli and Logan, 1986; Pfeiffer 1985); and the California red scale, *Aonidiella aurantii* (Maskell) (Ervin et al., 1985; Moreno and Kennett, 1981, 1985; Sternlicht et al., 1981). Sex pheromones have even been used for mating disruption for the California red scale (Bar-Zakay et al., 1989). Synthetic matsuone produced by Webster et al. (1990) trapped significantly more male *M. resinosae*, *M. thunbergianae*, and *M. matsumurae* than control traps in the present experiments. The results from the present paper indicate that synthetic matsuone may be a valuable component in the management programs of *M. resinosae*, *M. thunbergianae*, and *M. matsumurae*.

Acknowledgments—We thank Aijun Zhang for synthesizing the matsuone and **2** used in this study, Mr. Ray Vaughan from the Department of Environmental Conservation at Stonykill for help in locating field sites in New York, Mr. Randy Randazzo from the Sprout Lake Camp and Mr. Dick Conkline for cooperation in using their land for field sites in New York. We also thank Mr. Conkline for permission to down red pine trees for laboratory work. Mr. Hyung-Sun Kim from the Chonnam Forest Experiment Station assisted in the Korean field tests. Funding was provided in part by a grant from the National Science Foundation and the Department of Entomology, Forestry Research Institute of Korea.

(Received May 23, 1990; accepted August 20, 1990)

Abstract—Structure–activity relationships for 6-, 7-, 8-, and 9-alkyl substituted analogs of (*Z*)-5-decenyl acetate, a pheromone component of the turnip moth, *Agrotis segetum*, have been studied by electrophysiological single-sensillum recordings, and interpreted in terms of a receptor–interaction model. The compounds were prepared by alkenyl cuprate reactions with α,β-unsaturated carbonyl derivatives or alkyl halides. The electrophysiological results indicate steric repulsive interactions between the alkyl groups and the receptor in all the positions studied. This demonstrates a high complementarity between the receptor and the terminal alkyl chain.

Key Words—Structure–activity, single-sensillum recordings, receptor interaction, pheromone, (*Z*)-5-decenyl acetate, alkenyl cuprate, alkyl substitution, *Agrotis segetum*, Lepidotera, Noctuidae.

INTRODUCTION

(*Z*)-5-Decenyl acetate (**1**) is a pheromone component of the turnip moth, *Agrotis segetum* (Bestmann et al., 1978; Arn et al., 1980; Löfstedt et al., 1982). In previously reported structure–activity studies on analogs of compound **1**, we

*To whom correspondence should be addressed.

0098-0331/91/0100-0103$06.50/0

have developed a receptor-interaction model based on the analysis of single-cell data and molecular mechanics calculations. With this model a strong correlation was established between measured single-cell activities and calculated conformational energies required by the analogs to structurally mimic a particular conformation of the natural pheromone component (Liljefors et al., 1985; Bengtsson et al., 1987). This conformation is shown in Figure 1. The model has been applied successfully to chain-elongated (Liljefors et al., 1985, 1987), chain-shortened (Bengtsson et al., 1990), and dienic analogs (Bengtsson et al., 1987), and to configurational isomers (Liljefors et al., 1987), and is furthermore supported by studies on conformationally constrained cyclohexene analogs of **1** (Bengtsson, 1988).

The results of these investigations have provided information about the dimensions and 3D shape of the receptor cavity tuned to (*Z*)-5-decenyl acetate. In particular, our studies on chain-shortened analogs indicate that the terminal alkyl chain interacts with a highly complementary hydrophobic "pocket" approximately extending over the two methylene units of **1** closest to the terminal methyl group (Bengtsson et al., 1990).

In the present study, branched alkyl analogs **2–10** (Figure 2) of compound **1** were synthesized and employed to further characterize the nature of the interaction between the substrate and its receptor, and the degree of complementarity between the terminal alkyl chain and the receptor. These analogs are monomethyl substituted in the 9-, 8-, 7-, and 6-positions (compounds **2–5**) and geminally dimethyl substituted in the 9-, 8-, and 7-positions (compounds **6–8**). The series also includes analogs with ethyl substitution in the 8-position (**9**) and propyl substitution in the 7-position (**10**). The receptor responses to the structural variations were determined by the electrophysiological single-sensillum (single-cell) technique.

Three major effects on the activity may be anticipated for alkyl-substituted analogs of the natural pheromone component **1.** Alkyl substitution increases the lipophilicity of the substrate and the affinity for a lipophilic (hydrophobic) receptor site should increase. Secondly, steric repulsive interactions between

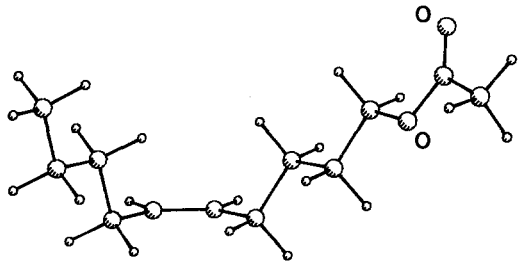

FIG. 1. The deduced biologically active conformation of (*Z*)-5-decenyl acetate.

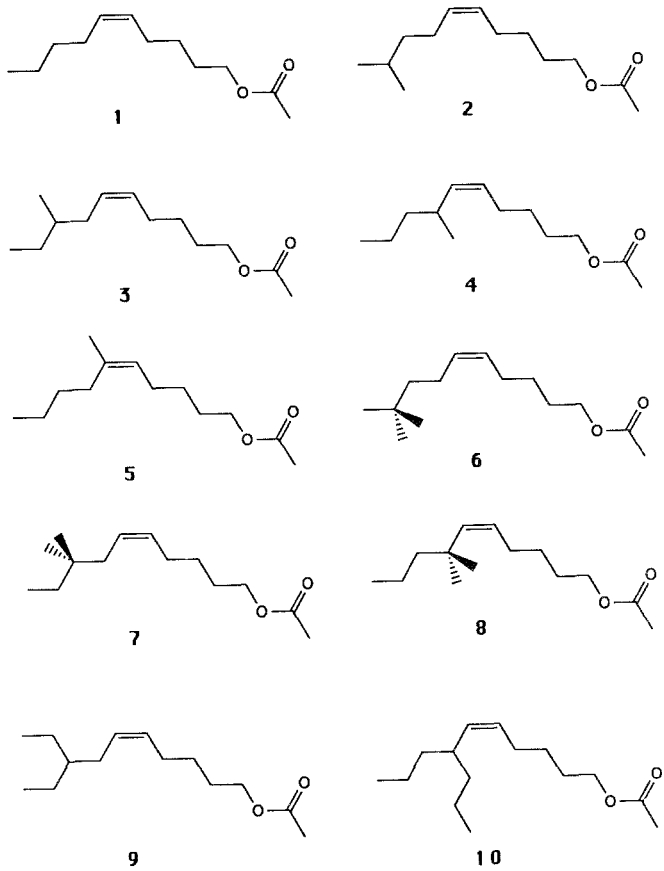

FIG. 2. Compounds studied.

the alkyl substituent and the receptor may cause a decrease or even complete elimination of the activity. Finally, the energy required by an alkyl substituted analog to acquire the biologically active conformation may be high due to steric repulsive interactions caused by the alkyl substituent. This, of course, decreases the activity. In the present study we have attempted to separate the latter two effects by calculating the required energy by the molecular mechanics method using the conformation shown in Figure 1 as a template for the biologically active conformation.

Structure–activity relationships for alkyl-branched pheromone analogs of the monoene acetate type have been reported previously by Priesner et al. (1977), Bestmann et al. (1979, 1980), and Schwarz et al. (1989). The extensive studies performed by Priesner et al. and Bestmann et al. on monoalkyl-substi-

tuted pheromone components of various species of Noctuidae, Tortricidae, and Cochylidae are based exclusively on electroantennographic (EAG) data, while the study by Schwarz et al. (1989) employs flight tunnel and male sex stimulation assays. Such data cannot be directly interpreted in terms of interactions with a single receptor. Only single-cell data are unambiguous in this respect. To our knowledge no single-cell study of alkyl-branched pheromone component analogs has been reported previously.

METHODS AND MATERIALS

All reactions of air- and water-sensitive materials were performed under a nitrogen atmosphere in oven-dried glassware. Anhydrous diethyl ether (ether) and tetrahydrofuran (THF) were distilled from dark-blue solutions of sodium benzophenone radical anion. *N,N'*-Dimethyl-*N,N'*-propylene urea (DMPU), purchased from Fluka AB, was distilled under vacuum from calcium hydride prior to use. The dimethyl sulfide complex of cuprous bromide was prepared by the method of House et al. (1975). The crude pheromone products were purified by flash chromatography with TLC silica gel 60H and petroleum ether–ethyl acetate (20:1) as eluent. Flash chromatographed products were further purified by preparative GLC using a 6-m × 4-mm 15% OV-351 column and/or by argentation chromatography (Houx et al., 1974). Analytical GLC was performed with a Varian 3400 capillary GLC fitted with a DB-Wax 30-m column or a OV-240-OH 25-m column, which is able to separate geometrical isomers. The purity of the isolated final products was >99%. No sample contained any detectable amount (<0.05%) of the natural pheromone component. [^{1}H]-and [^{13}C]NMR spectra on final products were recorded on a Varian XL-300 spectrometer. High resolution mass spectra were recorded on a Jeol JMS-SX 102 spectrometer. The procedures employed in the preparation of the pheromone analogs were modifications of methods described by Alexakis et al. (1980), and Gardette et al. (1985). The synthetic scheme is shown in Figure 3.

Preparation of Alkyl Iodides. The iodides in Figure 3 were prepared (unless otherwise mentioned) from the corresponding commercially available alcohols. The alcohol (0.1 mol) was dissolved in ether (40 ml) and pyridine (1.1 ml) was added. The mixture was cooled with an ice bath and PBr_3(3.8 ml, 0.04 mol) was slowly added. It then was stirred at room temperature for 6 hr and refluxed overnight. The mixture was cooled, poured into ice-water, and extracted with ether. The extracts were washed with $NaHCO_3$, dried, and the solvent evaporated. The crude bromide was added to a solution of NaI (22 g, 0.15 mol) in anhydrous acetone (100 ml). A white precipitate was formed immediately or slowly depending on the presence or position of the alkyl substituent. The mixture was stirred for 2–24 hr (monitored by GLC), and pentane (100 ml) was

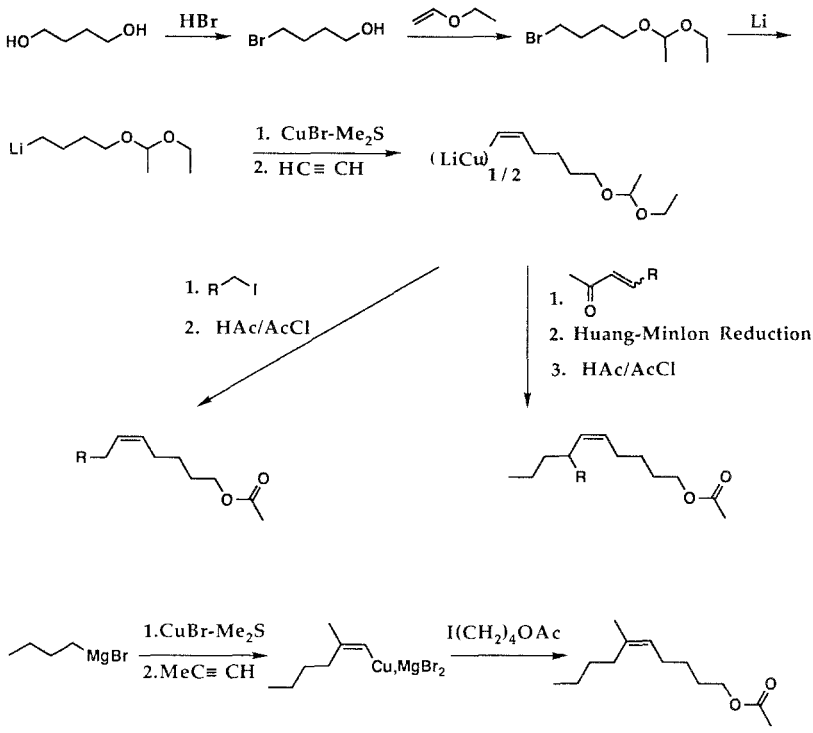

FIG. 3. Scheme for the preparation of compounds **2–10.**

added. After filtration and evaporation, the residue was taken up in another 100 ml of pentane and again filtered. Careful evaporation of the solvent afforded the iodide as a pale yellow oil (60–70% yield). The iodides were homogeneous by NMR and were used without further purification.

Preparation of 4-(1-Ethoxyethoxy)-Butyl Lithium. 4-Bromo-1-butanol was prepared according to the method of Kang et al. (1985). 1,4-Butanediol (44.6 ml, 0.5 mol) and 48% HBr (62.5 ml, 0.55 mol) in benzene (800 ml) were heated at reflux for 5 hr, while the formed water was trapped using a Dean-Stark separator. The solvent was removed under reduced pressure and the residue dissolved in anhydrous CH_2Cl_2 (200 ml). The mixture was cooled on ice to $<18°C$, then ethyl vinyl ether (48 ml, 0.5 mol) was added dropwise during 45 min, keeping the solution temperature between 10 and 16°C. The colorless solution was stirred for an additional hour at room temperature. The solution then was washed with 5% Na_2CO_3 (50 ml), dried with anhydrous Na_2CO_3 + $MgSO_4$, and the solvent evaporated. The product was distilled in carefully base-washed glassware to give 45 g (40% yield, bp 58–68°C/0.7 mm Hg) of

4-(1-ethoxyethoxy)-butyl bromide with a purity >96% (GLC). δ_H (300 MHz) 1.0–1.3 (6H, m, CH_3), 1.4–2.1 (4H, m, CH_2), 3.2–3.7 (6H, m, CH_2Br, CH_2O), 4.7 (1H, q, OCHO).

To freshly cut small chips of lithium in ether (20 ml), a solution of 4-(1-ethoxyethoxy)-butyl bromide (22.5 g, 0.1 mol) in anhydrous ether (60 ml) was added dropwise at −15°C during 1 hr. After the addition was complete, the solution was stirred for 1 hr at 0°C. The greyish turbid solution was then transferred to a 100-ml graduated glass cylinder, carefully dried, and purged with argon. The cylinder was stored at −15°C, allowing cloudy material to precipitate. After 1–2 days, the clear pale yellow solution was titrated by the method of Watson and Eastham (1967) and normally found to be 0.7–0.8 N (yield 70–80%). The solution of the organolithium reagent was stable for at least two months at this temperature.

Preparation of Lithium Bis[(Z)-6-(1-ethoxyethoxy)-hex-1-enyl]cuprate. This compound was prepared by carbocupration of acetylene (Gardette et al., 1985). To a well-stirred suspension of CuBr–Me_2S complex (2.88 g, 14 mmol) in ether (50 ml) at −50°C, 25 mmol of the ethereal solution of 4-(1-ethoxyethoxy)-butyl lithium was slowly transferred by using a double-tipped needle. The solution was warmed to −40°C and stirred for 30 min at this temperature. The almost clear colorless solution was cooled to −50°C, and acetylene (0.6 l, 25 mmol) was bubbled slowly into the reaction mixture. Stirring of the resulting dark green solution was maintained for 30 min at −25°C.

(Z)-5-Decenyl Acetate (1). This was prepared as previously described (Olsson et al., 1983).

9-Methyl-(Z)-5-decenyl Acetate (2). To a stirred solution of lithium bis[(*Z*)-6-(1-ethoxyethoxy)-hex-1-enyl]cuprate (12 mmol) at −30°C, DMPU (6 ml) in THF (40 ml), 3-methylbutyl iodide (4.7 g, 24 mmol) in 10 ml THF and triethyl phosphite (7.5 ml, 25 mmol) were successively added. The mixture was slowly allowed to reach room temperature and stirred overnight. It was then cooled to −20°C and quenched with 5 N HCl (40 ml). After stirring for 15 min with air bubbling into the mixture (which helps the work-up procedure), hexane (50 ml) was added and the precipitate filtered off. The aqueous layer was extracted once with ether (50 ml) and the combined organic extracts were washed once with 17% NH_3 (25 ml), then with saturated NH_4OH solution (25 ml), and finally dried over $MgSO_4$. The solvents were removed, and the residue was treated with glacial acetic acid (15 ml) and acetyl chloride (1.5 ml). The mixture was stirred at 30–40°C overnight and then poured onto ice (50 ml) in saturated sodium chloride solution. The acetate was extracted three times with pentane (25 ml); the organic phase was washed with $NaHCO_3$ solution and dried over $MgSO_4$. After evaporation of the solvent in vacuo, the crude product was purified by flash chromatography to give 2.3 g (45%) of **2** δ_H (300 MHz) 0.88 (d, 6H, J = 6.6 Hz, CH_3C), 1.18–1.26 (m, 2H, CH_3CCH_2), 1.36–1.46

(m, 2H=CCCH$_2$), 1.49–1.69 (m, 3H CH$_3$C**H**, CH$_2$CO), 1.98–2.10 (m, 4H, =CCH$_2$), 2.05 (s, 3H, COCH$_3$), 4.06 (t, 2H, CH$_2$O), 5.27–5.42 (m, 2H, J = 10.9 Hz, CH=CH). δ_C (75.4 MHz) 21.0, 22.5, 25.1, 26.0, 26.7, 27.6, 28.2, 38.9, 64.5, 128.9, 130.7, 171.2. MS (high resolution) for $C_{13}H_{24}O_2$ calcd 212.1776, found 212.1772.

8-Methyl-(Z)-5-decenyl Acetate (3). This was prepared from 2-methylbutyl iodide (4.7 g, 24 mmol) in the same manner as for **2** to give 2.7 g (53%). δ_H (300 MHz) 0.85 (d, 3H, J = 6.6 Hz, C**H**$_3$CH), 0.87 (t, 3H, C**H**$_3$CH$_2$), 1.05–1.22 (m, 1H, CH), 1.28–1.46 (m, 4H, =CCCH$_2$, CH$_3$C**H**$_2$), 1.58–1.68 (m, 2H, CH$_2$CO), 1.82–1.90 (m, 1H, =CCH$_2$) 1.97–2.09 (m, 3H, =CCH$_2$), 2.04 (s, 3H, COCH$_3$), 4.06 (t, 2H, CH$_2$OC), 5.36–5.40 (m, 2H, CH=CH). δ_C (75.4 MHz) 11.5, 19.1, 21.0, 26.0, 26.8, 28.2, 29.2, 34.2, 35.1, 64.5, 129.2, 129.7, 171.2. MS (high resolution) for $C_{13}H_{24}O_2$ calcd 212.1776, found 212.1788.

7-Methyl-(Z)-5-decenyl Acetate (4). 3-Penten-2-one was prepared by aldol condensation between acetone and acetaldehyde according to Stetter (1976). The product was distilled in the presence of 1 g of iodine crystals, giving a two-phase distillate in a temperature range of 100–132°C at atmospheric pressure. The formed water was separated off, the product dried with Na_2SO_4 and redistilled to give 22.7 g (15% yield, a major component, 55%, and a minor one, 40%, by GLC) of the product, bp. 119–122°C; lit. 122°C (Weast, 1971). [^{1}H]NMR in $CDCl_3$ showed three sharp signals at 1.8, 2.1, and 2.2 ppm, along with two separated multiplets at 5.8–6.2 and 6.5–7.1 ppm, which indicated a 3-penten-2-one/mesityl oxide mixture. To a stirred solution of 25 mmol of lithium bis[(Z)-6-(1-ethoxyethoxy)-hex-1-enyl]cuprate at −70°C, the freshly prepared α,β-unsaturated compound (2.4 ml) was added (Alexakis et al., 1980). After 10 min, the mixture was warmed to −10°C during 1 hr. The mixture was then hydrolyzed with saturated NH_4Cl (50 ml), hexane (50 ml) was added, the precipitate was filtered off, and the organic phase dried over $MgSO_4$. The yellow residue, 10 g, was added to a solution of ethylene glycol (45 ml) and KOH (8 g) at 90°C followed by 85% hydrazine hydrate (6 ml). The reaction mixture was heated at reflux temperature (145°C) for 1 hr, the volatile components were then allowed to distill off, increasing the temperature to 205°C. After 3 hr at this temperature, the mixture was cooled to ca. 80°C, poured into ice water (100 ml), and extracted with pentane (3 × 100 ml). The combined extracts were washed with brine, dried with $MgSO_4$, and concentrated in vacuo to give 4.4 g of a pale yellow oil as residue. The oil was acetylated in the usual manner, as described for compound **2**, followed by flash chromatography, yielding 1.1 g (41%) of **4**, 84% pure by GLC. The by-products were easily removed in the final purification. δ_H (300 MHz) 0.86 (t, 3H, C**H**$_3$CH$_2$), 0.91 (d, 3H, J = 6.7 Hz, C**H**$_3$CH), 1.12–1.31 (m, 4H, CH$_3$C**H**$_2$, CH$_3$CC**H**$_2$), 1.34–1.45 (m, 2H, =CCCH$_2$), 1.58–1.68 (m, 2H, CH$_2$CO), 2.00–2.09 (m, 2H, =CCH$_2$), 2.03

(s, 3H, $COCH_3$), 2.33–2.48 (m, 1H, CHCH=), 4.06 (t, 2H, CH_2O), 5.12 (m, 1H, J = 10.19 Hz, CHCH=), 5.26 (m, 1H, J = 10.9 Hz, =$CHCH_2$). δ_C (75.4 MHz) 14.2, 20.6, 21.0, 21.3, 26.2, 27.0, 28.2, 31.4, 39.8, 64.5, 127.5, 137.0, 171.2. MS (high resolution) for $C_{13}H_{24}O_2$ calculated 212.1776, found 212.1793.

6-Methyl-(Z)-5-decenyl Acetate (5). To an ice-cooled mixture of pyridine (50 ml) and acetic anhydride (30.6 g, 0.3 mol), crude 4-bromo-1-butanol (prepared from 0.2 mol of 1,4-butandiol and HBr, as described in the preparation of 4-(1-ethoxyethoxy)-butyl lithium) was added dropwise. The mixture was stirred for 4 hr at room temperature, water (200 ml) and ether (300 ml) were added, and the organic phase was washed with 1 M HCl (100 ml) and $NaHCO_3$ (100 ml). The mixture then was dried with $MgSO_4$, evaporated, and distilled to give 25.8 g (66% yield) of pure acetate bp 98–106°C /16 mm Hg). δ_H 1.5–2.1 (m, 4H, CH_2), 2.0 (s, 3H, $COCH_3$), 3.5 (t, 2H, CH_2Br), 4.1 (t, 2H, CH_2O). Butylmagnesium bromide was prepared from butyl bromide and magnesium turnings in ether and titrated. Propyne was prepared according to the method described by Jäger (1977). To a colorless suspension of CuBr–Me_2S complex (6.1 g, 30 mmol), ether (40 ml), and dimethyl sulfide (30 ml) at −45°C, the ethereal solution of butyl magnesium bromide (30 mmol) was added. After 2 hr of stirring at −45°C, propyne (0.71, 30 mmol) was bubbled into the yellow-orange suspension over a period of 10 min. The resulting greenish mixture was allowed to warm up to −25°C and stirred for 2 hr. DMPU (7.3 ml) in 30 ml of THF was added, followed by the 4-iodo-1-butyl acetate (7.3 g, 30 mmol) in 10 ml THF, and finally triethyl phosphite (7.7 ml). The mixture was then allowed to warm to room temperature (2 hr) and stirred for 8 hr. Hydrolysis with 3 M HCl (50 ml) at −20°C and filtration with subsequent washings, as described for compound **2,** followed by acetylation, afforded 14.6 g of crude product. Purification by flash chromatography gave 2.2 g (35% yield) of the trisubstituted olefin, along with small amounts of disubstituted olefin (which was carefully removed in the final purification). δ_H (300 MHz) 0.90 (t, 3H, CH_3CH_2), 1.23–1.42 (m, 6H, CH_3CH_2, CH_3CCH_2, $=CCCH_2$), 1.57–1.64 (m, 2H, CH_2CO), 1.65–1.67 (m, 3H, CH_3C=), 1.94–2.05 (m, 4H, $=CCH_2$), 2.02 (s, 3H, $COCH_3$), 4.06 (t, 2H, CH_2O), 5.06–5.11 (t, 1H, =$CHCH_2$). δ_C (75.4 MHz) 14.0, 21.0, 22.7, 23.4, 26.3, 27.3, 28.3, 30.3, 31.5, 64.5, 124.4, 136.1, 171.2. MS (high resolution) for $C_{13}H_{24}O_2$ calcd 212.1776, found 212.1782.

9,9-Dimethyl-(Z)-5-decenyl Acetate (6). Through the same procedure as described for **2,** but with 3,3-dimethylbutyl iodide (5.1 g, 24 mmol) in place of 3-methylbutyl iodide, 2.8 g (55%) of **6** was obtained. δ_H (300 MHz) 0.89 (s, 9H, CH_3C), 1.18–1.24 (m, 2H, CH_3CCH_2), 1.36–1.46 (m, 2H, $=CCCH_2$), 1.59–1.69 (m, 2H, CH_2CO), 1.93–2.10 (m, 4H, $=CCH_2$), 2.04 (s, 3H, $COCH_3$), 4.06 (t, 2H, CH_2O), 5.26-5.43 (m, 2H, J = 10.8 Hz, CH=CH). δ_C

(75.4 MHz) 21.0, 22.0, 26.0, 26.6, 28.2, 29.3, 30.4, 44.1, 64.5, 128.6, 131.2, 171.2. MS (high resolution) for $C_{14}H_{26}O_2$ calcd 226.1933, found 226.1964.

8,8-Dimethyl-(Z)-5-decenyl Acetate (7). 2,2-Dimethylbutanol was prepared from the Grignard reagent of 2-methyl-2-bromobutane and paraformaldehyde, bp 130–140°C/ 760 mm Hg. δ_H 0.8–1.0 (9H, s+t, CH_3), 1.1–1.4 (2H, m, CCH_2C), 3.3 (2H, s, CH_2O). The alcohol (26.4 mmol) was converted into the iodide by refluxing with triphenyl phosphite (6.9 ml, 26.4 mmol) and methyl iodide (2.3 ml, 37.0 mmol) for 24 hr. The resulting 2,2-dimethyl-1-butyl iodide was distilled off, and the fraction between 98 and 105°C /100 mm Hg was collected (2.8 g, 50% yield). The iodide was treated with lithium bis[(*Z*)-6-(1-ethoxyethoxy)-hex-1-enyl]cuprate (8 mmol) as described above for compound **2,** to give 0.2 g (7% yield) of compound **7**. δ_H (300 MHz) 0.81 (t, 3H, CH_3CH_2), 0.82 (s, 6H, CH_3C), 1.19–1.27 (q, 2H,CH_3CH_2), 1.35–1.46 (m, 2H, $=CCCH_2$), 1.59–1.68 (m, 2H, CH_2CO), 1.89–1.91 (m, 2H, $CH_3CCH_2C=$), 2.01-2.09 (m, 2H, $=CCH_2$), 2.04 (s, 3H, $COCH_3$), 4.06 (t, 2H, CH_2O), 5.40–5.44 (m, 2H, CH=CH). δ_C (75.4 MHz) 8.5, 21.0, 26.0, 26.4, 26.8, 28.3, 33.6, 34.1, 38.8, 64.5, 127.0, 130.5, 171.2 MS (high resolution) for $C_{14}H_{26}O_2$ calcd 226.1933, found 226.1937.

7,7-Dimethyl-(Z)-5-decenyl Acetate (8). This compound was prepared as described for **4** from mesityl oxide instead of 3-penten-2-one (2.2 ml, 19 mmol), affording 1.6 g (37%) of the product. δ_H (300 MHz) 0.88 (t, 3H, CH_3CH_2), 1.07 (s, 6H, $CH_3CC=$), 1.20–1.34 (m, 4H, CH_3CH_2, CH_3CCH_2), 1.36–1.46 (m, 2H, $=CCCH_2$), 1.60–1.70 (m, 2H, CH_2CO), 2.04 (s, 3H, $COCH_3$), 2.14–2.21 (m, 2H, $=CCH_2$), 4.07 (t, 2H, CH_2O), 5.11–5.25 (m, 2H, J = 12.1 Hz, CH=CH). δ_C (75.4 MHz) 14.9, 18.1, 21.0, 26.6, 27.9, 28.3, 29.0, 36.4, 46.7, 64.5, 128.6, 139.2, 171.2. MS (high resolution) for $C_{14}H_{26}O_2$ calcd 226.1933, found 226.1917.

8-Ethyl-(Z)-5-decenyl acetate (9). This compound was prepared from 2-ethylbutyl iodide (5.1 g, 24 mmol), following the standard procedure described above for **2**, to give 2.0 g (40%). δ_H (300 MHz) 0.85 (t, 6H, J = 7.1 Hz, CH_3CH_2), 1.18–1.34 (m, 4H, CH_3CH_2), 1.36–1.46 (m, 2H, $=CCCH_2$), 1.55–1.59 (m, 1H, CH_3CCH), 1.59–1.69 (m, 2H, CH_2CO), 1.96–2.10 (m, 4H, $=CCH_2$), 2.05 (s, 3H, $COCH_3$), 4.06 (t, 2H, CH_2O), 5.36–5.39 (m, 2H, CH=CH). δ_C (75.4 MHz) 11.1, 21.0, 25.4, 26.0, 26.9, 28.25, 30.5, 41.2, 64.5, 129.2, 129.8, 171.2. MS (high resolution) for $C_{14}H_{26}O_2$ calcd 226.1933, found 226.1943.

7-Propyl-(Z)-5-decenyl Acetate (10). 3-Hepten-2-one was prepared in analogy with the preparation of 3-penten-2-one, described above for compound **4**. The distillate, in the dehydration step, was obtained in a temperature range of 58–120°C /200 mm Hg and redistilled (bp 54–60°C /17 mm Hg), affording

28.8 g (26% yield, major component, 65% by GLC) of 3-hepten-2-one; lit. 62°C /15 mm Hg (Weast, 1971). δ_H 0.8–1.1 (3H, t, CH_3), 1.2–1.9 (4H, m, CH_2), 2.2 (3H, s, CH_3), 5.8–7.1 (2H, m, CH=CH). The conjugate addition was run with 19 mmol of lithium bis[(*Z*)-6-(1-ethoxyethoxy)-hex-1-enyl]cuprate, as described for analog **4**, to yield 3.6 g of crude product and after purification by flash chromatography 1.4 g (31%) of the product (80% pure by GLC). The by-products were easily removed in the final purification. δ_H (300 Mz) 0.85 (t, 6H, CH_3CH_2), 1.13–1.42 (m, 10H, CH_3CH_2, CH_3CCH_2, $=CCCH_2$), 1.58–1.68 (m, 2H, CH_2CO), 1.98–2.08 (m, 2H, $=CHCH_2$), 2.03 (s, 3H, $COCH_3$), 2.20–2.35 (m, 1H, CHC=), 4.06 (t, 2H, CH_2O), 5.12 (m, 1H, J = 10.9 Hz, CHCH=), 5.26 (m, 1H, J = 10.9 Hz, $=CHCH_2$). δ_C (75.4 MHz) 14.3, 20.5, 21.0, 26.2, 27.2, 28.3, 36.8, 38.2, 64.5, 128.7, 135.7, 171.2. MS (high resolution) for $C_{15}H_{28}O_2$ calcd 240.2089, found 240.2079.

Electrophysiology. Biological activities were determined by the single-sensillum technique (Kaissling, 1974). Olfactory receptor cells specifically tuned to (*Z*)-5-decenyl acetate (**1**) are present in antennal sensilla type SW1 of *Agrotis segetum* and are readily accessible for single-cell recordings (Hallberg, 1981; Löfstedt et al., 1982, van der Pers and Löfstedt, 1983). The method used was modified according to van der Pers and Den Otter (1978) and has been described previously (Liljefors et al., 1987; Bengtsson et al., 1990). Dose–response curves were constructed using five different stimulus concentrations. The concentration for the pheromone component **1** and the analogs ranged from 10^{-4} μg to 1 μg and $10^{-3}$$\mu$g to 100 μg, respectively, in decadic steps. For each stimulus concentration, 10 replicates were recorded and the mean value of the number of action potentials generated during 1 sec from the onset of stimulation was used in the construction of the dose–response curves. Errors are expressed as standard errors of mean (SEM). The relative activity of each compound is expressed as the reciprocal of the relative quantities required to elicit the same response from the receptor cell, as the natural pheromone component elicited.

Corrections for differences in volatility have been made using relative vapor pressures, as previously described (Liljefors et al., 1985; Bengtsson et al., 1990). The correction factors for compounds **2–8** are based on vapor pressure data for saturated hydrocarbons (pentane–tridecane) and their methyl-substituted analogs (Weast, 1971). The correction factors used are 2.2 for the methyl analogs **2–5** and 4.6 for dimethyl analogs **6–8.** The correction factor for compound **9** is 7.1.

Molecular Mechanics Calculations. Energy-minimized geometries and conformational energies were calculated using the molecular mechanics program MM2(85) (Burkert and Allinger, 1982). Starting structures for the energy-minimization program were obtained from the molecular modeling system MIMIC (Liljefors, 1983, von der Lieth et al., 1984). Van der Waals volumes

and surfaces were calculated and plotted by the program system SYBYL (Tripos Associates, Inc., 6548 Clayton Road, St. Louis, Missouri 63117).

RESULTS

Chemicals. The method used for the preparation of compounds **2–10** is based on the carbocupration of acetylene. This synthetic method affords products of very high (>99.9%) *Z* purity and is well suited for the synthesis of insect sex pheromones. It is also preparatively versatile, since both α- and ω-substituted analogs (with respect to the double bond) are obtained with the same synthetic intermediates. The 7-alkyl-substituted analogs were thus obtained by conjugate addition of (*Z*)-alkenyl cuprate to α,β-unsaturated ketones with subsequent Huang-Minlon reduction, while the 8- and 9-substituted analogs were obtained by alkylation of (*Z*)-alkenyl cuprate with alkyl halides (Figure 3). The trisubstituted olefin analog **5** was obtained in a similar way by carbocupration of propyne followed by alkylation. As pointed out by Gardette et al. (1985), a decisive factor for a successful preparation of the organocuprate reagent is the quality of the cuprous salt. The best results are obtained with the dimethyl sulfide complex of cuprous bromide. The choice of the protective group for the hydroxy function in the preparation of the lithium reagent is equally decisive (Gardette et al., 1985). Only a hydroxy function protected as an ethoxyethyl ether gives acceptable results.

Receptor Cell Responses. The results of the electrophysiological single-cell activity determinations for compounds **1–10** are shown in Figure 4. The

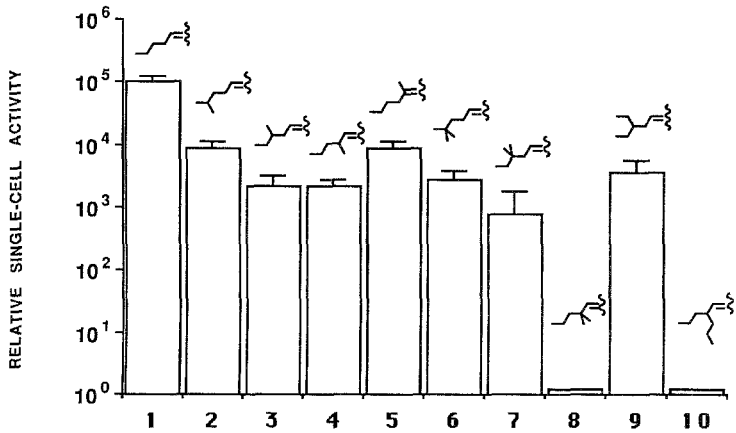

FIG. 4. Relative single-cell activities (+SEM) for compounds **1–10.**

data include corrections for differences in volatility (see Methods and Materials).

All analogs display reduced activity compared to the natural pheromone component **1.** Mono-methyl substitution in the 9- or 6-position (compounds **2** and **5,** respectively) reduces the activity by a factor of 10. This is the smallest activity decrease in the present series of analogs. A corresponding substitution in the 8- or 7-position (compounds **3** and **4,** respectively) results in a somewhat larger drop of the activity, by a factor of about 45 compared to the natural substrate **1.** These results are in qualitative agreement with those obtained by Priesner et al. (1977) in their EAG screenings of monomethylated pheromone components for several species of Noctuidae and Tortricidae. For analogs of (*Z*)-7-dodecenyl acetate, (*Z*)-9-tetradecenyl acetate, and (*Z*)-11-hexadecenyl acetate with the same terminal alkyl chain as compounds **2–4,** they report activity reductions by a factor of 10–30, largely irrespective of the position of the methyl group.

The 8-ethyl analog (compound **9**), displays an activity loss of about a factor of 30, close to the activity observed for the 8-methyl analog **3.** The 7-propyl compound **10** was found to be essentially inactive.

Geminal dimethyl substitution in the 9-, 8- or 7-positions (compounds **6–8**) results in a successive diminution of the activity. Compounds **6** and **7** are about 40 and 95 times less active than compound **1,** while compound **8** is essentially inactive. The activity decrease on the introduction of a second methyl group in the 9- or 8-position is essentially identical. However, a second methyl substitutent in the 7-position eliminates all receptor activity.

Conformational Energies. Conformational energies were calculated by the molecular mechanics method to evaluate the energies required by each of compounds **2–10** to attain their biologically active conformations, according to our model (Liljefors et al., 1987). These calculations were performed by first calculating the global energy minimum for each of compounds **2–10.** This was done by energy minimizations of all staggered conformations of the terminal alkyl chain for the cisoid and transoid conformers with respect to the vinylic bonds, while the acetate-substituted chain segment was kept in an all-anti conformation.

In a second series of calculations, energy-minimization was performed for the biologically active conformations of each of these compounds according to our model, which requires mimicking the positions of the acetate group, the double bond, and the terminal methyl group of the natural substrate in the conformation shown in Figure 1. This requires the main chain of the terminal alkyl part to adopt an all-anti conformation. An alkyl group in the 7-, 8-, 9-position may then adopt two different directions denoted A and B in Figure 5. In the B direction, the alkyl group is oriented towards the acetate substituted alkyl chain (''inwards'') and may suffer from steric repulsive interactions with this chain.

In direction A, an alkyl group is directed away from the other chain (''outwards''). For compound **2** the A and B directions correspond to different rotamers and the 9-methyl group may change its direction by rotation about the C8—C9 bond. In compounds **3** and **4** the methyl substituent in the A and B positions corresponds to different enantiomers. Compounds **9** and **10** are nonchiral, and the alkyl substituent may be oriented in the A or B directions through rotations about carbon–carbon single bonds.

The energy differences between the two sets of calculations correspond to the energies required by each of compounds **2–10** to acquired the biologically active conformation according to our model (Liljefors et al., 1987).

The results of these calculations are shown in Table 1. The most pronounced steric interactions are found for 8- and 7-alkyl substituents in direction B (compounds **3, 4, 7, 9,** and **10**). This is due to repulsive interactions between

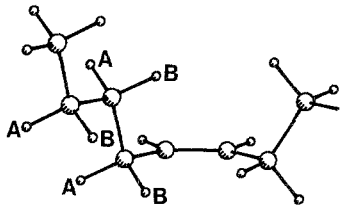

FIG. 5. Possible alkyl group directions in the biologically active conformation of compounds **2–10.**

TABLE 1. CALCULATED CONFORMATIONAL ENERGY DIFFERENCES (kcal/mol) BETWEEN BIOLOGICALLY ACTIVE CONFORMATION OF EACH OF COMPOUNDS **1–10** AND THEIR LOWEST ENERGY CONFORMATIONS[a]

Compound	A	A + B	B
1		0.0[b]	
2	0.3		0.1
3	0.7		1.8
4	0.4		2.0
5		0.2[b]	
6		0.7	
7		1.9	
8		0.8	
9	1.3		3.4
10	0.5		1.7

[a] A and B denote alkyl group directions according to Figure 5.
[b] the A/B designation is not applicable in this case

the alkyl substituent and the acetate-substituted alkyl chain in the cisoid conformation. An 8-ethyl substituent in direction A results in a conformational energy of 1.3 kcal/mol. All other substitutions result in small conformational energies, 0.1–0.8 kcal/mol. Figure 6 illustrates the difference in conformation between the global energy minimum and the biologically active conformation for compound **7** and the energy required to attain this conformation. Note that the conformation of the global energy minimum has to be rearranged with respect to the C7–C8 and C8–C9 bonds in order to mimic the structure of the natural pheromone component shown in Figure 1, as required by our model.

DISCUSSION

In previous structure–activity work on analogs of compound **1**, we found that a conformational energy increase of 1.7 kcal/mol for the analog to acquire its biologically active conformation corresponds to an activity decrease of a factor of 10 (Bengtsson et al., 1987). This finding may be employed in the present study to investigate if a decrease in the observed activity may be due to

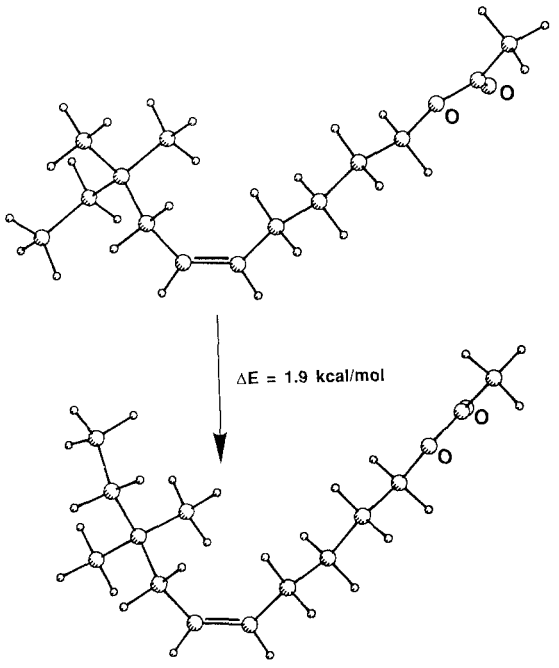

FIG. 6. Global energy minimum (top) and biologically active (bottom) conformations of compound **7**.

a conformational energy penalty or to steric repulsive interactions with the receptor.

A methyl substitutent in the 6-position, compound **5**, decreases the electrophysiological activity by a factor of 10 compared to the natural substrate **1** (Figure 4). The conformational energy required by compound **5** to mimic the natural component is calculated to be very small, 0.2 kcal/mol (Table 1). Thus, the observed activity decrease most probably is due to repulsive steric interactions between the methyl substitutent and the receptor. The van der Waals volume of compound **1** is illustrated in Figure 7. This volume represents the smallest cavity that can accommodate the natural pheromone component in its deduced biologically active conformation. The extra volume required by compound **5** is shown in Figure 8a. The surface shown represents the difference in volume between compound **5** and compound **1.** It is clear that a bulk of this size in the indicated area is not tolerated by the receptor, demonstrating a close fit between the receptor and the natural substrate in this area of the receptor cavity.

The 9-methyl compound **2** is nonchiral, and a methyl group may be oriented in either direction A or B (Figure 5) through rotation about the C8–C9 bond. The bulk produced in these directions by a methyl group is illustrated in Figure 8b, which shows the difference in the van der Waals volumes of the 9,9-dimethyl substituted compound **6** and compound **1.** If one of these directions is sterically unhindered, compound **2** may place its methyl group in the unhindered direction, and since the calculated conformational energy is very low (Table 1), the activity should be comparable to the natural component **1.**

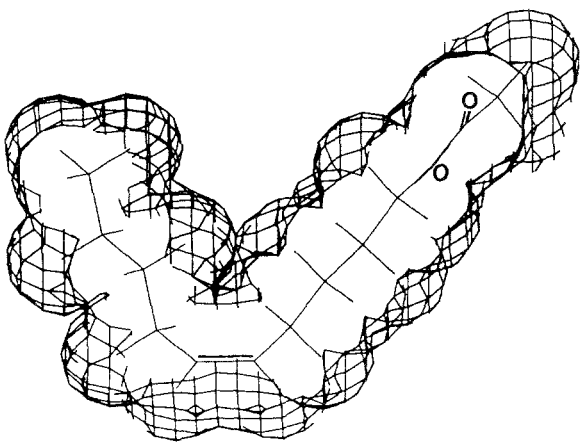

FIG. 7. Van der Waals surface of compound **1** in its deduced biologically active conformation.

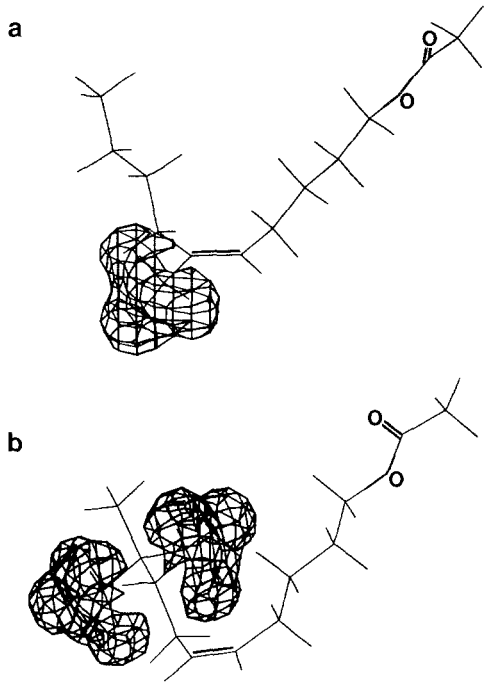

FIG. 8. The difference between the van der Waals volumes of (a) compounds **5** and **1** and (b) compounds **6** and **1.**

However, the observed activity for **2** is a factor of 10 lower than that of **1.** This strongly indicates that a methyl group in either direction A or B in Figure 5 causes repulsive steric interactions with the receptor. This is supported by the further decrease in activity of the geminally dimethyl substituted compound **6** by a factor of 5, in spite of the higher lipophilicity of this compound (Figure 4). Thus, the receptor displays high complementarity with respect to the natural substrate on both sides in the vicinity of the terminal methyl group.

A methyl substituent in the 8-position (compound **3**) decreases the electrophysiological activity by a factor of 45. Compound **3** is chiral and is tested as its racemate. In terms of our receptor interaction model, this means that half the molecules have the 8-methyl group in direction A (Figure 5) and the other half in direction B. The A direction results in a small calculated conformational energy, 0.7 kcal/mol, to acquire the biologically active conformation, while the B direction gives a somewhat higher energy, 1.7 kcal/mol (Table 1). The racemate should then display an activity decrease by less than a factor of 10 due to the conformational energy penalty. If both directions A and B are without steric hindrance at the receptor and if the difference in lipophilicity between com-

pound **3** and **1** is taken into account, the activity of **3** should be of the same magnitude as that for compound **1.** As this is not the case, our conclusion is that the receptor "wall" destructively interferes with a methyl group in the area about the 8-position as well. This also is indicated by the low activity of the dimethyl-substituted compound **7.** However, the question of whether the steric hindrance is caused by a methyl group in the A or B direction (or both) cannot be answered on the basis of the present data for compounds **3** and **7.** A study of the pure enantiomers of compounds **3** may give more information on this problem.

An ethyl substituent in the 8-position (compound **9**) decreases the electrophysiological activity by a factor of 30. In this case our result is somewhat different from that obtained by Prienser et al. (1977) in the EAG study mentioned above. In their study, an ethyl group in the β-position, with respect to the double bond, causes a drop of the activity by a factor of 100–300, which is the largest decrease they found for alkyl-branched analog of pheromone components with the same terminal alkyl part as **1.**

Compound **9** is nonchiral and displays the highest calculated conformational energies in the present series of molecules (Table 1). The calculated conformational energy for the B direction (Table 1 and Figure 5), in conjunction with the higher lipophilicity of compound **9** in comparison with compound **1,** is compatible with the observed activity decrease according to the relationship between conformational energy and electrophysiological activity discussed above. However, a combination of steric hindrance by the receptor in the A direction and the calculated conformational energy penalty, 1.3 kcal/mol (Table 1) for an ethyl group in this orientation, is also compatible with the observed activity.

Alkyl substitution in the 7-position (compounds **4, 8,** and **10**) causes drastic variations in the activity, depending on the number of substituents and alkyl size. One methyl group (compound **4**) decreases the activity by a factor of 45, while two methyl groups in this position result in an essentially inactive compound (**8**). As the calculated conformational energy penalty for compound **8** is only 0.8 kcal/mol (Table 1), this clearly indicates that an alkyl substituent in at least one of the directions A and B destructively interacts with the receptor in a severe way. An investigation of the pure enantiomers of the chiral compound **4** is necessary for further information on the exact nature of this interaction. Bestmann et al. (1980) studied the EAG response of the enantiomers of the 13-ethyl substituted analog of (*Z*)-11-tetradecenyl acetate, a pheromone component of *Ostrinia nubilalis* and *Argyrotaenia velutinana*. The *R* and *S* enantiomers were found to be 10 and 1000 times less active, respectively, than the natural pheromone component. This demonstrates that pheromone receptors tuned to achiral monoene acetates are capable of differentiating between enantiomers of alkyl substituted analogs.

The 7-propyl compound **10** is essentially inactive in our study. This is in sharp contrast to the very high EAG activities observed by Priesner et al. (1977) for α-propyl analogs corresponding to compound **10.** They report activity reductions by only a factor of 3–30. No corrections for differences in volatilities were made in their work. If such corrections are made, these α-propyl analogs are in fact at least as active as the natural pheromone component. Our calculated small conformational energy penalties for compound **10** (Table 1), and the lack of single-cell response to this compound, indicate that the bulk of the propyl group can not be accommodated by the (*Z*)-5-decenyl acetate receptor of *Agrotis segetum.*

CONCLUSIONS

The results of the structure–activity analysis of alkyl-substituted analogs of the natural pheromone component **1** strongly indicate a high complementarity between the receptor and the terminal alkyl part of its natural substrate. This confirms our previous conclusions based on studies of chain-shortened analogs (Bengtsson et al., 1990). The introduction of bulky groups in the terminal alkyl part of the substrate substantially reduces the electrophysiological response. In particular, the introduction of a propyl group, or geminal dimethyl substitution, in the α-position with respect to the double bond results in essentially inactive compounds. The inactivity of the α-propyl compound is in sharp contrast to previously reported EAG results for homologous pheromone components of other noctuid species.

(Received May 25, 1990; accepted August 21, 1990)

Abstract—Optimal conditions for extraction of tannins and other phenolics from tree foliage and their subsequent storage rarely have been investigated. We investigated methods of drying leaves, optimal solvents, and the effects of light and temperature on the extractability and stability of condensed tannins (proanthocyanidins) and total phenolics from leaves of *Eucalyptus* trees. Aqueous acetone was a better solvent than aqueous methanol for condensed tannins and total phenolics, but condensed tannins were less stable in aqueous acetone than aqueous methanol. Stability of condensed tannins also was decreased substantially by room temperature versus 4°C and by exposure to indirect sunlight, although the assay for total phenolics was unaffected. For quantitative estimation of condensed tannins, extraction with 50% acetone was better than methods of direct analysis of leaf tissue. The highest estimates of total condensed tannins were obtained by exhaustive extraction with 50% acetone followed by direct analysis of the residue. Lyophilization of fresh leaf increased yield of condensed tannin (although usually by less than 10%). Lyophilization and subsequent storage of extracts had little effect on assays for condensed tannins or total phenolics.

Key Words—Tannin extraction, plant phenolics, *Eucalyptus*, browse analysis.

INTRODUCTION

Much attention has been paid to chemical analysis of tannins and other phenolics in plant foliage because of their postulated ecological importance in plant–plant and plant–animal interactions. Methods for chemical and biochemical

analysis of tannins have been reviewed in detail (Mole and Waterman, 1987a,b; Hagerman and Butler, 1989). However, methods of preparing leaf samples for chemical analysis, which can introduce greater errors than the analyses themselves, have received little critical attention apart from a recent paper by Hagerman (1988).

Frequently it is inconvenient to analyze fresh leaf tissue and some form of drying is needed. It is well established that air- or oven-drying, especially at temperatures above 70°C, decreases yield of tannins and other phenolics (Bate-Smith, 1975; Price et al., 1979; Gartlan et al., 1980; Lindroth and Pajutee, 1987; Hagerman, 1988). Lyophilization (freeze-drying) is the most promising compromise and is adopted uncritically by many workers. However, the few studies that have investigated the effects of lyophilization on yield of phenolics have shown that some loss, no loss, or some enhancement of tannin extractability is possible (Martin and Martin, 1983; Price et al., 1979; Hagerman, 1988).

Debate about the best solvent for tannins in plant tissues has been based on a limited number of studies of few plant species, and conclusions are not always consistent with one another. Aqueous methanol (boiling or at room temperature), acidic methanol, and aqueous acetone have been recommended by various authors. Usually one solvent is recommended without comparison with alternatives or without measurement or estimation of the extent of extraction achieved. The suitability of methanol as an extractant for hydrolyzable tannins has been questioned (Haslam et al., 1961; Swain, 1979), and its ability to extract condensed tannins from some plants also is low (Bate-Smith, 1973, 1975; Foo and Porter, 1980). Many workers now use aqueous acetone for extraction of tannins, although it does not give high recoveries with all plants (Martin and Martin, 1984; Stafford and Cheng, 1980). The presence of water in organic extractants can both increase extraction of phenolics and enhance their breakdown after extraction (Swain, 1979; Lindroth and Pajutee, 1987). The choice of water content usually appears to be arbitrary between 0% and 50% and to follow precedents set by other workers analyzing other plant species.

Extraction time has been studied even less rigorously. Times from a few minutes to one or more days have been used. Short extraction times aim to minimize chemical degradation of extracted tannins, and long times to maximize extraction, but seldom is the extent of extraction or degree of degradation quantified. Similarly, few published methodologies make any recommendations about exposure to light, which might affect the stability of phenolics.

We investigated the best pretreatment, solvent, time, and temperature for extraction of tannins and other phenolics from the foliage of *Eucalyptus* trees, as a preliminary to a survey of tannins in eucalypt forests in southeast Australia. The foliage of eucalypts contains a wide range of phenolic compounds, including condensed and hydrolyzable tannins and nontannin phenolics (Hillis, 1966;

Fox and Macauley, 1977; Cork, 1984; Cork and Pahl, 1984). We observed several trends that probably have general applicability, have been reported seldom or never before in the literature, and could substantially alter conclusions from chemical analyses of tannins in plants unless taken into account.

METHODS AND MATERIALS

Samples and Their Collection. We collected mature leaves from low branches of *Eucalyptus* spp. trees growing in the grounds of CSIRO Division of Wildlife and Ecology in Canberra. The following codes are used throughout this paper to designate the trees that were sampled: EMAN1 and EMAN2—two individuals of *Eucalyptus mannifera*; EMEL1 and EMEL2—*E. melliodora*; EVIM—*E. viminalis*; EPAUC—*E. pauciflora*; EHYB—unidentified hybrid eucalypt. The leaves were immediately frozen and ground in liquid nitrogen in a small coffee-grinder or by mortar and pestle. A portion of this ground, undried leaf was stored at −20°C and another portion was lyophilized first.

During all of the tests described below, the dry matter content of samples (including those lyophilized) was determined by oven-drying a subsample to constant mass at 70°C. Total phenolics in acetone or methanol extracts (details of extraction procedure are given below) were analyzed by the Folin-Ciocalteu method (Singleton and Rossi, 1965). Condensed tannins (a subset of total phenolics) in acetone or methanol extracts, solid residues remaining after extraction, and unextracted solid samples were analyzed by the HCl–butanol (proanthocyanidin) method (Reed et al., 1982; Mole and Waterman, 1987a). The HCl–butanol reagent used in all of these analyses (Mole and Waterman, 1987a) contained a transition-metal salt ($FeSO_4 \cdot 7H_2O$) to ensure consistency of proanthocyanidin yield (Porter et al., 1986). Correction was made for interference from chlorophyll by running unheated reagent + sample blanks (Swain and Hillis, 1959). The extent of interference was small compared with the tannin concentrations, so it was deemed unnecessary to take more comprehensive precautions, such as suggested by Watterson and Butler (1983). Due to the difficulty of obtaining suitable standards for phenolic analyses (Hagerman and Butler, 1989; Mole et al., 1989), we expressed all values relative to quebracho tannin (a condensed tannin). The quebracho tannin was purified (Asquith and Butler, 1985) from crude material supplied by A. E. Hagerman (Hagerman and Butler, 1989). Quebracho clearly produced relatively more color than eucalypt total phenolics in the Folin-Ciocalteu assay and/or less color than eucalypt condensed tannin in the HCl–butanol assay, resulting in estimates of condensed tannin often being greater than total phenolics. This did not, however, affect any of the comparisons made or conclusions drawn. We did not analyze for hydrolyzable tannins because a suitable method was not available, although one has come to our attention since (Inoue and Hagerman, 1988).

Investigation of Extraction Conditions (Experiment 1). We observed in preliminary experiments that when either acetone- or methanol-based aqueous solvents were used at room temperature with exposure to indirect sunlight (normal daytime room light), the concentration of condensed tannins (although not of total phenolics) in the extract fell rather than rose after about 2–5 hr. This suggested instability due to light and/or temperature. Therefore, experiment 1 was set up to investigate the stability of leaf extracts (in 50% and 70% acetone, and 50% methanol for reasons given below) under three storage conditions: (1) unprotected from indirect sunlight (on laboratory bench) at room temperature; (2) in a dark cupboard at room temperature; and (3) in the dark at 4°C. The extracts were sampled initially and after three days.

Investigation of Solvents (Experiment 2). In this experiment we compared methanol-based with acetone-based solvents because these are most often recommended. Preliminary investigations showed that anhydrous acetone or methanol extracted less than 50% of the total phenolics and condensed tannins that aqueous mixtures extracted, so no further investigation of anhydrous solvents was made. We had found previously that 50% methanol was superior to higher proportions of methanol in water for extracting phenolics from eucalypts. Fifty percent methanol was compared with 50% and 70% acetone in the experiments reported here.

Samples were extracted (0.02 g wet leaf per 5 ml solvent) in test tubes at 4°C in a sonicator (to minimize extraction time) for three successive 30-min periods. Previous tests had shown that negligible amounts of condensed tannins or total phenolics were removed by further extraction. After each period, the tubes were centrifuged (3000 rpm, 15 min, at 4°C) and the supernatant was removed, sampled, and replaced with fresh solvent. As an alternative to sonication, we also tested continuous agitation on a mechanical shaker at the maximum speed possible without loss of solvent by splashing and found it to give identical results (unpublished data).

Comparison of Extraction with Analysis of Whole Sample (Experiment 3). Because some authors (Bate-Smith, 1973, 1975; McArthur, 1988) have suggested that higher yields of condensed tannin can be obtained by analyzing whole tissue rather than extracts, we compared five alternative ways of estimating the total condensed tannin present in leaf samples: (A) leaf samples were extracted exhaustively in 50% acetone, as above; (B) samples were extracted exhaustively as in (A) and condensed tannins were also measured in the remaining solid residue; (C) condensed tannin was measured directly in unextracted, undried, ground leaf tissue; (D) analysis was performed as in (C) after pretreatment with boiling methanol (1 ml to 20 mg sample) for 5 min (Bate-Smith, 1973); and (E) analysis was performed as in (C) after sonication in 50% acetone (1 ml to 20 mg sample) for 30 min. Subsamples for all five treatments were taken from the same sample at the same time and processed simultaneously.

Effects of Methods of Drying (Experiment 4). With leaf samples from the same trees as used in the experiments described above, but sampled two months later, we tested the effects of three drying treatments on extraction and measurement of condensed tannins and total phenolics. Leaves were sampled and immediately ground in liquid nitrogen, then subsamples were analyzed after: (1) no drying; (2) lyophilization; or (3) oven drying at 70°C for 24 hr. We also investigated the feasibility of lyophilizing 50% acetone extracts for storage: subsamples were analyzed either immediately or after lyophilization, storage for up to a week, and reconstitution with water.

Statistical Analysis. Treatment means were compared using a two-factor analysis of variance (Zar, 1984) with eucalypt species as one factor and the treatment as the other. Arcsine transformation (Zar, 1984) was applied to percentages before analysis.

RESULTS

Experiment 1. Both light and temperature had pronounced effects on the stability of condensed tannins in leaf extracts (Table 1). Storage at 4°C in the dark, regardless of solvent, resulted in only small reductions in measurable condensed tannin, but room temperature and exposure to indirect sunlight caused much greater reductions. In most cases, the effects of light and temperature were less pronounced for 50% methanol than for the two concentrations of aqueous acetone. There was a statistical trend towards higher recovery of total phenolics after storage at room temperature in the dark than after the other two storage treatments, but the magnitude of this difference seems biologically insignificant (Table 1).

Experiment 2. As expected, all three solvents removed very little additional condensed tannin or total phenolics after 2 × 30-min sonications (Table 2). Aqueous acetone extracted considerably more condensed tannin and total phenolics than did aqueous methanol. Fifty percent acetone consistently extracted more condensed tannins than did 70% acetone and extracted as much or more total phenolics (Table 2).

Experiment 3. Of the five extraction–analysis treatments compared in experiment 3, exhaustive extraction with 50% acetone followed by analysis of the residue (treatment B) usually gave the highest estimate of total condensed tannins (Table 3). Direct analysis of ground leaf consistently gave a lower estimate of condensed tannin than did extraction alone. Pretreatment of the ground leaf with either boiling butanol or 50% acetone and sonication before adding the reagent improved the yield of condensed tannin but still gave an estimate at best 105% of treatment B and at worst 62% (Table 3). In all of these direct analyses the leaf tissue was colored red after boiling in HCl–butanol, indicating

that not all tannin was extracted and measured. This problem appeared to be less pronounced for treatment B, which was concluded to give the best possible estimate of total condensed tannins.

Experiment 4. Oven-drying greatly reduced the amounts of condensed tannin and total phenolics extractable by solvents and the amount of condensed tannin detectable in the residue remaining after extraction with 50% acetone (Table 4). Lyophilization caused a consistent increase in extractability and measurability of condensed tannin and total phenolics from leaf, although this increase was small in all but one case (Table 4). Lyophilization and reconstitution of 50% acetone extracts had no consistent effect on measurements (Table 4).

DISCUSSION

To interpret the role of tannins and other phenolics in plant–plant or plant–animal interactions, it is important that at least the total amount present in plant samples can be estimated confidently and preferably that quantitative extracts

can be obtained for chemical and biochemical analyses (Mole and Waterman, 1987a,b; Hagerman, 1988). The present study questions some untested notions prevalent in the literature about how best to estimate total condensed tannins, adds to the meagre data on the relative effectiveness of various solvents for phenolics in plant tissues, and focuses on some major errors that can occur if extractions are not performed, or extracts are not subsequently stored, under appropriate conditions.

Bate-Smith (1975) concluded that condensed tannins (proanthocyanidins) seldom are completely extractable from plants. He suggested direct analysis of unextracted leaf to estimate total condensed tannin. McArthur (1988) applied this approach to analysis of eucalypt foliage where it appeared that oven-drying had seriously reduced extractability of phenolics. Reed et al. (1982) analyzed residual phenolics in isolated cell-wall fractions of shrub foliage. However, direct analysis of plant tissue rarely has been compared with other ways of estimating total condensed tannins when fresh samples are used. We found that, for eucalypts, summing the results of analysis of the 50% acetone extracts and of the leaf residues gave 20–40% higher estimates of total condensed tannin

[a] Five treatments were employed: A, exhaustive extraction in 50% acetone as in Table 2; B, extraction as in A followed by direct analysis of condensed tannin remaining in the extracted residue; C, direct analysis of leaf tissue; D, analysis of leaf tissue after pre-treatment with boiling methanol for 5 min; and E, analysis of leaf tissue after sonication in 50% acetone, at 4°C for 30 min. Values are expressed as percentage of treatment B, which in all but two instances gave the highest estimate of total condensed tannins. Data are means of duplicate determinations on extracts and quadruplicate determinations on leaf tissues and residues.

than direct analysis of unextracted leaf and that extraction in 50% acetone alone also is superior to the direct analysis. Bate-Smith (1973, 1975) recognized the need to pretreat some leaf samples for tissue analysis, but we found that pretreatments gave only small improvements in most cases. A major benefit of combining use of solvent with analysis of the residue is that an estimate of the extractability of tannins (and other phenolics if a total phenolic analysis of the residue can be performed) is obtained. Extractability of tannins might have at least as much physiological and/or ecological significance for herbivores as the total amount present (Mole and Waterman, 1987a).

Very few studies that have included analysis of phenolics have stipulated extraction at low temperatures (e.g., Lindroth and Pajutee, 1987; Inoue and Hagerman, 1988), although boiling during extraction has been discouraged (Foo and Porter, 1980; Hagerman, 1988). We know of no studies that have emphasized protection from light during extraction. We presume that many workers perform their extractions without these precautions, as we have previously. In the present study, instability of condensed tannins caused by sunlight and room temperature was evident and substantial within 2–5 hr of the start of extraction. Therefore, it probably causes significant underestimates of extracted tannin even in short extraction periods. Inclusion of water in solvents is another source of

(hydrolytic) degradation of phenolics (Lindroth and Pajutee, 1987), but there is no alternative if quantitative estimates of phenolics are needed, because extraction usually is poor in anhydrous solvents. It appears from Table 1 that the structure of *Eucalyptus* spp. condensed tannins is altered in an aqueous solvent enough to reduce their reactivity with the HCl–butanol reagent but not sufficiently to reduce the intensity of color production on reaction with the Folin-Ciocalteu (total phenolics) reagent. This might be due to light-catalyzed polymerization (oxidative coupling) of condensed tannin chains that would not affect the phenolic hydroxyls with which the Folin-Ciocalteu reagent reacts (P. G. Waterman, personal communication). Consequently, if extraction and/or storage conditions are inappropriate, analysis of total phenolics might indicate stability but biochemical tests that rely on the reactivity of tannins with proteins or other substrates (Mole and Waterman, 1987b) could be seriously in error.

The optimal choice between acetone- and methanol-based solvents probably varies with the plant species under study (Hagerman, 1988), but some generalizations are possible. Extractability in methanol decreases with the size

of the tannin polymer (Goldstein and Swain, 1963; Foo and Porter, 1980), whereas no such trend is apparent for acetone (Jones et al., 1976; Foo and Porter, 1980). Acetone appears to break or prevent tannin–protein associations, whereas methanol does not (Foo and Porter, 1980; Hagerman and Robbins, 1987). Hagerman (1988) found aqueous acetone was superior to aqueous methanol for extracting tannins (mixtures of condensed and hydrolyzable) from several plant species, but the extent of superiority varied seasonally. We conclude that aqueous acetone should be the choice of solvent for extracting phenolics from eucalypts also, because it consistently extracted more condensed tannin and total phenolics than did aqueous methanol in the species we examined. This conclusion is strengthened by the observations that eucalypts contain high concentrations of hydrolyzable as well as condensed tannins (Hillis, 1966; Fox and Macauley, 1977; Cork et al., 1983; Cork and Pahl, 1984) and the aromatic ester (depside) bonds in hydrolyzable tannins are unstable in aqueous alcohols (see Hagerman, 1988).

Oven-drying of eucalypt foliage is reported to reduce the yield of total phenolics and condensed tannins by 12–100% (Cork et al., 1981; McArthur, 1988), and the reduction observed in the present study was 0–45% (Table 4). Reductions in extractability of tannins as a result of oven-drying have been reported for leaves of hickory, oak, and maple (Hagerman, 1988) and 20 African rain-forest species (Gartlan et al., 1980). Sun-drying produces similar reductions to oven-drying (Gartlan et al., 1980). In all but one of the eucalypt species investigated here, lyophilization increased extractability of condensed tannins and total phenolics by 2–10% (Table 4), which, depending on the reason for analysis, could be an error to be wary of. In one case (EPAU) lyophilization increased extractability from 73% to 90% (Table 4). Hagerman (1988) also concluded that lyophilization can affect extractability of tannins from foliage and that the effect can vary seasonally. The different effects of lyophilization and fresh analysis can be partly, but not fully, compensated for by analysis of residues as well as extracts to give an estimate of extractability and total tannin (Table 4).

Although the present study has concerned members of only one genus of plants, the phenolic chemistry of this genus is diverse (Hillis, 1966) and the species sampled were each from a separate infrageneric series (Chippendale, 1988). Therefore, the potential problems and pitfalls identified are likely to apply to many other plants. Inappropriate extraction conditions, especially lack of attention to the effects of light and temperature and the efficiency of the solvent in use, can make comparisons between plant species dubious and interpretation of physiological interactions between plants and animals very difficult. Therefore, we urge chemical ecologists analyzing plants for tannins and other phenolics to consider preparation and extraction conditions carefully, and we hope that this paper will assist.

Acknowledgments—We thank Ms. Mandy Yialeloglou for skilled technical assistance in the performance and development of the techniques used here. We also thank Dr. A. Hagerman and Dr. C. McArthur of Miami University, Ohio, U.S.A., for helpful advice on analytical techniques. However, we are solely responsible for the final choice and implementation of techniques. Financial support for this work was provided by a grant (8889/06) from the Australian National Parks and Wildlife Service.

TONGUE-FLICKING AND BITING IN RESPONSE TO CHEMICAL FOOD STIMULI BY AN IGUANID LIZARD (*Dipsosaurus dorsalis*) HAVING SEALED VOMERONASAL DUCTS: VOMEROLFACTION MAY MEDIATE THESE BEHAVIORAL RESPONSES

(Received June 25, 1990; accepted August 21, 1990)

Abstract—In the iguanid lizard *Dipsosaurus dorsalis*, chemical food stimuli were discriminated from other odorants by vomerolfaction. This was demonstrated in a 2 × 3 experiment in which groups of lizards with sealed vomeronasal ducts or sham-sealed vomeronasal ducts responded to carrot chemical stimuli, cologne, and distilled water presented on cotton-tipped applicators. Abilities to detect and discriminate food chemicals were abolished in lizards having sealed vomeronasal ducts. For tongue-flick attack score and number of lizards biting, the sham-sealed group responded more strongly to carrot stimuli than to the control stimuli, but the group having sealed ducts did not. Lizards having sham-sealed ducts responded more strongly to carrot stimuli than did lizards having sealed ducts; responses by the two groups of lizards to control stimuli did not differ. Tongue-flicking occurred when the vomeronasal system detected a chemical stimulus from either carrot or cologne. Biting occurred only when the vomeronasal organ detected food stimuli (from carrot). Most duct-sealed lizards opened their mouths, some repeatedly. Mouth-opening thus occurs when the vomeronasal organ does not detect chemicals. It may be an attempt to stimulate or prime the vomeronasal organ or to dislodge the sealant.

Key Words—Vomeronasal system, vomerolfaction, feeding, food vomodor, Reptilia, Lacertilia, Iguanidae, *Dipsosaurus dorsalis*.

INTRODUCTION

Squamate reptiles use chemical senses in diverse contexts, including detection of prey and predators, aggregation, identification and scent-trailing of conspecifics, and determination of sex, reproductive condition, and degree of relatedness of conspecifics (e.g., Burghardt, 1970; Duvall, 1979; Chiszar and Scudder, 1980; Garstka and Crews, 1981; Ford, 1982; Heller and Halpern, 1982; Weldon, 1982; Simon, 1983; Cooper and Vitt, 1984a,b, 1986a,b; Cooper et al., 1986; Thoen et al., 1986; Werner et al., 1987; Dial et al., 1989). Three major chemical senses could participate in these discriminations: vomerolfaction, olfaction, and taste (Cooper and Burghardt, 1990b).

Squamates chemically sample the environment by tongue-flicking. Chemicals gathered by the tongue eventually reach the vomeronasal organs via the vomeronasal ducts, one of which opens at the roof of the mouth on each side of the midline. These findings on chemical access to the vomeronasal organ hold for garter snakes (Halpern and Kubie, 1983) and a single lizard of the family Scincidae (Halpern and Kubie, 1980; Graves and Halpern, 1989). Because the relatively nonvolatile materials sampled by the tongue do not appear to reach the main olfactory epithelium (Graves and Halpern, 1989), chemical discriminations requiring lingual sampling of such nonvolatiles must be made by other chemical senses. The most likely candidates are taste and vomerolfaction (Cooper and Burghardt, 1990b), but some other chemical sense could be involved. For example, the trigeminal, facial, glossopharyngeal, and terminal nerves might support chemical sensitivity.

There is little indication that olfaction is necessary for some of the discriminations noted above (Burghardt and Hess, 1968; Burghardt and Pruitt, 1975; Kubie et al., 1978; Halpern and Frumin, 1979; Burghardt, 1980; Heller and Halpern, 1982), but it might be important for responses to airborne odors (e.g., Duvall et al., 1980). Another function of olfaction may be to activate chemical sampling by the tongue (Burghardt, 1970; Cowles and Phelan, 1958; Duvall, 1981; Simon and Moakley, 1985).

Gustation is virtually unstudied in squamates (Burghardt, 1970). In snakes taste cannot be a factor in lingually mediated chemical discriminations because the tongues of snakes lack taste buds (Morgans and Heidt, 1978). Lingual taste buds are present in most lizard families (Schwenk, 1985); preliminary examination suggests that they may be most abundant in iguanids and perhaps next in skinks (Schwenk, personal communication). Despite the presence of taste buds, gustation was not sufficient to allow normal lingual responses to novel environments or normal prey consumption by a scincid lizard (Graves and Halpern, 1990).

Several chemical discriminations by garter snakes require a functional vomeronasal system (Kubie et al., 1978; Halpern and Frumin, 1979) but may

be performed normally after olfactory nerve sections. The skink *C. ocellatus* responds normally to food only when the vomeronasal system is functional (Graves and Halpern, 1990). These findings suggest that the vomeronasal system may mediate important chemical discriminations, especially in feeding and pheromonal communication, in diverse squamates.

We examined the effect of blocking the vomeronasal ducts on responses to chemical food stimuli by the desert iguana, *Dipsosaurus dorsalis*. The desert iguana is the only iguanid species known to discriminate prey odors by tongue-flicking (Krekorian, 1989; Cooper and Alberts, 1990). It also can detect conspecific semiochemicals (Alberts, 1989; but see Pederson, 1988). This species has an unspecialized iguanid tongue having widely distributed taste buds (Schwenk, 1985). Reliance on the vomeronasal system for discrimination of food odors in such a species would suggest its widespread importance in lizards having tongues more specialized for chemical sampling.

METHODS AND MATERIALS

Desert iguanas were captured in Riverside County, California. They were housed for over a year at the University of California at San Diego, where they were used in studies of pheromonal communication and prey odor discrimination. They then were shipped to Auburn University at Montgomery, Alabama, where they were allowed to acclimate to laboratory conditions for over 45 days before the present experiment was conducted. Each lizard was housed individually in a 50 × 30 × 26-cm glass terrarium equipped with an undercage heater and a 75-W heat lamp. Each cage contained a 6-cm-deep layer of sand, a food bowl, and a ceramic shelter. The lizards were fed to satiation. The diet consisted of fresh vegetables, usually a mixture of grated carrots, turnips, yellow squash, zucchini, spinach, and broccoli. They also were fed crickets about once a week. A water bowl was not provided because the lizards remained fully hydrated from water obtained in food.

To determine whether access to the vomeronasal organ is necessary for prey odor discrimination, responses of two groups of desert iguanas to chemical food stimuli and two control substances were tested. The experimental group was composed of eight lizards that had the vomeronasal ducts sealed to prevent chemicals sampled by the tongue from reaching the vomeronasal epithelium; the control group originally consisted of eight lizards subjected to a sham sealing procedure. Under cold anesthesia, both vomeronasal ducts of lizards in the experimental group were sealed with surgical tissue adhesive (Three Bond of America, Inc., Torrance, California) as described by Graves and Halpern (1989, 1990). Lizards in the control group were treated identically except that the tissue adhesive was placed lateral to the openings of the vomeronasal ducts to

avoid sealing them. After the adhesive was dried with the help of an electric fan blowing air across the anesthetized lizards, the lizards were allowed to warm to room temperature before being returned to their home cages. All subjects recovered from the procedure quickly. They appeared to be normally active during the experiments and responded to the experimental situation as did untreated lizards except that behaviors related to chemosensory responses were affected.

In a randomized blocks (repeated measures) design, each lizard responded to chemical stimuli derived from carrot, to cologne, and to distilled water. Carrot was selected because it is a favored food in the laboratory and because the lizards respond strongly to its chemical cues (Cooper and Alberts, 1990). Cologne (Mennen Skin Bracer, Spice Scent) served as a control for responses to a substance having a readily detectable odor lacking import as food, predator odor, or as a social signal. Water was an odorless control for responses to the experimental situation. The stimuli were presented on cotton-tipped applicators that were prepared as follows: Initially, the cotton tip was dipped in distilled water; cologne was added by dipping the moistened applicator in cologne; carrot stimuli were imparted to the cotton by rubbing the moistened swab on the surface of a freshly cut carrot.

The stimuli were presented in an incompletely counterbalanced sequence, one per day, beginning two days after the sealing procedure on May 24, 1989. In the original design, all possible sequences were represented as evenly as possible, with remaining sequences selected randomly. However, two of the sham-sealed subjects could not be used because one repeatedly fled after the sham procedure and another appeared to be sick. The lizards were fed the day before the sealing procedure, but were not fed again until the experiment was over. Because the counterbalancing assured that almost equal numbers of lizards were tested with each stimulus at each of the three trials, hunger had no differential effect on results.

A trial was begun by slowly approaching a lizard's cage, removing its top, and placing the cotton swab 2 cm anterior to the lizard's snout. Tongue-flicks directed to the applicator were recorded for the ensuing 60 sec if the lizard did not bite the applicator. If it did bite, the trial was terminated and number of tongue-flicks before biting and latency to biting were recorded. The response variable analyzed was the tongue-flick attack score (TFAS), which combines tongue-flicking and latency to bite to give an overall index of feeding response strength (Burghardt, 1967, 1970; Cooper and Burghardt, 1990a). If a lizard did not bite, its TFAS was the number of tongue-flicks in 60 sec. If it did bite, TFAS was (60 sec minus latency to bite in seconds) plus a base unit, the base unit being the maximum number of tongue-flicks given by that lizard in response to any of the stimuli (Cooper and Burghardt, 1990a). The base unit selected assures that a predatory bite is weighted at least as heavily as the highest number

of tongue-flicks, which reflects our assumption that a bite is a stronger food-related response than any number of tongue-flicks.

Nonparametric analysis of experimental results was conducted as follows: Friedman two-way analysis of variance (Siegel, 1956) was used within each group, followed by individual comparisons according to procedures described by Hollander and Wolfe (1973); between-group comparisons were made for each condition by Mann-Whitney U tests (Siegel, 1956). Assessment of experimental effects for TFAS by a 2×3 factorial ANOVA for an experiment having repeated measures on one factor and unequal cell frequencies (Winer, 1962) had been planned, but could not be used as the primary analysis due to nonnormality. This analysis and a similar 2×2 ANOVA restricted to carrot and cologne stimuli were used to obtain approximate significance levels for interaction effects. The assumption of homogeneity of variance was met by testing for heterogeneity with Hartley's F_{max} and removing any significant heterogeneity by a logarithmic transformation [$\log_{10}$ (TFAS + 1)]. All tests were two-tailed with $\alpha = 0.05$.

RESULTS

All lizards in the control group tongue-flicked in response to all stimuli except for two that did not tongue-flick in response to distilled water. In contrast, individuals in the experimental group rarely tongue-flicked. Only three of eight tongue-flicked, one in all three conditions, one only to carrot, and another only to cologne. However, six of the lizards having sealed ducts opened and closed their mouths during trials, four of them in cologne trials. All three that tongue-flicked also opened and closed their mouths without tongue-flicking in at least one condition. Thus, they were capable of tongue-flicking, but usually did not. The experimental procedure produced no apparent restraint on lingual movements.

Because so few duct-sealed lizards tongue-flicked, the assumption of normality required for parametric ANOVA was violated, requiring nonparametric analysis that did not allow examination of interaction terms for tongue-flick data (Table 1). For the experimental group, tongue-flicks did not vary significantly over stimuli ($X_r^2 = 0.44$, $df = 2$, $P > 0.10$). However, numbers of tongue-flicks did differ significantly among conditions for the control group ($X_r^2 = 6.33$, $df = 2$, $P < 0.05$). Individual comparisons revealed that cologne and carrot induced significantly more tongue-flicks than water ($P < 0.05$ for cologne, $P = 0.05$ for water). Numbers of tongue-flicks by control lizards did not differ for carrot and cologne ($P > 0.10$). The control group tongue-flicked significantly more times than did the experimental group in response to carrot stimuli ($U = 4$; $N = 6, 8$; $P = 0.004$; one-tailed) and cologne ($U = 7.5$; $N =$

TABLE 1. NUMBERS OF TONGUE-FLICKS AND TONGUE-FLICK ATTACK SCORES (TFAS) BY EXPERIMENTAL AND CONTROL GROUPS OF DESERT IGUANAS RESPONDING TO CARROT CHEMICAL STIMULI, COLOGNE, AND DISTILLED WATER

	Tongue-flicks			TFAS		
	Carrot	Cologne	Water	Carrot	Cologne	Water
Vomeronasal ducts sealed						
Mean	0.88	1.13	0.50	0.88	1.13	0.50
SE	0.74	0.99	0.50	0.74	0.99	0.50
Range	0–6	0–8	0–4	0–6	0–8	0–4
Vomeronasal ducts open						
Mean	4.33	5.50	1.00	49.50	5.50	1.00
SE	1.05	1.67	0.37	10.52	1.67	0.37
Range	3–8	1–12	0–2	5–69	1–12	0–2

6, 8; $P = 0.02$; one-tailed). Tongue-flicks did not differ between groups for distilled water ($U = 23$; $N = 6, 8$; $P > 0.10$).

Biting occurred only in the carrot condition and only control lizards bit (five of six, Figure 1). Thus, significantly more control lizards bit in response to carrot stimuli than to the other stimuli ($X_r^2 = 7.5$, $df = 2$, $P < 0.025$). Carrot stimuli induced biting by significantly more lizards than did the other stimuli ($P < 0.05$ each). Within the carrot stimulus condition (and overall), significantly more control lizards bit applicators than did experimental lizards ($U = 4$; $N = 6, 8$; $P = 0.04$, one-tailed).

The analysis of TFAS data (Table 1) was conducted nonparametrically because less than half the duct-sealed lizards tongue-flicked, violating the assumption of normality required for parametric ANOVA. Responses by the experimental group did not differ among odor conditions ($X_r^2 = 0.44$, $df = 2$, $P > 0.10$). TFAS did vary significantly among conditions in the control group ($X_r^2 = 9.25$, $df = 2$, $P < 0.01$), being significantly greater for carrot than for cologne ($P < 0.01$) or water ($P < 0.01$) and for cologne than for water ($P < 0.05$). The control group had a significantly higher TFAS than the experimental group in response to carrot stimuli ($U = 2$; $N = 6, 8$; $P = 0.001$, one-tailed). TFAS did not differ between groups for the other stimuli (cologne: $U = 15$; $N = 6, 8$; $P > 0.10$; water: $U = 18$; $N = 6, 8$; $P > 0.10$).

Because these nonparametric tests do not directly examine interaction between treatment and odor condition, ANOVAs were conducted to determine the approximate significance of the interaction term. Because variances were heterogeneous ($F_{max} = 754.24$; $df = 3,5$; $P < 0.001$), the data were logarithmically transformed. Variances were homogeneous for the transformed data (F_{max}

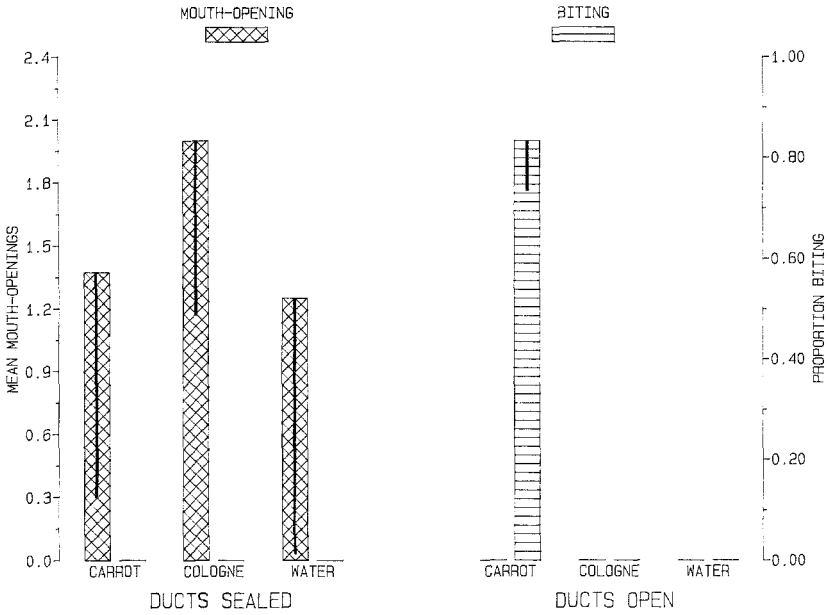

FIG. 1. Mean number of mouth-openings and proportion of lizards biting in response to chemical stimuli from carrot, cologne, and distilled water in groups having sealed and patent vomeronasal ducts. Dark lines represent 1.0 standard error of the mean for mouth-opening and 1.0 standard error of a proportion for biting.

= 3.59; $df = 3,5$; $P > 0.05$). The main treatment and odor effects for the 2 × 3 ANOVA were significant ($F = 112.15$; $df = 1, 12$; $P < 0.01$ and $F = 16.688$; $df = 2, 24$; $P < 0.001$, respectively). The interaction term was also significant ($F = 14.91$; $df = 2, 24$; $P < 0.001$), indicating that relative responsiveness differed among stimuli in the control group and the duct-sealed group. When the trials with water were eliminated from the analysis, a 2 × 2 ANOVA yielded similar results, with both main effects (treatment $F = 77.93$; $df = 1, 12$; $P < 0.001$; odor stimulus $F = 13.44$; $df = 1, 12$; $P < 0.005$) and the interaction ($F = 35.40$; $df = 1, 12$; $P < 0.001$) highly significant.

Only lizards with sealed vomeronasal ducts exhibited mouth-opening (Figure 1). The number of lizards showing this behavior in one or more conditions was significantly greater in the experimental group than in the control group (Fisher $P < 0.01$, one-tailed). However, this difference was not significant for any one condition. Furthermore, the frequency of mouth opening did not differ among conditions in the experimental group ($X_r^2 = 0.06$, $df = 2$, $P > 0.10$; carrot: SE = 1.1, range = 0–9; cologne: SE = 0.8, range = 0–6; water: SE

= 1.2, range = 0–8). Numbers of individuals opening the mouth at least once were three each for the carrot stimuli and water and four for cologne.

DISCUSSION

Patent vomeronasal ducts are necessary for desert iguanas to respond to food odors with normal rates of tongue-flicking and attack. This conclusion is supported by the findings that (1) lizards having sealed vomeronasal ducts tongue-flicked at lower rates than those having open ducts in response to odorous stimuli; (2) only those having open, unobstructed ducts showed higher tongue-flicking rates to odorous stimuli than to water; (3) individuals having patent vomeronasal ducts bit only applicators bearing carrot stimuli; and (4) individuals having patent ducts bit more frequently in response to carrot stimuli than did those having sealed ducts, which bit no applicators.

Failure by lizards having sealed vomeronasal ducts to respond to chemical food stimuli is best indicated by the TFAS data. That lizards having sealed ducts did not respond differentially among stimuli whereas lizards having patent ducts did so, with the greatest responses elicited by the food stimuli, suggests that the vomeronasal system is required for such discrimination. Three additional results in aggregate demonstrate that sealing the ducts induces a deficit in responsiveness to a chemical food stimulus. First, TFAS for lizards having patent vomeronasal ducts was significantly greater in response to carrot stimuli than for lizards having sealed ducts. Second, TFAS did not differ within the experimental group for cologne and carrot stimuli. Finally, the interaction between treatment and stimulus condition shows a specific elevation of TFAS in response to carrot stimuli by lizards having patent ducts, but not by lizards having sealed ducts.

Desert iguanas discriminate food from other chemicals (Cooper and Alberts, 1990; control group in this study), but those having sealed vomeronasal ducts do not by our measures. Vomerolfaction may be needed for food odor discrimination, but desert iguanas might discriminate chemical food stimuli without vomerolfactory cues, yet not respond by biting or by increased tongue-flicking. Vomeronasal feedback may provide an intrinsic reward for maintaining elevated tongue-flicking (Halpern, 1987). If vomodors (Cooper and Burghardt, 1990b) stimulate tongue-flicking, the apparent lack of discrimination could actually be a motivational deficit. However, because tongue-flicking is intimately associated with discrimination of chemical food stimuli by squamates (e.g., Burghardt, 1970), it is likely that in the absence of vomerolfaction, squamates are simply unable to recognize chemical food stimuli. Taste, olfaction, and other putative chemical senses were not affected by the experimental procedure. These senses, therefore, are not sufficient to elicit biting or elevated

tongue-flicking, at least for the food tested and in the absence of visual cues typical of food. The duct-sealing procedure clearly affected responsiveness (as indicated by tongue-flicking) to cologne, which presumptively was readily detected via olfaction. Presumably, the animals having sealed ducts detected cologne normally via olfaction, but exhibited a reduction in tongue-flicking because the tongue-flicking did not result in delivery of chemical stimuli to the vomeronasal organs.

Results on tongue-flicking are concordant with those for TFAS, except that tongue-flicking provides no evidence for discrimination of food stimuli by the control group. Several lizards bit applicators bearing carrot stimuli, some at short latency. Presumably, they did not tongue-flick more to carrot stimuli because they had less time than in other tests (Cooper and Vitt, 1980; Cooper and Burghardt, 1990a). Thus, the discrepancy does not indicate failure to discriminate.

Mouth-opening occurs in diverse squamates during tests of responses to odors on applicators (Cooper, unpublished observations), but frequent mouth-opening has not been reported previously during such tests. In desert iguanas, some openings were similar to yawning; others were more rapid and were repeated several times. That mouth-opening is restricted to individuals having blocked ducts suggests that it may indicate discomfort or have some chemosensory significance, as proposed for rattlesnakes (Graves and Duvall, 1983, 1985). It could be an attempt to stimulate the vomeronasal organ or clear the vomeronasal ducts. Our strong impression is that the observed results reflect the inability of experimental lizards to deliver chemical samples to the vomeronasal organs. Nevertheless, if mouth-opening does indicate discomfort, the possibility remains that the effect of duct closure is not specific to the vomeronasal sense.

The importance of vomerolfaction in feeding behavior has been confirmed in garter snakes (Halpern and Frumin, 1979) and very strongly suggested in a scincid lizard (Graves and Halpern, 1990) and an iguanid lizard (this paper). Iguanids and skinks have among the least specialized of lizard tongues. Their tongues are relatively rounded, fleshy, and lack the deep forking of snakes and some other lizards. One might expect that such tongues would be less efficient in transferring molecules to the vomeronasal ducts than would deeply forked, elongated tongues having fine tines. Although vomeronasal stimulation is possible after removal of the tip of the tongue (Halpern and Kubie, 1980) and strike-induced chemosensory searching is possible in the absence of the entire tongue (Carr et al., 1982), numerous studies show that tongue-flicking is the major means of collecting chemicals for transport to the vomeronasal organ (e.g., Wilde, 1938; Burghardt, 1980).

The greatest reliance on tongue-flicking during foraging occurs in families of lizards that are active foragers. Members of actively foraging families rely

on prey odors to detect prey whereas lizards that are ambush foragers do not (Cooper, 1989a,b, 1990b). Lingual elongation and tine development are greatest in families of active foragers (see McDowell, 1972). The desert iguana is an actively (but not intensively) foraging herbivore in a family consisting largely of insectivorous ambush foragers. Although it can discriminate chemical food stimuli from other chemical stimuli, it has a typically generalized iguanid tongue that is not elongate and lacks tines. If prey odor discrimination depends on vomerolfaction in such a lizard, it may well do so in other squamates having tongues more specialized for chemical sampling. Thus, despite a lack of evidence for lizard and snake families beyond the three mentioned, it can be hypothesized that vomerolfaction is the primary sense allowing prey odor discrimination in all of the major squamate families capable of it.

Acknowledgments—This work was partially supported by a grant-in-aid from Auburn University at Montgomery, Alabama, by a training grant to the University of California at San Diego from the National Institutes of Health, and by our respective Departments of Biology. We thank Brent Graves for discussion of the technique used to seal the vomeronasal ducts and for providing the sealant. We are also grateful to Mimi Halpern for making detailed useful comments on the manuscript and for encouraging cautious interpretation of the findings. Anonymous reviewers also made insightful comments that allowed material improvements.

(Received June 21, 1990; accepted August 28, 1990)

Abstract—Natural leachates of *Eucalyptus globulus* (throughfall, stemflow, and soil percolates) were collected daily during rainy spells in the vegetative period (February–July), and their effects on the germination and radicle growth of *Lactuca sativa* were measured. Concurrently, the effects of *L. sativa* of topsoil and leachates from decaying litter were determined. The results suggest that toxic allelochemicals released by *Eucalyptus globulus* may influence the composition and structure of the understory of the plantation and that this effect is attributable mainly to the decomposition products of decaying litter rather than to aerial leachates. The soil may neutralize or dilute allelopathic agents, at least below the top few cms.

Key Words—*Eucalyptus globulus*, allelopathy, *Lactuca sativa, natural leachates, soil, litter.*

INTRODUCTION

E. globulus is an exotic species of economic importance in Galicia (northwest Spain). It often has been implicated in the degradation of the environment where it has been planted. However, the ecological mechanisms controlling the struc-

*To whom correspondence should be addressed.

0098-0331/91/0100-0147$06.50/0

ture and diversity of a woodland understory are numerous and their individual effects difficult to distinguish. Any degradation produced by *E. globulus* is likely to be due to a group of related stress factors acting synergistically, rather than to a single well-defined cause.

Several authors (Bellot, 1949, 1966; Castroviejo, 1973; Alvarez and Malvar, 1979) have reported that planting *E. globulus* over heath decreases the number of species in the understory as compared with the original heath vegetation. Bara et al. (1985) found that plantations of *E. globulus* were no lower in species richness than *Pinus pinaster*, *Castanea sativa*, or *Quercus robur* plantations, but cover was less and the distribution of life forms different, with a scarcity of hemicryptophytes and geophytes and a preponderance of tall herbaceous species such as *Pteridium aquilinum* over heathland species such as heather and *Ulex* spp. They suggest that the kind of vegetation beneath *E. globulus* depends on water use (Diaz Fierros et al., 1982), on the accumulation and chemical composition of residues (which might give rise to allelopathic phenomena), and on competition for nutrients in poorer soils, and have observed that *E. globulus* increased the concentration of exchangeable Al, K, and Mg. Bara (1970), had found previously that the C:N ratio and acidification tended to increase in 5- to 12-year-old *E. globulus* plantations, whereas Guitian (1963) concluded that *E. globulus* extracts mobilized more Fe and Al than those from *Q. robur*, thus contributing to the degradation of the surrounding area.

The concurrence of plant species may involve both competition for nutrients (competition *sensu strictu*) and allelopathic phenomena in which toxic organic substances are released into the environment by certain species. The importance of the latter kind of process in forest ecology, especially in the case of *E. globulus* stands, has been emphasized by several researchers (Rice, 1974). Arias (1982) found *E. globulus* leaves to contain water-soluble and volatile compounds capable of inhibiting the germination and growth of grassland species; Baker (1966) reported that volatile compounds released by *E. globulus* suppressed germination and hypocotyl growth in *Castanea sativa* seedlings but did not affect *E. globulus* seedlings. In California *E. globulus* plantations, Del Moral and Muller (1969) have shown the importance of fog-drip in the transport and deposition of foliar metabolites and the potential influence of these metabolites on the diversity and structure of the understory community. The latter authors ruled out the possibility that conditions of illumination, nutrient availability, or soil humidity might suffice to explain the exclusion of grassland species (soil humidity may even be increased by nocturnal condensation beneath the canopy) and pointed out that in Australia, where *Eucalyptus* is native, there are usually few bushes and fewer grasses in the vicinity of eucalyptus trees.

Other species of the genus *Eucalyptus* containing soluble and volatile compounds that suppress the growth of grassland species include *E. camaldulensis* (Del Moral and Muller, 1970), *E. microtheca* (Al-Mousawi and Al-Naib, 1975,

1976; Al-Naib and Al-Mousawi, 1976), and *E. citriodora* (Nishimura et al., 1984). Del Moral et al. (1978) concluded that foliar leachates of *E. baxteri* can prevent the growth of certain heathland shrubs beneath its canopy in its native habitat and that this is not due to competition. Inhibition of test plants such as *E. viminalis* by foliar leachates, radicle exudates, litter, and soil extracts was also observed in their laboratory. On the other hand, Willis (1980) found that artificial leachates of green and fallen dead leaves of *E. regnans* only produced inhibition at high concentrations.

Chemical analysis of leaves and leachates of *E. globulus* has revealed a large number of water-soluble compounds of proven phytotoxic potential, including the phenolic compounds ellagic, gallic, caffeic, gentisic, *p*-coumaric, and chlorogenic acids and the terpenoids cineole, camphorol, and α-pinene (Hillis, 1966a,b; Del Moral and Muller 1969; Guenther, 1950). Terpenoids can be phytotoxic at concentrations as low as 1–3 μM (Asplund, 1968), and their effective involvement in allelopathic aggression by *Eucalyptus* spp. was noted by Putnam (1983). Trenbath and Fox (1976) reported that *E. bicostata* leachates did not contain the terpenoids found in artificial leaf extracts and suggested that their release into the environment might be brought about by the action of leaf-chewing insects.

The results discussed above show the allelopathic potential of eucalpytus trees but do not prove conclusively that allelopathic phenomena actually occur in plantations. Harper (1977) has emphasized that the techniques traditionally used for detecting allelopathic processes do not guarantee the validity of results under field conditions, and Stowe and Bong-Seop (1984) have maintained that hitherto research on allelopathy has been very extensive but insufficiently intensive. In order to evaluate the importance of allelopathy in a given situation and to distinguish between laboratory artifacts and genuine plant–plant interactions, it is necessary to establish a relationship between naturally released products and observed symptoms of phytotoxicity and to understand the dynamics of the substances involved.

In this paper we have assessed the phytotoxic potential of natural *E. globulus* leachates (stemflow, throughfall, and soil percolates) together with the capacity of the soil for controlling the phytotoxicity of decaying *E. globulus* litter.

METHODS AND MATERIALS

Description of the Site. The source of material was a 23-year-old *E. globulus* plantation located 250 m above sea level near Santiago de Compostela, Spain (42°50′N, 8°27′W). The plantation faces 218°N with a slope of 26 : 100. The density of the trees is 1289/ha, the average height is 28 m, and the average

diameter 1.3 m above ground is 22.6 cm. According to the FAO classification, the soil is a Humic Andosol, although local variations in depth produce areas of Humic Cambisol with Andic properties. The litter layer is deep and has an average depth of 35 dm, is rich in humic acids, and lies over a reddish brown transition layer and weathered amphibolite bedrock. The characteristics of the topsoil (0–20 cm) are listed in Table 1.

The average annual temperature of the area is 12.9°C, the average temperature during the coldest month is 5.2°C and the average annual precipitation is 1288 mm, of which only 137 mm fall during the three summer months. According to Papadakis' classification, the area has a mild maritime thermal regime and a humic humidity regime (Carballeira et al., 1983). The meteorological data for the period of the study (Figure 1) were obtained from the nearest weather station (C.S.I.C., Santiago de Compostela) and the rainfall sequence adjusted to the data obtained from pluviometers located in the proximity of the plantation.

Leachates, etc., were obtained from a 30 × 80-m plot lying parallel to the slope and containing 58 trees whose distribution by diameter is shown in Table 2.

Collection of Material. Foliar leachates were collected in 10 randomly placed PVC pluviometers 1 m deep and 20 cm in diameter. A layer of glass wool at the bottom of each prevented splashing and retained organic debris that might otherwise have contaminated the leachate.

Stemflow was taken from 13 randomly chosen trees over 25 cm in diameter by means of runnels encircling the bole at least three times.

Soil percolates were collected by means of 17 flat PVC lysimeters 22.5 cm wide, 50 cm long, and 15 cm deep, which were pushed horizontally into the soil without damage to its natural structure.

TABLE 1. CHEMICAL CHARACTERIZATION OF ANDOSOL USED

				Exchangeable bases ($AcONH_4$, pH 7) (meq/100 g)				pH	
Organic	C (%)	N (%)	C/N	Na	K	Ca	Mg	H_2O	ClK
	8.83	0.76	12	0.50	0.37	0.94	0.43	4.60	4.40

0.83	38.92	4.22	5.47

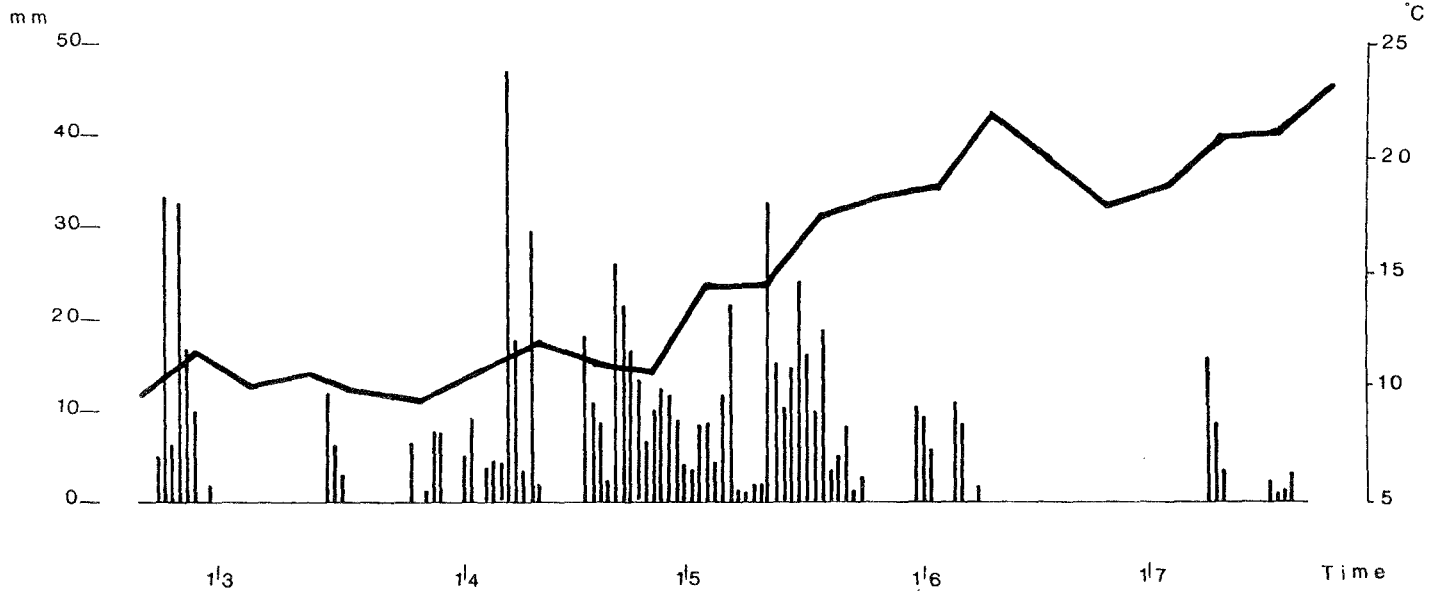

FIG. 1. Meteorological data for the period covered by the study.

TABLE 2. DIAMETER AND HEIGHT OF *E. globulus* TREES

Basal diameter at 1.3 m (cm)	Height min–max(m)	Trees %
4.6–15	7–29.5	37
15–25	8.5–31.5	18
25–35	25–48.5	26
35–45.9	39.5–49.5	19

All the above leachates were accumulated over 24-hr periods (9 AM to 9 AM) in opaque plastic bottles, which, like the collectors (pluviometers, etc.), were washed with distilled water before each collection period. After the amount collected each day had been measured at the site, samples were rapidly taken back to the laboratory for assay.

Leachates from decaying litter were obtained by collecting all the eucalyptus material that had fallen in the course of seven days onto randomly located 1-m squares (leaves, bark, twigs, etc.). Thus the material obtained was from natural abscission; Attiwill et al. (1978) pointed out that the composition of "artificial litter" obtained by manual abscission differs from "natural litter." The litter collected was thoroughly mixed to obtain homogeneous samples, and three samples were taken to determine dry weight at 80°C. Thirty-five 30-g samples then were placed in nylon litter bags of 2 mm mesh. Bocock (1964), MacCauley (1975), and Gloaguen and Touffet (1980) found no significant differences between rates of decomposition in bags with mesh sizes of 0.5–2.0 and 2.5–5.0 cm. On April 25, the bags were placed in groups of seven at five randomly chosen points on the site, and one bag was removed from each group after 1, 15, 30, 60 and 90 days.

Fifteen soil samples of the top 5 cm were taken at random using an auger 5 cm in diameter. Organic material and stones were removed and the sample was homogenized before assay.

Bioassays. Ideally, the effect of the leachates collected would be tested on species that are abundant in the vicinity of the plantation but not present in its understory. However, since all such species germinate and grow slowly and since it was found that the leachates lose most of their biological activity within 96–112 hr, such bioassays were not feasible. To measure the relative phytotoxic efficiency of the various natural release mechanisms investigated, we therefore used *Lactuca sativa* (var. Great Lakes), a fast-growing species commonly used in bioassays due to its well-known sensitivity to most phytotoxic substances and plant growth regulators.

Bioassays of throughfall, stemflow, soil percolates, and litter leachates (see

below) consisted of sowing 50 lettuce seeds on 3MM Whatman paper in each of five Petri dishes 10 cm in diameter and wetting them with 7.5 ml of the leachate being assayed (controls were wetted with water collected in the gauges placed outside the plantation). In bioassays of soil, the seeds were sown on 3MM Whatman paper laid over 30 g of soil at field capacity. After incubation in the dark for 48 hr at 24°C and 80% relative humidity, germination rates and radicle lengths were recorded and the statistical significance of the results was calculated by means of analysis of variance (Vesereau, 1968).

Litter leachates were prepared by saturating the collected material with distilled water, allowing it to soak for 24 hr in the dark at 15°C, and then washing with a distilled-water spray until 50 ml of extract per 100 g dry wt had been obtained, a dilution of 1:1. By further dilution with distilled water, 1:2, 1:10, and 1:50 (v/v) extracts were prepared.

In all assays, the pH lay within the range of acidities at which germination and root elongation of *L. sativa* are not affected (Table 3).

RESULTS AND DISCUSSION

Figure 2 shows that the only date on which the biological activity of foliar leachates differed from that of water from the control pluviometers at the $d = 0.01$ level was May 30. Radicle growth was significantly depressed by these leachates, in which leaf exudate had accumulated on the eucalyptus trees during six days without rain (see Figure 1). Although there had been 30 days without rain prior to rainfall on July 9, the amount of rain that fell on this occasion, and the manner in which it fell, apparently produced greater dilution of the exudates than on May 30.

Germination was significantly depressed (by over 65%) by samples of stemflow collected on March 14 and radicle growth was significantly reduced (by over 66%) by samples collected on July 9 (Figure 3). These dates marked

TABLE 3. AVERAGE VALUES AND VARIATION OF pH IN BIOASSAY EXTRACTS

	Min	Mean	Max
Rain water (control)	4.3	5.1	5.8
Foliar leachates	3.6	4.0	5.4
Cortical leachates	3.7	3.9	4.6
Edaphic percolates	3.7	4.1	4.7
Soil (pH in water 1:1 v/v)	3.5	4.6	4.9
Litter leachates	3.8	4.5	5.0

the ends of the longest exudate accumulation periods (15 and 31 days, respectively).

The above results suggest that aerial leachates are not a significant source of allelochemical agents unless a set of fairly infrequent conditions coincide. Toxins must accumulate (Figure 4) during a long rainless period without leaching, and their allelopathic effects also depend on the quantity of rain falling, the duration of the rainfall, and on the phenological state of the plant (Mitchell, 1968; Tukey, 1969; Turner and Quarterman, 1975; Squires and Trollope, 1978). Figure 4 shows the height of the electrolyte concentration in the leachates after light rainfall.

Soil percolates (Figure 5) exhibited relatively little biological activity when compared with that of topsoil (Figure 6). Germination was unaffected, and radicle growth was only inhibited by soil leachates collected on April 18 and July 7, when the concentration of allelochemicals was high in the first leachate after long periods without rain.

Topsoil (Figure 6) had no significant effect on germination levels, but severely reduced radicle growth (up to 70% reduction, compared to controls). The three inhibition maxima coincide with the ends of the longest rainless periods of exudate accumulation (31, 10, and 8 days, ending on July 7, June 16, and May 30, respectively). Phytotoxicity increased notably as the summer

progressed, possibly due to variation in the quantity or nature of decomposing litter (Figure 8 below), acceleration of decomposition and toxin release due to higher temperatures (Molina et al., 1984), or changes in the phenology of the trees, the activity of soil microorganisms or water and redox potentials.

Figure 7 shows the germination and radicle growth bioassay data analyzed

by a two-way analysis of variance, which showed no interaction. LSDs were calculated in two one-way analyses of variance. Germination was depressed by all the leachates prepared, but radicle growth was significantly decreased only by leachates 1 : 1 and 1 : 2. The maximum reductions in both germination levels and radicle growth were about 50%. Maximum toxicity was exhibited between 15 and 45 days after abscission, and leachates 1 : 1 and 1 : 2 still caused severe inhibition after 90 days, even though toxins should have leached out of the litter on site during this period. Leachates 1 : 10 and 1 : 50 depressed radicle growth up to day 30 and germination up to day 60. In assessing the significance of these results, it should be borne in mind that the total quantity of litter falling during the period covered by the study was well over 400 dry wt/m^2 (Figure 8), making the concentrations of the extracts bioassayed well within the concentration range that might be expected under natural conditions. *Eucalyptus* trees are peculiar in shedding litter continually, so that the release of toxic leachates from decaying litter occurs year-round. Most litter falls just before

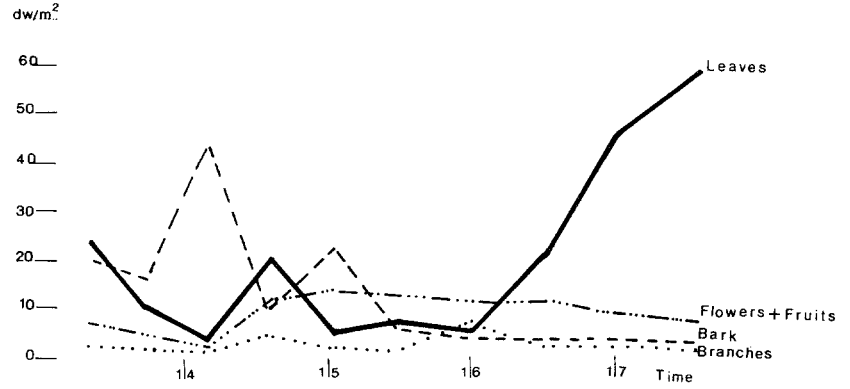

FIG. 8. Litter fall components of *E. globulus* over the study period.

the summer (Reichle, 1981), not in autumn as in the case of native species such as *Quercus robur*, thus circumventing the defensive strategies of native understory species.

The above results indicate that the most important mechanisms by which eucalyptus toxins are released into the soil are through the decomposition of fallen litter. Some seemingly contradictory findings should be noted, however. First, in the present study the high inhibitory activity of both litter leachates and topsoil were washed away by rainfall, whereas the contrary was observed by Becker and Drapier (1985) in *Abies alba* Mill. plantations. Second, litter leachates are more toxic than soil or soil percolates (although the loss of toxicity by the percolates may have been due merely to their already being diluted when collected). Third, and most strikingly, while litter leachates mainly depress germination, topsoil reduces radicle growth.

The processes in the soil to which allelochemicals released by plants are subjected are complex and largely unknown and may result in either synergistic or antagonistic effects (Rice, 1974; Kaminsky, 1981). Possible interactions include the breakdown of active compounds after absorption by soil colloids and the induced release from colloids of growth promotors, which might compensate for the inhibition caused by the eucalyptus toxins. Such promotors might proceed either from other species in the community or from microbial synthesis. Without a doubt, the allelopathic effects of *E. globulus* on the decomposition and structure of its own understory can only be fully elucidated by means of a thorough biochemical study of the soil, including its microflora and mycorrhizae. The interaction between direct and indirect allelopathic processes, and between these processes and water availability, pathogenic agents, the perturbation of nutrient uptake and ionic toxicity must all be considered. The present results, nevertheless, demonstrate that the chief mechanisms for the release of

allelochemicals by *E. globulus* is the decomposition of litter and that the toxicity of the litter is especially effective during the delicate establishment stage of the target species. This would explain the paucity of the understory, when compared with nearby groups of trees of other species, and might also affect the balance among different life forms (Bara et al., 1985).

CHEMICAL DETECTION OF CONSPECIFICS IN THE CRAYFISH *Procambarus clarkii:* ROLE OF ANTENNULES

JIN W. OH and DAVID W. DUNHAM*

Department of Zoology
University of Toronto
Toronto, Ontario, Canada M5S 1A1

(Received November 10, 1989; accepted September 4, 1990)

Abstract—Tests with female crayfish (*Procambarus clarkii*) confirm that conspecifics can be detected chemically. The subjects were more attentive in the presence of water from a stranger's tank than in the presence of water from their own tank. Animals with intact antennules performed this discrimination best, but animals with one intact inner ramus and one intact outer ramus also clearly responded. Conspecific chemical discrimination after loss of both inner or both outer rami was weak (trial 2) or absent (trial 1). The relevance of this outcome to previous conflicting reports on the use of antennules in sex and species discrimination in crayfish is discussed.

Key Words—*Procambarus clarkii*, Crustacea, Decapoda, crayfish, antennule, chemical detection, chemical communication.

INTRODUCTION

There has been some interest in the ability of crayfish to detect other crayfish chemically. Reports in the literature address two kinds of discrimination. The first of these is the ability to discriminate conspecifics on the basis of sex. This ability has been demonstrated in *Orconectes virilis* by Hazlett (1985a), and in *Procambarus clarkii* by Ameyaw-Akumfi and Hazlett (1975) and Ameyaw-Akumfi (1976). Since the ablation of both the inner and outer rami, or of only the inner rami, of the antennules resulted in the loss of this ability in *Procambarus clarkii*, these authors implicated the inner rami in the relevant chemical transduction. Response to conspecifics of the opposite sex in the crayfish *Orco-*

*To whom correspondence should be addressed.

nectes propinquus was shown by Tierney et al. (1984) to occur only when the outer antennular rami were intact. Ablation of the outer rami resulted in the loss of ability to respond, while ablation of the inner rami did not affect this ability.

The second kind of discrimination investigated in the literature involves the ability of the test animal to distinguish itself from another conspecific. This type of discrimination has been studied in *Procambarus clarkii* by Little (1975), Itagaki and Thorp (1981), Thorp (1984), and Rose (1984), and in other species of crayfish by Little (1976), Thorp and Ammerman (1978), Tierney and Dunham (1982, 1984), Tierney et al. (1984), and Hazlett (1985b, 1989).

Rose (1986) reported chemical detection of non-self conspecifics, by intact *Procambarus clarkii* but showed equivocal results for discrimination of self from other stimuli.

We report here the results of a study of self versus stranger chemical discrimination by female *Procambarus clarkii*. We examine the role of both rami of the antennules in performing this discrimination.

METHODS AND MATERIALS

The subjects, mature, nongravid, intermolt female *Procambarus clarkii*, were obtained from a supplier in Louisiana. They were maintained on a light cycle of 12 hr dark–12 hr light, at 18–20°C, and fed raw fish daily. They were held in aerated, individual glass jars containing 2.5 liters of distilled water and a gravel substrate for five days before testing.

Antennule ablation was performed after anesthesia by immersion in ice water, and the animals were given at least 24 hr to recover from this procedure before testing. Stimulus water was obtained by gently scooping out 50 ml from a jar that had held one crayfish for five days, 1 hr before testing. Stimulus water came from a different crayfish for each trial.

A test consisted of first placing a crayfish and 2 liters of its own jar water in a 20 × 36 × 22 cm (high) aquarium. After 15 min, the stimulus water was placed in a 50-ml burette and adjusted to drip onto an airstone in the aquarium at a rate of about 1 drop every 2.5 sec. The experiments were performed at night, when the animals were most active (2100 to 0200 hr).

The behaviors of the animals were video-monitored for 1 hr from an adjacent room, using an infrared-sensitive camera. Both the order of the treatments (intact, inner ablates, other ablates, cross ablates), and the order of individual animals used in each test, were randomized. In trial 1, 10 different animals were used in each of the four tests (a total of 40 crayfish), and each animal was tested once with self water and once with stranger water. In trial 2, different animals were similarly tested, but only with stranger water. Trial 2 was a replicate of the stranger water test in trial 1, conducted with a new set of animals. The procedure followed was similar in most respects to that used by Rose (1986).

RESULTS AND DISCUSSION

Behaviors exhibited by the test subjects were resting, in which the subject neither moved or displayed; locomotion; and attention to the stimulus source. Attention included touching the airstone, climbing on the airstone, and chela displays of meral extension and meral spread (Bruski and Dunham, 1987).

The median attention scores from trial 1 for the four test groups of 10 crayfish each are shown in Figure 1. The raw scores for attention during the self and stranger water tests were compared, using the Wilcoxon signed-rank test (Castellan and Siegel, 1988), at the 1% significance level. The intact animals were more attentive in the presence of water from another crayfish than in the presence of their own water ($P < 0.001$), as were the cross ablates ($P < 0.003$). Both the inner ablates and the outer ablates showed no difference in attention between the two tests ($P > 0.50$ and $P > 0.28$, respectively).

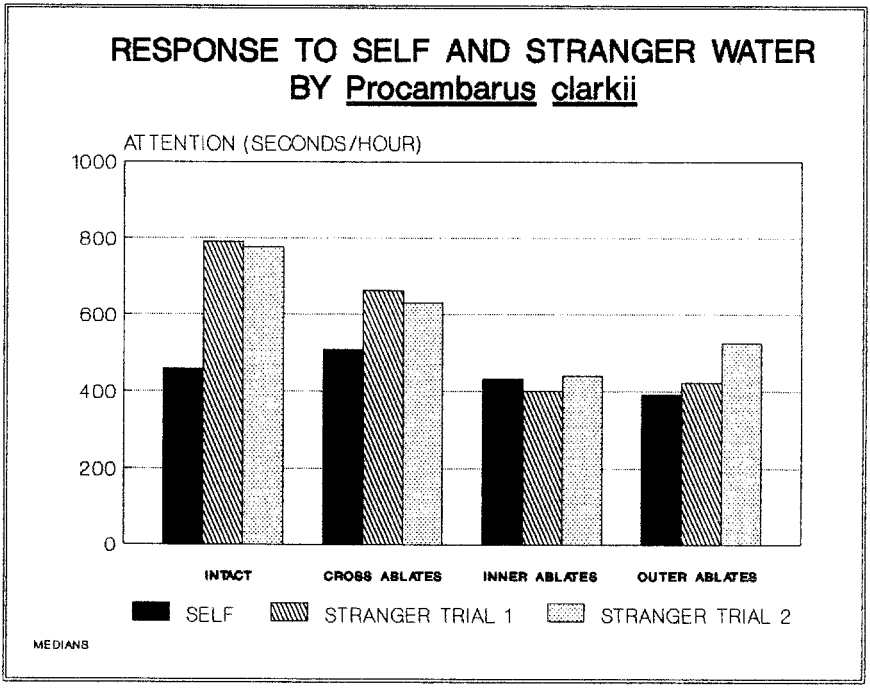

FIG. 1. Median attention scores from trial 1 of four groups ($N = 10$) of female crayfish (*Procambarus clarkii*) tested individually with water from their own home tank or a stranger's home tank. Cross ablates had one inner and one outer antennule ramus intact; inner ablates had only two outer rami; outer ablates had only two inner rami. Medial attention scores from trial 2, a replicate of the stranger water test in trial 1, with different animals, are shown also. Significance values are given in the text.

Attention scores from trial 1 also were compared across treatment groups, using the Wilcoxon-Mann-Whitney test (Castellan and Siegel, 1988), at the 1% significance level. The scores in the presence of self water were marginally greater (significance at the 5% level) for the cross ablates than the inner ablates ($P < 0.02$) or the outer ablates ($P < 0.03$). Otherwise, the scores in the presence of self water did not differ across groups. The attention scores in the presence of stranger water did not differ significantly between the inner ablates and the outer ablates ($P > 0.42$). The scores of intact animals in the presence of stranger water were significantly greater than those of the cross ablates ($P < 0.006$), and the scores of the latter were significantly greater than those of the inner ablates ($P < 0.0007$) or the outer ablates ($P < 0.001$).

Attention scores from trial 2 were compared across treatment groups using the Wilcoxon-Mann-Whitney test (Castellan and Siegel, 1988). Trial 2 scores also were compared with scores from the equivalent treatment groups in trial 1. The attention scores in the presence of stranger water did not differ significantly between the inner and the outer ablates ($P > 0.192$). The scores of intact animals in the presence of stranger water were significantly greater than those of the cross ($P < 0.007$), inner ($P < 0.0001$), and the outer ablates ($P < 0.0002$), but there was only a marginal difference (significant at the 5% level) between the cross ablates and the inner ($P < 0.05$) and the outer ablates ($P < 0.022$). The attention scores from trial 2, when compared with scores from the equivalent treatment groups in trial 1, showed no significant difference in all four cases ($P > 0.456$; $P > 0.100$; $P > 0.341$, and $P > 0.106$, respectively).

The attention-promoting effect of water from another isosexual conspecific shown here is consistent with the results of Rose (1986). What is surprising is the inability of animals with intact outer antennule rami to discriminate self from stranger water. The minimal requirement for this discrimination in our tests was one intact inner ramus and one intact outer ramus. Ameyaw-Akumfi and Hazlett (1975) reported that chemical sex discrimination in *Procambarus clarkii* was impaired when either both rami, or only the inner antennule rami were ablated. They did not report a test with only the outer rami ablated. However, Tierney et al. (1984), showed in *Orconectes propinquus* that response to conspecifics was only possible with intact outer rami and that the inner rami were not required (see also Gleeson, 1980).

Two hypotheses suggest themselves in considering these differences: (1) Discrimination of conspecifics in crayfish may be a fundamentally different process from stranger detection, regardless of the species involved. Different chemicals, different sensilla, or different CNS processing may be involved. (2) Alternatively, these two species (and genera) may differ in their means of transducing socially relevant chemicals, regardless of the particular discrimination being made. Further experiments are needed to define precisely the anatomical basis of semiochemical responses.

Tierney et al. (1986) presented indirect but persuasive evidence that one of two setal types, found on the outer, but not on the inner antennule ramus, was the sensillum where this kind of chemical transduction took place. We have examined *Procambarus clarkii* antennules under the light microscope and scanning electron microscope. We found that aesthetascs resembling those described and illustrated by Tierney et al. (1986) for the antennules of *Orconectes propinquus*, were present in *Procambarus clarkii*. The distribution of the aesthetascs on only the outer ramus of the antennule also resembled that of *Orconectes propinquus* (Oh and Dunham, unpublished data). Although we have no direct knowledge of the way in which the rami effect semiochemical transduction, there is no gross anatomical difference that suggests a different physical arrangement of sensilla.

Acknowledgments—This study was supported by an operating grant from the Natural Sciences and Engineering Research Council of Canada to D.W.D. We acknowledge helpful comments on the manuscript by two anonymous referees.

Abstract—Callus and suspension cultures of *Antennaria microphylla* (small everlasting) and the noxious weed *Euphorbia esula* (leafy spurge) can glucosylate benzene-1,4-diol (hydroquinone) to the corresponding monoglucoside, arbutin. HPLC analysis of extracts from callus tissue corroborates the presence of hydroquinone in the cells of small everlasting. Constitutive levels of a UDPG-dependent glucosyltransferase were detected in cell-free extracts of this tissue. Although this detoxification enzyme was induced in leafy spurge suspension culture cells grown in the presence of hydroquinone, the activity was six-fold lower than that measured in small everlasting. Differential ability to detoxify hydroquinone provides a basis for the observed allelopathic interaction between small everlasting and leafy spurge.

Key Words—Allelopathy, *Antennaria microphylla*, small everlasting, *Euphorbia esula*, leafy spurge, tissue culture, hydroquinone, arbutin, glucosyltransferase, biotransformation.

INTRODUCTION

Environmental concerns about herbicide use have stimulated the search for alternative weed-control strategies. The natural phenomenon of allelopathy offers a potential new methodology to supplement conventional weed control programs. The use of allelopathy for weed control relies upon the species-specific responses of a target weed to chronic, sublethal doses of an allelochemical,

*To whom correspondence should be addressed.

0098-0331/91/0100-0167$06.50/0

available as an exudate or leachate from a neighboring plant or supplied as an exogenous formulation. Many allelopathic, noncompetitive plants have been examined for potential endogenous phytotoxins. These investigations have focused on the isolation, characterization, and bioassay of putative allelochemicals to identify major allelochemical sources and to specify structure–activity relationships. This basic chemical and biological research is vital to corroborate the existence of an allelopathic interaction. The exploitation of allelopathy for weed control, however, may not be fully utilized until the underlying biochemical mechanisms are defined.

Euphorbia esula (leafy spurge) and the low-growing, noncompetitive forb *Antennaria microphylla* (small everlasting) grow in close association in rangeland habitats. The reduction of leafy spurge growth in these stands has been attributed to natural chemical phytotoxins (allelochemicals) produced by small everlasting. Hydroquinone, a simple phenol that is strongly phytotoxic to leafy spurge, is biosynthesized by small everlasting (Manners and Galitz, 1985). We have reported recently the biotransformation of hydroquinone to its nonphytotoxic monoglucoside, arbutin, in callus and suspension cultures of small everlasting and leafy spurge (Hogan and Manners, 1990). Differences in the ability of the two species to detoxify hydroquinone could be a prominent factor in the observed dominance of small everlasting over leafy spurge. We now report the isolation of uridine diphosphoglucose (UDPG) -dependent hydroquinone glucosyltransferase activity from cell-free extracts of small everlasting and leafy spurge tissue cultures. These in vitro systems exhibit species-specific differences in the efficiency of enzyme-mediated glucoside formation.

METHODS AND MATERIALS

Tissue Cultures. Suspension and callus cultures of leafy spurge and small everlasting were grown as previously described (Hogan and Manners, 1990). Test hydroquinone solutions were prepared in absolute methanol and introduced aseptically into flasks of leafy spurge suspension culture cells at a final methanol concentration of 1% or less (Davis et al., 1978). HPLC analysis of media extracts showed that all the hydroquinone was absorbed by the cells within 24 hr (data not shown).

Barley Roots. Seeds of *Hordeum vulgare* cv. Larker were grown in vermiculite in 2-liter beakers (dark, 27°C) and watered biweekly with 100 ml of distilled water or 500 μM hydroquinone. Seven-day-old seedlings were harvested and washed free of vermiculite, and the root tissue was separated, frozen in liquid nitrogen, pulverized in a mortar and pestle and stored frozen until used.

Enzyme Extraction and Assay. All procedures were carried out at 4°C, unless otherwise stated. Callus tissue or cell suspensions of small everlasting

and leafy spurge were frozen with liquid nitrogen, pulverized with a mortar and pestle, and stored frozen until used. These homogenates and those from barley roots were extracted in a Bead Beater Cell Disrupter (Biospec Products, Bartlesville, Oklahoma) with 50% (w/v) 0.1-mm glass beads and the following cold extraction buffer: 0.1 M Tris MES (pH 7.0) containing 1 mM dithiothreitol and 2 mg/ml protease inhibitor. The homogenate was filtered through Miracloth, stirred for 5 min with 5% (w/v) Dowex 1X2 (Cl^- form) and filtered through another layer of Miracloth. The filtrate was centrifuged for 20 min at 15,000 rpm. The resulting supernatant was applied to a DEAE–Sephacel column (1.2 × 5 cm) and washed with five column volumes of elution buffer. Proteins were eluted from the column using a step gradient of KCl (8 ml each of 100, 250, and 500 mM KCl) in the elution buffer at a flow rate of 40 ml/hr and a fraction volume of 2 ml each. Protein concentrations of various fractions were determined with Coomassie blue by the method of Bradford (1976). Fractions containing glucosyltransferase activity were assayed in reaction mixtures containing UDPG (0.8 μmol), hydroquinone or arbutin (0.8 μmol), cysteine (0.2 μmol), Tris MES at pH 7.0 (40 μmol), and the enzyme preparation (90 μl) in a total volume of 200 μl (Tabata et al., 1976). These reaction mixtures were incubated under nitrogen (37°C, 1 hr) and analyzed for biotransformation products by HPLC analysis (Waters carbohydrate analysis column, 3.9 × 300 mm; acetonitrile–water, 65:35 v/v; 1 ml/min; UV detection at 280 nm, 10 μl injection). Retention times under these conditions were as follows: hydroquinone, 3.18 min; arbutin, 3.80 min; *p*-hydroxyphenyl-β-gentiobioside, 4.76 min. The specific activity of the enzyme was expressed in nkats (nanomoles of arbutin produced per hour per milligram protein).

Synthesis of p-Hydroxyphenyl-β-gentiobioside. This compound was synthesized from arbutin according to the method of Takiura et al. (1974), and the purity of the synthetic product was established by HPLC. Physical properties were in close agreement with reported values and yield was consistent with that reported.

RESULTS

Typical results from DEAE–Sephacel ion-exchange chromatography of enzyme extracts are shown in Figure 1. In all experiments, fractions exhibiting enzyme activity in subsequent assays were eluted in buffer containing 250 mM KCl (fractions 4–8). These fractions lost glucosylating activity within 24 hr when stored at 4°C or when frozen (−20°C). Acetone powder preparations did not possess enzyme activity; however, fresh plant or cell culture samples could be ground in liquid nitrogen and stored in the freezer without significant loss of enzyme activity over several months. This apparent lability of phenol gluco-

sylating enzymes has been reported previously in the literature (Kleinhofs et al. 1967) and has hampered present attempts at purification.

Enzyme assays with cell-free extracts of untreated small everlasting callus tissue confirmed the presence of constitutive levels of a UDPG-dependent glucosytransferase capable of biotransforming hydroquinone to arbutin (Table 1). No constitutive levels of this enzyme were measured in leafy spurge, but activity was substrate-induced when suspension culture cells of this species were fed 500 μM hydroquinone before extraction. The specific activity of the enzyme preparation from small everlasting callus was six-fold greater than in prepara-

tions obtained from treated leafy spurge and comparable to levels in barley roots, a control species in which hydroquinone-glucosylating activity has been previously reported (Glass and Bohm, 1971).

When arbutin was used as substrate for enzyme preparations from all three species, the unaltered monoglucoside was recovered from the assay mixture at the starting concentration. No diglucoside (i.e., *p*-hydroxyphenyl-β-gentiobioside) was formed (Table 2), suggesting that the enzyme activity measured in these assays is substrate-specific. Evidence for the existence of a second substrate-specific transferase capable of glucosylating arbutin to *p*-hydroxyphenyl-β-gentiobioside has been presented by other workers (Yamaha and Cardini, 1960b).

UDPG was the required high-energy glucose donor for hydroquinone biotransformation. Arbutin production via reverse β-glucosidase activity did not occur in the absence of UDPG. Cysteine also was shown to be an absolute cofactor for measurable glucosyltranseferase activity but EDTA was without effect and consequently was dropped from subsequent assays. β-Gluconolactone, a known inhibitor of β-glucosidase activity (Anderson and Hough, 1960), had no effect on hydroquinone glucosylation by cell-free extracts of all three species. UDPG-dependent glucosyltransferases have been reported to have freely reversible activity in vivo (Anderson and Hough, 1960); however, β-glucosidase activity was not detected in enzyme preparations from small everlasting, leafy spurge, or barley by using the described protocol, as evidenced by the lack of arbutin hydrolysis to hydroquinone. In vitro biotransformation

reactions with commercial β-glucosidase resulted in both *p*-hydroxyphenyl-β-gentiobioside and arbutin hydrolysis to hydroquinone, with or without added UDPG. Further purification of the enzyme fraction from these species will be required to detect and quantify reverse hydroquinone glucosyltransferase activity.

DISCUSSION

The detection of hydroquinone in extracts of small everlasting callus and the observed toxicity of this compound to leafy spurge (in both callus and suspension culture) indicates the participation of this phytotoxin in the allelopathic interaction between small everlasting and leafy spurge (Hogan and Manners, 1990). Previous work has suggested that the mechanism of this interaction is based on differential metabolism of hydroquinone (Manners and Galitz, 1985; Manners, 1987).

The absorption of hydroquinone from the medium by tissue cultures of both species suggested that the cells detoxified hydroquinone via glucosylation to form arbutin (Hogan and Manners, 1990). Most angiosperms possess the ability to glucosylate the phenolic hydroxyl groups of exogenously applied compounds (Pridham, 1964), and there have been numerous reports of enzyme-mediated phenol glucosylation reactions, both in whole plants (Pridham and Saltmarsh, 1963; Miles and Hagen, 1968) and plant tissue cultures (Tabata et al., 1976, 1988; Ushiyama and Furuya, 1989; Suzuki et al., 1987). Our results show leafy spurge to be considerably less efficient in the detoxification of hydroquinone than small everlasting.

Phenolic compounds are rarely present in unconjugated form in vivo (Kleinhofs et al., 1967), and therefore the hydroquinone pool size should remain fairly low. If hydroquinone uptake in these species is limited only by diffusion rates, as has been reported for barley (Glass and Bohm, 1971), then hydroquinone pool sizes should be regulated by the kinetics of its biotransformation enzymes. As was shown in the present study, hydroquinone and arbutin pool sizes could be directly correlated with glucosyltransferase activity; however, the situation in vivo would be more complex. Reversible glucosyltransferase activity (β-glucosidase activity) may hydrolyze arbutin to hydroquinone, and/or a second enzyme could utilize arbutin preferentially as the substrate for glucosylation to *p*-hydroxyphenyl-β-gentiobioside (Anderson and Hough, 1960). The latter reaction has been confirmed to occur via a substrate specific enzyme in cell-free wheat germ extracts (Yamaha and Cardini, 1960a,b). Tabata et al. (1976) observed a continual decrease in arbutin pool size during the stationary growth phase of *Datura innoxia* suspension culture cells, which they interpreted as the metabolism of arbutin to other compounds.

Continuous exposure of leafy spurge to physiological concentrations of hydroquinone in the field over a long period of time could produce chronic inhibition of growth. Differences in the kinetics of the hydroquinone glucosyltransferase enzyme as well as in the regulation of related enzymes (e.g., β-glucosidase, and other glucosyltransferases) may explain the differential toxicity of hydroquinone in the two species at sublethal (chronic) levels. Continued work is needed to define the biochemical factors affecting the relative pool sizes of hydroquinone and its glucosides in vivo. This problem is complex, involving examination of the regulation schemes for several different enzymes.

Knowledge of the biochemical basis for differential sensitivity to allelochemicals will facilitate the use of natural phytotoxic interactions in weed management and in the development of new herbicides. For example, an increased understanding of the regulation of enzymes responsible for xenobiotic conjugation could provide the basis for an alternative weed control strategy. Inhibitors or other exogenously applied compounds may shift the equilibrium of an enzyme-mediated conjugation reaction. Enhanced expression of latent genes encoding these detoxifying enzymes could be used to protect crops and reduce competition from susceptible weed species.

Acknowledgments—The authors wish to express their appreciation to Dr. David Davis of the USDA/Bioscience Research Laboratory in Fargo, North Dakota, for providing the leafy spurge suspension culture cells and for many helpful discussions. The technical assistance of Deborah Mark is gratefully acknowledged. This work was funded in part by USDA/CSRS grant 88-383000-3626.

(Received July 9, 1990; accepted September 6, 1990)

Abstract—A sex pheromone produced by female *Keiferia lycopersicella* (Walsingham) was isolated and identified as (*E*)-4-tridecenyl acetate, based on chemical analyses, electroantennogram assays, and field trapping in California and Florida. Males were captured equally well in traps baited with (*E*)-4-tridecenyl acetate alone or a variety of (*Z*)- and (*E*)-4-tridecenyl acetate blends, although the *Z* isomer was not detected in extracts of female glands.

Key Words—Sex pheromone, *Keiferia lycopersicella*, tomato pinworm, Lepidoptera, Gelechiidae, (*E*)-4-tridecenyl acetate.

INTRODUCTION

The tomato pinworm (TPW), *Keiferia lycopersicella* (Walsingham), is a major pest of tomatoes in North and Central America. TPW larvae are leaf rollers and also burrow into fruit, and as a result they are effectively sheltered from most

insecticides. There is thus considerable impetus to develop other control strategies, such as the use of the sex pheromone to directly suppress populations via mating disruption (Jiménez et al., 1988; Jenkins et al., 1990) or as a monitoring tool in IPM programs.

McLaughlin et al. (1979) were the first to demonstrate that female TPW emit a pheromone that can attract males in the laboratory and the field. We report here the isolation and identification of that pheromone as (*E*)-4-tridecenyl acetate and document its effectiveness as a trap lure for conspecific males in the field.

METHODS AND MATERIALS

Insects were shipped as pupae from Riverside, California, and Gainesville, Florida. The emerging adults were used directly for experiments or to establish a colony to provide additional adults. The insects were reared (Schuster and Burton, 1982) to fourth instar on tomato foliage in the greenhouse at 28 ± 4°C and then were transferred to environmental chambers held at 27 ± 1°C and on a 16L:8D photoperiod. The pupae were segregated by sex, and adults were separated daily.

Preparative glass GLC columns were packed with 3% OV-101 (methyl silicone) on 100–120 mesh Gas Chrom Q (2 m × 2 mm ID), and 10% XF-1150 (50% cyanoethyl methyl silicone) on 100–120 mesh Chromosorb W-AW-DMCS (3 m × 2 mm ID). The capillary columns used included a glass 7-m × 0.3-mm-ID Carbowax 20 M, and fused silica 30-m × 0.25-mm-ID Supelcowax 10 (Supelco) and 50-m × 0.25-mm-ID Silar 10C (Quadrex) columns.

Extracts were obtained by extruding and excising the ovipositors, including the pheromone gland, of 2- to 4-day-old females during early scotophase; glands were extracted in redistilled Skelly B (mainly hexanes) or *n*-heptane. The crude extract was concentrated using a nitrogen stream and an aliquot was injected onto the XF-1150 or OV-101 column. Fractions (generally 1 min) were collected from the columns using chilled 30-cm glass capillary tubes. Active fractions were identified by recording electroantennograms (EAGs) from excised antennae of 1- to 4-day-old males as described in Roelofs (1984). Antennae also were screened with a series of synthetic positional isomers of 12-, 13-, and 14-carbon *Z* and *E* monounsaturated acetates and alcohols, using a 10-μg loading on filter paper for each compound.

The isolated compound was further characterized by microozonolysis and hydrolysis with ethanolic NaOH followed by acetylation with acetyl chloride (Bjostad et al., 1980), as well as by capillary GLC analysis, and GLC-mass spectrometry. Microozonolysis was carried out by dissolving samples in 50 μl of carbon disulfide in 3-mm × 3-cm glass tubes chilled in a Dry Ice/acetone

bath. A stream of ozone was bubbled through the solution for 20 sec. This solution then was analyzed immediately by capillary GLC, and the products compared with ozonized standards. A Hewlett-Packard 5880 gas chromatograph equipped with a splitless injector and a flame ionization detector was used for the GLC analyses. By chromatographing a series of synthetic tridecenyl acetate standards on polar and very polar capillary columns, we were able to separate and identify all of the geometric and positional isomers (Heath et al., 1980). Comparison of the retention time of the pheromone with those of the standards allowed confirmation of the position and geometry of its double bond. Chemical ionization mass spectra were obtained with a Hewlett-Packard 5985 mass spectrometer interfaced with a Supelcowax 10 capillary column with isobutane as the reagent gas. Electron impact mass spectra were obtained with a Hewlett-Packard 5970 series Mass Selective Detector coupled with a 30-m Supelcowax 10 capillary column using helium as the carrier.

The (*E*)-4-tridecenyl acetate (*E*4–13 : OAc), (*Z*)-4-tridecenyl acetate (*Z*4–13 : OAc), (*E*)-8-tridecenyl acetate (*E*8–13 : OAc) and (*E*, *E*)-4,7-tridecadienyl acetate (*E*4, *E*7–13 : OAc) used in field tests were purchased from Farchan Chemical Co. GLC analyses of these compounds on XF-1150 and OV-101 revealed that they were >99% pure with no detectable amounts of other positional or geometric isomers.

Trapping studies were conducted in tomato fields in California and Florida using Pherocon 1C (Zoecon Corp., Palo Alto, California) traps baited with rubber septa (rubber stoppers, sleeve type, 5 × 9 mm, A.H. Thomas Co.) loaded with test chemicals dissolved in dichloromethane or four caged virgin female moths. Traps were deployed in a randomized complete block design with treatments replicated three to five times and replicates separated by at least 50 m. Traps were hung on stakes at plant canopy height (0.3–1.8 m), and separated from one another by 3–15 m. Every 3–10 days, trapped males were counted and the traps were rerandomized within blocks. Data were transformed to $(X + 0.5)^{1/2}$ prior to analysis of variance and means were separated using the Ryan-Einot-Gabriel-Welsh multiple range test (SAS Institute, 1985) to control the experiment-wise type-I error rate (Day and Quinn, 1989).

RESULTS

Following fractionation of the crude extract on XF-1150 (160°C), the largest peak and most of the EAG activity was found in the 6- to 8-min fraction; by comparison, saturated 13 : OAc, and 14 : OAc standards eluted at 6.7 min and 9.4 min, respectively. On OV-101 (150°C), the highest activity was localized in the 5- to 6-min fraction; under the same conditions, 12 : OAc eluted at 4.3 min and 13 : OAc at 6.1 min. Thus, on polar and nonpolar columns, the

compound had retention times characteristic of an unsaturated 13-carbon acetate. Injection of this purified active fraction on the Carbowax 20 M capillary column revealed that only one major peak was present. Upon coinjection with a series of synthetic positional isomers of *Z* and *E* tridecenyl acetates on Supelcowax 10 and Silar 10C capillary columns, the retention time of the active peak was found to match that of synthetic *E*4–13 : OAc exactly.

Saponification and reacetylation of the active fraction verified that the compound was an acetate. When the active fraction was hydrolyzed and the reaction products were injected onto the OV-101 and XF-1150 columns, all fractions were inactive by EAG. On both columns the retention time of the major peak now conformed to that of a monounsaturated alcohol. Following collection of the alcohol peak from OV-101, the fraction was acetylated and injected onto the OV-101 and XF-1150 columns, and activity was restored in the original 5- to 6-min and 6- to 8-min fractions, respectively.

The Δ4 position of the double bond in the EAG-active compound was determined by microozonolysis. This procedure produced two peaks on the Supelcowax-10 capillary column whose retention times were identical to those of the 4-oxobutyl acetate and nonanal generated from ozonolysis of authentic *E*4–13 : OAc.

Isobutane CI mass spectra of the active compound established that its molecular weight was 240 with diagnostic ions at 241 (M + 1) and 181 (M + 1 − 60, indicating the loss of acetic acid) again consistent with our interpretation that the compound was a monounsaturated 13-carbon acetate. The EI spectrum was identical in all respects to that of synthetic *E*4–13 : OAc; the parent ion (240) was not observed in the EI spectrum (Figure 1A).

Standardized EAG responses from the synthetic compound series showed that the highest depolarizations were elicited by the monounsaturated 13-carbon acetates, followed by the 12-carbon and the 14-carbon acetates. The alcohols were mostly inactive. Within the 13-carbon acetate series, the best antennal responses were obtained for *E*4–13 : OAc; *E*8–13 : OAc gave only slightly less activity, with *Z*4, *Z*5, and *E*7 compounds also giving good responses.

Despite the high EAG respones obtained from the latter four compounds, capillary GLC chromatograms of gland rinses showed only one major peak corresponding to *E*4–13 : OAc with no evidence (detection limits > 0.1% of *E*4–13 : OAc) of *Z*4–13 : OAc or other monounsaturated acetates (Figure 1B). The mean titer of *E*4–13 : OAc in females whose glands were extracted at lights-off on the day of emergence (age 2–24 hr) was 10.1 ng/female (based on two samples of 10 and 20 pooled glands).

The first field test compared male captures in response to different loadings of *E*4–13 : OAc, as well as to the highly EAG-active *E*8–13 : OAc alone or in combination with *E*4–13 : OAc. Also tested was another compound, *E*4, *E*7–13 : OAc, which was discovered to be an attractant for TPW males during the

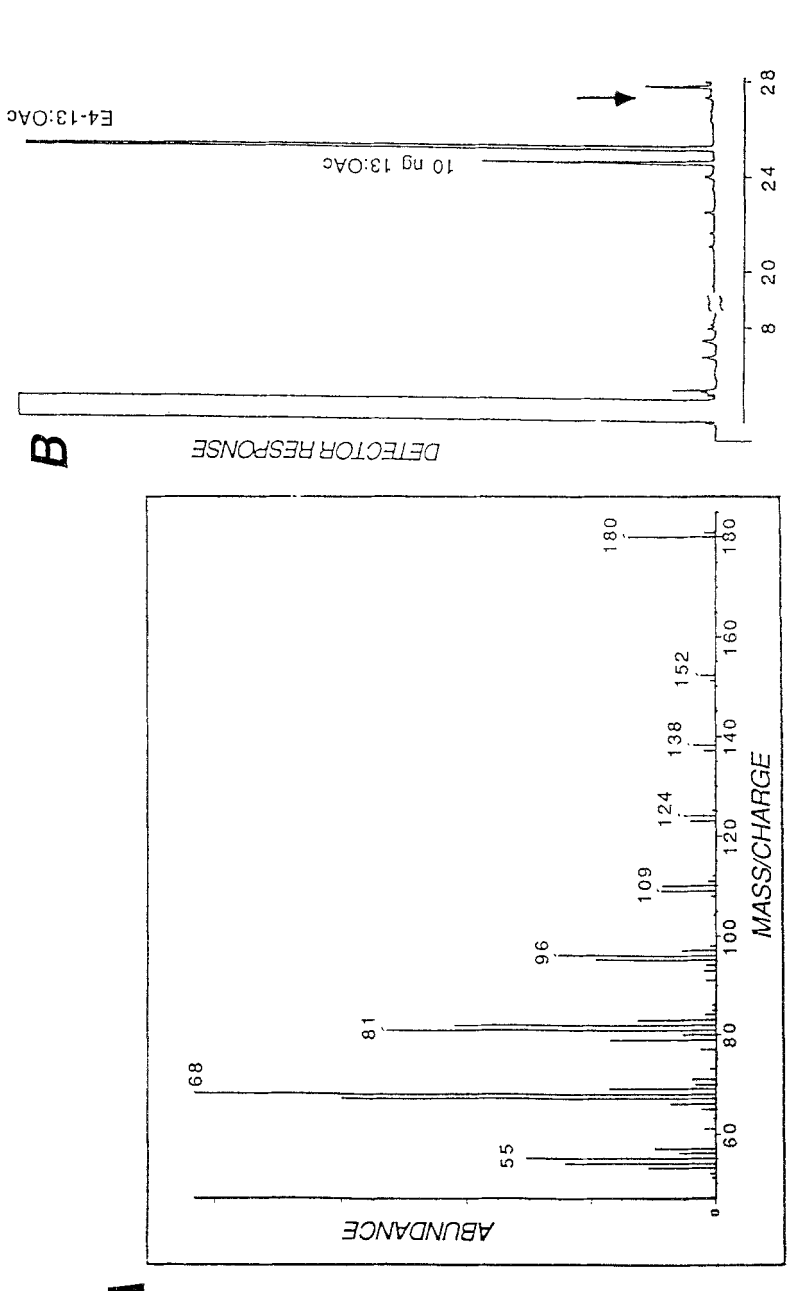

FIG. 1. (A) Electron impact mass spectrum of (*E*)-4-tridecenyl acetate from female gland extract. (B) Chromatogram of *K. lycopersicella* pheromone gland extract (pooled sample of 10 glands) with 10 ng 13:OAc added as internal standard. Arrow indicates retention time of tetradecanyl acetate. All monounsaturated acetates eluted between 13:OAc and 14:OAc under these conditions (30-m × 0.25-mm-ID Supelcowax 10; Temperature program: 80°C (2 min), then 4°C/min to 220°C (10 min).

course of field screening tests for *Phthorimaea operculella* (Zeller) attractants (G. Kennedy, personal communication). The 100- and 300-μg doses of *E*4–13:OAc captured the highest numbers of males but the 1-mg dose captured significantly fewer males (Table 1). These lures retained their potency over the entire 46 days they were deployed in the field. The 100-μg loading generally caught the highest number of males, but the relative effectiveness of the 300-μg and 1-mg dosages appeared to increase as the lures aged, probably due to declining emission rates.

*E*8–13:OAc and *E*4,*E*7–13:OAc by themselves were ineffective as trap lures (Table 1). When varying amounts of *E*4,*E*7–13:OAc were added to *E*4–13:OAc, it significantly depressed trap catch in a dose-dependent manner over the test as a whole and caused a reduction in captures during all but the last trapping interval (36–46 days); nevertheless, these traps still captured significantly more males than unbaited traps (Table 1). When *E*8–13:OAc was added to *E*4–13:OAc, the results were more erratic: total trap catch was significantly lower for both loadings, but during several of the trapping intervals, the low

Unbaited	0.5[d]	0.3[e]	0.2[d]	0.6[c]	0.4[e]	(16.4)

[a] Five replicates per treatment. Means in a column followed by the same letter are not significantly different according to Ryan-Einot-Gabriel-Welsh multiple range test ($P \geq 0.05$). All treatments dispensed from rubber septa except 1 mg loading of *E*4–13:OAc, which was released from polyethylene caps.

dosage captured as many males as *E*4–13:OAc alone (Table 1). The lack of captures in the *E*4,*E*7–13:OAc-baited traps was inconsistent with the results from the *P. operculella* test; possibly, the baits used in the earlier study were contaminated with small amounts of *E*4–13:OAc.

The second set of trapping experiments compared different ratios of *Z*- and *E*4–13:OAc. In both California and Florida, TPW males responded equally well to a wide range of *Z*:*E* ratios with optimal catch occuring to the 3% *Z* blend (Table 2). *Z*4–13:OAc alone captured significantly fewer males than any of the *E*:*Z* blends. Nonetheless, this compound had some intrinsic activity since it captured more males than did unbaited traps. In California, the best synthetic baits caught as many males as did virgin females (Table 2); females were not included in the results of the Florida test due to insecticide-induced mortality.

DISCUSSION

The evidence presented here indicates that the sex pheromone of the tomato pinworm is (*E*)-4-tridecenyl acetate. This compound apparently is unique among identified lepidopteran sex pheromones (Arn et al., 1986). Only a few moth species have been found to use 13-carbon acetates as pheromones (Baker et al., 1985) or attractants (Voerman and Heerebout, 1978; Willemse et al., 1987). Furthermore, pheromone components with unsaturation in the 4-position have

been encountered from only a handful of species belonging to three lepidopteran families: Saturniidae (Bestmann, 1987), Gracillariidae (Beevor et al., 1986), and Gelechiidae. In the latter family, the only other identified Δ4 13-carbon acetate pheromone is the blend of di- and triunsaturated acetates, (*E*, *Z*)-4,7-tridecadienyl acetate and (*E*, *Z*, *Z*)-4,7,10-tridecatrienyl acetate, which are used by *P. operculella* (Roelofs et al., 1975; Persoons et al., 1976). Willemse et al. (1987) found that (*Z*)-4-tridecenyl acetate was an attractant for males of another gelechiid, *Sophronia semicostella* (Hübner), but it is not known whether this compound is actually produced by the females. The pheromones of almost all other gelechiids are even-carbon-numbered chain acetates ranging from 10 to 16 carbons in length with one or two double bonds at odd-numbered carbon positions.

Our results show that 100 μg of pure *E*4–13 : OAc is an effective trap lure for monitoring *K. lycopersicella* populations. Curiously, even though *Z*4–13 : OAc was not found in extracts of female glands, traps baited with a broad range of *Z*4/*E*4–13 : OAc blends captured as many males as those baited with pure *E*4–13 : OAc. The *Z*4–13 : OAc is clearly not a behavioral antagonist, and therefore it should not be necessary to use geometrically pure *E*4–13 : OAc in field tests. In fact, a 96 : 4 *E* : *Z* mixture currently is generally used for monitoring traps and disruptant formulations (Jenkins et al., 1990). Optimal trap catch was obtained with pheromone dosages of 100 or 300 μg whereas 1 mg inhibited male attraction. These results are in agreement with those reported by Wyman (1979), who found that hollow-fiber dispensers emitting pheromone at lower rates captured significantly more males than did ones releasing high amounts. The TPW pheromone now is used widely to monitor infestations of this pest and to time insecticide treatment programs (Van Steenwyk et al., 1983). Moreover, it has been registered by the EPA, and commercial controlled-release formulations of the pheromone already provide effective control of TPW populations through mating disruption (Jiménez et al., 1988; Jenkins et al., 1990).

Abstract—Phagostimulant activity of glycerolipids such as digalactosyldiacylglycerol (DGDG), 6-sulfoquinovosyldiacylglycerol (SQDG), phosphatidylcholine (PC), phosphatidylethanolamine (PE), etc., have been examined using the Avicel plate method for three kinds of marine herbivorous gastropods, the abalone *Haliotis discus*, the turban shell *Turbo cornutus*, and the topshell *Omphalius pfeifferi*. DGDG showed strong activity for all the test animals. SQDG was much less active than the other glycerolipids for abalone. The turban shell and the top shell responded more or less sensitively to all tested glycerolipids at doses of 10–20 μg/sample zone.

Key Words—Feeding-stimulants, phagostimulants, herbivorous gastropods, abalone, *Haliotis discus, Turbo cornutus*, DGDG, PC, SQDG, glycerolipids.

INTRODUCTION

In the course of our chemical studies on marine herbivorous gastropods, we have established a simple and reliable bioassay, the Avicel plate method, as a feeding stimulant assay for abalone, *Haliotis discus* (Sakata et al., 1984), turban

[*] To whom correspondence should be addressed.

shell, *Turbo cornutus*, and top shell, *Omphalius pfeifferi* (Sakata et al., 1988a). Several glycerolipids such as digalactosyldiacylglycerol (DGDG), 1,2-diacylglyceryl-4′-*O*-(*N*,*N*,*N*-trimethyl)-homoserine (DGTH), 6-sulfoquinovosyldiacylglycerol (SQDG), phosphatidylcholine (PC), etc., have been isolated as potent feeding stimulants for marine herbivorous gastropods from algal methanol extracts (Sakata et al., 1984, 1986, 1988a, b; Sakata and Ina, 1983, 1985).

In a preliminary experiment (Sakata et al., 1985), abalone were found to respond to 10–20 μg of DGDG, PC, etc., in a sample zone on an Avicel plate, suggesting that these glycerolipids are responsible for feeding behavior.

In this paper we describe results of feeding-stimulant assays with five kinds of glycerolipids: DGDG, DGTH, and SQDG (from the green alga *Ulva pertusa*; Sakata et al., 1988b), and PC and phosphatidylethanolamine (PE) (from a soybean lecithin; Sakata et al., 1989). Feeding responses of three taxonomically closely related gastropod species, *Haliotis discus*, *Turbo cornutus*, and *Omphalius pfeifferi*, are compared. DGDG showed strong activity for all test animals. Abalone responded more sensitively and selectively to the tested glycerolipids except for PE than the other herbivorous gastropods.

METHODS AND MATERIALS

Test Aquarium. A test aquarium (36 × 35 × 15 cm) was made of a polyvinyl chloride plate (5 mm thick) colored gray and separated into three compartments (12 × 35 × 15 cm) (Figure 1). This aquarium was set in a preformed

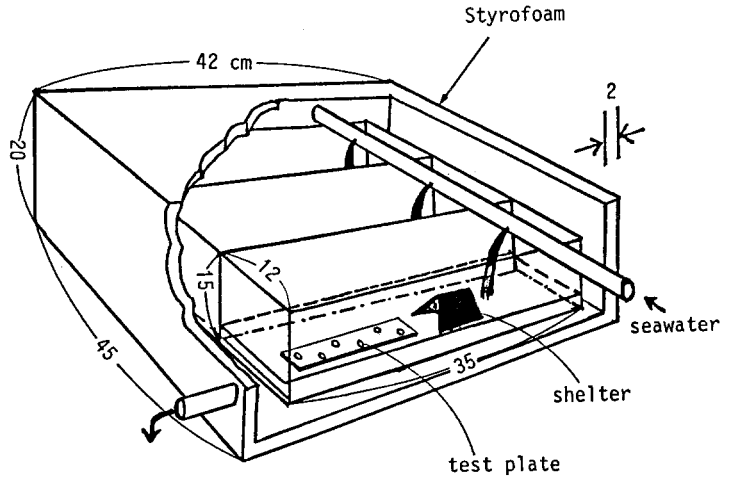

FIG. 1. A diagramatic view of an experimental aquarium.

box of polystyrol (Figure 1). Water temperature strongly influenced responses of test animals. At water temperature lower than 18°C, turban and top shells stopped feeding. Assay temperatures were maintained at 20–21°C, the optimum feeding temperature. Water depth was maintained at 5 cm with a drain. Seawater was circulated through a 2-mm-diameter hole in the water circulation tube at about 250 ml/min (Figure 1).

Test Animals. Abalone, *Haliotis discus* (1.5–2 years old), turban shell, *Turbo cornutus* (1.5 years old), and top shell, *Omphalius pfeifferi* (age unknown) were used. Abalone and turban shells were supplied by the Shizuoka and Toyama Prefecture Fish Farming Centers, respectively. Adult top shells were from Izu (Shizuoka Prefecture) and were purchased at a city market. Fifteen specimens of the abalone (shell length, 25–30 mm) and 20 specimens of the turban shell (opercula diameter, 10 mm) were kept in each compartment of the test aquarium. Turban shells used here were smaller than those used in earlier studies. The smaller-sized animals gave more reproducible results. Seven specimens of the top shell (opercula diameter, 6–8 mm) were also kept in each compartment. The air-dried brown alga, *Laminaria angustata* var. *longissima* ("nagakonbu" in Japanese) was fed test animals once every a few days as maintenance food.

Assay Method for Feeding-Stimulant Activity. This assay method is slightly modified from the previous one (Sakata and Ina, 1983; Sakata et al., 1984, 1988a). Test animals were starved for a day before the assay. Test glycerolipids were applied on the sample zones (23 mm diameter for abalone and top shell and 16 mm diameter for turban shell, whose area was half of the former, because the size of the turban shell was approximately half that of the other test animals) drawn on an Avicel plate. The Avicel plate (5 or 10 × 20 cm with 0.25 mm thickness) was made in the same way as previously reported (Sakata et al., 1984). Each glycerolipid solution was prepared with methanol at 1.0–4.0 mg/ml and contained an antioxidant, butylated hydroxytoluene (BHT, 2,6-di-*t*-butyl-4-methylphenol, ca. 3 μg/ml) to be able to apply each sample solution within 20 μl/sample zone. The test plates were set at the bottom of the test aquarium 2–3 hr after sunset. Circulation of seawater was maintained during the assay.

The next morning, test plates were scored for feeding activity. The assay was repeated at least 10 times at each dose for each sample. Typical assay results for the turban shell *T. cornutus*, and scoring of feeding activity are shown in Figure 2.

GLC Analysis of Fatty Acid Methyl Esters Obtained from Five Kinds of Glycerolipids. Each glycerolipid (2 mg) in methanol (2 ml) was extracted with 2 drops of methanolic N KOH at room temperature for 2 hr. The reaction mixture was treated with hexane (2 ml × 3). The hexane extract was subjected to GLC analysis, which was carried out on a Hitachi gas chromatograph model

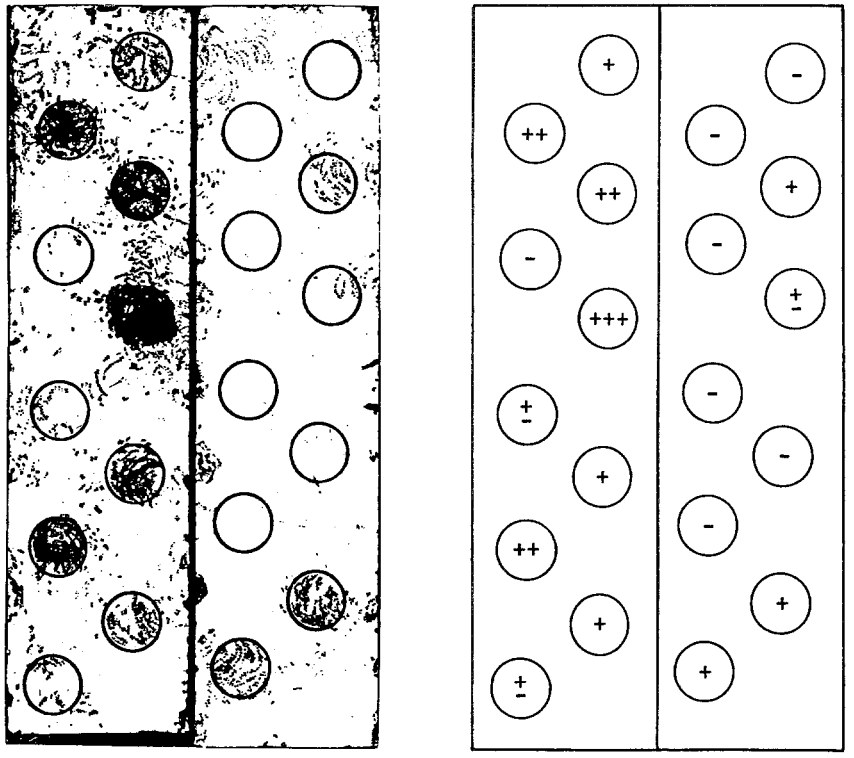

FIG. 2. Typical assay results for the turban shell, *Turbo cornutus* and judgment of the feeding activity. The feeding stimulant activity of each sample was judged in same way as previously reported (Sakata et al., 1984) for the abalone *Haliotis discus*. +++: Avicel in the sample zone and also around the sample zone has been bitten off. ++: almost all the Avicel in the sample zone has been bitten off. +: clear difference of traces are observed between inside the sample zone and outside. ±: a few more traces are observed inside the sample zone than outside. -: no or nearly the same number of traces are left inside the sample zone as those outside.

263-30 (FID) under the following conditions: PEG-HT packed column, ID 3 mm × 2 mm × 2 m; oven temperature: 210°C; carrier gas: N_2, 30 ml/min; injection and detection temperature: 240°C. Analytical data are shown in Table 1.

Recovery of Glycerolipids from Sample Zones. A pair of test plates was prepared with sample zones (3.3 cm in diameter) to which 200 μg of each glycerolipid was applied. One plate was set in an aquarium under the same conditions as in the bioassay, removed after 12 hr, and dried. Each sample zone was scraped off and extracted with methanol (500 μl). The other plate was loaded with the sample, and each zone extracted after evaporation of the sol-

vent. Benzyl alcohol (20 μg) was added to each methanol extract as an internal reference. The sample solution was analyzed by HPLC under the following conditions: column, Asahipak GC-310 porous polymer (MeOH, ID 7.6 × 500 mm); flow rate, 1 ml/min; detector, UV 210 nm. Analytical data are shown in Table 2.

RESULTS AND DISCUSSION

Fatty acids of the glycerolipids were mixtures of C_{16-22} and mainly C_{18} fatty acids (Table 3). Average molecular weight of each glycerolipid calculated from the GLC analysis data was as follows: DGDG, 914; DGTH, 757, SQDG, 843, PC, 774 and PE, 729, respectively. The molecular weight of SQDG was calculated as a sodium salt. Structures of these glycerolipids are shown in Figure 3, and the prominent differences were in polar groups. As shown in Table 2, recovery of each glycerolipid from each sample zone determined by HPLC was consistent and between 70 and 98%. Activity of each glycerolipid is shown in minimum sample amount (μg)/sample zone necessary to show + activity and to show ++ activity (definition, see Fig. 2) at a frequency of more than 80% in all trials.

Table 3 shows the activities of five glycerolipids (DGDG, DGTH, SQDG, PC, and PE) for the three closely related herbivorous gastropod species. DGDG showed strong activity for all test animals. A dose of 40 μg/sample zone, which was used as a positive control throughout this experiment, is enough to show strong activity at the surprisingly high reproducibility of 96.4% in 136 trials. This may suggest strong feeding attractant and phagostimulant activity of DGDG, because DGDG was desorbed from the Avicel plate slightly faster than the other glycerolipids tested (Table 2).

SQDG was much less active than the other glycerolipids for abalone. In the case of DGDG and DGTH, larger amounts of the compound are more potent than stimulants. SQDG showed no significant difference in the activity at doses

TABLE 3. FEEDING-STIMULANT ACTIVITY OF GLYCEROLIPIDS

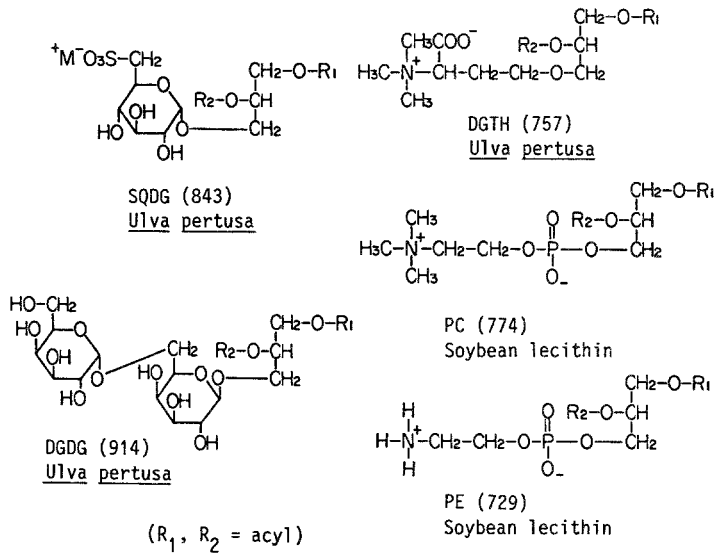

FIG. 3. Structures of feeding stimulants for marine herbivorous gastropods and their origin.

of 50, 100, and 300 μg/sample zone, respectively (Figure 4). Although the reason for this is not clear, this dose–response may suggest that SQDG causes saturation of its receptors at very low levels.

PE showed ++ activity at 50 and 40 μg for the turban shell and the top shell, respectively but had no activity for abalone even at a dose of 200 μg/zone, in spite of its structural similarity to PC which showed ++ activity at a dose of 40 μg for abalone.

Although these test animals belong to the Prosobranchia and are taxonomically closely related species, each glycerolipid showed different activity for each species.

For abalone, DGDG, DGTH, and PC showed ++ activity at doses of 40, 40, and 30 μg/sample zone, respectively, but PE showed no activity. SQDG showed dose-independent activity. Because abalone responded to the lowest doses, we considered that the chemical receptor of abalone is more selective and sensitive than that of the other test animals.

The turban shell and the top shell responded to all the tested glycerolipids, but the selectivity was not as sensitive as that of abalone.

Sea urchins also have been reported to show feeding preference to some particular species of algae (Vadas, 1977; Hay et al., 1986; Machiguchi, 1987). Recently we found that this unique bioassay method is also applicable to the sea urchin, *Strongylocentrotus intermedius* (''ezobafun'uni'' in Japanese), and

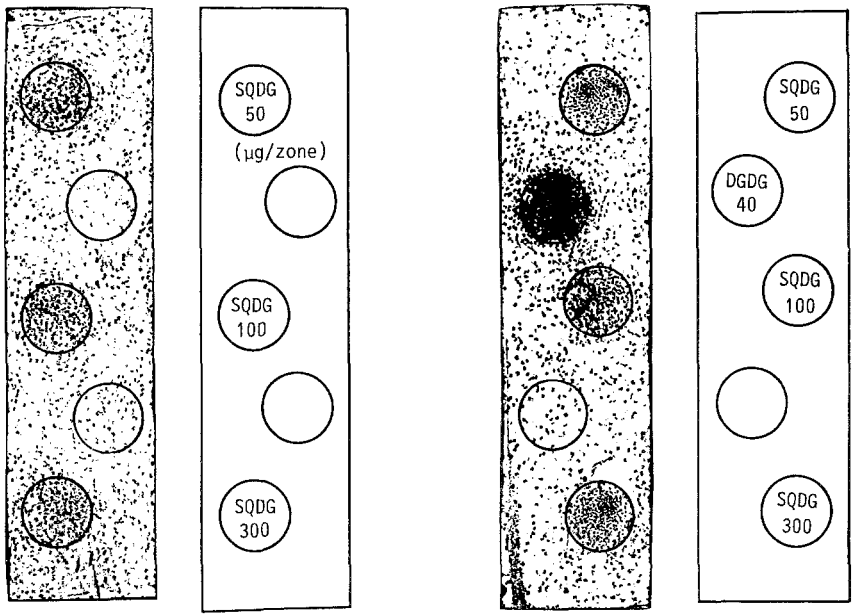

FIG. 4. Typical assay results of SQDG for the abalone, *Haliotis discus*.

glycerolipids such as PC, SQDG, etc., were effective feeding stimulants not only for the marine herbivorous gastropods but also for the sea urchin (Sakata et al., 1989).

Glycerolipids such as DGDG and PC are potent feeding stimulants for marine herbivorous gastropods and sea urchin. It is likely that glycerolipids occurring widely in the plant kingdom have evolved a role as feeding stimulants. Many biological studies, however, clearly show some algae are not preferred by these herbivores (Uki et al., 1986; Vadas, 1977; Hay et al. 1986). These observations suggest the presence of feeding inhibitors in those algae. Recently we have succeeded in establishing a bioassay method to screen algal feeding inhibitors (Sakata et al., 1990) by modifying the Avicel plate method. Application of this assay procedure to algal extracts resulted in isolation of feeding inhibitors and will be published elsewhere.

Acknowledgments—The authors wish to thank Shizuoka and Toyama Prefecture Fish Farming Centers for their generous gifts of the baby abalones and the young turban shells, respectively.

DUAL ROLE OF PYRROLIZIDINE ALKALOIDS IN NECTAR

ALAN R. MASTERS

Department of Zoology, University of Florida
Gainesville, Florida 32611

(Received July 16, 1990; accepted September 10, 1990)

Abstract—Pyrrolizidine alkaloids occur in several plant families, attracting ithomiine and danaine butterflies that specialize on the flowers. I show that pyrrolizidine alkaloids in artificial nectar also inhibit at least one butterfly, *Agraulis vanillae* (Nymphalidae: Heliconiinae), a more general forager. Inhibition was demonstrated in two ways: quantity of nectar consumed and number of artificial flowers visited. The amount of sucrose solution consumed by individual butterflies was measured using a microcapillary tube. Number of flower visits was determined using an array of artificial orange and yellow flowers. *A. vanillae* drank less sucrose solution with monocrotaline, a pyrrolizidine alkaloid, than without. When monocrotaline was placed into yellow flowers, *A. vanillae* learned to visit predominantly orange flowers. Evolutionarily, pyrrolizidine alkaloids in nectar may represent an adaptation to exclude butterflies. Ithomiines and danaines, seeking these compounds in larval food plants, were not excluded. Alternatively, ithomiines and danaines overcame the nectar defense. In either case, the plant effectively increased floral constancy by inhibiting generalist butterflies and attracting specialists.

Key Words—Pyrrolizidine alkaloids, pollination, nectar constituents, Ithomiinae, Danainae, Heliconiinae, Lepidoptera, Nymphalidae, agraulis vanillae.

INTRODUCTION

Secondary compounds are common in nectar (Baker and Baker, 1975). Whether their placement is incidental (Mothes, 1966) or naturally selected (Fraenkel, 1959; McKey, 1974), their presence in nectar may currently enhance plant fitness. Some nonsugar nectar constituents inhibit nectar consumption and flower visits by nectar robbers or poor pollinators (Janzen, 1979; Rhoades and Bergdahl, 1981; Stephenson, 1981, 1982). Moreover, secondary compounds in nec-

0098-0331/91/0100-0195$06.50/0

tar could enhance fitness by attracting more efficient pollinators (Baker and Baker, 1982).

Pyrrolizidine alkaloids are secondary compounds found in the Compositae, Boraginaceae, Fabaceae, and Apocynaceae (Bull et al., 1968; Mattocks, 1986). Ithomiine (Nymphalidae: Ithomiinae) and danaine (Nymphalidae: Danainae) butterflies are attracted to pyrrolizidine alkaloids (Masters, 1968; Pliske, 1976). These butterflies collect such alkaloids for mate attraction and defense (Edgar, 1982; Vasconcellos-Neto and Lewinsohn, 1984; Brown, 1984, 1985; Boppré 1978, 1986). Pyrrolizidine alkaloids may be acquired from dried plant parts, plant wounds (Edgar and Culvenor, 1975; Boppré, 1983), and floral nectar (Pliske, 1975a; Masters, 1990). While consuming nectar, ithomiines and danaines contact anthers and carry pollen to conspecifics (Pliske, 1975b).

Plants increase fitness when pollinators confine their visits to flowers of fewer species (Heinrich, 1976). Receipt or delivery of foreign pollen provides no benefit for the plant but incurs nectar and pollen costs (Rhoades and Bergdahl, 1981). Pyrrolizidine alkaloids increase flower constancy by attracting lepidopterans that seek flowers with these compounds in their nectars (Pliske, 1975b). Pyrrolizidine alkaloids may enhance flower constancy further by inhibiting other, more generalist visitors.

Here, I show that monocrotaline, a pyrrolizidine alkaloid, inhibits (1) amount of nectar consumed and (2) number of visits to artificial flowers by a generalist butterfly forager, *Agraulis vanillae* (Nymphalidae: Heliconiinae). In examining these two forms of inhibition, I provide the first evidence that a secondary nectar constituent attractive to some flower visitors plays a dual role of inhibiting another.

METHODS AND MATERIALS

Agraulis vanillae occurs from the United States (Opler and Krizek, 1984) to South America and the West Indies (De Vries, 1987). It is common in Gainesville, Florida, from June to November where it inhabits open areas, using *Passiflora incarnata* (Passifloraceae) as its principal larval food plant (May, 1986; Gannon, 1986). *A. vanillae* feeds on nectar from a variety of flowers, including "bee flowers" (Baker and Baker, 1975) such as shepard's needle *Bidens alba*, (Asteraceae) (May, 1986). *A. vanillae* is palatable to blue jays, *Cyanocitta cristata)*, silverbeak tanagers, *Rhamphocelus carbo magnirostratus*, and parson's tanagers, *Tachyphonus rufus* (Brower and Brower, 1964; Brower, 1984), and to the spider, *Nephila clavipes* (personal observation).

Two experiments tested the influence of monocrotaline (99%, Aldrich Chemical Co., 1984), a pyrrolizidine alkaloid isolated from *Crotalaria* sp. (Fabaceae) (Bull et al., 1968; Mattocks, 1986), on the foraging behavior of *A.*

vanillae. Both experiments were performed in autumn 1984 and summer 1985 in Gainesville, Florida.

Experiment 1. Effect of Monocrotaline on Consumption of Artificial Nectar by A. vanillae. Nectaries generally contain greater than 0.1 μg alkaloid/μg plant tissue (Brown, 1984); however, concentrations of pyrrolizidine alkaloids in natural nectars have not been reported. Consequently, a logarithmic scale of monocrotaline concentration from 0.001 μg/ml to 1.0 μg/ml was used in an attempt to cover ecologically relevant nectar concentrations.

Twenty *A. vanillae* males, captured as adults, were fed 30% sucrose solution (by weight) to satiation on both the day of capture and two days later. Four, six, eight, and 10 days after capture, *A. vanillae* were fed 30% sucrose solution and one concentration of monocrotaline in 30% sucrose solution. Individuals were not fed on days 1, 3, 5, 7, 9, and 11. Feedings were ended on day 12 with a pure sucrose solution.

Two groups were created to separate effects of presentation order and concentration. A group of 10 individuals were offered an increasing series of 0.001, 0.01, 0.1, and 1.0 μg/μl monocrotaline. The remaining individuals were offered monocrotaline in decreasing concentrations.

A calibrated 100-μl microcapillary tube was used to measure nectar consumption by *A. vanillae* (May, 1985). Butterflies remained in a 30 × 30 × 30-cm styrofoam chamber with a Plexiglas front and maintained at 28°C using a heat lamp. All feedings took place between 1000 and 1400 hr. The proboscis was inserted into a capillary tube containing 30% sucrose solution with or without 1 μg/μl monocrotaline. This initiated drinking without restraint. To assure satiation, the proboscis was reinserted once voluntarily removed. After exposure to monocrotaline, butterflies were offered 30% sucrose solution to satiation. Butterflies were held in glassine envelopes at 23°C between feedings with 12 hr light and 12 hr dark.

Experiment 2. Discrimination and Avoidance of Artificial Flowers with Monocrotaline. To determine if plants with pyrrolizidine alkaloid nectars inhibit visits by *A. vanillae*, flower preference experiments were performed, using artificial flowers in two flight cages (2.5 × 2.5 × 4 m) receiving direct sunlight.

"Flowers" were 1.8-cm-diameter disks cut from painted sheets of 0.5-cm-thick pressed foam mounting board. Into each disk was inserted a 1-cm section of hollow glass pipe, 0.3 cm diameter, so that an open end was flush with the painted surface of the flower. The other end of the glass tube was sealed with silicon aquarium sealant. Artificial flowers were arrayed on a base of 60 × 60 cm plywood atop 49 evenly spaced dowels 15 cm high and 0.8 cm wide.

Results from experiment 1 suggested that prior experience with monocrotaline enhanced the inhibitory effect of monocrotaline on subsequent nectar consumption by *A. vanillae* (see Results). Therefore, flower choice tests were begun by feeding freshly emerged male *A. vanillae* from microcapillary tubes: 5 μl of

30% sucrose solution on day 1, and 30% sucrose solution + 0.001 μg/μl monocrotaline on day 2, the concentration of monocrotaline being the lowest showing a negative effect on nectar consumption from Experiment 1.

Individuals were released to empty flight cages for two days. *A. vanillae* were individually exposed to 24 yellow and 24 orange flowers arranged randomly by color (the center dowel remained flowerless). All flowers of a given color contained 0.5 μl of the same artificial nectar type and were refilled after nectar and had been removed. Refilling did not seem to inhibit further butterfly foraging in any way.

Each foraging bout began by placing *A. vanillae* on an orange flower and inserting its proboscis into the well until the butterfly began to drink. Once released, the butterfly would continue drinking and then either fly up to the top of the cage or would continue foraging by flying to and feeding on different flowers in the array. An initial foraging bout of 15 flowers (during which time the butterfly continuously visited flowers) was recorded for each individual, and then a subsequent foraging bout of 15 flowers. Fifteen consecutive flowers were observed because the frequency of continuous foraging on 16 or more flowers was rarely observed. Two foraging bouts per individual were followed because preliminary trials suggested the possibility that learning may be important. Between 30 and 60 min elapsed between the initial foraging bout and the subsequent one.

To detect a possible innate color preference, 15 *A. vanillae* foraged on yellow and orange flowers when both contained 30% sucrose solution. Such a "control" group allowed comparison of *A. vanillae* behavior in the absence or presence of alkaloids. To determine if pyrrolizidine alkaloids inhibit flower visits, a "treatment" group of 15 different *A. vanillae* were exposed to yellow flowers containing 0.5 μl of 0.001 μg/μl monocrotaline in 30% sucrose nectar and orange flowers with sucrose solution.

RESULTS

Monocrotaline is not immediately toxic to *A. vanillae*. *A. vanillae* showed no adverse effects while drinking monocrotaline or visiting flowers containing them. Instead, butterflies avoided exposure by recoiling the proboscis, flying from feeders, or quickly leaving artificial flowers containing monocrotaline. The death of one individual in experiment 1 occurred before exposure to monocrotaline.

Experiment 1. Monocrotaline Inhibits Nectar Uptake. Monocrotaline in sucrose solution inhibited drinking by *A. vanillae*. Figure 1a depicts increasing concentrations of monocrotaline: Friedman one-way ANOVA for seven related samples, six degrees of freedom, nine cases, chi-square corrected for ties =

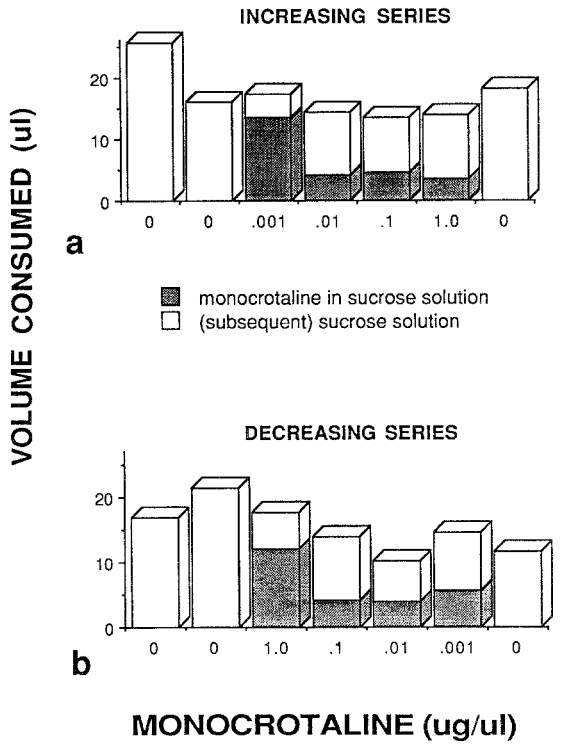

FIG. 1. (a and b) Mean amount of nectar taken for 10 wild-caught male *Agraulis vanillae* offered a diet of sucrose (0), followed by trials of sucrose solution with varying concentrations of monocrotaline ($\mu g/\mu l$), a pyrrolizidine alkaloid. Both increasing and decreasing concentrations show an initial decrease the first day of exposure to monocrotaline followed by a subsequent decrease upon the second exposure. Order was more important than concentration in determining amount taken (see text). Subsequent sucrose solution consumed showed that butterflies were still hungry, and consumed nearly equal volumes as those on days when monocrotaline was not offered.

36.156, $P < 0.001$; Figure 1b shows a decreasing series: Friedman one-way ANOVA for seven related samples, six degrees of freedom, 10 cases, chi-square corrected for ties = 39.497, $P < 0.001$. Sucrose uptake on the first two days and last day of presentation was variable but always exceeded 10 μl, in contrast to monocrotaline in sucrose solution, which never exceeded 10 μl after the first day of exposure (Figure 1). First exposure to monocrotaline inhibited nectar compared to the previous day (Wilcoxin matched-pairs sign ranks test, Figure 1a for increasing concentrations, $N = 9$, $P < 0.05$; Figure 1b for decreasing concentration $N = 10$, $P < 0.01$). However, the second day of monocrotaline exposure showed a further decrease in uptake rate, regardless of concentration.

Thus, there seems to be an effect of initial exposure that strengthens the degree of inhibition demonstrated later. There was a weak or no correlation between monocrotaline concentration and nectar consumption, however. (Simple parametric regression: increasing series $N = 63$, $r^2 = 0.154$, $P = 0.002$; decreasing series $N = 70$, $r^2 = 0.001$, $P = 0.8252$).

After rejecting the monocrotaline nectar twice, butterflies drank sucrose solution readily. The total amount of artificial nectar consumed per day (monocrotaline in sucrose solution + untainted sucrose solution offered immediately after) was the same or slightly less than days when only sucrose was offered (Figure 1a for total solution consumed in an increasing series, Friedman one-way ANOVA for seven related samples, six degrees of freedom, nine cases, chi-square corrected for ties = 13.751, $P = 0.0326$; Figure 1b for total solution consumed in a decreasing series, Friedman one-way ANOVA for seven related samples, six degrees of freedom, 10 cases, chi-square corrected for ties = 12.033, $P = 0.0612$).

Experiment 2. Monocrotaline Inhibits Flower Visits. When no monocrotaline was present, *A. vanillae* showed an innate preference for yellow flowers (Figure 2, open circles), choosing yellow over orange flowers 2.7 : 1 (based on totals, excluding the first visit when individuals were placed on an orange flower). The presence of monocrotaline in yellow flowers altered this preference, as the treatment group of *A. vanillae* preferred orange flowers, 6.5 : 1 over yellow flowers (Figure 2, closed circles; control and treatment groups are significantly different, Kolmogorov-Smirnov test on cumulative frequency distributions, $P < 0.05$).

The initial foraging bout of 15 flowers shows both control and treatment groups initially favor yellow flowers (Figure 3). However, the latter group gradually avoided yellow flowers, which contained monocrotaline (closed circles, Figure 3). This suggests multiple visits were required before *A. vanillae* learned to avoid flowers containing monocrotaline. Later, short-term memory allowed *A. vanillae* to avoid yellow flowers in subsequent foraging (closed circles, Figure 2).

DISCUSSION

Pollination efficiency may be enhanced by reducing pollen waste and foreign pollen loads associated with low flower constancy (Grant, 1950; Heinrich, 1976; Faegri and Van der Pijl, 1979). Floral constancy is enhanced in orchids (Orchidaceae) by secondary compounds that attract specialist bees (Faegri and Van der Pijl, 1979). Conversely, iridoid glycosides of *Catalpa speciosa* increase floral constancy by inhibiting nectar thieves but no legitimate pollinators (Stephenson, 1981, 1982). Pyrrolizidine alkaloids in nectar have been shown to be

FIG. 2. Artificial flower choice by a control (open circles) and treatment group (closed circles) of 15 freshly emerged male *A. vanillae* in a flight cage. Control butterflies were offered a random array of yellow and orange flowers, each with 0.5 μl sucrose solution. Treatment butterflies had a choice between orange flowers with sucrose solution and yellow flowers with a sucrose solution containing monocrotaline, a pyrrolizidine alkaloid. Proportion of yellow flowers corresponds to the percentage of 15 males that drank from a yellow flower. Males that did not visit a yellow flower chose to visit an orange flower instead. All males foraged 15 visits depicted here as a sequence of visits numbered 1 through 15. This bout was scored after an initial bout of 15 flower visits (Figure 3). Members of each group were first placed on an orange flower, shown here with a flower character.

butterfly attractants (Pliske, 1975a; Boppré, 1986), suggesting the ecological significance of pyrrolizidine alkaloids in nectar may be, at least in part, more effective pollination. This study indicates that a second role of pyrrolizidine alkaloids in nectar is to further increase floral constancy by inhibiting more generalized butterfly foragers, like *A. vanillae*.

Nitrogen is generally limiting in plants (Robinson, 1968; Jones, 1972), and nectar, with its nitrogen-containing alkaloids, is likely to be carried away by foragers. Evolutionarily, the placement of pyrrolizidine alkaloids in nectar may be incidental (Mothes, 1966) or the result of active secretion (McKey, 1974), but its continued presence is either maladaptive or is maintained by some selective advantage.

Baker and Baker (1975) proposed that alkaloids are maintained in nectar to inhibit butterfly visitors. They examined a large number of plants and found that all species with nectar alkaloids were principally pollinated by bees. In addition, not one of 46 species visited regularly by lepidopterans contained

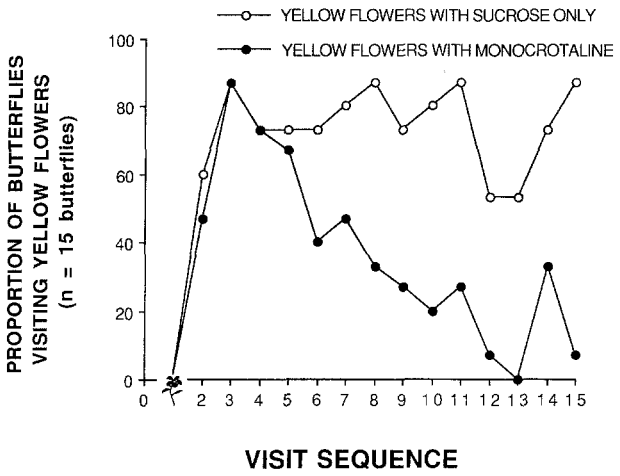

FIG. 3. Initial foraging bouts by the control and treatment groups of 15 freshly emerged *A. vanillae* males exposed to artificial flowers from Figure 2. Initial preferences for both groups was predominantly yellow flowers. However, butterflies exposed to monocrotaline in yellow flowers (closed circles) gradually stopped visiting such flowers, until orange flowers dominated their choices.

alkaloids. They suggested alkaloids in nectar inhibit butterflies without restricting pollination by bees, which tend to exhibit greater floral constancy than butterflies.

My findings support the hypothesis of the Bakers, showing that an alkaloid in artificial nectar inhibits at least one species of butterfly. Additional support for this hypothesis is not strong, at least in the case of pyrrolizidine alkaloids. Pyrrolizidine alkaloids have been found in honey (Denzier et al., 1977; Culvenor et al., 1981), and temperate *Senecio* spp. that contain pyrrolizidine alkaloids (Mattocks, 1986) are principally visited by bumblebees (*Bombus bifarius*) (Schmitt, 1980). However, Pliske (1975a, b) reports few or no visits by bees to flowers with pyrrolizidine alkaloids in the tropics. In addition, both bees and butterflies transfer pollen between *Senecio*, and while bees visit more flowers, butterflies are more likely to elicit outcrossing (Schmitt, 1980).

In the case of pyrrolizidine alkaloids, perhaps the Bakers' hypothesis should be extended to include specialist butterflies. The initial placement of pyrrolizidine alkaloids in floral nectar may have inhibited most butterflies, but not all. Ithomiines and danaines, already seeking pyrrolizidine alkaloids in larval food plants (Edgar, 1975, 1982, 1984; Drummond, 1981), may have readily specialized on such flowers. Alternatively, danaines and ithomiines may have broken through the defense and eventually sequestered the compounds for their own use (Ehrlich and Raven, 1964; Brower, 1969, 1970, 1984; Edgar, 1982;

Edgar et al., 1974). This may have further increased the plants' fitness if ithomiines and danaines became specialist foragers on such nectar at the same time.

The difference in proportion of bee visits between tropical and temperate plant species with pyrrolizidine alkaloids may underscore the role of a chemical that at once attracts and inhibits pollinators. In the temperate zone, where ithomiines never occur and danaines are represented by one species (*Danaus plexippus*), it is possible that bees are neither inhibited nor attracted, while most butterflies are inhibited (as the Bakers suggest). However, in the tropics, where ithomiines and danaines are more common, these specialist butterflies are attracted to flowers with pyrrolizidine alkaloids. This may increase the total number of visits per flower as butterflies that have fulfilled energetic needs continue to forage for chemicals (Boppré, 1986). Bees may choose to forage where competition for nectar is less intense. Conversely, their absence at pyrrolizidine alkaloid-containing flowers may be explained if their numbers are swamped by the increased visits by butterfiles. In the temperate zone, then, pyrrolizidine alkaloides serve to increase floral constancy only by inhibition of generalist butterflies. In the tropics, pyrrolizidine alkaloids also attract, further increasing the likelihood of pollination through increased flower visits.

(Received March 26, 1990; accepted September 10, 1990)

Abstract—Fruits of *Pastinaca sativa* (Apiaceae), the edible parsnip, contain six different furanocoumarins that are differentially capable of ultraviolet-mediated cross-linkage of DNA and inhibition of DNA transcription. Individually, none of the other furanocoumarins present in parsnip seeds is as toxic as the photosensitizer xanthotoxin. Nevertheless, the natural mixture of compounds is toxicologically more effective against *Heliothis zea* (Lepidoptera: Noctuidae), both in the presence and absence of UV light, than is an equimolar amount of xanthotoxin. The difference in toxicity diminishes with increasing light levels. Thus, a series of structurally related natural products can display toxicity lacking in individual compounds and may represent an adaptive compromise to varying environmental conditions.

Key Words—*Heliothis zea*, corn earworm, Lepidoptera, Noctuidae, *Pastinaca sativa*, wild parsnip, Apiaceae, furanocoumarins, defense, xanthotoxin, photoactivation, bioassay.

INTRODUCTION

All plant species produce a variety of endogenous compounds. The abundance of chemical diversity is comprehensible in the context that compounds of different structures and modes of action can interact additively or synergistically

*To whom correspondence should be addressed.

0098-0331/91/0100-0207$06.50/0

(McKey, 1979; Berenbaum, 1985). Yet many plants display not only a diversity of biosynthetically unrelated chemical classes but also a diversity of compounds within a single chemical class. This within-class structural diversity of toxicologically similar compounds is puzzling in that such diversity necessitates the maintenance of biosynthetic pathways that may exact metabolic costs to the plant (McKey, 1979; Chew and Rodman, 1979). We therefore designed an experiment to determine whether a mixture of biosynthetically related secondary chemicals in a single plant species is toxicologically more effective against a generalized insect herbivore than is an equivalent amount of any single chemical of that structural type.

We chose as the focus for our study *Pastinaca sativa* (Apiaceae), the edible parsnip. This species contains a series of furanocoumarins, which are benz-2-pyrone derivatives with a furan ring at the 6,7 or 7,8 positions. Several of the furanocoumarins in parsnip leaves and seeds are phototoxic to a variety of organisms, including insects (Murray et al., 1982). Of the five furanocoumarins known to occur in the fruits of parsnip (Berenbaum et al., 1984), xanthotoxin is the most photoactive according to a number of criteria (Table 1). The linear furanocoumarins xanthotoxin and bergapten are capable in vitro of appreciable ultraviolet-catalyzed cross-linkage of DNA and subsequent interference with

transcription and replication. Angular furanocoumarins, such as sphondin and angelicin, are not known to form cross-links (although angelicin can form monoadducts and cause mutation and cell death; Ashwood-Smith et al., 1980); the remaining linear furanocoumarins are substantially less active in vitro as photosensitizers (Table 1).

METHODS AND MATERIALS

The furanocoumarin composition of ripe seeds of parsnip (Hollow Crown Improved; Stokes, Buffalo, New York) was quantified according to Berenbaum et al. (1984). The total furanocoumarin concentration in fruits was approximately 35.5% xanthotoxin, 31.8% imperatorin, 18.1% bergapten, 8.5% sphondin, 5.6% isopimpinellin, and 0.5% angelicin. Although reported as present in roots and buds, psoralen was not found in this fruit extract and was absent from fruits of several other varieties of edible parsnip and of wild parsnip (Berenbaum et al., 1984). Thus, 53.6% of the total furanocoumarin content (xanthotoxin and bergapten) consists of strongly photoactive furanocoumarins. We compared the toxicological efficacy of the Hollow Crown extract with equimolar amounts of a single photosensitizing constituent, xanthotoxin, against *Heliothis zea* (Lepidoptera: Noctuidae) (corn earworm), a highly polyphagous herbivore with over 100 recorded host plants (Kogan et al., 1978). *H. zea* feeds primarily on the fruits or seeds of most of its hosts and thus is an appropriate species for use in bioassays of toxicity of seed extracts.

To 50 g fresh weight of semidefined artificial diet (Nitao and Berenbaum, 1988), we added 138.84 mg furanocoumarin extract of parsnip (39 ml of an ether solution of 3.56 mg/ml); to a second 50-g aliquot of diet we stirred in 39 ml of ether containing 3.20 mg xanthotoxin/ml ether (Sigma, St. Louis, Missouri). Xanthotoxin is a known photosensitizer, the toxicity of which to insects is demonstrably dependent upon ultraviolet light (Berenbaum, 1978). The resulting concentration of xanthotoxin in the diet was equimolar (5.8×10^{-4} M) to that of the diet containing the furanocoumarin mixture. A 50-g aliquot of control diet was prepared in a similar manner but with 39 ml of ether only. The diet was kept liquid at 60°C and vigorously stirred until all of the ether was driven off.

We elected to use an extract of furanocoumarins from plant tissue, rather than reconstitute the observed mixture with pure compounds, largely for one reason—by using an extract, we hoped to include those furanocoumarins present in concentrations below our ability to detect and quantify them. Despite the fact that HPLC analysis of the extract failed to reveal the presence of nonfuranocoumarin constituents, the possibility does exist that other compounds possessing biological activity were present in the extract and, hence, in the diets.

Therefore, conclusions drawn from this study must be tempered by the possibility that unknown phytochemical constituents may contribute to treatment differences.

After the diets cooled and solidified, cores were punched out and placed in 0.7-ml Kimax test tubes (6 × 50 mm). One neonate *H. zea* larva was placed in each tube, and the tubes were plugged with cotton-tipped applicator sticks. To approximate the solar spectrum, the light source consisted of a 40-W Sylvania cool white fluorescent bulb and a 40-W Westinghouse FS 40 fluorescent sun lamp. The ultraviolet light dosage was varied by adjusting the distance between the light source and the larvae. Caterpillars were placed 85 cm ("high UV") and 100 cm ("low UV") away from the lights. Because light diminishes as the square of the distance, these distances constitute a 40% difference in UV intensity. Kimax glass test tubes screen out wavelengths below 280 nm, which are not present in the solar spectrum. A third light treatment was designed to protect larvae from ultraviolet light by means of a Kodak Wratten 2E filter, which eliminates all wavelengths of 400 nm or less.

Larvae in all three diet types were placed in all three light treatments; diet treatments at each UV level had two replicates with 15 larvae per replicate. Lights were automatically switched on for 16 hr each day and a constant temperature of 26°C was maintained throughout the assay period. First-instar mortality was recorded daily for six days, twice the average time for all control larvae to molt to second instar. Arcsine-transformed data were analyzed by multivariate repeated-measures analysis. The dependent variable was the proportion of initial larvae surviving each day. As such, survival is a within-subject repeated measure reflecting changes with time. UV level and furanocoumarin content are between-subject main effects.

To assess differences among parsnip furanocoumarins as larval feeding deterrents, as opposed to outright toxins, furanocoumarins were incorporated into artificial diet at the same concentrations and in the same manner as in the previous experiment. After evaporation of the ether, diets were poured into four-compartment 100 × 15-mm Falcon "X plate" Petri dishes. Three grams of diet were spread uniformly into each of two opposing compartments; the remaining two compartments were left empty. Three treatments of seven replicates were prepared in a no-choice bioassay; dishes contained either control diet, xanthotoxin diet, or mixed-furanocoumarin diet. After the diets cooled and solidified, 30 neonate *H. zea* were placed onto the diets in each dish. The dishes were covered and placed in the dark in a random arrangement. Larvae were free to move on or off the diet within the dishes, and the number of larvae on each diet was recorded at 2, 4, 8, 12 and 20 hr. Some larvae could not be located during the course of the assay. Two factors may explain the disappearance of larvae—very small neonate larvae may have escaped or larvae may have consumed one another (*H. zea* larvae are highly cannibalistic, particularly when their diet is less suitable). To avoid ambiguity in interpretation of plates in

which several larvae disappeared and to maintain balanced replicate sizes, we dropped the plate with the highest absentee rate in each of the three treatments (mixed, nine absent; xanthotoxin, seven absent; control, three absent). No more than three larvae disappeared from any of the remaining plates. The number of larvae observed off the diet was assumed to reflect the relative palatability of the diets. Arcsine-transformed proportions of larvae off diet each hour were treated as within-subject repeated measures. Data were analyzed in a multivariate repeated-measures design with treatment as the main effect.

RESULTS

Survivorship was significantly reduced by dietary additions of either xanthotoxin or the mixture of furanocoumarins ($P < 0.001$ for treatment effects in comparisons of xanthotoxin and mixture with control diet) (Figure 1). However, the pattern of mortality on xanthotoxin diets was consistently different from that on the diets containing the natural mixture of furanocoumarins in parsnip. Overall, mortality was significantly higher in the mixture than in the xanthotoxin treatment (Table 2). UV light exposure alone also had a significant negative effect on survivorship. In the absence of ultraviolet light, mortality on xanthotoxin diet was not significantly different from that on control diet ($P > 0.05$, t test); in contrast, nearly 50% of the larvae on the mixed-furanocoumarin diet died by the end of the six-day bioassay ($P < 0.001$, t test). Although, as the amount of ultraviolet light increased, the difference in overall mortality between the two furanocoumarin diets decreased from 43% (no UV) to 30% (low UV) to 17% (high UV), no significant UV by treatment interaction was found, indicating that differences between furanocoumarin diets were not influenced by UV level.

In the deterrency test, the number of larvae off diets containing either xanthotoxin or the mix of furanocoumarins was significantly greater than the number off diets without added chemicals (Figure 2), demonstrating that both furanocoumarin treatments are deterrent to *H. zea*. However, contrary to expectations, the diet containing xanthotoxin was effectively more deterrent at all time intervals than the diet containing the mix of furanocoumarins (Table 3). The lack of a significant interaction between furanocoumarin treatments and time suggests that the relative deterrency of the two diets did not change over the course of the experiment.

DISCUSSION

Assuming that effects of trace amounts of nonfuranocoumarin contaminants in the parsnip extract were absent or minimal, the pronounced toxicity of the natural mixture of furanocoumarins in the absence of UV suggests that a

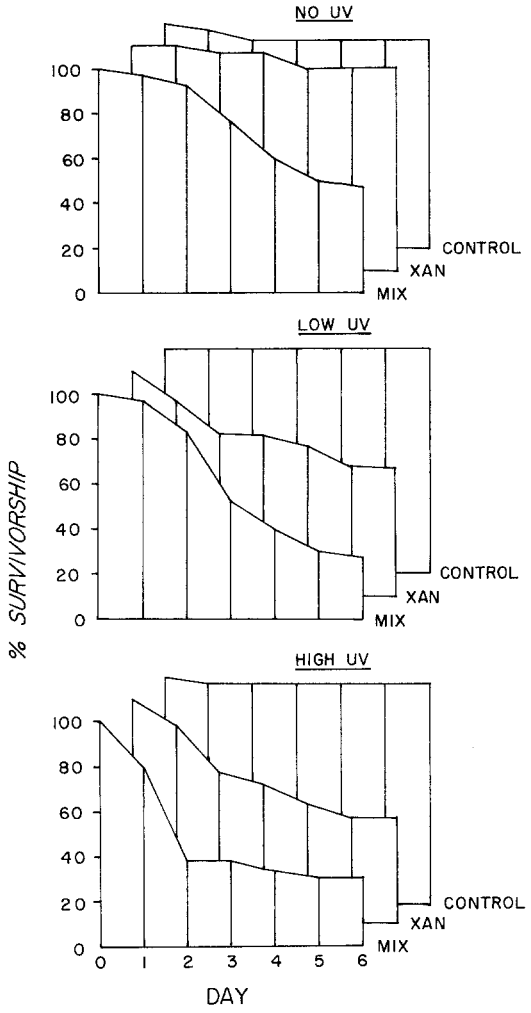

FIG. 1. Percent survivorship of *Heliothis zea* larvae on diets containing no furanocoumarins (control), one furanocoumarin (xanthotoxin), or a mixture of six furanocoumarins (mix) at different UV light intensities.

mechanism other than phototoxicity is involved. Detrimental effects of furanocoumarins unrelated to photoactivation have been observed in previous studies and were attributed to the fact that furanocoumarins are behavioral deterrents as well as postingestive toxins (Yajima et al., 1977; Berenbaum, 1978). In our experiments, however, xanthotoxin proved more deterrent than the mixture in

the absence of UV. The differential mortality of the two furanocoumarin diets, then, cannot be attributed to behavioral effects, such as deterrency, alone.

Physiological effects of furanocoumarins independent of UV-mediated photoaddition to DNA have previously been observed (Murray et al., 1982; Grossweiner, 1984; Caffieri, 1988) and may explain the enhanced toxicity of the furanocoumarin mix. The nature of the mode of action of the nonphotosen-

sitizing insecticidal furanocoumarins is open to speculation. Several coumarins that do not cross-link DNA are nonetheless effective frame-shift mutagens in the absence of UV light (Ashwood-Smith et al., 1980). As a plant of roadsides, waste places, and disturbed areas, *P. sativa* is occasionally subjected to shading conditions (Zangerl and Berenbaum, 1990) under which photosensitizing furanocoumarins would be less effective. Under these circumstances, furanocoumarins whose primary mode of action is UV-independent can maintain the toxicological efficacy of the mixture in shaded environments. Evidence in support of such an adaptive role for a mixture of leaf furancoumarins in wild parsnip was obtained in a shading experiment in the greenhouse. Parsnip plants experiencing a 20% reduction in incident light decreased the overall quantity of leaf furanocoumarins by 38% but increased the proportion of nonphototoxic furanocoumarins from 39% to 51% (Zangerl and Berenbaum, 1987). The great structural diversity of furanocoumarins within the Apiaceae may well represent an adaptive compromise in defensive chemistry in the face of varying environmental conditions.

(Received March 14, 1990; accepted September 12, 1990)

Abstract—Two chemicals implicated in resistance of the tomato plant, chlorogenic acid and polyphenol oxidase, are known to form orthoquinones in damaged plant tissue. Orthoquinones have been reported to alkylate $-NH_2$ and $-SH$ groups of proteins and amino acids, altering solubility, digestibility, and, for some pathogenic viruses, infectivity. Here we explore effects of quinone alkylation on toxicity of an important microbial insecticide, *Bacillus thuringiensis* subsp. *kurstaki* (BTk), to larval *Heliothis zea*. BTk incubated with these phytochemicals and fed to larvae was more toxic than untreated BTk. Similar but less dramatic results arose when BTk was incubated with polyphenol oxidase alone. Digestibility experiments suggest that alkylation enhanced the solubilization and/or proteolysis of crystal protein in vivo. Implications of our results for compatibility of BTk with host-plant resistance and biological control are discussed.

Key Words—*Bacillus thuringiensis* subsp. *kurstaki*, chlorogenic acid, *Heliothis zea*, *Lepidoptera*, *Noctuidae*, host-plant resistance, *Lycopersicon esculentum*, polyphenol oxidase, tomato.

INTRODUCTION

Widespread concern over the use of broad-spectrum insecticides has enhanced the appeal of host-plant resistance (HPR) and microbial insectides as environmentally sound tactics for insect control. Although simultaneous use of these

"biorational" tactics (Ferguson and Alford, 1985; Couch and Ross, 1980) is assumed to optimize plant defenses against herbivory (Kogan, 1986; Adkisson and Dyck, 1980; Bergman and Tingey, 1979), other workers have reported that compatibility among biological control agents may be the exception rather than the rule (Berenbaum, 1988; Shepard and Dahlman, 1988; Price et al., 1980). Most evidence of incompatibility has been obtained through studies of predators and parasitoids as affected by host-plant chemicals (Campbell and Duffey, 1979; Duffey and Bloem, 1986; Duffey et al., 1985; Price, 1986; Shephard and Dahlman, 1988).

Despite recognition that entomopathogens and other microorganisms are also influenced by the host plant (Berenbaum, 1988; Shephard and Dahlman, 1988; Barbosa and Saunders, 1985; Jones, 1984), few interactions between HPR and entomopathogens have been explored at a causative level. Many studies have shown that unspecified factors in plant foliage alter the severity of insect disease (Hare and Andreadis, 1983; Merdan et al., 1975; Stubblebine and Langenheim, 1977; Kunimi and Aruga, 1974) and that crude extracts of foliage can inhibit the growth of entomopathogens in vitro (Smirnoff and Hutchinson, 1965; Morris, 1974; Masymiuk, 1970). Fewer studies have demonstrated that specific plant natural products alter the course of disease in insects. For example, caffeic acid and other plant-derived phenolics in the gut of *Bombyx mori* were converted to compounds active against *Streptococcus faecalis* (Iizuka et al., 1974; Koike et al., 1979). Chlorophyll-A from mulberry was shown to bind to protein in the gut of *B. mori*, forming an antiviral complex (Hayashiya, 1978). Nicotine inhibited colony formation by *Bacillus thuringiensis* and rendered it less toxic to *Manduca sexta* (Krischik et al., 1988). The phenolics rutin and chlorogenic acid suppressed infectivity of two baculoviruses and lengthened the survival time of virally infected noctuids (Felton et al., 1987). Clearly, more biological and biochemical information is needed to predict the usefulness of insect control through simultaneous use of chemically based HPR and microbial insecticides. Modern trends in genetic enhancement of plant resistance, e.g., the transformation of crop plants to express delta-endotoxin of *B. thuringiensis* (MacIntosh et al., 1990; Gasser and Fraley, 1989; Meeusen and Warren, 1989; Adang et al., 1987; Barton et al., 1987; Vaeck et al., 1987), increases the urgency of this need.

A portion of our work on chemical bases of resistance of the tomato, *Lycopersicon esculentum*, to the noctuids *Heliothis zea* and *Spodoptera exigua*, has involved compatibility among biological control agents (Felton and Duffey, 1990; Bloem et al., 1989; Bloem and Duffey, 1990a, b; Felton et al., 1987; Duffey et al., 1985; Duffey and Bloem, 1986). We have focused particularly on the role of oxidative enzymes and phenolics in antinutritive bases of resistance against these insects. This resistance is based on the ability of oxidative enzymes such as polyphenol oxidases and peroxidase to activate certain *o*-dih-

ydroxyphenolics (e.g., chlorogenic acid) to *o*-quinones (e.g., chlorogenoquinone), which in turn alkylate dietary protein and reduce its nutritiousness to the insect (Felton et al., 1989b). Recently we showed this resistance to be incompatible with the action of a *Heliothis*-specific, singly embedded nuclear polyhedrosis virus (HzSNPV) against *H. zea* (Felton and Duffey, 1990). The incompatibility arose because alkylation by chlorogenoquinone altered proteinaceous occlusion bodies chemically and reduced the infectivity of virions.

Considering that *B. thuringiensis* subsp. *kurstaki* (BTk) is a recommended control measure for noctuid larvae on tomato (Anon., 1985) and that the active agent in BTk is a protein whose amino acids are susceptible to aklylation (Schnepf et al., 1985; Chestukhina et al., 1982; Pierpoint, 1983; Hurrell et al., 1982; Huber et al., 1981), we reasoned that alkylation from chlorogenoquinone production may alter the efficacy of BTk as it did with HzSNPV. Here we report that alkylation of BTk enhances its toxicity to *H. zea*. The relevance of our results to conventional and modern HPR is discussed.

METHODS AND MATERIALS

Insects

Eggs of *Heliothis zea* were obtained weekly from the Bioenvironmental Insect Control Laboratory, USDA (Stoneville, Mississippi). To disinfect eggs and free them from cloth on which they were oviposited, cloths were agitated 3 min in a 1% bleach solution and rinsed at least 4 min with distilled water. The eggs were sprinkled over multicellular rearing units placed in plastic trays of soy–wheat germ diet (Hartley et al., 1982). Larvae were reared under a 16:8 light–dark photoperiod until completion of their molt to the desired instar, when they were removed from the unit for use in assays.

Bacillus thuringiensis

A stock culture of *B. thuringiensis* subsp. *kurstaki* (BTk) (var. HD-1) was acquired from Prof. P. Baumann (University of California, Davis). Cells transferred from this and daughter cultures were grown in tryptone–yeast–glucose (TYG) medium containing the following per liter: 25 ml 1 M KH_2/Na_2HPO_4, pH 6.8; 10 ml of solution containing (per liter): 20 g $MgSO_4 \cdot 7H_2O$ and 1 g $CaCl_2$; 2 g D-glucose; 5.85 mg $MnCl_2 \cdot 4H_2O$; 5 ml 20% NH_4Cl; 2.5 g yeast extract (Difco), and 2.5 g tryptone (Difco). Solid medium contained TYG plus 20 g/liter agar, and stock cultures were grown on agar slants for three to four days and stored at 4°C. To obtain BTk for experimental use, cells were grown in liquid TYG medium at 30°C aerated by rotation. After complete sporulation, cultures were centrifuged 10 min at 27,500*g* in a Sorvall RC-5B centrifuge.

Spore-crystal pellets were washed once in 1 M NaCl to remove adsorbed proteases and once in 25 mM KH_2/Na_2HPO_4, pH 6.8. Pellets were then frozen, lyophilized, pooled, and stored at −20°C. The resulting preparation contained spores, crystals, and bacterial debris and is henceforth described as "whole" BTk. Its toxicity to *H. zea* was equivalent to that of a commercially available preparation of BTk, Dipel 2X (Abbott Laboratories, North Chicago, Illinois), containing 32,000 IU of potency per milligram. Unless specifically noted otherwise, all BTk used here was whole.

Intensification of Crystal Activity in BTk

Creation of Gradients. To create a preparation of BTk with an intensified crystal component the method of Sharpe et al. (1975) for separating crystals from spores was used. Linear gradients of 50–90% Renografin-76 (Squibb Diagnostics, Lamirada, California) in double-distilled water were created with an Isco gradient former (model 570) connected by tubing to two 250-ml flasks. Fifty-milliliter gradients were prepared one at a time.

Preparation and Centrifugation of Sample. Whole BTk (about 100 mg) was added to 2 ml Tris HCl, pH 8, containing 0.2% Tween-80 (Sigma, St. Louis, Missouri). The suspension was disaggregated by sonication at 175 W for 3 min. Samples (300 μl each) were layered onto the gradients, placed in a Sorvall HS-4 swinging-bucket rotor, and centrifuged 2 hr at 9400*g*. After centrifugation, bands were collected with a nonsterile Pasteur pipet. The fractions were checked microscopically for the presence of crystals. Fractions containing crystals were pooled, washed twice with double-distilled water, lyophilized, and stored at −20°C. The resulting preparation consisted predominantly of crystals but contained spores as well (ca. 1.6×10^8 spores/mg crystal preparation).

Bioassays

Bioassays involved either larvae placed on treated, synthetic diet or larvae administered treatments per os. All bioassays were replicated at least three times with 24–96 larvae/treatment. For dietary bioassays, synthetic diet at 45°C (ca. 1 ml) was poured into each well of 24-well polypropylene culture dishes (Falcon) and cooled to solidify the diet. Treatments were mixed, stirred mechanically at room temperature for 1.5 hr, and applied in 100-μl aliquots to the diet surface in each well. Stirring continued during application to keep the BTk suspended. Treated dishes were dried in warm (ca. 30°C) air and shaken by hand at least once a minute to ensure even coverage of the diet surface. One third-instar larva then was placed in each well. After infestation, dishes were sandwiched between glass plates. The assembly of dishes and plates was sealed in a polyethylene bag to prevent desiccation of the diet. Dishes were held five

days at 28°C in a 16:8 light–dark photoperiod, after which larvae were prodded gently with a probe. Any larva not responding to this stimulus was classified as dead.

To test the effects of alkylated crystal by injections per os, fifth-instar larvae were first anesthetized by placing them on ice ca. 15 min prior to injection. A 10-μl Hamilton syringe with a blunted needle (gauge 26S) was used to administer 10 μl of treatment to each larva. The needle was inserted approximately halfway into the digestive tract to inhibit regurgitation after administration of material; insects that regurgitated were discarded. Treated larvae were held without diet in 25-well translucent plastic trays (Bio-Serv, Frenchtown, New Jersey) covered with glass plates. Mortality was assessed 24 hr after injection.

Dietary bioassays involved a range of concentrations of phytochemicals and of BTk that included known or estimated levels of these substances in field-grown, BTk-treated tomato plants. We considered: (1) recommended rates for spray application of Dipel 2X, (2) approximate grams of foliage per unit area of canopy, (3) average moles chlorogenic acid per gram of fresh foliage, and (4) average polyphenol oxidase activity per gram of fresh foliage. Values in (2), (3) and (4) were taken from studies of field-grown plants (Felton et al., 1989b); the value obtained for (4) was translated to an appropriate quantity of commercially obtained polyphenol oxidase based on oxidase activity per milligram of enzyme stated by the vendor. We thus estimated a ratio of BTk, chlorogenic acid, and polyphenol oxidase per unit area of tomato as 1:100:2. Absolute concentrations of chlorogenic acid and polyphenol oxidase followed this ratio, so that the high concentration of BTk required to achieve meaningful mortality in *H. zea* required correspondingly high concentrations of phytochemicals. In the case of chlorogenic acid, the highest concentrations used in bioassays exceeded those in field-grown plants (Felton et al., 1989b).

Effects of Chlorogenic Acid and Polyphenol Oxidase in Vivo

Dietary bioassays were used to address the following questions about chlorogenic acid (CHA), polyphenol oxidase (PPO), and BTk: (1) Do CHA and PPO alone alter the toxicity of BTk to *H. zea*? (2) Do combinations of CHA and PPO alter the toxicity of BTk to *H. zea*? To answer the first question, CHA (Sigma Chemical Co. St. Louis, Missouri) was dissolved in 0.1 M KH_2/Na_2HPO_4 buffer, pH 7 (sodium phosphate buffer) at a concentration of 30 mg/ml. The pH of the solution was readjusted to 7.0 with 2 N NaOH, and the solution was diluted serially with buffer to yield concentrations of 5–30 mg CHA/ml. BTk was added to dilutions at 0.24 mg/ml. A suspension of BTk in buffer (0.24 mg BTk/ml) acted as a control. Bioassays of PPO and BTk involved mushroom tyrosinase (Sigma) with an activity of 2200 units CHA oxidase activity/mg enzyme; a unit is defined as $\Delta 0.001$ OD_{470}/min/g. The range of PPO

tested was 0.05–1.2 mg/ml buffer. Again, BTk in buffer was the control treatment. In both cases treatments were stirred, applied to diet, infested, and monitored as described.

To determine if combinations of CHA and PPO alter the toxicity of BTk to *H. zea*, a solution of CHA in buffer (24 mg/ml) was prepared, diluted, and mixed with BTk (0.24 mg/ml) as described. Next, a known amount of PPO was dissolved in an aliquot of cold buffer. Enzyme solution was added to each CHA–BTk mixture to create a ratio of milligrams PPO to milligrams CHA per milliliter of 1 : 50. The bioassay was then performed as described.

Because foliar levels of PPO can vary substantially within and among plants, another series of bioassays tested the effect on BTk toxicity when varying levels of PPO were incubated with a fixed concentration of CHA. PPO was accordingly added to suspensions of BTk in solubilized CHA to produce a final ratio of PPO to CHA of 1 : 10, 1 : 50, 1 : 100, and 1 : 200 (0.06–1.17 mg PPO/ml). BTk and CHA were kept constant at 0.24 mg/ml and 12.5 mg/ml, respectively.

Feeding Rate

To account for the possibility that CHA and/or PPO act as phagostimulants to *H. zea*, bioassays were performed in which CHA and PPO, singly or together, were combined with BTk in 0.1 M $KH_2/Na_2/HPO_4$ buffer to yield the following concentrations: 24.0 mg CHA/ml, 0.48 mg PPO/ml, and 0.24 mg BTk/ml. The treatments (CHA + PPO + BTk, CHA + BTk, and PPO + BTk) were mixed and incubated as previously. Amaranth (Sigma), a water-soluble dye that is nontoxic to larvae and does not cross the gut barrier after ingestion, was added to each treatment after incubation (5% w/v). A solution of amaranth in buffer also was prepared as a control. After treatments were applied to diet, fifth-instar larvae of *H. zea* starved 24 hr were placed on the diet.

Eighteen hours later, the gut of each larva was removed according to the method of Broadway and Duffey (1986) with modifications. A hemostat was used to grasp the anesthetized insect behind the head while the last two abdominal segments were removed. The gut was pulled with forceps onto absorbent paper where it was left briefly to drain of hemolymph before transferral to a 15-ml polycarbonate centrifuge tube containing 1.0 ml 1.0% Triton X-100 (Sigma). Frass produced by a larva during the 24-hr feeding period also was added to that tube. Contents of tubes were macerated 10 sec with a Tekmar Tissumizer and centrifuged 8 min at 17,000 rpm. To assess the presence of dye in the extract, aliquots of each supernatant were read at 522.5 nm (Windholz et al., 1983). Ten tubes were prepared for each treatment, and the experiment was replicated three times.

Radioisotope Experiments

Preparation of Isotope. Tritiated CHA ([^{3}H]CHA) was isolated from a mixture of tritiated rutin and CHA (Research Products International Corp., Gif-sur-Yvette, France) according to Isman and Duffey (1983). Specific activity of [^{3}H]CHA was 153 mCi/mmol CHA.

Alkylation and Counting of BTk. To determine whether CHA and PPO alkylate BTk under conditions established in bioassay incubations, preparations of BTk (whole and crystals) were incubated with these compounds and labeled CHA as for dietary bioassays. This experiment was replicated three times. The method of Felton and Duffey (1990) for alkylation of polyhedral protein was followed with the following modifications. Using 0.1 M $KH_2/Na_2/HPO_4$ buffer at pH 7, one suspension each of whole BTk and BTk crystal was prepared, as was one 25-ml solution of CHA (25.4 mg/ml, adjusted to pH 7) and one of PPO (0.5 mg/ml). Three 8-ml aliquots of the CHA solution and two 8-ml aliquots of buffer were poured. Various combinations of 1×10^6 dpm [^{3}H]CHA, BTk, and PPO were added to these aliquots to create five treatments: BTk crystal only; crystal plus PPO (5 mg); crystal plus CHA (250 mg); crystal plus CHA (250 mg) and PPO (5 mg); and whole BTk plus CHA (250 mg) and PPO (5 mg). Volumes in all treatments were adjusted to 10 ml. Specific activity of [^{3}H]CHA in the last three treatments was 1.4×10^{-3} mCi/mmol CHA. All treatments were incubated and the pellets isolated, dialyzed, and lyophilized as described by Felton and Duffey (1990).

To achieve complete hydrolysis of BTk before scintillation counting, samples were placed in 3-ml reaction vials (Pierce) with 250 μl 12.4 N HCl. The vials were sealed with Teflon caps and heated 1 hr at 50°C. An equal volume of 12.4 N NaOH neutralized the solution and was followed by 250 μl 30% H_2O_2 as a bleaching agent. Samples were transferred to scintillation vials, mixed with aqueous scintillation cocktail (Amersham Corp., Arlington Heights, Illinois), allowed to stand for 12 hr to minimize quenching, and then counted 5 min by the external standard ratios method. Appropriate background controls of hydrolyzing, neutralizing, and bleaching agents added to scintillation cocktail were also run.

Digestion of Alkylated BTk in Vitro

To examine whether alkylated BTk was more susceptible than unalkylated BTk to digestion in the insect gut, experiments were performed to digest BTk in vitro, to bioassay the digest, and to examine digestion products via sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE).

Alkylation of Crystal. A 30-mg batch of BTk crystal was alkylated by incubating it with CHA and PPO in sodium phosphate buffer as described, except

that a ratio (in milligrams) of BTk, CHA, and PPO of 1:75:1.5 was used. A second 30-mg batch was incubated in buffer as a control. Both treatments were dialyzed as described, lyophilized, and stored at 4°C. They will be referred to henceforth as "alkylated crystal" and "unalkylated crystal," respectively.

Isolation of Proteases. Guts of 25 early fifth-instar *H. zea* were pooled in 3 ml chilled 0.09% NaCl containing 0.02 M $CaCl_2$. After maceration and centrifugation of the guts, supernatant was filtered over a 0.45-μm nylon membrane and checked for tryptic and chymotryptic activities (Broadway and Duffey, 1986). These were established, via toluenesulfonyl-L-arginine methyl ester and benzoyl-L-tyrosine ethyl ester (Sigma), respectively, as 7.4 and 2.3 Δ0.001 OD_{max}/μl gut juice/min.

Digestion. Alkylated and unalkylated crystal was divided into three portions of approximately 10 mg and solubilized in 500 μl 0.04 M Tris, pH 8.1, containing 0.02 M $CaCl_2$. An aliquot of gut juice was added to each tube, and tube volumes were adjusted with buffer to 2.5 ml. Unalkylated crystal was similarly divided into three batches, suspended in buffer, and treated with enzyme. As controls, buffer and the same volume of enzyme used in other treatments were added to an additional three tubes. Tubes were inverted several times and placed in a shaking bath at 25°C. Preliminary tests showed that BTk crystal suspended in the buffer used for this digestion remained intact (unpublished data).

Protein Assays. Treatments were monitored at 0, 60, and 120 min to assess the progress of digestion. We first measured amines via 2,4,6-trinitrobenzenesulfonic acid (TNBS) (Fields, 1972), then arginine and, to a lesser extent, other basic and aromatic residues of protein via Biorad dye reagent diluted fivefold (Compton and Jones, 1985; Bradford, 1976). After final monitoring at 120 min, treatments were divided rapidly into aliquots, frozen, and stored at −80°C for the next experiment.

Bioassays of Digests. To determine whether changes detected in treatments during digestion were accompanied by changes in larval mortality, individual frozen aliquots of digests were thawed at 4°C and administered per os to fifth-instar *H. zea*. As noted above, mortality was checked after 24 hr. This experiment was replicated by using larvae from six separate rearings.

SDS-PAGE. To ascertain whether alkylation of BTk alters the size of fragments normally produced during proteolysis of BTk crystal protein, digests from alkylated and unalkylated crystal were submitted to SDS-PAGE. One aliquot each of digested, alkylated BTk and of digested, unalkylated crystal was thawed at 4°C, transferred to 1-ml microfuge tubes, and centrifuged 5 min at 2000*g*. The supernatants were withdrawn and submitted to discontinuous SDS-PAGE in gels containing 12.5% (w/v) acrylamide and 0.1% SDS after Laemmli (1970). Molecular-weight standards were obtained from Sigma. Sample preparation and protocols for electrophoresis followed methods of Laemmli (1970). Gels were

stained for general protein using (1) a standard method with Coomassie brilliant blue R and (2) the silver-staining method with reagents and protocol provided by Biorad (Richmond, California).

RESULTS

Dietary Bioassays

Effects of CHA and PPO in Vivo. Placing BTk under alkylative conditions more than doubled its toxicity to third-instar *H. zea* as the concentrations of CHA and PPO rose. The increase in toxicity was highly significant (Figure 1) (least-squares regression, $F_{1,23} = 38.07$, $P < 0.001$). Mortality of *H. zea* also was enhanced when PPO combined with a fixed concentration of CHA rose from 0.06 mg PPO/ml to 1.17 mg PPO/ml (Figure 2) (least-squares regression, $F_{1,11} = 9.57$, $P < 0.025$). Polyphenol oxidase alone enhanced toxicity of BTk as well (Figure 3) (least-squares regression, $F_{1,16} = 11.24$, $P < 0.005$), but CHA alone did not (data not shown; (least squares regression, $F_{1,19} = 1.01$, $P > 0.3$).

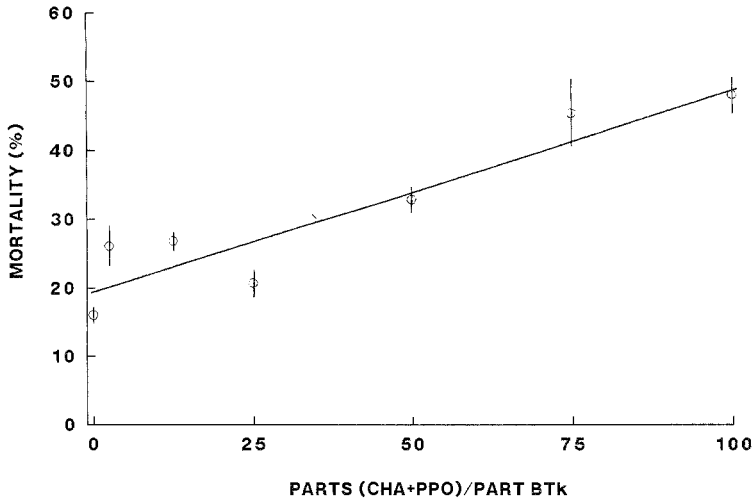

FIG. 1. Larval mortality in dietary bioassays of BTk treated with chlorogenic acid (CHA) and polyphenol oxidase (PPO). [BTk] = 0.24 mg/ml, [CHA] = 0–24 mg/ml, [PPO] = 0–0.48 mg/ml. Ratio of parts CHA to part PPO was constant at 50 : 1 while the ratio of parts CHA to part BTk varied (0 : 1–100 : 1). Each point represents mean mortality in three to five replicates containing 24–120 insects per treatment. Regression equation: $Y = 19.6 + 0.287X$; $r^3 = 0.623$. The slope is significantly greater than zero ($P < 0.001$).

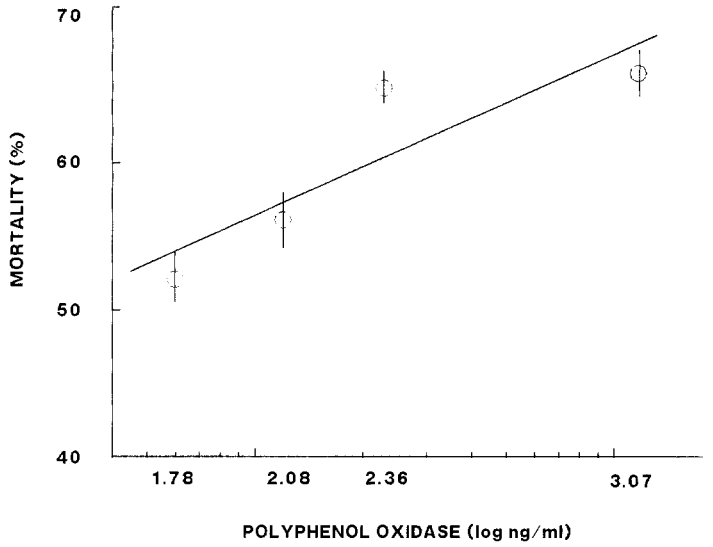

FIG. 2. Larval mortality in dietary bioassays of BTk with fixed CHA and increasing levels of PPO. [BTk] = 0.24 mg/ml, [CHA] = 12.5 mg/ml, [PPO] = 0.06–1.17 mg/ml (60–1170 ng/ml). Concentrations of PPO were log-transformed. Each point represents mean mortality (±SEM) in three replicates containing 72–96 insects per treatment. Regression equation: $Y = 4.534 (\log X) + 65.721$; $r^2 = 0.785$. The slope is significantly different from zero ($P < 0.025$).

Feeding Rate. The major influence on feeding rate of *H. zea* exposed to phytochemicals and BTk was BTk rather than CHA and/or PPO (Figure 4). The feeding rate of insects fed BTk, phytochemicals, and amaranth appeared several times lower than that of insects fed amaranth only. This difference was highly significant (t test, $P < 0.001$). Differences among BTk treatments were slight and not statistically significant except for treatments containing (1) BTk, CHA, and PPO and (2) BTk and PPO. Both (1) and (2) differed from each other but not from the other treatments containing BTk (two-sample test, $P > 0.05$). The low feeding rate in BTk treatments confirmed BT-induced feeding cessation noted here and elsewhere (Dulmage and Martinez, 1973; Retnakaran et al., 1983; Fast and Regniere, 1984; Alford and Holmes, 1986). No insect died in any treatment.

Radioisotope Experiments

BTk placed under alkylative conditions bound labeled CHA. In two of three experiments, crystal bound more CHA than did whole BTk (Table 1), suggesting that chlorogenoquinone interacted primarily with the crystal in this

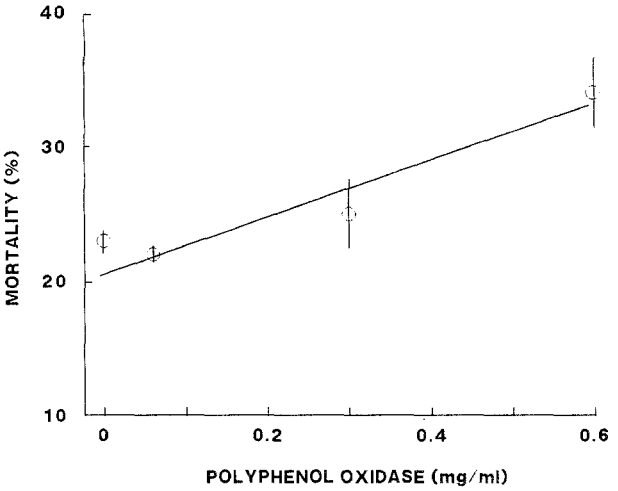

FIG. 3. Larval mortality in bioassays of BTk with PPO. [BTk] = 0.24 mg/ml, [PPO] = 0–0.06 mg/ml. Each point represents the mean mortality in two to four replicates containing 20–72 insects per treatment. Regression equation: $Y = 21.8 + 16.5X$; $r^2 = 0.413$. The slope is significantly different from zero ($P < 0.01$).

preparation. (The variation in binding evident in Table 1 may have been caused by clumping of spores in BTk preparations.) Radioactivity persisted in BTk despite prolonged dialysis against 8M urea. The binding therefore was deemed covalent, since urea is known to disrupt noncovalent interactions between protein and phenolics (Pierpoint, 1983).

Digestion of Alkylated BTk in Vitro

Protein Assays. Alkylated BTk was digested at a faster rate than unalkylated BTk (Figures 5 and 6). When TNBS reagent was used (Figure 5), the measured rate of increase in amines was the same for alkylated and unalkylated treatments between 0 min and 60 min but was greater thereafter for the alkylated treatment. The enzyme control gave lower absorbance throughout than either of the BTk treatments. Absorbance of the alkylated treatment was significantly higher at 0 min (t test, $P < 0.001$) than that from either the unalkylated or control treatment.

Except that readings of all treatments differed significantly from each other at 0 min (alkylated > unalkylated > enzyme control, $P < 0.05$), similar results were obtained with Biorad dye reagent (Figure 6) as with TNBS. Again, absorbance was consistently higher in the alkylated treatment than in the unalkylated or control treatment. Values increased for both BTk treatments but not for the enzyme control. At each reading, absorbance of alkylated and unalkylated BTk

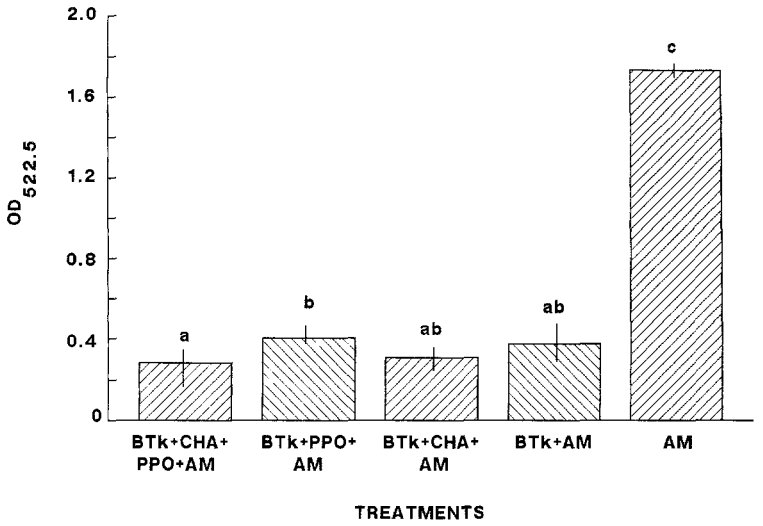

FIG. 4. Feeding rate of *H. zea* on treatments containing BTk and phytochemicals, as shown by absorbance of extracts of guts and frass. CHA = chlorogenic acid, PPO = polyphenol oxidase, AM = amaranth. [BTk] = 0.24 mg/ml, [CHA] = 24 mg/ml, [PPO] = 0.48 mg/ml, [AM] = 50 mg/ml. Each bar represents mean absorbance (±95% CI) of 10 extracts, each extract from one larva, replicated three times. Bars topped by different letters are significantly different.

TABLE 1. CHLOROGENIC ACID (CHA) BOUND TO BTk AFTER INCUBATION WITH TRITIATED CHA, UNLABELED CHA, AND POLYPHENOL OXIDASE (PPO) IN 0.01 M SODIUM PHOSPHATE BUFFER

Treatment[a]	Bound CHA (nmol CHA/mg BTk)		
	Exp. 1	Exp. 2	Exp. 3
Crystal + CHA + [^{3}H]CHA + PPO	49.1	4.3	10.0
Whole BTk + CHA + [^{3}H]CHA + PPO	35.0	13.7	7.5

[a] [BTk] = 5 mg crystal or whole BTk; [^{3}H]CHA = tritiated CHA at 1×10^6 dpm/incubation; CHA = 250 mg/incubation; and PPO = mushroom tyrosinase at 5 mg/incubation. Volume of each incubation = 15 ml.

differed significantly ($P < 0.02$). Absorbance from the control did not change between 0 and 60 min ($P > 0.3$) and dropped thereafter.

Bioassays of Digests. Alkylated BTk, which proved more digestible in vitro than unalkylated BTk, also proved more toxic in vivo (data not shown).

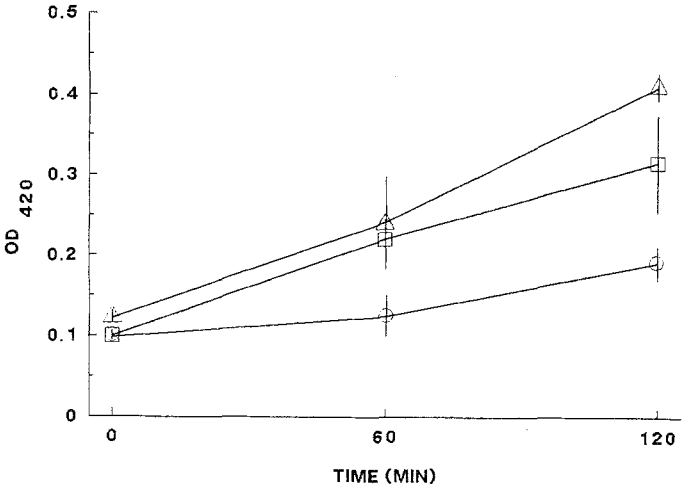

FIG. 5. In vitro digestion of BTk crystal by *Heliothis* proteases as measured by TNBS. △ = alkylated crystal; □ = unalkylated crystal; ○ = enzyme control. Each point is the mean (±95% CI) of six readings.

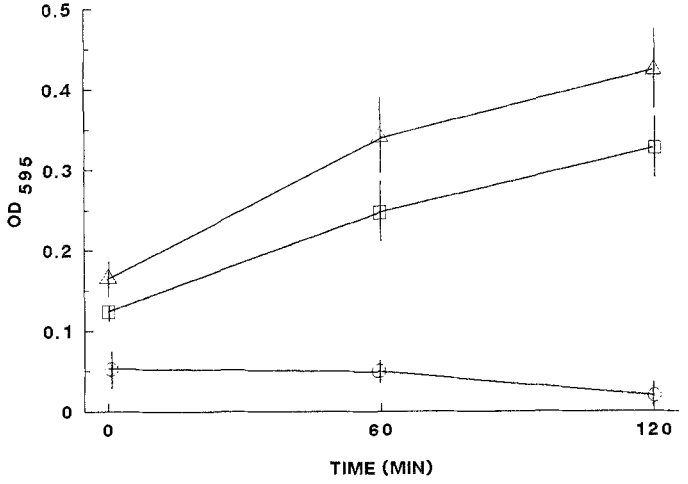

FIG. 6. In vitro digestion of BTk crystal by *Heliothis* proteases as measured by Biorad dye reagent. △ = alkylated crystal; □ = unalkylated crystal; ○ = enzyme control. Each point is the mean (±95% CI) of six readings.

The difference in mortality caused by alkylated and unalkylated BTk was significant (Wilcoxon matched-pairs signed-ranks test, $P < 0.05$).

SDS-PAGE. A complex banding pattern appeared when digests were submitted to SDS-PAGE. However, despite differences observed in the preceding experiments, no corresponding differences in banding by digests of alkylated and unalkylated material were apparent (data not shown).

DISCUSSION

Many factors are known to alter the insecticidal and bacterial activity of BTk. Abiotic factors (moisture, high temperature, and ultraviolet radiation) degrade BT in field applications (Beckwith and Stelzer, 1987; Leong et al., 1980; Ignoffo et al., 1974), while chemicals (pyrethroids, adjuvants, thuringiensin, organophosphates, and other synthetic insecticides) can diminish or enhance it (Bell and Romine, 1986; Moar et al., 1986; Salama et al., 1984; Mohamed et al., 1983; Faust and Bulla, 1982; Pfrimmer, 1979; Jaques and Morris, 1981; Bull et al., 1979). Plant natural products also influence the toxicity of BT. Soy protease inhibitors enhanced the insecticidal activity of BT when combined with BT, as did a protease inhibitor expressed with BTk insecticidal protein in genetically transformed tobacco (MacIntosh et al., 1990). Nicotine enhanced survivorship of *Manduca sexta* exposed to BTk (Krischik et al., 1988); the nonprotein amino acid L-canavanine had the opposite effect (Felton and Dahlman, 1984). However, chemical factors that change the toxicity of BTk often do so by influencing the insect and not the pathogen (Berenbaum, 1988; Krischik et al., 1988; Felton and Dahlman, 1984). Our paper presents evidence that two plant natural products, CHA and PPO, can alter pathenogenicity by acting directly on an entomopathogen.

Plant phenolics are known for their ability to form reactive *o*-quinones in the presence of oxidative enzymes like PPO, laccase, and peroxidase (Matheis and Whitaker, 1984; Pierpoint, 1983; van Sumere et al., 1975). Orthoquinones attack nucleophilic substituents of proteins, e.g., $-SH$ and $-NH_2$ groups, alkylating the proteins and changing them chemically (Barbeau and Kinsella, 1983, 1985; Matheis and Whitaker, 1984; Pierpoint, 1983; Blouin et al., 1982; Hurrell et al., 1982; van Sumere et al., 1975). Orthoquinones also may be formed by the monophenolase action of PPO on tyrosyl residues of proteins (Matheis and Whitaker, 1984), e.g., the toxic protein of BTk found predominantly in crystals but also in spore coats (Chestukhina et al., 1982; Huber et al., 1981; Tyrell et al., 1981; Bulla et al., 1980). These *o*-quinones cross-link with each other or with nucleophilic substituents of proteins (Matheis and Whitaker, 1984). In our study, *o*-quinone formation by the action of PPO on CHA (Figures 1 and 2) and of PPO on BTk (Figure 3) appears to have enhanced

toxicity of BTk protein to *H. zea*. Moreover, BTk was alkylated by chlorogenoquinone (Table 1), an expected result since crystal protein of BTk contains alkylatable amino acids such as cysteine, lysine, and methionine (Schnepf et al., 1985; Chestukhina et al., 1982; Huber et al., 1981; Tyrell et al., 1981; Bulla et al., 1980). How could alkylation have increased the toxicity of BTk? Three possibilities exist: (1) alkylation of the crystal protein altered interactions between the larval midgut and delta-endotoxin (Hofmann et al., 1988a,b; Bulla et al., 1980) or other events following hydrolysis of the native protein in vivo; (2) alkylation cross-linked the crystal protein, causing an unusually toxic molecule to be released by hydrolysis; or (c) alkylation sped the release of toxic fragments by enhancing solubilization and/or proteolytic cleavage of the crystal protein.

The first possibility, that alkylation influenced postproteolytic phenomena in BTk toxification, exceeded the scope of this study and requires further examination. The second possibility, that an unusually toxic peptide was formed by protein cross-linking, is unlikely. Chlorogenoquinone bound to BTk (Table 1) but did not cause protein cross-linking detectable by SDS-PAGE. Indeed, alkylation apparently failed to alter the gel retention time of any peptide released during digestion of BTk in vitro.

Inasmuch as alkylation enhanced the enzymatic hydrolysis of BTk (Figures 5 and 6), it is more plausible that alkylation improved solubilization and/or proteolysis of the crystal protein in vivo. Reductive alkylation of casein enhanced the solubility of this protein (Sen et al., 1981) while HzSNPV occlusion bodies (OBs) exposed to chlorogenoquinone proved less soluble than untreated OBs (Felton and Duffey, 1990). Proteins often are more digestible after they have interacted noncovalently with phenolics. As examples, noncovalent binding by CHA to fraction-1 protein from spinach rendered the protein more susceptible to trypsin hydrolysis (Barbeau and Kinsella, 1985), and tannins accelerated the enzymatic hydrolysis of bovine serum albumin after complexing with this protein (Mole and Waterman, 1985). Both these studies of protein–phenolic binding suggested strongly that complexing changed protein conformation and exposed new sites to proteolytic attack (Barbeau and Kinsella, 1985; Mole and Waterman, 1985). Protein appears to undergo conformational changes after covalent interactions with phenolics as well (Sen et al., 1981; Puigserver et al., 1979), although this protein–phenolic interaction often suppresses digestibility in the relatively few proteins studied (Hurrell et al., 1982; Puigserver et al., 1979; Duffey and Felton, 1989; Pierpoint, 1983; Pierpoint et al., 1977).

We propose that alkylation caused conformational changes in the toxic protein of BTk and that these changes enhanced digestibility and/or solubility of the protein. Consistent with the foregoing studies, it is plausible that conformational changes exposed more peptide bonds to proteolysis than were

accessible in unalkylated protein, speeding the release of toxic fragments. An acceleration in the release of proteinaceous products is evident in Figures 5 and 6. Moreover, bioassays of BTk digests show that the material produced at a faster rate (i.e., from alkylated BTk) was toxic to *H. zea*.

The chemical mechanism by which CHA and PPO accentuate the toxicity of BTk will require further clarification. However, we were able to eliminate three factors that could account for our results. The first was that stress imposed on *H. zea* by ingestion of CHA and PPO predisposed the insect to BTk toxification. However, *H. zea* exposed to both phytochemicals grew as well as insects not so exposed (data not shown). The second possibility was that either phytochemical alone could enhance the toxicity of BTk. This was true in the case of PPO only (Figure 3). The monophenolase activity of tyrosinase on tyrosyl resides in BTk protein accounts for this effect (Matheis and Whitaker, 1984), but enhancement was more pronounced when PPO acted on CHA (cf. percent mortality at highest x value, Figures 1 and 3). Finally, we excluded the possibility that both phytochemicals caused *H. zea* to ingest more BTk by acting as phagostimulants. Figure 4 illustrates that this is decidedly not the case.

Here we have provided further evidence that plant natural products can influence the efficacy of entomopathogens. To our knowledge, this is the first report that chemical alteration of protein in the entomopathogenic spore and toxin potentiates BTk. Although reports of inactivation by plant natural products substantially outnumber reports of potentiation (Shepard and Dahlman, 1988), most changes in the toxicity of entomopathogens are ascribed to effects of plant natural products on test herbivores (Berenbaum, 1988). It remains to be seen whether CHA and PPO in the plant have the same effect on BTk as occurred in our laboratory or whether they can enhance the potency of BT toxin expressed in transgenic plants (see especially MacIntosh et al., 1990, but also Meeusen and Warren, 1989; Barton et al., 1987; Adang et al., 1987; Vaeck et al., 1987). If so, we suspect that enhanced phenotypic expression of these phytochemicals would prove a mixed blessing: improved efficacy of BTk on the one hand, but simultaneously a threat to other forms of biological control and of HPR. We have mentioned the study in which chlorogenoquinone alkylated viral occlusion bodies (OBs), inhibiting their solubility and digestibility in vitro and reducing the infectivity of virions in vivo (Felton and Duffey, 1990). Chlorogenoquinone also may inactivate tomato and soy protease inhibitors (Felton et al., 1989a), implicated in resistance of these plants to insects (Ryan, 1979; Broadway et al., 1986).

Acknowledgments—This research was supported by USDA competitive grant 87-CRC-1-2371 awarded to S.S.D. and by a grant from O. Gass awarded to C.T.L. Critical reviews of an earlier draft by H. Kaya, S. Maeda, and L. Harshman were most useful.

(Received May 23, 1990, accepted September 10, 1990)

Abstract—Extracts of male *Mamestra brassicae* (L.) hairpencils were analyzed by capillary gas chromatography (GC) and by GC-mass spectrometry (GC-MS). The extracts were found to consist of six components. Benzaldehyde, 2-methylpropanoic acid, 2-methylbutanoic acid, and phenol were present in the extracts as well as the previously identified benzyl alcohol and phenyl ethanol. The two major components were 2-phenylethanol and 2-methylbutanoic acid. They represented, respectively, 74% and 12.5% of the total blend in 3-day-old male extracts. Electroantennograms were recorded on male and female antennae in response to stimulation by hairpencil compounds. Male and female antennae responded to each chemical but the female responses were significantly higher than those of the males.

Key Words—*Mamestra brassicae*, Lepidoptera, Noctuidae, hairpencils, male-produced compounds, identification, benzaldehyde, 2-methylpropanoic acid, 2-methylbutanoic acid, benzyl alcohol, 2-phenylethanol, phenol, electroantennography.

INTRODUCTION

Like many noctuid moths, male *Mamestra brassicae* (L.) possess evertable scent organs known as hairpencils, located in abdominal pockets situated on the first and second abdominal sternites. These structures are associated with two inter-

*To whom correspondence should be addressed.

0098-0331/91/0100-0239$06.50/0

nal glands, described by Stobbe (1912), and are everted during courtship behavior. In the vicinity of the female, they release an odor detectable by the human nose. In an attempt to elucidate the effect of male hairpencils and their associated odors on calling females, we compared in a previous work the courtship behavior of males with and without hairpencils (Jacquin, 1989). The number of attempted copulations, followed by either the rejection or the acceptation of the male by the female, was quantified. Our results, according to Birch et al. (1989), suggest that the presence of male hairpencils increases female acceptance. Observed behaviors suggested that hairpencil secretions could affect the recognition of the sexual partners and could be an important factor in sexual selection.

In order to provide further evidence for putative functions of the hairpencil secretions, biological tests using pheromonal blends could be used. A reinvestigation of the chemical composition of *M. brassicae* hairpencil extracts is therefore necessary since no recent study has been reported. Bestmann et al. (1977) identified two compounds in hairpencil extracts of males *M. brassicae*: 2-phenylethanol (96%) and benzyl alcohol (4%). This paper will discuss the identification of new components and their electrophysiological significance.

METHODS AND MATERIALS

Insects. The insects were reared on a cabbage semisynthetic diet (Poitout and Bues, 1974) and kept under a reversed light–dark 16:8 photoperiod at 20 $\pm$ 2°C at every life stage. The insects were sexed as pupae, and the adults were kept in hermetic plastic containers and fed with a sugar solution (10%). Only naive 3-day-old adults were used in this experiment.

Hairpencil Extracts. Four hours after the onset of the scotophase, hairpencils were carefully excised out of individual males that had previously been anesthetized with carbon dioxide. The third day of insect life corresponded to the optimum of male sexual activity under our experimental conditions. All dissections were carried out on males that presented a complete retraction of the hairpencils in their abdominal pockets. Each pair of individual male hairpencils was quickly immersed into a glass vial containing 200 μl of pentane (SDS, Vitry, France) and was left to extract at room temperature for one hour. This was repeated with 10 different males. Solutions were then condensed to 100 μl under a stream of nitrogen before analysis.

Chemical Analysis. Identifications were performed by capillary gas chromatography (GC) and by gas chromatography-mass spectrometry coupling (GC-MS). GC analyses were performed on a Hewlett-Packard 5890 gas chromatograph equipped with a flame ionization detector (FID) and a FFAP column 25 m $\times$ 0.32 mm (ID) (Chrompack) using helium as the carrier gas (P_{He} = 2.76

bar). Oven temperature was programmed to increase from 60°C to 140°C at 3°C/min. Samples were injected on a Ross injector after 10 sec of evaporation or on a split/splitless injector. Injector temperature was 220°C and detector temperature was 250°C.

GC-MS identification was conducted on a Nermag 10-10C quadrupolar mass spectrometer using a Sidar data system (EI, 70 eV, 30–400 amu). The GC was equipped with a nonpolar capillary column, CPSIL5 CB, 25 m × 0.32 mm (ID) (Chrompack) programmed to increase from 60°C to 140°C at 3°C/min.

Identifications of the extract components were determined by comparing their retention times on both polar and nonpolar columns and their spectra with those of reference compounds (Aldrich Chimie).

Electroantennography. Compounds identified in the crude extracts were tested on both male and female antennae. Electroantennograms (EAG) were recorded according to the technique described by Renou (1979). Chemicals were diluted in hexane and applied on filter papers at a dose of 10 μg. Stimulations with air alone and hexane alone (1 μl) were applied as check samples. The stimulation cartridges were only used twice and then renewed to prevent loss of charge due to the volatility of the chemicals. A 1-sec pulse of air, delivered at 60 liters/hr, was allowed to pass through the cartridge. Five male and five female antennae were tested twice each with the set of chemicals.

RESULTS

Identification of Hairpencil Components. GC analyses showed six peaks (Figure 1). The retention times of peaks 4 and 5 matched the retention times of, respectively, benzyl alcohol and 2-phenylethanol, which had previously been identified by Bestmann et al. (1977). GC-MS spectra confirmed these results. The first peak exhibited the same retention time as that of benzaldehyde. This identification was confirmed by the mass spectrum, which matched the reference benzaldehyde spectrum. Peak 6 had the same retention time and mass spectrum as phenol, whereas peaks 2 and 3 showed characteristic ions of 2-methylpropanoic acid and of 2-methylbutanoic acid. The retention times of both acids corresponded with those of the reference samples for the two types of columns.

Analyses of individual pairs of hairpencils from 10 individual males confirmed the occurrence of the six previously identified compounds. The percentage composition of the hairpencil extracts is: 1% benzaldehyde, 3.5% 2-methylpropanoic acid, 12.5% 2-methylbutanoic acid, 6.5% benzyl alcohol, 74% 2-phenylethanol, and 2.5% phenol (Table 1).

Studies of the correlations (Spearmann test) between the relative percent-

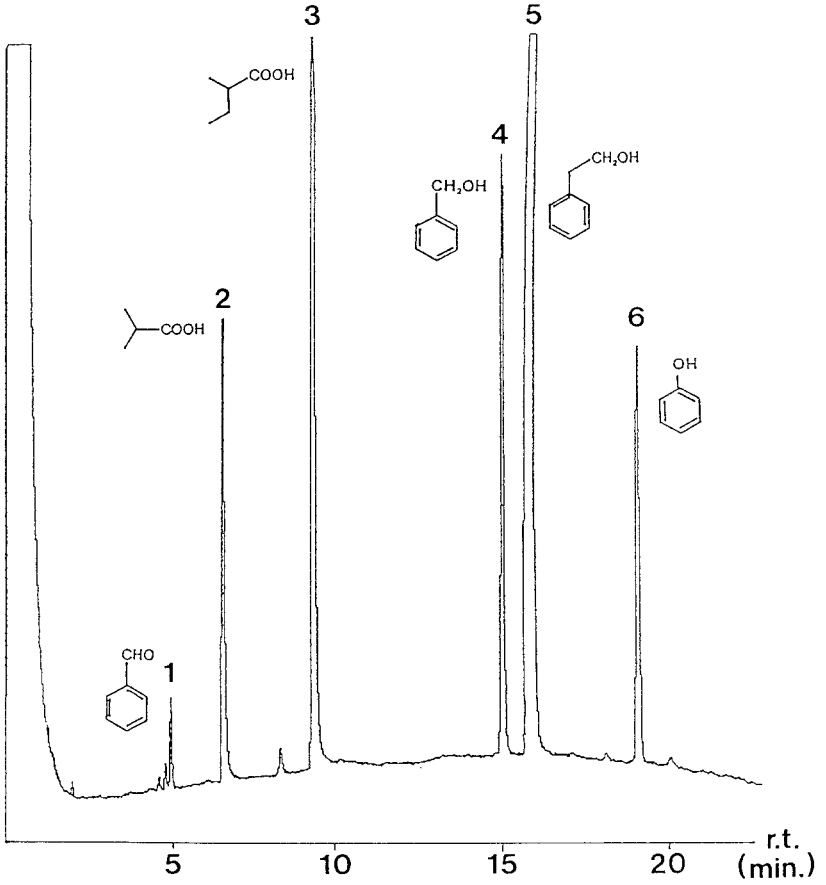

FIG. 1. Capillary column gas chromatogram of hairpencil extract of a virgin *Mamestra brassicae* male (2 μl out of 100 μl extract, other conditions in text). **1:** benzaldehyde; **2:** 2-methylpropanoic acid; **3:** 2-methylbutanoic acid; **4:** benzyl alcohol; **5:** 2-phenylethanol; **6:** phenol.

ages of these six compounds showed there to be negative correlations between phenylethanol and the other compound ratio ($P < 0.05$). However, phenol did not correlate with any of the five other compounds. The correlations were positive between each of the others ($P < 0.05$).

Electroantennographic Results. Electroantennogram recordings indicated that both male and female antennae responded to the six identified compounds (Figure 2). All six compounds were significantly better perceived by the female antennae than were the controls of hexane or air alone ($P < 0.01$). However, the responses of male antennae to the 2-methylpropanoic acid did not

TABLE 1. HAIRPENCIL EXTRACT COMPOSITION

Compounds	Percentage composition (means ± SEM, $N = 10$)
Benzaldehyde	1 ± 0.12
2-me.prop.ac.	3.5 ± 0.6
2-me.but.ac.	12.5 ± 1
Benzyl OH	6.5 ± 0.6
2-phenyl ethOH	74 ± 2.3
Phenol	2.5 ± 0.7

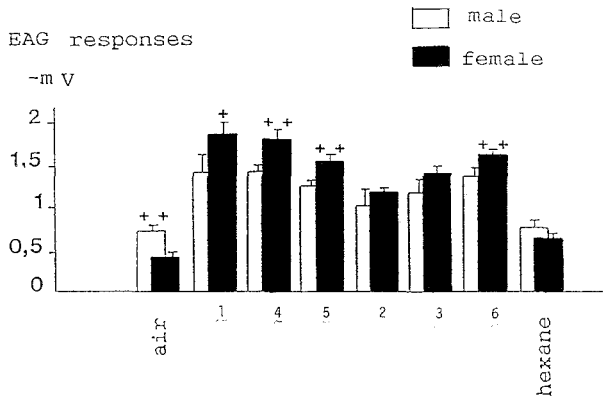

FIG. 2. Average values of EAG potentials evoked on five antennae of both male and female *Mamestra brassicae* by 10 μg of each identified compound. Vertical bars indicate the standard error. (+) or (++) above responses indicates that the responses are significantly different between male and female (Mann-Whitney: + $P < 0.05$, ++ $P < 0.01$). All the responses to the test compounds are significantly different from controls (air and hexane) ($P < 0.05$) except for the male response to 2-methylpropanoic acid (**2**).

significantly differ from the responses to the hexane control. The other compounds elicited significantly higher responses than hexane on male antennae ($P < 0.05$ for 2-methylbutanoic acid and $P < 0.01$ for all others).

Both males and females showed the same response pattern to the six components of hairpencil extracts. The highest responses were evoked by benzaldehyde, benzyl alcohol, 2-phenylethanol, and phenol for both sexes. The 2-methylpropanoic acid and the 2-methylbutanoic acid showed lower activities. The comparison of male and female EAG responses to the six compounds

showed that female antennae gave significantly higher responses, except for the two acids (Figure 2).

DISCUSSION

Low-molecular-weight compounds have been isolated previously from hairpencils of various noctuid males (reviewed by Zagatti, 1981; Boppré, 1984; Fitzpatrick and McNeil, 1988; Birch et al., 1990). All are simple terpenoids, aromatics, and carboxylic acids. The six compounds isolated in *Mamestra brassicae* hairpencil extracts are structurally similar and have been reported previously in other noctuids as hairpencil components (Aplin and Birch, 1970). However, phenol has never been identified in male hairpencils of any other lepidoptera. Nevertheless, phenols are described as defensive allomones of millipedes (Blum, 1987) and as a sex attractant for the grass grub beetle *Costelytra zealandica* (Henzell and Lowe, 1970). Phenols also are known to be produced by wounded trees and to act as a repellent or a toxic agent to bark beetles (Raffa and Berryman, 1983). Fitzpatrick et al. (1989) relate that many noctuids are attracted to exudates of tree wounds. It is curious to find phenol as a hairpencil constituent, and its biological function could differ from the other component functions. Further behavioral studies will be conducted to test the different functions of the hairpencil components.

Benzaldehyde is an extremely common hairpencil component and is found to be a major component of male scent brushes of many *Leucania* and *Mythimna* species, and a minor component in *Polia nebulosa* (Hufn.) and *Mamestra persicariae* (L.) (Aplin and Birch, 1970). Up to now, it has not been detected in *M. brassicae*. This was probably due to the low quantity present in hairpencil extracts (1%).

In our experiment, benzyl alcohol and 2-phenylethanol have been described as hairpencil components of *M. brassicae* with approximately the same relative ratios as those published by Bestmann et al. (1977). However, 2-methylpropanoic acid and 2-methylbutanoic acid have been newly identified in this study as components of *M. brassicae* hairpencil extracts. The 2-methylpropanoic acid has been found at a level of about 20% in hairpencil extracts of several Hadeninae [*Leucania impura* (Hueb.), *L. conigera* (Schiff.), *L. pallens* (L.)] (Aplin and Birch, 1970). 2-Methylbutanoic acid is also produced by some noctuid species (Amphipyrinae and Cucullinae) but has never been reported in Hadeninae. This compound appeared in our experiment to be one of the main compounds of *M. brassicae* male extracts (12.5%).

The 10 analyses of individual male hairpencil extracts reflected a low vari-

ability of the component percentages between individuals. However, the quantities detected seemed to be very variable from one male to another.

EAG recordings indicated that female antennae responded to the six compounds identified in male hairpencil extracts. It is of interest that male *M. brassicae* also responded to the majority of their own hairpencil components, except to 2-methylpropanoic acid. This suggests that the male scent could affect male behavior. Although Toth (1982) does not find any evidence for male-to-male inhibition, other effects should be considered.

Male and female antennae responded in the same way to the different hairpencil components. This is in accordance with the results on *Trichoplusia ni* (Hübn.) (Grant, 1970) and suggests that the antennae of both sexes possess similar receptors for detecting male scents. Nevertheless, nothing is known on the specificity of those receptors for the hairpencil components.

The female responses were higher than the male responses. As EAG is thought to be the summed potential of the activated receptor cells of the antennae (Boeckh, 1969), our results suggest that female antennae possess more acceptor sites for all of the compounds than do the male antennae.

The fact that the phenol ratio did not correlate with the ratios of the other identified compounds appears to be consistent with the hypothesis that there is a different metabolic origin between this chemical and the other aromatic compounds. Phenol is known to originate in tyrosine (Blum, 1987) while phenylethanol and benzaldehyde originate in L-phenylalanine (Clearwater, 1975). The two acid precursors are not known and could be valine and isoleucine for, respectively, 2-methylpropanoic acid and 2-methylbutanoic acid as described in other insects (Blum, 1987).

Identification of new components in *Mamestra brassicae* hairpencils may provide some clues for the understanding of the specificity of chemical communication between males and females. Many noctuid males within Hadeninae are considered to produce closely related scent blends, but it may be worthwhile to reinvestigate hairpencil secretions by GC on capillary columns and by GC-MS. Minor unidentified components could act to promote species isolation. To date, we do not know whether the female can discriminate variable blends of the same components or whether the quality of the blend can interact with sexual behavior and act on sexual selection. Males seem to produce variable quantities of the same blend of compounds. Does this fact interact with the female choice or acceptance? Further studies on this subject will be conducted on *Mamestra brassicae*.

Acknowledgments—The authors are pleased to thank Dr. P. Zagatti and Dr. M. Renou for their helpful comments, Dr. C. Descoins for reviewing the manuscript and C. Malosse for GC and GC-MS advice.

(Received July 12, 1990; accepted September 17, 1990)

Abstract—Compounds identified in sex pheromone gland extracts of female *Fumibotys fumalis* (Guenee) consisted of (*E*,*E*)-10,12-tetradecadienyl acetate, (*Z*)-11-tetradecenyl acetate, (*E*)-11-tetradecenyl acetate, and (*Z*)-9-tetradecenyl acetate in a ratio of 100:18:8:4, respectively. The compounds were identified by electroantennographic, gas chromatographic, mass spectrometric, and chemical derivatization procedures. In mint fields synthetic components in gray elastomeric septa at ratios found in the sex pheromone gland and at doses of 3 or 10 mg of the diene produced trap catch comparable to traps baited with three females.

Key Words—Lepidoptera, Pyralidae, Pyraustinae, Pyraustini, *Fumibotys fumalis*, sex pheromone, (*E*,*E*)-10,12-tetradecadienyl acetate, (*Z*)-11-tetradecenyl acetate, (*E*)-11-tetradecenyl acetate, (*Z*)-9-tetradecenyl acetate.

INTRODUCTION

The mint root borer, *Fumibotys fumalis* (Guenee) is widely distributed in North America (Monroe, 1976). It was first reported to be a pest of a cultivated crop

*To whom correspondence should be addressed.
[1]Lepidoptera: Pyralidae.

in 1971 when it was found damaging commercially grown peppermint, *Mentha piperita* L. in the Willamette Valley of Oregon (Berry, 1974). Subsequently, *F. fumalis* adapted to and damaged spearmint, *M. spicata* L., and became an established pest in the commercial mint fields of Washington, Idaho, and Oregon (Pike and Glazer, 1982). Damage occurs when the larvae bore into and feed on the mint rhizomes. Infested fields show declining yields and shortened stand life (Pike et al., 1988).

The taxonomy, morphology, and geographical distribution of *F. fumalis* were described by Monroe (1976). Studies of its biology and behavior (Forbes, 1923; Berry, 1974, 1977; Davis et al., 1984; Pike et al., 1988) and chemical and cultural control (Pike, 1979; Pike and Getzin, 1981; Pike and Glazer, 1982) have been reported.

Because control procedures would be enhanced by a lure to monitor adult flight periods, we undertook a chemical and biological study in order to develop an effective sex pheromone attractant. An earlier biological study (Davis et al., 1984) demonstrated a female sex pheromone in *F. fumalis*, that maximum mating occurred between 12 PM and 1 AM, that females were maximally attractive from age 0.5–7 days, and that females were not attractive the night following mating. Here we report the identification of four components of the female sex pheromone gland and the development of an effective field lure.

METHODS AND MATERIALS

Insects. F. fumalis hibernaculae containing prepupae were collected from soil samples taken from infested peppermint fields near Harrah, Washington, in February and early March in 1987, 1988, and 1989. The hibernaculae were placed in clear plastic shoe boxes (31 × 17 × 9 cm) on a 5- to 6-cm layer of moistened peat moss, covered with clear plastic lids, and held in a rearing room at a temperature of 12.8°C, relative humidity of 55–60%, and a 12 : 12 hr light–dark cycle. As adults were needed to conduct laboratory or field studies, boxes were removed and placed in another facility at a temperature of 21.1°C and a 15 : 9 hr light–dark cycle. The onset of the dark cycle was set at 0800 hr for the flight-tunnel studies and at 2100 hr for the field studies. Emergent adults were collected daily at least 1 hr before the dark period and placed in individual vials.

Collection of Pheromone. Female moths (3–4 days old) in their vials were collected 6 hr after the beginning of scotophase and placed in a refrigerator to inactivate them. They were removed individually and their abdominal tips containing the sex pheromone gland (SPG) were severed and steeped for 15–60 min in dichloromethane. Then the solution was removed with a syringe. To obtain pheromone that the females may have released while inside the vials, the vials were rinsed with dichloromethane and the rinses were combined.

Electroantennogram (EAG) Determinations. EAG determinations of model compounds were made with previously described apparatus (McDonough et al., 1980) except that 60-μg charges were used. Duplicate determinations were made of each compound. The model compounds used were synthesized mainly by the procedure of Voerman (1988). A few were obtained from commercial sources. All compounds were at least 98% pure by capillary gas chromatographic analysis and contained 1% or less of their geometric isomers. The compounds used were: all of the saturated and monoene 12- and 14-carbon alcohols and corresponding acetate; *Z* and *E* isomers of 7–, 9–, and 11–16 : Ac; *Z* and *E* isomers of 7–, 8–, and 9–12 : Al; *Z*7–14 : Al, *Z*9–14 : Al, *Z*11– and *E*11–14 : Al; *Z*5–16 : Al, *Z*7– and *E*7–16 : Al, *Z*9–16 : Al, *Z*11– and *E*11–16 : Al, *Z*13–16 : Al.

Gas Chromatography–Electroantennography (GC-EAG). Fractions of extracts from sex pheromone glands or vial washes containing female emissions were collected from a GC equipped with a 0.63-cm-OD × 180-cm-long glass column packed with 3% methyl silicone (SE-30) liquid phase on 80–100 mesh Gas Chrom Q and connected to an effluent splitter. The initial column temperature was 120°C for 8 min, then programmed at 4°/min to 210°C and held at that temperature. The fractions were collected from time zero to the time corresponding to the complete elution of 10 : Ac and then successively at times corresponding to the complete elution of each of the saturated acetates from 11 : Ac through 20 : Ac. Fractions were collected in 3-mm-OD, U-shaped, glass traps cooled by Dry Ice–acetone, and then dissolved in dichloromethane and deposited on the inside of glass tubes for EAG determinations. Fractions also were collected for EAG determination from a 0.63-cm-OD × 180-cm-long glass column packed with 5% Carbowax 20M liquid phase on 80–100 mesh Gas Chrom Q. Fraction 1 encompassed time zero to the beginning of the elution of 10 : Ac; succeeding fractions each encompassed two carbon increments to the beginning of the elution of 20 : Ac.

Gas Chromatography–Mass Spectrometry (GC-MS). A Hewlett-Packard (Avondale, Pennsylvania) gas chromatograph (model 5790) with a quadrupole mass spectrometer (model 5970) was equipped with either a DB-1 or DB-Wax capillary column, 60 m × 0.25 mm ID (J & W Scientific, Folsom, California). When the pheromone gland extracts were analyzed, the columns were held at 80°C for 2 min, programmed at 20°/min to 190°C for DB-1, and to 200°C for DB-Wax, and maintained isothermally thereafter. Total ion abundance was monitored. When the dimethyl disulfide derivatives of the monoenes were analyzed, the DB-1 column was used and was held at 80°C for 2 min, programmed at 20°/min to 255°C and held at that temperature for 30 min.

Determination of Positions and Configurations of Double Bonds of Monoenes. Monoenes from extract of sex pheromone glands were provisionally identified by comparing retention times on DB-1 (60 m × 0.25 mm; 2 min at 80°C then 20°/min to 190°C) and DB-Wax (45 m × 0.20 mm ID at 145°C)

GC capillary columns with synthetic monoenes. A Hewlett-Packard model 5880 GC was used.

Rigorous determination of double-bond positions was accomplished by mass spectral determinations of fragmentation patterns of the dimethyl disulfide (DMDS) derivatives (Buser et al., 1983). To prepare the derivatives, monoenes (15 ng) isolated as a GC fraction from extract of SPG in 200 μl of dichloromethane were transferred to a 1-ml Reacti-vial (Pierce Chemical Co., Rockford, Illinois). The solution was evaporated just to dryness in a stream of nitrogen, and the residue was dissolved in 50 μl heptane. Then 50 μl DMDS and 10 μl of a saturated solution of iodine in ether were added. The vial was sealed and heated overnight at 40°C in a convection oven. The solution was diluted with 200 μl of heptane and excess I_2 was removed by shaking with 100 μl of 5% of sodium bisulfite solution. The heptane solution was moved with a syringe and concentrated to 2 μl for injection into the GC-MS.

Determination of Positions and Configurations of Double Bonds of Diene. The GC purified diene (144 ng) was ozonized in predistilled dichloromethane at −70°C with an ultraviolet ozonizer (Orec Co. model 03V1, Phoenix, Arizona), and the ozonide was reduced with triply recrystallized triphenylphosphine. The ozonized sample was injected on a GC column (DB-1, 60 m × 0.25 mm), which was held at 80°C for 7 min, programmed at 6°/min to 200°C and held at that temperature. When the configuration of the diene was determined, the same column was held at 80°C for 2 min and programmed at 20°/min to 180°C and held at that temperature.

Flight Tunnel. A flight tunnel constructed as described by Miller and Roelofs (1978) was used. The flight tunnel room was maintained at 22°C. Males were released in groups of five. The number of males initiating and sustaining flight and contacting the lure were determined. All lures were formulated in gray elastomeric septa (formulation number 1888, size no. 1, West Co., Phoenixville, Pennsylvania) (Brown and McDonough, 1986) to prevent isomerization of the diene. Males were three to four days postemergence and were maintained on a reverse dark–light cycle (10 and 14 hr). Tests were conducted 3 hr after the onset of scotophase.

Field Tests. *Z*9–, *Z*11–, and *E*11–14:Ac used for the field tests were obtained from commercial sources and were pure by GC analysis and contained less than 1% of the geometric isomer. *E*10, *E*12–14:Ac was synthesized by a modification of the method for *Amorbia cuneana* (McDonough et al., 1982; McDonough and Smithhisler, 1989). The synthesis was carried through until a mixture of *E*10, *E*12– and *E*10, *Z*12–14:OH was obtained. Pure *E*10, *E*12–14:OH was obtained by low-temperature recrystallization from pentane and then was converted to the acetate. Isomeric purity was 98.5% *EE*, 1% *EZ* and 0.5% *ZE* for all of the experiments except the one in which the effect of purity was tested. Then the purity was 96.0% *EE*, 2.5% *EZ*, and 1.5 *ZE*. Candidate

lures in 100 μl of dichloromethane were impregnated into gray elastomeric septa; dichloromethane alone was added to control septa. Pherocon IC sticky traps (Trece, Corp., Salinas, California) were used. Traps were suspended from a movable metal arm (an 18 × 23-cm shelf bracket) attached by a metal hose clamp to a 120-cm-long wooden broom handle driven into the ground. This arrangement enabled the traps to be positioned just above the mint foliage, usually 45–60 cm above the ground, where most flight activity was believed to occur.

The position of each trap in the experimental plot was drawn randomly and traps were deployed at approximately 10-m intervals. Females used in the field tests were placed in aluminum wire screen cages (9 × 9 × 2 cm, three females/cage), which were suspended by a wire from the top of the trap equidistant between the top and bottom. There were four replicates of each lure tested and the trap data were transformed by $(x + 0.5)^{1/2}$ and compared by Duncan's (1955) multiple-range test ($P = 0.05$).

RESULTS AND DISCUSSION

Exploratory Study of Structure of Pheromone Components. Among the model compounds tested, the strongest EAG responses were obtained from the 14-carbon acetates (Figure 1). The 10 and 12 positions of unsaturation produced the strongest responses, and strong responses were also obtained from the 9 and 11 positions. After the 14-carbon acetates, the strongest responses were obtained from the 12-carbon acetates: *E*10- and *Z*10–12 : Ac produced responses of about 50% of the standard (*Z*10–14 : Ac) and the other positional isomers produced responses of about 25% of standard. Other tested compounds produced responses of 0–30% of the standard.

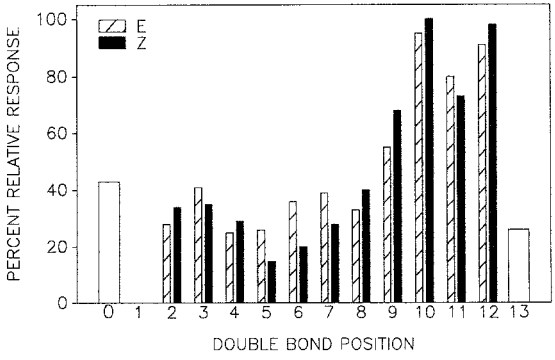

FIG. 1. Electroantennographic responses of male mint root borers (*Fumibotys fumalis*) to 14-carbon acetates. Numbers indicate double-bond position; zero indicates saturated.

The EAG response of GC fractions of SPG extract from the methyl silicone column was greatest for the fraction corresponding to the end of 14:Ac through the end of 15:Ac (1.9 mV vs. 0.1–0.8 mV for the other fractions), and from the Carbowax column for the fraction corresponding to the beginning of 16:Ac to the beginning of 18:Ac (0.7 mV vs. 0.2–0.4 mV for the other fractions). The EAG response to GC fractions (methyl silicone column) of the washes of the vials that held females was also greatest for the fraction corresponding to the end of 14:Ac through the end of 15:Ac (0.9 mV vs. 0.05–0.35 mV for the other fractions).

GC-MS analysis (DB-1 column) of SPG extract (50 female equivalents) at the retention time period that produced the strong EAG response indicated the presence of a tetradecadienyl acetate [M^+, 252; $(M\text{-}60)^+$, 192; $CH_3CO_2H_2^+$, 61] at a retention index (I_x) of 1838. Also, eluting prior to the tetradecadienyl acetate were three tetradecenyl acetates [$(M\text{-}60)^+$, 194; $CH_3CO_2H_2^+$, 61] at I_x values of 1776, 1781, and 1788. There was about 0.5 ng of the diene per female equivalent, and the ratio of the monoenes to the diene for each I_x value was 0.04:1 (1776), 0.08:1 (1781), and 0.18:1 (1788).

Positions and Configurations of Double Bonds of Pheromone Gland Components. Ozonolysis of the diene gave a single GC peak (methylsilicone column) with a retention time of 24.50 min near that of hexadecane (retention time = 24.77 min) and the same within experimental error ($\pm$0.04 min) as the ozonolysis product of 10,12–14:Ac (retention time = 24.52). The configuration of the diene was *EE* (retention time = 21.85 min) and the retention times of the four isomers of a synthetic standard (McDonough et al., 1982) were: *ZE*, 21.33; *EE*, 21.85; *EZ*, 22.10; *ZZ*, 22.29.

A comparison of retention times of the pheromone tetradecenyl acetates with those of the synthetic tetradecenyl acetates on polar and nonpolar capillary GC columns indicated the pheromone tetradecenyl acetates were *Z*9–, *Z*11–, and *E*11–. Mass spectral analysis of the DMDS derivatives confirmed these assignments. The monoene derivatives and their diagnostic peaks (Buser et al., 1983) were: *Z*9– [M^+, 348 (33%); A, 117 (53%); B, 231 (100%)]; *Z*11– [M^+, 348 (21%); A, 89 (34%); B, 259 (100%)]; *E*11– [M^+, 348 (19%); A, 89 (25%); B, 259 (100%)]. The retention times of the DMDS derivatives (in minutes) were: *Z*9–, 25.34; *Z*11–, 27.12; *E*11–, 27.54. The configurational assignments were confirmed by comparison of retention times with synthetic samples (*E*9– DMDS derivative at 25.66 min).

Male Response to Synthetic Pheromone Components. When lures containing 100 μg of *E*10,*E*12–14:Ac plus 18, 8, and 4 μg of *Z*11–, *E*11–, and *Z*9–tetradecenyl acetates were tested in a mint field (four replicated traps per test), total male captures (13) were not statistically different from blank traps but captures in female baited traps (98) were. In order to identify the reason for

the lack of significant capture, limited tests in a flight tunnel were conducted (Table 1).

When the pheromone components were tested individually (Table 1, tests 1–4), Z11–14:Ac was a weak attractant, but no response was obtained from the other components. When the four components were tested in the ratio found in the SPG and the dosage of *EE* was 100 μg (the same as the unsuccessful field test), 65% of males exhibited upwind flight and 50% touched the source (test 5). Lower doses of 33 and 10 μg of this ratio produced less response (tests 6 and 7), while a higher dose produced the highest percent responding (test 8). Subtraction of *E*11–14:Ac from the natural blend produced a response almost equivalent to the natural blend (test 9 vs. 5). Because of the limited numbers available for testing, more complete, systematic tests and statistical analysis were not undertaken. Nevertheless, collectively, these experiments established the attractiveness of the mixture of identified components and suggested that the initial field test may have produced low catches because the dose was too low.

In further field tests (test 1, Table 2) when the ratio of *EE*, Z11–, and Z9–

TABLE 1. RESPONSE IN FLIGHT TUNNEL OF ADULT MALE *F. fumalis* TO CANDIDATE LURES

[a] Gray elastomeric septa were used as the controlled release substrate. There were four replicate traps per treatment. Letters after the numbers within a test number indicate significance according to Duncan's (1955) multiple range test ($P = 0.05$).

[b] The isomeric purity of *E*10,*E*12–14:Ac in this test was 96%; in all other tests the isomeric purity was 98.5%.

found in the SPG was used and the dose of *EE* was varied from 100 to 3000 μg, the 3000-μg dose produced significant trap catch compared to controls and was equivalent to that produced by females. Captures produced by the lower doses were not statistically significant. In test 2, Table 2, lower isomeric purity of *EE* did not decrease catch; the absence of *E*11–14:Ac did not decrease catch; and the 10-mg dose produced higher catch than the 3-mg dose. Catches from both doses were statistically significant but only the 10 mg dose was equivalent to females. Test 3 was conducted to determine if a higher proportion of *Z*11–14:Ac would increase catch. At neither the 3- nor the 10-mg dose level did the increase in the proportion of *Z*11–14:Ac produce statistically significant increases in trap catch.

Collectively, these experiments demonstrated that the three- or four-component lure in the ratio found in the sex pheromone gland and at a dose of 3–10 mg of *E*10,*E*12–14:Ac in gray elastomeric septa produced a viable attrac-

tant, competitive with female baited traps in field tests. Flight-tunnel studies indicate at least two components are necessary to produce an effective attractant. *E*11–14 : Ac may not be a component of the pheromone emitted by females, since it is the expected biosynthetic precursor to *E*10,*E*12–14 : Ac (Löfstedt and Bengtsson, 1988). To fully define the importance of each of the four components, field or flight-tunnel tests with subtraction experiments over a range of concentrations are needed.

The relatively high septa doses required, coupled with the small amount of pheromone found in the glands, were unexpected. Nevertheless, these facts do not necessarily indicate there are undetected pheromone components. The low amount of pheromone in the glands could indicate close synchronization of biosynthesis with emission rather than a low emission rate. Moreover, the emission rate of septa at the 3- to 10-mg doses is not excessive compared with that required for some other Lepidoptera. Gray septa emit at rates about the same as red rubber septa (McDonough and Aller, unpublished). Also 16-carbon aldehydes and 14-carbon acetates emit at similar rates (McDonough, 1990). The most effective doses of the sex pheromone of *Heliothis zea* (16-carbon aldehydes) in red rubber septa are 3–10 mg (Halfhill and McDonough, 1985), and the most effective doses of *Heliothis virescens* sex pheromone (mainly a 16-carbon aldehyde) are even higher (Flint et al., 1979).

Although this is the first report of the chemical identification of *E*10,*E*12–14 : Ac in the female sex pheromone gland of a pyralid, in field screening tests Reed and Chisholm (1985) reported that *Pyrausta fodinalis* (L.) was captured in traps baited with *E*10,*E*12–14 : Ac. Taxonomically, *P. fodinalis* and *F. fumalis* are both grouped as *Pyraustini*.

FLIGHT ACTIVITY OF *Heliothis virescens* (F.) FEMALES (LEPIDOPTERA: NOCTUIDAE) WITH REFERENCE TO HOST-PLANT VOLATILES[1]

E.R. MITCHELL,* F.C. TINGLE, and R.R. HEATH

Insect Attractants, Behavior, and Basic Biology Research Laboratory
Agricultural Research Service, U.S. Department of Agriculture
Gainesville, Florida 32604

(Received June 11, 1990; accepted September 18, 1990)

Abstract—*Heliothis virescens* (F.) females responded positively via upwind flight in laboratory assays to volatiles emitted from methylene chloride washes of fresh whole leaves of host plants including cotton, tobacco, and a weed species, *Desmodium tortuosum* (Swartz) de Candolle. Except for *D. tortuosum*, the response increased positively with dose; the steepest slope occurred with an extract of cotton squares (flower buds). Almost all of the moths that landed on the extract dispenser also oviposited. Moths simulated by extracts from cotton squares exhibited a full array of behaviors (upwind flight, contact with the dispenser, examination of the cloth substrate with antennae, and oviposition) expected of gravid individuals seeking sites to propagate the species.

Key Words—Plant attractant, host phenology, oviposition stimulant, *Heliothis subflexa*, *Heliothis armigera*, Lepidoptera, Noctuidae.

INTRODUCTION

Many phytophagous insects use airborne volatiles emitted from plants to locate their hosts. The recent development of bioassay systems for studying host-plant finding and ovipositional behavior under controlled environmental conditions in the laboratory has intensified interest in characterization of the specific behaviors regulated by volatile emissions from plants and identification of the

active compounds. Information on volatile chemicals that attract phytophagous insects to their host to stimulate oviposition upon arrival could be of benefit to plant-breeding programs. For example, selective elimination or reduction in the level of these chemicals possibly could impart a degree of "resistance" to otherwise acceptable cultivars.

Heliothis and *Helicoverpa* spp. rank among the most destructive pests of crops in the United States and around the world. The evidence is growing that many of these species use plant constituents for host location and accep- tance. Allelochemicals that stimulate females to oviposit have been isolated for *Helicoverpa zea* (Boddie) (corn) (Wiseman et al., 1988), *Heliothis subflexa* (Guenée) (*Physalis angulata* L.) (Mitchell and Heath, 1987), and *Heliothis virescens* (F.) (tobacco) (Jackson et al., 1984; Mitchell et al., 1990). Mitchell et al. (1990) also isolated oviposition stimulant compounds for *H. virescens* from a late-season wild host plant, *Desmodium tortuosum* (Swartz) de Candolle, and leaves and squares (i.e., flower buds) of cotton.

In each of the cases cited above, the techniques used to demonstrate oviposition activity were unable to differentiate between tactile and olfactory stimuli. Other workers, however, have demonstrated a relationship between plant volatiles and attraction/oviposition stimulation in *Heliothis*. Rembold and Tober (1985) showed that *Heliothis armigera* (Hübner) females (an oligophagous species) responded differentially in oviposition trials to odors obtained by pulling air over seedlings of two cultivars of pigeonpea, *Cajanus cajan* L. Millsp. Tingle et al. (1989) showed that mated *Heliothis subflexa* females (a monophageous species) flew upwind in wind-tunnel bioassays to a methanol wash of fresh whole leaves from its host plant, groundcherry (*P. angulata*), culminating in ca. 50% of the responding moths depositing one or more eggs. The present study reports on the flight and ovipositional responses of females of a sibling species of *H. subflexa*, *H. virescens*, in a wind-tunnel system to extracts of selected cultivated host plants (cotton and tobacco) and *D. tortuosum*, a late-season weed host.

METHODS AND MATERIALS

A Plexiglas flight tunnel (60 cm wide × 60 cm high × 195 cm long) was used to observe flight and ovipositional responses of females to volatiles from crude extracts of three different plant hosts. The extracts were obtained by dipping ca. 400 g fresh plant material for 30 sec in 1 liter of solvent (methylene chloride), which was filtered and stored in 1-liter glass containers at 0°C until needed (Mitchell and Heath, 1987). Extracts were prepared from cotton (variety McNair 220) leaves and squares (flower buds) and from leaves of *D. tor-*

tuosum and tobacco [susceptible: NC 2326, and resistant: TI 1112 (Jackson et al., 1983)]. All plants were grown in small field plots using conventional cultural practices. The extracts were concentrated in a rotary evaporator before testing. All plants were in the flowering stage except tobacco, which was in the prebloom stage.

All test insects were reared in our laboratory on the modified pinto bean diet using methods described by Guy et al. (1985) and Mitchell et al. (1988). The insects were sexed in the pupal stage and held separately in 3.8-liter paper cans with screened tops until emergence. Upon eclosion, the sexes were confined together for two days for mating (21 females and 14 males/cage) in 5.5-liter plastic cages with screened tops. The moths were fed a 10% honey–water solution and held under a reversed 14 : 10-hr light–dark cycle in a holding room that was maintained at 25–26°C and 60–70% relative humidity. Preliminary studies indicated that >95% of the females mated under these conditions, as evidenced by the presence of a spermatophore in the bursa copulatrix.

On the day of testing, the moths were sexed by gently squeezing the abdomen to extrude the genitalia, and the females were confined in a 25 × 25 × 25-cm Plexiglas holding cage and placed in the flight tunnel room (3 × 2.6 × 2.1 m) ca. 1 hr before scotophase. An intake vent in the wall allowed a continuous flow of fresh unfiltered air from the outside into the room, which was maintained at the same environmental conditions as the holding room. An electric timer was used to control overhead fluorescent lights (two banks of two 40-W bulbs). Three incandescent 25-W red light bulbs that were equally spaced above the tunnel remained on continuously. The light level during scotophase was 1.4 lux. Air was pulled through the tunnel at ca. 0.4 m/sec. when measured at the center of the tunnel, and exhausted opposite the intake duct via a 30-cm-diam. flexible pipe equipped with a fan. The flight tunnel was the same as described by Tingle et al. (1989).

Crude extract (gram equivalent dosages) was deposited on white muslin cloth dispensers secured over the end of a glass cylinder (3.5-cm opening) with a rubber band. After a 5-min evaporation period, the dispenser was placed at the upwind end of the tunnel. Air was blown through the cylinder with an aquarium pump at the rate of 1 liter/min to provide a continuous flow (plume) of the extract odor through the tunnel. The location and form of the plume was verified by introducing smoke into the dispenser system and observing the smoke trail.

A moth was removed from the holding cage and placed into a cylindrical 4 × 6.5-cm plastic release cage with screened ends. After placement of the release cage into the downwind end of the flight tunnel, the moth was released immediately and observed for 2 min. Behavioral responses, including random and oriented flight, and contacts, landings, and oviposition on extract-treated substrates were recorded. Ten to 16 *H. virescens* females (mean = 14) were

tested individually in each replicate; each treatment was replicated 3–13 times. The data were converted to arcsin $\sqrt{\text{percentage}}$ and analyzed using ANOVA or regression analysis (Steel and Torrie, 1960).

RESULTS AND DISCUSSION

Heliothis virescens (Hv) females demonstrated upwind flight to volatiles emitted from cloth dispensers treated with each of the host-plant extracts (Figure 1). The flight sequence was similar to that previously described for a sibling species, *H. sublfexa*, to extracts of whole leaves from its host, groundcherry (Tingle et al., 1989). Typically, most of the females began nondirectional (random) flight after emerging from the release cage at the downwind end of the tunnel. Random flight usually began in an upwind direction. Shortly after exiting the release cage, moths detecting the odor plume flew upwind in a zigzag pattern towards the extract dispenser. A few moths flew directly to the dispenser and landed, probed the cloth substrate with their ovipositor, and deposited an egg. Others flew to within 5 cm of the dispenser and hovered for a short time

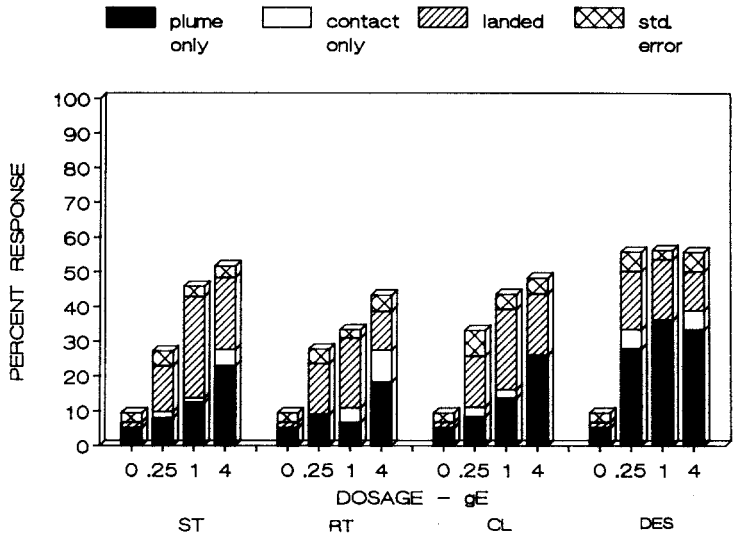

FIG. 1. Behavioral responses of *Heliothis virescens* females to volatiles from different dosages (gram equivalents) to methylene chloride washes of whole leaves of susceptible (ST) and resistance (RT) tobacco, cotton (CL), and *Desmodium tortuosum* (DES) in wind-tunnel assays. Differences between means within each response category were not significant ($P < 0.05$; ANOVA) (Steel and Torrie, 1960). The response totals do show a progressive increase with dosage for whole-leaf washes of tobacco and cotton.

before veering away or landing on the cloth substrate. The mean oriented flight response to control dispensers treated with methylene chloride was only 6.7 ± 2.6% (eight replicates). The few females orienting to the control dispenser flew upwind < 100 cm before veering away and continued flying about in random fashion or landed on the tunnel wall. None of these females contacted the control dispenser.

With the exception of *D. tortuosum*, the total response (oriented upwind flight, contact, and landing) recorded for Hv to each leaf extract showed a progressive increase with dose (Figure 1). The steepest slope occurred with an extract from cotton squares (Figure 2). It is unknown whether the apparent difference in response to extracts of cotton squares and cotton leaves was quantitative or qualitative. A comparable situation also might exist with tobacco and *D. tortuosum*; however, floral parts of these plants were not examined.

The flowering stage of corn, cotton, soybean, and tobacco is the most preferred phenological state for oviposition by *H. zea* (Johnson et al., 1975), although females will oviposit on certain host plants in the absence of flowering parts. Roome (1975) reached similar conclusions concerning the oviposition behavior of *H. armigera* in corn and sorghum. He also suggested that "flowering" corn and sorghum crops attract adults that, once in the crop, are "trapped" by suitable physiological cues from the plants. Thus, the increased response of females to extracts of cotton squares versus cotton leaves suggests

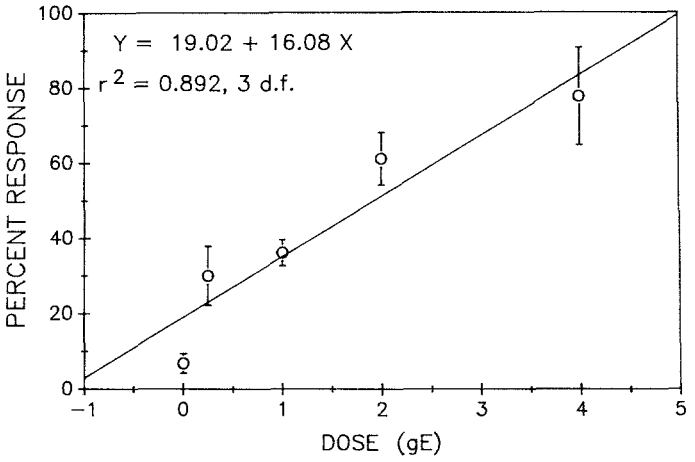

FIG. 2. Effect of dosage (gram equivalents) of a methylene chloride wash of cotton squares (flower buds) on the total response (upwind flight, contact, and landing) of *Heliothis virescens* females in wind-tunnel assays (regression analysis) (Steel and Torrie, 1960).

that, like the aforementioned species, Hv also are more strongly attracted to plants in the reproductive phase of their life cycle.

A test was conducted to establish whether attraction of Hv to cotton and tobacco was due to specific chemicals emitted by these plants or if the attraction response was due to the ubiquitous "green odor" factor. Using the flight-tunnel assay described earlier, female Hv were exposed to a 1-g equivalent dose of a methylene chloride wash of fresh whole leaves of cotton, susceptible tobacco, or elderberry (*Sambucus simpsonii* Rehd.), a nonhost weed species. Tingle and Mitchell (1986) showed that a methylene chloride wash (among others) of whole elderberry leaves was effective in deterring oviposition by Hv in laboratory assays. The mean percent flight responses for the three extracts were: cotton, 55.6 ± 3.5a; tobacco, 50.0 ± 5.4a; and elderberry, 23.6 ± 7.4 b [means ±SE, with different letters indicating significant differences, $P < 0.05$, Duncan's multiple-range test (Duncan, 1955)]. These results suggest that the flight responses recorded for Hv to cotton and tobacco extract were due to chemical qualities different from what is typically referred to as the green factor. It is unknown, however, whether the attractants from cotton and tobacco are the same compounds.

The total flight response (upwind flight, contact, and landing) by Hv to *D. tortuosum* was ca. 50% for each of the three doses tested. However, ca. two-thirds of the moths flying upwind and contacting the dispensers treated with *D. tortuosum* extract did not land. Mitchell et al. (1990) reported that *D. tortuosum* possessed compounds that stimulated oviposition by Hv females in laboratory assays. In Florida, *D. tortuosum* typically becomes abundant in late August and September in tobacco fields following harvest. Jackson and Mitchell (1984) showed that although Hv can survive to pupation on *D. tortuosum*, this species is less suitable than tobacco as a host. Thus, due to the proximity of *D. tortuosum* to moth emergence sites in abandoned tobacco fields, a strong long-range attractant is not needed for Hv females to locate and oviposit on *D. tortuosum*. The propensity for Hv to oviposit on *D. tortuosum* located outside of tobacco fields relative to *D. tortuosum* in tobacco fields is unknown.

There was no significant difference among treatments in the mean percentage of Hv moths (13.9 ± 1.5) depositing an egg upon contact with the cloth substrates. In a recent study using a system of individual chambers specifically designed to evaluate oviposition responses, Mitchell et al. (1990) showed that Hv females laid significantly more eggs on cloth substrates treated with whole-leaf wash extracts of leaves from susceptible or resistant tobacco, *D. tortuosum*, and cotton leaves or squares compared to the number of eggs laid on control cloths. Moreover, in competitive trials in which Hv females were given a choice between susceptible tobacco-leaf extract and extract from leaves of resistant tobacco, cotton, or *D. tortuosum*, significantly more eggs

were deposited on cloths treated with susceptible tobacco extract (Mitchell et al., 1990).

In this study, the response period was limited to 2 min/moth. This necessarily restricted the total number of eggs that a female could deposit within the observation period. Nevertheless, females were stimulated to exhibit an array of behaviors (upwind flight, contact, surface examination with antennae, and oviposition) characteristic of gravid individuals seeking sites to propagate the species. Work by Jackson et al. (1984) suggests that the chemicals eliciting egg laying in Hv most likely are contact stimuli. Thus, the chemicals that elicit long-range orientation (>1 m) and landing probably are different from those eliciting the oviposition response.

The role of plant volatiles in the selection and colonization process of oligophagous species such as Hv, and indeed most insect species regardless of their degree of host specificity, is poorly understood. Elucidation of the phytochemicals governing these processes will enhance greatly an understanding of the factors driving the establishment and development of insect pest populations on crops. Knowledge of the behavioral effects of such phytochemicals offers opportunities for creative management of crop insect pests via genetic modification of the host's chemical profile. Alternately, chemically defined plant attractants may be used alone or combined with insect sex attractant pheromones to monitor pest populations or for direct control as toxic baits by combining plant attractants, pheromones, and insecticides.

Acknowledgments—We gratefully acknowledge the technical assistance of P. Hall, W. Copeland, F. Adams, and B. Dueben of this laboratory; and D.M. Jackson, ARS USDA, Oxford, North Carolina, and G. Herzog, Tifton, Georgia, for providing the tobacco and cotton seed, respectively.

UNUSUAL POLYMETHYL ALKENES IN TSETSE FLIES ACTING AS ABSTINON IN *Glossina morsitans*

D.A. CARLSON[1] and Y. SCHLEIN[2,*]

(Received July 30, 1990; accepted September 18, 1990)

Abstract—The major alkene of the male tsetse fly, *Glossina morsitans morsitans*, was isolated for characterization by thin-layer and gas chromatography (GC). The mass spectra of the alkene and the alkene DMDS derivative indicated one isomer, 19,23-dimethyltritriacont-1-ene. The material is present at 1–2 μg/male fly and is partially transferred to the female preparatory to or during mating. A dose-dependent antiaphrodisiac effect was seen with exposed male flies using the isolated natural product, with 2 and 4 μg causing 80% loss of copulatory attempts, and 10 μg extinguishing the attempts. This effect was increased by addition of male-produced alkane. This compound and a 31-carbon homolog also appear in *G. m. submorsitans*. Similar quantities of alkenes that are species-specific appear in all tsetse males. Structures of male-produced trimethylalkenes that appear in two other species, *G. palpalis palpalis* and *G. fuscipes fuscipes*, were investigated.

Key Words—Mating inhibitor, abstinon, stimulatory, cuticle waves, diptera, extract, hydrocarbon, dimethylalkene, trimethylalkene, aphrodisiac, Diptera, Muscidae, *Glossina morsitans morsitans*, tsetse fly, 19,23-dimethyltritriacont-1-ene.

INTRODUCTION

Glossina morsitans morsitans (Westwood) males were reported to produce a chemical deterrent to mating (termed "abstinon"), that was hexane soluble and could be transferred to otherwise stimulatory decoys. Application of as little as

*To whom correspondence should be addressed.

0.5 and 0.25 male equivalent of crude extract caused 100% and 96% abolishment, respectively, of male *G. m. morsitans* response to freshly killed females. Application of up to 0.4 ml of solvent had no effect on the response of males. No chemical isolation accompanied this work, and no candidate material was identified (Schlein et al., 1981a).

Reports of the existence of antiaphrodisiac pheromones (abstinons) in tsetse flies were challenged by other workers who described solvent effects that moved cuticular hydrocarbon components about the cuticle of otherwise stimulatory female test flies (Coates and Langley, 1982). Recently, the physical masking of active sex pheromone by inactive compounds was described as more likely than the decline or loss of activity due to the addition of antiaphrodisiacs (Langley et al., 1987).

Sex-stimulant hydrocarbons are produced by female tsetse flies that stimulate the male to attempt copulation. Pheromones have been isolated, identified, and synthesized for *Glossina morsitans morsitans* (Westwood) including 15,19,23-trimethylheptatriacontane (morsilure, Carlson et al., 1978), and 13,23-dimethylpentatriacontane in *G. pallidipes* (Austen) (Carlson et al., 1981, 1984). The presence of a sex stimulant pheromone has been reported in *G. palpalis palpalis* (Rob-Des) (Offor et al., 1981). Synthetic 15,19-dimethyltritriacontane was stimulatory to male *G. austeni* (Newstead) (Huyton et al., 1980). Alkanes that are predominant in males are usually also present in females of the same species, (Huyton et al., 1980; Nelson and Carlson, 1986; Nelson et al., 1988), but sexual dimorphism is observed in higher chain-length alkanes that are present only in females.

The gas chromatographic (GC) analysis of cuticular hydrocarbons of several species of male *Glossina*, including *G. m. morsitans*, *G. austeni*, *G. fuscipes fuscipes* (Newstead), and *G. p. palpalis*, showed that sex-specific alkenes were present in each species of fly (Carlson and Langley, 1986). Laboratory-reared *G. m. morsitans* contained a major 33-carbon backbone alkene, whereas virgin females had only traces. However, mated females contained appreciable quantities of this compound for several days after copulation. Identical alkenes were found in males of *G. m. centralis* (Machado) and *G. m. submorsitans* (Newstead). *G. austeni* males produced a 31-carbon backbone alkene, whereas *G. p. gambiensis* (Vanderplank) and *G. p. palpalis* males produced a major 26-carbon backbone alkene. The compounds were also found in wild females. Gas chromatography showed that relatively large amounts of these alkenes are transferred from males to females, apparently upon contact (Carlson and Langley, 1986).

The concept that male-produced compounds affect conspecific male behavior has been extended to other insects that have female-produced sex pheromones. *Drosophila melanogaster* (L.) males produce *cis*-vaccenyl acetate (CVA) that is transferred to the female and functions to repel males in subse-

quent mating attempts (Jallon et al., 1981). Recently Scott et al., (1988) found that mutual pheromone exchange in *D. melanogaster* decreases the sexual attractiveness of these flies, due to (*Z*)-7-tricosene, a 23-carbon alkene, and not CVA. The male stable fly *Stomoxys calcitrans* (L.) possesses a large quantity of a triply unsaturated alkene, (*Z,Z*)-1,7,13-pentacosatriene (Muhammed et al., 1975, Sonnet et al., 1977), which has been synthesized (Sonnet, 1979, Carlson and Mackley, 1985). It is transferred in significant quantities to females upon mating (Carlson and Mackley, 1985). The reason for such a transfer is not known, but the alkene is recovered by extraction of old mated females (Muhammed et al., 1975). In insects other than diptera, studies of the cockroach *Nauphoeta cinerea* showed that an unsaturated ester, octadecyl (*Z*)-9-tetracosenoate, inhibits the wing-raising behavior released by contact with the stimulatory, wing-raising hydrocarbon fraction from conspecific females (Fukui and Takahashi, 1983). A similar phenomenon was reported in the tobacco budworm moth (Jacobson et al., 1984).

The only reported methyl alkenes are three 2-methyl alkenes from male house crickets, including 2-methyl-24-hexatriacontene and minor amounts of the 22- and 26- isomers (Warthen and Uebel, 1980). These structures were determined by ozonolysis and GC retention indices to establish the presence of branched 23-, 25-, and 27-carbon aldehydes. GC-MS was not helpful in determining which aldehydes were isomethyl-branched.

We studied the effect of male-produced alkene upon the sexual responses of male tsetse flies to show that it is primarily responsible for the antiaphrodisiac effect seen in *G. m. morsitans* males. Natural alkenes and synthetic alkanes and alkenes were assayed against male *G. m. morsitans*, establishing dose–response relationships to show the abstinon effect. We also describe the chemical structures of these unusual alkenes transferred between sexes in four species of tsetse flies.

METHODS AND MATERIALS

Biological Materials. Tsetse flies were obtained as pupae from the Tsetse Research Laboratory, University of Bristol. Adults were sexed on the first day, maintained at 26°C, and fed on guinea pigs. Flies used for the experiments were 5–10 days old. Treatments of extracts and samples onto subject decoys were as previously described (Schlein et al., 1981a). Freshly killed females with amputated legs and wings were pin-mounted on corks and used as decoys with or without test materials, which were applied to each in 50-μl *n*-hexane aliquots using a microsyringe. Other females were washed with *n*-hexane three times following amputation to remove the cuticular lipids. The bodies then were dried in an air stream and each was dosed with 20 μl hexane solution containing

4 μg synthetic morsilure (15,19,23-trimethylheptatriacontane) and different quantities of test materials. Test materials were: *G. m. morsitans* alkenes from males, *G. m. morsitans* and *G. pallidipes* alkanes, and vaseline, which consists of purified hydrocarbons (Merck Index, 1976). Treated decoy females were dried in an air stream for 30 min. Males that had been fed 24 hr earlier were each placed in a corked glass tube 7 × 2.5 cm diameter and allowed 1 hr acclimatization. For testing, the cork of each tube was replaced by one bearing a mounted female, and males were brought into contact with the decoy three times. The behavior of the male was scored "nil" for no response, stage I for a short arrest in the male's movements on the decoy female, stage II for correct positioning of the male, either with or without flexing of the genitalia, and stage III for an attempt at copulation.

Chemical Separations and Identifications. Extracts were made of frozen laboratory flies or wild flies by washing with hexane or diethyl ether solvent for 1 hr at the rate of 1 ml/fly (Carlson et al., 1978, 1984). The hydrocarbon fraction was obtained by chromatography on silica gel and was further fractionated by chromatography on silver nitrate-impregnated silica gel. Samples of alkenes were collected by preparative argentation TLC to ensure purity (Carlson et al., 1978).

Analyses by fused silica gas chromatography (FSGC) were conducted using a Varian 3700 GC with a 15-m × 0.32-mm-ID FS column of DB-1 via a split/splitless injector, temperature programmed at 150°C to 300°C at 12°/min and with H_2 carrier gas. Alkane standards were used to determine retention indices.

GC–mass spectrometry (GC-MS) utilized a Finnigan model 4000 fitted with a 15-m × 0.32-mm-ID FSGC column (DB-1, J & W Co., Rancho Cordoba, California) that was temperature programmed as above for GC, and an INCOS data system. Alternatively, a Hewlett-Packard model 5988A GC-MS was used, fitted with a 30-m × 0.32-mm-id FSGC column of DB-1, temperature programmed as above. Alkenes were derivatized using dimethyl disulfide (DMDS) and analyzed by GC-MS (Dunkelblum et al., 1985, Carlson et al., 1989).

Peak ratios for a small but consistently appearing alkane (KI 3265) were obtained by dividing the quantity found in each fly by that of another alkane (KI 3355). Similarly treated were the KI 3755 and 3775 alkanes, using the same samples used in Carlson and Langley (1986) in order to evaluate transfer of cuticular alkanes between flies.

RESULTS

Isolation and Characterization of Alkenes. Alkanes from male *G. m. morsitans* included about equal quantities of 2-methyltriacontane (KI 3065) and 11,15-dimethyltritriacontane (KI 3355). The latter was present at 3.3 μg/male

(range 1–4 μg), which comprised an average of 22% of the extracted hydrocarbon (range 13–28%). This quantitation is consistent with Nelson and Carlson (1986), in which alkanes were identified by GC-MS. A minor KI 3155 compound was homologous, as was one of the two homologs at KI 3555. Hydrogenation of the corresponding KI 3355 alkene gave an alkane, 11,15-dimethyltritriacontane, that produced major fragment ions at m/z 168, 169, 239, 280, and 351 (Carlson and Langley, 1986), but did not locate the double-bond position.

Here, the alkene fraction (MA) containing the major male alkene (MMA KI 3355) was isolated as previously described (Carlson and Langley, 1986). MMA was present at 1–2 μg/male (Figure 1), with much smaller quantities of homologs. Milligram quantities were obtained from extracts of large collections of each sex of *G. m. morsitans* and checked for the absence of appreciable quantities of female-produced alkenes (Figure 1) before bioassay. After development with hexane–20% benzene, the alkenes were collected from the region of a silver nitrate silica gel TLC plate consistent with (*Z*)-alkene standards (*Rf* = 0.5). No evidence was seen for (*E*)-alkenes (*Rf* = 0.65) by TLC or GC. Alkenes were collected from pooled samples of males of the other species and purified by the same procedures, with the resulting composition essentially the same as in the previous study (Carlson and Langley, 1986).

The EI mass spectra of the minor KI 3155 alkene homolog from *G. m. submorsitans* showed fragment ions at m/z 167, 250–251, and 462 (M) that were consistent with the structure 19,23-dimethylhentriacont-1-ene. The major KI 3355 alkene from both *G. m. submorsitans* and *G. m. morsitans* showed fragment ions at m/z 167 (C_{12}), 278–279 ($C_{20:1}$), 349 ($C_{25:1}$), and 490 (M), indicating a structure consistent with 19,23-dimethyltritriacont-1-ene (Figure 2). The minor ions at m/z 181 and 295 are consistent with "apparent β-cleavage fragmentation" internal to methyl branch points that was described for EI-MS of dimethyl-branched long-chain alcohols and their acetate esters (Nelson et al., submitted). This β-cleavage is apparently suppressed in saturated methyl-branched alkanes that normally undergo α-cleavage but is observed in unsaturated compounds, here causing the appearance of additional fragment ions that are otherwise difficult to explain, and also causing loss of 1–3 amu from diagnostic fragment ions. However, the homologous alkenes at KI 3155 and KI 3555 were consistent with the presence of the double bond on the longer end of this structure and with alkanes produced by a previous hydrogenation of similar alkene fractions.

The EI mass spectra of the major KI 2720 alkene from *G. p. palpalis* showed fragments at m/z 139 (C_{10}), 209 (C_{15}), 222/223 ($C_{16:1}$), and 406 (M), indicating a structure consistent with 4,8,12-trimethylhexacos-25-ene (Figure 3). Additional ions at m/z 154, 224, 238, and 308 could be ascribed to β-cleavage as described above. The minor alkene at KI 2640 showed fragments

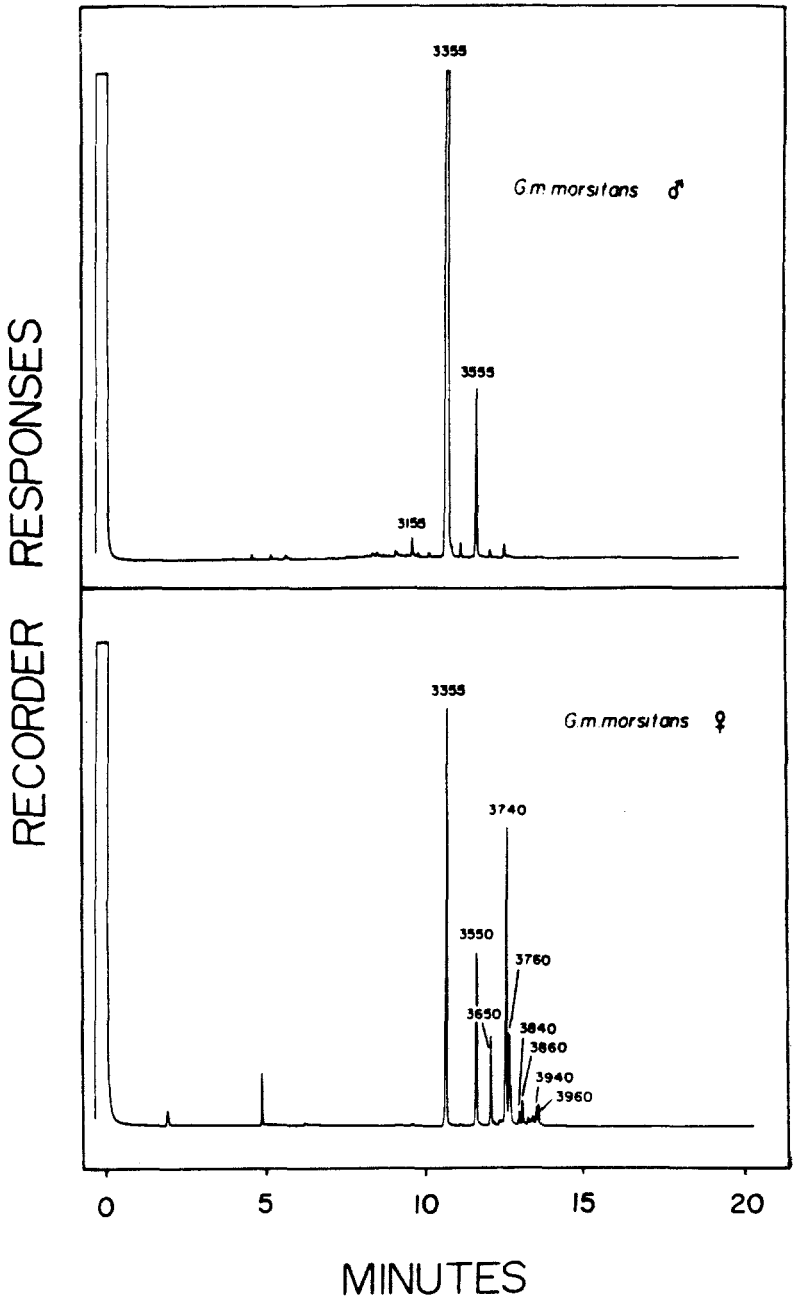

FIG. 1. Capillary gas chromatogram of alkenes from male and female *G. m. morsitans*.

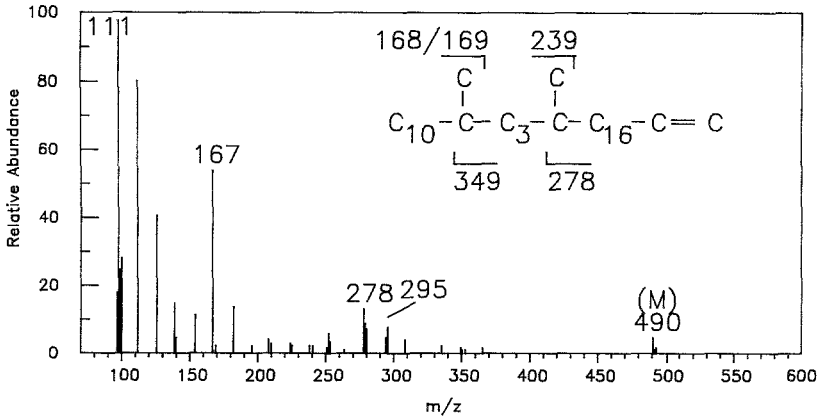

FIG. 2. Electron-impact GC-MS of major alkene from *G. m. morsitans* males.

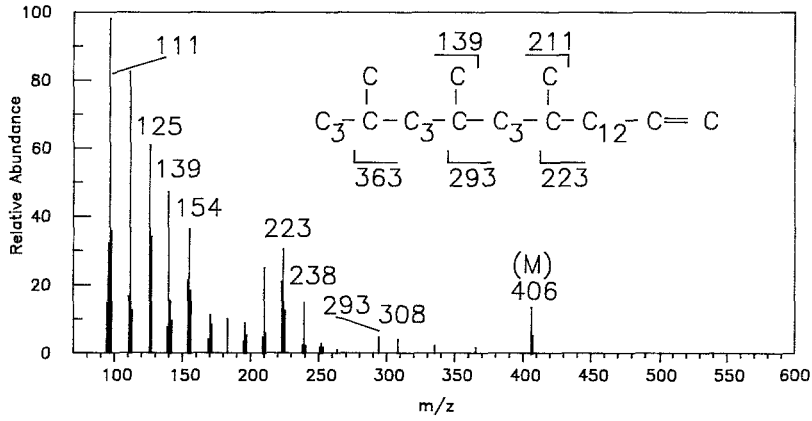

FIG. 3. Electron-impact GC-MS of major alkene from *G. p. palpalis* males.

at m/z 125 (C_9), 223 ($C_{16:1}$), and 392 (M), indicating a structure consistent with 3,7,11-trimethylpentacos-24-ene. Thus, the methyl branchings are analogous with the corresponding trimethylalkanes from these species (Nelson et al., 1988).

DMDS Location of Double-Bond Position in Alkenes from Males. The alkene fraction from *G. m. morsitans* males was derivatized with DMDS. The resulting major adduct eluted at KI 4000, indicating that an equimolar amount of DMDS had been added to the major male alkene KI 3355. Electron-impact GC-MS did not show a molecular ion for the monoadduct at m/z 582 or M-47 (m/z 537) (Figure 4). However, the adduct showed one major fragment ion at

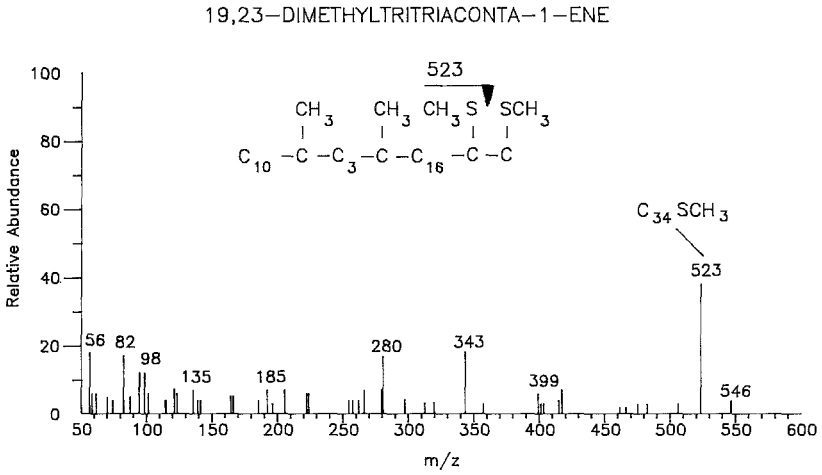

FIG. 4. Electron-impact GC-MS of major male alkene dimethyl disulfide adduct from *G. m. morsitans* males.

m/z 523 that was consistent with a structure of $C_{34}SCH_3$ in both species. This was consistent with addition of DMDS to a terminal position of unsaturation. The mass spectra presented fragment ions for $C_{18}SCH_3$ (*m/z* 297) and $C_{18}(SCH_3)_2$ (*m/z* 343), indicating fragmentation at a methyl branch located 19 carbons from the unsaturated end of the molecule. This is consistent with an alkene of structure 19,23-dimethyltritriacont-1-ene, in which the double bond is on the long alkyl chain. The fragments are inconsistent with the isomer 11,15-dimethyltritriacont-1-ene, for which cleavage at a methyl branch cannot be drawn to give an 18-carbon fragment, as the assignments do not fit.

The alkene fractions from *G. p. palpalis* and *G. f. fuscipes* males contained a major alkene at KI 2720, with minor quantities of an alkene, apparently homologous, at KI 2640 as reported by Carlson and Langley (1986). Derivatization with DMDS yielded one major adduct that eluted at KI 3300, indicating that an equimolar amount of DMDS had been added. Electron-impact GC-MS showed a molecular ion for the monoadduct (M+, *m/z* 500) in *G. p. palpalis*, and M-47 (*m/z* 453) was seen in both species (Figure 5). Both alkene adducts showed one major fragment ion at *m/z* 439 that was consistent with a structure of $C_{28}SCH_3$ in both species. This was consistent with addition of DMDS to a terminal position of unsaturation on the long alkyl chain. These mass spectra did not present any fragment ions suggesting fragmentation at methyl branches.

High-resolution proton NMR spectra were recorded on original alkene fractions from males of these species. The samples contained microgram quantities of the major alkene and minor amounts of other compounds as shown in Carlson and Langley, 1986. Chemical shifts of two allylic hydrogens (α-meth-

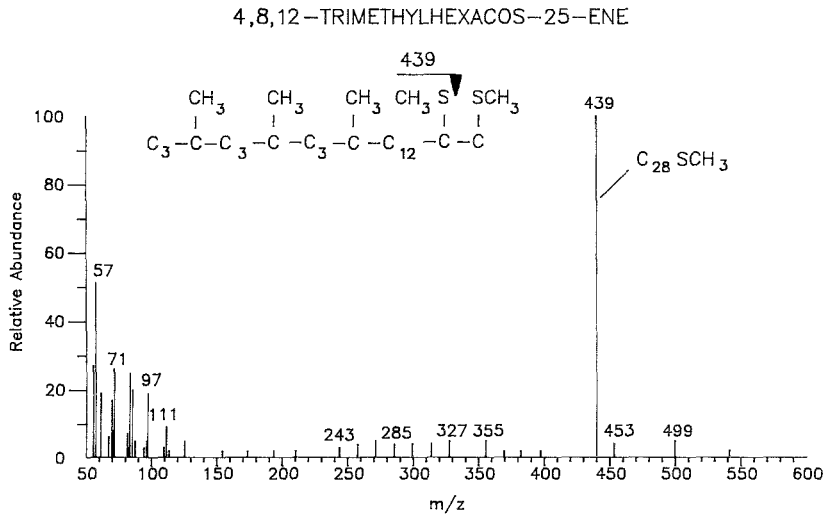

FIG. 5. Electron-impact GC-MS of major male alkene dimethyl disulfide adduct from *G. p. palpalis* males.

ylenes) were seen in all three samples, as were two homoallylic hydrogens (β-methylenes). Thus, the position of unsaturation could not be located on the short, two-carbon alkyl chain of the *palpalis* or *fuscipes* alkenes (A. Allerhand, unpublished data).

Bioassays. A clear dose–response relationship was obtained to natural MA treated onto unwashed but legless and wingless female decoys. Increasing dosages resulted in a clear antiaphrodisiac effect, with loss of all three progressive stages of sexual response, and concomitant increase of nil responses (Table 1). Stage III responses declined steadily to 24% with 1 μg MA, declined still more to 19% with 4 μg of MA, and were eliminated with 10 μg of MA, with nil responses increasing to 91%. In contrast, nearly obligatory stage III responses (93, 91, and 96%) were obtained to wingless, legless, untreated female controls; solvent-treated controls; and those treated with 5 μg vaseline, respectively. Even 25 μg of vaseline did not abolish male response, although 15% of males ignored decoys.

Similar dose–response relationships were obtained using hexane-washed female decoys that were treated with a uniform quantity (4 μg) of synthetic female pheromone (morsilure) mixed with increasing quantities of MA. A linear decline in response was observed with increasing quantities of MA, until a mixture of 1 : 1 proportion abolished all but 3% of stage III responses, or 85% of total male responses (Table 2). Similarly, *G. morsitans* alkanes at 4 μg and hydrocarbons of *G. pallidipes* at 8 μg [2 male equivalents (ME)] also had an

inhibitory effect on male courting behavior and reduced stage III responses to 4.7% and 12.1%, respectively (2 ME) (Table 2). There was, however, a difference in the stage in which the inhibition was elicited by MA or alkanes. The *G. morsitans* MA and alkanes differed in their effects on stages II and III of the courting behavior. This is evident from the frequency of responses at these stages in pairs of series where the proportion of nonresponses and stage I responses did not differ statistically (Fisher exact text, Table 2, group 3 vs. 6, group 4 vs. 7, group 5 vs. 8). Differences in the proportions of stage II responses were highly significant between series 3 (10.0%) and series 6 (25.6%), also between series 4 (8.3%) and series 7 (22.5%), and differences were significant between series 5 (3.2%) and series 8 (11.6%). Similarly there was a highly significant difference in courting cessation at stage III between series 3 (52.9%) and 6 (20.9%) and between series 4 (24.0%) and 7 (9.2%). The number of these responses in series 5 (2 flies) and 8 (4 flies) was too low for statistical analysis. Series of tests were compared where the overall effect of the inhibition was similar, regardless of the various stages of response.

Thus, with the alkenes, very few reactions stopped at stage II and most males completed the course of mating. In contrast, the largest group among the flies exposed to alkanes ceased courting at stage II. The effect of male hydrocarbons was enhanced when aliquots of both chemical classes were applied together. Abolishment of courting at stages II and III by 0.5 μg MA plus 1 μg

alkanes was similar to that of 4 μg alkenes and greater than that of 4 μg alkanes (Table 2).

Application to decoys of *n*-hydrocarbons at 4 μg with 4 μg morsilure also reduced male response. Of 40 repetitions with dotriacontane, the results for stages 0, I, II, and III were 12, 10, 10, and 8, respectively, and with tetracosane were 16, 10, 9, and 5, respectively (Table 2).

Transfer of Alkanes. Extracts of mated and unmated flies (5–10 days old) were analyzed by GC after Carlson and Langley (1986). Chemical analyses showed that quantities of alkanes were also transferred from males to females (Figure 6). Both KI 2965 and KI 3355 were more prominent in males than females, and both increased in females after mating, while KI 3065 and 3265 remained constant in all flies. In a pooled sample of female flies, the peak ratios R1 for KI 3355/KI 3265 were nearly double in mated females (Table 3). Similarly, small amounts of female-produced sex pheromone, KI 3755 and 3775, were found on males that were held for a short time (4 hr) with conspecific females, as the ratios R2 and R3 also increased (Figure 7, Table 3).

DISCUSSION

Dipteran sex pheromone receptors were described as pairs of shallow convex structures on both the inner and outer surfaces of the upper tibiae (Schlein et al., 1981b). However, Langley et al. (1987) describe active contact chemoreceptors as setae located on the tibiae and tarsomeres that possess straight longitudinal ribbing with pores and are confined primarily to the first two pairs of legs. All males have these setae (770), with nearly equal numbers on each leg, although females have more than half as many.

By isolating, identifying, and quantifying a compound responsible for "abstinon" behavior in tsetse males, we have made significant advances in understanding the nature of this phenomenon. Regardless of the current disagreement over the types and location of sex pheromone receptors and/or abstinon receptors, this information should allow further attack upon the type and location of receptors. Perhaps more importantly, we can then study the still obscure mechanism of reception for hydrocarbon pheromones.

It appears that in the higher diptera, production of sex stimulant pheromone is under gonadotrophic control, that is, its production is coincident with ovarian maturation and unavoidably continues with age. Thus, in several species there are indications of an antiaphrodisiac that would serve to lessen mating attempts by males upon mated females, as well as protecting males from excessive homosexual assault.

While somewhat variable, the average quantity of natural sex stimulant pheromone on a female is 9.4 μg (Carlson et al., 1978). When applied alone,

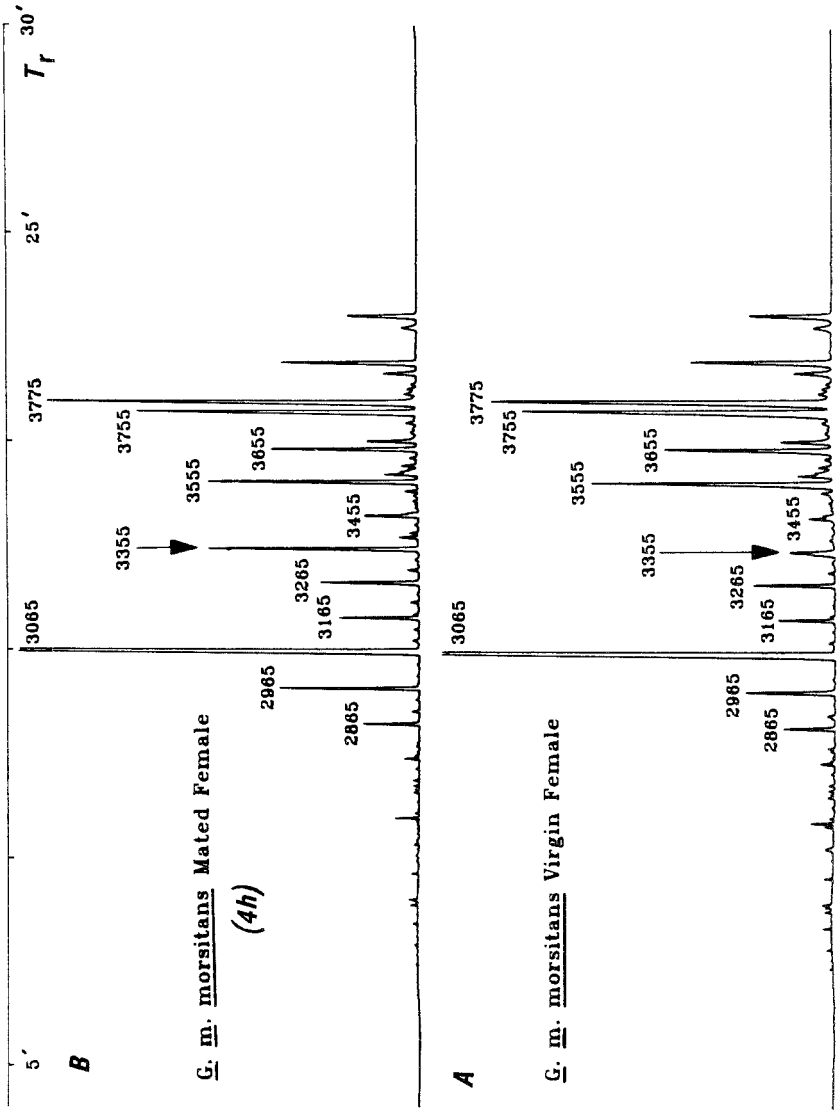

FIG. 6. Capillary GC of alkanes from *G. m. morsitans* females: (A) virgin; (B) mated.

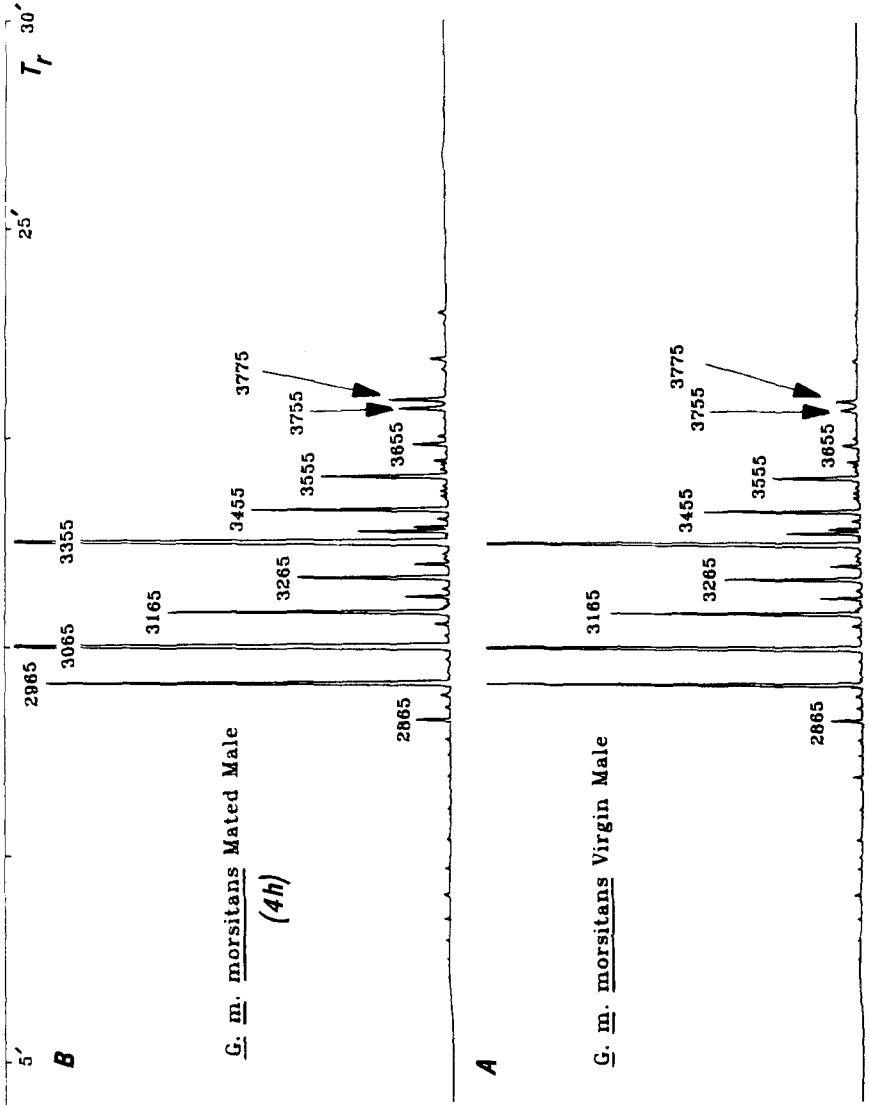

FIG. 7. Capillary GC of alkanes from *G. m. morsitans* males: (A) virgin; (B) mated.

TABLE 3. PEAK RATIOS OF ALKANES PRESENT ON CUTICLE OF *G.m. morsitans* MALES OR FEMALES HELD WITH OPPOSITE SEX

Ratios of alkanes	No. of insects	Females		Males	
		Virgin	Mated	Virgin	Mated
R1 = 3355/3265	10	0.9	2.1	4.6	5.2
R2 = 3755/3265	10	7.1	3.9	0.2	0.3
R3 = 3775/3265	10	7.8	5.2	0.2	0.4

4 μg of synthetic morsilure elicited copulatory responses in more than 90% of the males (Table 2), which is consistent with many previous tests.

Synergism is indicated between male-produced alkanes and alkenes: While it is obvious here that MMA are transferred, transfer of alkanes is less obvious. Nelson and Carlson (1986) show that the saturated analog of MMA (11,15-dimethyltritriacontane, KI 3355) is male-produced and not present in virgin females. Therefore, we rechecked samples of mated females for the male-produced KI 3355 alkane. It appears that small amounts of male alkanes are, in fact, transferred between the sexes with alkenes, as female-to-male transfer can be observed. It is known that male *G. m. morsitans* can be held in cages of conspecific females, then returned to cages of male flies, only to undergo prolonged attacks by sexually stimulated male flies (P.A. Langley, unpublished observations). Chemical analysis shows a small amount of female-produced sex pheromone in extracts of such males. Apparently, not much material is needed to evoke sexual stimulation in males, especially if it has been applied by physical contact rather than by a rather crude application in solvent. If surface contact is enough to transfer biologically active female material onto seti or other outer body parts of males, by analogy, not much material should be necessary to evoke an abstinon-type response in attacking males. A very small amount of male alkene may be sufficient to release this response. We believe that we have observed this effect. As mentioned in Carlson and Langley (1986), MMA or other alkanes are not present in seminal fluid but seem to be cuticular in nature. It appears that both male alkenes and alkanes are deposited on the cuticle of females.

The present tests demonstrated that male *G. morsitans* hydrocarbons include abstinons, which can inhibit male stimulation by female pheromones. Males have 1.3–4 μg of MA (Carlson and Langley, 1986), which was enough to demonstrate dose–response activity when applied to females, and inhibited all but 9% of stage I behavior at a quantity of 10 μg (Table 1). A similar effect was obtained when MA was applied to washed females in a mixture of 4 μg

together with 4 μg of morsilure. Tests with male alkanes similarly showed dose–response activity and inhibited most male response when used at 8 μg together with 4 μg of morsilure on hexane-washed females (Table 2). The alkenes and alkanes functioned synergistically and a combination of 1.5 or 3 μg of both was as effective as higher quantities of each of these compounds alone. The observed degree of synergistic effect is similar to the 96% inhibition of male response by the application of unfractionated extract containing 0.25 male equivalent, reported by Schlein et al. (1981a). The effect of male abstinons in the natural situation must be much stronger since they function without antagonists, and their unequivocal message is the one that inhibits courting. The perception of the female cue by the male must also be very specific to prevent courting of different species in the biotope. Thus, it is not surprising that (synthetic) linear hydrocarbons, which do not occur except as very minor components in tsetse flies of any species, were somewhat effective in reducing male sexual responses.

The classification of the response to alkenes and alkanes indicated differences in their effect. The quantities of MA and alkenes tested in the experiments were not the same, although the quantities of test materials can be compared most readily when their quantities are the same. In this situation, dissimilar quantities of test materials were used because the activity was similar, since the final stages of courting behavior were usually eliminated when responses were minimal. Conversely, initial and intermediate stages of behavior would not be represented adequately in tests with high doses of inhibitor. The alkanes of male *G. morsitans* produced alternating degrees of courting inhibition at stages II and III in series where their total effect was similar. The proportion of no responses in series 3, 4, 5 (192 flies), and also in series 6, 7, 8 (270 flies) was 56.3% The response to MA in the first group of these series amounted to 7.3% at stage II and 28.1% at stage III. The relative proportion of responses at these stages was reversed when alkenes were used and in the second group of experiments. The percentage of stage II responses was 20.0% and stage III was 11.5%. The increase in cessation at stage II in the presence of alkanes involved, in many cases, an unusual behavior expressed by prolonged grasping of the females without moving the genitalia. This behavior was not observed in other tests, including those carried out with *G. pallidipes* male alkanes. In view of these differences, it is suggested that the species-specific male alkenes and alkanes exert a different type of inhibition. The alkenes seem to block mostly the initial cue for courting, and copulation is completed once their effect is overcome, while the alkanes exert their effect in the initial stage, and in addition they mainly inhibit the engagement of the genitalia.

In this context, it is interesting to note that each of the three synthetic candidate pheromones treated against *G. morsitans* males in the first report (Carlson et al., 1978) appeared to elicit male reaction mostly to one specific

stage. For example, following the application of 10 μg of each to shoelace decoys, the respective responses at stages I, II, and III were, to 15,19-dimethylheptatriacontane (compound 1), 4%, 44%, and 8%; to the least active 17,21-dimethylheptatriacontane (compound 2), 16%, 0%, and 0%; to morsilure (compound 3), 4%, 36%, and 40%. Responses to application of a larger quantity of 40 μg of morsilure for stages I, II, and III were 0%, 16%, and 80%. Note that there were errors in numbering compounds 1 and 2 at two locations in this reference; in the center of p. 471 in the text and in Figure 1, compound 2 should refer to the 15,19-dimethyl isomer, and compound 1 to the least-active symmetrical 17,21-dimethyl isomer, as above, and elsewhere (Huyton et al., 1980).

It is tempting to suggest that each of the natural pheromones can initiate at least some courting stimulus, and afterwards each is mostly responsible for one step of the male's sexual behavior. Correspondingly, males possess a set of inhibitory compounds that are clearly transferred to females during courtship. Further studies with fractionated hydrocarbons are needed to clarify the actual role of the different compounds in *G. morsitans* courting.

It is interesting that MMA is structurally related to 15,19-dimethyltritriacontane, which was found to be a candidate pheromone in *G. austeni* and also had excellent sex stimulant activity against *G. morsitans*. Thus we present the first evidence that the unsaturated analog of a sex stimulant is a potent antipheromone.

The decline in responses to decoys treated with *n*-dotriacontane and *n*-tetracosane showed that a physical masking effect is partially responsible for the reduced activity. This effect is difficult to quantitate, but cannot be disregarded in evaluating behavioral effects of natural alkanes.

Acknowledgments—We thank S.K. Milstrey for technical assistance. We thank A.M. Jordan and P.A. Langley of the Tsetse Research Laboratory, University of Bristol, Bristol, England for biological material; and A. Allerhand, University of Indiana, for high-resolution MMR spectra.

Abstract—The attractiveness of representative host materials, host extracts, and individual host volatiles (primarily carboxylic acids, alcohols, and esters) to *Carpophilus hemipterus* (L.) (Coleoptera: Nitidulidae) adults in wind-tunnel bioassays was examined. Attractiveness of the materials was examined alone and in combination with the aggregation pheromone. Host materials and extracts were often attractive on their own, and the attractancy was synergized when they were combined with the pheromone. Propanoic and butanoic acids, methanol, 2-propanol, 1-heptanol, methyl butanoate, and propanal were among the most effective attractants relative to the pheromone, but many other compounds significantly synergized the pheromone (typically three- to four fold). Attractiveness and synergism were influenced by the carbon chain length and branching of the substitutents. Straight-chain compounds that had at least three carbon atoms were generally effective as synergists. Many branched-chain compounds were also effective synergists. In general, the degree of attractiveness and synergism could be predicted fairly well with the physicochemical steric (Es) parameter, although the lipophilicity (Pi) parameter also appeared to be useful in explaining the lower activity of short-chain substituents. Thus, many compounds that had only limited attractiveness on their own may nevertheless play and important role in synergizing the pheromone. Structure–activity studies appear to be appropriate not only for determining optimal attractants for these insects, but also for determining effective synergists for the pheromone.

INTRODUCTION

The use of host-derived volatiles to locate suitable hosts is important in many insects, including the Coleoptera (Metcalf, 1987). Aggregation pheromones also are produced by many Coleoptera (Jones, 1985). Host-derived volatiles and aggregation pheromones also can interact to produce synergized attraction of bark beetles (Jones, 1985). An increasing number of studies (e.g., Walgenbach et al., 1987; Burkholder, 1988; Oehlschlager et al., 1988) also have demonstrated that stored-product beetle attraction is synergistically enhanced by combining aggregation pheromones and host volatiles. However, synergized attraction of insects by combinations of host volatiles and pheromones is just beginning to be appreciated as a widespread phenomenon.

The driedfruit beetle, *Carpophilus hemipterus*, is a cosmopolitan pest of fresh and dried fruit, as well as many fresh and stored grains, spices, drugs, and seeds (Hinton, 1945). Past information indicates these insects also are attracted by host odors (especially fermenting ones) or isolated volatiles (Smilanick et al., 1978; Blackmer and Phelan, 1988). For example, a 1 : 1 : 1 combination of ethanol–acetaldehyde–ethyl acetate was a highly effective combination for attracting *C. hemipterus* (Smilanick et al., 1978). Fermented baits have been used successfully to reduce populations of this insect when the insects collected by the traps were not immediately killed (Warner, 1960, 1961). However, poisoned attractive baits were not able to outcompete naturally ripe (and presumably fermenting) figs in orchards (Smilanick, 1979). This information suggests that a combination of aggregation pheromone and host volatiles is necessary to equal the attraction of natural host materials with insects present and could potentially involve synergism as well. Bartelt et al. (1990a) recently reported the first example of an aggregation pheromone from nitidulids, which interacts synergistically with some host volatiles. To further examine this important interaction, host materials, host extracts, and individual host-derived volatiles were combined with the pheromone of *C. hemipterus* and tested for relative attractiveness versus individual components in wind-tunnel bioassays. Structure–activity studies of individual host components combined with the pheromone extract also were run to determine if optimal host-derived individual attractancy, synergism, and overall attractancy could be predicted by quantitative analysis of physiocochemical parameters or use of other structural relationships.

METHODS AND MATERIALS

Insects. The *C. hemipterus* were reared according to previously described methods (Dowd, 1987). Adults used in assays were 7–10 days old. The insects were conditioned for flight by 16 hr starvation (see Bartelt et al., 1990a).

Hosts and Chemicals. Whole oranges, bananas, and apple juice were obtained from a local grocery store. Oranges were squeezed for juice immediately before the assays. Milk-stage dent corn was obtained from greenhouse-grown plants. The *Saccharomyces cerevisae* used was a baker's yeast strain (Fleishman's dried activated). The culture of the wild yeast, *Zygosaccharomyces bailii*, a common contaminant of fermenting fruit (NRRL Y-2227), was obtained from the Northern Regional Research Center culture collection. Bananas were fermented with the two yeast strains by sprinkling or loop inoculating the freshly cut surface and capping in 35 ml cups. The liquid produced by the fermentation (after two months) was used in assays. Fresh *S. cerevisae* were obtained by sprinkling the dry yeast onto potato dextrose agar and scraping the colonies off the surface after two weeks. These yeast were made up as a 10% suspension in distilled water. Individual host volatiles and sources are reported in Table 1. A series of acids, alcohols, methyl esters, and acetate esters were used to determine structure–activity relationships.

Wind-Tunnel Bioassays. Assays were performed according to previously reported methods (Bartelt et al., 1990a). Briefly, ca. 300–600 starved insects were assayed at one time. Disks of filter paper (Whatman 541 or related, 7 cm diameter) were folded into quarters, treated with the liquid attractant(s), and hung with binder clips ca. 30 cm apart and 40 cm above the floor in the upwind end of the wind tunnel. The pheromone and host volatile were applied to different areas of the filter paper when tested in combination. For the liquid attractants, 20-μl quantities were applied to the folded filter paper. Esters, alcohols, aldehydes, ketones, and acids were applied as 10% solutions/suspensions in mineral oil, since these conditions provided a concentration and release rate previously proven effective in the field (Smilanick et al., 1978) and found to be effective in our wind-tunnel assays (see Results). When chemicals were combined in solution, the total contribution of an individual chemical was 10%. The pheromone source was the hydrocarbon fraction from extracts of cultures that contained male beetles (Bartelt et al., 1990). The concentration of the most abundant pheromone component, (2*E*,4*E*,6*E*,8*E*)-3,5,7-trimethyl-2,4,6,8-decatetraene, was ca. 50 pg/μl when quantitated by gas chromatography; 20 μl of this extract was used in each test (ca. 1 ng of the major component and proportional amounts of the cooccurring components). Comparisons of this initial material and an isolated Tenax-trapped volatile extract developed after the start of these assays (Bartelt et al., 1990a) did not yield significantly different results for representative combinations, so the diet extract was used throughout

this study for the sake of consistency. Two treatments were always compared in the wind tunnel at one time. The test duration was always 3 min. The number of beetles landing on each treatment was recorded.

Experimental Design. To evaluate each host volatile for attractiveness and synergistic activity, an experiment was conducted involving three treatments: the host volatile (A), the pheromone (P), and the host volatile plus the pheromone (A + P). These treatments were compared two at a time, and all possible combinations were tested an equal number of times (a balanced, incomplete block design). In general, each treatment was used a total of eight times. Treatment positions in the wind tunnel were reversed in successive replications to eliminate potential bias due to position effects. The pheromone served as a relative control in these experiments.

Our experience has been that counts for a particular treatment over the 3-min bioassay period varied widely over different days, depending on the number of beetles in the wind tunnel. The paired experimental design was used to

compensate for this variability, and the ratio of counts for two paired treatments tended to remain very constant despite changes in overall beetle numbers or activity.

Three ratios were of particular interest in this study. The first ratio, the bioassay count for the test volatile alone plus the bioassay count for the pheromone alone, divided by the counts for the pheromone treatments alone (*relative attractancy*, RA), expressed the activity of the volatiles relative to a "standard" attractant (the pheromone). An RA of 1.0 indicated no attractancy of the attractant by itself. The second value, the *synergist ratio* (SR), was the bioassay count for the pheromone combined with the host volatile, divided by the sum of the counts for the separated pheromone and volatile treatments. This ratio expressed the degree that the activity of the combined attractants exceeded the total activity of the separate attractants. An SR of 1.0 indicated the absence of synergism, in this case the resulting attractancy was merely additive. The third value, the *total attractancy* (TA), is the same as the relative attractancy times the synergist ratio. It is defined as the counts for the pheromone combined with the host volatile divided by the counts for the pheromone alone. Once again, a TA value of 1.0 indicated no attractancy relative to the pheromone. These values are more fully defined in the Results section, where actual data are examined.

One initial test involved a filter paper blank to see if a blank yielded useful information. Two additional experiments were run to evaluate the stability of beetle activity and the relative attractiveness of a treatment over time. Stability of these values is necessary to make relevant comparisons of synergistic activity.

The first of these two experiments involved examining the attractancy of apple juice and the pheromone over time after the insects were released directly into the cage. The activity was examined at constant intervals until a few hours after the number of responses peaked (22 total hr). Three 3-min tests were run every half hour, with 15 min between each group of tests.

The second experiment involved pheromone, octyl acetate, and octyl acetate plus pheromone in the balanced, incomplete block design and was run repeatedly for eight consecutive hours after starving the beetles overnight in the same manner as described for the apple juice assays. RA, SR, and TA ratios were calculated for each hourly segment (see Results).

The bulk of the study involved testing host materials, extracts, and volatiles in a balanced, incomplete block design such that there were eight replications of each treatment per hour (twelve 3-min tests per hour, with 2 min between tests). In cases where responses to the compounds were weak, the response of the insects was retested with a complex known to be effective (e.g., pheromone plus propyl acetate or octyl acetate) in order to ensure the insects were in a responsive mode.

In the final series of experiments, octyle acetate was used as a standard attractant for evaluating the relative synergistic activity of other host volatiles. The three treatments were: the pheromone, octyl acetate plus the pheromone, and the host volatile plus the pheromone. Once again, the balanced, incomplete block design was used.

Statistical Analyses. All bioassay experiments were analyzed by categorical methods (chi-square tests) applying a model of quasiindependence to the incomplete block designs (Fienberg, 1977; Bartelt et al., 1990b). Statistical tests were performed first to determine whether departures from this model were within allowable limits. A small chi-square statistic (large P value) for the model of quasiindependence indicated the model described the data set adequately. In our large series of experiments, we expected 95% of the chi-square statistics to have P values >0.05. This expectation was largely met ($P > 0.05$ for 109 of 116 experiments), validating subsequent tests on treatment effects. Thus, categorical analysis appeared to be appropriate for our data. The use of ratios of fitted values to summarize treatment effects followed naturally from the quasiindependence model. Conditional G^2 tests (analogous to t tests in analysis of variance; see Feinberg, 1977, p. 47) were used to test for the equivalence of treatments or the importance of other effects of interest, such as blocking effects. The treatments were concluded to differ if $P < 0.05$ when this statistic was compared with the chi-square distribution. Further details and examples of the statistical tests are provided in the Results.

Since prior work (Bartelt et al., 1990a) indicated synergism between the pheromone and host-derived volatiles could occur, we wished to determine when synergism was statistically significant. The presence of synergism could be tested for if the number of beetles responding to a treatment remained effectively constant within each set of three consecutive tests [P vs. A, P vs. (P + A), and A vs. (P + A)], regardless of what the treatment was paired with (in other words, if the six data values could be viewed as coming from one large block rather than three incomplete blocks—without inflating residual variance). Conditional tests indicated this interpretation was usually justified. A conditional G^2 statistic was constructed to determine whether the total responses to P plus the total responses to A differed from the total for (P + A) (i.e., whether SR > 1).

Quantitative Structure–Activity Analysis. The use of physiocochemical parameters to allow mathematical correlation between chemical structure and biological activity permits a better understanding of biological phenomena as influenced by chemical perturbation. Due to the obvious influence of branching and chain length on different types of attractancy (RA, SR, and TA), we concentrated on use of the sigma * electronic parameter, the Taft steric parameter (Es), and the Pi constant, respectively, in an attempt to evaluate the quantitative contribution of these types of modifications to the relative activity of alcohols,

acids, and esters tested. Values from the monograph of Hansch and Leo (1979) were used to attempt to evaluate activity based on electronic, steric, and lipophilic influences. Values were not available for all compounds that were tested. Initially, values were plotted to determine appropriate models for correlation analyses (e.g., linear, logarithmic) and to determine appropriate portions to consider in substituent analysis (e.g., include or exclude the carbon atom with the functional group in the carbon chain length). The MAXR STEPWISE procedure (SAS Institute, 1985) was used to obtain substituent constants for one- and two-parameter models and included reports of correlation coefficients and probability values. Plots were examined in light of correlation values to visually determine outliers, which might obscure underlying relationships. The procedure then was rerun without these values to see if better correlation resulted—up to an r^2 of 0.7 or 0.8. Typically, this only involved the removal of one or two points.

RESULTS

Properties of Bioassays

One property of the bioassay is that beetles land extremely rarely on filter paper blanks. The mean count for such a control was near zero in all cases we observed. For example, during 54 min or bioassay time in one experiment, 579 beetles landed at a combination of pheromone plus coattractant, but only one landed on the filter paper blank (Table 2). The filter paper blank did not provide any information on the activity of the beetles during the bioassays or any information on the relative attractiveness of other treatments. Thus, it was generally excluded in the experiments, and the response to the pheromone treatment was used as a standard (as described previously).

As our previous observations indicated (Bartelt et al., 1990a), a starvation period was necessary for the beetles to respond. The beetles did not respond to the apple juice, or pheromone, or even take flight, for several hours after being

TABLE 2. RESPONSIVENESS OF *C. hemipterus* TO FILTER PAPER BLANK

Treatment	Total count	Mean count (N = 18)
Filter paper blank	1	0.06
Pheromone	92	5.11
Ethanol + ethyl acetate + acetaldehyde	172	9.56
Ethanol + ethyl acetate + acetaldehyde + pheromone	579	32.17

transferred from rearing cups into the wind tunnel (Figure 1). After this time, the response level increased steadily until at 9–13 hr after release, an average of over 25 beetles responded to the apple juice–pheromone combination per 3-min test. During this period, the dramatic enhancement of the attraction of the apple juice by the pheromone was clearly evident, as we observed previously (Bartelt et al., 1990a). After 13 hr, however, the response level decreased again and became more erratic. This study demonstrated that ratios of numbers of beetles responding to the different attractants was quite consistent over a 6-hr period (between 7 and 13 hr after release). The quasiindependence model described the experiment adequately when just one parameter for each treatment was fitted over the entire 6-hr period ($G^2 = 46.82$, 34 *df*, $P > 0.05$), indicating essentially the same results could be expected at any interval during the 6-hr period. In addition, there was no significant interaction between the treatments and the time period ($G^2 = 7.38$, 4 *df*, $P > 0.10$), again indicating that the data obtained at any instant over the 6-hr time period would be reasonable. For this experiment, the fitted ratios were: apple juice/pheromone = 0.35, pheromone + apple juice/apple juice = 12.42, and pheromone + apple juice/pheromone = 4.37 (note that the product of the first two ratios essentially equals the third ratio; this is implicit in the quasiindependence model). The activity profile illustrated in Figure 1 is throught not to represent a circadian activity rhythm because the time of greatest activity depended more on when the beetles were separated from their food than on the time of day (see below).

The peak activity period could be adjusted so that it occurred at a more convenient time if the beetles were placed in the wind tunnel in the evening before the day the tests were to be run, with lights and fan off (see Methods and Materials). When the lights and fan were turned on the following morning, the beetles usually began to fly actively within 1 hr and responded consistently

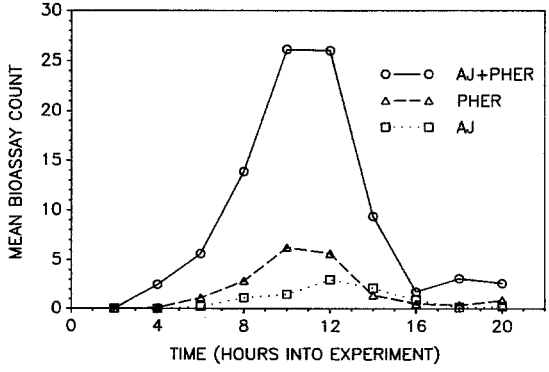

FIG. 1. Response of *C. hemipterus* adults to attractants over time in the wind-tunnel assays. AJ = apple juice, PHER = pheromone.

for about 6 hr once they became active (Table 3). Although there were obvious overall differences in the response to the different treatments ($G^2 = 512.7$, 2 *df*, $P \ll 0.001$), the treatment by hour interaction was not significant ($G^2 = 16.47$, 10 *df*, $P \geq 0.05$). Thus, the bioassay could give reliable data for as long as 6 hr in one day. The column for the TA in Table 3 represents an "acceptable" degree of variability, one that is not statistically significant.

Finally, the appropriateness of the 10% formulation of the coattractants in mineral oil was investigated. Methyl butyrate was used because it was one of the most active single compounds tested. This ester appeared to be inactive at a 0.1% concentration and exhibited only slight activity at 1.0% (Table 3). Thus, use of a 10% formulation appeared appropriate.

Representative compounds also were tested on different days, and variability remained within a reasonable range. For example, trials on completely different days yielded synergist ratios of 0.69 and 1.34 for 2-methylpropionic acid, 2.93 and 4.32 for 2-methylbutyric acid, 3.63 and 2.69 for ethanol, 1.75 and 1.68 for 3-methylpropionic acid. Thus, the values appear to be generally reliable $\pm 20\%$ of the synergist ratio.

Representative Hosts and Host Derivatives

Whole host materials, fermented host materials, and host extracts generally exhibited some attractancy on their own; fermented banana was among the most attractive based on the RA value (Table 4). They all acted as effective synergists for the pheromone in spite of the fact that relative attractancy was low in some caes. Significant synergism (SRs) occurred in all cases, and effective compounds were more widely distributed compared to those producing high RAs. Again, one of the fermented materials was most effective. Thus, it is not surprising that the total attractancy (TA) for the fermented banana material was among the greatest since it incorporates both high RA and SR values, although the TA of the orange juice was comparable.

Effectiveness of the individual volatiles was even more variable. Other than 2-methylpropanoic acid, many of the mono-branched acids were relatively effective attractants, having RAs above 1.5 (Table 4). The C_2 acids and those with greater chain length, except for those that had two methyl groups in the 2-position, were effective synergists. Propanoic and butanoic acid had the greatest TAs.

The pattern for alcohols was somewhat different. Methanol and 2-propanol were particularly effective as individual attractants. Significant synergism was seen in many cases and was of approximately the same level (2–3×). Most of the C_1–C_4 straight-chain and branched alcohols, and C_5 and longer straight-chain alcohols were the effective synergists, Methanol, 2-propanol, 1-heptanol, and 1-methyl-2-propanol had greatest TAs.

TABLE 3. TIME AND DOSE-RELATED RESPONSES OF *C. hemipterus*[a]

Treatment	Mean beetles attracted			Fitted ratios

0.1%	11.1a	0.6b	10.8a	1.06	0.91	0.86
1.0%	3.5a	2.4a	9.5b	1.59	1.62	1.90
10.0%	1.8a	2.6a	10.9b	2.52	2.49	5.46

[a] Treatments whose means are followed by the same letter are not significantly different ($P > 0.05$, conditional G^2 tests). The means were not used in calculation of statistical tests but are presented to show the magnitude of the biological responses.

Of the methyl esters, methyl butanoate had the greatest individual attractancy, followed distantly by methyl propanoate. Once again, significant synergism occurred in many cases, and generally was 2–3×. Methyl esters with straight-chain acids other than formate and branched-acid moieties having no more than one methyl group tended to be effective synergists. As would be expected by the high RAs, methyl butanoate and methyl propanoate had very high TAs.

For the acetate esters, pentyl acetate and propyl acetate had the highest RAs. Those acetate esters with straight-chain substitutions longer than methyl, as well as 1-methylethyl and 2-methylpropyl-substituted compounds were effective synergists, while those with other branched or secondary alcohols were not effective. Synergist ratios were fairly consistent for all of the linear esters, but some branched esters appeared antagonistic. Pentyl acetate and ethyl acetate had the highest TAs. Other esters with notable TAs were ethyl butanoate, ethyl propanoate, and heptyl hexanoate; all three had high and significant SRs.

Of the additional compounds, propanal had the highest RA of any individual compound tested. The aldehydes, ketones, hydroxy acid, and even water showed significant synergism. Propanal, 2-pentanone, and acetaldehyde had highest TAs. The mixtures of components all had very high individual attractancy. Synergist ratios were significant and comparable except for that of the ethanol–ethyl butanoate–2-hydroxypropanoic acid combination, which was at

[a] Treatments whose means are followed by the same letter are not significantly different ($P \geq 0.05$, conditional G^2 tests). The means were not used in the calculation of statistical tests but are presented to show the magnitude of the biological responses. The symbols *, **, *** indicate that synergism was significant at the 0.05, 0.01, or 0.001 level, respectively (conditional G^2 tests). (*) indicates that the response to the mixture was significant less than an "additive" response.

[b] *Saccharomyces cerevisae* and *Zygosaccharomyces bailii*.

least 2× the others. This mixture also had the highest TA, but TAs for other mixtures were generally higher than those of any individual components.

Many of these combinations were included in octyl acetate comparisons and yielded relative attractancy values that might be expected based on the previous results. The TA for octyl acetate did fluctuate throughout the experiment, but generally averaged around 6.0 (Table 5). As would be expected, the most potent individual compound tested, methyl butanoate, gave the highest attractancy relative to the octyl acetate, and one of the highest TAs. Poor attractants/synergists as revealed in prior assays, such as methyl formate, were again proven poor relative to octyl acetate. Thus, using the pheromone alone for a benchmark appeared generally reliable, although a simple combined comparison vs. pheromone plus octyl acetate may also prove useful for rapid determinations of relative effectiveness.

Quantitative Structure–Activity Relationships

Initial examinations of the electronic parameter, sigma *, indicated it was of little use in explaining differences of activity in compounds with different substituents, so it was excluded from further consideration. Transformations of the Es parameter were necessary to linearize equations for RA [(natural log of the absolute value of Es)/Es] and TA (natural log of the absolute value of (Es); the relationship between Es and SR appeared linear. In addition, consideration of whether or not to include the functional groups in the carbon count was important. They were excluded for free alcohols, free acids, and methyl esters (in other words, propyl alcohol was considered to have an ethyl substituent, and so on). Steric parameters were available for all linear chains except for heptyl, and all 5-carbon branched chains except for 1-methylbutyl and 2-methylbutyl. Lipophilic parameters were only available for 1- to 4-carbon compounds, but included all branched substitutents. In some cases, visual inspection of plotted curves suggested outliers. Exclusion of these outliers will be detailed for each set of equations.

Free Acids. The relative attractancy of acids was poorly described when all available compounds were included, but elimination of methyl, 1-methylpropyl, and 3-methylbutyl groups increased the r^2 to 0.81 (Table 6), indicating a high correlation between (log Es)/Es and RA. Inclusion of the Pi parameter helped somewhat (probably to compensate for the methyl derivitive), but the relationship was still poorly described when the 1-methylethyl value was included. Correlation for all included values was much better for the SR, but elimination of 1-methylpropyl and 1-methylethyl was necessary to get a significantly high correlation. Inclusion of the PI value did not appear to compensate for the low activity of the methyl derivative. The log (Es) factor was also a fairly good predictor of TA, but again correlation became highly significant

[a]TAA = total attractancy of attractant, TAO = total attractancy of octyl acetate, RAO = ratio of attractancy of attractant to octyl acetate. Treatments whose means are followed by the same letter are not significantly different ($P \geq 0.05$, conditional G^2 tests). The means were not used in the calculation of statistical tests but are presented to show the magnitude of the biological responses. The symbols *, **, *** indicate that the ratios were significantly different from 1.0 at the 0.05, 0.01, or 0.001 level, respectively (conditional G^2 tests).

when the methyl and 1-methylethyl values were removed. Inclusion of the Pi parameter in the model again did not help to explain the variation.

Free Alcohols. The RA of alcohols was reasonable, but not significant, when all available compounds were included. Elimination of the methyl group increased the r^2 somewhat, indicating some correlation between (log Es)/Es and RA. However, inclusion of the Pi parameter yielded a significant r^2 of 0.88, indicating both steric and lipophilic functions are important in predicting activity. A similar relationship was noted for the SR, although in this case the Es parameter alone provided a significant correlation. Exclusion of the 1-methylethyl group did provide some improvement for the Es model. Once again, in the case of the TA, the Es parameter appeared to most effectively describe the relationship. Exclusion of the 1-methylethyl group provided some increase in the r^2, but inclusion of the Pi parameter only slightly increased the r^2.

Methyl Esters. The relative attractancy of methyl esters was poorly described when all available compounds were included, but elimination of

[a]Es = steric parameter, Pi = pi parameter, INT = intercept. RA = relative attractancy = P + A/P; SR = synergist ratio = (P + A)/P + A; TA = total attractancy = (P + A)/P or (RA × SR). Values following group designations indicated those removed from consideration: 1 = methyl, 2 = 1-methylpropyl, 3 = 3-methylbutyl, 4 = 1-methylethyl, 5 = propyl, * = only contains propyl, 1-methylpropyl, 2-methylpropyl, 1-methylethyl, and 2,2-dimethylethyl; A = above, B = below original regression line.

methyl and propyl groups increased the r^2 to 0.79 (Table 6), indicating a high correlation between (log Es)/Es and RA. Inclusion of the Pi parameter helped slightly, but the relationship was still poorly described when the propyl value was included. Correlation for all included values was much better for the SR, but elimination of 1-methyethyl and 1-methylpropyl was necessary to get a significantly high correlation. Inclusion of the Pi value again appeared to help compensate for the low activity of the methyl derivative. The log (Es) factor also was a poor predictor of TA, but again correlation became highly significant when the methyl and propyl values were removed. Inclusion of the Pi parameter in the model helped to explain the variation.

Acetate Esters. The relative attractancy of the acetate esters was poorly described when all available compounds were included; elimination of over half the compounds (leaving only 2,2-dimethyl ethyl, 1-methyethyl, propyl, 1-methyl propyl and 2-methylpropyl) was necessary to obtain a significant r^2 of 0.86. Inclusion of the Pi parameter helped a great deal, but again this involved the elimination of a large part of the values. In contrast, correlation for all included values was much better for the SR and significant, but elimination of the 3-methylbutyl substituent was necessary, to get an r^2 of 0.79. Inclusion of the Pi value again appeared to help a great deal, but at the same time the 3-methylbutyl group was excluded due to the unavailability of the Pi parameter. The log (Es) factor also was a significant predictor of TA, but again correlation became highly significant when the methyl and 3-methylbutyl values were removed. Inclusion of the Pi parameter in the model helped to explain the variation.

DISCUSSION

Nitidulid Attractants

Attractancy. Prior work with *C. hemipterus* has involved testing a series of "plant" volatiles for field attractancy in fig orchards (Smilanick et al., 1978). Acetaldehyde was at least 10× more effective by itself than any other chemical tested, which included ethyl acetate, propyl acetate, methyl butyrate, ethyl butyrate, ethyl isobutyrate, and ethyl propionate. The combination of acetaldehyde–ethanol–ethyl acetate (1 : 1 : 1) was more than 10× better than acetaldehyde alone. The paper concludes that these insects appear to use a restricted number of "plant" volatiles, which are common to hosts such as fig (Jennings, 1977), and the more tropical pineapple (Dupaigne 1970) and guava (MacLeod and DeTroconis, 1982). However, the volatiles of corn tassels, which are highly attractive to these and other nitidulids, contain no acetaldehyde, only a trace of ethyl acetate, and some ethanol (Flath et al., 1978), which suggests other components also may be involved. Although acetaldehyde, ethanol, and ethyl ace-

tate are reported from these fruits, Jennings (1977) indicated that they are probably fermentation products from figs, which suggests the same could be the case for the other fruits. Fogleman (1982) also indicates in a review that these three compounds are common products of fermenting yeast. This information may explain why fermenting materials, which would produce these attractive compounds (especially ethanol) in greater abundance, are more attractive than unfermented materials to these insects. The greater attractancy of fermenting material would also be logical, considering *C. hemipterus* may actually prefer to feed on the yeast as opposed to the plant material (Miller, 1952; Miller and Mrak, 1954). In other studies on individual plant attractants for nitidulids, Alm et al. (1985, 1986), demonstrated the relatively high attractive specificity of butyl acetate in the field for *Glischrochilus guadrisignatus* (ca. 14× ethyl butyrate, the next best). Propyl acetate was similar in effectiveness to butyl acetate. Bouchier and Stewart (1986) reported that *G. quadrisignatus* could distinguish between isobutyl acetate and *n*-butyl acetate (the branched ester was more attractive). Alm et al. (1986) suggested the receptors are very specific.

In the present work, we found that some volatiles were obviously superior attracts when used alone. The most effective (having RAs above 2.0) were methanol, methyl butyrate, methyl propionate, and propanal. However, many other compounds were also obviously attractive on their own. These compounds are different from those previously reported to be effective attractants for *C. hemipterus* (Smilanick et al., 1978). Acetaldehyde had no attractancy in its own in our study, while methyl butyrate was more potent than any of the other compounds previously reported (Smilanick et al., 1978) that we also examined. In addition, propanal was found to be extremely attractive on its own. These insects are known to respond to humidity gradients (Amos and Waterhouse, 1967; Amos, 1969), so the attractiveness of water is not unexpected. However, although these particular compounds were very attractive on their own (possibly representing specific interactions), when combined with the pheromone, many other compounds produced a TA that was comparable to that for those attractants that were very effective on their own. The synergistic interaction with the pheromone was a potent phenomenon that needs to be considered in predicting the overall effect of any particular host volatile.

Synergism. Due to differences in relative attractancy of butyl acetate vs. banana baits to the nitidulid *G. quadrisignatus* when adults were excluded vs. allowed to feed on the baits, Alm et al. (1986) suggested an aggregation pheromone may be present but did not address potential synergism. Synergism between host volatiles and pheromones is reported for some insects [e.g., Coleoptera (Birch, 1984; Oehlschlager et al., 1988) and Diptera (Bartelt et al., 1988)]. Our prior results indicated that some representative host volatiles can synergize the attractancy of the pheromone from *C. hemipterus* (Bartelt et al., 1990a). The present study indicates that for *C. hemipterus* a wide variety of

hosts and host volatiles is capable of synergizing the pheromone. This information suggests that, in contrast to the limited number of individual compounds that act as attractants on their own, synergism in *C. hemipterus* is a more generally widespread phenomenon. The broad spectrum of compounds capable of synergism is consistent with the known wide host range of *C. hemipterus*, which also would be expected to involve a diverse range of volatiles. Nitidulids with a more restricted host range may not be synergistically attracted by such a wide range of potential host volatiles (theoretically being restricted to volatiles in common from suitable hosts). While a few specific volatiles may be effective in initially bringing *C. hemipterus* to a potential host, once the insects arrive and start producing the aggregation pheromone, the overall attractancy of the host will be dramatically increased due to the interaction of the pheromone with the many host volatiles that are likely to be present. Our discovery that heptanol, which is produced in relatively large amounts by corn (Buttery et al., 1978; Flath et al., 1978), is a potent overall attractant for *C. hemipterus* helps explain how these insects are able to infest corn in the absence of more commonly recognized nitidulid attractants such as esters.

Attractant Combinations. Substituting components into the complex reported by Smilanick et al. (1978) resulted in little change in synergistic potency in the present study, except when better or worse individual synergistic components (esters) were added (see Discussion on structure–activity relationships). Notably, acetaldehyde was found not to be necessary. This is important to consider in formulating a field-oriented synergistic combination, since acetaldehyde is inherently more volatile and unstable than potential ester, alcohol, or acid components. The importance of acetaldehyde as an attractant reported by Smilanick et al. (1978) was not noted in the present study. It is possible that insect strain differences may explain differences in acetaldehyde effects, although the strain used in the present study also was obtained originally from California. However, it is also possible that acetaldehyde oxidized in the field to form acetic acid, which was effective as a synergist in our study.

Structure–Activity Relationships

Overall the Es (bulkiness) parameter was a good predictor for many of the relationships, although an apparent outlier or two had to be removed to give a significant correlation. The outlier was frequently methyl, which appeared to be compensated for when lipophilicity (Pi) was entered into the model. Another frequent outlier was the 1-methylethyl moiety, since it became important in some cases for acids, alcohols, and methyl esters. It is possible that specific receptors may exist for these types of compounds. The equations generated were generally similar to each other, although RA equations typically had lower intercepts (probably a function of the linearization), and TA equations had neg-

ative coefficients (again caused by the transformations). The equations for the RAs tended to be the most variable for the different classes of substituents. The coefficients for the SR equations appeared most similar to one another, although the intercepts were more variable. This information suggests that the receptors, or entire transport–receptor–processing phenomenon is similar for all of the compounds. However, individual differences between attractant class and type of attractancy did exist and are worth considering in more detail.

Relative Attractancy. The optimized equations predicting the RA for the methyl esters and acetate esters were very similar, suggesting that the receptor involved in the generalized attractancy is similar and symmetrical (although specific receptors for more attractive "outliers" such as methyl butyrate are likely). The derived optimized equation for the RA of the acids was somewhat similar to those derived for the esters, but different enough to suggest that two different receptors may be involved for acid and ester attractancy. This was even more obvious for the alcohols, where both coefficients for Es and the intercept were very different from those for the esters and acids. The Es parameter appeared to have the greatest influence on the attractancy of the compounds, but lipophilicity (Pi) also appears to be involved. However, of the three types of attractancy examined, the relative attractancy was most difficult to fit with regression equations. This may have been due to the relatively lesser sensitivity of the assays involving the attractants alone, due to the smaller numbers of beetles that were usually attracted compared to when the attractants were combined with the pheromone.

Synergism. The synergism between the pheromone and the attractants appeared to be a more generalized phenomenon and, due to the higher counts involved, appears to be more suitable for considering relationships of the different classes of substituted compounds. If a single site is assumed for all esters, the binding site would appear to be relatively symmetrical, based on studies with the methyl- and acetate-substituted esters. Long-chain substituents, including compounds such as heptyl caproate, were generally effective, as were some branched compounds. However, the position of the branch affected activity differently depending on which "side" of the carbonyl it was positioned. Branching at the 2-position was acceptable for the methyl esters, but not always acceptable for the acetate esters.

It is possible that acids, alcohols, and esters were binding to the same site or that esters were hydrolyzed to acids and alcohols that then bound to the same or two different respective sites. However, in spite of the general similarity in effectiveness of the many analogous alcohols, acids, and esters, individual effectiveness of analogous compounds did significantly differ in some cases, suggesting different receptors are involved for all three classes of compounds. For example, 3-methyl butanoate was more active synergist than 2-methyl pro-

panoate was; the opposite was true for the corresponding methyl esters. Different effectiveness as synergists of corresponding alcohols and acetate esters also occurred for 1-methyl propyl, 2-methylpropyl, and 1,1-dimethylethyl analogs. However, highly effective "outliers" such as methyl butyrate suggest specific receptors are also likely to be present.

Total Attractancy. Based on structure–activity relationships of acid, alcohol, and ester synergists, it is clear that the best synergists are linear compounds and that there is a series of each of these components that is similar in effectiveness. However, since the total attractancy is a function of the relative attractancy of the individual compound alone coupled with the synergist ratio, the compound with the highest attractancy (RA) and the highest synergist ratio (SR) would be the most effective compound to use in combination with the pheromone. Theoretically, for the esters this would involve the most attractive alcohol and acid portion. For the methyl esters, clearly this would involve either a propanoate or *n*-butanoate moiety, since these functional groups had the greatest single attractancy as well as a high synergist ratio and, indeed, the highest TA. For the alcohol portion, this would involve most of the straight-chain moieties. Ethyl acetate was among the most effective esters in terms of total attractancy and was found to be very effective in the field as well (Smilanick et al., 1978). Predictably, propyl propanoate would be one of the most effective compounds to use as a synergist, and it yielded a octyl acetate–ester ratio of 3.26. Only methyl butanoate yielded a comparable ratio, and this is likely to involve a specific attractancy receptor for this compound. For the alcohols, since a different receptor appears to be involved, methanol, 2-propanol, or heptanol would appear to be the most effective alcohols to use, although the fermentatively obvious ethanol is also very effective. Propanoic acid is clearly the superior acid attractant, but butanoic and 4-methylpentanoic acids are also very effective. Prior success with combinations including an alcohol and ester (Smilanick et al., 1978) may reflect multiple receptor stimulation, which would logically be further enhanced if the acetaldehyde were converted to acetic acid, producing a stimulant for an additional receptor. However, the results of the present study suggest attractancy could be significantly improved by use of the appropriate ester, alcohol, and acid (propanoate). This combination was approximated with ethyl propanoate, ethanol, and propanoic acid, which were readily available. Additional attractancy was achieved by adding water to this mix, which may represent and additional receptor. Propanal also would appear to be an appropriate compound to incorporate in the mixture. The determination of appropriate ratios would be of value also. Of course, formulation and cost may limit the selection of suitable components, but substituent optimization as it influences the synergist ratio should be considered in developing an appropriate blend.

CONCLUSIONS

We believe the use of the pheromone of *C. hemipterus* in combination with the appropriate esters, alcohols, acids, and potentially other compounds such as water and propanal, is likely to yield a potent attractant for this insect. Appropriate selection of the component from a particular class is necessary to obtain optimum attractancy, as indicated by structure–activity relationships reported here. These combinations will be valuable tools for monitoring the population of *C. hemipterus* as well as controlling them by trapping, a method that provided economically acceptible control of insects infesting figs. Bait stations with simple fermentation products have been used successfully in the past to increase quality and quantity of figs produced (Warner, 1960, 1961). A synergistic combination of pheromone and host volatiles should overcome problems of poor competition of attractants with natural hosts cited in past reports. However, *C. hemipterus* is also a pest of other ripe and dried fruit, as well as stored maize, corn meal, wheat, oats, rice, beans, nuts, peanuts, cotton seed, copra, spices, drugs, bread, sugar, honey, and other items (Hinton, 1945). It is also responsible for vectoring organisms responsible for souring of figs (Hinton, 1945) and fungi that contaminate corn and produce mycotoxins (Lussenhop and Wicklow, 1990). Thus, the utility of the components we have discovered is likely to be widespread and may be applicable to the control of other nitidulids as well. Although specific receptors may sometimes be involved, structure–activity relationships appear to be useful in predicting optimal synergists for pheromones, a methodology that should prove useful in developing optimal synergistic blend for many other insects.

(Received November 1, 1989; accepted September 24, 1990)

Abstract—Catch rates of black army cutworm moths, *Actebia fennica* (Lepidoptera: Noctuidae), were determined for different types of traps and different dispenser loads of sex attractant. Of the five traps tested, highest catch (~35 males/per night) was obtained with Uni-Traps, whereas Pherocon 1CP, Delta and Hara traps rapidly became saturated at ~9, 6, and 11 males/per night, respectively. Multi-Pher traps, like the Uni-Traps, have a covered vertical cone with a large collecting bucket but only catch about 1/3 of the number of moths (~9 males/per night) as the Uni-Traps, thus reducing potential saturation. Red rubber septa loaded with 500 μg of attractant blend gave a consistent catch for at least 60 days; 1000 and 2000 μg loadings lasted for a minimum of 90 days. Polyvinylchloride and red rubber septa dispensers containing 100 μg of attractant had similar catch rates, which decreased rapidly with age. Based on these trap and lure-loading experiments, Multi-Pher traps baited with 1000 μg of attractant in a red rubber septum were selected for future calibration studies between catch density and population fluctuations on susceptible sites. Two years of monitoring results also are reported.

INTRODUCTION

Black army cutworm, *Actebia fennica* (Tauscher), recently has been recognized as an economic pest of forest regeneration (Ross and Ilnytzky, 1977). It has been a minor problem in agriculture for many years, causing damage to alfalfa, clover, barley, creeping fescue, and blueberries (Wood and Neilson, 1956). The first outbreak of significance to forestry occurred in eastern British Columbia in 1973 (Ross and Ilnytzky, 1977). Prior to that date there were only three recorded minor outbreaks in British Columbia, dating back to 1943; since 1983 outbreaks have occurred annually. Occasional outbreaks also have occurred on regenerated sites in Ontario and Newfoundland.

Females lay their eggs in the soil from mid-July to early September. The eggs hatch in autumn and first- or second-instar larvae overwinter in the soil. Spring feeding commences as soon as the snow disappears, resulting in patches of denuded herbaceous growth by June. Pupation occurs in June or early July followed by a flight period that can occur between July 1 and September 30, depending on the developmental season.

High densities of black army cutworm often appear one or two years after forest sites are burned by wild or prescribed fires. Planted seedlings are consumed, along with other herbaceous plants. Damage is usually evident for two successive years and then the population returns to endemic levels.

An early-warning system to predict impending high populations before feeding commences would allow land managers to take appropriate action to avoid damage. A pheromone-trap monitoring system is being developed to meet this need (Struble et al., 1989). This paper describes tests conducted to select an appropriate trap and lure for such a system. For this, a lure is required that retains a constant rate of capture throughout a flight period of at least 60 days (Humble et al., 1989) and a trap that catches sufficient moths to indicate an impending outbreak, without becoming saturated.

METHODS AND MATERIALS

Trapping studies were carried out 16 km southeast of Smithers, British Columbia, in the Telkwa River Valley in 1985 and 50 km northeast of Smithers near Torkelsen Creek in 1986. Each area consisted of several square km of a regenerated site, which had been cut and burned two years previous to our studies. Larval populations in 1985 and 1986 were high and caused patches of severe defoliation of vegetation and destruction of conifer seedlings. Thus,

numbers of moths caught in this study are representative of catches made under outbreak conditions.

Traps were hung in rows from stakes at a height of 1 m with 40 m between traps and at least 100 m between rows. The order of treatments was randomized along each row and a "guard" trap, baited with 105 μg of attractant, was placed at the ends of each row to reduce concentrating immigrating moths. Catches in guard traps were not analyzed. When traps and the first dispenser load tests were run in 1985, trap positions were randomized daily. When dispenser loads were being tested in 1986, the tests were so large that a modified design had to be used in order to complete changes on a daily basis. Therefore, dispensers were initially randomized and then advanced one position daily.

Data for trap-nights were deleted from the analysis whenever there was interference with the trap because of vole or wasp predation, trap breakage, etc. This resulted in a variable number of replications in any one test. Uni-Traps were used exclusively during dispenser load tests. Counts were made daily, and the captured dead moths were discarded to prevent both possible reduction of attraction (Sanders, 1986) and having to count the same moths repeatedly.

Type of Trap. Three types of nonsticky and two types of sticky traps were evaluated. The nonsticky traps were: Uni-Trap (International Pheromone Systems Limited, Wirral, Merseyside, United Kingdom), a white, yellow, and green trap; Multi-Pher (Bio-Contrôle Services, Ste. Foy, Quebec, Canada), a green and white trap but also available as all green; and Hara (Hara Products, Swift Current, Saskatchewan, Canada), a double cone, totally white trap. Squares of insecticide strip, approximately 2.5 cm^2, containing 18.6% dichlorvos (Zoecon Industries Limited, Port Perry, Ontario, Canada), were placed inside each of these traps. The sticky traps were Pherocon 1CP (Trécé, Salinas, California) and Delta (made by T.G.G. from 2-liter cardboard milk cartons and coated inside with Tangle-trap from Tanglefoot Co., Grand Rapids, Michigan). In initial tests the Hara, Pherocon, and Delta traps reached saturation after only a few nights of exposure. These were therefore eliminated from future consideration and performance of the Uni-Trap and Multi-Pher traps was further tested using a matched-pair design baited with a septum load of 105 μg. The test was run for two nights with the position of each pair exchanged on the second night. There were 15 pairs, resulting in 30 trap-nights for each type of trap.

Quantity of Attractant per Dispenser. Two types of pheromone dispensers were used. The first consisted of a red rubber septum (A.H. Thomas Co., Catalog No. 1780-J07, Philadelphia, Pennsylvania) impregnated with a hexane dilution of 105 μg of (*Z*)-7-dodecenyl acetate (*Z*7–12 : Ac) and (*Z*)-11-tetradecenyl acetate (*Z*11–14 : Ac) each, at a ratio of 1 : 20. In 1985 0.15% of (*Z*)-5-tetradecenyl acetate (*Z*5–14 : Ac) also was added, but subsequent tests indicated this ingredient had little or no effect on catches (Struble et al., 1989); therefore, it was deleted from the mixture in 1986. The hexane was allowed to evaporate

before the septa were stored at 0°C until required. The second type of dispenser was polyvinylchloride (PVC) rods (5 × 3 mm diam.) (Daterman, 1974) containing 100 μg (0.4% w/w) of pheromone. Both types of dispensers were pinned under the lid or inside of each trap.

Two tests were run to compare dispenser load. In the first test, carried out in 1985, dispenser loads of 50, 100, 500, and 1000 μg were placed in rubber septa and used without aging. Six traps per treatment were run for five nights. In the second test, run in 1986, pheromone dispensers were aged for 0, 30, 60, and 100 days before use. Red rubber septa containing 100, 500, 1000, and 2000 μg of the two acetates at a ratio of 1:20 were placed inside cone-orifice traps, with the cone openings blocked to prevent insect entry, and aged outdoors near Lethbridge, Alberta, starting on April 9, 1986. The PVC dispensers, containing 100 μg of pheromone, were aged inside a Stevenson screen within an unheated shadehouse in Victoria, British Columbia, starting on May 9, 1986. Temperatures were recorded at each site and the degree-days above 0°C were calculated for each aging period. When the dispensers had aged for a specific period, they were sealed in separate containers and stored at −15°C until used in field tests. Two additional traps baited with unmated females reared from field-collected larvae were added to this test. Each treatment was exposed for 26 trap-nights.

Data were transformed, after the method of Iwao and Kuno (1968), using the formula $y = \log(\sqrt{0.163x} + \sqrt{0.163x + 1})$. Bartlett's test of homogeneity of variance indicated no significant differences after transformation. An analysis of variance and Tukey's comparison of means was carried out on the transformed data.

Assessment of Traps under Operational Conditions. In 1987 and 1988, all-green Multi-Pher traps baited with 1000 μg of the two-component pheromone were used to monitor adult populations in eastern and northeastern British Columbia. Each trap was hung 1 m high within burned areas, which had been restocked with conifer seedlings, with the intent of evaluating the traps as tools to detect populations in the autumn before damaging populations occurred. Traps were left out for the entire flight period and captured moths were sorted and counted volumetrically (Shepherd and Gray, unpublished data).

RESULTS AND DISCUSSION

Type of Trap. The mean catches per trap night for the Uni-Trap and Multi-Pher traps were significantly different: 17.9 (SD = 13.7) and 5.8 (SD = 5.4) moths, respectively ($P < 0.005$, Wilcoxon matched-pairs signed-ranks test). This indicated that the Multi-Pher trap could adequately detect damaging populations at lower trap densities than the Uni-Traps and, therefore, would be less likely to become saturated before reaching action threshold densities. Incidental

to these trap tests, it was found that large numbers of bumblebees were attracted to yellow or white traps. Use of all-green traps reduced this problem.

Quantity of Attractant per Dispenser. The first test on the quantity of attractant in septa resulted in the highest mean catch occurring with 100 μg; slightly fewer were caught with 50 μg and progressively fewer were caught with higher quantities (Figure 1). The catch at 1000 μg was less variable than the 500-μg and 2000-μg lures and was significantly different ($P < 0.05$, Tukey's comparison of means) than that for 50 and 100 μg.

In the second test the average catch per night for female-baited traps was 17.2 (SD = 25.4) males, while that for fresh 100-, 500-, 1000-, and 2000-μg septa were 35.2 (SD = 30.5), 24.1 (SD = 16.1), 24.6 (SD = 18.1), and 21.5 (SD = 16.6) males, respectively. The relative variability of the catch in traps with females (CV = 148%) was greater than that for any of the four dispenser loads (CV = 87, 67, 74, and 77%, respectively). Thus the fresh synthetic dispensers attracted higher numbers per night and were more consistent in their catch than females due, in part, to their age and attractiveness.

The results of using PVC dispensers containing 100 μg of attractant and aged 0, 30, 60, and 90 days are included in Figure 2. This test is not strictly comparable to the test using septa as it was run at a different time and thus

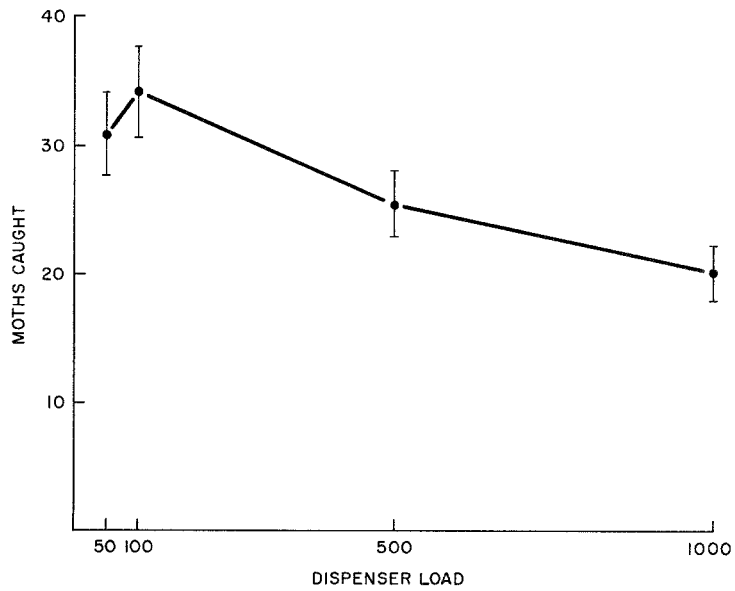

FIG. 1. Effect of dispenser load (μg) on average moth catch per night (N = 30 trap-nights per treatment).

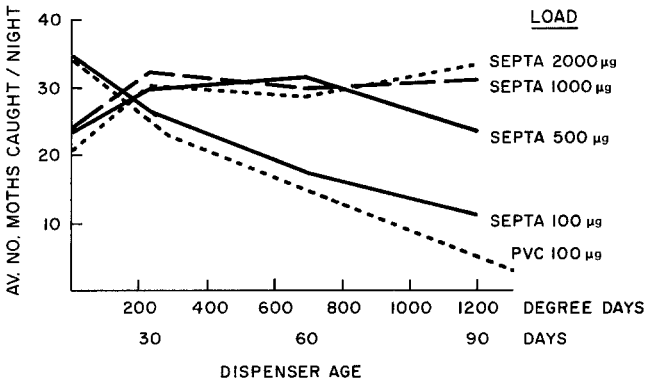

FIG. 2. Effect of dispenser age and load (μg) on average moth catch per night (N = 17–22 trap-nights per treatment).

exposed to different conditions, but the relative decrease with age appears to be similar with PVC as with rubber septa.

When exposing the pre-aged dispensers containing different quantities of attractant, the septum with 100 μg of attractant again gave a slightly higher initial catch than the other dosages. However, after 60 and 90 days of aging, 100 μg produced significantly lower catches than higher dosages aged for the same period of time ($P = < 0.05$, Tukey's comparison of means) (Figure 2). Catches in traps with 500, 1000, and 2000 μg/septum remained relatively consistent after 60 days and, even after 90 days of aging, catches were not reduced for traps with 1000- and 2000-μg dispensers. The reason for the consistency over time at higher dosages is not clear, but two other species of Noctuidae, responding to different attractants and traps, responded in a similar way (Struble, 1981; Struble and Byers, 1987). Thus, baits of 1000 or 2000 μg gave constant catch rates, which is ideal for a trap monitoring system. Based on the results of these experiments, a trap/lure combination of a totally green Multi-Pher trap and a septum lure with 1000 μg of pheromone was recommended for further field evaluation.

Assessment of Traps under Operational Conditions. By 1987 the populations at Smithers and Telkwa had collapsed but new populations were located near McBride, Golden, Clearwater, and Invermere, British Columbia where monitoring was carried out in 1987 and 1988 (Tables 1 and 2). The trap catches ranged from 0 to 1667 with a mean of 692 in 1987, and ranged from 89 to 1161 with a mean of 227 in 1988. Flight commenced in early July and lasted until late September; over 50% occurred in August during both years. Preliminary results indicate that when low catches (< 350 moths) were obtained, there was no risk of seedling damage and restocking could proceed the next spring. When

EUROPEAN CORN BORER: PHEROMONAL CATABOLISM AND BEHAVIORAL RESPONSE TO SEX PHEROMONE

J.A. KLUN,* M. SCHWARZ, and E.C. UEBEL

Insect Chemical Ecology Laboratory
U.S. Department of Agriculture, Agricultural Research Service

(Received July 10, 1990; accepted September 24, 1990)

Abstract—When physiologically excessive amounts of the female sex pheromone of the European corn borer (ECB) or esters analogous to the pheromone were applied to the antennae of males, their behavioral responsiveness to pheromone in a flight tunnel was significantly impaired for 2 hr. Concurrent quantitative analyses of heptane extracts of the male antennae by gas–liquid chromatography showed that the compounds applied to antennae were hydrolyzed and, at 2 and 4 hr posttreatment, little or none of the compound applied or hydrolysis product was detectable in the antennal extracts. After 4 hr of in vivo incubation, male responsiveness to pheromone was restored among moths treated with the analogs but not among moths treated with pheromone. Esterase activity on the antennae was moderately inhibited in vivo by a pheromone analog that is a so-called transition-state esterase inhibitor, 1,1,1-trifluoro-14-heptadecen-2-one. However, the analog did not inhibit male behavior when it was coevaporated with pheromone in a flight-tunnel assay. Therefore, in the presence of pheromone, the analog did not compete well for esterase or the pheromone receptor. Treating the antennae of intact males with tetrahydrofuran obliterated sex pheromone response capability in males, but the treatment did not significantly attenuate esterase and other catabolic activity of the antennae. Indications are that degradation of esters on the ECB antennae involves substrate-nonspecific esterase activity and other metabolic processes that in turn remove hydrolysis products from the antennae. Maintenance of a male's ability to respond to pheromone is linked to these processes.

Key Words—Antennal catabolism, *Ostrinia nubilalis*, Lepidoptera, Pyralidae, pheromone analogs, 11-tetradecenyl acetate.

INTRODUCTION

Degradation of female sex pheromones on the antennae and other body parts of male moths has been studied in a number of species. Earliest works involved studies of pheromone degradation in *Bombyx mori* (Kasang, 1971), *Lymantria dispar* (Kasang et al., 1974), and *Trichoplusia ni* (Ferkovich et al., 1972; Ferkovich, 1982) males. These studies generally showed that degradative activity against pheromone exists on various body parts of the moths and that the activity was usually greatest on the antennae. In *B. mori*, its major pheromone component, (*E*,*Z*)-10,12-hexadecadien-1-ol, was found to be converted to fatty acid and fatty acid ester. Kasang et al. (1989) confirmed this finding by using a radiotracer and presented evidence of formation of water and other polar metabolites on the antennae. Prestwich et al. (1989, 1990) showed in vitro that epoxide hydrolase from *L. dispar* males degrades its pheromone substrate, (7*R*,8*S*)-7,8-epoxy-2-methyloctadecane, to the corresponding *threo*-7,8-diol. In *T. ni*, esterase is known to convert (*Z*)-7-dodecen-1-ol acetate (*Z*7-12:OAc) to the corresponding alcohol.

It is believed that antennal catabolic activity is somehow tied to the transductory processes of olfaction and behavioral response; however, belief in this connectivity is based mostly on conjecture. As examples, Mayer (1975) found that *T. ni* male antennae hydrolyzed pheromone at a rate that was twice as fast as that of female antennae and that the esterase activity on antennae and legs of *T. ni* males was greater against *Z*7-12:OAc than its analogs in brief (4 sec) in vivo incubations. Based upon these findings, Mayer speculated that this enzyme activity might be related to the transductory process. Later, Taylor et al. (1981) observed that pheromone esterase activity on the antennae of *T. ni* against its pheromone was low before adult eclosion, but the activity rose sharply 24–72 hr after eclosion, a time when males become maximally responsive to female sex pheromone. The concurrent rise in esterase activity and behavioral responsiveness to pheromone was considered circumstantial evidence that ester hydrolysis and the olfaction process were associated.

More recently, in vitro studies of esterase activity associated with integument and body scales (Vogt and Riddiford, 1986) and sensilla (Vogt et al., 1985; Prestwich et al., 1986) of *Antheraea polyphemus* have been reported. These studies showed that the esterase associated with scales was not extractable, but esterase residing with the integument was soluble. Vogt and Riddiford surmised that the role of esterase on the scales of males and females was to prevent the adsorptive body surfaces from becoming uncontrolled pheromone sources. Vogt et al. and Prestwich et al. also speculated that sensillar esterase in *A. polyphemus* acts as a rapid acetate inactivator and maintains a low stimulus noise level in sensory hairs. The female sex pheromone of *A. polyphemus* is a 9:1 mixture of (*E*,*Z*)-6,11-hexadecadienyl acetate and (*Z*)-11-hexadecenal

(Kochansky et al. 1975), but it is not yet known what metabolic process limits stimulus noise level related to the aldehyde component of the species' pheromone. Furthermore, all studies of pheromone catabolism in *A. polyphemus* have been restricted to acetate hydrolysis, and the metabolic fate of the resulting alcohol has not yet been probed in detail, although radiotracer studies by Kasang et al. (1988) have indicated that the alcohol is degraded to water, aldehydes, acids, and long-chained fatty acid esters.

In the tobacco budworm (*Heliothis virescens*), a species also known to utilize aldehydes in its pheromone complement, in vitro studies have shown that the pheromonal aldehydes are converted to carboxylic acids by aldehyde dehydrogenase and oxidase enzymes (Tasayco and Prestwich, 1990). It is conceivable that similar enzymes occur in *A. polyphemus*.

Prestwich and Streinz (1988) have evaluated the in vitro esterase inhibition and electroantennogram (EAG) activities of various haloacetate analogs of a trace pheromone component, (*Z*)-11-hexadecenyl acetate (Z11–16:OAc), of *Plutella xylostella;* the major pheromone component for the species is (*Z*)-11-hexadecenal. The purpose of their research was to "correlate analogs active in signal transduction with the recognition of these analogs by catabolic proteins." Among the compounds they studied was 1,1,1-trifluoro-(*Z*)-14-nonadecen-2-one, a potential esterase inhibitor and putative mimic of Z11–16:OAc. An analogous trifluoroketone was known to be a transition state inhibitor of juvenile hormone esterase (Hammock et al., 1982). Results of their research indicated that fluoroacetate analogs elicited greater EAG responses than other haloacetate analogs and that the fluoroacetates were also better esterase inhibitors than the haloanalogs. They concluded that the steric bulk of the chloro and bromo analogs accounted for lesser activities in the esterase inhibition and EAG assays. They also reported that 1,1,1-trifluoro-(*Z*)-14-nonadecen-2-one had weak EAG activity and was a poor inhibitor of esterase. This result differs from the findings of Vogt et al. (1985), who found that 1,1,1-trifluorotetradecan-2-one was a potent inhibitor of sensillar esterase in *A. polyphemus*. Ostensibly, substitution of a CH_2 for oxygen in the acetate moiety is allowable for interaction with esterase in one species but not in the other. This indicates that esterases may differ from one species to another.

Most of the foregoing studies involved in vitro approaches using excised antennae, antennal homogenates, or extracted enzymes. It therefore became of interest to us to probe the in vivo effects of pheromone and analogs applied topically to the antennae of intact European corn borer (ECB), *Ostrinia nubilalis*, males, to determine what influence the compounds might have upon male behavioral response to pheromone and to follow, at the same time, loss of the compounds from the antennae in a time-course fashion. Although the whole-organism approach to study the phenomenon of pheromone perception has been discredited by some as being "black box" experimentation (Prestwich, 1987),

we were of the opinion that such a study might yield biologically pertinent insight into the overall characteristics of the system, which then eventually could be correlated with its mechanistic components.

Our research involved the pheromone of the *E* and *Z* types of ECB (Klun and Huettel, 1988) and ECB pheromone analogs. Compounds were applied to moth antennae at physiologically excessive doses, degradation and removal of the compounds from the antennae were monitored chromatographically, and the influence of these doses on male responsiveness to pheromone was evaluated behaviorally. We report evidence of intense esterase and other catabolic activity on the antennae of ECB adults and behavioral data, which indicates that catabolic activity is somehow linked to the behavioral sensitivity of ECB males to pheromone.

METHODS AND MATERIALS

ECB Adults. All ECB adults used in this study were from colonies that had been established in the laboratory using females collected from fields in the vicinity of Beltsville, Maryland. They were reared continuously since 1985 (Klun and Huettel, 1988). One colony had been selected for homozygosity of *ZZ* female sex pheromone production genes, and the other was selected for homozygosity in *EE* pheromone production genes. Females in these homozygous cultures produced 97 : 3 (*Z*,*E*)- and 3 : 97 (*Z*,*E*)-11-tetradecen-1-ol acetate, respectively, as their pheromone, based upon gas chromatographic analyses of the females. The colonies were maintained in incubators (80% relative humidity; 16 hr light–8 hr dark, 26°C : 20°C). Although the colonies were selected for homozygosity of females sex pheromone production genes, males in the respective colonies also were predisposed to respond to sibling female sex pheromone; flight tunnel assays showed that males from the *ZZ* culture responded only to 97 : 3 (*Z*,*E*)- and *EE* culture males responded only to 97 : 3 (*E*,*Z*)-11-tetradecen-1-ol acetate. Correspondingly, pheromone processing by the antennae was expected to be specific to either *trans* or *cis* pheromone, depending on the colony from which the males were derived.

ECB Pheromonal Analogs. The compounds selected for study were among those that we used in previous studies of chemical structure–activity relationships in the ECB (Schwarz et al., 1989, 1990). Details of the synthesis, purification, and characterization of the compounds are described in these publications.

Gas Chromatographic Analyses. In all cases, antennae treated with compound were extracted with ca. 50 μl heptane at room temperature for 30 min and then removed from the solvent. Extracts were analyzed quantitatively for starting material (compound applied to the tissue) and a presumed first product

(alcohol or acid) by capillary gas–liquid chromatography using the internal standard technique. Pentadecane, 100 ng, served as the internal standard. Analytical sensitivity was ca. 0.5 ng/compound. We used four 60 m × 0.25 mm (ID) fused silica capillary columns for the analyses; two SPB-1 columns (Supelco Inc., Bellefonte, Pennsylvania 16823-0048) and two DBWAX-60N columns (J & W Scientific, Folsom, California 95630-4714). The columns were installed in Hewlett-Packard models 5830, 5840, 5880A, and 5890 gas chromatographs that were equipped with flame ionization detectors (nitrogen carrier makeup gas flow) and splitless sample injectors. Injector and detector temperatures were 225°C and 300°C, respectively. Hydrogen was used as carrier gas at 30 psi. Oven temperatures and programmed heating rates were optimized for each compound. SPB-1 columns were used to analyze for free fatty acids because this liquid phase permitted direct analysis of the acids without derivatization.

Brief In Vivo Incubation of Pheromone and Analogs on Male and Female Antennae. Antennae of each sex and moths of both ECB pheromonal types were immersed in 10 μg/μl solutions of compounds, and, after 5–10 sec of incubation, antennae were excised and extracted for 30 min in heptane containing internal standard. The proportional amount of hydrolysis product formed was determined to evaluate comparative rates of hydrolysis for each compound. The purpose of the test was to document existence of esterase on the antennae and to determine if esterase activity on the antennae would exhibit substrate specificity during the first few seconds of reaction, a time when zero-order kinetics should predominate. Adults used in the studies were 48–72 hr old. Reciprocal tests were conducted in which *cis* and *trans* pheromones each were tested against both sexes of *E*- and *Z*-type moths. The brief incubation tests were replicated 12–18 times.

Application of Compounds to ECB Antennae, Extraction of Antennae, and Bioassay of Upwind Flight Response of Treated Males to Pheromone in a Flight Tunnel. Typically, study of the effects of a given compound applied to the insect's antennae involved a set of 36 males. Each male represented a replicate, and each treatment was replicated at least 12 times. Approximately 1 hr before the onset of scotophase, males were inactivated by placing them individually into a 2.5 × 8.5-cm plastic tube containing a bed of crushed Dry Ice covered with a 3-cm plug of tissue paper. They became anesthetized within a few seconds and were treated immediately. The antennae of 24 individuals were immersed in heptane solution held in a microconical vial and containing test compound. The concentration of compound in the heptane solution was always 10 μg/μl, with the exception of the treatment involving 11-dodecenyl fluoroacetate where a 1 μg/μl solution was used. A low dose of this compound was required because preliminary tests showed that immersion of antennae in a 10 μg/μl heptane solution was lethal to the moths; all moths treated with the solution were dead within 30 min. This toxicity is analogous to the toxic action of

a fluorinated pheromone analog of the western spruce budworm (McLean et al., 1989). In our case, the analog undoubtedly serves as a suicidal substrate; hydrolysis of the fluoroacetate produces highly toxic fluoroacetic acid. The *cis* and *trans* compounds were applied to *Z*-type and *E*-type males, respectively. As a control, six males were anesthetized and treated with heptane (control; C_7), and an additional six were anesthetized only (control; CO_2). A dissecting microscope was used in the treatment procedures to observe the rise of heptane to the base of the antennae by capillary action and to confirm complete coverage of the antennae. Care was exercised in this procedure because the insect was killed instantly if its head and mouth parts contacted solvent.

Once they were treated, all males were held individually in jelly cups. The antennae of six compound-treated males were excised, using fine dissecting scissors, at their bases after 3–9 min incubation (T_0). Each pair of antennae was transferred to 50 μl heptane containing 100 ng pentadecane as internal standard. The 30 remaining males then were placed into the scotophase (2.5 lux red light) of a flight tunnel room at 20°C.

Two hours later (T_2), the antennae of six males that had been treated with compound were excised and extracted with heptane containing the internal standard. At the same time, the remaining treated and control males were assayed for behavioral responsiveness to pheromone in the flight tunnel. The operating conditions for the tunnel bioassay were the same as described by Schwarz et al. (1989). Six males each from the compound-treated and the control groups were tested against pheromone alone; each male was positioned at the downwind end of tunnel in a stimulus plume generated by a 0.5 × 3-cm filter paper strip 3 m upwind that had been treated with 100 ng ECB pheromone in 5 μl heptane. The remaining six males from the compound-treated group were exposed to 3 μg of the same analog that had been applied topically to antennae plus 100 ng pheromone on a filter paper strip. The analog plus pheromone stimulus (A+P) was used in the assay because other experiments (Schwarz et al., 1990) had shown that when these analogs were presented at a 3-μg dose along with pheromone, they either inhibited or had no influence on male upwind flight response to 100 ng pheromone, depending on the structure of the analog. We wished to determine what effect dipping antennae in a solution of analog might have on subsequently male behavior as compared to the effects that were observed previously by Schwarz et al. (1990). In all cases, each male was allowed 3 min to respond after being exposed to stimulus. If a male responded by flying upwind in the stimulus plume and landing on the paper strip or by flying up to within 2 cm of the strip, a positive upwind response was recorded for that individual. A negative response was recorded for males that failed to respond in this manner within 3 min after exposure to pheromone. All males tested at T_2, other than those of control groups, were retrieved from the flight tunnel and assayed as a combined group for behavioral sensitivity to

pheromone alone at 4 hr after treatment (T_4), and then their antennae were excised and extracted.

In this time-course study, the antennal extracts of males that had been treated with tetradecyl acetate or 11-tetradecenyl acetate were analyzed for tetradecanoic acid and 11-tetradecenoic acid, respectively, as well as for the corresponding acetates and alcohols. We surmised that the acids might be logical metabolic products if the alcohols formed on the antennae served as substrate for an oxidative attack on C-1.

1,1,1-Trifluoro-14-heptadecen-2-one (TF). The *cis* and *trans* isomers of TF were synthesized as described by Shaw and Tuominen (1985). In our case, TFs were designed to be steric mimics of the geometric isomers of ECB pheromone and transition-state inhibitors of esterase. In a test of the in vivo effects of TF on antennal esterase, we dipped the antennae of *Z*- and *E*-type males in 10 μg/μl heptane solutions of *cis*- and *trans*-TF, respectively. Three minutes afterward, antennae of these males were treated with pheromone solution, and then the antennae were extracted at T_0, T_2, and T_4 posttreatment. The extracts were analyzed for starting material, alcohol, and residual TF. As control, the same number of males were treated with pheromone and their antennae extracted at the three time periods. The test was replicated 12 times with each ECB pheromonal type. The effect of *cis*- and *trans*-TF isomers upon *Z*- and *E*-type males' upwind flight response to pheromone in the flight tunnel was tested, respectively, by exposing 20 individual males to 3 μg TF plus 100 ng pheromone on a filter paper and by using the same assay methods described earlier. As a control, 10 untreated male cohorts of each ECB type were tested against their pheromone alone.

Tetrahydrofuran and Antennal Esterase Activity. In earlier tests of the effect of various solvents applied to male antennae upon male reactivity to pheromone in the flight tunnel, we found that immersing male ECB antennae in tetrahydrofuran destroyed the ability of males to respond to pheromone. Therefore, it became of interest for us to determine if the solvent also destroyed catabolic activity on the antennae. The antennae of 10 *Z*-type males were each dipped in tetrahydrofuran and then immediately into 10 μg 11–12:OAc/μl heptane. As control, a second set of 10 males was treated with 11–12:OAc solution alone. Individual pairs of antennae were excised and extracted from each of the two groups at T_0, T_2, and T_4. The extracts then were analyzed for starting ester and alcohol.

Statistical Methods. The ester and alcohol quantitative data exhibited large variance of heterogeneity, nonnormality, and there was a large number of zero-value observations. Consequently, the nonparametric median test was used to make comparisons among treatment groups. Pairwise median tests were protected by overall median tests, and the significance level was adjusted in order to hold the experimentwise error below 5%. The frequencies of ECB males

flying upwind were compared using Fisher's exact test protected by stratified Cochran-Mantel-Haenszel analyses, and the significance level also was adjusted to hold the experimentwise error rate below 5%. (SAS Institute, 1988).

RESULTS AND DISCUSSION

Brief In Vivo Incubation of Pheromone and Analogs. Analyses of antennal extracts for acetate to alcohol proportions showed (Table 1) that hydrolysis of most esters took place within seconds after they were applied, with the exception of the methyl-11-tetradecenoate; no free acid was formed in the 5 to 10-sec incubation period. This compound clearly was not processed well by males of either ECB type. In *Z*-type males, 11-dodecenyl fluoroacetate was hydrolyzed more rapidly than all other esters with exception of *Z*-11,13-tetradecadienyl acetate. The fluoroacetate was also hydrolyzed more rapidly than any of the esters tested against the *E*-type males. The rapid hydrolysis of the fluoroacetate is most likely due to the inductive effect of the fluorine atom, which makes it

[a] In cases where a compound has two geometric forms, the *cis* isomer was applied to the *Z*-type male and *trans* isomer was applied to the *E*-type male. In the reciprocal test, both isomers were applied to each type and sex. Medians withn the same column followed by the same letter are not significantly different at the 5% level.

[b] The ester : free acid was determined in case of methyl-11-tetradecenoate.

more susceptible to hydrolysis. Pheromone, 11-tetradecenyl acetate, was not hydrolyzed more rapidly than any of the analogs in both types of insects. Therefore, the data indicate that esterase activity of the antennae is substrate-nonspecific. This finding has relevance to the observation of Schwarz et al. (1990) that when pheromone analogs that mimicked the biological activity of natural pheromone at a low dose were coevaporated at a high dose along with pheromone, male response to the pheromone was not inhibited. However, when analogs that lacked pheromone mimicking quality, such as 11-dodecenyl acetate and 11,13-tetradecadienyl acetate, were evaporated at high dose with pheromone, male response to pheromone was inhibited. They speculated that the inhibitory analogs bind to the pheromone receptors without provoking behavioral response but are not cleared from the receptor as efficiently as the pheromone or pheromonally active analogs, which are more effectively recognized and removed by substrate-specific catabolic enzymes. Data in Table 1 show that the behavioral inhibitors identified by Schwarz et al. (1990), 11-dodecenyl acetate and 11,13-tetradecadienyl acetate, were hydrolyzed as effectively as pheromone. Therefore, it would seem that if the speculation by Schwarz et al. (1990) was correct, then the catabolic specificity they reported must reside with catabolic enzymes other than esterase.

As has proven to be the case for other species of moths in which esterase activity has been assayed, results of the reciprocal test (Table 1) showed that esterase activity in the ECB is associated with female antennae as well as with male antennae. The proportions of alcohol formed indicate that the rate of hydrolysis of *cis* and *trans* pheromone by Z-type ECB did not differ from one geometric isomer to another or from one sex to another. This was also generally true with the *E*-type; however, *E*-type males hydrolyzed *cis* isomer more rapidly than *E*-type females hydrolyzed *trans*. Moreover, esterase activity toward pheromonal isomers did not differ significantly between types of insects. This is, perhaps, not surprising because the pheromones in the two types are comprised of both isomers, albeit in different proportions, and it is reasonable that they should be capable of processing each isomer.

Time-Course Assay of Upwind Flight Response of Males Treated with Compound and Concomitant Analysis of Male Antennal Extracts. Chromatographic analyses (Table 2) showed that at T_0 (3 min after the antennae were treated) predominantly starting ester and somewhat lesser amounts of hydrolysis product were detected in the antennal extracts of all males independent of the ester with which they were treated. In the case of methyl decanoate at T_0, only small amounts of ester and acid were detectable in the extracts, and there was proportionately more acid present than ester at that time, an indication that the latter was removed from the antennae more rapidly than any other compound. The amount of 11-dodecenyl fluoroacetate detected at T_0 was about one order of magnitude less than that observed in other treatments at T_0. This was expected

[a] Where geometrical isomers exist, *cis* isomer was applied to Z-type males and *trans* isomer was applied to *E*-type. Medians within the same column and compound followed by a different letter are significantly different at the 5% level. An asterisk after a letter indicates that upwind flight response of compound-treated cohort males to pheromone in a flight response of compound-treated cohort males to pheromone in a flight tunnel was significantly inhibited ($P = 0.05$) at 2 hr post-treatment compared to control moths. nt = not tested. na = not applicable.

[b] Antennae were dipped in a 1 $\mu g/\mu l$ heptane solution; treatment of males with a 10 $\mu g/\mu l$ solution was lethal.

[c] In cases of methyl esters, the hydrolysis product quantified was the corresponding free fatty acid.

because, as was mentioned earlier, the compound was applied at one-tenth the dose of other compounds.

In subsequent time-course samples, none of the esters applied to the antennae were detectable in the antennal extracts at T_2, but hydrolysis product was often found in the extracts. When hydrolysis product was detected at T_2, it was most often at a level that was significantly lower than the amount detected at T_0, an indication that alcohols were removed from the antenna as they formed. However, inspection of all chromatograms from the polar and nonpolar columns showed no other apparent chromatographic components that might have represented other metabolites, and the specific chromatographic analyses of the extracts of antennae treated with tetradecyl acetate or 11-tetradecenyl acetate showed no evidence of tetradecanoic or 11-tetradecenoic acid, respectively. Therefore, indications are that degradation of alcohol on the ECB antenna does not involve metabolism resulting in formation of fatty acid as has been observed in studies of *B. mori* (Kasang et al., 1989) and *A. polyphemus* (Kasang et al. 1988).

Analyses of insects treated with tetradecyl acetate and 12-cyclopropyl-(*E*)-11-dodecenyl acetate indicated that these compounds represent a special case. Although no tetradecyl acetate was detected in T_2 extracts of *Z*- and *E*-type males, the amounts of tetradecanol present were not significantly different from the amounts detected at T_0. This result indicates that both moth types processed tetradecanol less effectively than the pheromone-derived alcohol 11-tetradecenol. In the case of 12-cyclopropyl-(*E*)-11-dodecenyl acetate, antennal extracts of *E*-type males at T_2 also showed that the amount of the corresponding alcohol present was not significantly different from the amount present at T_0 and that residual acetate was present at T_2. Thus, among all the compounds tested, tetradecyl acetate and the cyclopropyl analog were cleared least effectively from the antennae. This conclusion is reinforced by the fact that trace amounts of only these compounds persisted in the antennal extracts at T_4. Assuming that enzymatic degradation of the alcohols involves attack of the olefinic site, we surmise that the slowed catabolism of these two compounds may be related to the absence of a double bond in tetradecyl acetate and steric hinderance caused by the cyclopropyl group in the vicinity of the double bond in the other compound.

Flight-Tunnel Assay. Statistical analyses revealed that responses of control groups, C_7 and CO_2, to pheromone in the tunnel were not different from each other. Similarly, upwind flight responses of compound-treated males exposed to pheromone alone (P stimulus) or a mixture of pheromone and 3 μg analog (A+P stimulus) at 2 hr after treatment were not different from one another for all compounds tested. Therefore, upwind flight response values of the P and A+P groups and the control groups were pooled, respectively, to test for statistically different responses between compound-treated moths and control

moths. The mean percentage upwind flight response to pheromone among Z-type control males was 67% (N = 154), and in the E-type it was 65% (N = 216).

Analyses of the flight-tunnel data showed that the upwind flight response to pheromone of all males that had been treated with pheromone or analogs (including the 11-dodecenyl fluoroacetate, which was applied at a 1/10 dose) was significantly impaired at T_2 relative to the control males. Treatments causing significant impairment of response are indicated by asterisks in Table 2, and the mean percentage upwind responses of the males at T_2 are presented in Table

TABLE 3. COMPARISON OF PERCENTAGE ECB MALE UPWIND FLIGHT RESPONSE TO PHEROMONE IN TUNNEL AT 2 AND AT 4 HR AFTER THEIR ANTENNAE WERE TREATED WITH INDICATED COMPOUND[a]

[a] Where geometrical isomers exist, *cis* isomer was applied to Z-type males and *trans* isomer was applied to E-type. Percentages within the same column and same compound followed by the same letter are not significantly different at the 5% level. The number of individual males tested in each time period is in parentheses. In some cases, the number of males tested at 4 hr within compounds was fewer than the number tested at 2 hr because some males escaped recapture after testing at 2 hr. nt = not tested.

3. The impairment was often independent of whether or not GC-detectable amounts of applied compound or hydrolysis product were present on the antennae at the time of flight-tunnel assay. As examples, among all males treated with 11-dodecenyl fluoroacetate or methyl-11-tetradecenoate, or *Z*-type males treated with 11-dodecenyl acetate, no esters or hydrolysis products were detected in the antennal extracts; yet male response in these groups was significantly impaired. This indicates that impairment of response may be related to a build-up of pools of catabolic products beyond the hydrolysis product, which tie up olfactory-behavioral response capability. However, we cannot rule out the possibility that physiologically relevant levels of ester or hydrolysis product might have been present on the antennae at levels below GC detection limits. In contrast, hexadecane and methyl decanoate, compounds that have no structural analogy to pheromone, did not impair response capability. It would seem that, owing to their dissimilarity to pheromone structure, they were processed differently from pheromone or pheromone analogs and therefore did not tie up the olfactory response system.

Data in Table 3 compare the mean upwind responses of males to pheromone at T_2 and T_4 posttreatment. All males treated with pheromone analogs, with the exception of the *E*-type males treated with (*E*)-11,13-tetradecadienyl acetate, showed a significant recovery of response capability 4 hr after they were treated with compound. In the case of the *E*-type males against 11,13-tetradecadienyl acetate, the flight assay data indicated that the males also were showing signs of response recovery because a 17% upwind flight response was recorded at T_4, whereas it had been zero at T_2. Insects that were treated with tetradecyl acetate or 12-cyclopropyl-(*E*)-11-dodecenyl acetate were among those showing a significant recovery of response despite the fact that extracts of their antennae at T_4 (Table 2) showed that trace amounts of acetate and/or alcohol were still present on their antennae. In this case, the amount of compound remaining on the antennae presumably fell to a level that no longer disrupted response capability.

Quite unexpectedly, the only instance where males did not show recovery of behavioral response at T_4 was among moths treated with pheromone, 11-tetradecenyl acetate. Application of physiologically excessive doses of pheromone to the moth clearly had a traumatizing effect that was measurably greater than similar does of any of the pheromone analogs. This was true despite the fact that GC analyses of the antennal extracts of the pheromone-treated males indicated that their antennae had been freed of compound at T_4. This fact is reminiscent of observations made at T_2 where neither ester nor alcohol of several analogs was detected in the antennal extracts, yet male response to pheromone was inhibited. Therefore, it seems that esterase activity alone or removal of hydrolysis product from the antennae is not a limiting factor involved in recovery of response capability; if they were, one might have expected response

capability to be restored as soon as ester or hydrolysis product were depleted from the moth antennae at T_2 or T_4. This was not the case whether pheromone or its analogs were involved. However, as discussed earlier, it is also likely that the compounds merely fell below GC detection limits and that the undetected, but physiologically significant, amounts of compound persisted on the antennae. Because all males treated with analogs recovered response capability before they were treated with pheromone, it appears that the males processed the physiologically excessive analog doses more effectively than they processed an equivalent dose of pheromone.

Influence of 1,1,1-Trifluoro-14-heptadecen-2-one (TF) on 11-Tetradecenyl Acetate In Vivo Degradation and Male Flight Response to Pheromone. Results reported in Table 4 show that TF was a weak inhibitor of esterase activity in both *Z*- and *E*-type ECB. The inhibitory effect of the compound is evidenced by the facts that at T_0 (3 min incubation) significantly smaller amounts of alcohol were present in TF-treated males than in the controls and significantly larger amounts of acetate were present in the treated males than in the control insects at 2 hr. After 4 hr of incubation, trace amounts of acetate were detectable in the TF-treated group, whereas none was detected in the controls. It is noteworthy that the data show that TF also was removed from the antennae over time, an indication that degradative activity related to the antennae may not be restricted to attack on esters.

Although TF had a modicum of inhibitory activity against 11-tetradecenyl acetate hydrolysis, the tunnel assay (Table 4) showed that the compound had no effect upon male upwind flight response to pheromone by the two ECB types. Moreover, the esterase inhibition and the behavioral data indicate that TF was not a good competitive inhibitor of ECB esterase and did not effectively compete for putative behavior-inducing pheromone receptor sites on the antennae because it did not interfere with male behavioral response to pheromone. These results are similar to those obtained by Prestwich and Streinz (1988) inasmuch as they found that their trifluoromethylketone stereochemical mimic of the *P. xylostella* pheromone component, (*Z*)-11-hexadecenyl acetate, was also only a weak esterase inhibitor and elicited a negligible electrophysiological response in EAG assays. Thus, in the ECB and *P. xylostella* the trifluoromethylketones have proven to be ineffectual as chemical probes in efforts to further our understanding of the role of antennal esterase activity in pheromone perception.

Influence of Tetrahydrofuran on Antennal Esterase and Catabolic Activity. Inasmuch as THF was found to destroy the ability of males to respond to pheromone, one might have expected the treatment to obliterate esterase activity and other degradative processes on the antennae. However, data in Table 5 show that immersion of male antennae in tetrahydrofuran (THF) did not have such an effect. The data show that the amounts of acetate and alcohol on THF-treated and control insects did not differ significantly 3 min (T_0) after ester was

applied to the antennae. However, at T_2 and T_4 after treatment, there were significantly more residual acetate and alcohol detected in extracts of THF-treated males than in control insects. Thus, the THF treatment had only a slight attenuating effect on antennal catabolic activity. This indicates that male behavioral response capability to pheromone and catabolism are separate but presumably coupled elements of the antennal chemosensory system. THF uncoupled the elements but did not have a significant adverse impact upon the catabolic processes. It also is interesting to note that the solvent, heptane, used in the application of compounds to moths' antennae did not exert this denaturing effect, and the disassociating effect of THF must be attributed to its comparatively polar solubilization characteristic.

SUMMARY

Overall, our studies indicate that catabolism of esters on the ECB antennae involves a combination of substrate-nonspecific esterase activity as well as other undiscovered processes that in turn remove hydrolysis products from the antennae. The catabolism takes place on the antennae of both sexes of the moth. The processes responsible for degradation of the hydrolysis products need to be elucidated because esterase activity does not appear to be the only factor involved in the maintenance of behavioral response capability in the male. Chromatographic evidence showed that degradation of hydrolysis products in the ECB does not involve conversion to carboxylic acid, although such conversion is known to take place in other lepidopteran species. Behavioral data show that catabolism is linked to the ability of males to respond to pheromone inasmuch

as results showed that males exposed to the physiologically excessive doses of pheromonal analogs were incapable of responding to pheromone, but once the compounds were cleared from the antennae, response capability to pheromone was restored. In the time-course study, we did not observe a similar restoration of response among moths treated with pheromone, and there is no ready explanation for this result. Treatment of antennae with THF showed that catabolic activity persisted on the antennae even though the treatment destroyed the ability of males to respond to pheromone. Thus, response and catabolism must be considered as separate but coupled components in the insect's chemosensory system. No doubt, intense catabolic activity is operative when physiologically relevant doses of pheromone impinge on the insect antennae, but the exact molecular linkage between the catabolism, responsiveness to pheromone, and the transductory process remain to be discovered.

Acknowledgments—We thank William Potts for conducting statistical analyses of the data and Ingrid Orentas for technical assistance in the flight-tunnel studies.

(Received July 11, 1990; accepted September 24, 1990)

Abstract—An undescribed species of *Myrmica* collected in Idaho has been shown to have the same substances in its mandibular glands (3-octanol and 3-octanone and related 3-alkanols and 3-alkanones) and in its Dufour gland (linear alkanes, alkenes, and farnesene isomers and homologs) as previously examined European species of *Myrmica*. The poison gland contains the trail pheromone 3-ethyl-2,5-dimethylpyrazine, common to all *Myrmica* species studied so far. The Dufour gland contains large amounts of bishomofarnesene, which easily distinguishes it from some 13 other *Myrmica* already known.

Key Words—Ant, *Myrmica*, Hymenoptera, Formicidae, exocrine secretions, mandibular gland, Dufour gland, trail pheromone, 3-ethyl-2,5-dimethylpyrazine, bishomofarnesene.

INTRODUCTION

Yensen et al. (1977), in their checklist of Idaho ants, list 12 species of *Myrmica*. Recently, an undescribed species was discovered in the Idaho National Envi-

*To whom correspondence should be addressed.
[1] Species description to appear elsewhere.

0098-0331/91/0200-0335$06.50/0

ronmental Research Park, which is located in the desert area of southeastern Idaho. André Francoeur has recognized this as a new species in the course of revision of the Nearctic species and will describe it in the near future. The species is not confined to Idaho; it is a western species found infrequently in warm habitats (Francoeur, personal communication). In order to define this new species more fully, a chemotaxonomic study has been made of its exocrine secretions. There is an increasing awareness that such characteristics can be a valuable addition to the use of morphological characters in the diagnosis of a species. Numerous studies of ants have shown that in all cases examined, the Dufour gland in particular contains a species-specific mixture of substances, dominated by oily hydrocarbons.

Crewe and Blum (1970a,b) carried out the earliest studies on the mandibular gland secretions of *Myrmica* species and showed that 3-octanol and 3-octanone are the principal constituents in each one, although the proportions varied. Subsequently a systematic study was carried out on the eight species of *Myrmica* commonly found in Great Britain (Cammaerts et al., 1982; Attygalle et al., 1983a), and it was further extended to five other European species (Jackson et al., 1989, and unpublished). In each case we have found a species-specific mixture of alcohols and ketones, usually dominated by 3-octanol and 3-octanone. Similarly, we have studied the Dufour gland contents of the eight species of British *Myrmica* (Cammaerts et al., 1983; Attygalle et al., 1983b) and the five European species (Jackson et al., 1989, and unpublished) and have found a mixture of alkanes, alkenes, and (*Z*,*E*)-α-farnesene and it homologs with one, two, or three extra carbon atoms (Attygalle and Morgan, 1982). Whether the linear or terpenoid hydrocarbons are dominant in the gland varies widely with species (Attygalle et al., 1983b).

Ant trail pheromones commonly are shared by more than one species (Attygalle and Morgan, 1985). Our investigation of the trail pheromone of *Myrmica* (Evershed et al., 1981, 1982; Jackson et al., 1989, and unpublished), has shown that the same single substance 3-ethyl-2,5-dimethylpyrazine (EDMP), present in the poison gland as a trace component, provides the trail pheromone in each of 12 species examined.

We show here that this undescribed species from Idaho, while fitting perfectly within the pattern found for its European cousins, has a specific composition of secretion in its mandibular and Dufour glands that should distinguish it from other species of *Myrmica*. It shares the same trail pheromone as all the other *Myrmica* species.

METHODS AND MATERIALS

A colony of this *Myrmica* sp. collected at the Idaho National Environmental Research Park (WHC #8919, 30-IX-1989) was sent live to Keele, where it was maintained in an artificial nest until analysis could be carried out. A colony

of *Myrmica rubra*, collected near Keele was maintained in a similar artificial nest and used in the trail pheromone tests.

For analysis of the mandibular gland substances, whole worker heads were sealed in soft glass capillaries (2 × 20 mm). For the analysis of the Dufour glands, whole poison apparatuses (sting lance, Dufour gland, poison filaments, and reservoir) were similarly sealed in soft glass capillaries. These capillaries were introduced into the gas chromatograph as described by Morgan and Wadhams (1972) and there heated and crushed to produce the chromatogram.

The samples were analyzed by GC-MS, on a Hewlett Packard 5890 gas chromatograph and 5970B mass selective detector with HP59970C chemstation software. A fused silica capillary column (12 m × 0.2 mm) coated with immobilized dimethylsiloxane of 0.33 μm film thickness was used. The injection port temperature was 140°C, and the capillary tubes were equilibrated in the solid injector for 2 min. The oven temperature was initially set at 30°C for two minutes and then increased at 8°C/min. The flow rate of the helium carrier gas was 1 ml/min. The mass selective detector was set to detect ions with *m/z* 35–350. Calibration was achieved by injecting external standards of C_{15} to C_{18} hydrocarbons for Dufour gland substances 3-octanone, 3-octanol, 3-nonanone, and 3-nonanol for mandibular gland substances, and EDMP for the trail pheromone.

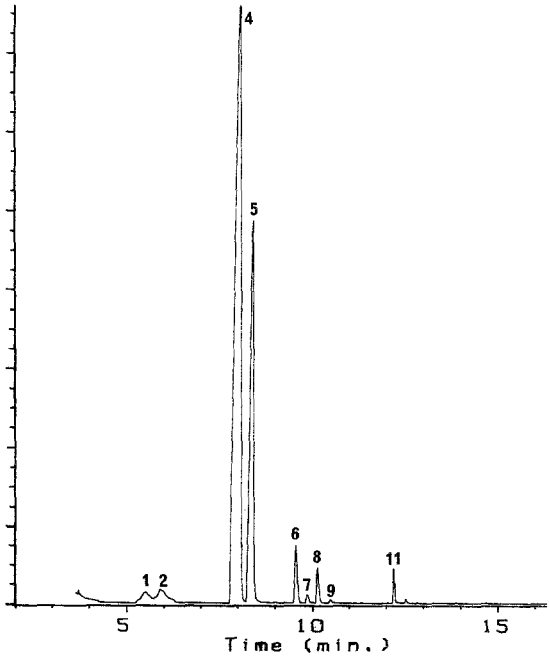

FIG. 1. Gas chromatogram of the volatiles from the mandibular glands of a single worker of *Myrmica* sp. (undescribed). Peak numbers refer to compounds listed in Table 1.

These substances also were used for comparison of retention times and mass spectra in identification of the various substances. Farnesenes were identified by comparison with retention times and mass spectra of those identified in other *Myrmica* species (cf., Attygalle and Morgan, 1982).

The method of Pasteels and Verhaege (1974), using circular trails, was used for determination of the activity of the trail pheromone and for cross-activity testing between *Myrmica rubra* and *Myrmica* sp. Solutions of extracts were prepared in hexane (100 μl) applied to the circumference of a circle (r = 5 cm) drawn on paper, with 1-cm arcs marked off on the circumference, and after allowing 2 min for the hexane to evaporate, the paper was presented to foraging workers. The number of 1-cm arcs for which each worker followed the circular trail before deviating from it were recorded. The median value of 30 such observations was calculated for each test. Hexane solvent alone was used for control tests. Synthetic 3-ethyl-2,5-dimethylpyrazine was tested similarly.

Voucher specimens are deposited in the collection of College of Idaho

TABLE 1. AMOUNTS AND PERCENTAGES OF VARIOUS SUBSTANCES FOUND IN MANDIBULAR GLANDS OF WORKERS OF UNDESCRIBED SPECIES OF *Myrmica* FROM IDAHO[a]

	Compound	Amount ± SD (ng/ant)	Percentage (% ± SD)

Museum of National History (CIDA), André Francoeur, and the William F. Barr Entomological Museum, University of Idaho (UICM).

RESULTS

The mandibular glands of this undescribed species contain chiefly 3-octanone, with less of 3-octanol and traces of other related alcohols and ketones (Figure 1). The mean amount of each substance and the mean percent that each substance represents of the total, plus their sample standard deviations are given in Table 1. As found elsewhere, the amounts in the gland vary widely, but the composition remains within a fairly narrow band of values.

The Dufour gland contained very little linear hydrocarbons but was dominated by a large amount of (*Z*,*E*)-α-bishomofarnesene (Figure 2). The amounts and percentages of the major components are given in Table 2.

The presence of EDMP was evident in the chromatogram obtained from the poison apparatus (Figure 2). The amount was similar to that found in *M.*

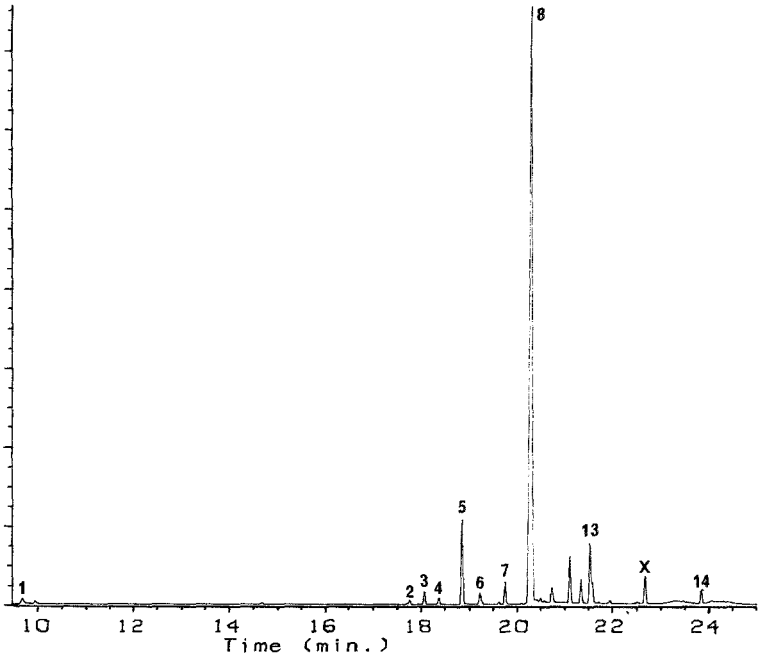

FIG. 2. Gas chromatogram of the poison apparatus of a single worker of *Myrmica* sp. (undescribed). Peak numbers refer to compounds listed in Table 2; X is isopropyl myristate, a contaminant.

TABLE 2. AMOUNTS OF 3-ETHYL-2,5-DIMETHYLPYRAZINE (EDMP) IN POISON RESERVOIR AND AMOUNTS AND PERCENTAGES OF VARIOUS SUBSTANCES FOUND IN DUFOUR GLAND OF WORKERS OF UNDESCRIBED SPECIES OF *Myrmica* FROM IDAHO[a]

	Compound	Amount (ng/ant ± SD)	Percentage (% ± SD)

13	Trishomofarnesene 2	67.8 ± 121	6.0 ± 2.9
14	Nonadecane	11.6 ± 14.5	1.4 ± 0.7
	Total	780	

[a] Results are the means (with sample standard deviations) of 10 determinations on individual workers.

[b] The whole poison apparatus was used, consisting of poison glands, poison reservoir, and Dufour gland. The protein venom of the poison reservoir is not seen in the chromatogram, and the EDMP is the only substance not coming from the Dufour gland.

rubra (Evershed et al., 1981). All control experiments gave zero median values, and all test results were significantly different ($P < 0.001$) from controls using the Mann-Whitney-Wilcoxon test (Siegel and Castellan, 1988). The results of the activity tests are shown in Table 3.

DISCUSSION

The results obtained here are conveniently compared with those recently obtained for *M. gallieni* and *M. specioides*, collected in Switzerland (Jackson et al., 1989) and examined under almost identical conditions. The mandibular gland contents of *Myrmica* sp. are superficially very similar to that of *M. gallieni*, with octanone and octanol comprising over 80% of the total contents, but there are minor differences, such as the absence of undecanone and undecanol in *M. gallieni*. The size of the gland is somewhat larger here (1.8 μg secretion)

than in either *M. gallieni* (1.3 μg) or *M. specioides* (1.1 μg). The unknown compounds are trace substances from the head. They have been recognized in other chromatograms where large amounts of insect tissue have been injected. The sample standard deviations of amount are very large because the quantity of substance in an individual gland varies widely; for example, there was 3.0 μg of 3-octanone in the largest gland, and 0.2 μg in the smallest.

The Dufour gland is rather distinct from the European species in having bishomofarnesene representing 70% of the total contents. It also is unusual in having small amounts of other isomers of homofarnesene, bishomofarnesene, and trishomofarnesene. If these have been present in other species, the amounts have been too small to detect. Comparatively, the Dufour gland is smaller in this species (contains 0.8 μg) compared to *M. rubra*, *M. gallieni* (1.8 μg), or *M. specioides* (0.9 μg). Large variations in the amount per gland were again observed.

The quantity of EDMP found in the poison glands (4.9 ng) is comparable with what has been found in other *Myrmica* species, and the trail tests (Table 3) show that the trail-following ability of this species is similar to, or slightly less than, that of *M. rubra*. Moreover, *M. rubra* readily followed artificial trails made with extracts of the gaster of this species and vice versa. It can be seen from Table 3 that the activity of a single gland and the equivalent amount of pure EDMP are comparable.

Myrmica sp. clearly fits into the pattern of trail pheromone and exocrine secretions of its geographically distant cousins from Europe.

(Received August 20, 1990; accepted September 27, 1990)

Abstract—To understand the interference mechanism of the weed, cogongrass, *Imperata cylindrica* (L.) Beauv., its effect on nutrient availability and mycoflora of its soil rhizosphere as well as nodule characteristics, root length, and root/shoot ratio of *Melilotus parviflora* Desf. were investigated. Additionally, the effect of the leachates of leaves and root/rhizome of cogongrass on seed germination and seedling characteristics of radish, mustard, fenugreek, and tomato were examined. Furthermore, to assess the qualitative and quantitative differences in phytochemical components, the leachates and the soils from three sampling sites (with cogongrass and 1.5 m and 3 m away from cogongrass) were analyzed with high-performance liquid chromatography (HPLC) on a C18 column. No significant difference in nutrient availability was found, but qualitative and quantitative differences in phenolic fractions were recorded in the three sampling sites. Furthermore, of the 19 fungi recorded in the soils, decreases in the number of colonies (per gram of soil) of *Aspergillus fumigatus, A. niger, A. candidus*, and an increase of *A. flavus* was recorded in the soils with cogongrass. The inhibition in nodule number, weight, nitrogen fixation (acetylene reduction activity), root length, and root/shoot ratio of *Melilotus parviflora* were noted. Percent seed germination, root and shoot length, fresh and dry weight of seedlings of different seeds were affected by the leachates of leaves and root/rhizome. It was found that root/rhizome leachate was more inhibitory than leaf leachate. However, the inhibition was higher in soil + leaves leachate than soil + root/rhizome leachate. HPLC analysis established that four compounds were contributed by the weed to the soil system even though their relative concentration varies in various leachates. It is surmised that these compounds cause allelopathic inhibition of growth characteristics of seeds tested. Significance of the data vis-à-vis the interference potential of the cogongrass is discussed.

Key Words—Allelopathy, cogongrass, competition, *Imperata cylindrica*, HPLC, interference, weed.

INTRODUCTION

Cogongrass, *Imperata cylindrica* (L.) Beauv. is among the 10 worst weeds of the warmer regions of the world (Holm, 1969). However, how this weed achieves success has not been thoroughly explained. Abdul-Wahab and Al-Naib (1972) identified scopoletin, scopolin, chlorogenic acid, and isochlorogenic acid in water extract of leaves and culm of this weed. These phenolic acids have been reported to effect growth and physiological characteristics of plant species (Rice, 1984; Einhellig and Kuan, 1971; Lodhi and Rice, 1971), but whether these compounds were present in the rhizosphere of this weed, thus giving allelopathic success to the weed, has not been established. In view of such a gap in our understanding, the present investigations on this weed have been undertaken.

METHODS AND MATERIALS

These investigations were conducted at the Botanical Garden, University of Delhi, where cogongrass is distributed in various densities. Data to study the effect of the weed on nutrient availability, soil mycoflora, nodule forming characteristics of *Melilotus parviflora* Desf., seed germination, seedling characteristics, and phenolic fractions of soils and test solutions were collected. The methods for each of these investigations are described below.

Analysis of Phenolic Fractions. Different test solutions [leaf leachate (TS1), soil + leaves leachate (TS2), root/rhizome leachate (TS3), soil + root/rhizome leachate (TS4), garden soil leachate, as well as soils from the three different sampling sites (with cogongrass and 1.5 and 3 m away from cogongrass)] were analyzed for phenolic fractions by high-performance liquid chromatography (HPLC). Soils (5 g) and plant materials (0.1 g) were shaken with 10 ml of methanol for 1 hr at room temperature. The ratio of extractant to soil was 2 : 1 (v/w) and that for plant material was 100 : 1 (v/w). The extracts were carefully filtered and subjected to HPLC (Shimadzu LC-4A) using a variable wavelength UV detector set at 275 nm. Reversed-phase chromatography was carried out using a steel column (15 cm × 4.6 mm ID) containing Zorbax C18 with the flow rate of 1 ml/min. The volume injected each time was 10 μl and 30 μl for leaf and soil leachates, respectively. The phenolic fractions, differentiated on the basis of their respective retention times and relative concentrations, were recorded (Table 1 below).

Effect of Weed on Root Length, Root/Shoot Ratio and Nodule-Forming

Characteristics of Melilotus parviflora. *Melilotus parviflora* Desf. growing wild with (considered as treated in the investigation) and without (considered as control) cogongrass was selected to study the effect of this weed on its root length, root/shoot ratio, and nodule characteristics. After careful uprooting of the plants, number and weight of nodules, root length, and root/shoot ratio were recorded (Table 2 below). Nodules of each of the sites were carefully washed with double distilled water (DDW), and then the N_2 fixation rate following the acetylene reduction activity was determined. Acetylene was injected into vials containing weighed nodules so as to give a partial pressure of 0.1 atmosphere. Samples of gas phase were drawn after 45 min and their acetylene and ethylene concentrations were assessed by gas chromatography (GC). Acetylene reduction was calculated as per gram fresh weight of the nodules. All trials were made in triplicate.

Effect of Weed on Soil Mycoflora. For analysis of the effect of the weed on mycofloral components, 12 localities, with (considered as treated) and without (considered as control) cogongrass were selected. Soils for fungal analyses were collected by carefully inserting vertically a sterilized glass tube. These tubes were immediately plugged to avoid any contamination and then were stored at 0–4°C. The soil plating technique was employed to isolate fungal colonies. For preparation of the soil suspension, 1 g of soil was shaken with 100 ml of DDW. Three replicates were made by pouring 1 ml of the aliquot from each of the soil suspensions into Petri plates containing 20 ml of cooled and melted Czapek's Dox yeast extract agar medium (Dickinson, 1971) supplemented with streptomycin. Culture plates were thus made and incubated in the culture room at 25 ± 3°C. Total population of fungal colonies was calculated using the following formula:

$$\text{Total number of fungal colonies} = \frac{\text{Mean No. of fungal colonies} \times \text{dilution factor}}{\text{weight of dry soil}}$$

Effect of Weed on Nutrient Availability. To study the effect of this weed on nutrient availability, three contiguous regions, one with the weed present, and the others 1.5 m and 3 m away from it were selected. Soil samples from the rhizosphere (to a depth of 15 cm) of these three sampling sites were collected, air dried, sieved, stored in paper bags and analyzed following standard procedures (Allen, 1989) for pH, electrical conductivity, organic matter, Cu^{2+}, Zn^{2+}, K^{+}, Na^{+}, Mg^{2+}, Ca^{2+}, Cl^{-}, and PO_4^{-3}.

Effect of Weed on Seed Germination and Growth. For this, the effect of different test solutions (TS1, TS2, TS3, and TS4) on seed germination and seedling characteristics of radish (*Raphanus sativus* var. pusa desi), mustard (*Brassica juncea* CV PR 45), fenugreek (*Trigonella foenum-graecum* var. pusa early bunch), and tomato (*Lycopersicon esculentum* var. pusa ruby), the commonly cultivated crops of the region, were investigated. These leachates were

prepared by taking 15 g of each of the plants' parts; leaf and root/rhizome, either alone (for TS1 and TS3) or mixed with garden soil (for TS2 and TS4), were soaked, the former in 100 ml of DDW and the latter in 1:5 soil–DDW for 72 hr. Each of these was filtered and made to 100 ml with DDW. These leachates were used in the experiments without any further dilution. For germination studies, 50 seeds of the respective crop plants were sown on filter paper moistened with DDW (control for plant leachate), garden soil leachate (control for soil leachate), or test solutions, each in equal volume and placed in 15-cm-diameter Petri plates. To maintain uniform moisture status in Petri plates, a cotton pad soaked in DDW or any of the test solutions was placed below the filter paper. Observations on root and shoot length were made every 24 hr up to seven days. Each treatment was replicated thrice. During the period of experimentation, the temperature regime of 22 $\pm$ 5°C and the diurnal regime of light conditions were maintained. After seven days, fresh and dry weights (after keeping at 60°C for 24 hr) of seedlings were recorded (see Table 5 below).

RESULTS

Phenolic Fraction Analysis through HPLC. The presence of this weed brought about distinct qualitative and quantitative changes in the phenolic fractions of the soil samples of different sampling sites (1–3) and the test solutions (TS1, TS2, TS3, and TS4) analyzed (Table 1). In all, 18 phenolic fractions were detected from eight extracts, of which fractions 6 and 14 were common to all. Fraction 8 was present in all the extracts except TS1, and fraction 3 was present in all except sampling site 3 and TS4. However, since these fractions also were detected in control soil, it could be surmised that these must be present in traces but did not show up on the HPLC. On the contrary, fraction 9, although absent in control soil and TS4, was present in rest of the extracts. Furthermore, the relative concentrations of fractions 3, 8, and 9 decreased with the increase in distance from the immediate vicinity (rhizosphere zone) of the weed. The relative concentrations of fractions 3, 5, and 7 were higher in plant extracts (TS1 and TS3) than in soil extracts (TS2 and TS4), while the reverse was true of the quantitative distribution of fraction 8. However, the phenolic fractions 4, 12, and 17 present in the soil with the weed were found to be absent in the test solutions (except TS1 with fraction 4). Phenolic fractions 1, 2, 11, and 13 could be detected only in the HPLC profiles of the soil extracts. It should be noted that even the concentrations of fractions that were common to all the extracts (fractions 6 and 14) exhibited a relative increase wherever the influence of the weed plant part was present.

Nodule Experiments. In the present investigation nodule characteristics, root length, and root/shoot ratio of *Melilotus parviflora* were significantly

Root length (cm)	10.540 ± 1.390	7.460 ± 2.48*
Root/Shoot ratio	0.367 ± 0.101	0.228 ± 0.055**

[a] *$0.05 \leq P < 0.1$, **$0.01 \leq P < 0.05$, ***$0.001 < P < 0.01$.

affected by the weed (Table 2). Nodule weight, root length ($0.05 \leq P < 0.1$), nodule number, root/shoot ratio ($0.01 \leq P < 0.05$) and nitrogen fixation ($P < 0.1$) were reduced in plants occurring with the cogongrass.

Soil Mycoflora Studies. The fungal components of soil were found to be affected by this weed. Significant differences in the number of colonies per gram of soil of four species of *Aspergillus* were recorded in soils associated with the weed (Table 3). Thus, in comparison to control, reductions in the number of colonies were as follows: 50.13% in *Aspergillus fumigatus* ($P < 0.25$), 36% in *A. niger* ($P < 0.25$), 49.35% in *A. candidus* ($0.05 < P < 0.07$); whereas augmentation (65.27%) was recorded in *A. flavus* ($0.05 < P < 0.07$).

Soil Nutrient Studies. Data from Table 4 suggest that no significant changes were brought about by the weed in the concentration of nutrients in the soil samples analyzed.

Seed Germination and Growth Experiments. All the four leachates affected variously the seed germination and seedling characteristics of the different seeds tested (Table 5). Inhibition in percentage seed germination and shoot length in

tomato was brought about in all test solutions. In general, tomato was found to be the most affected by the test solutions. In fact, except for dry weight (TS1, TS2, and TS3) and root length (TS2, TS3, and TS4), all other parameters studied showed maximum inhibition in tomato. TS1 inhibited most of the seedling characteristics of all the seeds studied except a marginal increase in dry weight in fenugreek and tomato. Inhibition by TS2 was least in radish as compared to other systems investigated. Similarly, TS3 suppressed all the seedling characteristics except dry weight in radish, mustard, and tomato, where it showed an increase. TS4 did not decrease the fresh weight of the seedlings of any of the seeds tested. Even the dry weight was not reduced except for the significant reduction (23.21%) noted in tomato. The germination response of different seeds varied: increases in radish and fenugreek and reductions in mustard and tomato were observed. It may be noted that the reduction in values of all the characters by TS1 and TS3 was markedly significant as compared to TS2 and TS4, respectively. Moreover, inhibition in TS2 and TS3 was more than in TS1 and TS4.

DISCUSSION

These data clearly establish that cogongrass produces phenolic compounds, especially those represented by phenolic fractions 5, 7, 9, 10, and 12, which get incorporated in the soil and cause an allelopathic effect on other plant spe-

cies. This also is supported by the fact that even the concentrations of those compounds that are common to control soils and test solutions were higher in the soils collected either from or near the rhizosphere of the weed. Furthermore, that these compounds move from the weed plant to the soil through the medium of water (as leachates were prepared in the aqueous medium) explains the success of the weed in lawns, orchards, and cultivated fields where irrigation is frequent. Furthermore, since the contribution of allelochemics is more by the root/rhizome than by the leaves, etc. (Table 1), and the percentage germination and seedlings is concentration-dependent, it is not difficult to conclude that the weed succeeds through allelochemics in the rhizosphere zone. As a matter of fact, this may be the most important means to totally eliminate any other plant species from its vicinity, as no buried or sown propagules would be able to establish themselves beyond the germination stage. This is borne out also by the observation that both root and shoot lengths of the germinated seeds tested were inhibited by the test solutions. Furthermore, the relative decrease in the

concentrations of phenolic fractions in the different sampling sites suggests that the zone of influence of the weed is much beyond the immediate vicinity of the weed. That the allelopathic effect is very efficient is suggested also by the reduction in the nodule characteristics and thus the N_2 fixation capacity of the legume *Melilotus parviflora*, as well as by an overall reduction in the soil mycoflora. The inhibitory effect of the weed on rhizosphere mycoflora may account for the insignificant change in the nutrient status of the rhizosphere soil of the weed, as the release of the nutrients would be affected under such conditions. Although this is in contrast to the observations of Glass (1973) and Mersie and Singh (1988), it proves that cogongrass is a very effective competitor because, in spite of its aggressiveness toward other plant species, the weed does not create stress for itself by changing the substratum. Interestingly, despite such allelopathic potential, the weed seems to be selective, as exhibited by the data on seed germination and seedling characteristics (Table 5). However, as opined by Williams and Hoagland (1982), since such a selection can also be because of seed characteristics such as size or seed coat permeability or other physiological characteristics, any inference in this regard requires further investigation.

The data in Table 1 show that the concentrations of the common phenolic fractions were higher in field soil leachates than in any of the test solutions. This could be due to the constancy of availability of the phenolic compounds for longer periods as compared to the test solutions, where the time allowed for leaching was shorter and the quantity of plant parts per gram of soil was less than the plant biomass available in the sampling sites. Furthermore, a decrease in concentration of phenolic fractions (Table 1) and percent germination and seedling characteristics in TS2 and TS4 as compared to TS1 and TS3, is now shown. This suggests selective release of the compounds in the medium. Similarly, this may be the explanation for the detection of phenolic fractions 5, 7, and 10 in the test solutions and 9 and 12 in the soils from the sampling sites. This observation is of significance since the quantity leached and made available to bring allelopathic effects should be crucial for understanding the mode of interference. The presence of fractions 4, 12, and 17 only in the soil with the weed (except TS1 with fraction 4) but their absence in the test solutions where fractions 5, 7, and 10 are present, could be due to phased release (quantitative as well as qualitative) of both these groups of compounds, as well as their stability outside the tissue of the plant. As suggested by Rice (1984), the role of mycoflora may also be important in the breakdown of the compounds in the soil system and may explain the differences in the phenolic fractions as noted above. Furthermore, it is very likely that the compounds released later are resistant to such processes as compared to those released earlier. Detailed studies on these aspects are necessary before any final comment is made on this aspect.

These investigations also brought out that tomato seeds can be used as an

assay system for such studies. A major outcome of the present investigation has been importance of HPLC analysis of soils and leachates as a tool for rapid and routine delimitation of the causes or the mode of achieving interference success by a weed. However, there remains the need to characterize the allelochemics to understand the interference mechanism.

Acknowledgments—We are grateful to Professor K.G. Mukerji for his help in identifying fungal members. We would like to thank Ms. Neena of University Science Instrumentation Centre, Delhi University, for help in HPLC analysis. The financial grant of University Grants Commission, India, is gratefully acknowledged. We are extremely grateful to Professor Elroy L. Rice, Oklahoma, U.S.A., for his critical evaluation and valuable suggestions.

Abstract—Urine samples from C3H congenic house mice (*Mus domesticus*) differing only at the *t* complex were examined by capillary gas chromatography to assess variations in the volatile components that may cause olfactory discrimination between animals bearing *t* lethal and + (wild-type) haplotypes. Urine was collected from 192 males and females varying in age from 1 to 9 months. C3H congenic mice that have the same genetic background at all loci but differed in their *t* complex genotypes: +/+, $+/t_{w1}$, T/t_{w1}, *T*/+ were used. No urinary volatiles were unique to the *t* complex. However, significant differences among *t* complex genotypes and among ages occurred for concentrations of 12 male volatiles and four female volatiles. Usually young males (1–2 months of age) had significantly higher concentrations of cyclic enol ethers and ketones than older males (4–9 months of age). Moreover, some urinary volatiles (cyclic enol ethers, one ketone, dehydrobrevicomin, and thiazoline) were excreted in the urine of *T*/+ and/or *T*/*t* males in significantly higher concentration than in the urine of +/+ males. Age and *t* complex genotype influences on the urinary volatiles in females were observed for four ketones. Gas chromatography of urinary components has the potential to be used in field studies of the *t* complex because the two *t* complex genotypes found in wild populations, +/+ and +/*t*, had significant differences in concentration for two males volatiles and three female volatiles.

Key Words—Urinary volatiles, house mouse, chemosignals, *T* locus, *t* complex, *Mus domesticus*, capillary gas chromatography.

INTRODUCTION

The house mouse (*Mus domesticus*) *t*-complex covers the proximal one-third of chromosome 17 of the mouse, and includes the *T* locus (defined by mutations that express both a recessive lethal phenotype and a dominant tail-length phenotype) as well as the major histocompatibility complex (Bennett, 1975; Klein, 1975; Silver, 1985). The *t* complex in the mouse is a set of dominant and recessive mutations, some of which have profound effects on embryonic development, sperm production and function, genetic recombination, and behavior. Approximately 20–25% of wild mice are heterozygous (+/*t*) for various recessive *t* haplotypes and 75–80% are homozygous (+/+) for the wild-type haplotype (Bennett, 1978; Lenington et al., 1988b). Despite strong selection against *t* haplotypes (prenatal deaths of *t* lethal homozygotes), they are maintained with high frequency because of their association with strong segregation distortion in males (Silver, 1985). When a heterozygous (+/*t*) male reproduces, about 90–95% of his offspring will carry his *t* haplotype. The frequency of *t* haplotypes in wild population of house mouse is considerably lower than predicted by a deterministic model incorporating selection against homozygotes and segregation distortion (Bruck, 1957).

Factors controlling the frequency of *t* haplotypes in wild populations are not known. One possibility explored by Lenington et al. (1988a), is that social behavior associated with this polymorphism may select against mice bearing *t* haplotypes. They found that both male and female mice can discriminate +/+ from +/*t* individuals of the opposite sex on the basis of their odor alone and prefer +/+ odors. This odor preference for +/+ over +/*t* individuals could provide a cue for selective mating that might reduce the frequency of *t* haplotypes in wild populations (Lenington, 1983; Lenington et al., 1988a,b; Drickamer and Lenington, 1987).

Mouse urine is a rich source of specific olfactory messengers (Novotny et al., 1991), which include another example of "genetic signaling," also on chromosome 17, the major histocompatibility complex mating preference (Yamazaki et al., 1978, 1979). The purpose of our study was to examine the urinary volatile profiles of male and female mice that differed only in genotype at the *t* complex.

METHODS AND MATERIALS

The mice used in this study were F_1, F_2, and F_3 progeny derived from C3H congenic laboratory animals, heterozygous for a dominant marker allele (*T*) at the *T* locus. Congenic mice have the same genetic background at all loci and differ only at the *t* complex. This allows us to distinguish if differences in urinary volatiles are the result of differences among *t* complex genotypes. The

founders of our colony were a gift from Dr. Dorothea Bennett of the Department of Zoology, University of Texas, Austin.

Urine was collected from four *t* complex genotypes: $T/+$; T/t_{w1} (hereafter T/t); $+/+$ and $+/t_{w1}$ (hereafter $+/t$). The marker allele (T), in conjunction with the + haplotype ($T/+$), produces mice with a short tail and, in conjunction with a *t* haplotype (T/t), produces tailless offspring. The *t* complex genotype $+/+$ (normal tail phenotype) was verified by breeding our mice until they produced at least six $+/+$ and no $+/t$ progeny. Because $+/t$ mice (normal tail phenotype) had to be bred to $T/+$ mice to determine their *t* complex genotype, all our $+/t$ mice were reproductively experienced and more than 6 months old.

All mice were weaned when 21 days old and kept as two of the same sex per cage until they reached an established age (1–2, 2–4; 4–6, or 6–9 months) for urine collection or mating.

All mice used as urine donors were housed in plastic cages (12 × 28 × 27 cm), with metal tops. The animals were kept in an air-conditioned room at 21 ± 1°C and 50–70% humidity with a 12-hr light–12-hr dark daily regime. Unlimited amounts of Purina Mouse Chow (Ralston Purina Corp., St. Louis, Missouri) and water were supplied throughout the entire experimental period. Bedding was changed weekly.

Fresh urine was collected by holding a mouse over a glass vial and gently squeezing the abdomen and flanks. Each 1-ml of sample of female urine was collected for six days and pooled from six to eight animals to reduce the individual variation and estrous cycle effect on the urinary volatiles concentration. For each 1-ml sample of male urine, the specimens were collected for two days and pooled from six to eight animals. Thus, each 1-ml sample was a good representative mixture of urine from different animals (six to eight) collected for same period of time (two to six days). Immediately after collection, samples were stored at −20°C and analyzed within 10 days. All urine was analyzed three times by using a new 1-ml sample each time, obtained from three different collections, from the same six to eight animals for a total of 3 ml of urine per *t* haplotype/age/sex. Different mice were used for each age period: 1–2, 2–4, 4–6, and 6–9 months. We used a total of 192 mice as follows: (3 ages) × (3 haplotypes) × (2 sexes) × (8 animals per group) = 144 mice, and (1 age) × (4 haplotypes) × (2 sexes) × (6 animals per group) = 48 mice.

The urinary volatiles were analyzed using the headspace technique, employing Tenax GC (a porous polymer) as the adsorption medium (Novotny et al., 1974). The volatiles were sparged from 1-ml urine samples at room temperature with purified helium gas at a flow rate of 100 ml/min and adsorbed onto a precolumn packed with 4 mg of Tenax GC. The sample was subsequently desorbed in the heated injection port (220–240°C) of a Varian 1400 gas chromatograph equipped with a flame ionization detector, and retrapped into a cooled section of a glass capillary column [60 m × 0.25 mm ID, soda-lime glass

capillary, coated statically with UCON 50-HB-2000 (Schwende et al., 1984a,b)].

While quantitative comparisons were obtained through peak integration routines (Sigma 10 Data System, Perkin-Elmer, Norwalk, Connecticut), identification of the individual profile constituents was established through a combined gas chromatograph–mass spectrometer (Hewlett-Packard 5980 A dodecapole instrument, Palo Alto, California) using electron impact ionization at 70 eV. Identification made through mass spectrometry was further verified through chromatographic retention time of authentic compounds, either purchased or synthesized in the laboratory.

Statistical comparisons of the levels of excreted volatiles were made using the single-factor analysis of variance with the Duncan new multiple-range test and two-factor analysis of variance with the Tukey test for multiple comparison (Zar, 1984).

RESULTS

Preliminary Assessment of Urinary Profiles

Volatiles we identified (Table 1) are characteristic of other laboratory house mouse strains (Andreolini et al., 1987; Jemiolo et al., 1987; Harvey et al., 1989). Certain urinary volatiles of *t* complex mice exhibited strong dependency on age and *t* complex genotype. These compounds are marked in the chromatographic profiles shown on Figures 1 and 2.

The gas chromatograms shown in Figures 1 and 2 are representative of the substance profiles obtained from externally voided urines of the *t*-bearing mice. Figure 1A and B represent the urinary profiles of males, 1–2 months of age, whose genotypes at the *t* complex were *T*/*t* and +/+, respectively, while Figure 1C and D represent the urinary profiles of males, 6–9 months old, whose genotypes were +/+ and +/*t*, respectively. A visual inspection of these chromatograms easily reveals that heights of the individual peaks greatly decrease in the older males, (A, B vs. C, D), and that the urinary profile of *T*/*t* males at the age of 1–2 months contains volatile compounds in higher concentration than +/+ mice at this same age (A vs. B). Urinary profiles presented on Figure 2A and B are representative for +/+ and *T*/+ females, 1–2 months old. Few female urinary profiles varied with age and *t* complex genotype, whereas more male urinary profiles varied with age and *t* complex genotype.

The urinary constituents have been identified by mass spectrometry as cyclic enol esters, acetate esters, various ketones, *o*-toluidine, dehydro-*exo*-brevicomin and 2-(*sec*-butyl)-4,5-dihydrothiazole (Table 1). These constituents are the same as in other *Mus domesticus* strains (Andreolini et al., 1987; Jemiolo et al., 1987; Harvey et al., 1989). Seventeen urinary volatiles occurred in con-

sistently measurable quantities. Significant differences in concentations were caused by age for 12 male volatiles, by *t* complex genotype for seven male volatiles, by age for three female volatiles, and by *t* complex genotype for three female volatiles.

Male Volatile Constituents

Age. Quantitative comparisons of the selected urinary compounds from males of different ages revealed that the youngest males (1–2 months old) had significantly higher concentrations of urinary volatiles than older males (2–9 months old). This trend occurred in +/+, *T*/+, and *T*/*t* males for the ketones and cyclic enol ethers. After two to four months, there is little change in excretion of these two type of compounds (Table 2). For +/+, *T*/+, and *T*/*t* males,

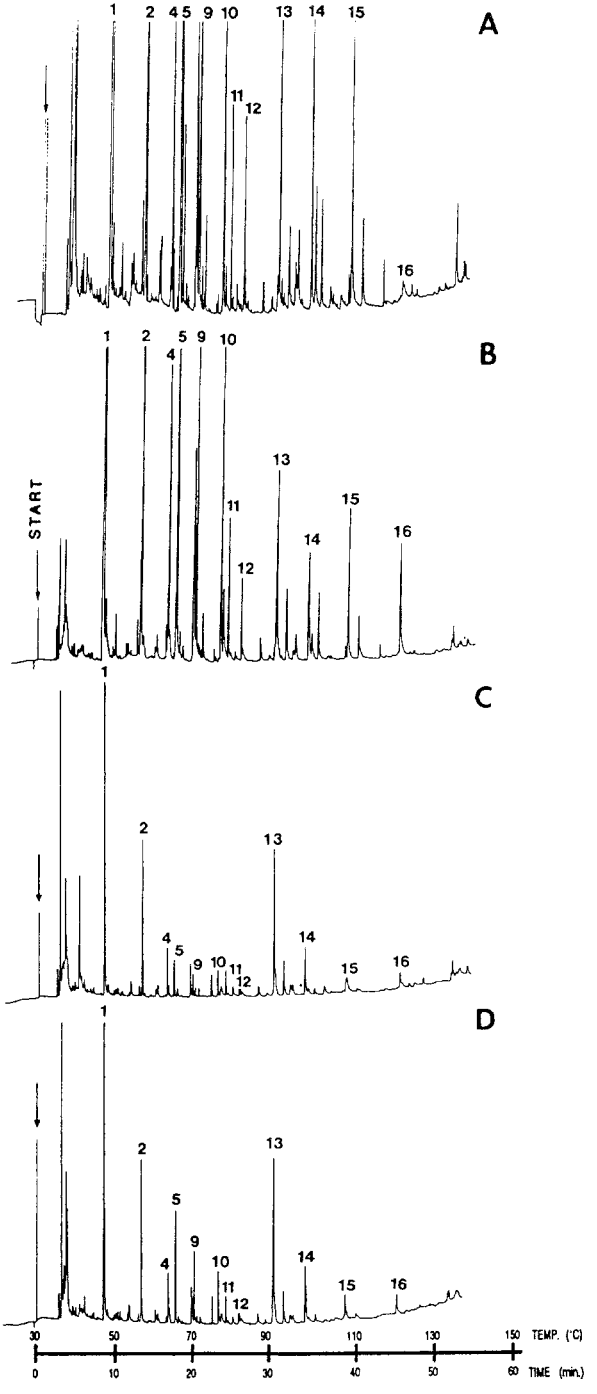

FIG. 1. Gas-chromatographic urinary volatile profiles from (A) 1 to 2-month-old *T/t* males; (B) 1 to 2-month-old +/+ males; (C) +/+ males over 6 months of age; (D) +/*t* males over 6 months of age.

[a] Effect of age and *t* complex genotype on mean areas of each peak was calculated by two-factor of analysis of variance; multiple comparison was done using the Tukey test at the 0.05 level. Those means in the same vertical column (within each peak) not marked with the same superscript letter (a, b, c, d) are significantly different. Those means in the same horizontal row (within each peak) not marked with the same superscript letter (A, B, C) are significantly different. Where there are no superscript letters in a row or column, there are no significant differences among the means in that row or column.

concentrations of cyclic enol ethers (Table 2, peaks 1, 2, 4) decreased by 71–84% and remained at low values throughout the remaining age intervals.

The average concentration of the urinary ketones for +/+, *T*/+, and *T*/*t* older males (Table 2, peaks 5, 9, 10–12, 15), is 61–84%, lower than in 1 to 2-month-old males of the same *t* complex genotypes. Among ketones, only acetophenone (peak 15) from *T*/*t* male urine exhibited a significant increase in concentration for old (6–9 months) animals when compared to 2 to 4- and 4 to 6-month age groups. However, this concentation increase was not significantly greater than the level originally found in the urine of animals 1–2 months old.

As seen in Table 2, peak 13, dehydro-*exo*-brevicomin exhibited a very different trend from the ketones and cyclic enol ethers, as its urinary concentration varies with the age of *t*-bearing animals (significant interation age × *t* complex genotype). The 4 to 6-month-old +/+, *T*/+, and *T*/*t* males showed a significantly higher concentration of dehydro-*exo*-brevicomin (peak 13), than the younger males. Higher levels of dehydro-*exo*-brevicomin were still observed in *T*/+ and *T*/*t* males 6–9 months of age, but dropped significantly in +/+ males. 2-(*sec*-butyl)-4,5-Dihydrothiazole (peak 14) was produced at comparable levels by +/+ and *T*/+ males of all ages. Only the *T*/*t* males exhibited age dependency in peak 14. The highest level of this compound was observed in the urine of animals 1–2 months old. *o*-Toluidine (peak 16) exhibited fluctuations with age for all investigated *t* complex genotypes. The lowest concentration of *o*-toluidine, however, was commonly observed in urine of all *t* complex genotypes at ages 6–9 months (Table 2, peaks 16).

t Complex Genotype. A quantitative comparison of the selected urinary compounds from males of different *t* complex genotypes revealed that certain constituents were excreted in the urine of *T*/+ and *T*/*t* males in significantly higher concentrations than in the urine of +/+ males. As shown in Table 2, peaks 1, 2, 4, the urine of *T*/*t* males at age 1–4 months contained significantly more cyclic enol ethers than the urine of +/+ and *T*/+ males (exception for peak 1 in 2 to 4-month-old *T*/*t* animals, where their concentration was found elevated but not significantly). Furthermore, these same cyclic enol ethers were found at significantly higher concentrations in *T*/*t* and *T*/+ mice of older age (4–9 months) when compared to +/+ males (exception for peak 1 in 4 to 6-month-old *T*/*t* and *T*/+ animals, where their concentration was elevated non-significantly.

A *t* complex genotype influence on concentration of a ketone (peak 15) was evident for the youngest (1–2 months) and oldest (6–9 months) *T*/+ and *T*/*t* males in comparison to +/+ mice of the same age (Table 2, peak 15). In the urine of *T*/+ males of all ages, 2-(*sec*-butyl)-4,5-dihydrothiazole (Table 2, peak 14) exhibited significant increase of concentrations compared to urine of +/+ and *T*/*t* males (exception for 1 to 2-month-old *T*/*t* mice, which exhibited a similar urinary concentration of peak 14 as *T*/+ males). Urinary concentration

of dehydro-*exo*-brevicomin (peak 13) was significantly elevated for *T/t* males at ages 2–4 and 6–9 months and for *T/+* males at age 4–9 months. As shown in Table 2, peak 16, *o*-toluidine exhibited significant increase of concentration in *T/+* males in comparison to *+/+* and *T/t* males, but only in 1 to 2- and 4 to 6-month-old animals.

The changes in concentration of urinary volatiles from *+/+*, *+/t*, *T/+*, and *T/t* males, at the age of 6–9 months, are presented in Table 3. The *t* complex genotypes *T/t* and *T/+* at this age clearly exhibited a greater concentration of most investigated compounds. Statistically significant differences, however, were found for the cyclic enol ethers (peaks 1, 2 and 4), two ketones (peaks 9 and 15), dehydro-*exo*-brevicomin (peak 13), and 2-(*sec*-butyl)-4,5-dihydrothiazole (peak 14) when compared to the genotypes *+/+*, and *+/t*. At 6–9 months, *+/+* males had significantly higher concentration than *+/t* males for a cyclic enol ether (peak 4) and a ketone (peak 10). These significant differences have a potential use in field studies because only *+/+* and *+/t* mice occur in field populations.

Female Volatile Constituents

Age. Age had no influence on most female urinary volatiles. However, three ketones were exceptions (Table 4). *T/+*, *T/t*, and *+/+* females at 2–4 months of age had greater concentrations of 2-hexanone (peak A), 2-heptanone (peak 5) and 4-hepten-2-one (peak 9) than females of older ages.

t Complex Genotype. Quantitative comparisons among different *t* complex genotypes of the same age revealed that 2-heptanone (peak 5) and 4-hepten-2-one (peak 9) were significantly elevated in *T/+* and/or *T/t* females when compared to 1 to 4-month-old *+/+* females. Due to high excretion of volatile compounds by 2 to 4-month-old females, the *T/t* haplotype can easily be distinguished from *T/+* and *+/+* on the basis of the levels of 2-heptanone (peak 5) and 4-hepten-2-one (peak 9), while *+/+* mice appear to differ significantly from *T/+* and *T/t* mice on the basis of 2-hexanone (Table 4, peak A).

At the age of 6–9 months *+/t* females had significantly more 2-hexanone (peak A) and 3-hepten-2-one (peak 10) than *T/+*, *T/t*, and *+/+* females (Table 5). A significantly higher concentration of 4-hepten-2-one (peak 9) was found in the urine of *T/+* and *+/t* females when compared to *+/+* and *T/t* females. No statistically significant haplotype differences were found in the excretion of remaining volatiles by the females at the age of 6–9 months.

DISCUSSION

The urinary volatile constituents obtained from C3H congenic mice with the *t* complex had been found in other strains [C57BL/6J; BALB/cWt; ICR/Alb; C57BL/10; B10(H-2^b); B10.A(H-2^a); B10.BR(H-2^k); B10.RIII(H-2)^r]

[a]Effect of *t* complex genotype on mean areas for each peak was calculated by single-factor of analysis of variance; $F(df = 3, 8)$, $P < 0.05$, using Duncan's new multiple-range test for genotype comparison at the 0.02 level. Those means in the same row not marked with the same superscript letter (A, B, C) are significantly different. Where there is no superscript letter in a row there are no significant differences among the means.

(Harvey, 1988; Jemiolo et al., 1987; Andreolini et al., 1987; Schwende et al., 1984a). No C3H congenic mice differing only at the *t* complex have urinary volatiles unique to *t* complex genotypes.

Comparison of the urinary profiles from all *t* complex genotypes leads to the following conclusions: (1) younger males (1–2 months) have higher concentrations of urinary cyclic enol ethers and ketones than older (2–9 months) ones, (2) the known male mouse pheromone (Novotny et al., 1985; Jemiolo et al., 1985, 1986) dehydro-*exo*-brevicomin (peak 13) is in higher concentration in the urine of older (4–9 months) males; (3) males with a *T* allele produce considerably more urinary volatiles than males carrying a *t* haplotype or wild-type + haplotype; (4) 6 to 9-month-old +/+ males can be distinguished from +/*t* males on the basis of differences in cyclic enol ether (peak 4) and 3-hepten-2-one (peak 10) concentration; (5) younger (1–4 months old) +/+, *T*/+, and *T*/*t* females have greater concentrations of three ketones than older females; (6) +/*t* females 6–9 months old have greater concentrations of ketones 2-hexanone (peak A), 4-hepten-2-one (peak 9), and 3-hepten-2-one (peak 10) than +/+ mice.

The preference tests conducted by Egid and Lenington (1985) demonstrated that *t* complex genotype recognition signals were airborne. Males showed

[a] Effect of age and *t* complex genotype on mean areas of each peak was calculated by two-factor of analysis of variance; multiple comparison was done using the Tukey test at the 0.05 level. Those means in the same vertical column (within each peak) not marked with the same superscript letter (a, b, c, d) are significantly different. Those means in the same horizontal row (within each peak) not marked with the same superscript letter (A, B, C) are significantly different. Where there is no superscript letter in a row or column, there are no significant differences among the means in that row or column.

strong preference for the odors of +/+ females over +/*t*. However, when males were tested with the odor or recombinant females (differing at the *t* complex but carrying the same *H-2* haplotype), males had no preference (Egid and Lenington, 1985). In contrast, females were able to discriminate +/+ from +/*t* recombinant males on the basis of *t* complex genotype alone.

A lack of unique *t* complex compounds responsible for the haplotype discrimination supports the concept of a nonspecific influence of *t* complex on olfactory cues. Significant olfactory differences between +/+ and +/*t* mice may well be due to a variation in the overall pattern of general secondary metabolites rather than differences in metabolic production of specific components. Results presented in this paper have shown that the T/+ and T/*t* males differed in volatile profiles from +/+ and +/*t* males. As well +/+ and +/*t* males had significantly different concentration for two compounds, and females for three compounds.

TABLE 5. MEAN PEAK AREAS (SEM) IN ARBITRARY UNITS FOR URINARY VOLATILES FROM +/+, +/*t*, *T*/+, AND *T*/*t* FEMALES AT 6–9 MONTHS OLD[a]

13	0.49 (0.05)	0.46 (0.39)	0.63 (0.09)	0.73 (0.19)

[a]Effect of *t* complex genotype on mean areas for each peak was calculated by single-factor of analysis of variance; $F(df = 3, 8)$, $P < 0.05$, using Duncan's new multiple-range test for genotype comparison at the 0.02 level. Those means in the same row not marked with the same superscript letter (A, B) are significantly different. Where there are no superscript letters in a row, there are no significant differences among the means.

Furthermore, most significant differences occurred among younger mice. Future studies might find more significant differences in concentations of urinary volatiles of +/+ and +/*t* mice when mice younger than 6 months old are tested. The lack of a significant interaction between haplotype and age for most volatiles means that mice of unknown ages, such as trapped in the field, might be accurately assessed for *t*-complex genotype (+/+ or +/*t*) using gas chromatography of urine.

(Received June 27, 1990; accepted October 1, 1990)

Abstract—Experiments were conducted to determine whether changes in soil microbial populations that occur in response to additions of certain allelopathic phenolic acids to bulk soil also occur in the rhizosphere. Cucumber seedlings were transplanted into cups containing a nutrient-enriched mixture of Portsmouth B_1 soil and sand and were watered five times (once every 48 hr) with aqueous solutions of ferulic, *p*-coumaric, or vanillic acid (each at 0, 0.25, or 0.50 μmol/g soil material). Nutrient solution was applied on alternate days. Leaf growth was suppressed by up to 42% by phenolic acids, but changes in root growth varied with the compound and concentration in solution. Significant increases (over 600% relative to controls) in populations of fast-growing bacteria in the rhizosphere were detected after two but not after five treatments, and increases (400% relative to controls) in numbers of fungal propagules were detected after five treatments. Such increases suggested that chronic exposure to a phenolic acid might result in high populations of rhizosphere microorganisms that could metabolize the compounds and thus alter observable responses by the plant. To test this, plants were watered repeatedly with a low-concentration solution of ferulic acid (chronic treatments; 0.0 or 0.1 μmol/g soil material in one experiment, 0.000 or 0.025 μmol/g soil material in a second) and then once with a high-concentration solution (acute treatment; 0.0, 0.5, or 1.0 μmol/g soil material in the first experiment; 0.000, 0.125, or 0.250 μmol/g soil material in the second).

The use of trade names in this publication does not imply endorsement by the North Carolina Agricultural Research Service or the United States Department of Agriculture of the products named, nor criticism of similar ones not mentioned.

Acute treatments and some chronic treatments suppressed leaf growth, but results were inconsistent for root growth. Acute treatments increased numbers of several types of bacteria in the rhizosphere but had inconsistent effects on fungi. Chronic treatments had no effect on numbers of bacteria or fungal propagules in the rhizosphere. Furthermore, chronic treatments did not alter responses of plants or microbial populations to the subsequent acute treatment. Results demonstrated that phenolic acids in soil, which must pass through the rhizosphere before interaction with plant roots can occur, alter the microbial ecology of the rhizosphere. However, microbially mediated acclimation of plants to relatively high concentrations of ferulic acid was not observed.

Key Words—Allelopathy, ferulic acid, *p*-courmaric acid, vanillic acid, *Cucumis sativus*, bacteria, fungi.

INTRODUCTION

Plant growth and function in nature can be influenced by allelopathic interactions (Rice, 1984; Thompson, 1985; Putnam and Tang, 1986). The intensity of allelopathic activity by different chemicals varies with the compounds involved, concentrations available for uptake, and plant sensitivity to the compounds.

Derivatives of benzoic and cinnamic acids with allelopathic properties are released during the decomposition of plant debris (Flaig, 1964; Turner and Rice, 1975; Martin and Haider, 1976). Ferulic acid is a cinnamic acid derivative with allelopathic properties (Rice, 1984) that suppresses photosynthetic rate (Patterson, 1981), changes osmotic pressure and closes stomata (Einhellig et al., 1985), modifies root function such that water utilization and ion uptake are suppressed (Balke, 1985; Blum and Dalton, 1985; Blum et al., 1985), and generally inhibits leaf expansion, root elongation, and biomass accumulation (Blum and Rebbeck, 1989; Einhellig and Eckrich, 1984; Rice, 1984). Other phenolic acids identified in soil, such as *p*-coumaric acid and vanillic acid, also may exhibit allelopathic activities similar to those described for ferulic acid (Blum et al., 1985; Rice, 1984).

Soilborne microorganisms may modify allelopathic interactions among plants. Some microorganisms produce herbicidal compounds that can affect plant growth and function (Cutler, 1986). Others utilize phenolic acids as carbon sources and deplete the chemicals from the soil solution (Blum et al., 1987; Vaughan et al., 1983). Some microorganisms catabolize ferulic acid and produce compounds such as caffeic, protocatechuic, and vanillic acids (Evans, 1963; Flaig, 1964; Dagley, 1971; Turner and Rice, 1975; Martin and Haider, 1976) that also exhibit allelopathic characteristics under appropriate conditions (Wang et al., 1967; del Moral and Muller, 1970; Blum et al., 1985). Conversely, phenolic acids in soil can alter the indigenous microbial community.

Ferulic, *p*-hydroxybenzoic, vanillic, or caffeic acid added to soil from cropped fields stimulated soil respiration, microbial biomass, and amylase activity (Sparling et al., 1981). Applications of ferulic, *p*-coumaric, *p*-hydroxybenzoic, or vanillic acid to nonsterile soil induced numerous changes among population densities of bacteria, fungi, and actinomycetes, and applications of ferulic acid stimulated specific populations of bacteria (Blum and Shafer, 1988). Clearly, nonbiological properties of soil are important in mediating the activity of allelopathic compounds (Blum et al., 1987; Dalton et al., 1983). However, certain aspects of plant response to allelopathic phenolic acids depend upon the microbiological characteristics of the soil and must be investigated with nonsterile soil (Schmidt, 1988).

Microbiological characteristics of the rhizosphere are usually quite different from the bulk soil and are very important to plant development (Curl and Truelove, 1986). Allelopathic compounds exude from roots into the rhizosphere, leach from leaves, or leach from plant debris (Hoagland and Williams, 1985). Such compounds in the soil solution must pass through the rhizosphere before uptake by plants can occur. Interactions that involve allelopathic chemicals in soil are probably mediated by rhizosphere microorganisms (Hoagland and Williams, 1985). Indeed, a *Pseudomonas* sp. and *Syncephalastrum racemosum* Cohen ex J. Schrot., a bacterium and fungus, respectively, isolated from field soil reduced the toxic effects of ferulic, *p*-coumaric, and *p*-hydroxybenzoic acids on wheat (*Triticum aestivum* L.) in the laboratory (Vaughan et al., 1983). Another pseudomonad, capable of degrading the allelotoxin juglone, was isolated from soil under *Juglans nigra* L. (Schmidt, 1988). Conversely, a bacterium found in the seed carpels of *Sida spinosa* L. modified ferulic acid into 2-methoxy-4-ethylphenol, a styrene derivative that was more phytotoxic than ferulic acid (Liebl and Worsham, 1983). Studies on allelotoxins in nonsterile soils are required to evaluate further the importance of allelopathic compounds in plant–plant interactions (Schmidt, 1988; Williamson and Weidenhamer, 1990).

The experiments described here were designed to examine the influence of phenolic acids on certain aspects of the ecology of the rhizosphere and were based on results of prior studies. Previous experiments demonstrated that population densities of phenolic-acid-metabolizing microorganisms could be stimulated by repeated applications of the compounds (Blum and Shafer, 1988). Therefore, the first experiment described here was conducted to determine whether several phenolic acids cause such effects in the rhizosphere, in which microbial populations are already strongly influenced by physical and chemical conditions caused by the root.

In the second experiment, the mediating effect of rhizosphere microorganisms on plant response to ferulic acid was examined. Responses of cucumber plants (*Cucumis sativus* L.) to ferulic acid have been quantified in several other

investigations (e.g., Blum and Dalton, 1985; Blum and Rebbeck, 1989; Blum et al., 1984, 1985, 1987). In solution culture, chronic concentrations of ferulic acid did not affect plant growth responses to the subsequent occurrence of a high concentration (Blum and Dalton, 1985). However, a typical rhizosphere cannot develop in a frequently changed solution. If rhizosphere populations of ferulic-acid-metabolizing microorganisms could be stimulated by chronic exposure to ferulic acid, plant response to a high concentration of the compound might be weaker than expected because microorganisms near the root could decrease the availability of ferulic acid. This possibility was examined in experiments described here, in which plant measurements were collected to confirm that effects of the phenolic acids on plant growth were consistent with earlier studies and, therefore, that effects on the rhizosphere occurred in relation to typical plant responses.

METHODS AND MATERIALS

General Procedure. All experiments were conducted with nonsterile Portsmouth B_1-horizon soil mixed with quartz sand (1 soil:2 sand), adjusted to pH 5.2 with $Ca(OH)_2$ (to maximize availability of the phenolic acids yet maintain the plants), and enriched with $Ca(H_2PO_4)_2 \cdot H_2O$, $KHCO_3$, $ZnSO_4 \cdot 7H_2O$, and $MnCl_2 \cdot 4H_2O$ to support plant growth (Blum et al., 1987). Microbiological properties of this modified soil, hereafter designed "soil material," were quantified (Blum and Shafer, 1988). Polyethylene cups (150 ml capacity) each were filled with 150 g of soil material. Germination of cucumber seeds (cv Early Green Cluster), transplanting of the seedlings, and culture of the plants under light banks in a laboratory were conducted according to procedures developed in earlier experiments (Blum et al., 1987). Periodic nondestructive measurements of total leaf area per plant (Blum and Dalton, 1985) were collected to assess effects of treatments on plant growth.

All phenolic acids were applied in filter-sterilized, aqueous solutions adjusted to pH 5.2 with NaOH. All control treatments were sterile distilled water adjusted to pH 5.2. On all days on which no phenolic acid or control treatment was applied, plants were watered with the nutrient solution described above.

Microbial populations in the rhizosphere, cumulative length of primary plus secondary roots, and dry weight of the entire root system were quantified for each plant. The root system of each plant was dipped briefly into 250 ml of sterile deionized water to dislodge large aggregates of soil material. The entire root system was adhering soil material was transferred to a 99-ml blank of sterile diluent (0.1% aqueous agar) and shaken for 30 min on a wrist-action shaker. The resulting suspension of rhizosphere soil was diluted and assayed

by the plate-dilution frequency technique on agar media in Petri plates (Harris and Sommers, 1968). The roots were recovered from the diluent, and the cumulative length of primary + secondary roots was measured (Blum and Rebbeck, 1989). Fragments of fine roots in the diluent bottle were recovered on a sieve, and all roots were dried for 48 hr at 70°C and weighed. Microbial populations were quantified after plates had been incubated at 30°C in the dark for six days. Media and procedures used for quantification of microbial populations in these studies have been described (Blum and Shafer, 1988; Shafer, 1988). Media included a bacteriological mineral salts–glucose agar (BMS) for bacteria; a modified bacteriological nutrient agar (BNA) for "total" and phosphatase-positive bacteria; a modified nutrient agar for gram-negative bacteria (GNB); and a medium (FGI) for fungi modified from BMS. A ferulic acid medium (FAM) was modified from BMS by adjustment to pH 5.5 and substitution of glucose with ferulic acid (0.5 mmol/liter) to select for bacteria that could use ferulic acid as a carbon source. Fast-growing bacteria, which were defined as those that produced colonies at least 1 mm in diameter after six days, were quantified on FAM. Fast-growing bacteria also were quantified in addition to the total recovered on BMS and BNA. Microbial populations were expressed as the logarithm of the number of colony-forming units per gram of root ($\log_{10}$ CFU/g), and conclusions concerning statistical significance of treatment effects were based on analyses conducted with the log-transformed data. However, for ease in interpretation, all data sets that include statistically significant differences are presented as graphs of arithmetic values (i.e., CFU/g).

Effects of Different Phenolic Acids on Rhizosphere Populations and Plant Growth (Experiment 1). Cucumber seeds were sown on day 0, and seedlings were transplanted into cups of soil material on day 4. Treatments were initiated on day 7. Each cup received up to 0.5 ml of a solution of ferulic, *p*-coumaric, or vanillic acid (Sigma Chemical Company, St. Louis, Missouri) so that the total applied was equivalent to 0, 0.25, or 0.50 μmol/g soil material. Water then was added to bring the total application to 25 ml. Each solution was applied to eight seedlings, and seedlings were arranged in a randomized complete block design. Treatment applications were repeated on day 9, and four blocks per treatment (28 seedlings total) were harvested and assayed on day 10 with media BMS, GNB, and FGI. The remaining seedlings (28 total) received additional treatments on days 11, 13, and 15, and leaf areas were measured before each treatment. These plants were harvested and assayed on day 16 with BNA and the three media used for the day-10 assays. Final leaf area, primary + secondary root length, root dry weight, and microbiological data were analyzed by analysis of variance (ANOVA) for each date as a randomized complete block design with four blocks. An ANOVA also was conducted with day-16 leaf area data. For each phenolic acid, orthogonal contrasts (SAS Institute, 1988) compared populations associated with the 0.25 μmol/g treatment versus the 0.50

μmol/g treatment. Significant differences between the control treatment versus each ferulic, *p*-coumaric, or vanillic acid treatment were detected with Dunnett's procedure (Steel and Torrie, 1980). Significance was accepted at $P < 0.05$ in all statistical analyses.

Effect of Repeated Low-Concentration Applications of Ferulic Acid on Rhizosphere Populations and Plant Growth Responses to Subsequent High-Concentration Application (Experiments 2A and 2B). Cucumber seeds were sown on day 0, and seedlings were transplanted into cups of soil material on day 4. Repeated low-concentration applications (hereafter designated "chronic treatments") were initiated on day 7. On days 7, 9, 11, and 13, each cup received 0.1 ml of distilled water or ferulic acid solution to provide 0 or 0.1 μmol, respectively, of ferulic acid per gram of soil material. Water then was added to bring the total application to 25 ml. On day 15, each cup received a high-concentration application (hereafter designated "acute treatment") of up to 1 ml of solution so that the total applied was equivalent to 0, 0.5, or 1.0 μmol ferulic acid per gram of soil material (experiment 2A). Water again was added to bring the total application to 25 ml. This factorial treatment design (2 chronic levels × 3 acute levels) was replicated with six cups per combination arranged in a completely randomized design. Leaf area per plant was measured on days 15, 16, and 17. Plants were harvested on day 17 for root length and dry weight measurements and quantification of microbial populations on all media. The experiment was designed to test (by ANOVA) the significance of the chronic × acute interaction, which, if significant, would indicate that chronic treatments modified responses of the plant–rhizosphere system to an acute treatment. In the absence of a significant interaction, independent effects of acute and chronic treatments could be identified. Analyses of leaf area data were conducted for each date.

A similar experiment was conducted at a later date (experiment 2B) with chronic treatments at 0 or 0.025 μmol/g of soil material and acute treatment at 0, 0.125, or 0.250 μmol/g of soil material. Because the experiments involved different application concentrations, ANOVAs were conducted separately for each experiment.

RESULTS

Effects of Different Phenolic Acids on Rhizosphere Populations. Final leaf area per plant was suppressed significantly by each of the three phenolic acids (Figure 1). By day 16, leaf area per plant was suppressed by 37, 42, or 37% after five applications of ferulic, vanillic, or *p*-coumaric acid, respectively (0.50 μmol/g treatments). Differences between 0.25 and 0.50 μmol/g treatments for each phenolic acid were not significant. These results confirmed that the com-

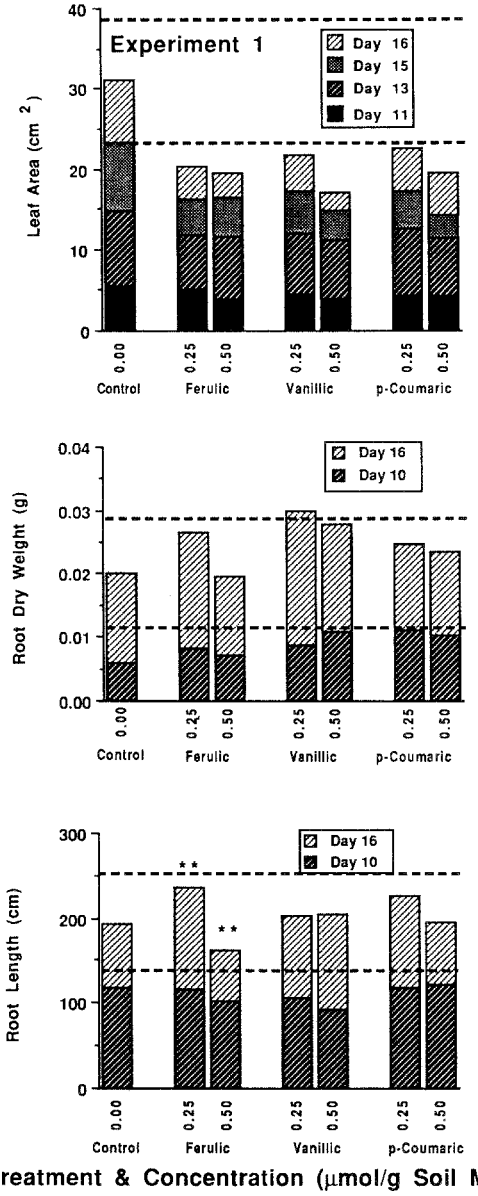

FIG. 1. Effect of multiple additions of phenolic acids to Portsmouth B_1 soil–sand mix on cucumber seedlings. Seeds were germinated on day 0, seedlings were transplanted into the soil-sand mix on day 4, and treatments were applied on days 7, 9, 11, 13, and 15. The horizontal dashed lines indicate the range of values that are not significantly different from the control on day 16 (according to Dunnett's procedure, $P < 0.05$). Means represented by columns marked with ** are significantly different from each other on day 16 (according to a single-degree-of-freedom contrast, $P < 0.01$).

pounds elicited the previously described suppression of foliar growth (Blum et al., 1985). Effects on root growth were less clear (Figure 1). By day 10, cumulative length of primary and secondary roots and dry weight of the entire root systems were not significantly affected by two applications of ferulic, *p*-coumaric, or vanillic acid. By day 16, total root length of plants treated with five applications of 0.50 μmol/g of ferulic acid was significantly less (32%) than that of plants treated with 0.25 μmol/g of ferulic acid. Final root dry weight of plants treated with 0.25 μmol/g vanillic acid was significantly greater (50%) than that of controls, but the 0.50 μmol/g treatment did not have this effect. Applications of *p*-coumaric acid did not affect root growth by day 16.

Only ferulic acid affected any microbial population in the rhizosphere by day 10 (after two applications). Numbers of fast-growing bacteria recovered on BMS from the rhizospheres of plants treated twice with 0.50 μmol ferulic acid per gram of soil material averaged approximately seven times that associated with controls (Figure 2). Fungal populations were not changed by any treatment relative to controls.

By day 16, bacterial populations after five treatments with phenolic acids were not different from populations associated with controls. Although numbers of fungal propagules after treatments with either concentration of *p*-coumaric acid were not significantly different from that of controls, the 0.50-μmol treatments resulted in numbers of fungal propagules that were significantly greater (nearly 10×) than those in the rhizosphere of plants that received the 0.25-μmol treatments (Figure 2).

Effect of Repeated Low-Concentration Applications of Ferulic Acid on Rhizosphere Populations and Plant Growth Responses to Subsequent High-Concentration Application. In experiment 2A, the chronic × acute interaction for leaf area was not significant for any day. However, repeated chronic treatments of 0.1 μmol ferulic acid per gram of soil material were sufficient to suppress leaf area significantly relative to controls by day 15, and this effect persisted through day 17 (Table 1). The suppressive effect of an acute treatment of 0.5 or 1.0 μmol/g on day 15 was not significant until day 17 (Table 1). Leaf expansion halted after day 16 for plants that received the 1.0 μmol/g acute treatment regardless of chronic treatment (Figure 3). In experiment 2B, the chronic × acute interaction again was not significant for leaf area (Table 1). Chronic treatments had no effect on leaf area on any day, but acute treatments applied on day 15 significantly suppressed leaf area on days 16 and 17 (Figure 3, Table 1).

The chronic × acute interaction was not significant for root length in either experiment. In experiment 2A, length of primary + secondary roots was stimulated by chronic treatments but was not significantly affected by acute treatments (Figure 4, Table 1). In experiment 2B, acute treatments (mainly the

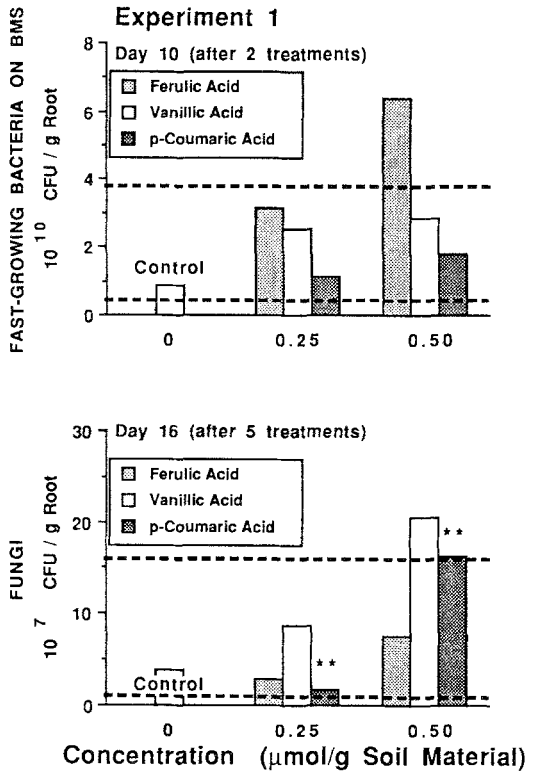

FIG. 2. Effect of multiple additions of phenolic acids to Portsmouth B_1 soil–sand mix on population densities of microorganisms in the rhizosphere of cucumber seedlings. Legend for Figure 1 details planting and treatment schedules. Data are shown only for populations that exhibited statistically significant differences. The horizontal dashed lines indicate the range of values that are not significantly different from the control on day 16 (according to Dunnett's procedure, $P < 0.05$). These ranges do not appear to be symmetrical about the control means because statistical calculations were performed with $\log_{10}$-transformed data, and arithmetic values are graphed. Means represented by columns marked with ** are significantly different from each other (according to a single-degree-of-freedom contrast, $P < 0.01$).

0.250 μmol/g application) suppressed root elongation, but effects of chronic treatments were not significant (Figure 4, Table 1).

Root dry weights provided the clearest indication of treatment effects on roots. The chronic × acute interaction was not significant for root dry weight in either experiment (Table 1). Chronic treatments significantly stimulated root dry weight in experiment 2A, and a similar (but not significant) trend occurred

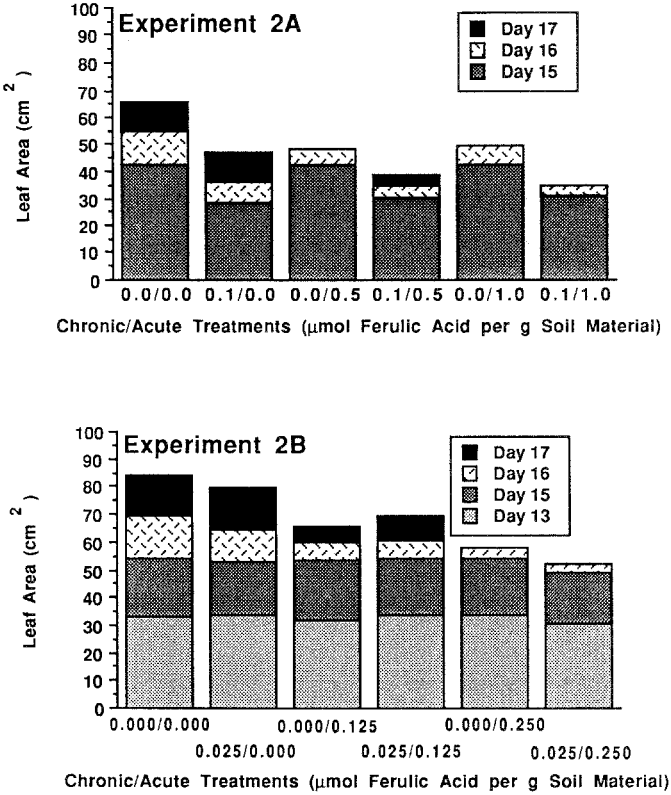

FIG. 3. Effect of chronic and acute applications of ferulic acid to Portsmouth B_1 soil–sand mix on leaf area of cucumber seedlings. Seeds were germinated on day 0, seedlings were transplanted into the soil–sand mix on day 4, and chronic treatments were applied on days 7, 9, 11, and 13. An acute treatment was applied on day 15. Experiments 2A and 2B were conducted at different times.

with the lower-concentration chronic treatments in experiment 2B (Figure 5, Table 1). In both experiments, acute treatments suppressed root dry weight (Figure 5, Table 1).

Populations of microorganisms in the rhizosphere were significantly altered by acute treatments of ferulic acid. However, neither the chronic treatments nor the chronic × acute interaction had significant effects on populations in either experiment 2A or 2B (Table 1). Therefore, effects of the acute treatments were averaged over all chronic treatments and indicated that numbers of most types of bacteria were increased by the acute treatments (Figure 6). For example, populations of fast-growing bacteria recovered on FAM from the rhizosphere of plants that had received the highest acute treatment in either experiment were

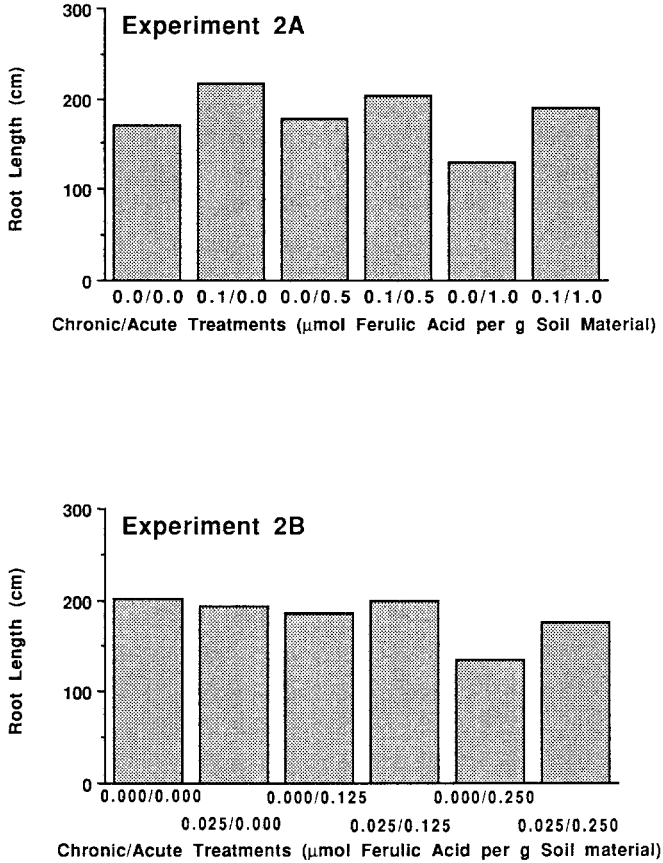

FIG. 4. Effect of chronic and acute applications of ferulic acid to Portsmouth B_1 soil–sand mix on final length of primary + secondary roots of cucumber seedlings. Legend for Figure 3 details planting and treatment schedules.

four to five times the populations in the rhizosphere of control plants. However, increases caused by acute treatments for "total" populations of bacteria (quantified on BNA and BMS) in the rhizosphere were significant only with BNA in experiment 2A.

Changes in different populations relative to each other were induced by the acute treatments and are illustrated by proportional changes averaged over chronic treatments (Table 2). In both experiments, ferulic acid treatments had no significant effect on the "total" bacterial that were isolated from the rhizosphere on BMS medium, yet the fast-growing isolates on this medium significantly increased with acute treatments. Among control plants, fast-growing isolates represented approximately 20% of the population recovered on BMS from

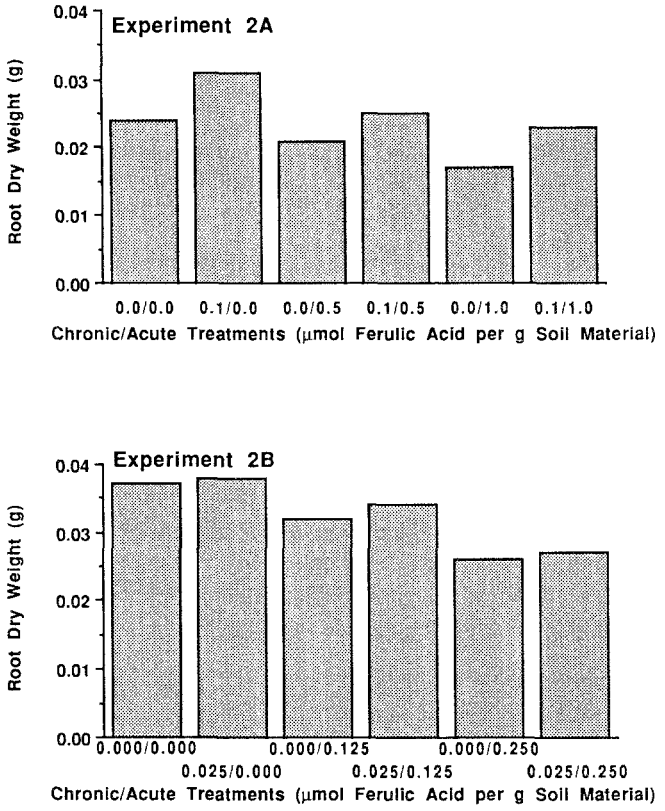

FIG. 5. Effect of chronic and acute applications of ferulic acid to Portsmouth B_1 soil–sand mix on root biomass of cucumber seedlings. Legend for Figure 3 details planting and treatment schedules.

control plants (averaged across experiments and chronic treatments). However, fast-growing isolates increased to approximately 45% of the population recovered on this same medium after plants had received the highest acute treatments. The highest acute treatments in both experiments more than doubled the proportion represented by fast-growing bacteria on FAM relative to the total numbers recovered on BMS (in which glucose was the carbon source). Similarly, the highest acute treatments increased the average proportion represented by gram-negative bacteria from 22% (from control plants) to 44% of the total numbers recovered on BNA. Acute treatments increased the total recovered on BNA only in experiment 2A. However, numbers of fast-growing bacteria and phosphatase-positive bacteria recovered on BNA were increased two to five times by acute treatments compared to controls in both experiments. Although

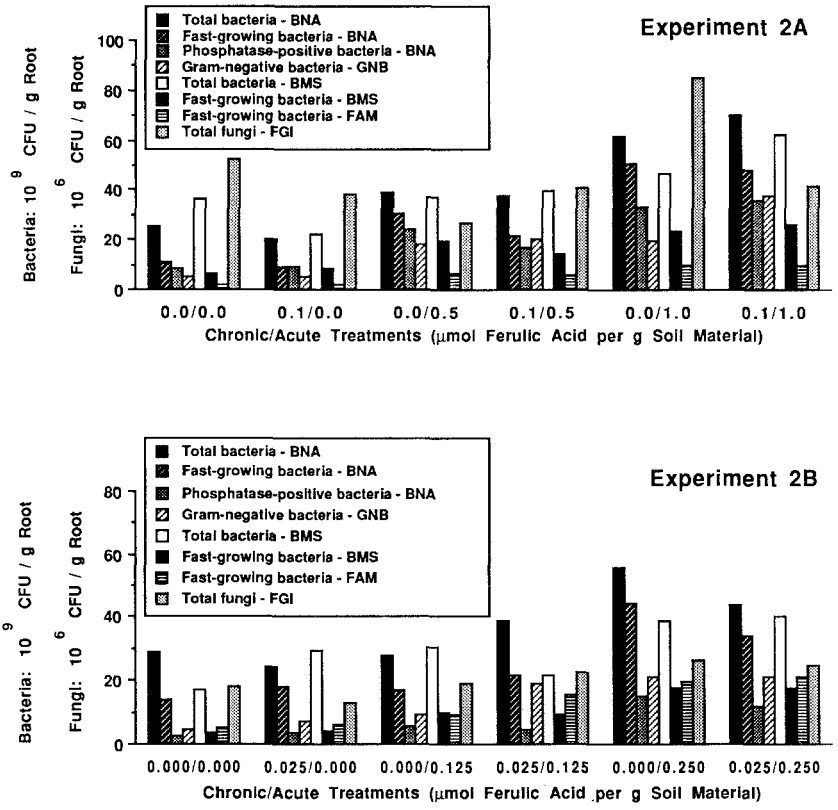

FIG. 6. Effect of chronic and acute applications of ferulic acid to Portsmouth B_1 soil–sand mix on population densities of bacteria and fungi in the rhizosphere of cucumber seedlings. Legend for Figure 3 details planting and treatment schedules. Populations recovered on different media (see Methods and Materials for media abbreviations) are shown.

ferulic acid treatments tended to increase numbers of fungal propagules, increases were significant only in experiment 2B.

DISCUSSION

Phenolic acids occur in all higher plants and often have allelopathic properties when released into the environment. Once in the soil, the compounds modify the microbial ecology of the soil as demonstrated with experiments reported here for the rhizosphere and earlier (Blum and Shafer, 1988) for the bulk soil. Thus, responses of plants to phenolic acids in soil may be determined

TABLE 2. INFLUENCE OF ACUTE APPLICATION OF FERULIC ACID ON POPULATION RATIOS OF MICROORGANISMS IN THE RHIZOSPHERE OF CUCUMBER[a]

Population ratio[b]	Acute treatment (μmol/g)					
	Experiment 2A			Experiment 2B		
	0.0	0.5	1.0	0.000	0.125	0.250
FAM – Fast / BMS – Total	0.07	0.16	0.17	0.24	0.47	0.51
BMS – Fast / BMS – Total	0.25	0.44	0.45	0.17	0.36	0.44
GNB – Total / BNA – Total	0.23	0.50	0.44	0.22	0.43	0.43
BNA – Fast / BNA – Total	0.44	0.68	0.75	0.61	0.58	0.79
BNA – Ph / BNA – Total	0.38	0.53	0.53	0.12	0.16	0.27
FGI – Total / BNA – Total	0.0020	0.0009	0.0010	0.00058	0.00063	0.00051

[a] All values averaged over chronic treatments, which were not significant.

[b] Based on recovery on different media (see Methods and Materials): FAM = bacteriological ferulic acid medium; BMS = bacteriological mineral salts medium; GNB = nutrient agar selective for gram-negative bacteria; BNA = bacteriological nutrient agar modified for identification of phosphatase-positive bacteria among the total recovered; FGI = medium for fungi. Fast = bacteria that produced colonies >1 mm diam.; Ph = phosphatase-positive bacteria.

in part by prior responses of microorganisms and changes in the rhizosphere environment.

Controlled experiments with allelochemicals require selection of concentrations for study, and selecting such concentrations is difficult. Actual uptake of allelotoxins from the soil solution determines plant response. Data on concentrations of the compounds in the soil are not necessarily representative of plant uptake. Unfortunately, no data on plant uptake of allelotoxins from field soil are available, so treatments presently used in studies of allelopathy can only reflect information from the soil. Treatments may be based on concentrations of a particular compound (e.g., ferulic acid) or an entire class of compounds (e.g., phenolic acids) extracted from field soil. In the latter case, a single compound at times may be used to represent the entire class. Such approaches clearly present problems. Hypothetically, a large quantity of an allelotoxin may be available in soil over time, but the concentration measured in the soil solution may be low if high rates of input are balanced by equivalent losses. For exam-

ple, concentrations of ferulic, vanillic, and *p*-coumaric acid in soil in a no-till field [rotation of wheat and soybean, *Glycine max* (L.) Merr.] exhibited only minor fluctuations during the first $3\frac{1}{2}$ months of the growing season, suggesting similar rates of input and loss (Blum, unpublished data). Treatments also can be based on inputs to soil, but input estimates are based on litter pools and are crude at best. For example, as much as 600 g wheat straw/m^2 can accumulate in agricultural fields (Greb et al., 1967, 1974). Wheat, barley (*Hordeum vulgare* L.), and oat (*Avena sativa* L.) straw contain 0.3% and 0.21% *p*-coumaryl and ferulyl, respectively (Thelander, 1985), most of which is bound to hemicellulose and cellulose in cell walls. Therefore, the potential inputs of *p*-coumaric and ferulic acids in an agricultural field can be estimated at 1800 and 1260 mg/m^2, respectively, although these estimates are conservative because plant residues involve leaf and root tissue in addition to stems. Based on these input estimates, equivalent inputs to the soil cups used in the present experiments would be 34 μg *p*-coumaric acid/g soil and 24 μg ferulic acid/g soil, respectively. These values exceed the chronic treatment applications of ferulic acid used in the first chronic/acute experiment (0.1 μmol/g soil material = 19.4 μg/g soil material) and in the second (0.025 μmol/g soil material = 4.9 μg/g soil material).

Phenolic acids are depleted rapidly from soil due to microbial utilization of the compounds under favorable environmental conditions in laboratory studies (Blum et al., 1987; Blum and Shafer, 1988), so the compounds were added to the system periodically to maintain desired levels. The sequence of experiments described here allowed examination of responses of the plant–soil system to successively smaller concentrations of ferulic acid, based on the supposition that concentrations in soil are low and relatively stable.

Although plant responses to phenolic acids have been studied earlier, foliar area data were collected in the present experiments to confirm that the compounds had typical effects on the plants (Blum et al., 1987), and rhizosphere responses are interpreted in that context. Experiment 1 was a test of several phenolic acids that had induced substantial changes in microbial populations in bulk soil (Blum and Shafer, 1988), but repeated applications of these compounds at concentrations previously used caused few obvious or detectable changes in the rhizosphere. Phenolic acids stimulated some microbial populations in the rhizosphere in experiment 1, but numbers were variable. Thus, apparent increases in mean populations that were often not significantly different (e.g., suggested by trends in Figure 2) could have achieved significance with increased replication. Nevertheless, significant increases in fast-growing bacteria on BMS in the rhizosphere occurred after only two applications of ferulic acid, and these increases were followed by a stabilization of the population to a level similar to that of controls. This result is consistent with changes that occurred with bulk soil (Blum and Shafer, 1988). Furthermore, increases

in numbers of fungal propagules occurred after increases in bacterial populations in these studies, as in the earlier bulk-soil studies (Blum and Shafer, 1988). However, other aspects of fungal responses were inconsistent in comparison of rhizosphere and bulk-soil studies. In bulk soil (Blum and Shafer, 1988), numbers of fungal propagules were increased by ferulic acid but not by *p*-coumaric acid, but the reverse occurred in the rhizosphere in experiment 1. The root presents a major disruptive influence on the soil as a source of carbon, other nutrients, and chemicals and of physical forces (Curl and Truelove, 1986). Although leaf expansion was inhibited by the compounds in the expected manner, the influence of the root apparently obscured the effects of even high concentrations of phenolic acids applied to the soil.

In two subsequent experiments, the repeated application of a low-concentration solution of ferulic acid did not modify growth responses of leaves or roots to the one-time application of a high-concentration solution. The significant suppression of leaf growth by the combination of a no-chronic (water)/acute treatment in each experiment again verified that the plant–soil system functioned typically with respect to that type of application. These observations supported prior experiments in which chronic exposure of plants to ferulic acid in a nonsterile solution culture system did not influence growth response to a later acute exposure (Blum and Dalton, 1985). In the first chronic/acute experiment, leaf growth was suppressed by both chronic and acute treatments, although effects were independent. In the second chronic/acute experiment, when treatment concentrations were lowered further, chronic treatments did not affect leaf growth, but the suppressive effect of acute treatments on the leaves was still evident. An improved understanding of plant responses to these allelotoxins under field conditions may require development of continuous low-input systems to replace the use of repeated applications that maintain availability of the compounds but also cause fluctuations (Blum and Shafer, 1988; Blum et al., 1987).

As anticipated, acute treatments suppressed root growth. However, the stimulation of root growth (final length and dry weight) that was observed for chronic treatments in the first chronic/acute experiment and suggested ($P < 0.09$, despite the low concentration) in the second was unexpected. In another experiment (Blum and Rebbeck, 1989), ferulic acid treatments caused a consistent suppression of elongation of primary + secondary roots. Furthermore, root growth improved rapidly after ferulic acid was removed from solution culture. However, that study was conducted with plants grown in a nonsterile, aerated nutrient solution that was completely replaced at 48-h intervals. Such liquid culture conditions do not permit establishment of the physical, chemical, and microbial gradients typical of the rhizosphere. The more variable effect of phenolic acids on root elongation in soil versus solution culture probably reflects major differences in the root environment, including differences in mobility of

the compounds, between the two methods. Although root growth responses to ferulic acid cannot be generalized yet, chronic exposure of roots to ferulic acid in the field may elicit plant responses that would not be expected from studies conducted with highly fluctuating concentrations.

The increase of bacterial populations in the rhizosphere induced by ferulic acid in both chronic/acute experiments was not uniform across all populations assayed, as reflected by significant changes in some populations but not in others. Applications of ferulic acid stimulated the proportion of bacteria in the rhizosphere that grew quickly on a medium amended with ferulic acid as the major source of carbon. This is consistent with results from bulk soil. When Portsmouth B_1 bulk soil material was treated with a plant nutrient solution only (Blum and Shafer, 1988), 45% of all bacterial isolates tested were classified as ferulic-acid metabolizers. When bulk soil material was treated with nutrient solution plus ferulic acid, ferulic-acid-metabolizing bacteria increased to 92% of all isolates tested. In the present study, nutrients were incorporated into the soil and periodically added to sustain plant growth, so mineral nutrients were provided for microorganisms as well. Recovery of fast-growing bacteria on FAM from control plants in the first or second chronic/acute experiment was only 7% or 24%, respectively, of the total recovered on BMS. Although the reason for the difference in this proportion between the first and second chronic/acute experiments is unclear, acute ferulic acid treatments approximately doubled the proportion in each experiment. These results suggest that ferulic-acid-utilizing bacteria represent a smaller proportion of the total community in the rhizosphere than in bulk soil.

Ferulic acid (chronic or acute) failed to change significantly the numbers of fungal propagules in the rhizosphere in the first chronic/acute experiment. Different species composition of the fungal communities in the rhizosphere versus bulk soil could explain differences in changes observed for ferulic versus *p*-coumaric acid, but fungi recovered in the assays were not identified. Although acute treatments had no effect on numbers of fungal propagules in the first chronic/acute experiment, acute treatments increased fungi in the second. This inconsistency remains unexplained, unless the significance for fungi in the second chronic/acute experiment occurred by chance alone ($P < 0.05$).

The chronic/acute experiments were intended in part to test the hypothesis that small quantities of ferulic acid added to the soil solution would increase microbial populations that could metabolize the compound and therefore lessen the impact of a subsequent high concentration on the plants. Increases in rhizosphere populations in response to chronic applications, which would have provided evidence for this mechanism, did not occur. Plant responses in the first chronic/acute experiment support the assumption that ferulic acid solution applied in chronic treatments to the soil surface was available in the rhizosphere. In the second, however, neither plants nor microorganisms reponded to

the very low concentrations applied in chronic treatments, so the presence of the compound in the rhizosphere was not confirmed in that case. Acute treatments caused changes of plant growth and rhizosphere populations in both chronic/acute experiments independent of chronic treatments, so the potential for acclimation of the plant-rhizosphere system to phenolic acids remains uncertain.

Effects of allelopathic compounds on rhizosphere microorganisms in these experiments were detected in several broadly defined types of microorganisms. Pathogens in the rhizosphere that infect roots cause diseases that can have major impact on plant growth, development, and mortality. However, noninfectious rhizosphere microorganisms also influence plant growth and function through competition for nutrients, production of toxins, stimulation or suppression of parasites, release of growth regulators, or improvement of nutrient relations (Curl and Truelove, 1986). One example of an effect of ferulic acid on a potentially growth-promoting population occurred in the chronic/acute experiments, when acute treatments increased populations of bacteria that release phosphate from organic complexes. Responses of plants to allelopathic compounds in nonsterile systems probably represent a balance of direct effects on the plant, indirect effects caused by microbial populations that have been suppressed, and indirect effects caused by other populations that have been stimulated. Such interactions are extremely complex but should be carefully studied for a thorough understanding of the importance of allelopathic substances in the field.

In summary, these experiments demonstrated that allelopathic phenolic acids in soil after rhizosphere ecology in terms of both plant response (root growth) and changes in population densities of bacteria and fungi in adjacent soil. Some changes in bacterial populations in the rhizosphere were consistent with changes induced by phenolic acids in earlier studies with bulk soil, but population responses of fungi to specific phenolic acids in the rhizosphere were different from responses in bulk soil (Blum and Shafer, 1988). The physical and chemical influences of the root itself may explain the differences in effects on bulk soil versus the rhizosphere. A major increase in microbial populations associated with roots was rejected as an explanation of the failure of chronic concentrations of ferulic acid to acclimate cucumber plants to subsequent high concentrations in liquid culture (Blum and Dalton, 1985) or soil. The magnitude of microbial mediation of plant responses to allelopathic compounds in nonsterile systems may remain uncertain until techniques can be developed to simulate a balance of concentrations, inputs, and sustained availability typical of the compounds in field soils.

RESPONSES OF TWO HYMENOPTERAN PREDATORS TO SURFACE CHEMISTRY OF THEIR PREY: SIGNIFICANCE FOR AN ALKALOID-SEQUESTERING CATERPILLAR

Abstract—Larvae of *Uresiphita reversalis* (Guenée) (Lepidoptera: Pyralidae) sequester quinolizidine alkaloids from their leguminous hosts and store them primarily in the cuticle. Stored alkaloids are lost with the last larval molt. Extracts of late-instar larvae and of pupae were applied to larvae of the potato tuber moth, *Phthorimaea operculella* (Zeller) (Gelichiidae), which are normally palatable to two hymenopteran predators, the Argentine ant, *Iridomyrmex humilis* (Mayr) (Formicidae), and the paper wasp, *Mischocyttarus flavitarsus* (Sauss.) (Vespidae). Larvae of *P. operculella* treated with alkaloid extracts of *U. reversalis* larval exuviae, or with surface extracts of whole larvae, were deterrent to both predators, compared to untreated prey. Extracts of pupal exuviae added to *P. operculella*, however, were not deterrent. *P. operculella* larvae treated with the authentic alkaloids sparteine and cytisine were also deterrent to these hymenopteran predators. Storage of small but concentrated amounts of plant secondary compounds in the cuticle appears to be an efficacious means of defense against at least two common predators of lepidopteran larvae.

Key Words—Lepidoptera, Hymenoptera, predation, sequestration, chemical defense, cuticle.

INTRODUCTION

Many Lepidoptera have evolved mechanisms that serve defensive functions against vertebrate and invertebrate predators. Examples of chemical defense are

well known (Blum, 1981; Brower, 1984; Witz, 1990), including defense derived by sequestration of host-plant secondary compounds, reinforced by aposematic characteristics of larvae or adults. Of 35 studies on chemical defense of Lepidoptera appearing in the literature in the last 20 years (Witz, 1990), only seven specifically dealt with invertebrate predators, in spite of the fact that invertebrates have been implicated as major mortality factors in lepidopteran populations in natural and experimental systems (e.g., Dempster, 1984; Feeny et al., 1985; Jones, 1987; Shaw et al., 1987; Steward et al., 1988; Watt, 1989) and also may have indirect negative effects on larval fitness (Stamp and Bowers, 1988). Consequently, invertebrate predators potentially exert a large selection pressure on lepidopteran populations.

It is assumed that aposematism evolved in response to vertebrate predators such as birds because they are visual hunters capable of learning to avoid distasteful prey. In addition, aposematic Lepidoptera often store plant compounds that are known vertebrate toxins, such as cardenolides (e.g., Brower, 1984), alkaloids (e.g., Rothschild et al., 1979; Kelly et al., 1987; Boppré, 1990; Montllor et al., 1990), cyanogens (e.g., Jones et al., 1962; Nahrstedt and Davis, 1983; Franzl et al., 1988), or the more unusual azoxyglycosides (Bowers and Larin, 1989). As a result of the association between aposematism and vertebrate predation, the importance of invertebrate (arthropod) predation on aposematic species is seldom studied. Although the responses of many invertebrate predators may not be affected by visual aposematic characteristics, it is possible that chemical protection of asposematic species may be effective against invertebrates as well as vertebrates (e.g., Berenbaum and Miliczky, 1984; Bowers and Larin, 1989). Moreover, invertebrate predators can learn to avoid chemically defended prey. For example, an insect predator (Mantidae) of the aposematic milkweed bug, *Oncopeltus fasciatus*, learned to avoid palatable *O. fasciatus* after encountering cardenolide-containing conspecifics (Berenbaum and Miliczky, 1984); whether aposematism facilitated learning in this case was not clear.

Larvae of *Uresiphita reversalis* have typically aposematic features. They are brown with white, black, and yellow patches laterally on each segment, feed conspicuously on terminal branches of their hosts (Bernays and Montllor, 1989), and sequester quinolizidine alkaloids (QAs) from *Genista monspessulana* (Papilionaceae), a major host plant in California (Montllor et al., 1990). Although the larvae excrete most of the QAs ingested, about 1% is retained and deposited in the larval cuticle, which contains about 2.5% dry weight QAs in the last larval instar (Montllor et al., 1990). Two hymenopteran predators, the Argentine ant, *Iridomyrmex humilis*, and the paper wasp *Mischocyttarus flavitarsus*, have been shown previously to strongly prefer other, more palatable, lepidopteran larvae over *U. reversalis* in choice tests (Bernays, 1988; Bernays and Cornelius, 1989). Because observations indicated that these two predators rejected *U. reversalis* larvae after only superficial contact with them, we thought

that these predators might be responding to chemicals in the larval cuticle. Specifically, we sought to determine whether the alkaloids that *U. reversalis* sequesters from its host plant and deposits in the larval cuticle might influence the behavior of invertebrate predators, apart from the other characteristics of these larvae (e.g., hairness and conspicuous coloration). We performed several experiments to test the response of ants and wasps to alkaloids and alkaloid extracts from *U. reversalis* on the surface of otherwise palatable prey, larvae of *Phthorimaea operculella*.

METHODS AND MATERIALS

Prey and Predators. Late-instar larvae of *P. operculella*, reared on potatoes in an insectary, were used as palatable prey. These larvae could be treated with various *U. reversalis* extracts and alkaloid solutions, in order to determine whether such treatments affected their acceptance to the Argentine ant *I. humilis*, and the paper wasp *M. flavitarsus*. *U. reversalis* were reared in an insectary on cut branches of French broom, *G. monspessulana*.

Treatments of Experimental Prey. Alkaloidal extracts (to be added to experimental prey) were made from dried material in methanol, taken up in HCl, basified, and extracted with chloroform or dichloromethane as previously described (Montllor et al., 1990), yielding alkaloids in the free base form. Three types of alkaloidal extracts were made from *U. reversalis* larvae. The first was an extract of cast exuviae (total of 112 mg dry weight) from approx. 90 last-instar larvae. The dried extract was dissolved in 400 μl of methanol, and 10 μl was added to each of 20 *P. operculella* larvae recently frozen on Dry Ice. This gave an extract equivalent of approx. two *U. reversalis* exuviae per test larva (assuming 100% efficiency of extraction, which is not likely). Control *P. operculella* larvae were treated with 10 μl of methanol alone. Pairs of treatment and control larvae then were presented to foraging ants as described below (ant experiment 1).

Second, pupal exuviae, which contain little or no alkaloid (Montllor et al., 1990), were collected when adults eclosed and were extracted by the same method as larval exuviae. An extract of 105 mg of pupal exuviae (from approx. 200 pupae) was taken up in 400 μl of methanol, and 10 μl was applied to each of 15 *P. operculella* larvae. Another group of 15 *P. operculella* larvae were treated with the larval exuviae extract described above. Pairs of larvae, one treated with larval exuviae extract, and the other with pupal exuviae extract were presented to foraging ants (ant experiment 2). A separate extract of 80 mg of pupal exuviae was taken up in 152 μl of methanol, and 5 μl was applied to each of 20 test larvae of *P. operculella*, giving the same concentration of extract per test larva as in ant experiment 2. These were paired with solvent-treated controls and presented to ants in choice tests (ant experiment 3).

Third, and finally, a surface extract of 100 late-instar *U. reversalis* larvae (freshly killed by freezing on Dry Ice) was made by swirling them in chloroform for 1 min. The dried extract was redissolved in 200 μl of chloroform, and 5 μl was added to *P. operculella* larvae (an extract equivalent of approx. 2.5 *U. reversalis* larvae per test larva). Pairs of extract-treated and solvent-treated larvae were presented to ants (ant experiment 4) and wasps as explained below.

In order to confirm that QAs in larval extracts might account for predator reactions, authentic quinolizidine alkaloids, sparteine (obtained from R. Molyneux, USDA, Albany, CA) and cytisine (Sigma Chemical Co.), were also used to treat *P. operculella* for choice tests. These are similar to, although not the same as, the QAs found in the plant and insect (dehydroaphylline and *N*-methylcytisine have been identified tentatively as the major alkaloids in the host plant) and have a positive effect on feeding and growth of larvae (Montllor et al., 1990). Larvae of *U. reversalis* contain approximately 17 μg total QAs per insect, derived from the host plant (Montllor et al., 1990). Alkaloid solutions were added to *P. operculella* larvae to give concentrations of 25 or 100 μg cytisine/test insect, and 25, 50 (wasp experiments only), or 100 μg sparteine/insect. Pairs of larvae, one alkaloid-treated and one solvent-treated, were presented to ants (ant experiments 5–8) and wasps in choice tests.

Predator Choice Tests. For ant trials, experimental larvae were placed on a 9-cm-diam. filter paper, one pair at a time, under a small potted citrus bush where large numbers of ants were foraging for homopteran honeydew in the greenhouse. For every pair of control and treated larvae, the number of ants contacting each larva was counted at 10-sec intervals (trials were videotaped) and summed over the duration of each trial. A trial lasted 1 min, unless ant activity was low; in such a case, the trial was allowed to continue up to a maximum of 2 min. The total number of ants at control and treated larvae were averaged for all the trials in an experiment (N = 11–20), and the means compared with a paired t-test.

The response of wasps to treated larvae was determined by placing a Petri dish containing a pair of larvae in the greenhouse where several nests of foraging wasps had been established (see Bernays, 1988). As soon as one of the pair was removed, a new pair of larvae was set out. Between each trial, the position of the control and treated larva was reversed to avoid any positional bias. There were at least 15 trials for each experiment. The numbers of treatment or control larvae taken first by the wasps was compared using a sign test.

RESULTS

Ant Experiments. P. operculella larvae that had been treated with extracts of *U. reversalis* fifth-instar exuviae or with chloroform surface extracts of fourth- and fifth-instar larvae were contacted by significantly fewer, and/or were con-

tacted for shorter times by foraging ants in greenhouse choice tests, compared to solvent controls (experiments 1 and 4, Table 1). Because of the nature of the assay, it is not possible to determine whether ants were deterred or repelled by these extracts; we will only assume that ants were deterred. Similar extracts of larval exuviae had been shown previously to contain 2.5% (dry weight) alkaloid (Montllor et al., 1990), presumed to be sequestered from the host plant *G. monspessulana*. The surface extracts of *U. reversalis* gave a positive indication for the presence of alkaloids (Montllor, personal observation) by forming a precipitate when mixed with a solution of potassium iodide and iodine (Montllor et al., 1990), although levels were not quantified.

Extracts of larval exuviae were significantly more deterrent than pupal exuviae of *U. reversalis*, and pupal exuviae did not significantly deter ants when paired with solvent controls (experiments 2 and 3, Table 1). Extracts of whole pupae previously had been shown to contain little or no alkaloid (Montllor et al., 1990), and pupae have been attacked by *Iridomyrmex humilis* and other (unidentified) species of ants in the insectary and the field (Montllor, personal observation).

Finally, ants were deterred by *P. operculella* larvae that had been treated with 25 or 100 μg of cytisine, or with 100 μg of sparteine, compared to solvent controls. Ants did not discriminate between control and test larvae treated with 25 μg of sparteine (Table 1). Thus, cytisine is a more effective deterrent, and in this context, it is interesting that cytisine was shown to be more phagostimulatory to *U. reversalis* than sparteine when added to an artificial substrate (Montllor et al., 1990).

TABLE 1. MEAN TOTAL NUMBER OF ANTS CONTACTING TREATED (*T*) AND CONTROL (C) *P. operculella* LARVAE IN PAIRED CHOICE TESTS[a]

Ant exp.	Treatment/control	*N*	Ants (*N*)		*P*
			T	C	
1	Larv exuv/Solv	15	2.7	17.8	0.002
2	Larv exuv/Pup exuv	13	1.7	5.9	0.03
3	Pup exuv/Solv	19	14.4	16.5	ns

6	Cytisine (100 μg)/Solv	16	6.9	17.7	<0.0001
7	Sparteine (25 μg)/Solv	14	7.1	9.2	ns
8	Sparteine (100 μg)/Solv	20	7.7	11.8	0.01

[a] *N* = number of trials. *U. reversalis* extracts: Larv exuv = fifth-instar exuviae; Pup exuv = pupal exuviae; surface = late-instar surface. Solv = solvent control (MeOH or $CHCl_3$). *P* value derived from *t* test (one-tailed); ns, $P > 0.08$.

Wasp Experiments. M. flavitarsus, given a choice between a *P. operculella* larva treated with a surface extract of *U. reversalis* or a solvent-treated control larva, took control larvae first in 75% (15/20) of the trials (Figure 1). *P. operculella* treated with 100 μg of sparteine or cytisine, or 50 μg of sparteine, were also deterrent to wasps relative to controls (wasps took control larvae first in 13–14 of 15 trials in each experiment), but alkaloids at the lowest concentration (25 μg/larva) had no statistically significant effect on wasp choice (Figure 1).

DISCUSSION

Extracts of larval cuticle or surface extracts of whole larvae of *U. reversalis* were highly deterrent to ants and wasps, as were authentic alkaloids, when added to the surface of the normally palatable *P. operculella* larvae. These two hymenopteran predators were shown previously to be deterred by *U. reversalis* larvae: the paper wasp *M. flavitarsus* avoided larvae of *U. reversalis* as prey (Bernays, 1988), and Argentine ants spent significantly more time contacting *P. operculella* compared to *U. reversalis* larvae in choice tests in which larvae were freshly killed (Bernays and Cornelius, 1989). Our results suggest that at

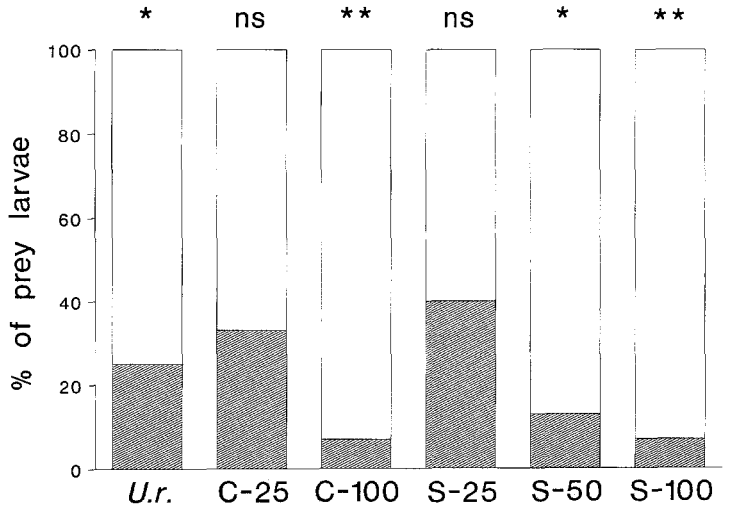

Fig. 1. Proportion of treated (hatched portion) and solvent control (open portion) *P. operculella* larvae taken first by foraging wasps (*M. flavitarsus*) in six experiments. Extract or chemicals added to dead larvae: *U.r.* = surface extract of late-instar *U. reversalis*; C-25 = 25 μg cytisine; C-100 = 100 μg cytisine; S-25, -50, and -100 = 25, 50, or 100 μg sparteine. $N = 15$ trials for each experiment, except *U.r.* ($N = 20$) and C-25 ($N = 27$). Sign tests within experiments: $*P < 0.02$; $**P < 0.001$; ns = $P < 0.05$.

least part of the deterrence of *U. reversalis* for these predators is due to the alkaloids sequestered from the host plant and deposited in the cuticle. Preliminary results suggest that cocoon silk also contains QAs (Wink, personal communication); if larval silk also contains QAs, this may add to the protection of larvae in the natural environment, since larvae feed and rest on leaves sparsely spun with silk.

Sparteine and cytisine only deterred wasps at the higher concentrations used, and the same was true for sparteine and ants, showing that deterrence of alkaloids to ants and wasps can be dosage-dependent. The high levels of QAs required to elicit a response from wasps (probably three times that found in the larval cuticle) and the differential effects of the two authentic alkaloids for ants indicate that the composition of the sequestered alkaloids may be important to predator deterrence or that other larval factors, such as hairiness or silk production, may be involved. The *Genista* host plant contains up to 27 alkaloids (Montllor et al., 1990), and we were not able to reflect the composition of *U. reversalis* cuticle with authentic alkaloids.

Deposition of plant compounds in the integument of larval Lepidoptera has not been studied extensively, but several examples are known. Included are pyrrolizidine alkaloids in *Creatonotos transiens* (Egelhaaf et al., 1990; von Nickisch-Rosenegk et al., 1990b; Boppré, 1990); cannabinoids in *Arctia caja* (Rothschild et al., 1977); and cardiac glycosides in *Syntomeida epilais* (von Nickisch-Rosenegk et al., 1990a). Larvae of *Zygaena trifolii* store cyanoglycosides in cuticular cavities (Franzl et al., 1988). Storage of plant secondary compounds in the integument appears to be an efficacious means of deterring potential predators: only a small portion of plant compounds ingested (about 1% in the case of *Uresiphita*) needs to be sequestered, if they are concentrated in the cuticle, in order to reach concentrations that are potentially deterrent to predators. Sequestration of larger amounts may pose potential autotoxicity problems, although little is known of the effects of most alkaloids on insects (Brattsten, 1986). Alternatively, or in addition, uptake may be physiologically difficult or "expensive" to accomplish; there is evidence that uptake of QAs is facilitated by a carrier in the gut of *U. reversalis* (M. Wink, unpublished), as has been found in *Creatonotos* for pyrrolizidine alkaloids (Wink and Schneider, 1988), and in a ctenuchid for cardiac glycosides (von Nickisch-Rosenegk et al., 1990a).

The significance of predators to *U. reversalis* in the natural habitat was estimated in long-term observations in the field (Bernays and Montllor, 1989). Predation was estimated to account for between 15 and 40% of mortality of young larvae on *Genista monspessulana*, and mortality was reduced when predators were excluded. In the field, wasps (Vespidae) and hemipterans (Anthocoridae) were observed preying on larvae. In addition, *Chrysoperla carnea* (Chrysopidae) and unidentified spiders (Thomisidae and Salticidae) did con-

sume larvae in no-choice experiments in the laboratory (Bernays and Montllor, 1989). An examination of responses of nine species of invertebrate predators to larvae of *U. reversalis* suggests that larvae are unpalatable to all but three (Montllor, Cornelius, and Bernays, unpublished). Therefore, the deterrence of *U. reversalis* to potential arthropod predators, without being absolute, is still impressive. Considering particularly the potential impact of such predators as ants and wasps on lepidopteran larvae (e.g., Gould and Jeanne, 1984; Jones, 1987; Laine and Niemela, 1980; Risch and Carroll, 1982; Skinner and Whittaker, 1981; Weseloh, 1989), the degree of deterrence documented here is probably a significant advantage.

(Received May 31, 1990; accepted October 9, 1990)

Abstract—Predator-based repellents have been used experimentally to control wildlife damage in both agriculture and forestry, but they have not always been effective. We examined the relative importance of cover and predator odors in forage patch selection by Townsend's vole, *Microtus townsendii*, and its behavior related to cover and predator cues. Experiments were conducted in which forage patch and area choices were related to available habitat alternatives. Outdoor enclosures were divided into halves: one side was treated and the other used as a control. Treatments consisting of "cover," "repellent," and "cover plus repellent" were compared to controls (no cover, no repellent). In the absence of cover, voles preferred to feed on the side without repellents. When cover was present, voles preferred to feed on the side with cover, regardless of whether or not repellents were present. Voles visited more feeding stations on the side without cover when repellents and cover were present than they visited during cover-only treatments. These additional feeding stations, visited outside of cover, were used only lightly as food sources. The amounts of oats eaten by voles decreased with increasing distance from cover. This inverse relationship had a steeper slope in cover-only treatments compared to cover plus repellent treatments. A selection model based on forage patch selection and a habitat preference hierarchy is proposed. We conclude that predator odors are effective as repellents, but their efficacy depends on habitat conditions. Managers intending to use

predator-based repellents must ensure that alternative sites available to pests are better quality habitat than that in areas to be protected.

Key Words—Wildlife damage, Townsend's vole, *Microtus townsendii*, predator odors, repellents, cover.

INTRODUCTION

As intensive reforestation becomes more widely practiced in North America, wildlife pest problems are becoming more evident, especially in young forest plantations. Damage to forest regeneration projects caused by deer, snowshoe hares (*Lepus americanus*), and rodents can be considerable (Crouch, 1969; Black et al., 1979; Maguire, 1989). Seedlings can be killed by clipping, and established trees can be damaged through debarking and girdling of their stems (Sullivan and Sullivan, 1982; Harper and Harestad, 1986; Sullivan and Sullivan, 1986).

Predator odors affect behavior of various wildlife species (Stoddart, 1976; Stoddart, 1980; Gorman, 1984), and their use as repellents can reduce feeding damage (Sullivan et al., 1985a,b; 1988a,b). Initially, crude predator-based repellents were made using extracts from feces, urine, and scent glands of predators (Sullivan et al., 1985a,b). The major sulfur-containing compounds in these materials were identified as 2-propylthietane, 2-pentylthietane, and 3-propyl-1,2-dithiolane (Crump, 1978, 1980; Crump and Moors, 1985). These compounds were tested for their repellency to voles (Sullivan et al., 1988a) and a mixture of 2-propylthietane and 3-propyl-1,2-dithiolane has been suggested for commercial repellents. These compounds can be synthetically produced in large quantities and incorporated into controlled-release devices.

Predator-based repellents depend on an innate avoidance of predator cues by prey species. Gorman (1984) showed that this response is innate by demonstrating that common voles, *Microtus arvalis*, that have been isolated for at least 5000 years on an island devoid of mammalian predators, strongly avoided the odor of anal gland preparations from ermine, *Mustela erminea.*

Predator-based repellents are not always effective in field trials because environmental factors apparently influence their efficacy. If predator-based repellents are to become effective tools for controlling wildlife damage in forests and agricultural crops, the constraints imposed by environmental factors must be examined.

Field experiments involving animal behavior are difficult to design and conduct because many variables cannot be controlled. For this reason our experimental trials were conducted in bioassay pens. Although pen trials allow variables to be controlled, animals in pen trials are not subjected to all environmental influences encountered in the field, and their behavior may

deviate from that in the wild. Given this potential constraint, the purpose of our experiment was to examine use of cover and food in the presence or absence of predator semiochemicals. Cover, food, and predator odors are basic requirements or stimuli of animals. Even if animals are penned, they need to feed and should continue to be vigilant. It is reasonable to assume that if test animals are given the appropriate stimuli in captivity, then their actions should reveal behavioral processes concerning trade-offs in response to these stimuli.

Animals living in a patchy environment must travel to find food and meet their other requirements. During periods of travel, they are exposed to many risks. Individuals unsuccessful in their search for food or spending too much time and energy doing so are liable to starve, fail to reproduce, or risk predation. Animals should behave so as to minimize these combined risks (Holmes, 1984; Lima et al., 1985; Anderson, 1986; Lima and Valone, 1986).

Prey can avoid predators by moving about under or near cover (Rose and Birney, 1985; Getz, 1985). Another method of predator avoidance is linked to predator cue recognition. Many mammalian predators have specialized scent glands that are used to mark their territories. Although these secretions are of adaptive significance as pheromones to the emitter, they can be a detriment to the emitter by acting as kairomones to prey species. Prey species avoid these odors or reduce their activity in the presence of them (Stoddart, 1976, 1980; Gorman, 1984; Sullivan, 1986; Sullivan et al., 1988b). Recognition of and response to predator odors by prey is of adaptive significance because it reduces predation risk.

Given that voles are attracted to cover and repelled by predator cues, some process of balancing the risks of predation while meeting energy requirements must occur when both cover and predator cues are encountered simultaneously. Our objectives were to examine behavioral processes and to determine the relative importance of cover and predator cues as they relate to forage patch selection by Townsend's vole, *Microtus townsendii*.

METHODS AND MATERIALS

Test Animals. Townsend's voles were live-trapped from the George C. Reifel Migratory Bird Sanctuary in Delta, British Columbia, between September 1988 and September 1989. In British Columbia, this species can be found in the alluvial areas of the Fraser River Delta and similar areas on Vancouver Island. Its prefered habitat consists of moist fields and sedge meadows. The voles were held individually in wire-top animal cages and fed a diet of Purina Laboratory Rat Chow and whole oats ad libitum until needed for experiments.

Bioassay Pen. An outdoor enclosure was divided into three 6 × 11-m pens and vole-proofed by plugging holes and constructing a wire mesh fence (6-mm

mesh size) to a depth of 50 cm below ground between pens. Within each pen, four 20 × 30 × 15-cm plastic nest boxes filled with raw cotton were buried flush to the ground along the transverse midline of each pen (Figure 1). Each nest box was covered with a 50 × 100-cm galvanized pan. To provide cover near the nest boxes, a strip of straw, 5–15 cm deep, was placed along the line of nest boxes. Fifteen feeding stations were established at a 2 × 2-m spacing in a diagonal grid pattern in each half of the three pens. Feeding stations were constructed from two 1-liter plasticized cardboard milk cartons slid one into the other to form a cross. A 5-ml plastic Petri dish was placed in the center of each feeding station to hold oats. Four water bottles were placed in each pen.

Experimental Procedure. In each of four 15-day-long replicates, between September 1 and November 9, 1989, there were three experimental treatments, each paired with a control. Experimental treatments, consisting of "cover," "repellent," or "cover plus repellent" were in one side of the pen and the control, (no cover plus no repellent) in the other side. Treatments were assigned randomly to pen and side. The same treatment was not applied to the same pen twice in a row. Cover was provided by dispersing straw from one 11.4-kg bale to a depth of 5–15 cm over the treatment side of the pen. Repellents, comprised of a 1 : 1 mixture of 2-propylthietane and 3-propyl-1,2-dithiolane, were released from a 4-cm-long piece of 4-mm-diameter PVC in which they were impregnated at 1% by weight (Phero Tech Inc., Delta, British Columbia, Canada). The PVC

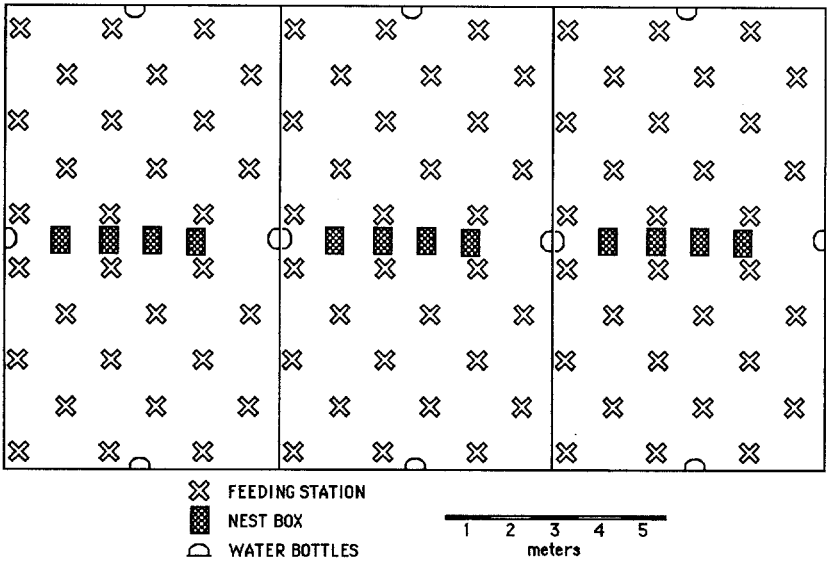

FIG. 1. Three bioassay pens showing nest box and feeding station placement. During each replicate half the pen was treated and the other half used as a control.

release devices were secured by a pin to the inside of each feeding station on the treatment side of the pen. Nonimpregnated release devices were secured to the insides of feeding stations not containing repellents. When treatments were repositioned at the start of each replicate, whole feeding stations with the repellent still attached were moved. The same repellent devices were used through all four replicates.

Before each replicate, the vegetation in each pen was mowed to 1 cm above ground level, burrows and runways previously constructed by voles were buried, and clean dishes filled to capacity were placed in each feeding station. Four female voles then were released directly into the nest boxes in each pen and left undisturbed for four days. On the fifth day, 10 g of oats were placed in each dish. Oats were removed and replaced with 10 g of fresh oats every other day for 10 days. Oats remaining in the feeding dishes were weighed to the nearest 0.1 g.

RESULTS

In the absence of cover, more oats were removed from feeding dishes on sides of pens not treated with repellents than from feeding dishes on sides with repellents (Figure 2). Most feeding from repellent-treated stations occurred

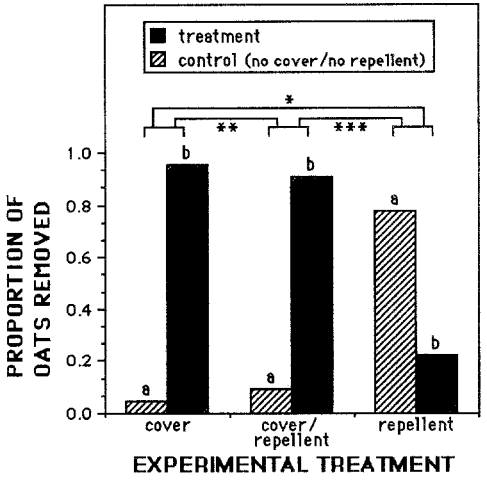

FIG. 2. Proportion of total weight of oats removed by voles from treatment and control sides of pens. Paired bars topped by different letters indicate significant difference between treatment and control, Wilcoxon signed rank test (Sokal and Rohlf, 1981), $P < 0.01$, $N = 4$. Asterisks indicate differences in consumption between treatments, von Mises distribution analysis (Stephens, 1982), $*F_{1,38} = 115.13$, $P < 0.005$; $**F_{1,38} = 5.75$, $P < 0.05$; $***F_{1,38} = 106.96$, $P < 0.005$.

around the periphery of the pens or in close proximity to the nest boxes. When cover was present, voles preferred to feed on the side with cover, regardless of whether or not repellents were present, with a slight, but significant difference between proportions in cover and cover plus repellent treatments (Figure 2). No trend in these proportions over time occurred for repellent and cover plus repellent experimental treatments (Spearman's rank correlation; repellent, $r_s = -0.2$, $P > 0.05$; cover plus repellent, $r_s = -0.8$, $P > 0.05$).

Oats were removed from more stations by voles on the control side in cover plus repellent treatment pens than in cover-only pens (Figure 3). Further evidence for this increased frequency of feeding station visitation was found when we examined the amount of oats removed from feeding stations (Figure 4). More feeding stations were visited on both sides of the pens when the experimental treatment was cover plus repellent. The greatest difference between cover and cover plus repellent treatments is a shift from stations never fed at (0.0 g) to stations fed at low levels (0.1–1.0 g). There is also a slight shift from high-use stations (9.1–10.0 g) to lower levels of use. More feeding stations were visited on the control side of the pen when the experimental treatment was predator odors plus cover than were visited on the control side when the experimental treatment was cover only. Although more feeding stations were visited, most of these were only slightly used. When the experimental treatment was repellent with no cover, stations that were visited on the repellent side were used less intensively than those on the control side (Figure 4). These differences

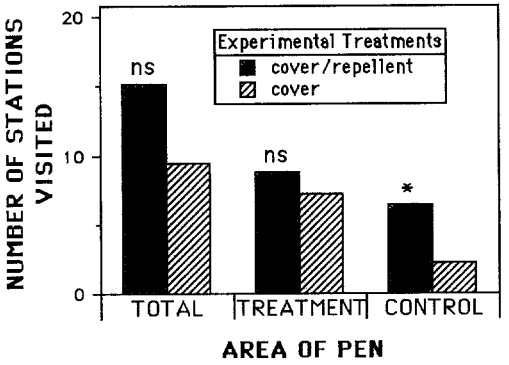

FIG. 3. Average number of stations visited per sampling period in the total, treatment, and control area of the pen for cover and cover plus repellent experimental treatments. Total number of stations visited was not significantly different between treatments, t test with equal variances, $t_6 = 1.05$, $P > 0.05$. Number of stations visited on the control side of the pen were significantly different, t test with equal variances, $t_6 = 3.79$, $P < 0.005$. No significant difference in means for treatment side was found, modified t test for means with unequal variances (Sokal and Rohlf, 1981), $t_3 = 0.625$, $P > 0.05$.

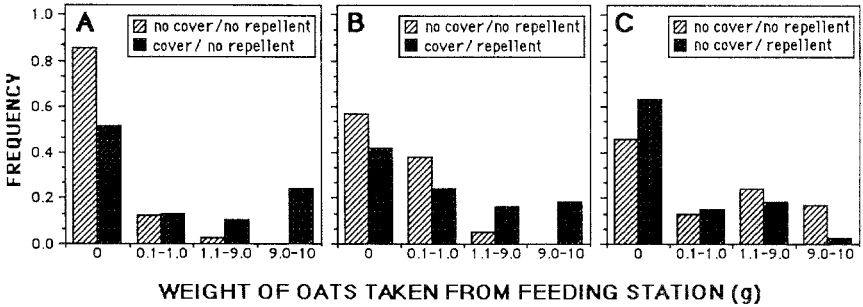

FIG. 4. Distributions of use for (A) cover, (B) cover plus repellent, and (C) repellent treatments. Differences between control and treatment distributions are significant for all treatments; (A) $\chi^2 = 113.96$, $df = 3$, $P < 0.0005$; (B) $\chi^2 = 86.98$, $df = 3$, $P < 0.0005$; (C) $\chi^2 = 41.34$, $df = 3$, $P < 0.0005$. Differences between the overall distributions of A and B are significant, von Mises distribution analysis (Stephens, 1982), $F_{7,210} = 9.33$, $P < 0.005$. This test is designed for use with continuous variables but can be used for discrete variables (as here) providing that there is high significance. Given the level of significance, the test is valid (Micheal Stephens, personal communication, Department of Mathematics and Statistics, Simon Fraser University, Burnaby, British Columbia, Canada).

suggest that in the absence of cover, voles may spend less time at repellent-treated feeding stations and consume a smaller fraction of the available food than at repellent-free stations.

When weights of oats taken from feeding stations (excluding those that were not visited) were compared to relative distance from cover for cover and cover plus repellent experimental treatments (Figure 5), the weight of oats removed decreased with increasing distance from cover. For this analysis, cover was considered to be that supplied by straw or afforded by the pen barriers or nest boxes. When the weights were $\log_{10}$-transformed and linear regressions calculated (Table 1), the r^2 values were significant, and the slopes of the two regression lines were different. Because the slope of the relationship between weight of oats removed and distance was steeper for cover treatments than for cover plus repellent treatments (Table 1), the effect of cover was reduced by the presence of repellents.

DISCUSSION

Although foraging theory predicts that animals maximize their net rate of energy intake, they should do so only within the constraints of predation risk (Krebs and Davies, 1981). Animals balance risks of predation and starvation both in laboratory and field studies (Milinski and Heller, 1978; Sih, 1980;

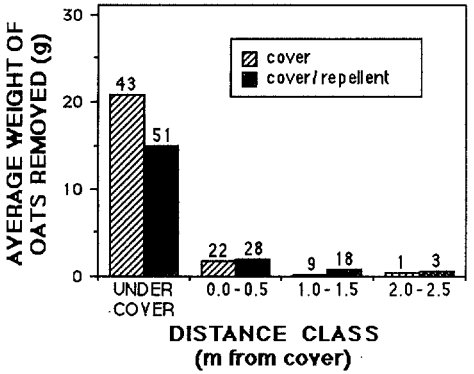

FIG. 5. Weights of oats taken from feeding stations over 10 days compared to distance from cover for cover and cover plus repellent experimental treatments. *N* is given above bars for each distance class and weight combination and is the sum of all stations over the entire experiment. See Table 1 for analysis.

TABLE 1. REGRESSION COEFFICIENTS AND STATISTICS OF LOG_{10} (WEIGHT OF OATS REMOVED) AND DISTANCE FROM COVER FOR COVER AND COVER PLUS REPELLENT TREATMENTS

Treatment	Intercept (SE)	Slope (SE)[a]	r^2	Significance
Cover	1.672 (0.197)	−0.861 (0.113)	0.442	$P < 0.001$
Cover plus repellent	0.986 (0.156)	−0.421 (0.081)	0.217	$P < 0.001$

[a] Analysis of covariance revealed that the treatment by distance interaction is significant, $F_{1,171} = 10.31$, $P = 0.002$.

Holmes, 1984). For animals to balance these risks, choices must be available to them. Food is often patchily distributed, and animals will move from patch to patch to sample individual patches for quality. Once they determine which patches have the "highest" quality, they should feed from those patches first until the patches are depleted or the quality of the patch is reduced. The animal should then move on to the next most favorable patch.

Patch quality is likely affected by many parameters, e.g., food quality and predation risk. Food quality at the feeding stations remained constant, or at least nearly constant, being equalized every second day of each replicate. Only parameters relating to perception of predation risk were altered. Given equal food quality, voles should have preferred low-predation risk patches over high-predation risk patches (Holmes, 1984).

Preferences in patch choice (Figure 2) suggest that cover is more important for security from predators than is avoidance of mammalian predator odors. However, when predator odors and cover were both present, voles visited more food patches on the sides of pens without cover (Figures 3 and 4) and consumed greater amounts of food further from cover (Figure 5, Table 1) compared to when predator odors were not present under cover. The reduction in perceived patch quality due to the presence of predator odors may have caused voles to search more actively for better quality patches, including the feeding stations on the sides without cover, which were used only slightly as food sources. These differences in intensity of feeding station use suggest that voles are either sampling food quality on sides without cover or trying to correct an energy deficit. The latter hypothesis is unlikely given that patterns of intensive patch use are similar for both cover and cover plus repellent treatments (Figure 4). Voles are likely visiting these extra feeding stations to sample food quality and may accept greater exposure for patches of higher food value. They would be balancing the risks of predation associated with both habitat types with varying food levels. They are more likely to search for high-quality food patches outside of cover when perceived predation risk under cover is increased through the presence of predator odors. This type of behavior has been described as "risk-balancing" (Fraser and Huntingford, 1986). In our experiment there was no difference in patch food quality between sides of the pens with and without cover; therefore, voles still preferred feeding under cover, accepting the increased risk of predation imposed by predator odors.

An alternate explanation for these results could be that voles habituated to the predator-based repellents during the first four days of the replicates. This hypothesis can not be tested directly with our experimental results. We hypothesize that such learning behavior would be selected against because any mistake in habituating to the odor when warnings should be taken seriously would be maladaptive.Given that voles isolated from predators for many generations were still repelled by predator odors (Gorman, 1984), this response is innate and clearly of high evolutionary significance. Furthermore, if voles could habituate to predator odors, then the consumption of oats in the repellent-only experimental treatments would have been uniform between treatment and control sides of the pen.

Risk of predation increases with distance from cover (Holmes, 1984). The hypothesis that animals should prefer to forage as close to cover as possible, balancing patch quality with predation risk was upheld by our results (Figure 5). However, when predator cues were present under cover, voles consumed a greater weight of oats as a function of distance from cover than they did when predator odors were not present under cover (Table 1). This result suggests that when predator odors were present under cover, voles sample for patch quality more frequently at greater distances from cover.

Voles are repelled by predator odors (Figure 2) (Sullivan et al., 1988a) and attracted to cover (Taitt et al., 1981; Getz, 1985), and their feeding behavior is affected by both predator odors and cover (Figures 2–4). As voles move about in their environment, they likely acquire information related to cover, food, and predator odors (information variables) and use it to maximize the benefit of their actions. Based on this assumption, a selection model outlining habitat preferences of voles with respect to information variables was developed (Figure 6). When voles are hungry, they begin searching for food, encountering habitats with varying levels of cover, food, and predator odors. If an encountered patch has no cover or contains predator odors, then voles should leave the patch and search for more suitable patches. If better patches are not available, then voles should return to and feed from the highest-value patch available. The selection model is based on a hierarchy of habitat preferences for voles. In our experiment, voles preferred patches with cover and no predator cues over all other patches given equal food quality. The least favored habitats smelled of predators and offered no cover.

Our results support the hypothesis that herbivore behavior is linked to habitat characteristics (Taitt et al., 1981; Holmes, 1984) and that manipulation of these habitat characteristics will cause shifts in areas used by voles (Taitt et al.,

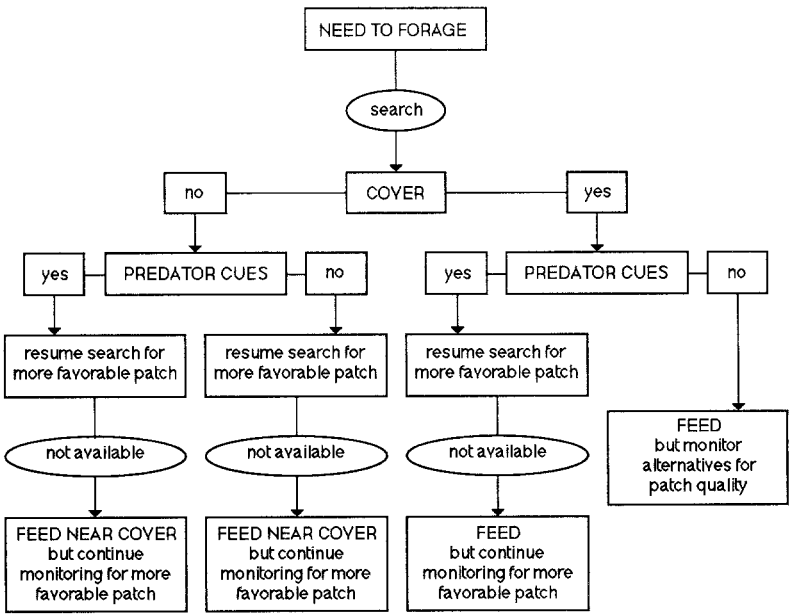

FIG. 6. Selection model outlining forage patch preference hierarchy based on cover, food, and predator cues.

1981). In our model, voles should consider habitat information and internal motivational states to determine which forage patch will be most beneficial to them. Application of predator-based repellents is intended to alter both the habitat information, and internal motivational states of target animals, thereby reducing the perceived quality of a treated forage patch, by increasing the apparent predation risk. If better alternatives are not available to searching voles, then they will be forced to feed in the repellent-treated patches. If voles are able to habituate to predator odors, then they would continue to feed in repellent treated areas until the repellents are reinforced by an encounter with a predator. Paramount to the control of vole damage is the existence or provision of better-quality patches in the vicinity of repellent-treated areas. This is a key factor in the success of any repellent-based management technique. By enhancing preferred browse in plantations, this principle has been used to reduce damage to seedlings by ungulates (Campbell, 1974). The challenge to pest managers is to examine vertebrate pest situations in the context of habitat conditions, not only on site but also adjacent to it, and to ensure that habitat alternatives are better than the areas to be protected.

Acknowledgments—We thank Phero Tech Inc. and The Science Council of British Columbia for providing financial support and the Canadian Wildlife Service and the Canadian Coast Guard for permission to trap animals on land under their jurisdiction.

INTRASPECIFIC VARIATION AND INTERSPECIFIC DIFFERENCES IN SEX PHEROMONES OF SIBLING SPECIES IN *Ctenopseustis obliquana*[1] COMPLEX

(Received August 9, 1990; accepted October 9, 1990)

Abstract—The specific status of *Ctenopseustis obliquana* pheromone-types I, II, and III has been more fully examined. Females of types I and III produce a mixture of (*Z*)-8- and (*Z*)-5-tetradecenyl acetates (Z8–14 : Ac, Z5–14 : Ac). The previously reported different ratios of these two components in females of the two types (type I = 80 : 20, III = 90 : 10) have been reinvestigated. The median ratios of each type differed significantly, although there was some overlap in the ranges of these ratios. A field cage trial showed that males of type III are attracted to females of type I, so the observed differences may be ascribed to intraspecific variation. In contrast to females of types I or III, females of type II produce Z5–14 : Ac but no Z8–14 : Ac. The electroantennogram (EAG) profile of antennae of type II males shows a maximum response to Z5–14 : Ac, while the EAG profiles of types I and III show a strong response to Z8–14 : Ac. In wind tunnel tests using mixtures of these two compounds, type II males prefer blends consisting of all or mostly Z5–14 : Ac, while type I males showed a preference to a mix of 70% Z8–14 : Ac plus 30% Z5–14 : Ac. We found that type I males are attracted to type I females when offered a choice between type I and type II females in a field cage test and that type II males similarly prefer type II females. Males of types I and II have specialist cells for Z8–14 : Ac and Z5–14 : Ac but differ with respect to relative densities of these cells and to further cell types responsive to other alkenyl acetates. Type II *C. obliquana* is considered therefore a sibling species of types I and III. In addition, the amount of Z5–14 : Ac produced by type II females varied geographically. Females from the North

*To whom correspondence should be addressed.

[1]Lepidoptera: Tortricidae: Tortricinae.

Island produced significantly less (median = 1.2 ng) Z5–14:Ac than females from the South Island (median = 2.2 ng). Type II populations in the North Island morphologically resembled sympatric type I, rather than type II from the South Island and are designated as type II (North Island). Type II (North Island) populations have so far been found only at Rukuhia (near Hamilton) and from Kerikeri. In contrast, type II populations are sympatric with type III populations over much of the South Island. In a field cage trial, males of types II and II (North Island) were attracted to females of both II and II (North Island). We tentatively ascribe the differences between type II and type II (North Island) to intraspecific variation.

Key Words—*Ctenopseustis obliquana*, Tortricinae, Lepidoptera, pheromones, (*Z*)-5-tetradecenyl acetate, (*Z*)-8-tetradecenyl acetate, sibling species, blend preferences, electrophysiology, intraspecific variation.

INTRODUCTION

In New Zealand, members of the endemic brownheaded leafroller (BHLR) complex, *Ctenopseustis obliquana* (of authors), are primary pests of horticultural crops (Wearing et al., 1990). Prior to 1984, *C. obliquana* was regarded as a single species (Green and Dugdale, 1982). Studies of the female-produced pheromone of a population from Mt. Albert (Auckland) had identified two components, (*Z*)-8-tetradecenyl acetate and (*Z*)-5-tetradecenyl acetate (*Z*8–14:Ac, *Z*5–14:Ac) in a 4:1 ratio (Young et al., 1985).

Between 1983 and late 1985, BHLR populations from 30 localities from Northland (ND) to Stewart Island (Figure 1) were sampled. Sex pheromone analyses of laboratory-reared females showed that BHLR included "at least three and possibly four sibling species" (Foster et al., 1986) that could be differentiated by sex pheromone components or ratios in the pheromone glands of female moths. These sibling species were called *Ctenopseustis obliquana* types I, II, III, and IV (Foster et al., 1986). The initial separation into four types was based on differences in ratio between *Z*8- and *Z*5–14:Ac (types I, III); presence of *Z*5–14:Ac (type II), and presence of a large quantity of (*Z*)-10-hexadecenyl acetate (*Z*10–16:Ac) (type IV) (Foster et al., 1986; Foster and Roelofs, 1987). It was later shown that the less common type II populations from the North Island differ morphologically from the South Island type II populations (Dugdale, 1990).

The differences perceptible to a human observer may not necessarily be important to male and female moths during courtship and mating. In this paper we examine the pheromone systems of types I, II, II(North Island), and III of BHLR. The components of the pheromone system investigated include female pheromone production, responses of male antennal receptor cells, blend preferences of males flying in a wind tunnel, and the preferences for females by

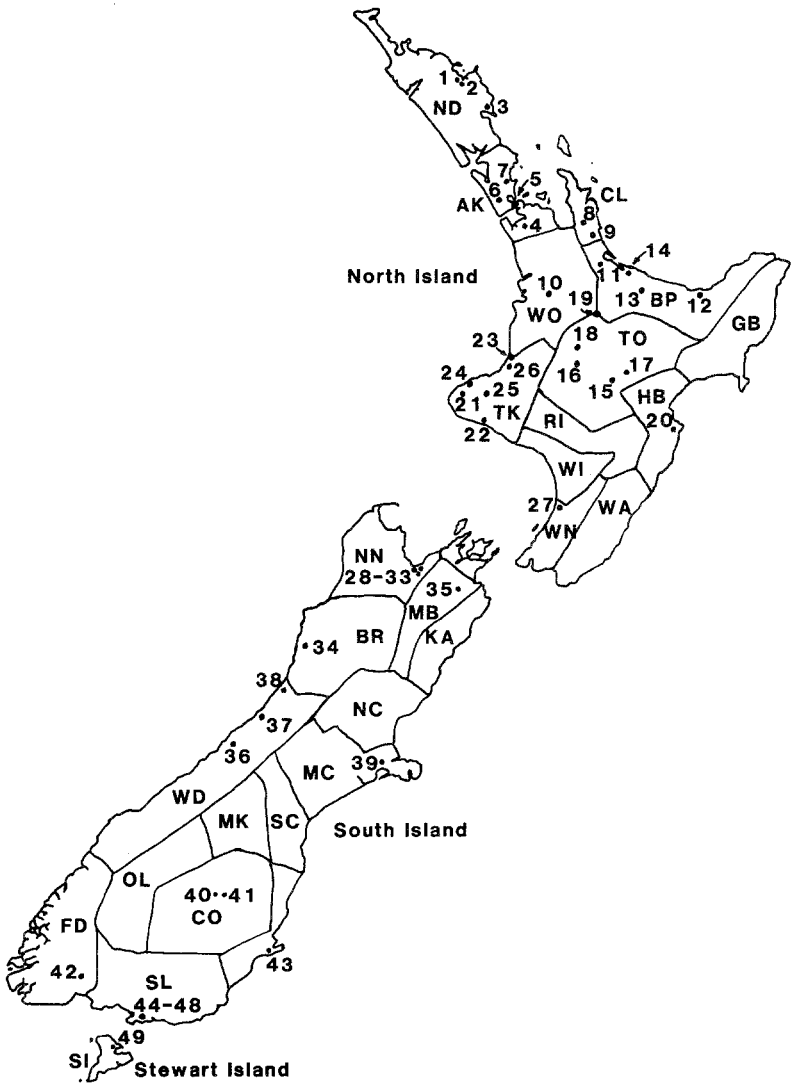

FIG. 1. Map of New Zealand with regional collection codes as defined by Crosby et al. (1976). Collection sites listed in Table 1 are numbered 1–49.

males flying freely in a field cage. These tests have enabled us to distinguish between differences that greatly affect mate choice and differences that do not appear to significantly affect mate choice.

METHODS AND MATERIALS

Collection and Rearing of Insects. Larvae were collected from localities listed in Table 1 or taken from laboratory colonies. Our main laboratory colonies of type I, originally from Mt. Albert, Auckland, of type II originally from Tai Tapu (near Christchurch), of type II(North Island), originally from Rukuhia

[a]Two-letter area codes, e.g., AK, as in Crosby et al. (1976); ° = localities relevant to Foster et al. (1986).

(near Hamilton), and of type III, from Alexandra, were the sources of insects used in the various bioassays unless otherwise specified. Larvae were reared on a semisynthetic diet (Young et al., 1985).

Male and female pupae were incubated separately and underwent different temperature regimes depending on their planned use. Females for use in gas–liquid chromatographic (GLC) analyses of the sex pheromone gland and males for use in wind-tunnel experiments were kept under a reverse-phase light cycle (16:18 light–dark) at 18°C. Insects used in the field cage experiments were maintained on a normal phase light cycle (16:18 light–dark). Temperatures were manipulated in order to synchronize the emergence of adults for use in these field cage experiments. For example, for the comparison of types I and III, a group of larvae from the type I culture were reared at 22°C. The larvae for the type III group were reared at 20°C during early development, followed by periods at 15°C and 10°C. For all field cage experiments, male pupae and the resulting adults were conditioned outdoors in a screen cage sheltered by shrubs; the adults were allowed to feed on 10% honey solution during the conditioning period. Males were released into the field cage when they were 2–3 days old. For the experiment comparing responses of males of types I, II, and II(North Island) to caged females, female pupae underwent the same conditioning as the male pupae. Female pupae used in the earlier type I vs. type III experiment were taken from stocks held under ambient laboratory conditions. Females were fed with 10% honey solution applied to cotton wool plugging the entrance hole of the females container. During the type I vs. II vs. II(North Island) comparison, the honey solution and the feeding substrate were replaced daily to preclude the possibility that fermented food was affecting female behavior.

Capillary Gas Chromatographic Analyses. Pheromone gland epithelia were dissected from 3- to 6-day-old females, approximately 1 hr into the scotophase. Epithelia were individually extracted in 5–10 μl of distilled *n*-pentane for approximately 24 h at ambient temperature. Extracts were analyzed using a Pye Unicam 4500 gas chromatograph with splitless injector and a flame ionization detector. Capillary columns and temperature programs used were: a Quadrex Corporation (New Haven, Connecticut) 50 m × 0.25 mm ID CPS-1 (bonded SP2340 equivalent), at a program of 100–180°C/min after an initial delay of 1 min, and a 50 m × 0.32 mm ID (SGE Ltd., Victoria, Australia) BP-20 (cross-linked polyethylene glycol), at a program of 100–200°C at 4°C/min (delay of 1 min). Nitrogen was used as carrier gas, at a linear flow velocity of 20 cm/sec. Tridecanyl acetate was added to the extracts as an internal standard. Wilcoxon rank-sum tests were used to compare differences in pheromone production between the various groups.

Electrophysiology. The EAG responses of antennae of adult male *C. obliquana* to synthetic samples of monounsaturated acetates and alcohols (10 μg

on filter paper) were determined according to the procedures of Baker and Roelofs (1976). A normalized response profile was produced by comparison of each test response with the response to (*E*)-11-tetradecenyl acetate (*E*11–14:Ac) (10 μg on filter paper) presented alternately. Single cell analyses were carried out at Seewiesen according to the method of Priesner (1983).

Type I and II males were tested by the EAG and single cell analysis techniques. Type III males (Onamalutu Reserve, Marlborough) were tested with the EAG technique only.

Wind-Tunnel Experiments. Wind-tunnel design and techniques used are as described by Clearwater and Triggs (1991). Pheromone sources were rubber septa (Arthur H. Thomas Co., Philadelphia, Cat. No. 1780-B10) each loaded with a total of 1 μg of *Z*5–14:Ac and *Z*8–14:Ac in different ratios (see Figure 7 below). The two chemicals were synthesized by M.H. Benn (Department of Chemistry, University of Calgary, Alberta) and were greater than 98% isomerically pure. The numbers of type I and type II males flying in the plume of the chemicals and landing near the chemical source were recorded.

Field Cage Experiments. If the observed differences in pheromone production of the females from different regions are significant to males, then this may be detected by experiments in which males flying freely in a field cage are offered a choice of females. Females were placed in labeled wood/mesh containers (5 × 5 × 5 cm). The transfers were accomplished without the use of cold immobilization or CO_2 anesthetization. Each container was positioned in the center of a sticky tap (Pherocon IC, Zoecon Corporation, Palo Alto, California) and set out in a 10-m × 10-m × 2.4-m-high field cage. Males from the different localities were lightly dusted with contrasting dye powder, which could be discerned under UV illumination (long wavelength setting, "Chromato vue," Ultra-violet Products, California). The dyes used were from Dayglo Color Division, Switzer Bros. (Cleveland, Ohio). Traps were rerandomized in position daily. At the completion of each trial, the virgin status of each female was confirmed by examination of the bursa copulatrix.

For the type I vs. type III experiment, four containers each with three 2-day-old type III females, and four containers each with the same number of 2- to 3-day-old type I females were set out in sticky traps in a 3 × 3 array, with a single empty trap as a blank. Over the next four days, males were released into the field cage in the late afternoon. Males caught in the study traps were removed for identification (under UV light; to prevent transfer of dye powder between captured males, a fresh wooden spatula was used for each individual). For the type I vs. II vs. II(North Island) experiment, freshly emerged females were used. Females were caged singly, with five containers per type. Traps were hung in a 4 × 4 array (five of each population and a single blank trap). Other details were as for the preceding experiment. Each set of females in con-

tainers was tested for four nights, before being replaced with a fresh set of females for a further four nights.

RESULTS

Pheromone Gland Analyses. Of the 268 individually analyzed females originally collected as larvae from the field, 190 had both Z8- and Z5-14:Ac present, i.e., were either type I or type III of Foster et al. (1986); the remaining 78 had only Z5-14:Ac, i.e., were type II in the sense of Foster et al. (1986). Data from the group of females producing Z5- and Z8-14:Ac were divided into North (type I) and South and Stewart Island (type III) subgroups. Pheromone quantity (i.e., total amount of pheromone in the gland) did not differ between the two subgroups, the median quantities produced being 1.7 ng for both groups. Median pheromone quantity of the type I laboratory colony was the same, 1.7 ng ($N = 35$ females).

The frequency of ratios of Z8-14:Ac is presented in Figure 2. The two groups of females classified as type I and type III have significantly different median ratios ($P < 0.01$) of 84:16 ($N = 114$) and 93:7 ($N = 76$), respectively. However, there is some overlap of the respective ranges of ratios (Figure 2). Females of type III with the consistently lowest proportion of Z5-14:Ac (95:5, Z8:Z5) were collected from Bullock Creek (BR), Nelson Creek, Lake Ianthe, and Franz Josef (WD) ($N = 20$) (see Table 1, Figure 1). The 35 type I females from the laboratory colony (Figure 2C) gave a median ratio of 76:24 (range 94:6–69:31), i.e., a slightly higher Z5-14:Ac content in the pheromone than in the feral type I (North Island) samples.

The data from the type II females were divided into North Island and South and Stewart Island subgroups, types II(North Island) and II, respectively (Figure 3). Pheromone quantity from the two subgroups differed significantly ($P < 0.01$). Type II(North Island) females produced a median of 1.2 ng ($N = 16$), and type II females produced a median of 2.2 ng ($N = 62$).

Electrophysiology. The EAG response profiles of antennae from type I males (Figure 4) could easily be distinguished from those from type II males (Figure 5). The greatest responses of type I antennae stimulated by tetradecenyl acetates were observed to Z8-14:Ac and (*E*)-8-tetradecenyl acetate (*E*8-14:Ac). The response to Z5-14:Ac was lower than that to (*Z*)-7-tetradecenyl acetate (Z7-14:Ac), (*Z*)-11-tetradecenyl acetate and the internal standard, *E*11-14:Ac. Hexadecenyl acetates were generally less stimulatory; (*Z*)-8-hexadecenyl acetate and to a lesser extent Z10-16:Ac elicited the greatest EAG responses of this series.

In the type II population, the greatest EAG responses observed were to

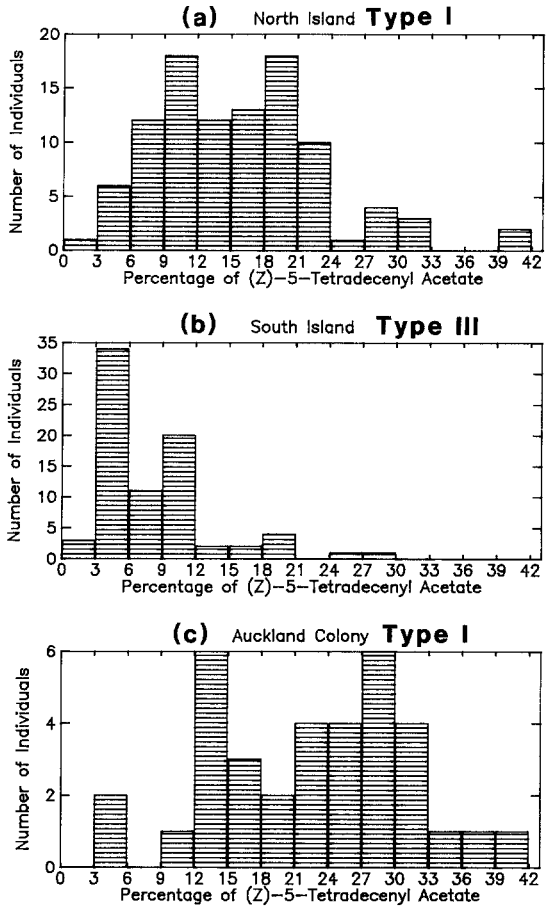

FIG. 2. Distribution of percentages of (*Z*)-5-tetradecenyl acetate in sex pheromone glands of *C. obliquana* [remaining percentage is (*Z*)-8-tetradecenyl acetate], (a) from the North Island (type I) (b) South Island (type III), and (c) the Auckland laboratory colony (type I).

(*Z*)-5-unsaturation in both the tetradecenyl and hexadecenyl acetate series. The response to *Z*8–14 : Ac was always low, indistinguishable from the response to most of the other *Z* isomers, and much smaller than the corresponding response observed from type I antennae.

The observed antennal responses (Figure 6) of type III males collected as larvae from Onamalutu Reserve (Marlborough) resembled the responses of type I (Figure 4), rather than type II males (Figure 5).

Single-cell analysis of sensilla trichodea on type I and type II male anten-

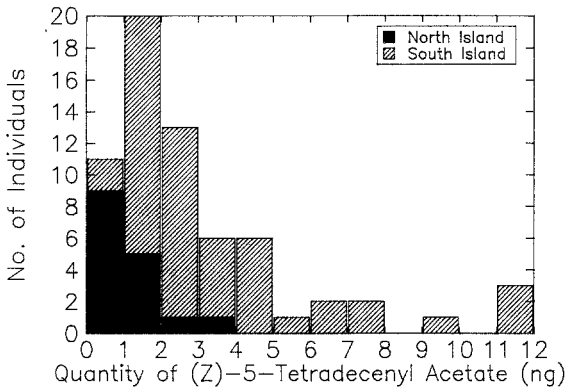

FIG. 3. Distribution of quantity of (*Z*)-5-tetradecenyl acetate in sex pheromone glands of individual females of type II *C. obliquana* from the South Island (shaded bars) and type II from the North Island (solid bars). Median values for the type II(South Island) sample = 2.2 ng, for type II(North Island) = 1.2 ng.

nae revealed the presence on both of specialist cells for *Z*8–14:Ac and *Z*5–14:Ac. The *Z*8–14:Ac cells of type I and the *Z*5–14:Ac cells of type II males consistently showed large amplitude spikes; the *Z*5–14:Ac cells of type I and *Z*8–14:Ac cells of type II males were recorded less frequently and showed spikes of small amplitude. In males of both types, three additional, less common, cell types, responsive to other alkenyl acetates were also discovered. The additional cells found on antennae of type I males responded specifically to *E*8–14:Ac, (*Z*)-8-dodecenyl acetate and (*E*)-8-dodecenyl acetate, while the additional cells on antennae of type II males responded to *Z*7–14:Ac, *E*8–14:Ac, and (*Z*)-10-tetradecenyl acetate.

Wind-Tunnel Experiments. Males from the type I and type II populations responded differently to a range of blends of *Z*5–14:Ac plus *Z*8–14:Ac presented in the wind tunnel (Figure 7). Sources with 100% or 80% *Z*5–14:Ac were significantly more attractive to type II males than sources with 10, 20, or 30% *Z*5–14:Ac ($P < 0.05$, contingency χ^2 analysis). The converse was true for type I males. The response profiles overlapped, with a small number of males capable of flying and landing in response to the optimal blend of the other type.

Field Cage Experiments. In experiments of type I vs. type III, traps baited with type I females caught more type I and III males than traps baited with type III females ($P < 0.05$, ANOVA followed by Fisher's protected LSD test on data transformed to their $\sqrt{x} + 0.5$ values) (Table 2). The catches of the type III females were not significantly different ($P > 0.05$) from the catch of the blank trap. The rate of recapture was low (39% of the type I, 18% of the type

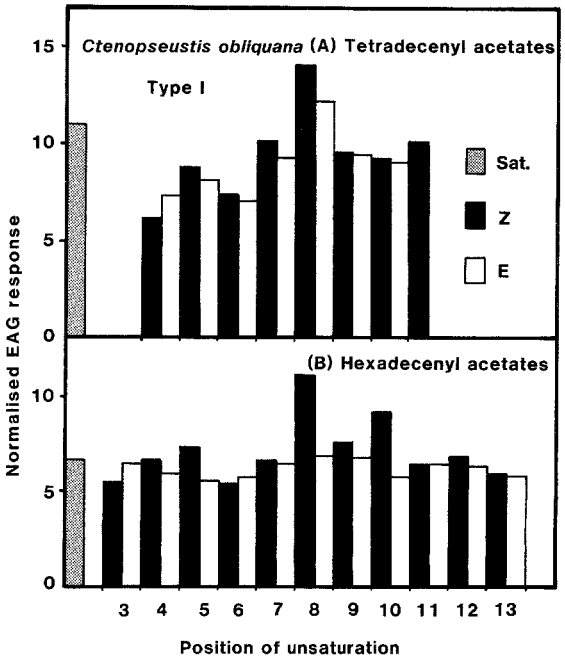

FIG. 4. Electroantennogram responses of antennae from male *C. obliquana* (type I). The profiles are each the average of 10 replicates and show the response to tetradecyl acetate or hexadecyl acetate (Sat) and various tetradecenyl and hexadecenyl acetate isomers. The moths were obtained from a culture of larvae collected from Mt. Albert, Auckland (AK).

III males). The catches of the traps were variable; three of the eight groups of three type I females caught 96% (44/46) of the males.

For type I vs. type II vs. type II(North Island) experiments, type I males were mostly caught in traps baited with type I females (Table 3). Traps baited with type II or II(North Island) females each caught nine [6 ± 2.4% (SE)] of the type I males compared with 125 (87 ± 3.4%) captured by traps baited with the type I females. The catches of type I males in traps baited with the type II and II(North Island) females were not significantly different ($P > 0.05$) from the blank trap catch. The number of males caught in each type I trap varied from 1 to 51.

Traps baited with type II(North Island) females caught very similar numbers of type II(North Island) (50) and type II (53) males. The traps with type II females also caught type II and type II(North Island) males in an almost 1 : 1 ratio (Table 3). However, the traps baited with type II(North Island) females

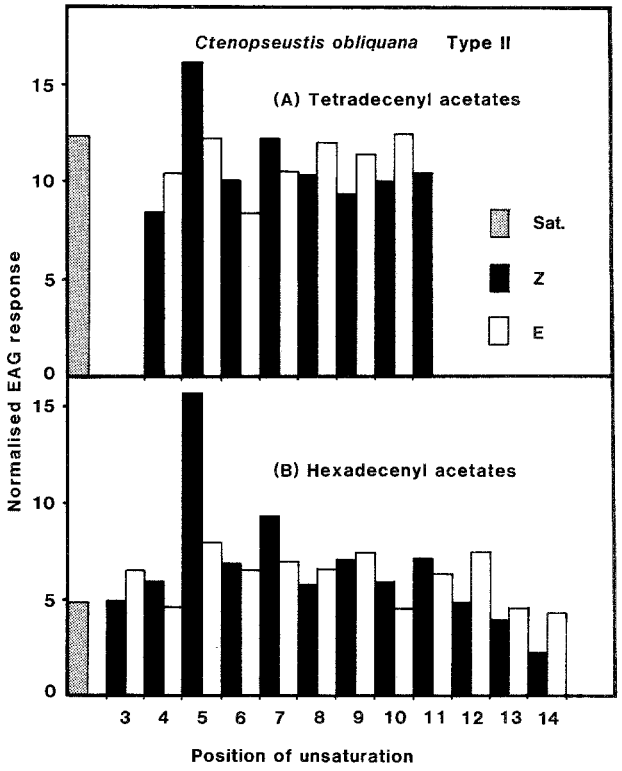

FIG. 5. Electroantennogram responses (as in Figure 4) of antennae of male *C. obliquana* (type II). The profiles are the average of (A) 10 and (B) two replicates. The moths were obtained from larvae collected at Tai Tapu near Christchurch (MC).

captured significantly more males (103) of these two groups than those with type II females (47) ($P < 0.05$, fitted log-linear model).

Of the total number of males released, greater than half were recaptured. Type I males were recovered in greatest numbers (73%) with type II and type II(North Island) males recovered in similar proportions (46% and 49%, respectively).

Distribution. We obtained collections from 49 localities around New Zealand (Table 1, Figure 1). While these are insufficient to establish the boundaries of the populations studied, they suggest that the degree of contact between Z8–14:Ac plus Z5–14:Ac populations (types I/III) and Z5–14:Ac populations [types II, II(North Island)] differed in the North and South Island. In the South Island almost half the collection sites provided individuals of type III and type II, while in the North Island, type II populations were found only in two sites,

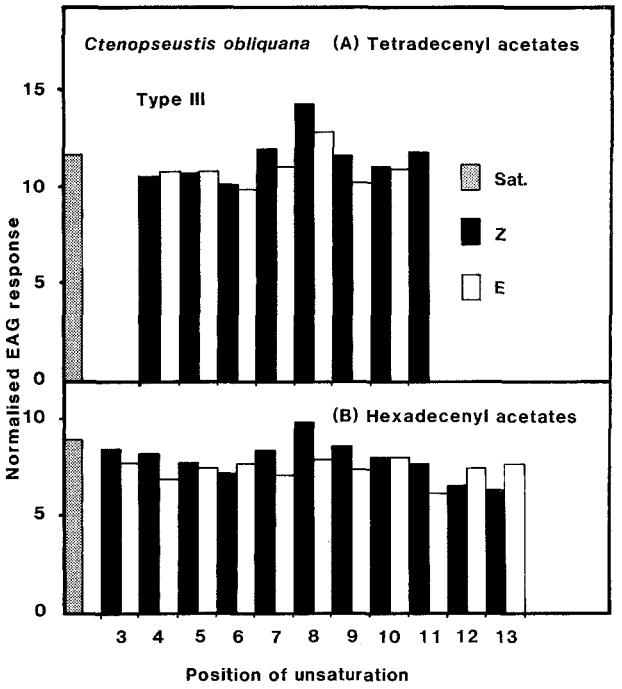

FIG. 6. Electroantennogram response (as in Figure 4) of antennae of male *C. obliquana* (type III). The profiles are the average of (A) 10 and (B) five replicates. The moths were obtained from larvae collected at Onamalutu Reserve (MB).

and only at Kerikeri were they sympatric with type I. Individuals of both types were collected on the same host at the same time of year at Kerikeri.

DISCUSSION

Our preliminary investigation divided *C. obliquana* (sensu Green and Dugdale, 1982) into types I, II and III, primarily on the basis of differing chemical content of the female pheromone gland (Foster et al., 1986). The additional data reported here support the earlier separation of type II from types I and III. Males and females of type II can be distinguished from their types I and III counterparts on the basis of content of female pheromone glands, EAG response profiles of male antennae, spike amplitudes of Z8–14 : Ac and Z5–14 : Ac specialist cells on the antennae of males, preferences for specific blends in wind-tunnel tests and preferences of males for females of their own type in field-cage tests. We conclude that these differences indicate that type II is a sibling species

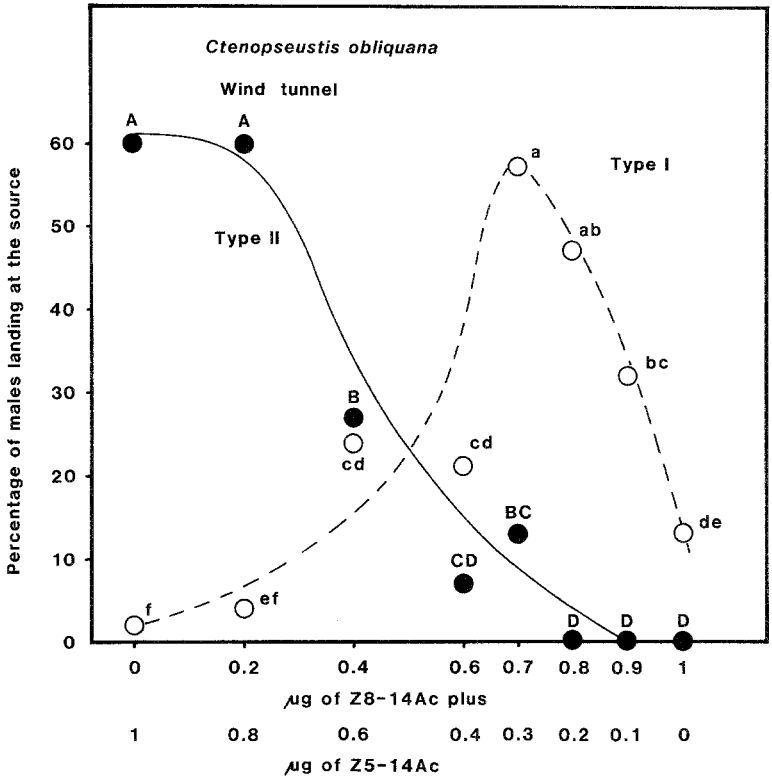

FIG. 7. Landing response profiles of type I (○) (Auckland) and type II (●) (Tai Tapu) to mixtures of Z5–14 : Ac plus Z8–14 : Ac (total 1 µg). Forty-seven type I males were flown to each septum. Thirty type II males were flown to each septum. Treatments accompanied by the same letter are not significantly different ($P < 0.05$). $\chi^2 = 72.94$ (type I) and = 101.471 (type II).

of types I and III. Nomenclatural changes consequent to this are dealt with elsewhere (Dugdale, 1990).

Greater sampling of populations has shown that type I and type III *C. obliquana*, while not as different as indicated in Foster et al. (1986), remain distinguishable on the basis of the median ratio of Z5–14 : Ac to Z8–14 : Ac. As the ranges of this ratio overlap, it would not be appropriate to distinguish between them nomenclaturally as a given idividual could not be assigned with confidence to either type I or III. Our field-cage experiments indicated that males both from Alexandra (type III) and from Auckland (type I) are attracted to Auckland females. However, males of neither type were attracted to Alexandra females, suggesting that either males of both types preferred the type I

[a] Sum of two trials conducted February 27, 1986, and March 7, 1986, at Mt. Albert Research Centre, Auckland. Numbers followed by the same letter are not significantly different at $P < 0.05$ (fitted log-linear model).

females or that the Alexandra females were not releasing pheromone. If these females did not call, the artificial temperature manipulation conducted in order to synchronize populations could have been responsible. The two cultures also differed in the number of generations that had experienced laboratory conditions

(23 generations for type I, one for type III). Despite these reservations, the data suggest that types I and III are variant populations of a single species.

South Island type II populations are distinguishable from the sympatric type III populations on details of morphology, in addition to the above differences in the pheromone. However, type II(North Island) populations cannot be distinguished morphologically from type I populations (Dugdale, 1990). Differences were detected between attractiveness of the type II and II(North Island) females in the field cage bioassays, and this is paralleled by a difference in the pheromone content of the gland. These differences do not appear to be sufficient for specific status for both II and II(North Island) populations. Our conclusion that these two populations are variant populations of the same species is, however, tentative.

Specialist cells for Z8–14 : Ac are very common in the sensilla trichodea on the antennae of type I males, while specialist cells for Z5–14 : Ac are common in type II males. The large numbers of each specialist and their large spike amplitude determine the shape of the EAG profile for each type. This relationship between the number of specialist cells and the shape of an EAG profile has been demonstrated previously by Van der Pers and Löfstedt (1986). Z8–14 : Ac specialist cells in type II males and Z5–14 : Ac specialist cells in type I males are insufficiently common to clearly influence the EAG profile of their types. Although uncommon, the Z5–14 : Ac specialist cells of type I males clearly have an important role in mediating flight behavior. Sources lacking Z5–14 : Ac are much less attractive to males of type I (Figure 7). No function has yet been discovered for the Z8–14 : Ac specialists in type II males or for the other alkenyl acetate receptor cells found in both type I and type II males. Single-cell recordings have not yet been made from type III males, although the similarity of types I and III in EAG profiles (Figures 4 and 6) suggests that males of these two populations may share a similar set of antennal receptor cells.

Previous researchers have had little success when using laboratory-reared females of some New Zealand species to capture feral males. R. Galbreath and D. Catt (personal communication) recorded very low catches (0–4) of males when *Ctenopseustis obliquana* (sensu lato) and *Planotortrix excessana* (sensu lato) females were placed in gauze cages in sticky traps. Galbreath et al. (1985) consequently chose to use female extracts when comparing the responses of males from populations of *Planotortrix excessana* from Tokoroa and Lincoln. Our first experiment using live females in cages (Table 2) substantiated the difficulties encountered by Galbreath and Catt (personal communication). Very few of the traps baited with females caught males, even though GLC analyses of females handled similarly showed that these females produced the two pheromone components. Other authors have similarly reported failure of laboratory-reared females to attract males into traps, e.g. *Paralobesia viteana* (Clemens), the grape berry moth (Taschenberg et al., 1974). Our care in keeping the female

pupae in a cool shaded position outside, daily replacing of cotton wool and honey solution, and using newly emerged females without a one- or two-day maturing period probably contributed to the production of a much more attractive group of females for our second experiment.

We aim to study the differences in the pheromone systems of these sibling species more fully in order to investigate possible evolutionary processes.

Acknowledgments—We thank our colleagues and friends for providing collections of leafroller larvae from many parts of New Zealand; Dr. Wendell Roelofs (Cornell University, Geneva, New York) for advice and encouragement, and Dr. Yoshio Tamaki, Department of Sericulture, MAFF, Tsukuba, Japan, for helpful discussions. We thank Michael Benn of University of Calgary, Canada, for supplying Z5-14 : Ac and Z8-14 : Ac. Pritam Singh and David Roger (Rearing Group, DSIR) provided pupae of *C. obliquana* type I. Statistical analyses or advice were provided by John Maindonald and Chris Triggs, AMD Auckland, and W.C. Black, Kansas State University, Kansas.

EXPERIENCE EARLY IN LIFE AFFECTS VOLUNTARY INTAKE OF BLACKBRUSH BY GOATS

R.A. DISTEL and F.D. PROVENZA*

Range Science Department
Utah State University
Logan, Utah 84322-5230

(Received July 23, 1990; accepted October 10, 1990)

Abstract—Low nutritional quality and high levels of condensed tannins adversely affect voluntary intake of blackbrush (*Coleogyne ramosissima* Torr.) by goats. We studied: (1) how consumption of blackbrush or alfalfa pellets by young goats affected their consumption of those foods later in life, and (2) whether previous ingestion of blackbrush or alfalfa pellets affected the excretion of condensed tannins and total phenols from blackbrush in urine and feces, production of proline-rich proteins in saliva, excretion of nitrogen in feces, and mass of the liver, kidneys, parotid glands, and reticulorumen in goats. From 6 to 26 weeks of age, experienced goats were exposed to blackbrush, while inexperienced goats ate alfalfa pellets. Following exposure, both groups were offered older-growth blackbrush twigs (OG) or a choice between OG and current season's blackbrush twigs (CSG). A similar feeding trial was repeated nine months after exposure, and, in addition, both groups were offered a choice between OG ad libitum and alfalfa pellets at six levels of availability. Immediately after exposure, experienced goats ingested 95% more ($P < 0.01$) OG per unit of body weight than inexperienced goats, but both groups rejected CSG. Nine months after exposure, experienced goats ingested 27% more ($P < 0.01$) OG than inexperienced goats. Experienced goats ingested 30% more OG than inexperienced goats at every level of alfalfa pellet availability. The fate of condensed tannins and total phenols was similar for both groups, but experienced goats excreted 63% more ($P < 0.05$) uronic acids per unit of body weight. Neither experienced nor inexperienced goats produced proline-rich proteins in saliva. Experienced goats excreted 32% more ($P < 0.01$) nitrogen in feces per unit of nitrogen ingested than did inexperienced goats. The mass of the reticulorumen was 30% greater ($P < 0.05$) for experienced than for inexperienced goats one month after exposure, but did not differ 10 months after exposure. The mass of the liver, kidneys, and parotid glands did not differ between treatments. The results

show that experience early in life can have profound and persistent effects on consumption of diets high in chemical defenses and low in nutritional quality. The results also suggest that several physiological and morphological factors are involved.

Key Words—Experience, condensed tannins, plant defense, intake, goats, blackbrush, *Coleogyne ramosissima*.

INTRODUCTION

Empirical evidence indicates that prior experience ingesting foods increases preferences for those foods by animals (Arnold, 1964; Leuthold, 1971; Arnold and Maller, 1977; Martin, 1978; Frost, 1981; Narjisse, 1981; Bartmann and Carpenter, 1982; Otsyina, 1983). Moreover, experiences early in life apparently have a more lasting effect than those later in life (reviewed by Arnold and Dudzinski, 1978; Matthews and Kilgour, 1980; Provenza and Balph, 1988; Squibb et al., 1990). Neurological, physiological, and morphological processes are amenable to change early in life and can be altered permanently so animals can better forage in the environment where they are reared (Provenza and Balph, 1987, 1988, 1990). Some authors suggest that previous experience, particularly in early life, may counter chemical defenses of plants, thus attenuating their negative effects on voluntary intake (Provenza and Balph, 1987, 1988; Lindroth, 1988).

Low nutritional quality and high levels of condensed tannins adversely affect voluntary intake of blackbrush by goats (Provenza et al., 1983, 1990; Provenza and Malechek, 1984). However, consumption of blackbrush by young goats could influence the physiological processes that deter consumption later in life. Mammals have evolved physiological (i.e., reduced uptake or transport of toxins) and biochemical (i.e., enzymatic transformation of toxins) adaptations to cope with plant chemical defenses such as tannins (Lindroth, 1988). For example, deer (Robbins et al., 1987) and rats (Mehansho et al., 1983) produce proline-rich proteins in saliva that bind tannins. In rats, the ingestion of tannins induces a marked increase in the size of the parotid salivary glands (Mehansho et al., 1983). Voles (Lindroth and Batzli, 1983) and snowshoe hares (Bryant et al., 1985) possess enzyme systems that detoxify phenolic compounds through conjugation with glucuronic acid. Such enzymes are located primarily in the liver and kidneys (Freeland and Janzen, 1974), but also occur in visceral tissues such as the rumen wall (Smith, 1986).

Experience early in life could also influence morphological processes. For example, the alimentary canal of red deer (Milne et al., 1978) and mule deer (Baker and Hobbs, 1987) may enlarge when they ingest poor-quality forages. Because distension of the reticulorumen wall may limit intake of roughage that

is low in nutrients (Grovum, 1988), young goats may adapt to a low-nutrient, high-fiber diet such as blackbrush by increasing gut size.

The objectives of this study were to determine the effects of experience early in life with blackbrush or alfalfa pellets on: (1) voluntary intake of those foods by goats; (2) the fate of blackbrush condensed tannins and total phenols, production of proline-rich proteins in saliva, and excretion of nitrogen in feces of goats; and (3) the mass of the liver, kidneys, parotid glands, and reticulorumen of goats.

METHODS AND MATERIALS

Plant Material. Blackbrush is a small (< 1 m) shrub that grows in nearly monospecific stands on millions of hectares in the southwestern United States (Bowns and West, 1976). Blackbrush is low in crude protein (4–7%) and low in digestible dry matter (38–48%) (Provenza et al., 1983). In addition, blackbrush twigs are high in phenols, which are composed primarily of condensed tannins (T. Clausen, personal communication). The allocation of tannins varies according to plant part (Provenza and Malechek, 1983). Current season's growth (CSG) from previously browsed plants contains 2.4 times more tannins than does older growth (OG) from unbrowsed plants. Even though CSG is higher than OG in crude protein (7% vs. 5%) and digestible dry matter (48% vs. 38%), goats prefer OG to CSG (Provenza and Malechek, 1984, 1986). Condensed tannins cause goats to avoid CSG (Provenza et al., 1990; Clausen et al., 1990).

Exposure. Thirty Spanish goats 6 weeks old were randomly assigned to either a treatment (experienced) or a control (inexperienced) group. Inexperienced goats ate alfalfa pellets in Logan in northeastern Utah, while experienced goats browsed blackbrush near Gunlock in southwestern Utah. Goats were exposed to blackbrush or alfalfa pellets from 6 to 26 weeks of age. This period covered the transition from monogastric to ruminant, which may be a "sensitive period" in the development of food preferences in ruminants (Squibb et al., 1990). The young goats remained with their mothers during exposure to enhance the establishment and persistence of their dietary habits (Thorhallsdottir et al., 1990a,b; Nolte et al., 1990; Mirza and Provenza, 1991).

Experienced goats browsed blackbrush from November 10, 1989, to February 10, 1990, on a 5-ha pasture that had been heavily browsed by another group of goats during the winter of 1988–1989. Vegetation on the site was a monospecific understory of blackbrush shrubs with an overstory of scattered juniper (*Juniperus osteosperma*) trees. The removal of terminal buds by herbivores during winter, when blackbrush is dormant, stimulates production of CSG during spring (Provenza et al., 1983). Thus, the blackbrush plants were composed of both OG and CSG. We observed young goats browsing on both

OG and CSG, and virtually all OG and CSG terminal branches had been browsed by the end of exposure. Experienced and inexperienced goats were weaned 10 days before feeding trials began to minimize the effects of weaning stress on the results.

Feeding Trial 1. The objective of the first trial was to determine the intake of blackbrush by experienced and inexperienced goats immediately after exposure. The goats were penned individually in southwestern Utah and offered alfalfa pellets ad libitum for four days. They then were offered chopped blackbrush OG ad libitum for the next seven days (period 1), a choice between OG and chopped blackbrush CSG ad libitum for the next seven days (period 2), and a choice between half of their ad libitum intake of OG in period 2 and CSG ad libitum for the final five days (period 3). Goats had access to the food from 0900 to 1700 hr daily. All the animals were weighed at the beginning and at the end of each period. Intake of blackbrush was expressed as grams of oven-dry tissue weight ingested per kilogram of body weight.

Both blackbrush OG and CSG were harvested by hand daily and chopped, in a mechanical chipper, into segments 1–3 cm in length. When a choice was involved (periods 2 and 3), OG and CSG were offered in separate food boxes. The position of the food boxes containing OG or CSG was changed each day to avoid bias. All animals had ad libitum access to water and salt. At 1700 hr goats were given enough Calfmanna, a concentrate-based pellet high in protein (25%) and energy, to cover 30% of their estimated energy requirements (NRC, 1981). The amount of Calfmanna offered was adjusted according to the body weight of each individual.

Feeding Trial 2. The objective of the second trial was to determine the intake of blackbrush by goats nine months after initial exposure. After the first feeding trial, both groups of goats grazed the same grass–legume (*Dactylis glomerata–Medicago* spp.) pasture for eight months. The procedures described in trial 1 were repeated, except that the length of period 3 was reduced to two days; the production of CSG was low as a result of drought, which precluded feeding CSG for five days as in trial 1.

Feeding Trial 3. The objective of the third trial was to determine the intake of blackbrush OG by goats when offered OG ad libitum and alfalfa pellets at six levels of availability. After trial 2, we determined the ad libitum intake of alfalfa pellets for each individual. Experienced and inexperienced goats then were offered a choice between blackbrush OG ad libitum and alfalfa pellets ad libitum on day 1. Subsequently, the amount of alfalfa pellets offered was reduced by 20% each day, whereas OG was offered ad libitum. On the last day of the trial, only OG was offered ad libitum. The intake of OG was measured throughout the trial.

Fate of Condensed Tannins and Total Phenols. During trial 1, five goats from each group were penned individually in metabolism stalls to collect feces

and urine. Urine samples were collected in a bucket containing 1 ml of concentrated mercuric chloride to prevent microbial growth. All samples were frozen at −20°C. Before the chemical analyses, blackbrush and fecal samples were freeze-dried and ground to pass a 1-mm screen. Blackbrush, fecal, and urine samples were analyzed for days 3 and 5 (representative of period 1), 11 and 13 (representative of period 2), and 17 and 19 (representative of period 3).

Phenols were extracted from blackbrush and feces according to a procedure developed by A.E. Hagerman (personal communication). Blackbrush and feces were extracted with 10% acetic acid in ether to remove pigments, and then with 1% sodium dodecyl sulfate in 70% acetone to remove phenols. A 150-mg sample was mixed with 5 ml of acetic acid in ether, extracted for 10 min, centrifuged (2000 rpm), and the supernatant was discarded. This procedure was repeated four times. The sample then was mixed with 5 ml of sodium dodecyl sulfate in acetone, centrifuged for 10 min, and the supernatant was collected. This procedure was repeated four times. Finally, the samples were analyzed for condensed tannins (Porter et al., 1986) and total phenols (Price and Butler, 1977). Condensed tannins and total phenols were expressed as blackbrush condensed tannin equivalents per unit organic matter, using standard curves prepared daily for the conditions used in the analysis. Condensed tannins used as standards were extracted from blackbrush CSG and purified according to the method of Hagerman and Butler (1980).

Urine samples were analyzed for total phenols (Price and Butler, 1977) and uronic acids (Bitter and Muir, 1962). The presence of uronic acids is an index of phenol detoxification in animals (Lindroth and Batzli, 1983). Total phenols in urine were expressed as blackbrush condensed tannin equivalents, whereas uronic acids in urine were expressed as glucuronolactone equivalents.

Excretion of Nitrogen in Feces. Blackbrush and fecal samples were analyzed for nitrogen using the Digesdahl procedure (Hach Company, 1987).

Production of Proline-Rich Proteins in Saliva. Saliva samples from five goats in each group were analyzed for days when fecal and urine samples were collected. Samples were collected in the morning before feeding. A sponge, placed in the mouth of each animal, was removed after the animal had chewed on it for 2–3 min, which enabled us to collect total mixed saliva (some salivary glands secrete only when the animal is chewing). The sponge was squeezed to collect saliva in a small tube containing 100 μl of phenylmethyl-sulfonyl fluoride, an antiproteolytic agent. One milliliter of saliva was collected per individual. The samples were frozen immediately in Dry Ice and later placed in a freezer at −20°C. Saliva samples were analyzed for proline-rich proteins according to the method of Austin et al. (1989).

Mass of Reticulorumen, Liver, Kidneys, and Parotid Glands. One month after exposure, four goats from each group that was in trial 1 were sacrificed and the fresh mass of the liver, kidneys, parotid glands, and reticulorumen was

determined. The contents of the reticulorumen were removed and the reticulorumen was washed and dried with a towel before weighing. The mass of the reticulorumen was measured in four goats from each group again 10 months after exposure.

After goats had ingested blackbrush OG, we determined how many alfalfa pellets they would ingest voluntarily to ascertain whether physical limitation in rumen volume might limit intake. Both groups of goats were offered blackbrush OG from 0900 to 1300 hr and then alfalfa pellets from 1300 to 1700 hr on the day following trial 1.

Statistical Analyses. The statistical design for the analyses of variance was a randomized block with experience as the main effect and individual goats as blocks. Periods and foods within periods were analyzed separately in trials 1 and 2. When the same measurement was repeated for more than one day, a repeated measures analysis was used (Winer, 1971).

RESULTS

Feeding Trial 1. Experienced goats ingested 12 g/kg of body weight or 95% more ($P < 0.01$) OG than inexperienced goats in periods 1 and 2 (Figure 1). On average, experienced goats ingested 332 g of OG, whereas inexperienced goats ingested 232 g of OG. In period 2, both groups rejected CSG when allowed to choose between OG and CSG. However, when OG was restricted and CSG was offered ad libitum in period 3, both groups ingested all the OG and experienced goats ingested 6 g/kg of body weight or 46% more ($P < 0.01$) CSG than did inexperienced goats. The average intake of CSG was 245 g and 225 g for experienced and inexperienced goats, respectively.

Feeding Trial 2. Experienced goats ingested 7 g/kg of body weight or 27% more ($P < 0.01$) OG than inexperienced goats nine months after exposure (Figure 2). On average, experienced goats ingested 716 g of OG, whereas inexperienced goats ingested 618 g of OG. When allowed to choose between OG and CSG in period 2, both groups rejected CSG. In period 3 when OG was restricted and CSG was offered ad libitum, goats did not differ ($P > 0.05$) in the amount of CSG they ingested.

Feeding Trial 3. When allowed to choose between OG and alfalfa pellets, experienced goats ingested more ($P < 0.05$) OG than inexperienced goats at every level of alfalfa pellet availability (Table 1). On average, experienced goats ingested 6 g/kg of body weight or 30% more than inexperienced goats.

Body Weight. In trial 1, there was no change in the weight of experienced goats (13 kg), but inexperienced goats lost an average of 4 kg, from 21 to 17 kg. Differences in the nutrient and energy contents of blackbrush OG and alfalfa pellets caused the differences in weight at the beginning of trial 1. There were

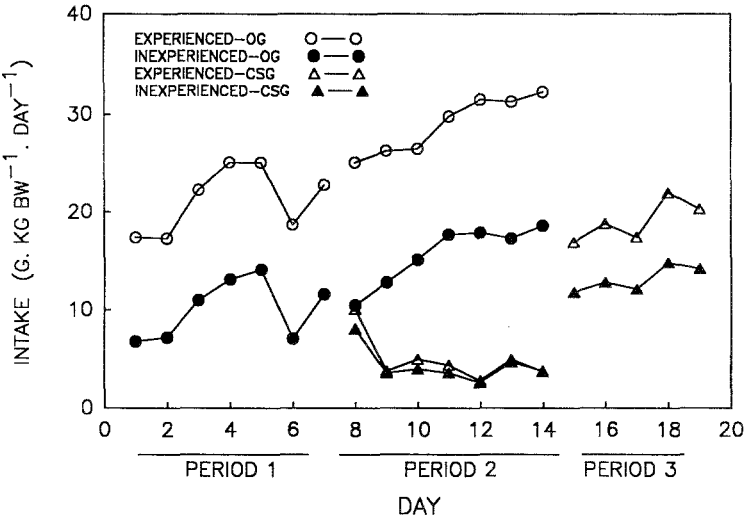

FIG. 1. Intake of blackbrush by goats immediately after exposure. Each value represents the mean of 14 (experienced) or 16 (inexperienced) goats. Goats were offered OG in period 1, a choice between OG and CSG in period 2, and a choice between half their ad libitum intake of OG in period 2 and CSG ad libitum in period 3. Differences between treatments are significant ($P < 0.01$), except for intake of CSG in period 2. There was no treatment by day interaction ($P > 0.05$). The standard errors of the means for periods 1, 2, and 3 are 1.0, 1.0 (OG) and 0.5 (CSG), and 0.7, respectively.

no changes in the weights of experienced (25 kg) or inexperienced (27 kg) goats during trial 2.

Fate of Condensed Tannins and Total Phenols. Experienced goats ingested more ($P < 0.05$) condensed tannins and total phenols than inexperienced goats in trial 1 (Table 2). Experienced and inexperienced goats did not differ ($P > 0.05$) either in the amount (milligrams excreted per gram ingested) of condensed tannins and total phenols in feces or in the amount of total phenols and uronic acids in urine (Table 3). However, experienced goats excreted more ($P < 0.05$) uronic acids than inexperienced goats during the trial when expressed on a per unit body weight basis (Table 3).

Excretion of Nitrogen in Feces. Experienced goats excreted 32% more ($P < 0.01$) nitrogen in feces, per unit of nitrogen ingested, than inexperienced goats and ingested a higher ($P < 0.01$) proportion of nitrogen as blackbrush protein (45% vs. 30%) throughout trial 1 (Table 4).

Production of Proline-Rich Proteins in Saliva. No proline-rich proteins were detected by electrophoresis in the saliva of either experienced or inexperienced goats.

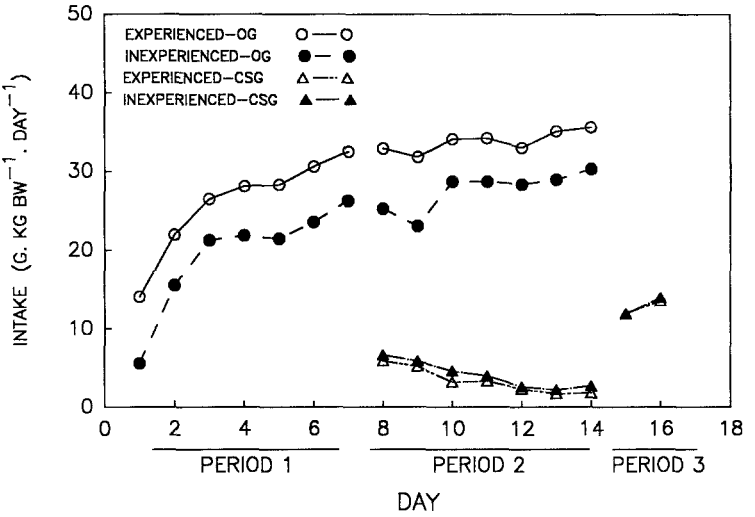

FIG. 2. Intake of blackbrush by goats nine months after exposure. Each value represents the mean of 10 (experienced) or 12 (inexperienced) goats. Blackbrush twigs offered were as described in the legend for Figure 1. Differences between treatments in intake of OG, but not CSG, are significant ($P < 0.01$). There was no treatment by day interaction ($P > 0.05$). The standard errors of the means for periods 1, 2, and 3 are 1.4, 1.2 (OG) and 0.5 (CSG), and 0.3, respectively.

[b] ab, means within a row are different (LSD 0.05).

Mass of Reticulorumen, Liver, Kidneys, and Parotid Glands. One month after exposure, the mass of the reticulorumen was 30% higher ($P < 0.05$) in experienced than in inexperienced goats (Table 5). Treatments did not differ either in the thickness of the reticulorumen wall or in the development of rumen papillae. Thus, the larger reticulorumen mass meant experienced goats had a larger reticulorumen capacity. There were no differences ($P < 0.05$) between treatments in the mass of liver, kidneys, or parotid glands. Ten months after

and 111% of the OG ingested from 0900 to 1300 hr by experienced and inexperienced goats, respectively.

DISCUSSION

First we discuss the mechanisms that may underlie the responses of experienced and inexperienced goats, then we address artifacts of the experimental design that may have influenced those responses, and finally we consider implications of the findings for the biological manipulation of shrubs.

Mechanisms that May Underlie Responses of Goats

Experience early in life with blackbrush increased voluntary intake of blackbrush OG and CSG by goats in trial 1 and increased intake of and preference for blackbrush OG in trials 2 and 3. These results may reflect differences between experienced and inexperienced goats in: (1) preference for blackbrush OG and CSG, (2) ability to detoxify phenols in OG and CSG, and (3) distension of the reticulorumen.

Preference for Blackbrush OG and CSG. Preference was the relative amount of blackbrush OG ingested when goats could choose between blackbrush OG and alfalfa pellets or between blackbrush OG and CSG. Exposure to blackbrush increased preference for blackbrush OG when offered with alfalfa pellets (Table 1). Animals develop preferences for foods ingested early in life in the presence of social models such as the mother (reviewed by Immelmann 1975; Matthews and Kilgour, 1980; Provenza and Balph, 1987, 1988, 1990; Provenza et al., 1991). The enhanced ingestion of blackbrush OG shows that goats can develop a preference for a food high in tannins and low in nutritional quality. Grazing experience early in life also increases the preference of sheep for various unpalatable plants, and these differences persisted for at least two

years even when sheep were exposed to a wide range of forages (Arnold, 1964; Arnold and Maller, 1977).

When allowed to choose between blackbrush OG and CSG, goats always preferred OG. The fact that the concentration of condensed tannins in CSG is over twice that in OG may explain the preference. Alternatively, differences in the structure of condensed tannins in OG and CSG may have affected the goat's response and are known to cause snowshoe hares to prefer bitterbrush CSG to blackbrush CSG (Clausen et al., 1990). The ratio of epicatechin to catechin in condensed tannins from blackbrush CSG is five times higher than that of condensed tannins from bitterbrush CSG.

Condensed tannin structure can vary with the age of plant parts. The epicatechin–catechin ratio of condensed tannins of *Pinus taeda* differs between the phloem and the heartwood (Karchesy and Hemingway, 1980), and most condensed tannins from the ripe fruit of *Cydonia oblonga* are bound covalently with sugars whereas condensed tannins from unripe fruit have no carbohydrate substituents (Porter et al., 1985). Porter (1984) argues that branching increases with the molecular weight of condensed tannins. Thus, condensed tannins from OG, which form larger polymers, may branch more than newly formed condensed tannins from CSG and may be less aversive to goats than those in CSG (Provenza et al., 1990).

Inexperienced goats initially ingested more ($P < 0.01$) CSG than experienced goats (Figure 1, day 8). Intake of CSG by inexperienced goats subsequently declined and their consumption of OG increased. Goats associate the taste of CSG with postingestive distress caused by condensed tannins and quickly learn an aversion to blackbrush CSG, presumably when condensed tannins stimulate the emetic system of the midbrain and brain stem (Provenza et al., 1990, 1991). Toxins can stimulate the emetic system by afferent nerves from throughout the body (e.g., gastrointestinal tract, cardiovascular system, liver, kidneys) (Borison, 1986; David et al., 1986; Grahame-Smith, 1986; Kosten and Contreras, 1989). This explains why inexperienced goats ingested more ($P < 0.01$) CSG on day 8 than on subsequent days.

Experienced goats also ingested more ($P < 0.01$) CSG initially than in subsequent days, perhaps because chopping CSG changed cues such as sight, odor, and taste that goats use to recognize CSG (Provenza et al., 1990, 1991). This is a likely explanation for why experienced goats sampled more CSG on day 8 than on day 9 (Figure 1).

Detoxification of Phenols. Only a small proportion of blackbrush condensed tannins and total phenols were excreted in feces (6% and 9%, respectively) and urine (1% of phenols ingested) (Table 3). Condensed tannins form strong hydrogen bonds with proteins, polysaccharides, and other cell constituents (Swain, 1979), and the technique used in this study may not have recovered all of them (A.E. Hagerman, personal communication).

In both treatments, the most nitrogen was excreted in feces during period 3 of trial 1, the time when goats ingested the most tannins. Experienced goats excreted more nitrogen in the feces than inexperienced goats (Table 4), perhaps because they ingested more tannins and because a higher proportion of the nitrogen they ingested was from the poorly digestible twigs of blackbrush. Nastis and Malechek (1981) also found that goats' excretion of nitrogen in feces increased with the tannin content of an alfalfa–gambel oak diet.

An alternative explanation for the fact that only a small proportion of blackbrush condensed tannins was excreted in the feces and urine is that part of the condensed tannins were depolymerized, absorbed from the gastrointestinal tract, and then detoxified. Depolymerization of condensed tannins, particularly procyanidins (Hemingway and McGraw, 1983; Hemingway et al., 1983), occurs readily under acidic conditions similar to those in the digestive tract of mammalian herbivores (Butler et al., 1986; Clausen et al., 1990). Condensed tannin depolymerization products may be toxic (McLeod, 1974; Kumar and Singh, 1974; Lindroth and Batzli, 1984; Mehansho et al., 1985; Butler et al., 1986). For example, voles die when fed quebracho tannins (Lindroth and Batzli, 1984), and hamsters fail to sexually mature or die if condensed tannin levels in their diets are sufficiently high (Mehansho et al., 1985, 1987). Condensed tannins also increase mixed-function oxidase activity in the liver and levels of phenols in urine (Sell and Rogler, 1983), which suggests that they are absorbed and metabolized to some extent.

Experienced goats excreted 63% more uronic acid than inexperienced goats (85 vs. 52 mg/kg body weight; Table 3), perhaps because experienced goats ingested more condensed tannins and total phenols (Table 2), or because they were better able to detoxify phenols. A greater ability to detoxify condensed tannins would lower concentrations of phenols in blood and might affect intake. Phenols in blood may stimulate emetic receptors in the midbrain and brain stem, thereby causing a conditioned food aversion and reducing intake (Provenza et al., 1990, 1991). Thus, experienced goats may have ingested more blackbrush OG and CSG, and consequently more blackbrush condensed tannins and total phenols, because they were better able to detoxify them. If detoxification required time for induction, this lag could explain the difference in intake of CSG between experienced and inexperienced goats during period 3 of trial 1, and the lack of any difference during period 3 of trial 2.

Freeland and Janzen (1974) hypothesize that mammalian herbivores ingest toxins in amounts that they can detoxify. By the end of trial 1, average tannin intake by experienced and inexperienced goats was 2560 and 1745 mg/kg body weight, respectively (average of days 17 and 19 in Table 2), which may be the maximum amount of tannins goats could detoxify. Sheep (Burritt and Provenza, 1989) and goats (Provenza et al., 1990, 1991) regulate intake of foods that contain lithium chloride (LiCl), a potentially toxic compound. When LiCl is

mixed with an otherwise nutritious food, sheep and goats will voluntarily ingest between 25 and 50 mg/kg body weight (DuToit et al., 1991).

Our results do not support the hypothesis that mixed-feeders such as goats (Hofmann, 1988) produce proline-rich proteins in saliva as a mechanism for neutralizing tannins (Robbins et al., 1987). Different animal species may have evolved different mechanisms to cope with tannins. Species such as goats may have evolved the ability to detoxify tannins or their metabolites to some extent, while species such as deer apparently evolved proline-rich proteins as a partial defense against tannins (Robbins et al., 1987).

Distension of Reticulorumen. Our data support the hypothesis that the capacity of the reticulorumen can increase when ruminants ingest foods high in fiber and low in nutrients (Milne et al., 1978; Baker and Hobbs, 1987), but do not support the hypothesis that experience early in life causes a permanent increase in the capacity of the reticulorumen. One month after exposure experienced goats had greater reticulorumen capacity than did inexperienced goats, but after eight months of grazing on the same grass–legume pasture the size of the reticulorumen did not differ between treatments.

Grovum (1988) argues that intake of roughage can be limited by the distension of the reticulorumen. While experienced and inexperienced goats ingested a considerable amount of alfalfa pellets immediately after they ingested blackbrush OG (Table 6), distension of the reticulorumen may still have limited their intake of blackbrush OG. Difference in the density of blackbrush OG and alfalfa pellets may explain the results in Table 6. The blackbrush OG ingested by experienced and inexperienced goats (29 and 19 g/kg body weight) occupied volumes of 112 and 73 cm^3, while the alfalfa pellets ingested by experienced and inexperienced goats (26 and 22 g/kg body weight) occupied volumes of 34 and 29 cm^3. Furthermore, finely ground and pelleted alfalfa breaks down much more quickly when masticated than the coarse, fibrous chipped blackbrush OG. Thus, rumen volume and distension of the reticulorumen may partially explain the large differences in intake between experienced and inexperienced goats in trial 1, and the reduction in such differences in trial 2.

Experimental Artifacts That May Have Influenced Responses of Goats

The differences in intake of blackbrush OG and CSG between treatments were greater immediately after exposure (Figure 1) than nine months after exposure (Figure 2). The nutritional plane of goats during the experiment and the exposure of inexperienced goats to blackbrush during trial 1 may help explain this result.

Effects of Nutritional Plane on Responses of Goats. Experienced and inexperienced goats were on drastically different planes of nutrition during exposure and differed in fat reserves and body weight during trial 1. The difference in

the amount of back fat and kidney fat between groups was apparent when the animals were sacrificed to measure visceral mass. The difference in fat reserves between treatments was probably even greater at the beginning of trial 1 when inexperienced goats weighed 21 kg and experienced goats weighed 13 kg. During trial 1, inexperienced goats lost 430 g/day during the first seven days (3 kg) and 70 g/day during the next 14 days (1 kg). By the end of trial 1, inexperienced goats weighed 17 kg while experienced goats weighed 13 kg. Inexperienced goats probably lost weight when they mobilized fat reserves to compensate for their low intake of blackbrush. There were no differences between treatments in fat reserves and body weight (26 kg vs. 24 kg for inexperienced vs. experienced goats) after both groups of goats grazed a grass–legume pasture for eight months.

The disparity in nutritional plane between experienced and inexperienced goats prior to trial 1 and the similarity in nutritional plane for the eight months prior to trial 2 may partially explain the differences in intake immediately after exposure and nine months later. Rats deprived of protein early in life ingest more food, and utilize protein more efficiently, than normal rats (Beck et al., 1983). Protein levels in blackbrush are not adequate to meet requirements of young goats (Provenza et al., 1983; NRC, 1981), and long-term protein deprivation may have caused experienced goats to ingest more blackbrush than experienced goats during trial 1. Unfortunately, we know of no data concerning the role of protein deprivation early in life on intake in ruminants. In addition, levels of body fat affect insulin levels in the blood, which may also affect intake and could explain why inexperienced goats consumed less food immediately following exposure than experienced goats. Evidence supports this hypothesis in rats, but there is no evidence to support this hypothesis in ruminants (Weston, 1982; deJong, 1985; Grovum, 1988).

Experience of the Control Group. Exposing inexperienced goats to blackbrush during the first trial also may help explain why the differences in intake of blackbrush OG between treatments were larger immediately after exposure than nine months later. In the feeding trial nine months after exposure, young goats in the control group had been exposed to blackbrush for 20 days. This duration of exposure relatively early in life, which represented 20% of the exposure of the treatment group, may have increased inexperienced goats' intake of blackbrush OG.

Implications

Goats are an alternative to chemical or mechanical control of undesirable plant species (Wood, 1987). Goats also can be used to modify the growth form of shrubs to increase their productivity and nutritional value (Provenza et al., 1983). Our results show that young goats exposed to blackbrush consequently

ate more of the shrub, findings which could enhance biological manipulation efforts. For example, if goats (average weight of 30 kg) forage on blackbrush-dominated rangeland for 90 days during the dormant season, as was typical of the studies of Provenza et al. (1983), 15 experienced goats would ingest 284 kg more blackbrush than 15 inexperienced goats based on the data in Figure 2 (0.007 kg more ingested/kg body weight/day × 30 kg body weight/goat × 15 goats × 90 days). These differences would be much larger using the intakes shown in Figure 1: experienced goats would ingest 486 kg more blackbrush than inexperienced goats (0.012 kg more ingested/kg body weight/day × 30 kg body weight/goat × 15 goats × 90 days). The results of Flores et al. (1989a–c) indicate that the differences in intake of blackbrush between experienced and inexperienced goats would be even greater under free-ranging conditions because herbivores learn foraging skills. In our studies, goats were offered chopped blackbrush twigs in food boxes so that plant form and foraging skills would not confound the results.

CONCLUSIONS

Results from our study show that experience early in life with different diets can have profound and persistent effects on intake. The results also suggest that several physiological and morphological factors are involved. Clearly, more research is needed to understand the relationship between preference and the ability to detoxify condensed tannins. It is also important to study the interrelationships among intake, rumen volume, rate of passage of particles through the gastrointestinal tract, and factors such as rumination efficiency, which are influenced by experience and could affect intake (Welch and Hooper, 1988). Moreover, the role of nutrient deficiency on intake of blackbrush by young animals must be understood. Finally, it is important to determine how age at exposure and duration of exposure to blackbrush influence physiological and morphological processes that affect intake of and preference for blackbrush by goats.

IDENTIFICATION OF VOLATILE COMPONENTS OF BOBCAT (*Lynx rufus*) URINE

M.J.I. MATTINA,* J.J. PIGNATELLO, and R.K. SWIHART

Connecticut Agricultural Experiment Station
123 Huntington Street
New Haven, Connecticut 0650

(Received July 23, 1990; accepted October 11, 1990)

Abstract—Bobcat (*Lynx rufus*) urine reduces scent-marking activity of woodchucks (*Marmota monax*) and feeding activity of snowshoe hares (*Lepus americanus*) and deer (*Odocoileus virginianus*, *O. hemionus*). In order to identify the semiochemicals responsible for these behavior modifications, a dichloromethane extract of the bobcat urine was analyzed by GC-MS. Among the known compounds identified in the extract are phenol, indole, dimethyl sulfone, and 3-mercapto-3-methylbutanol. Compounds for which spectroscopic data are presented for the first time include one sulfide, two disulfides, and two trisulfides. The sulfur compounds are derived from an amino acid, *S*-(1,1-dimethyl-3-hydroxypropyl)cysteine ("felinine"), which was identified several years ago in the urine of the domestic cat (*Felis domesticus*).

Key Words—Behavior modification, bobcat, *Lynx rufus*, urine components, crop protection, deer, *Odocoileus*, felinine, predator odors, repellent, volatile sulfur compounds, woodchuck, *Marmota monax*.

INTRODUCTION

Mammalian predator odors are effective in altering the behavior and activity of the corresponding mammalian prey (Fulk, 1972; Müller-Schwarze, 1972; Gorman, 1984; Sullivan and Crump, 1986). Recent reports focus on the reduction of herbivore damage to agricultural crops through the application of compounds produced by the natural predators of the herbivores (Sullivan and Crump, 1984; Sullivan et al., 1985a,b, 1988a,b; Swihart, 1990; Swihart et al., 1990). Specifically, sulfur-containing semiochemicals, which reduce feeding damage of

*To whom correspondence should be addressed.

0098-0331/91/0200-0451$06.50/0

snowshoe hares (*Lepus americanus*) on coniferous tree seedlings, have been identified in the glandular secretions of mustelids, a natural predator of hare (Sullivan and Crump, 1984).

Several studies have documented the repellent effect of the urine and/or feces of felids on felid prey, such as deer (*Odocoileus hemionus*, *O. virginianus*) (Müller-Schwarze, 1972; Sullivan et al., 1985b), snowshoe hare (*L. americanus*) (Sullivan et al., 1985a), and woodchuck (*Marmota monax*) (Swihart, 1990). Although a search of *Chemical Abstracts* uncovered no reports detailing the chemical composition of felid urine or feces, three volatile sulfur compounds, which may function as pheromones, have been identified in the urine of red fox (*Vulpes vulpes*): Δ^3-isopentenyl methyl sulfide, 2-phenylethyl methyl sulfide (Jorgenson et al., 1978; Wilson et al., 1978), and 3-methylbutyl methyl sulfide (Bailey et al., 1979). Since volatility is an important property of compounds identified as semiochemicals (Wheeler, 1976), we attempted to identify the volatile components in bobcat urine as the first step in the characterization of the semiochemicals in the urine responsible for the suppression of agricultural damage inflicted by woodchuck and deer.

METHODS AND MATERIALS

The bobcat urine was purchased from Hoosier Trapper Supply (Greenwood, Indiana). Information from the supplier indicated that the urine is sold as collected from caged animals. The material is subject only to screening through cheesecloth or nylon mesh at the time of collection and is supplied in 1-gallon plastic jugs. One liter of the urine was transferred to a 2-liter separatory funnel and extracted with three 50-ml portions of dichloromethane (Optima grade, Fisher Scientific). The extracts were combined and concentrated on a steam bath using a Kuderna-Danish apparatus fitted with a three-ball Snyder column and a 10-ml concentrator tube.

Gas chromatographic (GC) fractionation of the dichloromethane extract was used to obtain relatively pure solutions of several compounds of interest for [^{1}H]NMR and high resolution mass spectrometric (MS) characterization. Fractionation was carried out on a Hewlett-Packard 5840A gas chromatograph fitted with a 2-m × 2-mm glass column packed with 10% SP2100 on 100/120 Supelcoport (Supelco, Bellefonte, Pennsylvania). Helium was used as the carrier gas and chromatograms were recorded with flame ionization detection to establish retention times (*RT*). Fraction collection was accomplished by disconnecting the column from the detector and reconnecting it to 50 cm of uncoated, 0.53-mm-ID fused silica tubing. The approximately 15 cm of tubing that exited the GC oven wall was passed through a 1/8-in.-ID copper tube wrapped in glass wool and heating tape in order to maintain the temperature of

the tubing at 250°C. The end of the fused silica tubing was fitted to a 1/16-in. zero-dead-volume connector (Supelco). A 9-cm length of 1/16-in. stainless-steel tubing, which was attached to the connector with a Fingertight II threaded fitting (Rainin, Woburn, Massachusetts), was used to convey each effluent fraction into 3 ml of deuterochloroform ($CDCl_3$) or methanol contained in a 10-ml culture tube fitted with a septum screw cap. The end of the 1/16-in. stainless-steel conveyance tubing was positioned well below the surface of the $CDCl_3$ or the methanol. The septum was also pierced with a short length of stainless tubing to provide ventilation of the carrier gas. The culture tubes were chilled in an ice bath prior to, during, and following fraction collection. Some condensation of effluent occurred in the conveyance tube, which was at ambient temperature, necessitating a final rinse of the tube into the trap with the appropriate solvent. The GC temperature zones were programmed as follows: injection temperature, 300°C; initial oven temperature, 40°C, ramped at 5°C/min for 20 min then at 3°C to 310°C and held for 20 min.

The GC-MS studies were carried out by injecting the dichloromethane extract in splitless mode on a 30-m × 0.25-mm SPB-608 capillary column (Supelco). An HP 5890 GC was connected via a capillary direct interface to an HP 5988A quadrupole mass spectrometer. The temperature zones were set as follows: injector temperature, 220°C; interface temperature, 250°C; initial oven temperature, 40°C for 3 min, then ramped at 5°C/min to 100°C and held for 5 min, finally ramped at 20°C/min to 280°C, and held for 5 min. The mass spectrometer was operated in electron impact (EI) mode with electron energy set at 70 eV and source temperature at 200°C. Instrument tuning and acquisition were under HP 59970C ChemStation software control (version 3.2). Spectra were acquired in full scan operation from m/z 40 to m/z 500.

High-resolution accurate mass data were acquired either on a Kratos MS80 magnetic sector instrument under DS90 software control or on a VG 70SEQ under OPUS software control. [^{1}H]NMR data were acquired at 500 MHz.

RESULTS AND DISCUSSION

The total ion chromatogram (TIC) for the GC-MS analysis of the dichloromethane extract is shown Figure 1. The TIC peaks are assigned to the compounds illustrated in Figure 2. 3-Methyl-3-buten-1-ol (II), pyrazine (III), methylpyrazine (IV), 2,6-dimethylpyrazine (VII), phenol (IX), trimethylpyrazine (X), dimethyl sulfone (XI), δ-valerolactam (XIII), indole (XVI), 1-methylhydantoin (XVII), and phenylacetamide (XVIII) were positively identified by matching the *RT* and the mass spectrum of the urine extract peak with authentic material. Phenol and dimethyl sulfone (Williams et al., 1966) have been reported to be constituents of mammalian urine. δ-Valerolactam has been

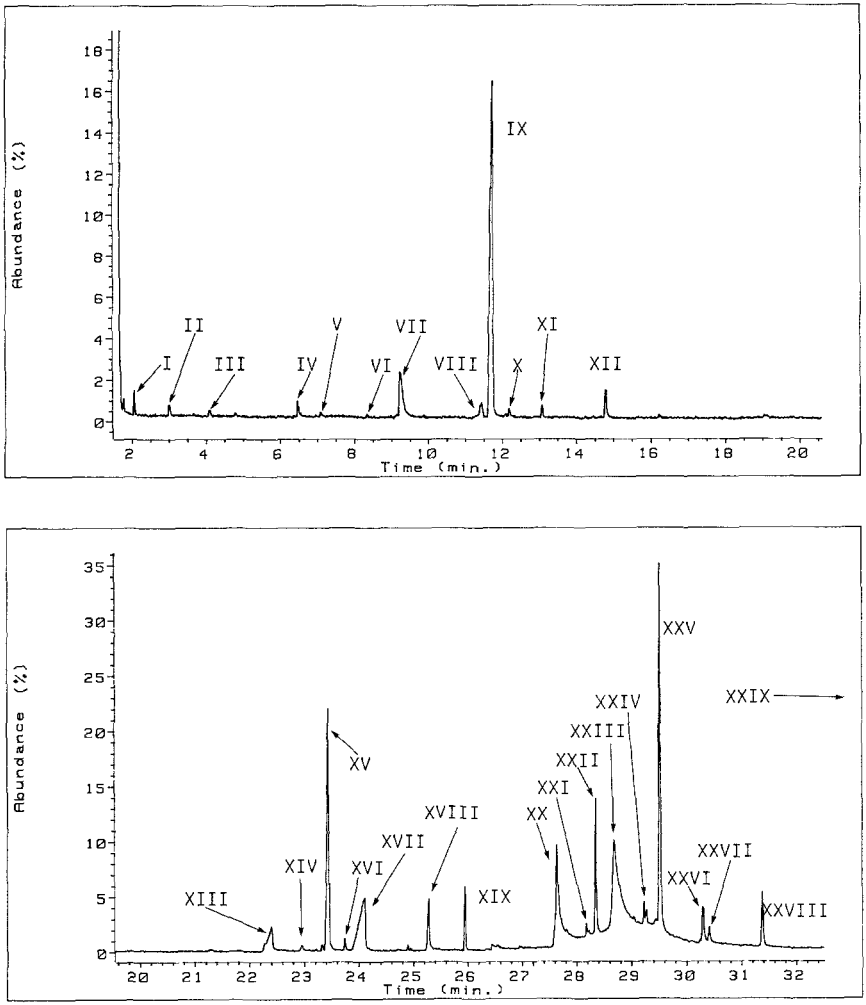

Fig. 1. TIC from the GC-MS of the dichloromethane extract of bobcat urine. I is an artifact from the CH_2Cl_2 solvent. V, VI, XIV, XXI, and XXVII are unidentified compounds.

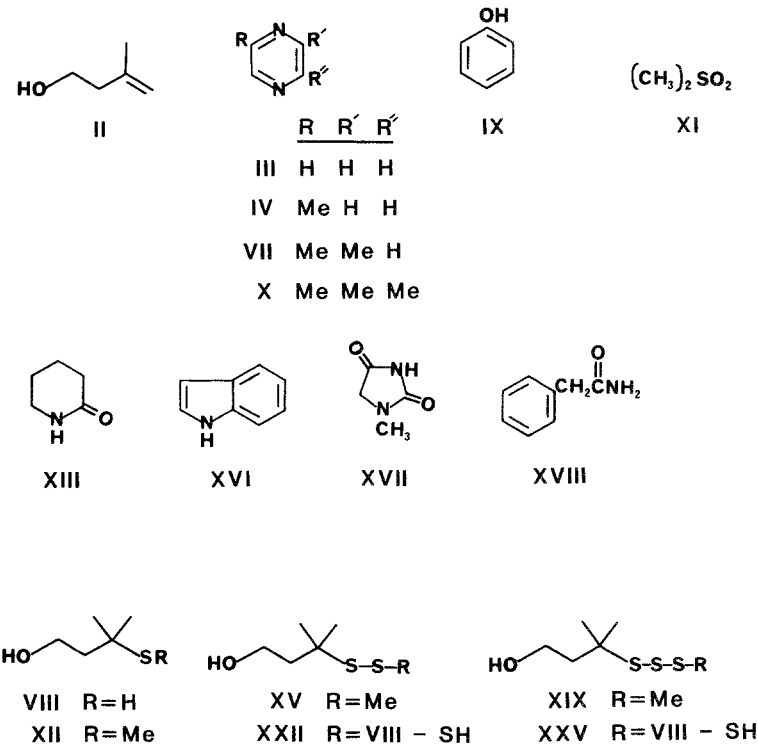
found in the anal sac secretions of *Felis domesticus* (Preti et al., 1976). Indole has been identified in the anal sac secretions of several mustelids (Brinck et al., 1983).

Fatty acids (XX and XXIII), compounds XXIV, XXVI, bis-(2-ethylhexyl) phthalate (XXVIII), and cholesterol (XXIX) were identified by the probability-based matching algorithm in the HP software. It is not surprising to find fatty



XX	palmitic acid	XXVI	octadecanamide
XXIII	9-octadecenoic acid	XXVIII	phthalate ester
XXIV	nonanamide	XXIX	cholesterol

Fig. 2. Compounds identified in the dichloromethane extract of bobcat urine.

acids and cholesterol as urinary constituents. The phthalate ester (XXVIII) may be derived from laboratory contamination or from plasticizers frequently used in plastic containers such as those in which the urine is supplied. It should be noted that the identification of these high-boiling compounds based solely on the software matching algorithm must be considered tentative. Positive identification awaits spectral and *RT* matching with the authentic materials.

The mass spectra of compounds VIII, XII, XV, XIX, XXII, and XXV are shown in Figures 3–8. None of these spectra matched library entries in the 42,000-entry NBS Library supplied with the HP ChemStation software. All of the spectra are characterized by a base peak at m/z 69. The mass spectra of

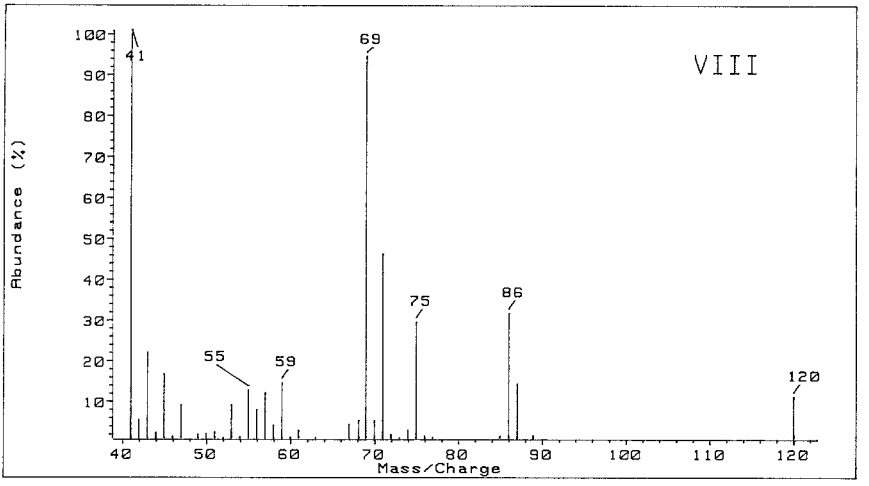


Fig. 3. Mass spectrum of compound VIII.

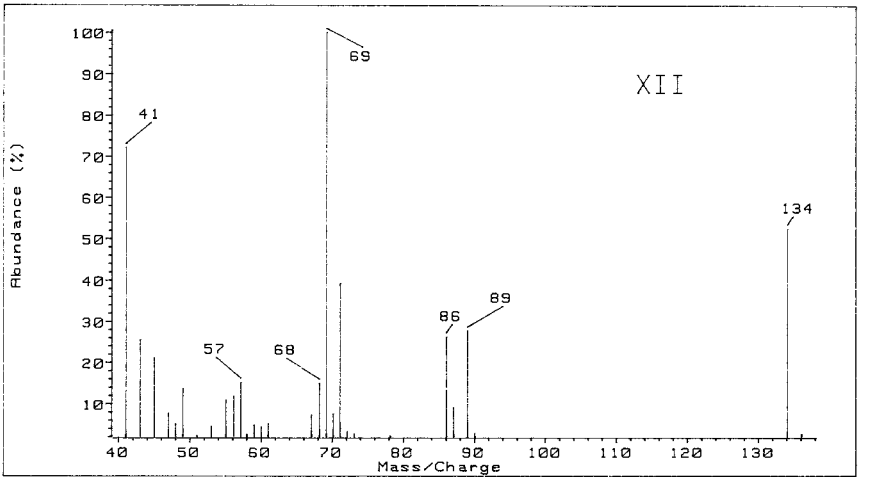

Fig. 4. Mass spectrum of compound XII.

several of the sulfur-containing compounds identified by Crump (1980a,b) and Brinck et al. (1983) in the anal gland secretions of mustelids have a base peak at m/z 69 due to $C_5H_9^+$. The similarity between our mass spectral data and that of Crump and Brinck prompted us to hypothesize that compounds VIII, XII, XV, XIX, XXII, and XXV incorporate sulfur and the isopentyl backbone. The molecular formula for these compounds, as well as the formula for a fragment ion, have been confirmed by high-resolution accurate mass measurements.

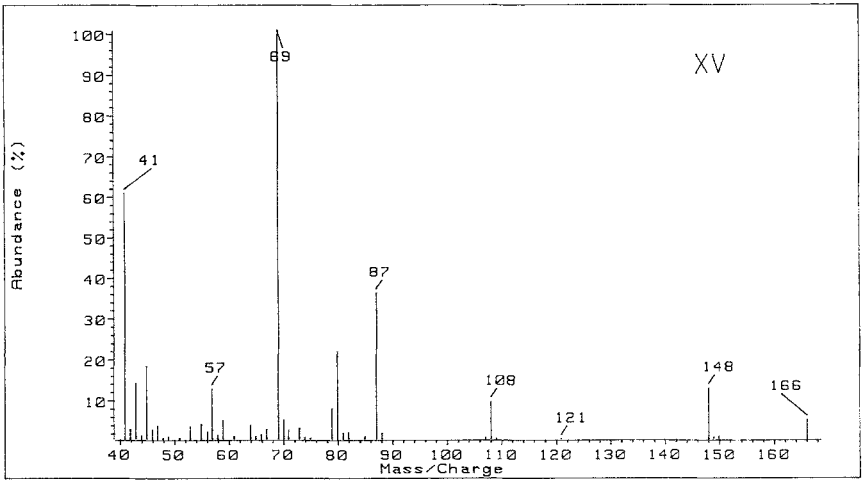

Fig. 5. Mass spectrum of compound XV.

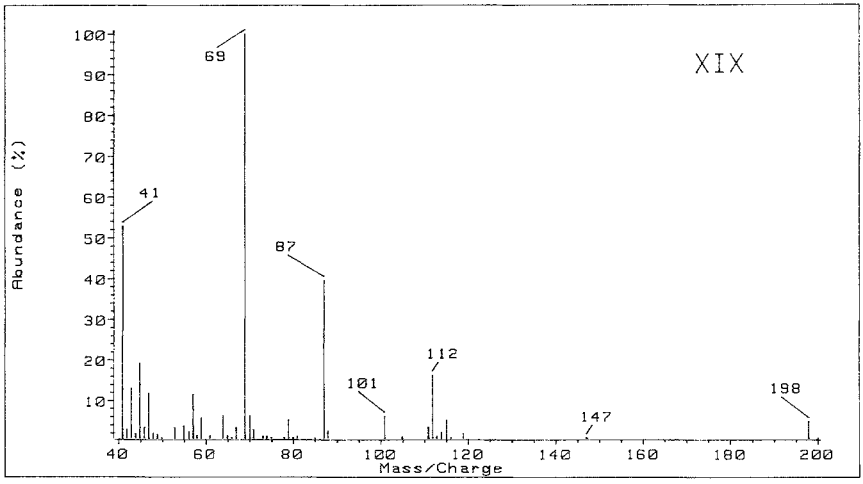

Fig. 6. Mass spectrum of compound XIX.

These data are summarized in Table 1. The 500 MHz [^{1}H]NMR spectral data for compounds VIII, XV, XXII, and XXV in $CDCl_3$ are summarized in Table 2. Compounds XII and XIX could not be obtained pure enough for NMR characterization.

On the basis of the high-resolution accurate mass data, the mass spectral fragmentation pattern (see Figure 3), and the [^{1}H]NMR data, compound VIII is identified as 3-mercapto-3-methylbutanol. This compound has been synthe-

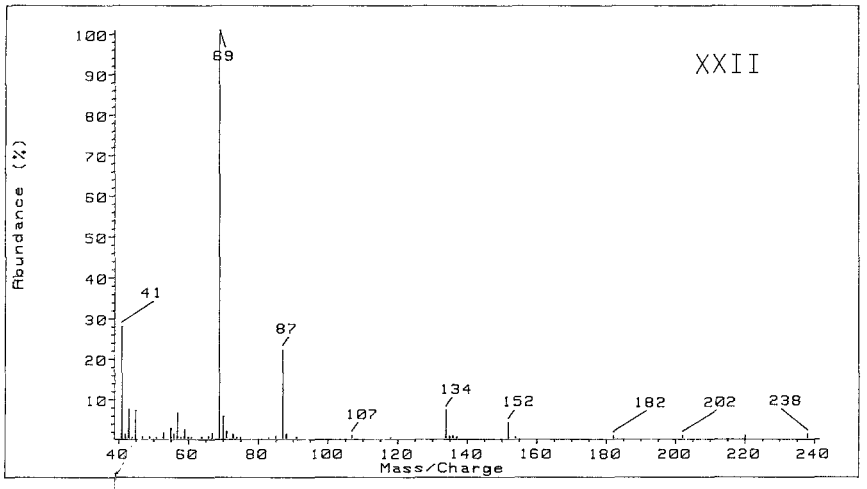

Fig. 7. Mass spectrum of compound XXII.

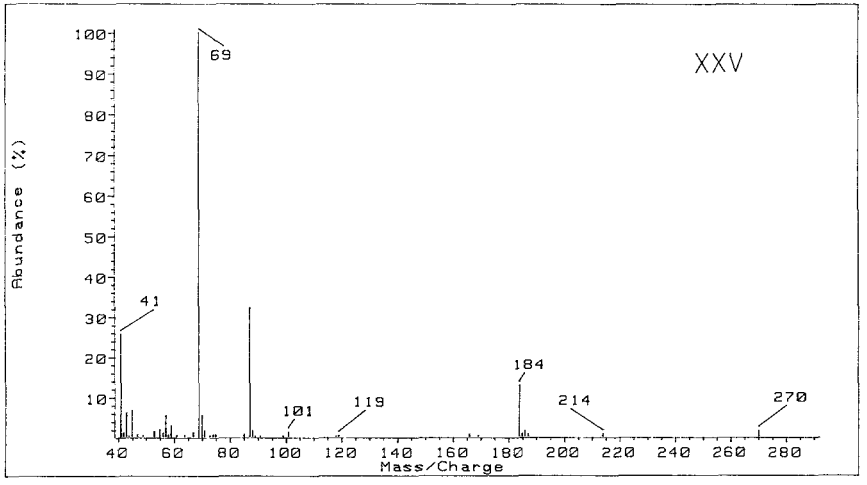

Fig. 8. Mass spectrum of compound XXV.

sized previously and its NMR and IR spectra obtained but not reported (Sweetman et al., 1971). Our [^{1}H]NMR data for compound VIII in $CDCl_3$ at 500 MHz agree with that of the previously synthesized 3-mercapto-3-methylbutanol obtained in CCl_4 at 60 MHz (L. Field, personal communication, 1990), allowing for solvent effects. The singlet (relative intensity 6) at 1.43 ppm and the two triplets (relative intensities 2) at 1.89 ppm and 3.87 ppm confirm the presence of an isopentyl backbone. The chemical shifts of the triplets indicate that

TABLE 1. COMPARISON OF THEORETICAL AND OBSERVED MASSES OF MOLECULAR AND FRAGMENT IONS PROPOSED FOR COMPOUNDS VIII, XII, XV, XIX, XXII, AND XXV

Compound	Formula[a]	Theoretical	Observed
VIII	$C_5H_{12}OS$	120.0606	120.0614
	$C_5H_{10}O$	86.0729	86.0756
XII	$C_6H_{14}OS$	134.0762	134.0765
	C_5H_9	69.0704	69.0702

	$C_5H_{12}OS_3$	184.0048	184.0056

[a]The first ion listed for each compound is the molecular ion.

the hydroxyl group is attached to the primary carbon and the sulfhydryl group is attached to the tertiary carbon (Jackman and Sternhell, 1969).

The structures for compounds XV (an unsymmetrical disulfide), XIX (an unsymmetrical trisulfide), XXII (a symmetrical disulfide), and XXV (a symmetrical trisulfide) are variations of the basis structure of compound VIII. The proposed structures are consistent with the high-resolution accurate masses of the molecular and fragment ions of each compound (see Table 1), the MS fragmentation patterns observed for the compounds (see Figures 5, 6, 7, and 8) and the [^{1}H]NMR data for the compounds (see Table 2), all reported here for the first time. Trisulfide compounds have been identified in nature, both in plants (Kjaer, 1977) and in animals (Singer et al., 1976). The identification of compounds VIII, XV, XIX, XXII, and XXV in the urine of *Felis catus* has been reported without additional experimental detail (Joulain and Laurent, 1989).

The presence of 3-methyl-3-buten-1-ol (compound II), as well as a very small amount of 3-methyl-2-buten-1-ol (RT = 3.4 min, Figure 1), in the dichloromethane extract should be noted. The structural similarity of the alcohol and the compounds VIII, XV, XIX, XXII, and XXV is apparent.

The most probable source of the 3-mercapto-3-methyl-butanol and its di- and trisulfide derivatives, which we have identified in bobcat urine, is the amino acid felinine. Felinine, an *S*-substituted-cysteine, was identified as a major constituent of the urine of another felid, the domestic cat (Westall, 1953). *C*-*S*-lyases are known, which catalyze the fragmentation of *S*-substituted cysteine into mercaptans. This pathway is discussed by Kjaer (1977) as the principal route for the biosynthesis of mercaptans, sulfides, disulfides, and trisulfides.

TABLE 2. [^{1}H]NMR CHEMICAL SHIFTS AND COUPLING CONSTANTS FOR COMPOUNDS VIII, XV, XXII, AND XXV

Compound	Chemical shift	Relative Intensity	Proton assignment
VIII[a]	1.43(s)	6	geminal methyl

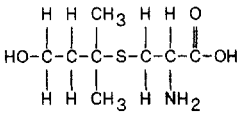
	3.82(T),[c] J = 6.9	2	methylene (primary carbon)

[a] The first set of chemical shifts and coupling constants are data obtained in the current study. The second set of data were obtained for the previously synthesized compound VIII (L. Field, personal communication).

[b] Typical uncertainty in the J values is ± 0.7 Hz.

[c] Additional fine structure in the methylene multiplet attributed to coupling to the hydroxyl proton is eliminated upon shaking in D_2O. A well-defined triplet at 3.8 ppm results.



Felinine

SCHEME 1.

A synthetic deer repellent based on felinine and the acidic component of lion (*Felis leo*) feces has been patented (Baines et al., 1988). The report does not discuss the presence of sulfur compounds other than felinine in the composition. The repellent is formulated with phenol, indole, δ-valerolactam, and palmitic acid, all of which we have identified as constituents of bobcat urine.

Both Brinck (1983) and Crump (1980a,b) have identified 3,3-dimethyl-1,2-dithiolane ($C_5H_{10}S_2$, molecular weight 134 daltons) in the

anal gland secretions of mustelids. We observe what we believe to be a very small amount of this dithiolane (RT = 14.3 min, Figure 1), identified by its mass spectral fragmentation pattern and the high resolution accurate mass measurement of the molecular ion (m/z = 134.0224), in the extract.

The low-resolution mass spectrum for compound XII (see Figure 4) indicates that the nominal molecular weight of this compound is also 134 daltons. The high-resolution accurate mass of the molecular ion of compound XII, however, is not consistent with the molecular formula of the dithiolane ($C_5H_{10}S_2$), but rather with that of 1,1-dimethyl-3-hydroxypropyl methyl sulfide, $C_6H_{14}OS$ (see Table 1). This methyl sulfide also can be derived from felinine. Further investigations on the structure of compound XII are in progress.

Field trials indicate that the dichloromethane extract of bobcat urine significantly reduces feeding damage to eastern hemlock (*Tsuga canadensis*) by white-tailed deer (Swihart et al., 1990). Similar but less dramatic reductions in damage to woody plants caused by scent-marking activity of woodchucks in apple orchards were noted. Reports on these field studies are forthcoming.

Acknowledgments—We are indebted to Dr. Lamar Field for generously supplying us with the original IR and NMR spectra from his 1971 publication. We acknowledge the work done at the Yale University Instrumentation Center by D. Pentek and P. Demeu in acquiring high-resolution mass spectrometric data and NMR data, respectively. High-resolution GC-MS data also were acquired at the USEPA Environmental Research Laboratory in Athens, Georgia, by Dr. Susan Richardson. We would like to acknowledge the technical assistance of Areej Al-Mudamgha, Marta Day, and Peter Picone in the experimental work described in this study. We are indebted to a reviewer for making us aware of the work of Joulain and Laurent at the Research Laboratories of Robertet S.A., B.P. 100, F-06333 Grasse Cedex, France.

Abstract—Using a simple two-choice bioassay and video analysis of individual locomotory tracks, it was determined that a preference for young-bee hosts over old-bee hosts in female honeybee tracheal mites, *Acarapis woodi* (Rennie), is chemically mediated. When presented with a choice of cuticular extracts from 5-day-old and < 1-day-old adult bees, mites showed a significant preference for the young-bee extract in three of four bee colony sources. This discrimination was due apparently to a greater positive response elicited by the young-bee extract rather than a deterrent effect of old-bee extract, as the extract of old bees evoked a significantly higher response than a hexane control. A bioassay of silica-gel fractions of young-bee extract indicated that cuticular hydrocarbons alone were responsible for tracheal mite response. Further fractionation of a hydrocarbon fraction by argentation chromatography demonstrated that both saturated and unsaturated hydrocarbons were involved in the mite response, but when presented in opposition, mites showed a stronger response to the saturated than to the unsaturated components. Mites placed in zones treated with cuticular extract of young bees exhibited higher angular velocities than those placed on hexane, causing them to remain in the extract-treated zones for extended periods. These results point to a possible control strategy whereby migration of tracheal mites to young-bee hosts could be disrupted by artificially altering the chemical profile of the honeybee cuticle.

INTRODUCTION

The honeybee tracheal mite, *Acarapis woodi* (Rennie), spends its entire life cycle primarily inside the first thoracic tracheae of adult European honeybees, *Apis mellifera*, as well as in other bees in the genus *Apis* (Delfinado-Baker and Baker, 1982). Both larval and adult stages pierce the tracheal walls with their mouthparts to feed on the hemolymph. Fertile adult mites transfer from the hair tips of infested bees to new host bees inside the hive. The axillary wing areas are initially sought by migrating mites, where they are protected from host grooming and can move safely to the tracheae of the new host (Royce et al., 1988); once inside the tracheae, females feed and lay several eggs. The economic importance of tracheal mites on the honeybee industry is difficult to assess at this time, with conflicting reports found in the literature (Bailey, 1989; Kjer et al., 1989a,b). This is due partially to the complexities of measuring the effect of the mites on honeybee colonies under controlled experimental conditions; however, numerous studies report that high infestation rates do engender detrimental effects on honeybee colonies, including decreased honey and brood production, shortened life-span, and increased winter mortality (Delfinado-Baker, 1988, and references therein).

Dispersing females rarely infest adult bees older than 4 days, and the susceptibility of bees to infestation declines precipitously from the first day of an adult bee's life (Morgenthaler, 1931; Bailey, 1958; Lee, 1963; Giordani, 1977; Gary and Page, 1987). Hirschfelder and Sachs (1952) suggested that decreasing susceptibility of adult bees to mite infestation was a consequence of the increasing stiffness of setae at the entrance of the thoracic spiracle of older bees; however, Lee (1963) found that neither these guard hairs, the muscles controlling the spiracle, nor the bee's second pair of legs were important in preventing dispersing mites from entering the tracheae of older bees. More recently, Gary and Page (1988) proposed that chemical cues were the most important factor determining host selection by the tracheal mite. In the present study, we: (1) demonstrate for the first time that tracheal mite host finding, as well as the preference for young bees, is chemically modulated; (2) present evidence concerning the chemical functionalities responsible for this preference; and (3) suggest how these chemicals affect the behavior of the mite through a preliminary video analysis of locomotory tracks.

METHODS AND MATERIALS

Combs containing emerging brood from four wild-type colonies (queens inseminated by several drones) were collected from the Ohio State University apiary and were placed in an incubator at 33°C, 50% relative humidity. The following morning, newly emerged worker bees (<24 hr) were collected in polystyrene cups and half of these were frozen immediately at −70°C, while the other half were provisioned with food (sucrose with 8% invert sugars, mixed with honey) and water. These bees were aged five days in the incubator (33°C, 50% relative humidity) and then frozen.

Cuticular extracts of 1- and 5-day-old bees obtained from each of the four colony sources were obtained by immersing 30 bees in 60 ml of hexane for 10 min and then concentrating the resulting extract to 6 ml under a stream of nitrogen (0.005 bee equivalents/μl). Young-bee extracts from colony 1 were fractionated by liquid chromatography using columns made from disposable pipets (70 × 5 mm), packed with silica gel (40–140 mesh). Fifteen bee-equivalents of extract (3 ml) were further concentrated under nitrogen to 0.5 ml and then loaded on the head of the column, which had been conditioned first with methylene chloride and then with hexane. Hydrocarbons were separated from non-hydrocarbon components of the extract by eluting the former with two 1-ml fractions of hexane and the latter with two 1-ml fractions of methylene chloride. Hydrocarbons were rechromatographed on silica gel impregnated with 20% silver nitrate (w/w); saturated hydrocarbons were eluted with two 1-ml fractions of hexane, while the unsaturated hydrocarbons were eluted by methylene chloride.

Gas-chromatographic analyses were carried out on a Hewlett-Packard 5890 capillary gas chromatograph equipped with a flame ionization detector and a Hewlett-Packard 5970 mass selective detector. Extracts or fractions (0.05 bee equivalents) were chromatographed using a splitless injection at 280°C onto a 0.25-mm × 30-m RSL-150 column (0.2 μm film thickness; Alltech Assoc., Deerfield, Illinois) held at 120°C for 1 min, then programmed to 300°C at 15°C/min, and a helium carrier flow of 0.9 ml/min. GC profiles of hydrocarbon silica-gel fractions from young and old bees of each colony were compared using a correlation matrix based on peak areas of the 20 most prominent hydrocarbon components.

Cuticular extracts and chromatographic fractions were tested for behavioral activity using a two-choice bioassay design. Glass cover slips (18 × 18 mm) were divided in half by drawing a line on the underside with an ink pen. A small ink dot was placed in the center of this line to designate the release zone for the mites. Treatments were applied to opposite halves of the top of the cover slip with a 20-μl micropipet (0.1 bee equivalents), and the solvent was allowed

to evaporate. Mites were collected using the dissection technique described by Smith et al. (1987) and Smith and Needham (1988), and transferred to the release zone of the cover slip with a human eyelash affixed to the end of a wooden dowel rod. Cover slips then were put in a glass Petri dish inside a transparent, plastic humidity chamber, held at ca. 93% relative humidity and 23°C by using a saturated salt solution of potassium nitrate. The influence of light was minimized by draping an opaque cloth over the entire system; the system was rotated 180° between tests. After 5 min, the response of the female mite was scored by locating her position on the cover slip with a Wild Heerbrugg® dissecting microscope (model M5A). The sequence of treatment presentation was randomized, with 50 female mites tested for each treatment; mites were tested individually and were only used once. The ratio of response in each bioassay was analyzed by chi-square ($P < 0.05$) to test for deviation from the expected ratio of 25:25 for 50 mites.

The locomotory behavior of individual mites was analyzed by videorecording the tracks of female mites placed on a 3-mm-diam. zone treated with either 5 μl of young-bee extract or an equivalent volume of hexane (five mites per treatment). Tracks were recorded using a Panasonic Solid State Color Videocamera (model WV-CD110A) attached to the microscope and then transcribed to clear acetate sheets placed over the video monitor. Lengths of tracks at 15-sec intervals were measured using an Alvin Curvameter, a hand-held instrument designed for measuring distances on maps.

RESULTS

Young- vs. Old-Bee Extracts. Female tracheal mites showed a significant preference for the cuticular extract of young bees over that of old bees in three of the four bee colonies tested (Table 1). Only in colony 2 was no significant discrimination between the extracts of young and old bees detected. When the extract of young bees from colony 2 was compared to old-bee extract from colony 1, mites showed a significant preference for the former (43:7, $\chi^2 = 25.92$). In addition, mites also preferred the extract of colony 2 old bees over that of colony 1 old bees (34:16, $\chi^2 = 6.48$). When extracts from young and old bees of colony 1 each were compared to a hexane blank, both elicited a significant positive response (Table 1).

In a comparison of hydrocarbon profiles from old bees of each colony with that from young bees averaged across the four colonies, profile similarity was inversely related to the degree of discrimination exhibited by females in the bioassay. Colony 2 old-bee profiles were most similar to young-bee profiles ($r = 0.82$), while old-bee profiles from colony 1 showed the greatest difference

($r = 0.47$). Similarity indices for old-bee hydrocarbon profiles from colonies 3 and 4 relative to young-bee profiles were 0.56 and 0.70, respectively.

Hydrocarbon vs. Nonhydrocarbon Components of Young-Bee Extract. The response of female mites to young-bee extract appeared to be due solely to the hydrocarbon lipids in that extract (Table 2). When the hydrocarbon-containing silica-gel fraction (hexane-eluted) was tested against the original extract, mites showed a significant preference for the former, while the nonhydrocarbon lipid fraction (methylene chloride-eluted) was significantly less active than the unfractionated extract. There was no difference in the response elicited by the recombined fractions and the crude extract.

Saturated vs. Unsaturated Hydrocarbons of Young-Bee Extract. When the above hydrocarbon fraction was refractionated on $AgNO_3$-impregnated silica gel, and these fractions were presented against the crude young-bee extract,

TABLE 1. DISCRIMINATION BETWEEN CUTICULAR EXTRACTS OF YOUNG (< 1-DAY-OLD) AND OLD (5-DAY-OLD) BEES FROM FOUR WILD-TYPE COLONIES BY FEMALE TRACHEAL MITES

Source	Young–Old	χ^{2a}
Colony 1	41:9	20.48*

[c] Eluted from silica gel by methylene chloride.

neither fraction 2 nor fraction 4 elicited a response significantly different from the extract, while fractions 1 and 3 were significantly less active than the extract (Table 3). GC-MS analysis of these fractions showed that fraction 2 contained saturated hydrocarbons, while fraction 4 contained unsaturated hydrocarbons. Furthermore, mites showed no preference for fraction 3 over a hexane control (Table 3), thus confirming the complete separation of the saturated and unsaturated hydrocarbons. When allowed to choose between saturated hydrocarbons (fraction 2) and unsaturated hydrocarbons (fraction 4), mites showed a strong preference for the former. In total, these results suggest that of the honeybee cuticular lipids, saturated and unsaturated hydrocarbons both possess positive behavioral activity, but saturated hydrocarbons may play the greater role in tracheal-mite host selection.

Analysis of Tracheal-Mite Locomotory Tracks. Preliminary observations of female mites walking in the vicinity of honeybee extract revealed no orientation of the mites toward treated areas; however, when placed in contact with a zone treated with young-bee extract, the locomotory tracks of the mites were dramatically different from those of mites placed in hexane-treated zones (Figure 1). Mites showed a much higher angular velocity in the presence of bee extract, exhibiting tracks that circled within the treated zone and causing them to remain in the zone for extended periods. Mean ($\pm$SEM) track lengths within the zones were 36.5 $\pm$ 4.8 mm for young-bee extract and 5.6 $\pm$ 1.7 mm for hexane ($t = 6.06$, $P = 0.004$, $df = 4$). Rates of locomotion within a track showed very low variance, with mites in extract-treated zones appearing to move slightly faster than those on hexane, although this difference was not significant, possibly due to the low number of tracks analyzed (0.14 $\pm$ 0.01 mm/sec in extract-treated zones and 0.11 $\pm$ 0.002 mm/sec in hexane, $t = 2.41$, $P = 0.07$, $df = 4$).

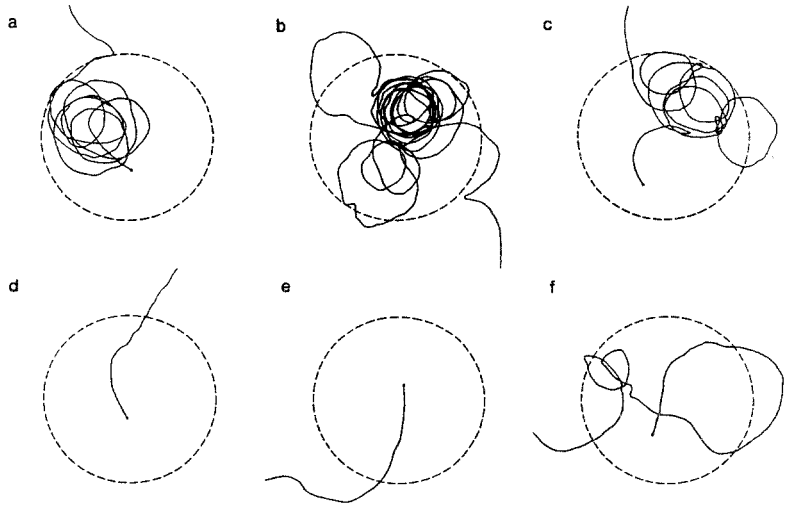

FIG. 1. Representative locomotory tracks of female tracheal mites in a 3-mm-diam. zone treated with young-bee extract (a–c) or hexane (d–f). The width of the female body was approximately four times the width of the line.

DISCUSSION

Several authors have documented the preference of tracheal mites for younger-bee hosts (Morgenthaler, 1931; Bailey, 1958; Lee, 1963; Giordani, 1977; Gary and Page, 1987). Although we do not know the adaptive function, if any, of this preference for young bees, there are several possibilities. First, the life cycle of the tracheal mite requires approximately 20 days (Bailey, 1963, Royce et al., 1988), while the average life-span of the honeybee is approximately 30 days during the peak flowering season (Wilson, 1971). Thus, the selection of young hosts may enhance the probability of completing development before host death. Alternatively, the preference may have originally arisen as a means to reduce competition with other mites, since, in the absence of any preference, the young bees would be less likely to have been colonized already by other mites. Finally, young bees stay in the colony, engaging in tasks such as brood care, while older bees assume the riskier roles such as foraging. By spending more of their developmental time inside the hive, these parasitic mites would enhance their survival.

Whatever its evolutionary significance, on a proximal level it is clear that the age-related preference of honeybee tracheal mites is mediated in some measure by chemoreception. Our preliminary video analysis suggests that the preference measured in this study is due to an increased angular velocity caused by cuticular lipids of young bees. Although we did not see any evidence for ori-

entation toward an extract-treated zone, once in contact with the extract, mites engaged in an extended series of circus movements that caused them to remain in that area for a longer period than when they were in contact with a hexane-treated zone. When mites that were walking on the extract came to the edge of the treatment, they generally turned back; however, most of the turning occurred well before they reached the border of the treated area. It also is interesting to note that despite the high angular velocity, turning was almost entirely in one direction, with little change from clockwise to anticlockwise.

Throughout this study, female tracheal mites consistently showed a significantly higher probability of contact with extracts of young bees than with a hexane control in our two-choice bioassay ($\bar{x} = 90\%$ across all experiments). In only one of the bee colonies did the mites not show a preference for the extract of young bees over old bees. When extracts of either young or old bees from this colony (colony 2) were presented to the mites against extract of colony 1 old bees, both elicited a significantly higher level of response. Thus, the lack of mite differentiation between young and old bees of colony 2 appeared to be due to a greater level of mite response to old bees of this colony compared to that of other colonies, rather than a lack of activity elicited by the cuticular extract of young bees. This view was supported by the fact that the GC hydrocarbon profile of colony 2 old bees was more similar to young-bee profiles than were old-bee profiles from any of the other three colonies. Even among the other three colonies, there appeared to be considerable variation in the level of female discrimination, and this discrimination appeared to be correlated with the degree of difference between hydrocarbon profiles of old and young bees. For colony 1, there was a 4.5-fold higher response to young-bee extract, while in colony 4, this response was only 1.7 times greater. Thus, colony 2 apparently only represents a greater extreme of this variability in age-related changes in surface-extractable lipids. The fact that the old-bee extract from colony 1 elicited a strong positive response when presented with hexane indicates that the age-related preference was due to the greater activity of the young-bee extract rather than a deterrent effect by old bees.

The combined results of the bioassays of fractionated extract of young bees suggest a mixture of both saturated and unsaturated hydrocarbons as the chemical constituents responsible for mite response, with the greater role probably played by the saturated components. Although almost all studies of honeybee cuticle have focused on hydrocarbons, a large portion of extractable cuticular lipids are nonhydrocarbons (Francis et al., 1989), such as long-chain fatty acids, the probable biosynthetic precursors of cuticular hydrocarbons. Not only does the positive response to young-bee extract appear to be elicited solely by the hydrocarbon constituents, the isolated hydrocarbons actually were preferred to the unfractionated extract, a preference that was lost when the hydrocarbon

fraction was recombined with the nonhydrocarbon components of the extract (Table 2). Francis et al. (1989) determined that surface-extractable nonhydrocarbon lipids increase by more than 10-fold in European honeybee workers during the 12 days after emergence as adults. Thus, a possible adaptive hypothesis for the reduced response to hydrocarbons caused by nonhydrocarbon lipids is that the concentration of nonhydrocarbons is used by tracheal mites as one indicator of honeybee age.

In addition to an age-related increase in extractable nonhydrocarbon lipids, Francis et al. (1989) also found dramatic and complex shifts in the relative proportion of hydrocarbon components. For example, unsaturated hydrocarbons increased proportionally relative to saturated hydrocarbons from 8% in newly emerged bees to 51% by day 6, and methyl- and dimethylalkanes decreased relative to normal-chain hydrocarbons from 46% to 2% during this same time period. Thus, the higher response to a fraction containing saturated hydrocarbons over the fraction containing unsaturated hydrocarbons suggests that the preference for young-bee extract may be due to a preference for alkanes, and particularly branched alkanes, which are virtually absent in older bees. The comparable level of response of the unsaturated hydrocarbon fraction relative to the crude cuticular extract is more difficult to understand, since these constituents are found in higher proportions in older bees. However, whereas all branched alkanes show a decline in the cuticle with age, the quantitative change in unsaturated constituents is more complex, with the overall increase due largely to an increase in the absolute amount of C_{33} and C_{35} alkenes and alkadienes alone (Francis et al., 1989). Many shorter-chain alkenes show a concomitant decline in absolute quantity with age. Thus, tracheal-mite response to the unsaturated hydrocarbon fraction may be due to a positive response to specific unsaturated components, or this response simply may represent a very general response to hydrocarbons, at least as measured by our bioassay. A more detailed study of the chemical modulation of tracheal-mite behavioral mechanisms might clarify the role of each of these chemical groups.

Chemoreception also may play a significant role in the host selection of other mite species. Hunter and Rosario (1988) have reviewed the evidence for olfactory perception of hosts in phoretic Mesostigmata. Olfactory receptors on tarsi I are specifically implicated in this process, as three distantly related species are unable to locate their hosts after amputation of these tarsi. These researchers suggest that cuticular hydrocarbons may play an important role in host seeking by Mesostigmata as well, although they present no evidence to support this supposition and erroneously refer to them as acting as a potential "attractant allomone." *Varroa jacobsoni*, another mite parasitic on honeybees, also uses olfactory chemoreception to locate suitable drone larvae (Le Conte et al., 1989). In this case, host finding is mediated by a blend of methyl palmitate,

ethyl palmitate, and methyl linoleate. Each ester evoked a significant response when presented individually against a solvent blank, and the blend of three components was no more active than methyl palmitate alone.

The results presented here demonstrate that host selection by the female tracheal mite is modulated at least in part by age-related changes in the cuticular-lipid profiles of the honeybee. We hypothesize that the preference for young bees over old bees observed for this species is due to changes in the tracheal-mite locomotory behavior caused primarily by saturated, and most probably branched, hydrocarbons, a response that may be attenuated by the presence of nonhydrocarbon lipids. We have not addressed, however, the mechanism by which the hydrocarbons act. Although members of the tracheal mite family Tarsonemidae have chemoreceptors on the tarsi of their front legs and gnathosoma (Krantz, 1978), we do not know if the mites are perceiving the chemicals via olfaction or gustation. Also to be resolved is the relative importance of mite chemoreception in relation to other modalities that might operate in tracheal-mite host selection. Nevertheless, it appears that extractable cuticular components must play a major role inasmuch as female mites showed a strong discrimination for young hosts in the absence of other potential cues. These findings point to a possible control strategy whereby migration of tracheal mites to young-bee hosts could be disrupted by artificially altering their chemical profile. In fact, the presence of vegetable oil on the integument of bees, which would increase the proportion of nonhydrocarbon lipids, significantly reduced the colonization of young bees by tracheal mites (Gary and Page, 1987; Smith, 1990). This novel control strategy is currently being investigated for possible implementation on a larger scale.

Acknowledgments—We thank A.C. Wayadande, and Drs. D.L. Wrensch, R.E. Page, Jr., and R.E. Treece for their helpful comments on the manuscript. R. Hendrickson kindly provided infested bees for a portion of the study, and J.L. Blackmer assisted in preparation of graphics. TRIMEDLURE ENANTIOMERS: DIFFERENCES IN ATTRACTION FOR MEDITERRANEAN FRUIT FLY, *Ceratitis capitata* (WIED.) (DIPTERA: TEPHRITIDAE)

R.E. DOOLITTLE,* R.T. CUNNINGHAM,[1] T.P. McGOVERN,[2] and P.E. SONNET[3]

Insect Attractants, Behavior, and Basic Biology Research Laboratory, Agricultural Research Service, U.S. Department of Agriculture, Gainesville, Florida 32604

(Received July 10, 1990; accepted October 22, 1990)

Abstract—The most biologically active enantiomer of trimedlure, a synthetic lure attractive to male Mediterranean fruit flies, is the 1*S*,2*S*,4*R* enantiomer of isomer C, the *tert*-butyl ester of *cis*-4-chloro-*trans*-2-methylcyclohexanecarboxylic acid. We also determined that the 1*R*,2*R*,5*S* enantiomer of isomer A is significantly more attractive than its optical antipode. Essential differences in the current synthetic work that are critical to possible commercialization of this preparation are detailed herein.

Key Words—Mediterranean fruit fly, *Ceratitis capitata* Diptera, Tephritidae, attractant, trimedlure, stereoisomers, enantiomers.

INTRODUCTION

The synthetic male lure, trimedlure, has been used for over 25 years as the best practical attractant for survey and detection traps for the Mediterranean fruit fly, *Ceratitis capitata* (Wied.). It is a mixture of the eight stereoisomers of the *tert*-butyl esters of the *cis*- and *trans*-4 and 5-chloro-*trans*-2-methylcyclohexanecarboxylic acids (Beroza et al., 1961; McGovern and Beroza, 1966; McGovern et al., 1986a) (Figure 1). The commercial lure also contains less

than 5% of materials where the methyl and carboxyl groups are *cis*. It was recognized early through olfactometer tests that the four *trans* isomers (designated A, B_1, B_2, and C, each consisting of a pair of enantiomers) differed in biological activity (McGovern et al., 1966). These differences in biological activity recently have been confirmed and the relative rankings clarified in statistically analyzed field plot tests (McGovern et al., 1986a,b).

Sonnet et al. (1984) prepared the enantiomers of these structures and found differences in attraction between the enantiomers of A and C. However, the details of the bioassay results were not reported. This is the first report of the results of field tests on the relative attraction of the eight enantiomers of *trans*-trimedlure. It confirms the initial observations and includes the enantiomers of B_1 and B_2. In addition, sufficient materials were prepared for replicated testing of the A and C enantiomeric pairs to allow for greater statistical confidence in the results that had been the case in previous studies. Amplification of the synthetic details is provided herein.

METHODS AND MATERIALS

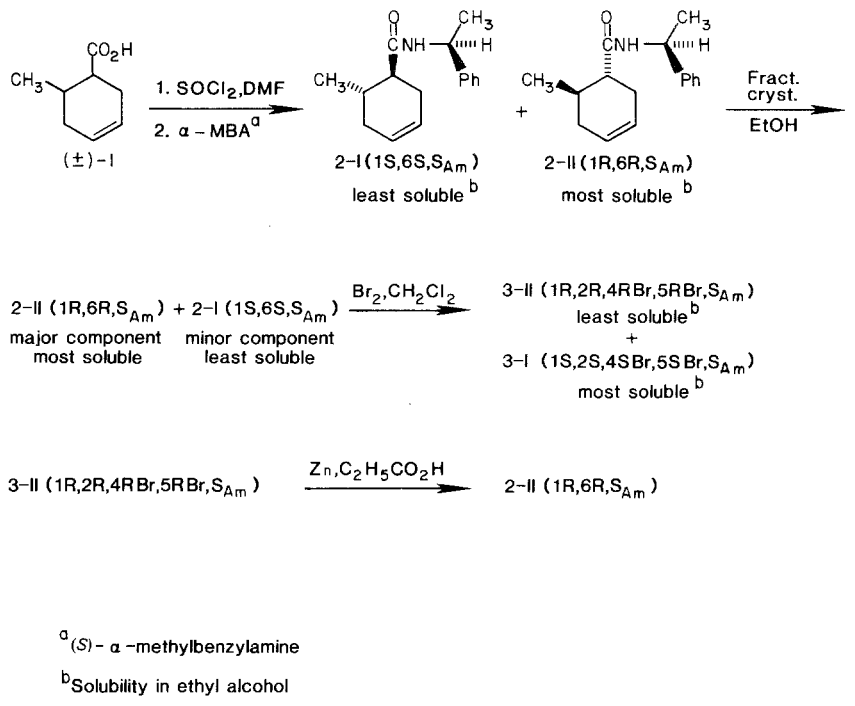
Chemical. Gas–liquid chromatography (GLC) was performed with Varian 1400, 1420, and 2100 instruments using the following capillary columns: column A, CPS-1 fused silica (0.25 mm × 34 m) (Quadrex Corp., New Haven, Connecticut); column B, BP-1 fused silica (0.22 mm × 12 m) (SGE, Inc.,

Austin, Texas); column C, OV-1701 fused silica (0.25 mm × 15 m) with helium carrier gas at 19 cm/sec and operated at temperatures as indicated. Infrared data were obtained with a Perkin-Elmer model 467 spectrophotometer using 3% solutions in CCl_4 or $CHCl_3$. A Nicolet 300-MHz FT NMR spectrometer was employed to obtain [^{1}H]- and [^{13}C]NMR data with 1 and 20% solutions in $CDCl_3$, respectively. Chemical ionization (methane) mass spectra were obtained with a Nermag model R10-10 spectrometer that was equipped with a chromatographic inlet served by a Varian 6000 instrument with a 3% OV-1 glass column (0.32 mm × 50 m). The HPLC column employed was a 2- to 10-μm BioSil-A (25 mm × 25 cm) operated with a Laboratory Data Control Constametric 2G pump and a Waters Associates model R401 differential refractometer detector with 1% diethyl ether in hexane as the eluting solvent. The α-methylbenzylamines were purchased from Hexcel Corp., Zeeland, Michigan. The (*S*)-α-methylbenzylamine was determined by the method described by Sonnet et al. (1984) to be 99.6% pure by GLC analysis of its methoxy (trifluoromethyl)phenyl acetamide. The *trans*-6-methyl-3-cyclohexene carboxylic acid (siglure acid) used as a starting material was obtained from Benzyl Products, Inc., Richmond, California. The commercially prepared acid had a mp of 46–57°C and contained approximately 3–5% of the *cis* isomer as determined by conversion to methyl esters with diazomethane and GLC analysis on column A at 100°C. One recrystallization from hexane at a ratio of 75 g of acid to 200–250 ml of solvent produced acid: mp 60–63°C. Green and Beroza (1959) reported mp 64–65°C for a sample of this acid that was 99+% isomerically pure by GLC analysis of the methyl ester.

The eight pure enantiomers of *trans*-trimedlure were prepared in a manner similar to the procedures described by Sonnet et al. (1984) (Figures 2 and 3). Only the essential and significant modifications are described at appropriate locations throughout this section. Authentic samples of intermediates and products were on hand from previous preparations for direct analytical comparison.

Synthesis and Partial Resolution of α-Methylbenzylamides 2-I and 2-II. The synthesis and resolution of the (*S*)-α-methylbenzylamide of *trans*-6-methyl-3-cyclohexenecarboxylic acid (±)-I was carried out as described previously, and the retention times were identical to those of authentic samples from the previous preparations. The 1*S*,6*S*,S_{Am} (Am = α-methylbenzylamine) amide (2-I) was produced in 50% yield of theoretical and 99.9% purity (as determined by GLC on column A at 230°C) by four to five recrystallizations from 95% ethanol using 5 ml/g of amide. The GLC κ's for the 1*S*,6*S*,S_{Am} and the 1*R*,6*R*,S_{Am} (2-II) were 14.22 and 14.59, respectively with α = 1.026. The [^{1}H]NMR and infrared spectra of these diastereomeric amides, as well as the mp were identical to those of authentic samples from the previous preparations.

Resolution of α-Methylbenzylamide 2-II. The 1*R*,6*R*,S_{Am} amide (2-II) [the more soluble diastereomer that was recovered from the mother liquors from



[a](*S*)-α-methylbenzylamine

[b]Solubility in ethyl alcohol

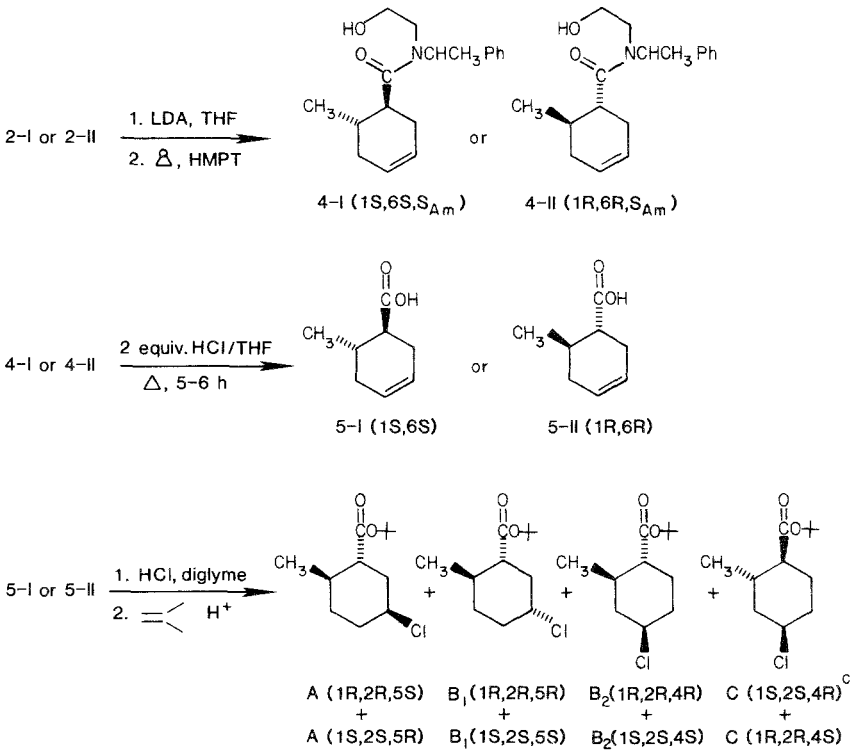
which the $1S,6S,S_{Am}$ amide (2-I) had been crystallized] was purified by the bromination–debromination cycle described by Sonnet et al. (1984). Six to seven recrystallizations of the dibromide (3-II) from 95% ethanol using 10 ml/g of dibromoamide were required to produce a product of 99.9% purity [determined by reducing aliquots (100 mg) of dibromamide to the unsaturated amide (2-II) followed by GLC analysis]. The debromination procedure was modified slightly in that after the removal of the unreacted zinc by filtration, the propionic acid solution was diluted with water and extracted with methylene chloride (it was not possible to filter the debrominated amides as described because of the very fine particle size of the precipitate). The methylene chloride extract was washed thoroughly with water and cautiously with saturated sodium bicarbonate, then dried over sodium sulfate. The use of diethyl ether as extraction solvent is to be avoided as it extracts large quantities of acetic acid that makes washing with satd. sodium bicarbonate difficult.

N-*Hydroxyethylation of Diastereomerically Pure Amides 2-I and 2-II.* Labilization of the purified amides to hydrolytic conditions was accomplished



[c] Most attractive (Table1.)

FIG. 3. Recovery of the configurationally pure isomers of *trans*-6-methyl-3-cyclohexane carboxylic acid from the resolved (*R*)- or (*S*)-α-methylbenzylamides and conversion to the enantiomers of trimedlure.

by *N*-hydroxyethylation of the diastereomerically pure amides (2-I or 2-II) as described. Particular attention should be given to the careful drying of the amides under vacuum over P_2O_5 prior to *N*-hydroxyethylation since the yield of the reaction is reduced drastically if this drying is not thorough. The yield of *N*-hydroxyethylated amides (4-I or 4-II) from this procedure was typicaly 80–90%. The [^{1}H]NMR spectra of the products were identical to those of authentic samples and the GLC on columns B and C at 200°C indicated purities of ≥99.9%.

(1S,6S)-(+)-, and (1R,6R)-(−)-6-Methyl-3-Cyclohexenecarboxylic Acid,

5-I and 5-II. The conversion of the *N*-hydroxyethylated amides to (1*S*,6*S*)-(−)- and (1*R*,6*R*)-(+)-6-methyl-3-cyclohexenecarboxylic acids (5-I and 5-II, respectively) was accomplished most conveniently by acid hydrolysis to a mixture of the acid and the amino ester rearrangement product (see Sonnet et al., 1984) with aqueous HCl in THF under reflux (using a ratio of 3 ml of 6 N HCl/g amide) until all the starting *N*-hydroxyethylated amide had been consumed as determined by GLC on column B at 200°C. The GLC κs of the *N*-hydroxyethylated amides and the amino ester rearrangement product were 12.73 and 6.64, respectively with $\alpha = 1.92$. These products were separated by dilution of the hydrolysis mixture with water and extraction with ether. The ether solution then was extracted several times with 15% NaOH, the alkaline extracts were combined and acidified with 6 N HCl, and extracted several times with ether. The ether extracts were washed with H_2O, saturated NaCl, and dried over Na_2SO_4. Removal of the drying agent, evaporation of the solvent, and distillation (bp 70–75°C, 0.2 mm) gave the two enantiomerically pure acids in about 40% yield. The enantiomeric purity of the acids could be verified by reconversion to the amides with (*S*)-α-methylbenzylamine and GLC analysis on column A. Both acids were obtained in $\geq$99.99% ee.

The amino ester rearrangement products were set aside for possible conversion to additional quantities of the two acids either via reduction with lithium aluminum hydride followed by oxidation as was reported originally (Sonnet et al., 1984) or via further acidic hydrolysis. The [^{1}H]NMR and mass spectra of the two enantiomeric acids were in complete agreement with those of authentic samples.

Preparation of Eight Isomerically Pure Chloro Acids of Figure 1 from 5-I and 5-II. The addition of HCl to the two enantiomerically pure 6-methyl-3-cyclohexenecarboxylic acids was accomplished most conveniently by a slight modification of the published procedure (Beroza et al., 1961) in that the substitution of diglyme for the dioxane originally used resulted in a much cleaner reaction without the formation of the dark purple color that results when dioxane is used. Each pure acid (5-1 and 5-11) undergoes addition of HCl to produce a mixture of A, B_1, B_2, and C (Figure 1) in which positions 1 and 6 are configurationally determined, i.e., instead of a mixture of four racemates, one now deals with two mixtures of four individual isomers that are chromatographically separable. The reaction is worked up by ether extraction and acid–base manipulation to remove neutral by-products. The four isomeric hydrochlorinated acids (A, B_1, B_2, C) produced from each enantiomerically pure unsaturated acid were resolved by GLC analysis on column A at 185°C. The κ' values are A = 3.8, $B_1 = 4.35$, $B_2 = 4.1$, C = 4.75. The assignment of the order of elution of the isomers was based on the reported ratios (McGovern et al., 1966) of these isomers A, 35%; $B_1 + B_2$, 15% (with B_1 in lesser quantity) and C, 50% produced in the hydrochlorination reaction. The [^{1}H]NMR and mass spectra of the

isomeric mixture of each enantiomeric pair of acids was in complete agreement with the structures. The yield from this reaction was typically about 85%. Attempts to partially separate this mixture of isomeric acids by conversion to salts with α-methylbenzylamine followed by fractional crystallization as reported by Sonnet et al. (1984) were unsuccessful.

Preparation of Eight Isomers of trans*-Trimedlure from Two Acid Mixtures.* The *tert*-butyl esters (Figure 2) were prepared from the enantiomerically pure hydrochlorinated acids by the procedure (reaction with isobutylene plus acid catalyst under pressure) reported by McGovern et al. (1966) and Rabjohn (1963) in 70% yield. This procedure is superior to that of Sonnet et al. (1984), involving conversion to the mixture of acid chlorides and reaction with *tert*-butyl alcohol and *N,N*-dimethylaniline in refluxing ether which led to numerous by-products and gave low yields. The [^{1}H]NMR and mass spectra of the two mixtures of *tert*-butyl esters was in complete agreement with their structures. The HCl adducts of the esters (configurationally pure at positions 1 and 6) were separated by a combination of HPLC and low-temperature crystallization. The elution order on HPLC is B_1, B_2, A, and C. It is possible to separate directly pure A, B_1, B_2, and a portion of the C isomers by HPLC. Samples of C collected by HPLC always contained residual amounts of A (even after repeated HPLC) due to overlap of peaks A and C. Crystallization of the chromatographed C from pentane solutions at Dry Ice temperatures (leaving isomer A and some residual C in the pentane mother liquor) resolved this problem. This mother liquor could be reprocessed by HPLC to provide additional quantities of pure A and C. It was not possible to resolve completely the two sets of the four isomeric esters (A, B_1, B_2, and C) by GLC on column A at 150°C because B_1 and B_2 coelute. However, since these two isomers are separated so well by HPLC, and since Sonnet (1984) had reported that B_1 and B_2 purified by this same HPLC method were essentially 100% pure, when analyzed by GLC with a column that resolved all four isomers, we decided it was safe to assume that these samples were not cross contaminated. The isomeric purities as determined by GLC on column A at 150°C are: 1*S*,2*S*,5*R* (A), 98.2% (1.8% B_2); 1*S*,2*S*,5*S* (B_1) 100%; 1*S*,2*S*,4*S* (B_2) 100%; 1*S*,2*S*,4*R* (C) 100%; 1*R*,2*R*,5*S* (A) 97.4% (2.6% B_2); 1*R*,2*R*,5*R* (B_1) 100%; 1*R*,2*R*,4*R* (B_1) 100%; 1*R*,2*R*,4*R* (B_2) 100%; 1*R*,2*R*,4*S* (C) 94% (6% A). The enantiomeric purities are considered to be $\geq$99.9% based upon the measured enantiomeric purities of the resolved *trans*-6-methyl-3-cyclohexenecarboxylic acids in which no enantiomer could be detected by GLC analysis of the amides prepared with α-methylbenzylamines. It had been shown by Sonnet et al. (1984) that no epimerization occurred during the hydrochlorination procedure. Epimerization of the carboxyl group (which is thermodynamically disfavored) during the esterification procedure was considered highly unlikely since the procedure is quite mild (catalytic sulfuric acid and excess isobutylene in anhydrous diethyl ether at room temperature or slightly

above for 12 hr) compared to the acid hydrolysis procedure for the hydrolytic cleavage of the *N*-hydroxyethylated amides which proceeds with no epimerization.

Bioassay. In this recent series of tests, treatments were applied to small cotton wicks in Jackson sticky traps (Harris et al., 1971) at the rate of 10 mg of candidate chemical as a 10% solution in reagent grade acetone or as 10 μl of the neat chemical (isomer A preparations). In the original two tests in Sonnet et al. (1984), only 5 mg or less per wick was used, and it was to confirm the original results that the tests were repeated. The treatments were replicated five times. The traps were hung in trees in a large macadamia nut orchard (not a breeding host) near Hilo, Hawaii. Traps were 7.6 m or more from each other. Laboratory-reared (Tanaka et al., 1970), sterile (Ohinata et al., 1978) Mediterranean fruit fly males (3 days old) were released in an even distribution throughout the test plot. This test system, using artificially high populations in the field, has proven to be an effective means of testing relative attractiveness (McGovern et al., 1986b) and has higher precision (lower coefficient variation) than tests utilizing unevenly distributed wild populations. The sticky inserts were removed at each examination and the flies counted (two-day intervals). Data were transformed to the square root and analyzed by analysis of variance. Back transformation produced weighted means that were separated by Duncan's multiple range test at the $P \geq 0.05$ level (Duncan, 1951).

In the original study (Sonnet et al., 1984), we conducted two bioassays of the C and A enantiomers before exhausting the supply. In this current study, we conducted the experiment reported in Table 1 with both enantiomers of all four *trans* isomers and their racemic mixtures (except racemic B_1). Due to the limited quantities of B_1 and B_2, we ran a second experiment with the enantiomers of only A, C, and B_2 and a third experiment with the enantiomers of only A and C. The results of these partial tests are not reported here, but were in statistical agreement with the data reported in Table 1.

RESULTS AND DISCUSSION

The greater effectiveness of the 1*S*,2*S*,4*R* enantiomer of isomer C over its mirror image and all other isomeric forms and standard commercial trimedlure mixtures is shown clearly in Table 1. Furthermore, the 1*R*,2*R*,5*S* enantiomeric form of isomer A was significantly more attractive than its mirror image. The preliminary work failed to show significant differences between the isomer A enantiomers. The greater quantities of isomer A enantiomers available for this current study enabled us to double the dosage in the traps and to do repeat testing. In all of our tests, the 1*R*,2*R*,5*S* form was significantly superior.

There were no significant differences in the attractiveness of the *RR* forms

TABLE 1. WEIGHTED MEAN CATCH OF MALE MEDITERRANEAN FRUIT FLIES WITH ENANTIOMERS AND RACEMIC MIXTURES OF *trans* ISOMERS OF TRIMEDLURE (KEAAU, HAWAII)

Isomer[a]	Weighted mean catch[b]

Enantiomer *R, R, S*	172.45c			46.79de	
Standard Trimedlure[c]					322.06b

[a] Isomers C and B_2 are the *tert*-butyl esters of *cis*- and *trans*-4-chloro-*trans*-2-methylcyclohexanecarboxylic acid, respectively; i.e., C = 1*S*,2*S*,4*R* and 1*R*,2*R*,4*S*. Isomers A and B_1 are the *tert*-butyl esters of *trans*- and *cis*-5-chloro *trans*-2-methylcyclohexanecarboxylic acid, respectively; i.e., A = 1*S*,2*S*,5*R* and 1*R*,2*R*,5*S*.

[b] Catches followed by the same letter are not significantly different [$P > 0.05$, Duncan's (1951) multiple range test; data were transformed to the square root for analysis and back-transformed to produce weighted means]. Two-day catch initial dosage 10 μl $\approx$ 10 mg. Randomized complete block field plot design with five replicates. F test = 26.95 with 11,44 degrees of freedom. $P < 0.01$. The flies in each trap were removed and counted every two days.

[c] Contains 27% A, 7% B_1, 18% B_2, 41% C *trans* isomer and 4% total *cis* isomers.

of the B_1 and B_2 isomers and their mirror images. However, because of the limited supply (i.e., small sample size) and the inherently low attraction of these isomers, such differences may exist and be demonstrated in larger-scale experiments.

Trimedlure exhibits in its attraction the same high specificity due to molecular configuration that we have come to expect from the natural attractants such as the sex pheromones (Brand et al., 1979), even though it would appear to be unrelated structurally to any of the components of the female produced attractant (Baker et al., 1985). It is clear from these results that the receptor system in the Mediterranean fruit fly is capable of discriminating between optical isomers even though the natural pheromone of this insect may or may not involve chemical chirality. This phenomenon has been observed in a lepidopteran system (Chapman et al., 1978). We would hope that these results emphasize the importance of considering the role of enantiomers when studying communication systems in insects and other biological systems.

Acknowledgments—We wish to acknowledge the valuable assistance of Tadao Urago, Vinnie Shishido, and Richard Mattos in these studies.

(Received November 14, 1990)

Abstract—The major component of the rectal glandular extract and volatile emission of male *Bactrocera cacuminatus* is racemic 1,7-dioxaspiro[5.5]undecane. 1-Hydroxy-5-nonanone as its open chain form, together with 6-*n*-butyl-3,4-dihydro-2H-pyran are minor components. 1,7-Dioxaspiro[5.5]undecan-4-ol is present at a low level and is shown to be exclusively the diastereomer with an equatorial hydroxy group by comparison with synthesized samples of both epimers. Examination of the trifluoroacetate by chiral gas chromatography has established the (4*S*,6*S*) stereochemistry (ca. 80% ee). The presence of 1,7-dioxaspiro[5.5]undecan-3-ol, or its isomerization product, 1,6-dioxaspiro[4.5]decan-2-ylmethanol, could not be confirmed. Trapping of the volatiles released by sexually mature male flies at dusk revealed that a number of the glandular components described above are released at mating time. Reexamination of the glandular secretion of sexually mature female olive flies (*B. oleae*) has failed to confirm the presence of any 1,7-dioxaspiro[5.5]undecanols, with the only volatile component (other than fatty acids) being 1,7-dioxaspiro[5.5]undecane.

Key Words—*Bactrocera cacuminatus*, *Bactrocera oleae*, Diptera, Tephritidae, olive fly, spiroacetal, ketoalcohol, chirality.

INTRODUCTION

Of the 80 or so fruit-fly species located in Australia, five are major pests of horticulture (Drew et al., 1982). Several are minor or incidental pests, with the remainder lacking economic importance and more or less confined to their natural rainforest habitats. Although studies of certain economically important species may lead to chemically based monitoring and control measures, examination of other species also is justified from the perspective of general fruit-fly biology, taxonomy, and communication. The dorsalis complex of fruit flies (Perkins et al., 1990) is a major scourge throughout the Indo-Pacific region, and it was considered of interest to examine the chemistry of an "Australian" member of the complex. *Bactrocera (Bactrocera) cacuminatus* (Héring)[4] is distributed in the coastal regions of eastern Australia from Cape York in the north to East Gippsland in Victoria. This medium-sized species, which has been regarded as being a minor pest of tomatoes and capsicums in Queensland, is of interest in that it appears to have a single natural host, the wild tobacco plant (*Solanum mauritianum*), which flourishes in fringing rainforest vegetation and along small watercourses. Some years ago, we commented (Kitching et al., 1986) on some aspects of the chemistry of this species, which was intriguing because of its similarity with that of the female olive fly (*B. oleae*) (Baker and Herbert, 1987), a major pest in Mediterranean and North African areas. Male tephritid fruit flies store a pheromone in a reservoir and secrete it from a sac, and both organs are located in the lower abdominal (rectal) area. Only in one species, *B. oleae* (olive fruit fly), does the female release the sac pheromone. As part of a careful study of members of the doralis complex, more detailed studies of the chemistry of *B. cacuminatus* have been conducted and are reported below.

METHODS AND MATERIALS

Bactrocera cacuminatus specimens were supplied from the culture maintained at the Department of Primary Industries, Indooroopilly, Queensland. This culture was initially bred out from infested wild tobacco fruit (*Solanum mauritianum*).

Gland Secretion Analysis and Identification

Sexually mature adult male flies were briefly chilled (0°C) and their rectal glands excised and stored in spectrograde pentane (Kitching et al., 1989). Combined GC-MS examinations were performed using a Finnigan Mat 1020 or

[4] *Bactrocera* is the new genus name applied in the general taxonomical revision (Drew, 1989) to a large number of fruit-fly species previously classified in the genus *Dacus*.

Hewlett-Packard HP 5992 or 5970 MSD instruments with a nonpolar column. Low-resolution mass spectra refer to combined GC-MS measurements and high-resolution mass spectra were recorded on a Kratos MS-25 RFA spectrometer. Proton magnetic resonance spectra were recorded at 400 MHz (FT mode) on a JEOL JNM-GX 400 spectrometer. Deuterochloroform was employed as solvent, and chemical shifts (δ values) are relative to residual chloroform at δ7.24. [^{13}C]NMR spectra were recorded at 100 MHz, utilizing $CDCl_3$ as solvent and chemical shifts are relative to the central component of the $CDCl_3$ triplet at 77.00 ppm.

Synthesis of Certain Glandular Components

1,7-Dioxaspiro[5.5]undecane (**1**), 6-*n*-butyl-3,4-dihydro-2H-pyran (**2**), and *N*-3-methylbutylacetamide (**4**) are known compounds (Baker and Herbert, 1987).

*1-Hydroxy-5-nonanone (**5**).* *n*-Butyllithium (2.5 M in hexane, 20 ml) was added slowly to a cooled solution (−10°C) of 1,3-dithiane (6 g, 50 mmol) dissolved in dry THF (60 ml) (N_2). The reaction mixture was stirred for 2 hr at 0°C, and then 0.5 hr at 20°C. The solution then was recooled (−10°C), and *n*-butyl bromide (7 g, 51 mmol) was added. After stirring overnight at ca. 20°C, the reaction mixture was poured into a saturated NH_4Cl solution, and the aqueous layer extracted twice with ether. The combined organic fractions were washed with saturated $NaHCO_3$ solution, 1 M KOH, and then H_2O. Distillation of the dried (K_2CO_3) organic fraction provided 2-*n*-butyl-1,3-dithiane (bp 80–83°C, 0.2 mm; 8.36 g, 95%). [^{1}H]NMR ($CDCl_3$): 0.84 (t, 3H), 1.24–1.30 (m, 2H), 1.38–1.46 (m, 2H), 1.66–1.71 (m, 2H), 1.77–1.84 (m, 1H), 2.03–2.07 (m, 1H), 2.73–2.86 (m, 4H), 3.98 (t, 1H). [^{13}C]NMR ($CDCl_3$): 47.52, 35.05, 30.37, 28.66, 25.95, 22.21, 13.73. Mass spectrum: 176 (M^+, 29), 118 (100), 106 (4), 87 (9), 73 (5), 72 (3), 60 (16), 45 (35), 41 (38). This 1,3-dithiane derivative (8.36 g) was converted to the lithio derivative as described above and reacted with 4-bromo-1-butene to provide the dialkylated-1,3-dithiane (as shown in Scheme 1) bp 101°C (0.2 mm), 9.63 g (88%). [^{1}H]NMR ($CDCl_3$): 0.89 (t, 3H), 1.26–1.42 (m, 6H), 1.78–1.83 (m, 2H), 1.88–1.95 (m, 2H), 2.12–2.17 (m, 2H), 2.70–2.83 (m, 4H), 4.91–5.04 (m, 2H), 5.74–5.82 (m, 1H). [^{13}C]NMR ($CDCl_3$): 137.94, 114.70, 38.08, 37.13, 30.41, 28.56, 26.03, 25.92, 25.42, 22.83, 13.91. Mass spectrum: 230 (M^+, 16), 188 (13), 175 (70), 173 (46), 155 (42), 114 (39), 107 (48), 99 (65), 81 (40), 67 (43), 141 (100).

Hydroboration–Oxidation of 2-(3'-butenyl)-2-n-butyl-1,3-dithiane. The dialkylated-1,3-dithiane (9.63 g, 87 mmol) was dissolved in dry THF (120 ml) and cooled to 0°C, after which a solution of BH_3–THF complex (64.5 ml of 1 M solution) was added slowly. The reaction mixture was stored for 1 hr

at 0°C and for 12 hr at 20°C, and then treated with 3 M NaOH solution at 0°C (130 ml) and 30% w/v H_2O_2 solution (22 ml). After stirring at room temperature for 4 hr, the reaction mixture was extracted with ether several times and the combined organic layers were washed with H_2O, separated, and dried ($MgSO_4$). After solvent removal at reduced pressure (Rotvaporator) the product was purified by flash chromatography (hexane–ethyl acetate, 1:1) to provide 8.32 g (80%) of 2-(4′-hydroxybutyl)-2-*n*-butyl-1,3-dithiane. [^{1}H]NMR ($CDCl_3$): 0.86 (t, 3H), 1.17–1.56 (m, 7H), 1.79–1.91 (m, 8H), 2.74–2.77 (m, 4H), 3.62 (t, 2H). [^{13}C]NMR ($CDCl_3$): 62.56, 53.21, 37.93, 37.88, 32.74, 26.14, 25.93, 25.46, 22.83, 20.42, 13.93. Mass spectrum: 248 (M^+, 20), 191 (47), 175 (100), 141 (56), 117 (33), 107 (29), 106 (21), 101 (37), 81 (36), 55 (53), 41 (93). HRMS: calcd. for $C_{12}H_{24}OS_2$, 248.1268, observed 248.1271. Dethioketalization of the above 1,3-dithiane derivative utilized the recently reported method (Stork and Zao, 1989). Thus, the thioketal (2.48, 10 mmol) in MeOH–H_2O (10 ml, 9:1), was treated with [bis(trifluoroacetoxy)iodo]-benzene (15 mmol) at 20°C for about 3 min, and the reaction mixture was poured into water, extracted with ether, and dried ($MgSO_4$). After solvent removal under reduced pressure, the product was purified by flash chromatography (hexane) and then hexane–ethyl acetate (3:1). [^{1}H]NMR ($CDCl_3$): 0.87 (t, 3H), 1.25–1.31 (m, 2H), 1.48–1.56 (m, 3H), 1.56–1.66 (m, 4H), 2.38 (t, 2H), 2.43 (t, 2H), 3.60 (t, 2H). [^{13}C]NMR ($CDCl_3$): 211.51, 62.29, 42.54, 42.23, 32.16, 25.98, 22.34, 19.67, and 13.82. Mass spectrum: 158 (M^+, <1), 140 (14), 116 (20), 111 (10), 101 (24), 98 (74), 85 (85), 83 (79), 57 (98), 55 (100), 43 (59). HRMS: calcd. for $C_9H_{19}O_2$(M + 1), 159.1384; observed (CI) 159.1386; calcd. for $C_9H_{22}NO_2$(M + NH_4), 176.1649; observed (CI), 176.1666. The 1-hydroxy-5-nonanone (**5**) just described, generally coexisted with varying proportions of the cyclic hemiacetal (**6**), and these were easily resolved under capillary GC conditions. Compound **6** was characterized by its [^{13}C]NMR signal at δ98.8. In the CI mass spectrum (NH_3), **6** exhibited no molecular ion, with the base peak (M − OH) at *m/z* 141. HRMS: calcd. for $C_9H_{17}O$, 141.1279 (CI); observed, 141.1267.

1-Trifluoroacetoxy-5-nonanone (7). The dithiane derivative (0.6 g, 2.5 mmol) was dissolved in CH_2Cl_2 (10 ml) and treated with $(CF_3CO)_2O$ (2.1 g; 10 mmol) for 1 hr at 20°C. The reaction mixture was poured into saturated aqueous $NaHCO_3$ and extracted twice with ether and dried ($MgSO_4$). Removal of the ether provided an oil, which was purified by flash chromatography (hexane) to provide 0.3 g (47%) of **7**. [^{1}H]NMR: 0.87 (t, 3H), 1.25–1.31 (m, 2H), 1.48–1.54 (m, 2H), 1.62–1.72 (m, 4H), 2.37 (t, 2H), 2.44 (t, 2H), 4.32 (t, 2H). [^{13}C]NMR: 210.27, 157.50 (q, J = 41.7 Hz), 114.51 (q, J = 285.7 Hz), 67.87, 42.59, 41.63, 27.60, 25.94, 22.32, 19.68, 13.78. Mass spectrum: 254 (M^+, 1), 212 (4), 197 (11), 141 (4), 98 (23), 85 (91), 69 (31), 58 (25), 57 (94), 55 (100), 43 (33), 41 (60). HRMS: calcd. for $C_{11}H_{17}O_3F_3$, 254.1129;

(94), 55 (100), 43 (33), 41 (60). HRMS: calcd. for $C_{11}H_{17}O_3F_3$, 254.1129; observed, 254.1127; calcd. for (M + 1), $C_{11}H_{18}O_3F_3$, 255.1163; observed (CI), 255.1212.

1,7-Dioxaspiro[5.5]undecan-4-ol (17). This was prepared from 2-(benzene-sulfonyl)tetrahydro-2H-pyran and the tetrahydropyranyl ether of 3,4-epoxy-1-butanol in the reported manner (Ley et al., 1986). Purification by flash chromatography (ether–hexane 1:1) provided the spiroacetal (**17**) with little contamination with the axial epimer (**18**). [^{1}H]NMR: 4.04 (m, 1H), 3.40–3.55 (m, 4H), 2.01 (m, 1H), 1.83–1.99 (m, 1H), 1.45–1.60 (m, 2H), 1.12–1.43 (m, 7H). [^{13}C]NMR (C_6D_6): 18.94, 25.49, 35.63, 35.84, 45.80, 58.77, 60.19, 64.24, 97.25. These spectral data agree well with those reported (Baker and Herbert, 1987).

Chirality Determination of Natural 1,7-Dioxaspiro[5.5]undecan-4-ol. The synthesized, racemic sample of 4*SR*,6*SR* **17** was converted to the trifluoroacetate with $(CF_3CO)_2O$ in CH_2Cl_2 at 20°C. Analysis was conducted on a Lipodex A 50-m glass column (MH-408-5) at 100°C (isothermal). Under these conditions, the enantiomers of **17** were resolved nicely, and comparison with an authentic sample of very predominantly (4*S*,6*S*)-1,7-dioxaspiro[5.5]undecan-4-ol (as the trifluoroacetate) showed this latter enantiomer was the more slowly eluting of the pair. Similar treatement and analysis of the natural extract demonstrated that the 4*S*,6*S* enantiomer was the predominant natural isomer with an ee of at least 80%. The 4*R*,6*R* enantiomer was definitely presented in the natural material.

RESULTS AND DISCUSSION

Specimens were obtained from a culture bred from infested wild tobacco fruit, and excision of rectal glands from sexually mature males was conducted as previously described (Kitching et al., 1989). Gas chromatography and combined GC-MS examinations were conducted on pentane extracts of ca. 10 glands and revealed the presence of one dominant component (~90% of volatiles), estimated at 8 μg / fly. An apparent molecular ion [(*m* / *z* 156 (14)], corresponding to $C_9H_{16}O_2$, was accompanied by fragment ions at 101 (100), 100 (60), 98 (83), and 83 (32), such features suggesting a spiroacetal on the basis of known fragmentation patterns (Francke and Reith, 1979) and in particular 1,7-dioxaspiro[5.5]undecane (1). This conclusion was confirmed by GC and GC-MS comparisons with an authentic sample synthesised according to Erdmann's procedure (Baker et al., 1980). A minor, earlier eluting compound (~1%) exhibited ions at *m* / *z* 140 (20) ($C_9H_{16}O$) with the base peak at *m* / *z* 98 and other prominent ions at *m* / *z* 83 (27) and 70 (18). The volatility of this component, its mass spectrum and possible structural connection with **1**

were suggestive of 6-*n*-butyl-3,4-dihydro-2H-pyran (**2**), and this was confirmed by comparisons of the mass spectrum with that of an authentic sample (Francke, unpublished results, 1984). The base peak (*m* / *z* 98) is attributed to ion **3** (Figure 1).

The next eluting compound (~ 1.5%) with apparent M^+ at *m* / *z* 129 (5), ($C_7H_{15}NO$) showed prominent ions at *m* / *z* 73 (53), 72 (45), 60 (29), 55 (16), and 43 (100), and its identity as *N*-3-methylbutylacetamide (**4**) was confirmed by comparisons with a synthesized sample. Compound **4** is present in the rectal glandular secretion of other species, e.g., *Bactrocera tryoni* (Bellas and Fletcher, 1979).

Two significant, more slowly eluting components are of interest. The first (~2%) showed a weak, apparent M^+ at *m* / *z* 158 (~ 1) with a more prominent ion at *m* / *z* 140 (16), and the mass spectrum showed a general resemblance to that of **2**, suggesting some constitutional similarity. However, its retention time was much longer and was indicative of the corresponding keto alcohol (**5**) with the ions at *m* / *z* 140 possibly representing M^+-H_2O. The rearrangement ion at *m* / *z* 98 (23) (M^+-H_2O, McLafferty) and other ions at *m* / *z* 101 (17, $HO(CH_2)_4C{\equiv}O^+$), *m* / *z* 85 (62, C_4H_9-$C{\equiv}O^+$) and *m* / *z* 83 (47,

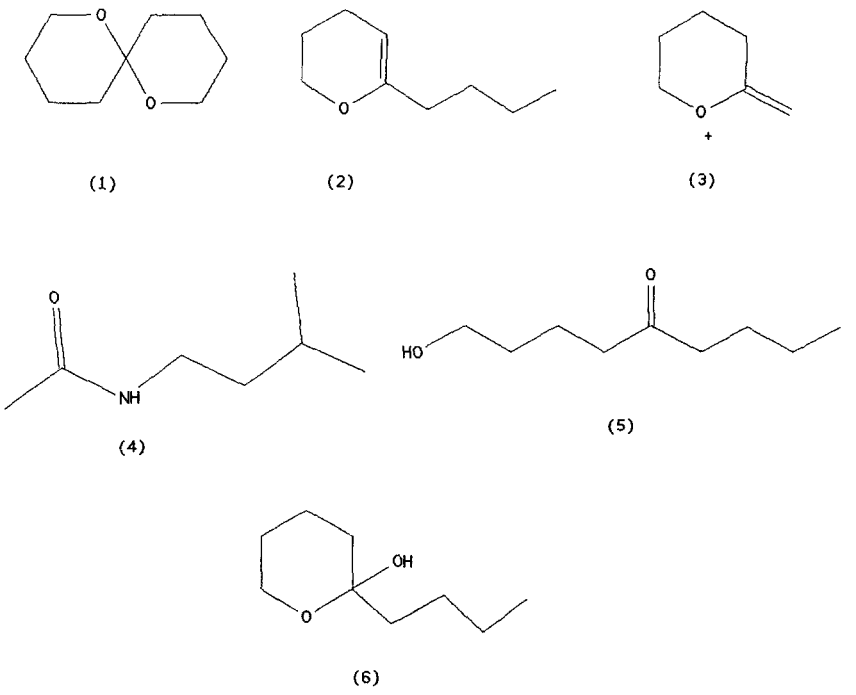

FIG. 1. Compounds associated with male *Bactrocera cacuminatus*.

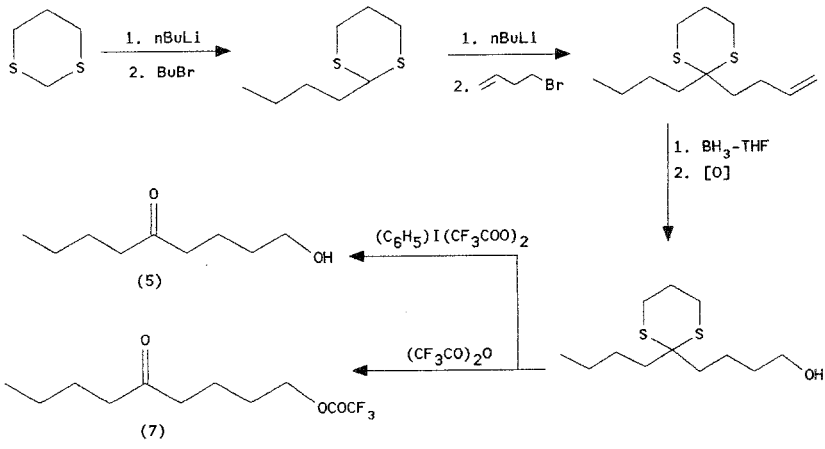
$C_4H_7C{\equiv}O^+$), pointed to 1-hydroxy-5-nonanone (**5**) or its cyclic hemiacetal (**6**). Although **6** is probably the immediate precursor of **2** (dehydration) or even of **1** (hydroxylation–cyclization), retention time comparisons with **2** and of authentic **5** and **6** confirm **5** to be present in the extract with no detectable level of the hemiacetal **6**. In addition, treatment of the complete glandular sample with trifluoroacetic anhydride produced the trifluoroacetate of **5**, viz. **7**, which exhibited gas chromatographic behavior identical with that of a separately synthesized sample (Scheme 1). Key compounds **5** and **7** were acquired by standard procedure based on dithiane chemistry summarized in Scheme 1. Deprotection of the thioketal with trifluoroacetic anhydride led directly to **7**, whereas use of [bis(trifluoroacetoxy)iodo]benzene provided **5**, which, depending on solvent and conditions, coexisted with its cyclihemiacetal **6**. Compounds **5** and **6** were well separated under capillary gas chromatography conditions and both were characterized mass spectrometrically, as well as by [^{1}H] and [^{13}C]NMR spectroscopy for **5**. The ketal carbon in **6** resonated at δ98.8. Full spectroscopic details are in Methods and Materials.

A slightly slower eluting compound ($\sim$0.5%) with an apparent $M^+\cdot$ = 172 ($C_9H_{16}O_3$) also was observed. The most striking feature of the mass spectrum was the presence of pairs of ions at *m* / *z* 98 (91) and *m* / *z* 101 (100) (**8** and **9**), and also at 114 (50) and 117 (100) (**10** and **11**). Recalling that **1** exhibits intense ions at *m* / *z* 98 (83) and 101 (100), the above data indicated this new component was a hydroxylated derivative of **1**, and this was supported by the ion at *m* / *z* 155 (M-OH) and a more intense ion at *m* / *z* 127 (30%) considered to correspond to **12** (Figure 2).

Assessment of available mass spectral data (Baker and Herbert, 1987) indi-



SCHEME 1. Synthesis of 1-hydroxy-5-nonanone (**5**) and its trifluoroacetate (**7**).

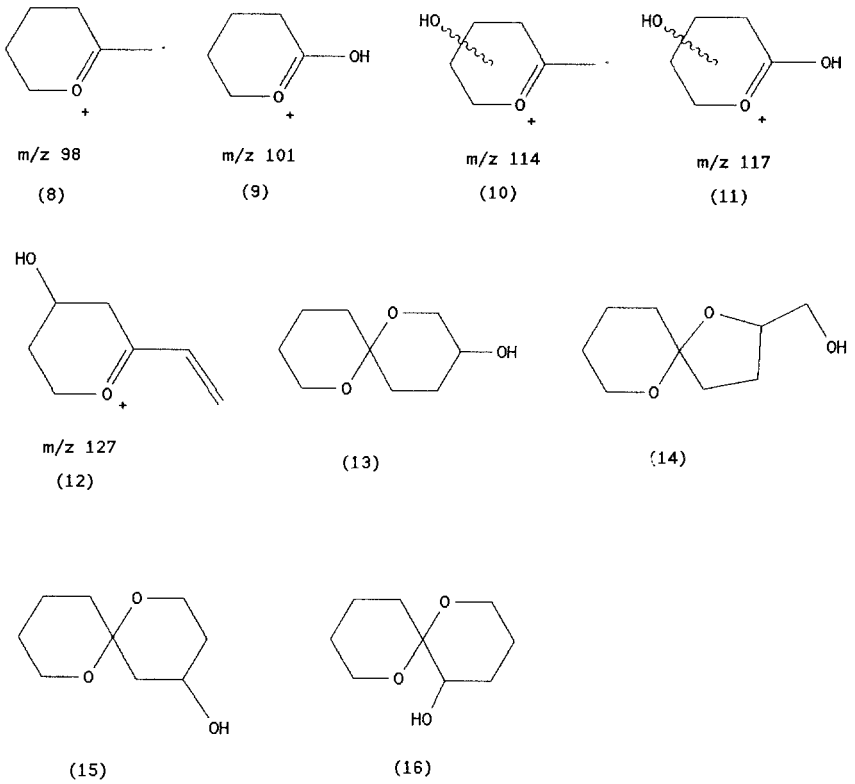


FIG. 2. Proposed structures of some ions and 1,7-dioxaspiro[5.5]undecanols.

cated that **13** and **14** could be ruled out and confirmation of the presence of **15** was obtained by examination of a synthesized sample that was an ca. 90:10 mixture of the epimeric alcohols **17** and **18** (based on [^{1}H] and [^{13}C]NMR analyses) from which pure **17** could be secured by flash chromatography (Figure 3).

Careful GC-MS comparisons established that the natural 1,7-dioxaspiro[5.5]undecan-4-ol was the equatorial epimer **17**, and none of the diastereomer **18** was detectable. Some fatty acids also were identified by mass spectral (library) comparisons and concluded to be the C_{14} saturated and C_{16} saturated and monounsaturated acids.

In our preliminary assessment of the chemistry of this species, there were indications from the GC-MS data that very small amounts of two isomers of another hydroxyspiroacetal were present. These were concluded to be isomers of **14** on the basis of a weak $M^{+}\cdot$ at 172 and the base peak at m/z 141 ($M\text{-}CH_2OH$), with other prominent ions at m/z 99 (30) and 101 (24). How-

ever, subsequent examinations of glandular extracts derived from male *B. cacuminatus* of varying ages did not confirm the presence of these minor components or the 3-hydroxy derivative (**13**) with which **14** is known to equilibrate (Baker and Herbert, 1987). All examinations of glandular extracts did, however, show the presence of the 4-hydroxy derivative (**17**). 1,7-Dioxaspiro[5.5]undecan-5-ol (**16**) has not been identified from a natural source.

Chirality of 1,7-Dioxaspiro[5.5]undecane and 1,7-Dioxaspiro[5.5]undecan-4-ol

In our previous report (Kitching et al., 1986), we mentioned that **1**, when extracted from male *B. cacuminatus* rectal glands, was shown to be racemic by enantiomeric resolution on a metal chelate stationary phase. We have repeated this examination utilizing a per-*n*-hexylated β-cyclodextrin phase (Lipodex A) and confirm the previous result.

Conversion of the 90:10 epimeric mixture of **17** and **18** to their trifluoroacetates and examination with the Lipodex A column showed both diastereomers **17** and **18** were nicely resolved into their enantiomeric sets. A sample of the (4*S*,6*S*)-1,7-dioxaspiro[5.5]undecan-4-ol, kindly provided by Professor K. Mori, established that this enantiomer (as its trifluoroacetate) was the more slowly eluting enantiomer on the chiral column. Comparisons with the derivatized natural product showed that the natural 1,7-dioxaspiro[5.5]undecan-4-ol was predominantly the 4*S*,6*S* stereoisomer **17** (ee = ca. 80%).

Nature of Volatile Compounds Emitted by Male B. cacuminatus

From the point of view of intraspecific communication, the nature of the volatile components emitted by males at mating time (dusk) is of most relevance. For this determination, air was drawn (by a small battery-driven portable

pump) over a group of ca. 12–15 virgin male flies housed in a glass chamber, which exited via a glass tube in which was set a fine disk (1 mm thick) of highly active charcoal. After ca. 1 hr, the tube was removed and the disk washed with carbon disulfide and methanol, and examined by GC-MS methods. Compounds identified as present in the glandular secretion were found to be emitted into the atmosphere in roughly the same relative proportions except that **4** and **5** were now absent. A similar experiment in which the volatile components were adsorbed on Tenax and thermally desorbed into the Finnigan GC-MS system provided the same results.

Comparison with Chemistry of Female Olive Flies (B. oleae)

Extensive studies of the glandular chemistry of female olive flies have been conducted, as it is the female of this species that secretes and releases a blend attractive to conspecific males (Mazomenos and Haniotakis, 1981). The presence of **1** in female glands and volatiles has been confirmed by a number of studies, and it was shown to be racemic, although the enantiomers of **1** elicit different responses under some conditions from male and female flies (Haniotakis et al., 1986). In addition to **1**, Baker and Herbert (1987) have reported that both the 3- and 4-hydroxy derivatives of **1**, i.e., **13** and **15** were present in the rectal glands of female olive flies. Although in different subgenera of the genus *Bactrocera*, male *B. cacuminatus* and female *B. oleae* show a strong chemical resemblance, in that both secrete racemic **1** (~90%) as the major volatile component with minor amounts of other oxygenated compounds. Having established that 4*S*,6*S* **17** was the predominant stereoisomer of 1,7-dioxaspiro[5.5]undecan-4-ol present in *B. cacuminatus* males, we decided to conduct a similar examination of this component reported as being present in female olive flies. A collection of glands excised from sexually mature female *B. oleae* was kindly provided by Dr. G. Haniotakis (Demokritos Research Centre, Biology Institute, Athens). Although **1** was present in substantial amounts in these glandular extracts, we could not detect any hydroxy spiroacetals and we were thus thwarted in our original endeavor. Indeed **1** was the only component of low to medium volatility present, and the results show that various collections of female olive flies may be different chemically, and this may be a function of location, maturity, diet, and history. There is the possibility that the taxonomy of olive flies requires attention. After all, the species has a wide geographical distribution and sibling species may have developed.

Acknowledgments—The authors are grateful to Professor K. Mori, University of Tokyo, for a sample of the 4*S*,6*S* stereoisomer of 1,7-dioxaspiro[5.5]undecan-4-ol, and to Dr. G. Haniotakis, Demokritos Research Centre, Athens, for excised glands of female *B. oleae*. The expert technical assistance of Mr. E. Hamacek is gratefully acknowledged. Dr. Krohn is grateful to Deutsche Forschungsgemeinschaft for the receipt of a fellowship.

ANNOUNCEMENT

EIGHTH INTERNATIONAL ANNUAL MEETING OF INTERNATIONAL SOCIETY OF CHEMICAL ECOLOGY

The International Society of Chemical Ecology will hold its Annual Meeting in Dijon, France, July 3–7, 1991, at the University of Dijon.

Symposia have been arranged under the headings: Plant-Insect Interactions; Semiochemicals in Vertebrates; Evolutionary Perspectives on Semiochemicals in Insects; and Human Pheromones and Perfumes.

Contributed papers (approximately 15 minutes) and poster presentations throughout the range of Chemical Ecology are invited. Questions regarding presentations, registration, housing, and other logistics should be addressed to:

Dr. Rémy Brossut
Laboratoire de Zoologie
Université de Dijon
Boulevard Gabriel
21000 Dijon, France

A full package includes registration, meals, a single room in a student residence, and the banquet. Tentative fees are $350.00 U.S. for full members, $250.00 U.S. for students, and $400.00 U.S. for non-members. Nearby hotels are available (30 minute walk, 10 minutes by bus).

(Received August 29, 1990; accepted October 24, 1990)

Abstract—The fumigant toxicity of 28 essential oils extracted from various spice and herb plants and some of their major constituents were assessed for adult coleopterans *Rhyzopertha dominica*, *Oryzaephilus surinamensis*, *Tribolium castaneum*, and *Sitophilus oryzae*. Three groups of active materials were distinguished: (1) The compounds terpinen 4-ol, 1,8-cineole, and the essential oils of three-lobed sage, sage, bay laurel, rosemary, and lavender were most active against *R. dominica;* (2) The compounds linalool, α-terpineol, and carvacrol and the essential oils of oregano, basil, Syrian marjoram, and thyme were most active against *O. surinamensis*; and (3) the compound 1,8-cineole and the essential oils anise and peppermint were active against *T. castaneum*.

Key Words—*Sitophilus oryzae*, Curculionidae, *Rhyzopertha dominica*, Bostrichidae, *Oryzaephilus surinamensis*, Cucujidae, *Tribolium castaneum*, Tenebrionidae, Coleoptera, essential oils, fumigant toxicity.

INTRODUCTION

Insect control in stored-food products at present relies heavily upon the use of gaseous fumigants and residual insecticides, both of which pose serious hazards to warm-blooded animals and the environment. Fumigation is still one of the most effective methods for the prevention of storage losses. However, the availability of fumigants for insect control has dwindled drastically lately. As of

*To whom correspondence should be addressed.

0098-0331/91/0300-0499$06.50/0

now, only two fumigants are still in use, namely, methyl bromide and phosphine. The former is suspected of leaving residues that are harmful to warm-blooded animals (Dansi et al., 1984), while the latter, which is in wide use, has shown alarming indications of development of insect resistance to it (Mills, 1983; Tyler et al., 1983). Thus, it would be of marked benefit for the preservation of stored products to discover and develop new compounds that have the potential to replace the toxic fumigants, are less harmful, yet are easy, simple, and convenient to use. The present study was conducted to investigate further the potential use of essential oils, extracted from various spice and herb plants in Israel, and some of their major constituents as fumigants for the control of stored product insect pests.

METHODS AND MATERIALS

The beetles were bred at 27°C and 70% relative humidity. *Sitophilus oryzae* (Curculionidae) and *Rhyzopertha dominica* (Bostrichidae) were reared on soft wheat, *Oryzaephilus surinamensis* (Cucujidae), on ground wheat with the addition of glycerin and yeast, and *Tribolium castaneum* (Tenebrionidae) on wheat flour. The essential oils were obtained from fresh plants by steam distillation (Marcus and Lichtenstein, 1979). Major oil constituents were purchased commercially. The English name of the essential oil is used; in case no English name was available, the Latin name is given.

The fumigation chambers were 3.4-liter glass flasks with round bottoms, closed with a glass stopper fitted with a hook. The test materials were applied on a small square piece of filter paper, which was suspended by the hook, together with the insect cages, in the fumigation chamber. To obtain even distribution of the oil during the treatment, a magnetic stirrer was placed on the bottom of each flask. Twenty insects of each species, aged 5–10 days, were placed in each of the four cages (4 cm in length and 1.5 cm in diam), which were perforated with small holes enabling penetration of the gas. Small amounts of ground wheat were placed in each cage. Treatments were carried out for 24 hr, and percent mortality was recorded.

RESULTS

The fumigant toxicity of 28 essential oils and 10 of their principal components (Table 1) was tested against four major stored-product insect pests: *S. oryzae*, *R. dominica*, *O. surinamensis*, and *T. castaneum*. At a concentration of 5–15 μl/liter of air, only 11 oils and five of their major components were found to be highly active (Table 1). Among the active materials, it was possible to distinguish three groups according to their activity: Group 1 compounds terpinen 4-ol, 1,8-cineole, and the essential oils of three-lobed sage, sage, bay

TABLE 1. ESSENTIAL OILS AND SOME MAJOR CONSTITUENTS TESTED AS FUMIGANTS AGAINST FOUR MAJOR STORED-PRODUCT INSECTS

Group A[a]	The essential oils of oregano, basil, Syrian marjoran, thyme, three-lobed sage, sage, bay laurel, rosemary, lavender, anise, peppermint. The compounds linalool, α-terpineol, carvacrol, terpinen 4-ol, 1,8-cineole
Group B	The essential oils of celery, savory, lemon grass, rue, clary sage, cumin, caraway, lemon, grapefruit, orange, coriander, *Salvia dominica*, fennel, chamomile, *Artemisia arboresence*, parsley, *Artemisia judaica*. The compounds β-caryophyllen, *p*-cymene, α-terpinene, sabinene, myrcene

[a] Group A was found to be very active, and group B had low or no activity.

laurel, rosemary and lavender were found most active against *R. dominica*. All of them gave 100% mortality at a concentration of 15 μl/liter of air. *O. surinamensis* was less susceptible than *R. dominica* and at a concentration of 15 μl/liter of air, only terpinen 4-ol, 1,8-cineole, and rosemary gave 100% mortality (Figure 1). Group 2 compounds linalool, α-terpineol, and carvacrol and the essential oils of oregano, basil, Syrian marjoram, and thyme were found most active against *O. surinamensis*. One hundred percent mortality was achieved by linalool, α-terpineol, oregano, basil, and Syrian marjoram at a concentration of 15 μl/liter, and by linalool and oregano at 10 μl/liter (Figure 2). *S. oryzae* was much more resistant than *O. surinamensis* and *R. dominica* to all the tested essential oils and their major components. For *S. oryzae*, 100% mortality was obtained only with sage oil at a concentration of 15 μl/liter (Figure 1, see also Figures 2 and 3). In group 3 the compound 1,8-cineole and the essential oils of anise and peppermint were the only active fumigants against *T. castaneum* of all the materials tested. Anise and cineole gave 100% mortality at concentrations of 10 and 15 μl/liter, respectively.

Among the other oils of low activity, *Artemisia judaica*, parsley, *Salvia dominica*, and clary sage were found to be active mainly against *O. surinamensis;* at a concentration of 15 μl/liter, mortalities of 80, 75, 55, and 45%, respectively, was recorded. On the other hand, fennel oil and the compound γ-terpinene were active only against *R. dominica*, at a concentration of 15 μl/liter with 83% and 49% mortality, respectively (data not shown).

DISCUSSION

Three groups could be distinguished of the 28 essential oils and some of their major constituents as active fumigants against four major stored-product insects: group 1, most active against *R. dominica*, followed by *O. surinamensis*

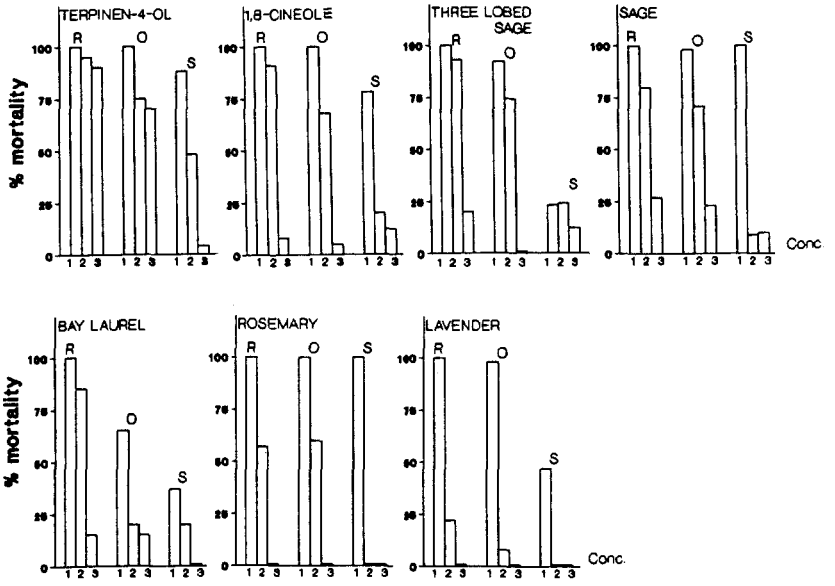

FIG. 1. Essential oils and compounds most active against *R. dominica*. Percent mortality of R = *R. dominica;* O = *O. surinamensis*, and S = *S. oryzae*, using various concentrations (1 = 15, 2 = 10, 3 = 5 μl/liter of air) of the test material. The results are the average of 5–10 replicates.

and *S. oryzae*, group 2, most active against *O. surinamensis*, followed by *R. dominica* and *S. oryzae;* and group 3, against *T. castaneum*, followed by *R. dominica*, O. surinamensis and *S. oryzae*.

From the activity of the various essential oils and their major constituents, it can be seen that alcohol and phenol, such as linalool and carvacrol, show greater activity against *O. surinamensis*. In the case of *R. dominica*, alcohol and ether, e.g., terpinen 4-ol and 1,8-cineole, are the most active, and ethers, such as 1,8-cineole, against *T. castaneum*. These differences in activity of the various compounds were used in the search for more potent compounds for the control of these insects. Recently, we were able to select a compound, ZP51, with much higher potency than all the essential oils and the various compounds tested. A concentration of 3 μl/liter was enough to obtain 100% mortality of the four test insects (Shaaya et al., in preparation). This should be compared with 20–30 mg/liter of methyl bromide recommended for control in the field of stored-product insects. In addition, this compound was most active against *S. oryzae*, a concentration of 1,5 μl/liter being enough to obtain 100% mortality.

The fumigant toxicity of a number of essential oils was also tested against *Sitotroga cerealella* and *Acanthoscelides obtectus* (Klingauf et al., 1983) and

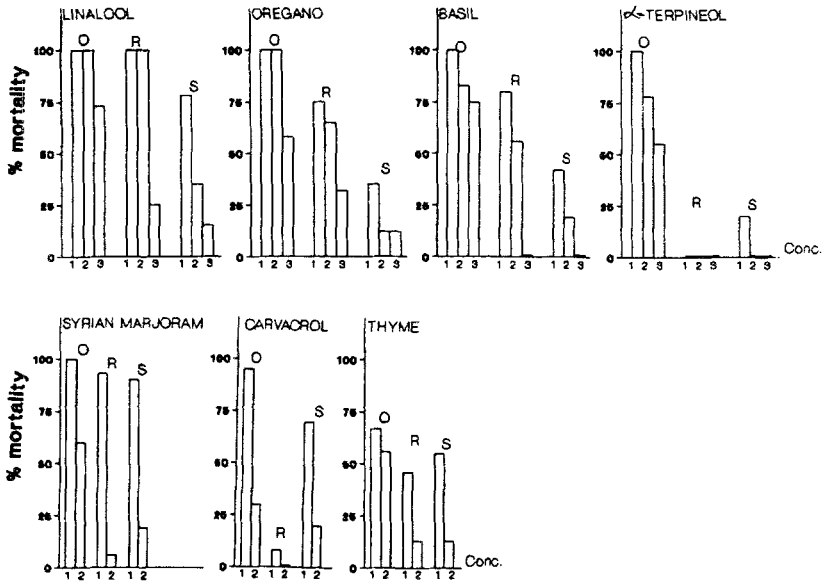

FIG. 2. Essential oils and compounds most active against *O. surinamensis*. Percent mortality of R = *R. dominica;* O = *O. surinamensis*, and S = *S. oryzae*, using various concentrations (1 = 15, 2 = 10, 3 = 5 μl/liter of air) of the test material. The results are the average of 5–10 replicates.

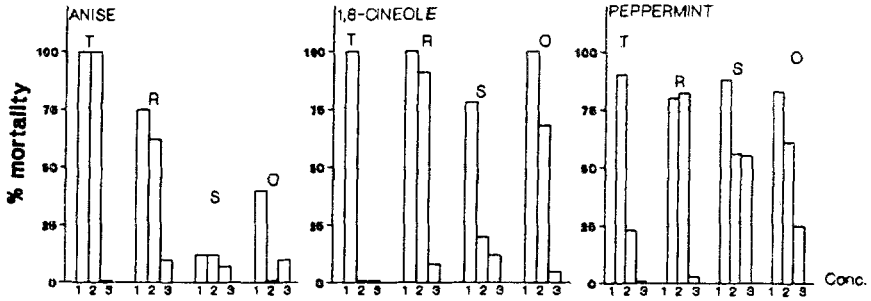

FIG. 3. Essential oils and compounds active against *T. castenaum*. Percent mortality of R = *R. dominica;* O = *O. surinamensis;* S = *S. oryzae*, and T = *T. castenaum*, using various concentrations (1 = 15, 2 = 10, 3 = 5 μl/liter of air) of the test material. The results are the average of 5–10 replicates.

of *Mentha piperita* against *T. castaneum* (Misra and Jitender, 1983). The various studies were done using different fumigation methods and exposure times, so it is not possible to correlate our results with those reported in the literature.

The existence of naturally occurring insecticidal plant components has been known for centuries. However, relatively few of these compounds are actually used in crop protection today (Marcus and Lichtenstein, 1979). Increasing problems concerning the use of modern synthetic insecticides, such as persistence of residues, resistance, and damage to the environment and human health have generated interest in naturally occurring compounds. It should be noted that biologically active compounds of food plants are assumed to be environmentally more acceptable and less hazardous than others to humans. The results presented in this study suggest that some oils or their major constituents could be efficient fumigants and also could be integrated with other pest management procedures.

RESPONSE OF TOTAL TANNINS AND PHENOLICS IN LOBLOLLY PINE FOLIAGE EXPOSED TO OZONE AND ACID RAIN[1]

D.N. JORDAN,[2] T.H. GREEN, A.H. CHAPPELKA,*

(Received August 6, 1990; accepted October 29, 1990)

Abstract—Tannin and total phenolic levels in the foliage of loblolly pine (*Pinus taeda* L.) were examined in order to evaluate the effect of atmospheric pollution on secondary plant metabolism. The trees were exposed to four ozone concentrations and three levels of simulated acid rain. Tannin concentration (quantity per gram) and content (quantity per fascicle) were increased in foliage exposed to high concentrations of ozone in both ozone-sensitive and ozone-tolerant families. No effect of acid rain on tannins was observed. Neither total phenolic concentration nor content was significantly affected by any treatment, indicating that the ozone-related increase in foliar tannins was due to changes in allocation within the phenolic group rather than to increases in total phenolics. The change in allocation of resources in the production of secondary metabolites may have implications in herbivore defense, as well as for the overall energy balance of the plant.

Key Words—Plant defense, air pollution, acidic deposition, biological indicators, plant polyphenols, total phenolics, proanthocyanidins, condensed tannins, secondary metabolites, *Pinus taeda*.

INTRODUCTION

Trees possess both chemical and structural defenses against pathogens and herbivory (Loehle, 1988; McLaughlin and Shriner, 1980; Stafford, 1988). While

*To whom correspondence should be addressed.

not the only defense available to plants, tannins may contribute to plant defense by increasing tissue toughness (Stafford, 1988) or by reducing nutritive value of foliage (Mole and Waterman, 1988). Tannins consist of polymerized phenols and are divided into two groups, condensed and hydrolyzable tannins (Goodwin and Mercer, 1983). Haslam (1988) states that hydrolyzable tannins are confined to the dicotyledons, indicating that the tannins produced by loblolly pine are condensed tannins (CT).

Foliar tannin content is affected by various environmental factors. Schultz and Baldwin (1982) and Schultz (1988) found increased tannin content in red oak leaves (*Quercus rubra*) following insect defoliation. Walters and Stafford (1984) found increases in condensed tannin concentration of Douglas-fir (*Pseudotsuga menziesii*) needles related to insect defoliation and also to mechanical damage. Mole et al. (1988) showed changes in condensed tannins in the foliage of several rain-forest species positively correlated with light intensity. Coley et al. (1985) suggest that chemical defenses are inversely correlated with resource availability. Gershenzon (1984) reported that deficiencies in nitrogen, sulfur, and other nutrients lead to increased production of phenolics in many plant species.

Plant susceptibility to disease or herbivory may be mediated by atmospheric pollution. Manning et al. (1969, 1970) found that ozone damage increased disease rates and infection severities of potato (*Solanum tuberosum*) and geranium (*Pelargonium hortorum*) plants inoculated with *Botrytis cinerea*. Hain (1987) discusses ozone effects on ponderosa pine (*P. ponderosa*) in conjunction with attacks by the western pine beetle (*Dendroctonus brevicomis*) and mountain pine beetle (*D. ponderosae*). He suggests that increased susceptibility is offset by decreased suitability, preventing an increase in overall infestation rate.

Ozone has been shown to affect tannin and total phenolic content of several plant species (Howell, 1974). Tingey (1989) discusses the importance of discovering an unambiguous indicator of pollution stress. Loehle (1988) states that leaf defenses should be a good variable for assessing pollution impact, because the allocation of carbon to defensive compounds in the foliage should be reduced as a result of decreased vigor in pollution-stressed trees. Jones and Coleman (1989) suggest that phenolics, in conjunction with some other biochemical indices, might be useful as an indicator of pollution effects, but differentiate between the effects of direct damage to plant structure and carbon stress due to interference with normal plant function by the pollutant. These authors predicted an increase in polymerized carbon-based secondary metabolites with pollution damage. The current study was conducted to determine whether atmospheric pollutants could alter foliar levels of defensive compounds (tannins and phenolics) in loblolly pine trees and to establish the basis for further inves-

tigations into the utility of plant phenolics as indicators of pollution stress, as well as the impacts of these stresses on forest pests and/or pathogens.

METHODS AND MATERIALS

Exposure Facilities. The effects of ozone and acid rain on loblolly pine in central Alabama were investigated using cylindrical open-top chambers (4.5 m diam. × 4.8 m high). The site is located on the upper Coastal Plain of eastern Alabama. The soil series present is a Cowarts, a Typic Kanhapludult. Six-month-old seedlings from two families of loblolly pine were planted in 24 chambers in January 1988. The families used were GAKR 15-23, considered to be ozone-tolerant (Reinert et al., 1988) and GAKR 15-91, regarded as ozone-sensitive (McLaughlin et al., 1988). The chambers were constructed with rain exclusion covers and were exposed to three target pH levels of artificial rain (pH 3.3, 4.3, and 5.3). Rain solutions were prepared by adjusting the pH of deionized water containing selected background ions (Cogbill and Likens, 1974) with a 1 N mixture of H_2SO_4 and HNO_3 in a 3 : 1 ratio. Rain was applied twice weekly through stainless-steel cone nozzles mounted at the top of each chamber. Rain volumes were based on monthly averages for the preceding 30-year period (Chappelka et al., 1990a).

In addition to the acid rain treatments, four ozone treatments were applied as multiples of the ambient concentration. Treatments were attained by filtering ambient air through charcoal filters (CF), applying nonfiltered ambient air (NF), and supplementing ozone concentrations to 1.7 and 2.5 times ambient (1.7 × NF and 2.5 × NF) (Chappelka et al., 1990a). The experiment was established as a 4 × 3 factorial with two replications. Actual ozone concentrations and rain pH, as well as a more detailed description of the application system, are reported by Chappelka et al. (1990b).

Additional trees from both families, which had been grown on the site outside of chambers, were also sampled to evaluate chamber effect. These trees were planted in a similar configuration to those in chambers but were exposed to natural air and rainfall.

Sampling Technique. In November of the second growing season, four trees in each chamber were sampled. Six fascicles per tree were removed from the second flush of current-year (1989) growth on a south-facing primary branch in order to limit potential differences in tannins and phenolics due to light exposure or leaf age (Mole et al., 1988). Fascicles from two trees from each family from each chamber were composited, resulting in one sample per family per chamber.

Laboratory Analyses. The fascicles were weighed, stored on ice, and trans-

ported to the laboratory, where they were immediately cut into 0.5–2.0-mm sections. One-gram samples were ground in 5 ml of 70% acetone with a mortar and pestle and then centrifuged at 5000 rpm for 15 min. The resulting supernatants were stored in the dark at 4°C until analysis.

Tannin samples were analyzed in duplicate by a modification of the radial diffusion assay of Hagerman (1987). A gel containing 1% (w/v) agarose and 0.05% bovine serum albumin (BSA, fraction V) in 50 mM acetic acid and 60 μM ascorbic acid at pH 5.0 was formed by pouring 9.5-ml aliquots of warm solution into standard plastic Petri plates and allowing each to cool overnight at 4°C. Four 3-mm wells per plate then were punched in the gel. Four 8-μl aliquots of sample were applied to each well, with sufficient time allowed for absorption, but not for complete drying between applications. After incubation for 90–120 hr at 30°C, two perpendicular radii of each sample were measured with a binocular microscope and platform micrometer to the nearest 0.01 mm. The radii were averaged, and the area of binding was calculated. The areas of the duplicate samples were averaged for the statistical analysis. Results are presented in mm^2 per gram fresh weight for concentration data and mm^2 per fascicle for content data.

Phenolics in the extract were determined with a colorimetric assay using 2.0 N Folin and Ciocalteu's phenol reagent (Sigma Chemical Co., St. Louis, Missouri). This method yields molar absorptivity specific for each phenolic compound (Singleton and Rossi, 1965) and therefore gives results impossible to present in absolute concentration units. Phenolic results are presented in A_{760} per gram and A_{760} per fascicle for concentration and content respectively. Data were analyzed using SAS (SAS Institute, Cary, North Carolina), analysis of variance (ANOVA), and linear regression procedures. All significance was reported at the $P = 0.05$ level.

RESULTS

Ozone exposure caused an increase in concentration and content of foliar CT in loblolly pine trees (Table 1). Linear regression analysis showed a significant increase in CT concentration (CT/g = 33.4 + 5.3 × ozone, $r^2 = 0.37$, $P \leq 0.0001$) and content (CT/fascicle = 12.8 + 1.6 × ozone, $r^2 = 0.16$, $P = 0.005$) with increasing ozone concentration. There was no significant difference between families in foliar tannin levels. However, the ozone-sensitive family exhibited the highest tannin levels of the experiment in the high ozone treatment. No significant differences in CT were observed among acid rain treatments, nor were significant acid rain × ozone interactions observed in this study.

No significant differences were observed in the total phenolic (TP) con-

centration or content among either ozone or acid rain treatments or between families (Table 1). The overall ratio of CT to TP was significantly increased (CT/TP = 37.4 + 6.7 × ozone, $r^2 = 0.27$, $P \leq 0.0001$) with ozone exposure, indicating a redistribution within the phenolic group (Figure 1).

Chambers themselves had no effect on either foliar tannins or total phenolics. The trees growing outside the chambers had levels of tannins and phenolics comparable to the ambient (NF, pH 5.3) chambers. Phenolic concentrations of these trees were 1.022 A_{760}/g and 1.027 A_{760}/g, and tannin concentrations were 40.02 mm^2/g and 41.23 mm^2/g for the tolerant and sensitive families, respectively. These data were not used in statistical analyses for ozone or acid rain effects.

DISCUSSION

The increase in foliar CT with ozone exposure corresponds to an observed increase in visible injury and reduction in foliar biomass (Chappelka et al., 1990b). This is contrary to what is proposed by Loehle (1988), who predicted decreases in chemical defenses, including tannins, associated with reduced vigor

TABLE 1. TANNIN AND PHENOLIC CONCENTRATION (mm^2/g AND A_{760}/g, RESPECTIVELY) AND CONTENT (mm^2/FASCICLE AND A_{760}/FASCICLE, RESPECTIVELY) BY FAMILY, OZONE EXPOSURE, AND pH TREATMENT

resulting from pollution stress. Our data indicate that the increase in tannin production with increased ozone exposure is not a vigor-mediated response but is apparently a direct response to ozone-induced membrane damage. This interpretation agrees with Jones and Coleman (1989), who suggested that structural damage resulting from air pollution would cause an increase in polymerized carbon-based secondary metabolites.

The increases in secondary metabolites might have a substantial impact on the overall energy budget of the plant (McLaughlin and Shriner, 1980). Resources dedicated to production of defensive compounds cannot be utilized in growth and/or repair processes. From an energy or carbon allocation per-

spective, the ozone-treated trees have diverted a greater percentage of resources toward secondary metabolism. The qualitative correlation of visible injury, increased tannins, and high ozone exposure supports Howell's (1974) assertion that membrane damage and reallocation to secondary metabolites may contribute to ozone-related growth reductions.

Gershenzon (1984) reported increased phenolic production related to nutrient limitation in a number of species. In the current study, increased resource availability (nitrogen and sulfur supplied in pH treatments) did not alter the allocation of resources to defense, as represented by tannin content, although growth of the low pH-treated trees was significantly increased (Chappelka et al., 1990b). This is contrary to the carbon–nutrient balance hypothesis of Bryant et al. (1983), which suggests that at higher nutrient availability, less carbon is available for production of carbon-based defensive compounds. Based on this hypothesis, the trees exposed to low pH (higher nutrients) would have been expected to have lower foliar CT levels.

The ease of the radial diffusion assay of Hagerman (1987), the increase in tannins with ozone, and the lack of an acid rain effect indicate that foliar tannin levels would fit the criteria of Tingey (1989), who states that pollution indicators should: provide a readily detectable response to the pollutant, be easy to use and readily related to the response of interest, and have a distinctive syndrome not easily confused with other causes. Further studies are needed to establish whether foliar tannin levels are useful unambiguous chemical indicators of ozone stress, either alone or in combination with other measures.

If foliar tannin concentration is an important factor in deterring insect or pathogen attack, ozone and acid rain exposure at the applied rates does not appear likely to result in increased pest damage. Increased insect feeding has been associated with ozone by some researchers (Chappelka et al., 1988; Hain, 1987; Trumble et al., 1987). However, as Hain (1987) noted, increased host susceptibility does not imply increased infection or predation, provided that host suitability is also decreased. Decreased suitability may result from reduced foliar nutrient content or reduced digestibility of foliage (Coley, 1986). Increased attractiveness and decreased nutritive value would result in the type of susceptibility–suitability relationships described by Hain (1987). Further experiments are needed to determine whether tannin increases of this magnitude are effective against herbivory and if concurrent changes in foliar nutrient content or other defense mechanisms would further discourage attack or render the foliage more desirable.

Acknowledgments—The authors would like to thank Daureen Nesdill for her demonstration of tannin-binding evaluation; John Kush, Mark Bass, Karen Westin, and Efrem Robbins for their data collection; and Alan Tiarks, Bob Jones, Greg Somers, and Nancy Stumpff for their reviews of the manuscript. The study was partially supported by funds provided by the Southeastern Forest Experiment Station, Southern Commercial Forest Research Cooperative of the Forest Response

Program. The Forest Response Program, part of the National Acid Precipitation Assessment Program, is jointly sponsored by the USDA Forest Service, US Environmental Protection Agency, and the National Council of the Paper Industry for Air and Stream Improvement. (Received August 17, 1990, accepted October 29, 1990)

Abstract—The bark beetle *Ips pini* (Say) displays variation in its response to and production of enantiomeric blends of its pheromone ipsdienol. One of the principal predators of *Ips pini* is *Thanasimus dubius* (F.), which uses ipsdienol as a kairomone for prey location. During 1988 and 1989, in Wisconsin and Michigan, the response of both species to a range of enantiomeric blends of ipsdienol was investigated. Blends tested had the following ratios of the (*S*)-(+) to (*R*)-(−) enantiomers: 3%:97%, 25%:75%, 50%:50%, 75%:25%, and 97%:3%. Either 75% (+):25% (−) or 50% (+):50% (−) ipsdienol captured the most *Ips pini* in both years at both sites. The 25% (+):75% (−) blend also caught more *Ips pini* than the control during both years at both sites. All blends tested were attractive to *Thanasimus dubius* in both years at both locations. Blend preferences of both species were variable and labile at both sites. Response patterns of both species in Wisconsin were different from those in Michigan each year. Furthermore, response patterns of both species to the ipsdienol blends changed from 1988 to 1989 at both locations. A genetic component to this variation would permit predator-prey coevolution, as well as the development of resistance by *Ips pini* to management strategies based on mass-trapping with single blends.

Key Words—*Ips pini*, *Thanasimus dubius*, Coleoptera, Scolytidae, Cleridae,

INTRODUCTION

Bark beetles (Coleoptera: Scolytidae) are the most destructive insect pests of North American forests. The pine engraver, *Ips pini* (Say), colonizes pine and spruce throughout much of North America (Lanier et al., 1972; Birch et al., 1980; Wood, 1982) and is the most common bark beetle in the Great Lakes region (Schenk and Benjamin, 1969). Adults and larvae feed on the phloem of weakened and recently killed trees. Upon colonization of a suitable host, adult males emit a pheromone containing primarily ipsdienol (2-methyl-6-methylene-2,7-octadien-4-ol), which attracts other males and females to the tree (Vité et al., 1972; Birch, 1978; Birch et al., 1980; Borden, 1982; Miller et al., 1989).

Ipsdienol occurs as (*R*)-(−) and (*S*)-(+) enantiomers, the relative proportion of which determines response specificity in *Ips pini*. There is geographic variation among North American populations of *Ips pini* in their response to and production of pheromones (Lanier et al., 1972; Birch, 1978; Miller et al., 1989). Western North American populations respond to 97% (−)-and are inhibited by (+)-ipsdienol (Birch et al., 1980). New York populations respond preferentially to a racemic mixture, i.e., 50% (+):50% (−) (Lanier et al., 1980). In Wisconsin, traps baited with 75% (+):25% (−) or 50% (+):50% (−)-ipsdienol caught significantly more beetles than 100% (−), 25% (+), or 100% (+) (Raffa and Klepzig, 1989). The 75% (+)-ipsdienol caught more than three times the number of beetles than did the racemic mixture during a two-week test, but differences were not significant.

Thanasimus dubius (F.) (Coleoptera: Cleridae) is a principal predator of *Ips pini* in the Great Lakes region (Schenk and Benjamin, 1969). *Thanasimus dubius* and other *Thanasimus* species use bark beetle pheromones as kairomones for prey location (Vité and Williamson, 1970; Bakke and Kvamme, 1980; Mizell et al., 1982; Hansen, 1983; Payne et al., 1984; Raffa and Klepzig, 1989). Enantiomeric specificity in their responses (Hansen, 1983; Payne et al., 1984; Raffa and Klepzig, 1989) is considered evidence that clerid predators have coevolved with their scolytid prey (Payne et al., 1984; Raffa and Klepzig, 1989). For example, predation may select for changes in the pheromone system of *Ips pini*, allowing temporary escape from its natural enemy. *Thanasimus dubius* then could be under strong selection to track these changes, permitting location of its primary prey (e.g., Price, 1981). Coevolution, however, requires heritable variation in the selected traits within populations of both species (Janzen, 1980). Miller et al. (1989) concluded that intrapopulation variation in the production of ipsdienol enantiomeric blends by *Ips pini* most likely had a genetic basis; however, this variation has not been shown to be heritable. Kairomonal response preferences by *Thanasimus dubius* to *Ips* and *Dendroctonus* pheromones have been observed to vary from year to year, depending on the relative abundances of the different species of prey (Billings and Cameron, 1984).

Bark beetle suppression through mass-trapping, using aggregation pheromones as bait, is receiving much attention, but requires detailed knowledge of the pheromone preferences of target populations (Bakke, 1982, 1989). A high level of genetic variation within populations of *Ips pini* would create the potential for rapid development of "resistance" to pheromone-based programs that rely on only one pheromone blend (Lanier et al., 1972; Slessor et al., 1985; Borden et al., 1986; Miller et al., 1989).

The objectives of this study were: (1) to further characterize the preferences of *Ips pini* and *Thanasimus dubius* to enantiomeric blends of ipsdienol in the Great Lakes region, (2) to determine the degree of intrapopulational variation in the response of both species to the ipsdienol mixtures, and (3) to compare preferences between populations of the two species within the Great Lakes Region.

METHODS AND MATERIALS

Blend Preferences. The response of *Ips pini* and *Thanasimus dubius* populations to enantiomeric mixtures of ipsdienol was monitored in the field during 1988 and 1989, near Colfax, Wisconsin, and in Midland, Michigan. The Wisconsin study was conducted in an even-aged, 18-ha, pure stand of red pine (*Pinus resinosa* Ait.) planted in 1958. The Michigan study was conducted in a mature (ca. 75-year-old), naturally regenerated, 8-ha, mixed stand of red pine and eastern white pine (*Pinus strobus* L.), with a deciduous understory.

Populations were sampled using eight-unit Lindgren funnel traps (Lindgren, 1983) baited with 8-mg, C-flex, ipsdienol dispensers provided by Phero Tech, Inc., Delta, British Columbia. The lures had a pheromone release rate of 0.2 mg/day, and were replaced every four weeks. The following enantiomeric blends of ipsdienol were tested during 1989 in Wisconsin and both years in Michigan: 3% (+):97% (−), 25% (+):75% (−), 50% (+):50% (−), 75% (+):25% (−), 97% (+):3% (−), and a blank control. Only the 25% (+):75% (−), 50% (+):50% (−), and 75% (+):25% (−) mixtures were tested in Wisconsin in 1988.

In Wisconsin during 1988, and in Michigan during both years, each treatment was randomly assigned to one trap. Traps were separated by 15–25 m. Captured insects were removed and counted weekly. Traps remained in place throughout the season, but the locations of the pheromone baits were rerandomized weekly to guard against spurious effects due to position. Thus, the experimental design was a randomized complete block, with blocks replicated in time. The 1989 Wisconsin experiment was designed as the previously described experiments but with traps deployed in three spatially separated blocks. Within each block, traps were separated by 15–25 m, and each treatment was represented once. The three blocks were equally spaced throughout the stand.

In Wisconsin, sampling was conducted from June 5 until October 16, during 1988, and April 9 until October 22, during 1989. In Michigan, sampling was conducted from April 13 until October 20, in 1988, and March 13 until November 20, in 1989.

Statistical Analysis. Data were analyzed separately by year and site using analysis of variance (PROC GLM; SAS Institute, 1988). Because variances were proportional to means, data were square-root transformed before analysis. Means were separated using the protected LSD test. Weeks with less than two insect captures were excluded from analyses.

Chi-square analyses were used to test for changes in pheromone preference between years. (PROC CATMOD, log-linear model; SAS Institute, 1988). Only the 25% (+), 50% (+), and 75% (+) blends were used in the chi-square analysis of the Wisconsin and Michigan *Ips* data, and the Wisconsin *Thanasimus* data. The other blends were not tested in Wisconsin in 1988. In Michigan, they did not capture enough *Ips* to affect the analysis. All blends were used in the chi-square analysis of Michigan *Thanasimus* data.

RESULTS

Ips pini *in Wisconsin.* There were differences in the 1988 blend preferences of *Ips pini* in Wisconsin ($F = 4.2$; $df = 2,36$; $P = 0.022$). The racemic blend tended to capture more insects than the 75% (+):25% (−) blend, but differences were not significant (Table 1). Both mixtures captured significantly more insects than did 25% (+):75% (−) ipsdienol (Table 1).

There were also differences in the number of *Ips* beetles captured by the ipsdienol blends in 1989. The analysis of variance indicated that a much greater proportion of the total variance was due to the pheromone blends than effects due to site, date, or any interactions ($F = 321.1$ for blend compared to $F = 19.7$ for date and $F \leq 4.4$ for all other effects) (Table 2). The significant blend × date interaction was due to a reduction in the absolute difference between blends in weeks when few beetles were captured. The relative proportion of beetles captured by the different blends tended to remain constant across the season. The 75% (+):25% (−)-ipsdienol captured significantly more *Ips* beetles than all other blends, followed by 50% (+):50% (−) and 25% (+):75% (−)-ipsdienol, respectively (Table 1). The 97% (+):3% (−) and 3% (+):97% (−) blends caught significantly more *Ips* than the control traps, but far fewer than the preferred blends.

Patterns of response by *Ips pini* to ipsdienol enantiomers changed from 1988 to 1989. The proportion of total beetles captured by 50% (+)-ipsdienol dropped from 52% in 1988 to 32% in 1989, while the proportion captured by the 75% (+) blend increased from 36% in 1988 to 56% in 1989 (Table 3).

TABLE 1. COMPARISON OF *Ips pini* AND *Thanasimus dubius* RESPONSE TO ENANTIOMERIC MIXTURES OF IPSDIENOL IN MICHIGAN AND WISCONSIN DURING 1988 AND 1989

Ipsdienol enantiomeric blend	Insects/trap/week ($\bar{X} \pm$ SEM)[a]			
	Ips pini

97%(+): 3%(−)	not tested	16.2 ± 1.8a	9.2 ± 2.7ab	4.8 ± 2.3a
Control	not tested	0.1 ± 0.1e	0.3 ± 0.3c	0.0 ± 0.0c

[a] Means within a column followed by the same letter are not significantly different ($P > 0.05$; protected LSD test applied to square-root transformed data).

Patterns of response by *Ips pini* to ipsdienol enantiomers changed from 1988 to 1989. The proportion of total beetles captured by 50% (+)-ipsdienol dropped from 52% in 1988 to 22% in 1989, while the proportion captured by the 75% (+) blend increased from 36% in 1988 to 56% in 1989 (Table 3). There was little change in the proportion of insects captured by 25% (+)-ipsdienol.

Ips pini *in Michigan.* Pheromone blends differed in *Ips* capture rates in 1988 ($F = 15.4$, $df = 5,105$; $P < 0.001$) and 1989 ($F = 10.3$; $df = 5,105$; $P < 0.001$). During both years, 75% (+)-ipsdienol captured more *Ips* than the racemic mixture, although not significantly more; the 25% (+) mixture captured significantly fewer insects than the two preferred blends, but significantly

change was less than that observed in Wisconsin. The proportion of the total number of beetles captured by 75% (+)-ipsdienol dropped from 60% in 1988 to 50% in 1989, while the proportion captured by 50% (+)-ipsdienol increased from 31% in 1988 to 37% in 1989. There was little change in the proportion of *Ips* captured by the other pheromone blends (Table 3).

Thanasimus dubius *in Wisconsin.* In 1988, there also were apparent differences in the numbers of *Thanasimus* captured by different ipsdienol blends ($F = 3.0$; $df = 2,16$; $P = 0.079$). The racemic mixture captured more insects than the other two blends tested (Table 1).

There were highly significant differences among ipsdienol mixtures in numbers of *Thanasimus* beetles captured in Wisconsin in 1989 (Table 1). As with *Ips pini*, the variation accounted for by date, site, and all interactions was small compared with the variation due to pheromone blend (Table 2). The 75% (+)- and 97% (+)-ipsdienol blends were the most preferred; the racemic mixture captured significantly more *Thanasimus* than did 25% (+)-ipsdienol, which in turn was preferred over the 3% (+) blend (Table 1).

In Wisconsin, the pattern of response by *Thanasimus dubius* to ipsdienol enantiomers also changed significantly from 1988 to 1989 (Table 4), with the pattern of change similar to that of *Ips pini* at the same location. During 1988, the racemic mixture captured 54% of the total number of *Thanasimus*, compared to 24% and 22% for 75% (+)- and 25% (+)-ipsdienol, respectively. In 1989, however, the racemic mixture captured only 21% of the total *Thanasimus*, while the proportion captured by 75% (+)-ipsdienol increased to 31%. The 97% (+) blend, which was not tested in 1988, captured 27% of the total number of insects in 1989.

Thanasimus dubius *in Michigan.* In Michigan, all ipsdienol blends captured significantly more *Thanasimus* than the control during 1988 ($F = 8.2$; *df*

TABLE 3. PERCENT OF TOTAL NUMBER OF *Ips pini* AND *Thanasimus dubius* CAPTURED BY DIFFERENT IPSDIENOL ENANTIOMERS NEAR COLFAX, WISCONSIN, AND MIDLAND, MICHIGAN, IN 1988 AND 1989

[a] Trap weeks = the number of weeks in which insects were captured × the number of traps baited with each pheromone blend.

mus, while the proportion captured by 75% (+)-ipsdienol increased to 31%. The 97% (+) blend, which was not tested in 1988, captured 27% of the total number of insects in 1989.

Thanasimus dubius *in Michigan.* In Michigan, all ipsdienol blends captured significantly more *Thanasimus* than the control during 1988 ($F = 8.2$; $df = 5,70$; $P < 0.001$) and 1989 ($F = 6.5$; $df = 5,60$; $P < 0.001$). The racemic blend captured significantly more *Thanasimus* than 3% (+)-ipsdienol, but there were no significant differences among the other blends (Table 1). In 1989, however, 97% (+)-ipsdienol was favored over all other blends with no differences observed among the remaining blends (Table 1).

As with the other three populations studied, the response pattern of *Thanasimus dubius* in Michigan changed significantly from 1988 to 1989 (Table 4). The proportion of the total number of *Thanasimus dubius* captured by 97% (+)-ipsdienol increased from 21% in 1988 to 52% in 1989; all other blends captured a greater proportion of the total number of *Thanasimus* beetles in 1988 than in 1989 (Table 3).

TABLE 4. CONTINGENCY ANALYSES COMPARING RRESPONSE PATTERNS OF *Ips pini* AND *Thanasimus dubius* TO IPSDIENOL ENANTIOMERIC BLENDS FOR 1988 AND 1989 NEAR COLFAX, WISCONSIN, AND MIDLAND, MICHIGAN[a]

[c] Compares 3%, 25%, 50%, 75%, and 97% (+)-ipsdienol.

more similar to New York populations, which respond preferentially to 50% (+)-ipsdienol (Lanier et al., 1980), than to western North American populations, which respond preferentially to the 97% (−) enantiomer (Birch et al., 1980). However, our experiment found substantial variation in response to ipsdienol within *Ips pini* populations from both Michigan and Wisconsin. Miller et al. (1989) demonstrated variation in the production of ipsdienol enantiomers among individual *Ips pini* within New York, California, and British Columbia populations. This indicates that variation exists among individuals in both the response and production components of the pheromone system of *Ips pini*. We also found substantial intrapopulation variation in the response of the clerid predator *Thanasimus dubius* to ipsdienol in both Michigan and Wisconsin.

The pheromone preferences within *Ips pini* and *Thanasimus dubius* populations in Wisconsin and Michigan were labile, changing from 1988 to 1989. Furthermore, these species exhibited geographic variation in their response to ipsdienol on a relatively local scale. The pattern of response by the Michigan *Ips pini* population to ipsdienol was different than that of the Wisconsin population both years. The same was true of the *Thanasimus dubius* populations. In fact, our 1988 data for *Thanasimus dubius* in Wisconsin differed from that collected by Raffa and Klepzig (1989) during the same year only 150 km away.

It is unknown to what degree, if any, intrapopulation variation in the response of *Thanasimus dubius* or *Ips pini* to ipsdienol is heritable. However, hybridization studies with *Ips pini* indicate a genetic basis to the interpopulation variation in response to ipsdienol (Piston and Lanier, 1974; Lanier et al., 1980). The spatial and temporal variation that we observed suggests a possible genetic component to the intrapopulation variation, as well. High genetic variation within both predator and prey species would provide the potential for coevolutionary change. *Thanasimus dubius* may select for changes in the pheromone

system of *Ips pini*, resulting in reduced predation (Raffa and Klepzig, 1989). The high variation observed in the response of *Thanasimus dubius* to ipsdienol may facilitate rapid counter adaptation to changes in *Ips pini* populations.

The potential capacity of *Ips pini* for evolutionary change in its pheromone system has important implications for pest management strategies. In particular, *Ips pini* may develop resistance to mass-trapping programs, adapting to ipsdienol blends other than those used as bait (Lanier et al., 1972; Slessor et al., 1985; Borden et al., 1986; Miller et al., 1989). Variation within populations of *Ips pini* may require that blend preferences of local populations be well characterized before and monitored during the course of mass-trapping programs. Several blends may have to be used simultaneously and/or rotated as part of a resistance management program.

Acknowledgments—We thank Herbert H. Dow for allowing us to conduct the Michigan experiments on his property. We are grateful to Matt Ayres for his substantial contributions to the analysis and interpretation of the data. Dave Petty and Tom Young assisted with field collections in Michigan. Cathy Infante and Dave Petty counted the insects. Earlier versions of the manuscript were criticized and improved by Matt Ayres, Ronald P. Billings, Kelly S. Johnson, Daniel R. Miller, James R. Miller, David G. Nielsen, James K. Nitao, Kenneth F. Raffa, and Stephen Teale. This study was conducted in cooperation with the Department of Entomology and Pesticide Research Center, Michigan State University.

CHEMICAL CONSTITUENTS OF AN UNACCEPTABLE CRUCIFER, *Erysimum cheiranthoides*, DETER FEEDING BY *Pieris rapae*

M.B. DIMOCK,[1] J.A.A. RENWICK,* C.D. RADKE, and K. SACHDEV-GUPTA

Boyce Thompson Institute for Plant Research
Tower Road, Ithaca, New York 14853

(Received April 26, 1990; accepted November 5, 1990)

Abstract—The wild crucifer *Erysimum cheiranthoides* was found to contain extractable constituents that deterred feeding by larvae of the crucifer specialist *Pieris rapae* when applied to cabbage leaf disks in both choice and no-choice bioassays. High-performance liquid chromatography was used to separate the extract into several fractions, two of which retained the feeding deterrent activity of the extract. UV-absorption spectra of the fractions suggested that one contained cardenolides similar or identical to those reported to deter oviposition by *P. rapae* on *E. cheiranthoides*. The other active fraction evidently contains a compound that deters larval feeding but not adult oviposition. The results suggest that the chemical defense of *E. cheiranthoides* depends on two types of compounds acting on separate developmental stages of the insect.

Key Words—Feeding deterrents, Cruciferae, *Erysimum cheiranthoides*, cardenolides, *Pieris rapae*, cabbage butterfly, Lepidoptera, Pieridae.

INTRODUCTION

For many years, students of insect-plant relationships have been interested in the neurophysiological and behavioral mechanisms by which insect herbivores discriminate between host and nonhost plants. One hypothesis, advanced by Dethier (1982) and elaborated upon by Miller and Strickler (1984), suggests that host selection by phytophagous insects is mediated by both positive and

0098-0331/91/0300-0525$06.50/0

negative stimuli from potential host plants. When combined with other environmental factors, as well as internal excitatory and inhibitory inputs (i.e., the physiological condition of the insect itself), the balance of positive and negative plant stimuli determines whether or not the insect will attempt to feed or oviposit on that plant.

This hypothesis may explain why some specialist herbivores avoid certain plant species closely related to their preferred hosts, even when the host plant and its close relative share similar compounds that are known or presumed to stimulate oviposition or feeding. For example, certain flea beetles in the genus *Phyllotreta* feed only on plants containing glucosinolates, the mustard oil glycosides that characterize plants of the Cruciferae and a few related families (Feeny et al., 1970; Hicks, 1974; Nielsen, 1978a). However, crucifers in the genera *Iberis, Cheiranthus*, and *Erysimum* were rejected by flea beetles because these plants produced potent feeding deterrents in addition to the stimulatory glucosinolates. The phagostimulatory activity of the glucosinolates was apparently negated by the deterrent cucurbitacins of *Iberis* and the cardenolides of *Erysimum* and *Cheiranthus* (Nielsen, 1978b).

The cabbage butterfly, *Pieris rapae*, is another crucifer specialist that appears to select host plants on the basis of positive and negative chemical signals. Its larva, the imported cabbageworm, is stimulated to feed by the presence of glucosinolates (Verschaffelt, 1911), but will usually starve rather than feed on *Erysimum cheiranthoides*, a wild mustard found in Europe and temperate North America (F.S. Chew, personal communication and unpublished observations). *P. rapae* adults reject *E. cheiranthoides* as an oviposition substrate because the presence of deterrent compounds negates any positive response to oviposition stimulants, which are also present in extracts of the plant (Renwick and Radke, 1985, 1987). Our objective in these experiments was to determine if the reaction of *P. rapae* larvae to *E. cheiranthoides* can, like oviposition deterrence, be attributed to extractable chemical constituents of the plant.

METHODS AND MATERIALS

Extraction of Plant Material. E. cheiranthoides was grown from seed in a greenhouse at Ithaca, New York, under a combination of natural and artificial illumination. Mature foliage was harvested approximately four weeks after planting, plunged into boiling ethanol for 5 min, cooled in an ice bath, then homogenized in a blender. After filtration of the macerate through glass wool, the ethanol extract was dried under vacuum and the residue washed three times with hexane to remove lipids. The hexane-insoluble residue was dissolved in water, filtered, and extracted three times with *n*-butanol. The initial water extract, as well as the butanol and postbutanol water extracts were evaporated

to dryness under vacuum and stored at 4°C. Samples of each extract were later redissolved in water for bioassay against *P. rapae* larvae. Concentrations were expressed in gram leaf equivalents (gle) based on foliage fresh weight.

Feeding Preference Tests. Binary choice assays were conducted in a manner similar to the "disk test" of Jermy (1961) and Jermy et al. (1968). Leaf disks (176 mm^2) were cut from greenhouse-grown cabbage (cv. Golden Acre) with a cork borer and soaked 1 hr in different concentrations (log_2 dilution series) of each extract in aqueous solution. Control disks were soaked in distilled water. The leaf disks were patted dry on paper towels and fastened with No. 3 insect pins to a layer of paraffin wax on the bottom of a 250 ml waxed paper cup (75 mm diameter at base). Each disk was sandwiched between a pair of 16 mm^2 disks of dental dam rubber to support it on the pin about 5 mm above the bottom of the cup. The paraffin wax layer was covered with moist filter paper and a fine nylon screen that prevented larvae from feeding on the paper. Twelve disks (six experimental and six control) were pinned in an alternating circle around the periphery of each cup. The six experimental disks in each cup were treated with the same extract concentration. Ten fourth-instar larvae, from a laboratory colony maintained on greenhouse-grown cabbage, were released in the center of each arena. The cups were then covered with translucent polystyrene lids (perforated for ventilation) and placed on water-saturated paper towels in a large (40 × 27 × 9 cm) transparent polystyrene box. The box was covered to maintain high humidity and placed in a growth chamber at 25°C under fluorescent and incandescent lights. After 6 hr, larvae were removed and the box was refrigerated at 4°C overnight.

The following day, the leaf disks were removed, and the area consumed from each was measured to the nearest mm^2 using a graph paper template and a stereoscopic dissecting microscope. The template was made by stamping a circle on a piece of 1-mm^2 grid graph paper using the same cork borer used to punch leaf disks and an ink pad. This method allowed us to verify that disk shrinkage was minimal in undamaged disks as well as those fed upon by larvae. A feeding deterrent index (*FDI*) was calculated for each bioassay cup using the formula: $FDI = 100\ (C - T)/(C + T)$, where C and T represent the area consumed from control and treated disks, respectively. *FDI* thus reflects the difference in feeding rate due to treatment, expressed as a percentage of the total amount of feeding in each cup.

Fractionation of Extracts. Samples of extracts exhibiting strong feeding deterrent activity in the initial round of bioassays were redissolved in water, subjected to reverse-phase high-performance liquid chromatography (HPLC) using a Varian model 5000 liquid chromatograph equipped with a C-18 column, and eluted in a programmed gradient (3 ml/min) from 100% water to 100% acetonitrile (Figure 1, top). UV absorption by the column eluent was monitored at 219 nm and 254 nm with a Hewlett-Packard model 1040A diode array detec-

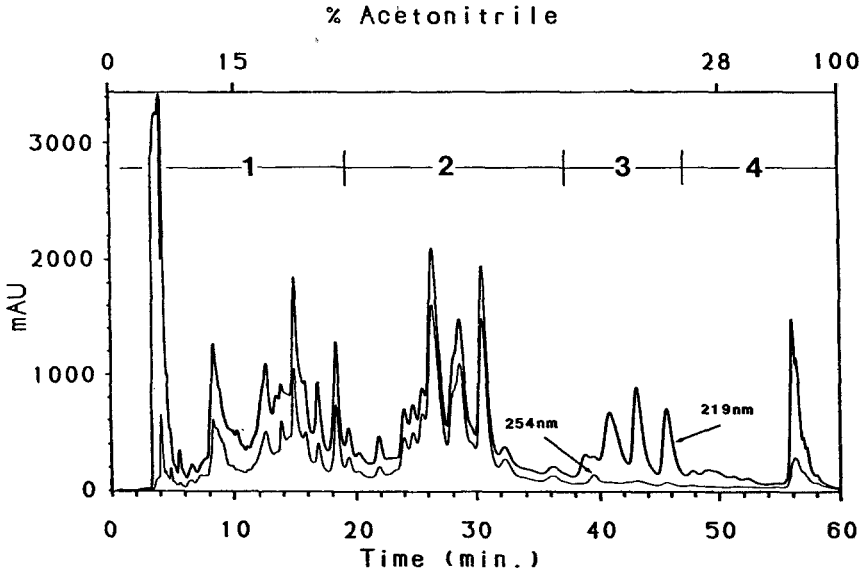

FIG. 1. Liquid chromatogram of *Erysimum cheiranthoides* butanol extract, with fractions 1–4 indicated. The injected sample (2 ml) contained the extracted equivalent of 20 g of fresh foliage. Elution gradient (100% water to 100% acetonitrile) is indicated at top.

tor. Several injections of 2 ml each (10 g leaf equivalent/ml) were performed in order to ensure sufficient material for bioassay. The eluted extract was collected as four fractions representing distinct but contiguous time intervals on the resulting chromatogram (Figure 1). Each fraction was dried under vacuum and redissolved in water for bioassay by the method described above.

No-Choice Tests. Cabbage leaf disks were soaked for 1 hr in serial dilutions (0.0625, 0.25, 1, and 4 gle/ml) of the butanol extract in water, patted dry, then placed on moist filter paper in 60 × 15-mm polystyrene Petri dishes, one leaf disk per dish. Control disks were soaked in distilled water and placed individually in dishes separate from the test disks. A young fourth-instar larva (collected from the laboratory colony within 12 hr of ecdysis) of known weight was placed in each dish. All dishes were placed on moist paper towels in a polystyrene box and held in a growth chamber at 25°C under fluorescent and incandescent lights. The number of larvae in contact with the disks and the number feeding were recorded at 2, 4, and 6 hr. At 6 hr the larvae were removed, and feeding rates were assessed visually as above. Relative consumption rate (RCR) was calculated for each larva by dividing the disk area consumed (mm^2)

by the initial larval weight. Two trials were conducted, the first using 15 and the second 10 replicate dishes per concentration.

RESULTS

The initial water extract of *E. cheiranthoides* was a strong deterrent of larval feeding, even at relatively low concentrations. This activity remained with the butanol-soluble portion of the extract, but the postbutanol water extract was inactive (Figure 2).

Despite the presence of numerous UV-absorbing compounds in HPLC fractions 1 and 2 of the butanol extract (Figure 1), these fractions did not deter larval feeding nearly as effectively as did fractions 3 and 4 (Figure 3). All four fractions were bioassayed again in duplicate (1 and 2) or triplicate (3 and 4) at a single concentration (0.25 gle/ml), and the results confirmed the previous finding that all deterrent activity resided in fractions 3 and 4 (Table 1). Fraction 4 was somewhat more active than fraction 3, but neither fraction alone was as deterrent at low concentrations as the butanol extract prior to HPLC fractionation (Figure 3, Table 1). The results of the choice bioassays for feeding deterrent activity are summarized in an extraction flowchart in Figure 4.

The butanol extract of *E. cheiranthoides* deterred larval feeding on treated disks even when no other food was available. In both trials, no larva was observed feeding at any time on any disk soaked in 4 gle/ml of the extract, and consumption rates were reduced by 50% or more (relative to controls) even at 1/16 of that concentration (Figure 5).

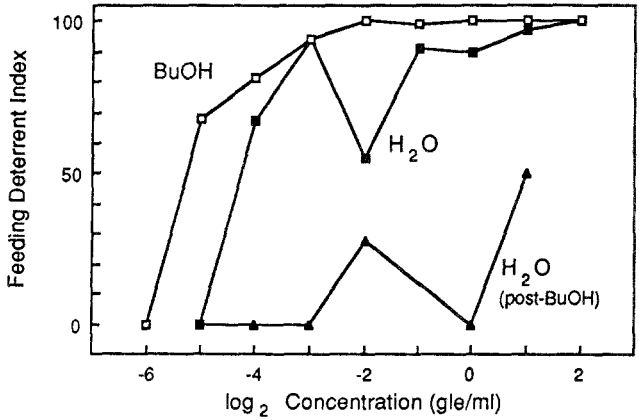

FIG. 2. Effect of *Erysimum cheiranthoides* extracts on feeding by *Pieris rapae* larvae in 6-hr choice bioassays.

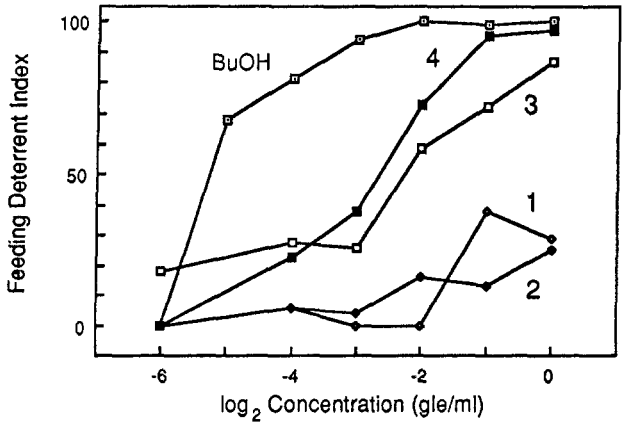

FIG. 3. Effect of *Erysimum cheiranthoides* butanol extract and HPLC fractions 1–4 on feeding by *Pieris rapae* larvae in 6-hr choice bioassays.

DISCUSSION

Our results indicate that rejection of *E. cheiranthoides* as food by *P. rapae* larvae involves deterrent chemical stimuli that can be extracted and transferred experimentally to otherwise acceptable host plant tissue. In combination with previous findings (Renwick et al., 1989; Sachdev-Gupta et al., 1990), the results also suggest that cardenolides are at least partly responsible for feeding deterrence. HPLC fraction 3 of the *Erysimum* butanol extract was highly active against larvae (Figure 3). The compounds represented by the three major peaks in this region of the chromatogram exhibited relatively high absorbance at 219 nm, but very little at 254 nm (Figure 1), a pattern characteristic of cardenolides (due to UV absorption by the butenolide ring). The specific cardenolides represented by the peaks of fraction 3 have been determined by Renwick et al. (1989) to be potent deterrents of oviposition by cabbage butterflies, and the most active constituents have been identified as the strophanthidin-based erysimoside and erychroside (Sachdev-Gupta et al., 1990).

Interestingly, fraction 4, although somewhat more active than fraction 3 as a larval feeding deterrent (Figure 3), is only a weak deterrent of oviposition (Renwick et al., 1989). The presence of an isolated, strongly UV-absorbing peak in fraction 4 (Figure 1) encourages speculation concerning the presence of other deterrents active against larvae, but not against adults. The large peak in fraction 4 may represent one or more additional cardenolides, but the strong absorbance at 254 nm relative to the fraction 3 peaks (Figure 1) suggests the presence of noncardenolide components that may or may not play a role in discrimination by larvae. We are currently addressing this question through

structural analyses of isolated pure compounds and concomitant bioassays similar to those described above. Preliminary results suggest the presence in fraction 4 of at least two active cardenolides with aglycones that differ from those of the oviposition deterrents of fraction 3.

Until positive identification of these feeding deterrent compounds is achieved, it is impossible to determine how closely our bioassay concentrations approached those occurring naturally in *E. cheiranthoides* foliage. For this reason we made no attempt to quantify uptake or surface retention of test solutions by the leaf disks, nor did we determine the amount of extract ingested by test larvae. However, the binary choice provided to larvae in our test chambers and the relative measure of activity provided by FDI were sufficient to separate deterrent from nondeterrent components of the *Erysimum* extract. It will likely prove more difficult to separate naturally active feeding deterrents from those with deterrent activity at unnaturally high concentrations without first identifying all deterrents, then relating the results of insect feeding assays of pure compounds to the quantities normally present in foliage.

The results suggest that *E. cheiranthoides* is protected from *P. rapae* by two distinct groups of compounds that may affect adult and larval behavior differently. The strophanthidin-based cardenolides act to deter adult oviposition (Renwick et al., 1989; Sachdev-Gupta et al., 1990), whereas a second group of putative cardenolides also serves to deter feeding by the larvae. The chemical identification of the most active feeding deterrents is currently underway.

(Received August 29, 1990; accepted November 5, 1990)

Abstract—Steam distillate prepared from leaves of *Medicago rugosa* Desr. could inhibit feeding by adult alfalfa weevils (*Hypera postica* (Gyll.) on membrane filters, whereas an equivalent amount of steam distillate prepared using *M. sativa* L. had no effect on weevil feeding. Earlier work established that a 12-carbon lactone, (*Z*)-oxacyclotridec-10-en-2-one, was responsible for the feeding deterrent properties of the steam distillate from *M. rugosa*. The concentration of this volatile varied with plant age and leaf position. The maximum concentration in leaves of *M. rugosa* (area basis) was estimated, on the basis of tests using an inert substrate, to be too low to cause a detectable inhibition of feeding. No correlation between lactone content and weevil feeding was detected when leaves from similar positions on plants of different ages were used in a multiple choice bioassay. Although small amounts (< 12.5 μg) of (*Z*)-oxacyclotridec-10-en-2-one can inhibit adult alfalfa weevil feeding on 13-mm-diameter membrane filters, because leaf concentrations (area basis) of this compound are lower than required to cause a detectable inhi-

bition of feeding on the inert substrate, and because concentrations do not correlate with weevil feeding, it is unlikely that this lactone is responsible for resistance to adult alfalfa weevil feeding exhibited by *M. rugosa*.

Key Words—Coleoptera, Curculionidae, *Hypera postica*, alfalfa weevil, *Medicago rugosa*, Medicago sativa, insect resistance, (*Z*)-oxacyclotridec-10-en-2-one, *cis*-9-dodecen-12-olide, (*Z*)-12-hydroxydodec-9-enoic acid lactone.

INTRODUCTION

The alfalfa weevil, *Hypera postica* Gyll., is an important pest of alfalfa, *Medicago sativa* L. (Barnes and Ratcliffe, 1969; Pandey and Singh, 1984; Shade et al., 1975). Some *Medicago* species are resistant to alfalfa weevil feeding (Barnes and Ratcliff, 1969; Danielson et al., 1987; Johnson et al., 1980a, b; Pandey and Singh, 1984).

M. rugosa, like other resistant, glandular-haired species (Shade et al., 1975), apparently owes its resistance to larval feeding to entrapment of larvae in exudate secreted by the glandular hairs (Johnson et al., 1980a). This species is also very resistant (but not immune) to adult feeding (Barnes and Ratcliffe, 1969; Johnson et al., 1980b; Pandey and Singh, 1984), although entrapment of adults does not occur (Johnson et al., 1980b). Johnson et al. (1980b) observed that weevil adults avoided contact with *M. rugosa* foliage and concluded that olfactory cues were probably responsible for resistance to adult feeding.

Following these observations, Doss et al. (1989) isolated a volatile lactone from leaves of *M. rugosa*, (*Z*)-oxacyclotridec-10-en-2-one [(*Z*)-12-hydroxydodec-9-enoic acid lactone], that could inhibit feeding by adult alfalfa weevils on phagostimulant-treated membrane filters. Results of studies undertaken to determine whether or not the resistance of *M. rugosa* to feeding by adult alfalfa weevils could be attributed to the presence of this lactone are described below.

METHODS AND MATERIALS

Plant Material. Medicago rugosa Desr. and *M. sativa* L. cv. Ranger were grown from seeds using the methods described earlier (Doss et al., 1989).

Insects. Insects were collected and maintained as described previously (Doss et al., 1989). Newly eclosed adults were used for all bioassays with membrane filters. Bioassays with leaflets were carried out with insects that had been maintained in continuous darkness at 5 $\pm$ 2°C on fresh sprigs of *M. sativa* cv. Ranger and supplied with water using moist dental wicks. These weevils were removed from cold storage and placed under the bioassay conditions 10 days before the bioassays.

Bioassays. Multiple choice bioassays with membrane filters (Doss and Shanks, 1986; Doss et al., 1989) were used to examine the influence of crude steam distillate and purified (*Z*)-oxacyclotridec-10-en-2-one on feeding by adult alfalfa weevils. In order to promote feeding, the 13-mm-diameter membrane filters were pretreated with either 400 μg sucrose (Shanks and Doss, 1987) or with 50-mg-equivalents of an exhaustive ethanolic extract prepared using leaves of *M. sativa* cv. Ranger.

Bioassays with terminal leaflets were conducted using the same conditions as those used with membrane filters, except leaflets were not treated with sucrose or any plant extract. Petiolules were inserted through a Parafilm membrane into water-filled vials.

Additional details for individual bioassays are noted in the text and in figure and table legends.

Extraction, Purification, and Analysis of (Z)-Oxacyclotridec-10-en-2-one. Steam distillate was extracted (into hexane) using a modified Nielsen-Kryger apparatus (Veith and Kiwus, 1977). (*Z*)-Oxacyclotridec-10-en-2-one was purified from the steam distillate using solvent partitioning and liquid chromatography as described previously (Doss et al., 1989).

Estimates of the amount of (*Z*)-oxacyclotridec-10-en-2-one were made by soaking samples of 30 leaflets of *M. rugosa* in 10 ml diethyl ether (redistilled to remove butylated hydroxytoluene) to which *cis* nerolidol had been added as an internal standard. The ether was removed after 10 minutes, combined with two 5 ml washings of the leaves, and extracts and washings were partitioned 2× against equal volumes of saturated NaCl. The ether was carefully removed in vacuo, and the extract was reconstituted in hexane.

The hexane solutions were subjected to gas–liquid chromatography on a packed SP 2100 column as described previously (Doss et al., 1989). (*Z*)-Oxacyclotridec-10-en-2-one concentrations were estimated based on peak height. Under these conditions, retention times for *cis*-nerolidol and (*Z*)-oxacyclotridec-10-en-2-one were 13.8 and 14.2, minutes, respectively. Estimates were not corrected for relative detector response (1.039 ± 0.008, $\bar{X} \pm$ SE for five determinations). Estimation of the loss of the lactone from 13-mm-diameter membrane filters was made using procedures similar to those used with leaves.

Data were analyzed using analysis of variance. Duncan's multiple-range test was used to compare means. Results of statistical analyses are given in figure and table legends.

RESULTS

In a three-choice bioassay (Figure 1), application of 0.31 g equivalents of steam distillate from *M. rugosa* significantly reduced adult alfalfa weevil feeding on 13-mm-diameter membrane filters relative to feeding on filters treated

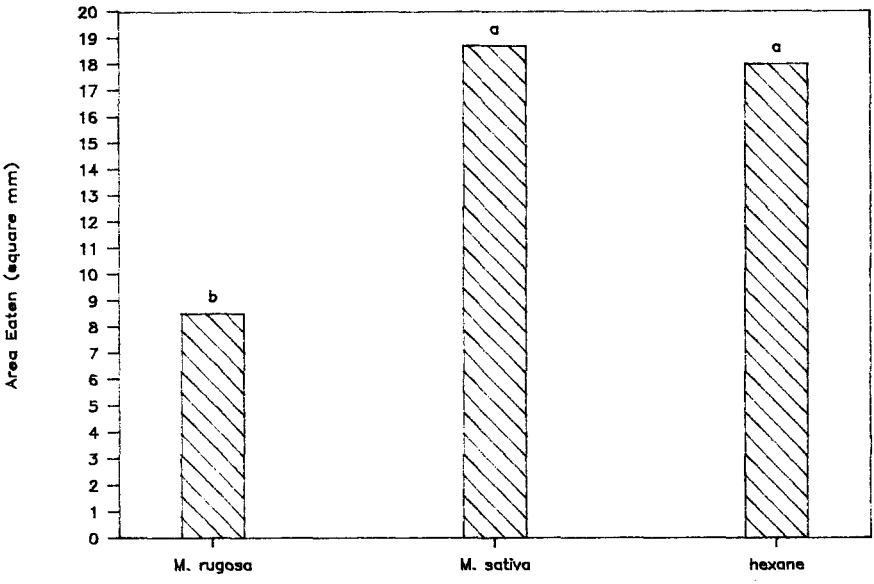

FIG. 1. Influence of steam distillate on feeding of adult alfalfa weevils on membrane filters. The bioassay was conducted for 24 hr with 12 weevils per bioassay arena. In order to stimulate feeding, filters were pretreated with 400 μg sucrose. Bars bearing different letters represent significantly different feeding ($P = 0.05$) as determined using Duncan's multiple-range test (F treatment = 8.9, $P = 0.0021$).

with hexane alone. A similar amount of extract from *M. sativa* cv. Ranger did not inhibit feeding. With the steam distillates used for this study the yield from *M. rugosa* leaflets was 0.16 mg/g fresh wt versus 0.02 mg/g fresh wt for *M. sativa* cv. Ranger. [Note that in other studies (Doss et al., 1989) exhaustive steam distillation of leaflets, petioles, and stems of *M. rugosa* yielded 0.23 mg/g fresh wt.] Leaflet masses per unit area were 0.024 $\pm$ 0.001 and 0.022 $\pm$ 0.001 g/cm^2 for *M. rugosa* and *M. sativa*, respectively ($\bar{X} \pm$ SE for $N = 5$).

(*Z*)-Oxacyclotridec-10-en-2-one, a prominent component of the steam distillate from *M. rugosa* (Doss et al., 1989), but not detected in steam distillate from *M. sativa* (data not shown) could inhibit adult alfalfa weevil feeding on membrane filters (Figure 2). About 70% of the lactone was lost from the membrane filters during the course of a 6-hr bioassay (Figure 3).

The amount of (*Z*)-oxacyclotridec-10-en-2-one extracted from leaves of *M. rugosa* varied significantly with plant age (Table 1) and with leaf position (data not shown). Adult alfalfa weevil feeding on leaves from plants of different ages did not correlate well with levels of extractable (*Z*)-oxacyclotridec-10-en-2-one (Table 1).

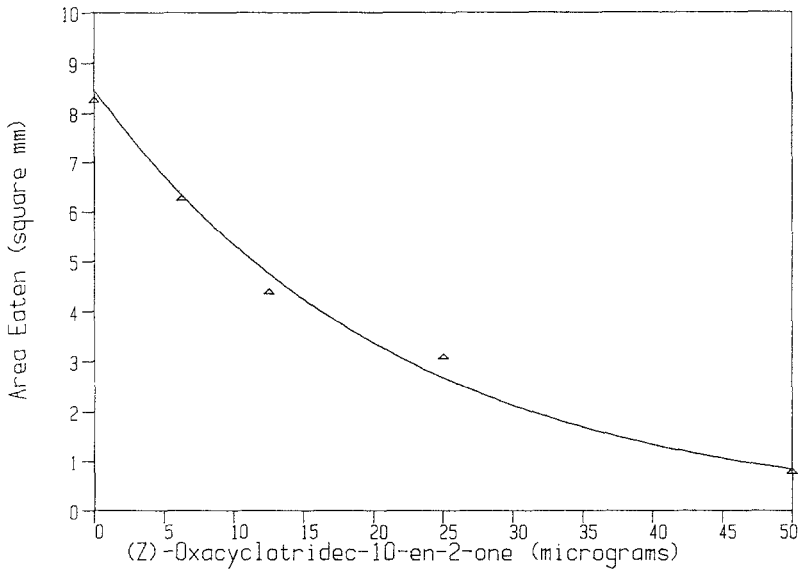

FIG. 2. Alfalfa weevil feeding on 13-mm-diameter membrane filters treated with several levels of (*Z*)-oxacyclotridec-10-en-2-one. The bioassay was conducted for 6 hr with 40 weevils per bioassay arena and 10 arenas (blocks). In order to stimulate feeding, filters were pretreated with 50-mg-equivalents of an exhaustive ethanolic extract of *M. sativa* cv. Ranger leaves. Data were analyzed using analysis of variance (minimum significant difference = 3.62, $F = 10.46$, $P < 0.001$) and were fitted using a straight-line semilog-type equation ($Y = ab^x$) where $a = 8.47$, $b = 0.955$, $r^2 = 0.99$, and $df = 3$.

DISCUSSION

M. rugosa has consistently shown resistance to adult alfalfa weevil feeding. In no-choice tests carried out by three separate groups of investigators, feeding on *M. rugosa* varied from 60% to 74% of feeding on *M. sativa* (Barnes and Ratcliffe, 1969; Johnson et al., 1980b; Pandey and Singh, 1984). Differences were much larger in choice tests (Pandey and Singh, 1984; Doss and Johnson, unpublished).

Search for a volatile feeding deterrent from *M. rugosa* was stimulated by the observation that adult alfalfa weevils avoided contact with this resistant annual species (Johnson et al., 1980b). Isolation of (*Z*)-oxacyclotridec-10-en-2-one from a steam volatile extract was guided by membrane filter bioassays (Doss et al., 1989). Results of these bioassays suggested that the lactone was the only material in the steam distillate that possessed feeding deterrent activity.

Leaflets of a susceptible alfalfa cultivar, *M. sativa* Ranger, yielded considerably less steam volatile materials than leaflets of *M. rugosa*, and no (*Z*)-

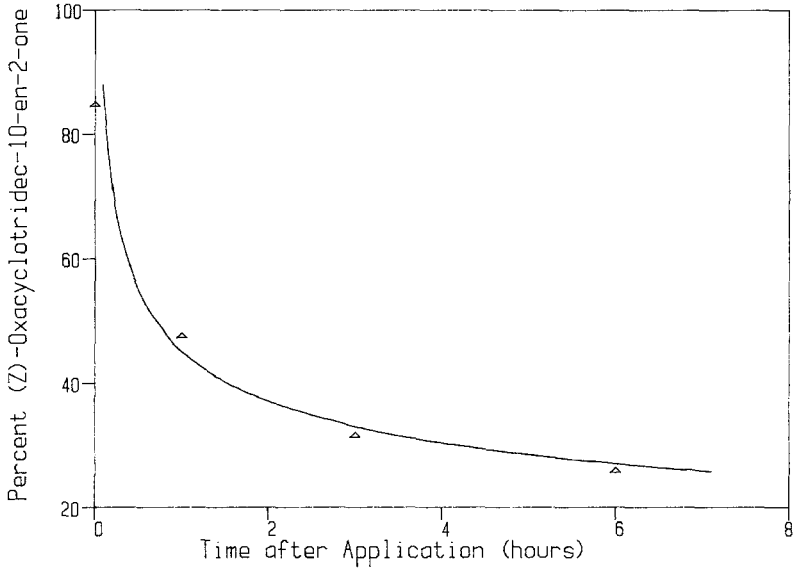

FIG. 3. The loss of (Z)-oxacyclotridec-10-en-2-one from 13-mm-diameter membrane filters. (Z)-Oxacyclotridec-10-en-2-one, 25 μg, was applied to each of 20 filters. Filters were placed under normal bioassay conditions and recovery of the added lactone was estimated gas chromatographically after extraction into hexane (See Methods and Material). Percent remaining is plotted on the Y axis. Each datum represents the mean for five determinations (standard errors ranged from 1 to 5 percent). The data were fitted with a straight-line log-type equation $Y = ax^b$ where $a = 45.3$, $b = -0.29$, $r^2 = 0.99$ and $df = 3$.

oxacyclotridec-10-en-2-one could be detected in the extract. Roughly similar yields of essential oils from leaves and stems (0.005–0.06 mg/g fresh wt) (Buttery and Kamm, 1980), or from aerial parts (0.09 mg/g fresh wt) (Kami, 1983) of alfalfa have been reported, but (Z)-oxacyclotridec-10-en-2-one has not been noted as a constituent of either of these volatile fractions.

Application of relatively small amounts of (Z)-oxacyclotride-10-en-2-one could inhibit adult alfalfa weevil feeding on phagostimulant treated membrane filters (Figure 2). Considering loss of material from the filters (Figure 3), the average concentration on the filters over the 6-hr bioassay period was about one half of the starting concentration.

The maximum concentration of (Z)-oxycyclotridec-10-en-2-one found in leaves of *M. rugosa* was 20.5 μg/g, or, on an areas basis, 0.49 μg/cm^2. A concentration of 1 μg/cm^2 would be expected on the basis of the relationship shown in Figure 2 to cause about a 5% reduction in area eaten from phagostimulant treated membrane filters. This is near the detection limits of the mea-

TABLE 1. (Z)-OXACYCLOTRIDEC-10-EN-2-ONE CONTENT OF AND ADULT ALFALFA FEEDING ON YOUNGEST FULLY EXPANDED LEAVES (TERMINAL LEAFLETS) OF *M. rugosa* PLANTS OF DIFFERENT AGES[a]

Plant age (weeks after sowing)	Sowing date	Condition of plants	(Z)-Oxacyclotridec-10-en-2-one ($\mu g/g$)	Area eaten (mm^2)
8	April 27	100% flowering 86% with seed pods early stages of senescence	0.5 ± 0.06[b]	12.8 ± 4.1[c]
6	May 11	59% flowering no seed pods green leaves	12.0 ± 0.8	59.3 ± 1.2
4	May 25	preanthesis	20.5 ± 0.8	47.8 ± 8.4
2	June 8	preanthesis no visible buds small plants	17.5 ± 3.8	26.6 ± 6.7

[a] Bioassay conducted June 22, 1988, analysis carried out June 23, 1988.
[b] Values are means ± SE for three determinations ($F_{age} = 13.4$, $P = 0.0046$).
[c] Values are means ± SE for 10 multiple choice bioassays. Each bioassay arena contained one terminal leaflet from a plant of each age (i.e., four leaflets per arena) ($F_{age} = 5.95$, $P = 0.0031$).

suring system used (about 0.5 mm^2), and it is substantially less than would be expected if (Z)-oxycyclotridec-10-en-2-one were the major factor in conferring the resistance to adult weevil feeding exhibited by *M. rugosa*.

It is possible that (Z)-oxacyclotridec-10-en-2-one could be more effective in inhibiting alfalfa weevil feeding when present at locally high concentrations, for example, in the glandular hairs of a leaf, than when uniformly distributed across a membrane filter. However, additional evidence that (Z)-oxacyclotridec-10-en-2-one is not responsible for the resistance to alfalfa weevil feeding exhibited by *M. rugosa* is derived from data presented in Table 1. There was no correlation between the concentration of the lactone and adult alfalfa weevil feeding even though the concentration varied about 40-fold. In fact, the least feeding occurred on leaves with the lowest concentration of the volatile. Notably, these plants were more mature than plants normally subject to infestation in the field would be. Weevils normally feed only on preanthesis plants. Thus, it remains possible that some other aspect of the physiology of these more mature plants inhibited weevil feeding and masked the effect of variation of (Z)-oxacyclotridec-10-en-2-one concentration.

The amount of the (Z)-oxacyclotridec-10-en-2-one obtained from young

leaves by extraction into diethyl ether (0.5–20μg/g fresh) (Table 1) was roughly comparable to the amount (8 μg/g fresh) obtained from an exhaustive steam distillate of similar leaves in an earlier study (Doss et al., 1989). It had been noted that the composition of the steam volatile fraction varied markedly with plant age, with much less lactone recoverable from postanthesis plants (Doss, unpublished).

The fact that this material was removed by short exposure to the extracting solvent suggests that it may have been sequestered in the glandular hairs. However, repeated efforts to detect the lactone in extracts made using detached (upright) glandular hairs did not yield conclusive results.

Although (*Z*)-oxacyclotridec-10-en-2-one, a prominent volatile component from *M. rugosa* leaves, can inhibit adult alfalfa weevil feeding on an inert substrate, evidence suggests that it does not play an important role in conferring resistance to weevil feeding possessed by this annual *Medicago* species. Because olfactory cues appear to be involved in this resistance (Johnson et al., 1980b), it is possible that a more volatile material, not detected in these studies, is responsible.

Abstract—Effects of methyl ketone (2-tridecanone and 2-undecanone)/glandular trichome-based resistance to insects of *Lycopersicon hirsutum* f. *glabratum* C.H. Mull, PI 134417, on the behavioral responses of *Trichogramma pretiosum* Riley and *Telenomus sphingis* (Ashmead) were observed in the laboratory. For *T. pretiosum*, these effects included (1) longer time required by the wasps to cross a leaf disk (diam. 16.3 mm), (2) higher percentage of wasps initiating flight from disks before reaching the edge, and (3) entrapment of wasps in trichome exudates. In tomato genotypes with varying densities of type VI glandular trichomes (3.1–9.2/mm^2) but with no methyl ketones in the trichome tips, no such adverse effects were observed. The time taken to cross a disk or initiate flight by *T. sphingis*, a larger wasp than *T. pretiosum*, was not significantly affected on 16.3-mm leaf disks, although the percentage of *T. sphingis* initiating flight was directly correlated with trichome density among lines with no ketones. When placed on whole leaflets of plant lines with or without methyl ketones, *T. sphingis* was entangled by trichome exudates. However, unlike *T. pretiosum*, *T. sphingis* was eventually able to free itself from entanglement. Landing rates by *T. sphingis* on PI 134417 foliage contained in dialysis tubes were also reduced. Data indicate that suppression of egg parasitism by *T. sphingis* on resistant foliage is due to both repellent action of its foliar volatiles and reduced searching rates by the parasitoids. Results indicate that a significant portion of the reduction of egg parasitism by *T. pretiosum* and *T. sphingis* is attributable to the effects

of 2-tridecanone and/or 2-undecanone present in the tips of type VI glandular trichomes on PI 134417 foliage, although the trichomes also adversely affect the wasps even in plant lines without ketones.

Key Words—*Lycopersicon hirsutum* f. *glabratum*, glandular trichomes, *Trichogramma pretiosum*, Hymenoptera, Trichogrammatidae, *Telenomus sphingis*, Scelionidae, plant-insect interaction, 2-tridecanone, 2-undecanone, parasitism.

INTRODUCTION

There have been many studies in which rates of parasitism by parasitic arthropods have been shown to be influenced by characteristics of their hosts' food plants, such as foliar morphology (Obrycki and Tauber, 1984; Keller, 1987) and plant volatiles (Altieri et al., 1981; Boethal and Eikenbary, 1986). On a finer scale, foliar trichomes (Rabb and Bradley, 1968; Obrycki, 1986; Kauffman and Kennedy, 1989a) or other plant surface characteristics may affect parasitoids (Hulspas-Jordaan and van Lenteren, 1978; Obrycki and Tauber, 1984) through repellency, alteration of searching behavior, physical entanglement, or toxicity.

The wild tomato, *Lycopersicon hirsutum* f. *glabratum* C.H. Mull, accession PI 134417, is highly resistant to the tobacco hornworm, *Manduca sexta* (L.) (Lepidoptera: Sphingidae) (Kennedy and Henderson, 1978) and Colorado potato beetle, *Leptinotarsa decemlineata* (Say) (Coleoptera: Chrysomelidae) (Kennedy and Sorenson, 1985; Kennedy and Farrar, 1987). This resistance is conditioned by the 13-carbon methyl ketone, 2-tridecanone, that occurs in type VI (Luckwill, 1943) glandular trichomes on the foliage. 2-Tridecanone also confers a limited degree of resistance to tomato fruitworm, *Heliothis zea* (Boddie) (Lepidoptera: Noctuidae), although higher levels of resistance to *H. zea* are conferred by factors associated with the foliar lamellae (Kennedy and Dimock, 1983; Dimock and Kennedy, 1983; Kennedy et al., 1985; Kennedy, 1986; Farrar and Kennedy, 1987a). The 11-carbon methyl-ketone, 2-undecanone, has been reported in the type VI trichomes of PI 134417 by Kennedy (1986) and Lin et al. (1987) and of other *L. hirsutum* f. *glabratum* accessions by Soost et al. (1968) and Lundgren et al. (1985). It is less abundant in PI 134417 trichomes and is less acutely toxic than 2-tridecanone against neonate *H. zea* (Dimock et al., 1982). However, in combination, 2-tridecanone and 2-undecanone are synergistic in their toxicity to several insect species, including *H. zea* (Farrar and Kennedy, 1987b, 1988; Lin et al., 1987). At levels frequently found in PI 134417, 2-undecanone also causes extensive mortality of *H. zea* pupae when ingested by fifth-instar larvae (Farrar and Kennedy, 1987b, 1988).

In North Carolina, eggs of *H. zea* on tomato are frequently parasitized by

Trichogramma spp. (Hymenoptera: Trichogrammatidae), while *M. sexta* eggs are parasitized by both *Trichogramma* spp. and *Telenomus sphingis* (Ashmead) (Hymenoptera: Scelionidae) (Kauffman and Kennedy, 1989a, Farrar and Kennedy, unpublished data). In the field, lower rates of parasitism by both species have been documented on tomato lines possessing high levels of glandular trichomes and 2-tridecanone (Farrar and Kennedy, unpublished data). Through trichome removal experiments, Farrar and Kennedy (unpublished data) demonstrated that differences among plant lines in rates of parasitism by *T. sphingis* were attributable to differences in density and composition of type VI glandular trichomes. In their experiments, they did not observe high levels of mortality among *T. sphingis* adults on foliage of PI 134417 or related plant lines, despite the occurrence of potentially toxic levels of 2-tridecanone associated with foliage of some of the plant lines. Since, in *T. sphingis* at least, reduction in rates of parasitism is evidently not due to wasp mortality, the present study was undertaken to investigate possible effects on wasp behavior as an explanation for the observed reduction in parasitism by both *Trichogramma* and *T. sphingis*. In addition, by comparing the two species, that have similar life histories but differ in size (*T. sphingis* is ca. 2.0 mm long; *Trichogramma* is ca. 0.5 mm), we hoped to gain insight into how such differences influence the interactions between trichome-mediated host plant resistance and biological control agents.

Because the trichome-based resistance of PI 134417 is well understood, it provides an ideal system for studying effects of host-plant resistance on organisms of the third trophic level. The results of this study should be useful in understanding host plant resistance and biological control interactions not only in tomato but in other crops as well.

METHODS AND MATERIALS

Colonies of *Trichogramma pretiosum* Riley and *T. sphingis* were maintained on *H. zea* and *M. sexta* eggs, respectively. All tomato plants were grown in a greenhouse using a commercial soil mix (Metro Mix 220) and were fertilized weekly (Peter's Professional 20-20-20 at 2.8 g/plant). Photoperiod was supplemented to 16 hr with metal halide lamps.

The following plant lines were included in this study: PI 134417, the susceptible *L. esculentum* Mill. cultivar Better Boy, F_1 (*L. esculentum* × PI 134417), BC-2 [a selection from an F_1 backcross family (F_1 × PI 134417)], BCS-9 and BCS-10 [selections from another F_1 backcross family (F_1 × *L. esculentum*)], and F_2-16 [a selection from an F_2 family (F_1 × F_1)]. The *L. esculentum* cultivar Walter was used to make crosses since Better Boy, a hybrid cultivar, does not cross readily with PI 134417. Insects respond similarly to Walter and Better Boy, and neither contains significant levels of 2-tridecanone (Farrar and Kennedy, unpublished data). The hybrid plants (except for F_1) were selected

based on the density of type VI trichomes on their foliage and the level of mortality of *M. sexta* in bioassays with excised foliage (Kennedy and Henderson, 1978).

To determine the levels of methyl ketones (2-tridecanone and 2-undecanone) associated with foliage of each plant line, the exudate of 1200 type VI trichome tips per plant line was collected using glass microcapillary tubes. The exudate was dissolved in 200 μl of methanol. The samples were analyzed using a Hewlett-Packard 5880 gas chromatograph with a 15-m Durabond DB5 capillary column, helium carrier gas, and temperature program analysis (100°C for 1 min, then to 275°C at 5°C/min, then 275°C for 5 min). 2-Tetradecanone (Wiley Organics, 4654 Kenny Rd., Columbus, Ohio 43220) was used as an internal standard. Collections of glandular trichome tips were made from disks (5.8 mm^2 in diameter) cut from each of four leaflets per plant line (one disk per leaflet). All type VI glandular trichomes on each disk were counted, and the exudate was collected from 300 trichomes per disk. These data were used to calculate the concentration of 2-tridecanone and 2-undecanone in tomato genotypes as weight per centimeter squared of foliage.

A test was conducted to evaluate the effect of methyl ketone-and/or trichome-mediated resistance on (1) rates of *H. zea* egg parasitism by *T. pretiosum* and (2) wasp entrapment (in the trichome exudates such that they could neither move nor fly and would ultimately die) on selected plant lines in laboratory cages. *H. zea* eggs were glued on the lower side of young fully expanded foliage of each plant line at a constant density of ca. 0.5 egg/cm^2. To obtain this density, a wire screen with a 0.4-cm^2 grid was supported above the leaf, and one egg was glued in each fifth square. A diluted (1 : 1) water-based white glue (Elmer's) was used. In preliminary tests, more than 70% of eggs on Better Boy foliage were parasitized when the ratio of female wasps to host eggs was 1 : 1.6. Thus, this ratio was maintained in all replicates of this test. After eggs were glued on each leaf, the petiole was placed in a Water-Pic (water-filled, rubber-capped plastic tube with tapering end). These tubes were then placed in empty flasks in clear Plexiglas cages (30 × 30 × 30 cm). One leaf of each plant line was placed in the cage. The parasitoids were collected from the colony in shell vials, anesthetized with carbon dioxide, sexed, counted, and, following their recovery, released in the cage. A small amount of honey was streaked on the inside top of the cage as food for the wasps. Only 0- to 24-hr-old wasps were used in the test. The cages were held at room temperature (25 ± 2°C) and the test was replicated seven times.

After 24 hr, the leaves were removed from the Water-Pics and scanned under a stereomicroscope to observe the entrapment of *T. pretiosum* in the trichome exudates. The eggs were removed from the foliage, placed in individual No. 0 gelatin capsules (Eli Lilly and Co., Indianapolis, Indiana 46285), and held at 27°C for 10 days. *T. pretiosum* requires seven to eight days to complete

development to adult emergence in *H. zea* eggs at this temperature (Kashyap, unpublished data). On the tenth day, eggs were categorized as parasitized or nonparasitized. Only those *H. zea* eggs from which adult *T. pretiosum* emerged successfully were categorized as parasitized. Our earlier data revealed that, at least on PI 134417 foliage, some *Heliothis* eggs that are stung by *T. pretiosum* do not yield adult parasitoids, presumably because of 2-tridecanone-mediated mortality of developing parasitoids inside the host eggs (Kashyap, Kennedy, and Farrar, unpublished data). Data on the percent *H. zea* egg parasitization as well as wasp entrapment on various tomato plant lines were normalized by arcsine$\sqrt{\%}$ transformation, analyzed by analysis of variance (ANOVA) with plant line means separated by least significant difference (LSD).

In another experiment, behavioral responses (walking and initiation of flight) of individual *T. pretiosum* and *T. sphingis* wasps were studied in insects placed on excised leaf disks of the six tomato lines. The leaf disks (diam. 16.3 mm) were cut from the first fully expanded leaf as described above. In preliminary tests, disks of this size were found adequate to observe the behavior of *T. pretiosum* adults on PI 134417 foliage. One hour prior to the start of the test, 1-day-old wasps, without any prior oviposition experience, were placed in a Petri dish (diam. 5.5 cm) with host eggs. The females were allowed to oviposit in the host eggs. An individual ovipositing wasp then was transferred to the center of the leaf disk by moving the egg with forceps. The egg was removed from the leaf-disk as soon as the wasp left it to walk on the leaf disk. The time (seconds) taken by the wasp to cross the edge of the leaf disk arena or initiate flight was recorded with a stopwatch. This behavior was observed under a magnifying ($\times 1.77$) lens (diam. 19.5 cm) illuminated evenly from all sides with a circular 22-W fluorescent tube. The incidence of flight initiation was considered an index of propensity to fly away from the leaf surface due to physical and/or chemical barriers on the leaf surface. Insects that spent more than 5 min at one spot were examined under a stereomicroscope to determine if they were entrapped in the trichome exudates. Each leaf disk and adult wasp was tested only once. Tests were conducted at room temperature (ca. 25°C). Fifty wasps of each species were observed on each plant line. Data on time to cross the disk or initiate flight were subjected to ANOVA; means were separated by LSD. Data on the proportion of wasps entrapped in trichome exudates were subjected to chi-square analysis.

Results obtained in this test with *T. sphingis* suggested that the disk size used was inappropriate for studying the full repertoire of behavioral responses of *T. sphingis*, which is larger than *T. pretiosum*. Thus, the responses of *T. sphingis* also were investigated on whole excised leaflets held horizontally 10–15 cm above a table top. The cut end of the petiole was placed in a Water-Pic held in a plastic cup. An adult female *T. sphingis* was transferred to the middle of the leaflet as described above and observed under the magnifying lens. The

time spent (1) walking rapidly or (2) not walking (characterized by grooming of mouthparts, legs, or antennae, or keeping the mouthparts close to the leaf surface, etc.) was recorded until the wasp flew or dropped from the leaf, or for 6 min, whichever was less. If the wasp spent more than 6 min on the leaflet, the total time it remained on the leaflet was also recorded. Each adult *T. sphingis* and leaflet were used only once. Twenty-five adult *T. sphingis* were observed on each Better Boy, F_1, and PI 134417. Surface area was measured for 10 leaflets of each plant line using a Li-Cor LI3100 leaf area meter. Percentage of time spent by an adult *T. sphingis* walking on the leaf surface (within the first 6 min) was calculated, and normalized using the arcsine$\sqrt{\%}$ transformation. Similarly, total time (seconds) on the leaflet was normalized using the logarithmic transformation. Data were subjected to ANOVA and the means separated by LSD.

The technique of Obrycki and Tauber (1984) was used to determine the influence of trichome/methyl ketone-mediated resistance in tomato on the landing rates of *T. sphingis*. Sections of dialysis tubing (Spectra/Por, molecular weight cutoff 6000–8000), 16 cm long × 7.6 cm diameter, were fitted with 3-cm-thick foam rubber plugs forming chambers 10 cm long × 7.6 cm diameter. Leaves of approximately equal area were collected from each of three plant lines (Better Boy, F_1, and PI 134417). One *M. sexta* egg was glued to each leaflet (adaxial surface) of the leaf with Elmer's glue. A leaf was inserted into each dialysis tube through a slit in one of the plugs. The petiole extended outside the plug and was inserted into a Water-Pic. The tubes were held horizontally, and about 10 unsexed *T. sphingis* adults were released in the tube. Time (minutes) taken by the first wasp to land on the leaf was recorded with a stopwatch, and observations were terminated at 15 min. Each group of wasps and each leaf were used only once. The areas of 10 leaves of each line were measured as above. The test was replicated ca. 30 times for PI 134417 and ca. 20 times each for F_1 and Better Boy. The percentage of observations in which one or more wasps landed within 15 min, and the frequency distribution of times taken by the first *T. sphingis* adult to land on the foliage, were analyzed by χ^2.

RESULTS AND DISCUSSION

In the laboratory cage test, percent parasitism of *H. zea* eggs by *T. pretiosum* was significantly lower on PI 134417, BC-2, and F_2-16 foliage than on foliage of the other plant lines, whereas significant entrapment of wasps occurred only on PI 134417 and BC-2 foliage (Table 1). 2-Tridecanone and 2-undecanone were found in the trichome tips of PI 134417 and BC-2 but not in the trichome tips of the other plant lines. In addition, these two plant lines had the highest densities of type VI trichomes (Table 2).

[a] Means separation vertical; means with the same letter are not significantly different at $P \leq 0.05$ (LSD).

When placed on leaf disks, the time taken by adult *T. pretiosum* to walk off the leaf disk varied significantly among plant lines ($F = 33.49$; $P = 0.0001$; treatment $df = 5$; error $df = 169$) (Table 2). There were no differences among plant lines lacking methyl ketones in their trichome tips, despite a range of type VI trichome densities among these lines of 3.1–9.2/mm^2. The wasps required significantly more time to walk from the leaf disks of BC2 and PI 134417, both of which contain methyl ketones, than from disks of plant lines lacking methyl ketones. Both BC-2 and PI 134417 also have much higher densities of type VI trichomes than the other plant lines, thus the reduced walking speed on these lines is likely due in part to the purely physical effects of trichome density (Keller, 1987). However, the methyl ketones very likely play a role in the observed effects of PI 134417 and BC-2 foliage as well. 2-Tridecanone and 2-undecanone are lethal toxins for *T. pretiosum* and direct contact of *T. pretiosum* adults with PI 134417 foliage, or exposure to its foliar volatiles, which are rich in 2-tridecanone (Dimock and Kennedy, 1983), causes some mortality within 4 hr (Kennedy et al., 1991). A comparison of the response to BC-2 and PI 134417 supports this hypothesis. Although there was little difference in type VI trichome densities between these two plant lines, PI 134417 foliage had a much higher concentration of methyl ketones than BC-2 foliage, and the wasps took over twice as long to walk from leaf disks of PI 134417 than from those of BC-2. In addition, entanglement of *T. pretiosum* in type VI trichome tips was significantly greater on PI 134417 than on all other plant lines including BC-2, whereas, although entrapment on BC-2 tended to be greater than on the

plant lines lacking methyl ketones, the differences were not significant ($P > 0.05$).

Differences among plant lines in the time to initiation of flight by those *T. pretiosum* that did so were significant ($F = 3.30$; treatment $df = 5$; error $df = 87$; $P = 0.0089$) but did not reflect differences in either type VI trichome density or methyl ketone levels (Table 2). Although these wasps tended to take longer to initiate flight from PI 134417 than from any other plant line, the time to initiate flight from PI 134417 did not differ significantly from either BC-2, which also contained methyl ketones, or BCS-10, which did not.

In contrast to *T. pretiosum*, when *T. sphingis* were tested on leaf disks, there were no significant effects of plant line on either the time taken to walk from the leaf disk ($F = 1.72$; $P = 0.1319$; treatment $df = 5$; error $df = 222$), or to initiate flight ($F = 1.98$; $P = 0.0927$; treatment $df = 5$; error $df = 65$) (Table 2). Further, no adult *T. sphingis* were entrapped by the glandular trichomes.

In tests with *T. sphingis* on whole leaflets, the larger test arenas (4.26, 3.89, and 4.35 cm^2 for Better Boy, F_1, and PI 134417, respectively vs. 2.08 cm^2 for leaf disks) provided more opportunity for parasitoid contact with trichomes before the edge of the foliage was reached. A consequence of this was that there was significantly more time spent on PI 134417 and F_1 than on Better Boy foliage and significantly more time spent on PI 134417 than on F_1 foliage (Table 3). Of the time spent on Better Boy foliage, most (78%) was spent walking (searching). In contrast, a significantly lower percentage of the total time spent on PI 134417 and F_1 foliage was spent walking, and a correspondingly greater percentage of time was spent standing still or actively grooming (41% and 57%, respectively, Table 3). During the course of these experiments, we observed that the tip contents of the type VI trichomes on PI 134417, and to a lesser extent F_1, adhered to the appendages (legs, wings, antennae) of *T. sphingis*, hindering its movement and stimulating grooming behavior. In many cases, *T. sphingis* exhibited grooming behavior for prolonged periods (>60 min) after it walked from a leaflet, before it would fly.

Landing rates of *T. sphingis* also were influenced by plant line ($\chi^2 = 6.789$; $P = 0.0336$; $df = 2$). The percentage of observations in which one or more wasps landed within 15 min was lower (69%) on PI 134417 than on F_1 and Better Boy (100% each). The frequency distributions of time (minutes) taken by the first adult *T. sphingis* to land on foliage also were influenced by plant line ($\chi^2 = 19.443$; $P = 0.0035$; $df = 6$) (Figure 1). The distributions on F_1 and Better Boy did not differ significantly ($\chi^2 = 0.2859$; $P = 0.9627$; $df = 3$) but the distribution on PI 134417 differed significantly from those on Better Boy ($\chi^2 = 10.1416$; $P = 0.0174$; $df = 3$) and on F_1 ($\chi^2 = 8.298$; $P = 0.0402$; $df = 3$). In both cases, the time taken for the first wasps to land was greater on PI 134417. The mean areas of leaves used in these tests were 17.25, 15.72,

and 14.69 cm^2 for Better Boy, F_1, and PI 134417, respectively. Farrar and Kennedy (unpublished data) found that *T. sphingis* adults avoided parasitizing *M. sexta* eggs in the presence of 2-tridecanone vapors, thus it is possible that the reduced landing rates on PI 134417 foliage observed in this study resulted from an avoidance response to the 2-tridecanone-rich volatiles associated with the foliage (Dimock and Kennedy, 1983), although effects of other foliar volatiles cannot be ruled out.

Results of these experiments help to explain previous observations that parasitism by both *T. pretiosum* and *T. sphingis* is greatly reduced on PI 134417 and related tomato lines possessing glandular trichome and/or 2-tridecanone-mediated resistance to *M. sexta*, relative to levels on susceptible *L. esculentum* cultivars. The type VI trichomes of PI 134417 act to impede movement and physically entrap adult *T. pretiosum*, as has been reported for several other species of small hymenopterans on hirsute plant types (Rabb and Bradley, 1968; Kantanyukul and Thurston, 1973; Elsey and Chaplin, 1978; Shah, 1982). On PI 134417, the adverse effects of type VI trichomes on *T. pretiosum* appear to be enhanced by the 2-tridecanone in their tips.

T. sphingis, which is larger and more robust than *T. pretiosum*, was less drastically affected by high type VI trichome densities and did not become permanently entrapped in their glandular tips. This is consistent with the observations of others that large-bodied parasitoid species were less affected by glandular trichomes on potato and tobacco than small-bodied species (Obrycki and Tauber, 1984; Belcher and Thurston, 1982). However, in the case of *T.*

sphingis, contact with the contents of the type VI trichome tips of both F_1 and PI 134417 prompted prolonged grooming and, hence, reduced searching efficiency. Factors other than the methyl ketones were responsible for stimulating the grooming behavior because the type VI trichomes of F_1 plants contain no detectable quantities of either 2-tridecanone or 2-undecanone. In addition to reduced searching efficiency on the foliage, adult *T. sphingis* also landed on PI 134417 foliage less frequently than on F_1 and Better Boy foliage, possibly in response to the repellent qualities of 2-tridecanone vapors associated with PI 134417 foliage. However, given the presence of other volatile compounds, including 2-undecanone in the trichomes of PI 134417, this repellency cannot be attributed with certainty to 2-tridecanone.

The type VI glandular trichomes that confer or contribute to the resistance of PI 134417 to a number of insect herbivores (Kennedy et al., 1986; Lin et al., 1987) also adversely affect an array of egg and larval parasitoids and predators of lepidopterous species (Kauffman and Kennedy, 1989a,b; Kennedy et al., 1990). A significant portion of the resistance to herbivores and, apparently, of the adverse effects on at least some species of natural enemies is due to the methyl ketones, 2-tridecanone and 2-undecanone, present in the trichome tips. In that a portion of the effects on natural enemies also is due to high densities of type VI trichomes, it may be possible to reduce the effects on natural enemies by selecting for plant lines with lower trichome densities but more 2-tridecanone per trichome tip. However, considering the toxic and/or repellent effects apparently attributable to 2-tridecanone, the effectiveness of this approach may be limited.

(Received June 8, 1990, accepted November 14, 1990)

Abstract—A series of new sesquiterpene ketones and norsesquiterpene ketones could be identified from the cephalic secretion of females of the cuckoo bee, *Nomada lathburiana* (K.). The major component proved to be 2,6,10-trimethylundeca-(5*E*)-2,5,9-trien-4-one. Large amounts of high-boiling-point straight-chain hydrocarbons serve as solvents for the volatile, unstable ketones.

Key Words—Bee, *Nomada lathburiana*, nest parasite, cephalic secretion, terpenoids, Hymenoptera, Anthophoridae, cuckoo.

INTRODUCTION

Bees of the genus *Nomada* are nest parasites, "cuckoo bees." The female oviposits in the nests of host bees. The provision, stored in the nest as food for the host brood, is appropriated for the rearing of the parasite larva, which also kills and consumes the host larva (Stephen et al., 1969).

A correspondence in odor production has been shown to occur in the relationships between several *Nomada* species and their hosts (Tengö and Bergström, 1977). In parasite–host pairs involving *Nomada* and species of the genus *Andrena*, the compounds in common are farnesyl hexanoate or geranyl octanoate (Tengö and Bergström, 1975), while in *Nomada–Melitta* pairs octadecyl

*To whom correspondence should be addressed.

0098-0331/91/0300-0557$06.50/0

butyrate is shared (Tengö and Bergström, 1976). In the host these compounds are produced in the females' Dufour's gland, while males of the kleptoparasite secrete them from cephalic glands. The host female utilizes the Dufour's gland secretion in lining the brood cell (Hefetz, 1987, and references therein). In addition, similar to *Evylaeus* species (Hefetz et al., 1986), the volatile components contribute to nest odor specificity (Tengö, unpublished). It has been suggested (Tengö and Bergström, 1977), that the odoriferous secretion of the parasite, on the other hand, is transferred from the male to the female during copulation, as is indicated by the presence of farnesyl hexanoate on the cuticula of the mated *Nomada* female thorax (Tengö and Bergström, 1977). The biological significance of 3,7-dimethyldeca-2,6-dien-1,10-diol, which was identified as a male-specific component of the mandibular gland secretion of *Nomada annulata* (Duffield et al., 1990) is yet unknown. The role of this bishomoterpene, which was previously known from the androconial organs of danaid butterflies (Meinwald et al., 1969), in host–parasite interactions has been discussed.

The *Nomada* females emit a sex-specific odor from cephalic glands. They seem to be territorial, defending host nest(s), which are a resource for oviposition (Tengö, 1984). Aggressive fights, comprising face-to-face flights, head-to-head butts, and pounces (Linsley and MacSwain, 1955; Tengö, 1984) occur between competing females outside the host nests. It is likely that female volatile compounds produced in cephalic glands play a role in these combats, since the characteristic smell, actively emitted by the *Nomada* females, is particularly intense during the antagonistic encounters between conspecific females (Tengö, unpublished). Preliminary investigations revealed the female cephalic odor to be species specific (Tengö and Bergström, unpublished).

The objective of the present study was to identify the volatile compounds emitted by females of the species *Nomada lathburiana* (K.).

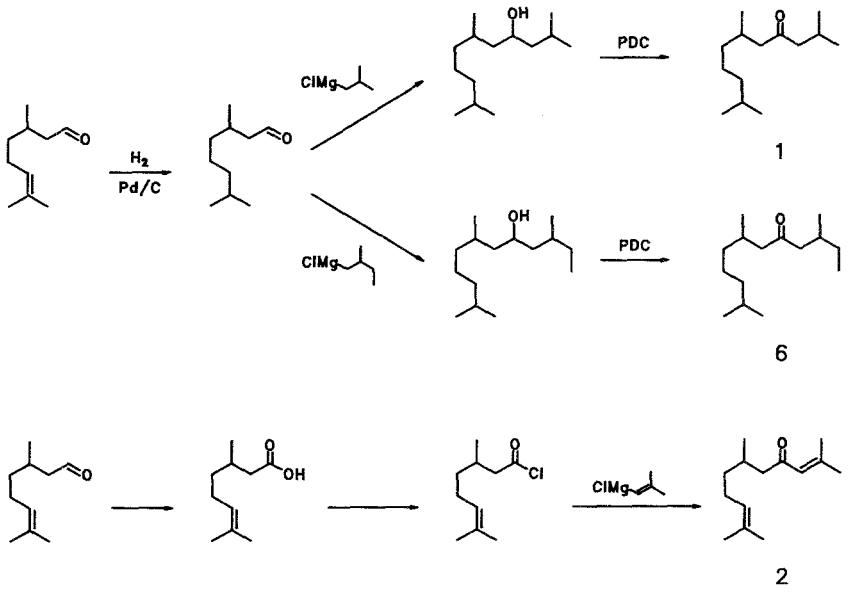
METHODS AND MATERIALS

Bees were collected during April and May in Sweden, outside Vallentuna, north of Stockholm. After being killed on Dry Ice in the field, the animals were decapitated. Subsequently, the mandibles were loosened from their attachments and, together with the heads, extracted with pentane. The extracts were concentrated in microvials (Klimetzek et al., 1989) and submitted to chemical analyses.

Gas chromatographic separation was carried out on a Carlo Erba Fractovap 2101 AC using fused silica columns (50 m, 0.25 mm ID) coated with WG 11 or FFAP, programmed from 60 to 200°C at a rate of 3°C/min. For identification of single components, the gas chromatograph was coupled to a Finnigan 311 A mass spectrometer, operated at 70 eV. Structural proof of natural com-

pounds was achieved by comparison of retention times and spectroscopic data with those of synthetic reference samples.

Syntheses of the new terpenoides are outlined in Schemes 1–3. Compounds **1, 6,** and **2** were prepared by Grignard coupling (Scheme 1). Dihydrocitronellal, 3,7-dimethyloctanal, obtained by hydrogenation (hexane, 5% PD/C) of citronellal, was reacted with 2-methylpropyl magnesium chloride (diethylether, usual procedure, reflux) to yield 2,6,10-trimethylundecan-4-ol or, with the Grignard reagent of 2-methylbutyl chloride, to yield 3,7,11-trimethyldodecan-5-ol. These secondary alcohols were oxidized according to the method of Corey and Smith (1979) to the respective ketones **1** and **6**. For the synthesis of compound **3**, citronellal was oxidized to citronellic acid (Corey and Smith, 1979), which was subsequently converted to citronellyl chloride following the method of Barnard and Bateman (1950). To get the target ketone 3, a Grignard reagent was prepared (THF, 50°C, N) from magnesium and 1-bromo-2-methylpropene (Braude and Evans, 1955) and, during an inverse procedure, added to the citronellic acid chloride (THF, −78°C, N). After complete addition, the reaction mixture was stirred at room temperature for 12 hr before work up in the usual manner. [^{1}H]NMR (C_6D_6) of **1:** 0.75–0.90 (15H); 0.95–1.30 (6H); 1.40–1.55 (m, 1H); 1.83–1.98 (3H); 2.0–2.2 (3H). [^{1}H]NMR (C_6D_6) of **6:** 0.8–0.92 (15H); 1.05–1.40 (8H); 1.45–1.52 (m, 1H); 1.85–2.04 (2H); 2.13–2.23 (2H); 2.3–2.41 (2H). [^{1}H]NMR (C_6D_6) of **2:** 0.90 (d, J = 7.3 Hz, 3H); 1.01–1.45 (m, 3H);

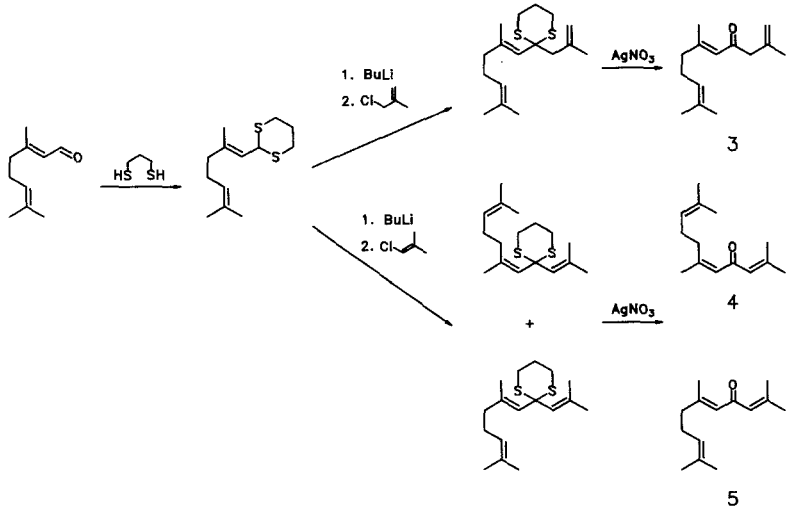


SCHEME 1. Syntheses of compounds **1, 6,** and **2.**

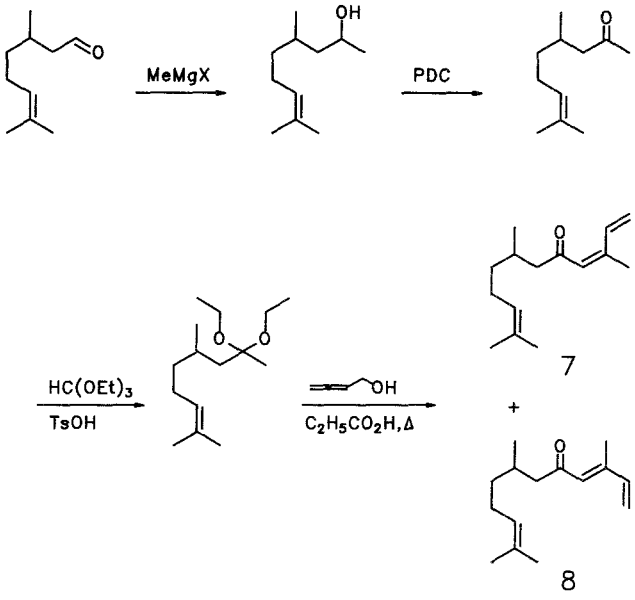
1.47 (s, 3H); 1.67 (d, J = 1.1 Hz, 3H); 1.85–2.32 (m, 4H); 2.15 (d, J = 1.1 Hz, 3H); 5.2 (t, J = 5.4 Hz, 1H); 5.46 (d, J = 1.1 Hz, 1H).

The syntheses of compounds **3, 4,** and **5** were carried out by Corey-Seebach coupling (Seebach, 1969) of the 1,3-dithiane derivative of geranial (Scheme 2). Similar to the method of Hoppmann and Weyerstahl (1978), the dithiane was dissolved in THF, cooled to −40°C, deprotonated with *n*-butyl lithium, held for 5 hr at −20°C, again cooled to −40°C, and subsequently coupled to 1-bromo-2-methyl-2-propene. The resulting 2,2-disubstituted 1,3-dithiane was converted to the corresponding ketone **3** by decomposition with silver nitrate in ethanol following the procedure of Reece et al. (1968). In the same way as described above, a mixture of the *E, Z* isomers of 2,6,10-trimethyl-2,5,9-undecatrien-4-one, **4** and **5**, was prepared from the anion of the dithiane derivative of geranial and 1-bromo-2-methyl-1-propene. [^{1}H]MNR (C_6D_6) of **3:** 1.46 (s, 3H); 1.6 (s, 3H); 1.68 (d, J = 1.1 Hz, 3H); 1.84–1.94 (m, 2H), 2.10 (t, 2H); 2.16 (d, J = 1.2 Hz, 3H); 2.94 (s, 2H); 4.74 (s, 1H); 4.84 (s, 1H); 5.06 (t, J = 5.6 Hz, 1H); 5.98 (s, 1H). [^{1}H]NMR (C_6D_6) of **4:** 1.48 (s, 3H); 1.54 (d, 3H); 1.62 (d, J = 1.1 Hz, 3H); 1.90–2.01 (m, 2H); 2.06 (t, 2H); 2.15 (d, 3H); 2.21 (d, J = 1.1 Hz, 3H); 5.06 (t, J = 5.6 Hz, 1H); 5.90 (d, J = 1.1 Hz, 1H); 5.97 (d, J = 1.1 Hz, 1H). [^{1}H]NMR (C_6D_6) of **5:** 1.48 (s, 3H); 1.54 (d, 3H); 1.62 (d, J = 1.1 Hz, 3H); 1.90–2.01 (m, 2H); 2.06 (t, 2H); 2.21 (d, J = 1.1 Hz, 3H); 2.28 (d, J = 1.1 Hz, 3H); 5.06 (t, J = 5.6 Hz, 1H); 5.93 (d, J = 1.1 Hz, 1H); 5.97 (d, J = 1.1 Hz, 1H).

The synthesis of the terpenes **7** and **8** (Scheme 3) started from citronellal



SCHEME 2. Syntheses of compounds **3, 4,** and **5.**



SCHEME 3. Syntheses of compounds **7** and **8.**

and proceeded via 2,2-diethoxy-4,8-dimethyl-7-nonene. In a manner resembling the synthesis of monoterpenes bearing a vinyl ketone moiety (Bäckström et al., 1987), the latter acetal was reacted with 2,4-pentadien-1-ol to yield **7** and **8** in a Claisen rearrangement. [^{1}H]NMR (C_6D_6) of **8:** 0.9 (d, J = 0.58 Hz, 3H); 1.56 (s, 3H); 1.68 (s, 3H); 1.9–2.5 (m, 7H); 2.27 (s, 3H), 5.12 (d, J = 10.6 Hz, 1H); 5.18 (t, J = 5.3 Hz, 1H); 5.32 (d, J = 17.4 Hz, 1H); 5.89 (s, 1H); 6.15 (dd, J = 10.6 Hz, J = 17.4 Hz, 1H).

Crude products were purified either by HPLC (Waters; Whatman column; 0.5 × 9.4 mm ID; Partisil 10 Pac, hexane–ethyl acetate) or by preparative gas chromatography (Carlo Erba 2400V; stainless-steel column 6 m × 6 mm ID; 10% OV17 on chromosorb G/AWDMCS; 60–80 mesh; helium).

RESULTS AND DISCUSSION

The cephalic secretion of *Nomada lathburiana* females is a complex mixture of minute amounts of some new mevalogenins, largely dominated by acetogenines, which are represented by straight-chain hydrocarbons. The latter contain uneven numbers of carbon atoms; the series starts at nonadecane and shows increasing concentration to tricosane, after which it decreases. The identified terpenoids are listed in Table 1; chemical structures are shown in Figure 1;

TABLE 1. SESQUITERPENOIDS IN CEPALIC SECRETION OF FEMALE *Nomada lathburiana*

1. 2,6,10-Trimethylundecan-4-one
2. 2,6,10-Trimethylundecan-2,9-dien-4-one
3. 2,6,10-Trimethylundecan-(5*E*)-1,5,9-trien-4-one
4. 2,6,10-Trimethylundecan-(5*Z*)-2,5,9-trien-4-one
5. 2,6,10-Trimethylundecan-(5*E*)-2,5,9-trien-4-one
6. 3,7,11-Trimethyldodecan-5-one
7. 3,7,11-Trimethyldodecan-(3*Z*)-1,3,10-trien-5-one
8. 3,7,11-Trimethyldodecan-(3*E*)-1,3,10-trien-5-one

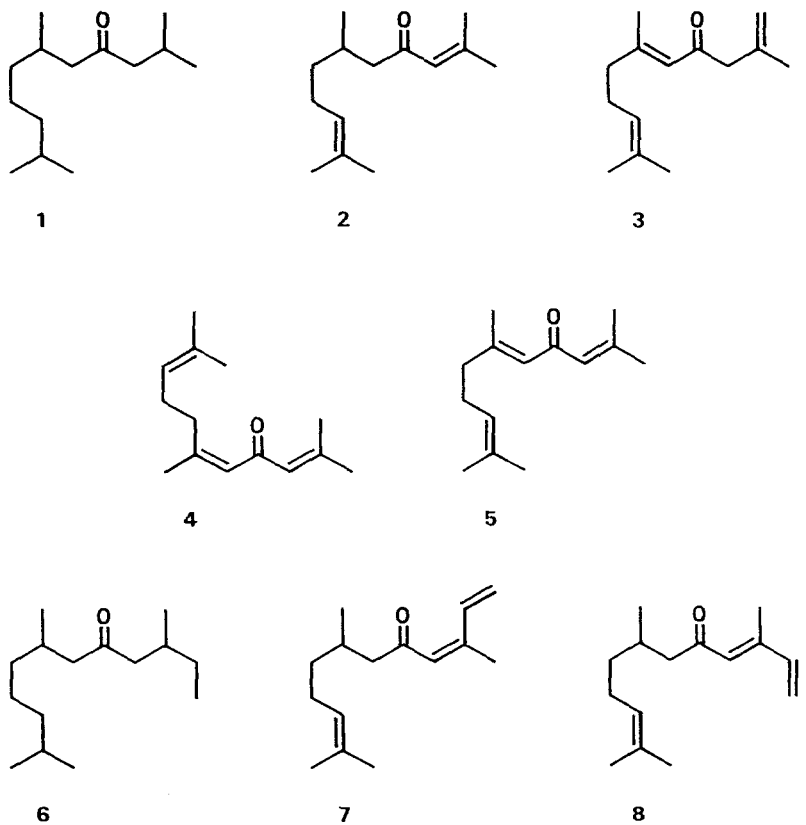


FIG. 1. Structural formulas of sesquiterpenoids and norsesquiterpenoids occurring in the cephalic secretion of *Nomada lathburiana* females.

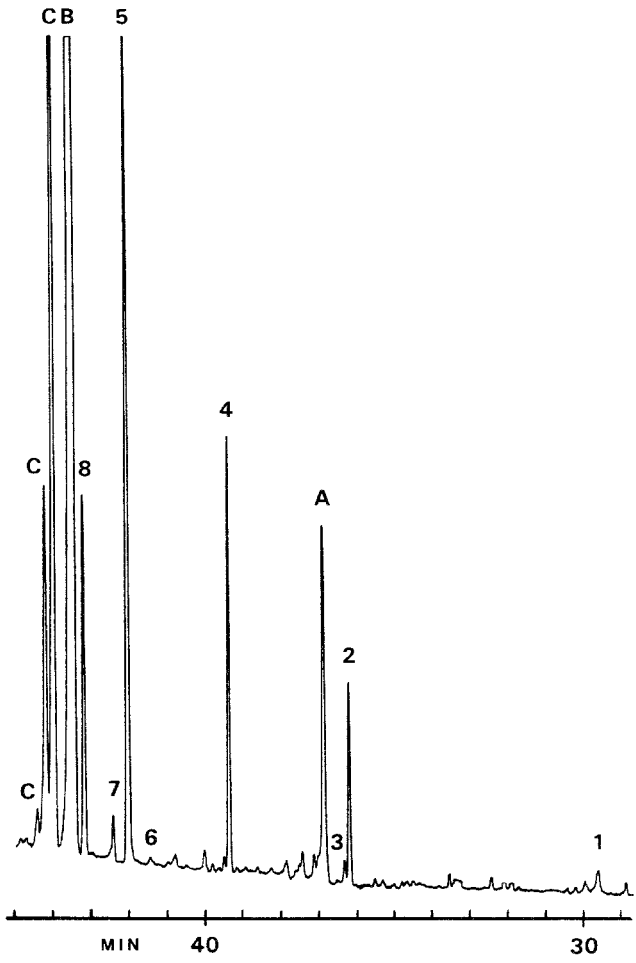

FIG. 2. Gas chromatogram of the terpenoid region of *Nomada lathburiana* female cephalic secretion, numbering according to Table 1 A = nonadecane, B = heneicosane, C = heneicosene (conditions, see text).

relative proportions can be seen in the gas chromatogram (Figure 2). Numbering in the table and in the figures are the same. Mass spectra of the major terpenoids **2, 4, 5,** and **8** are shown in Figure 3.

The characteristic strong odor, perceivable by the human nose, is represented by oxygenated sesquiterpenoids. The components are acyclic, showing a typical branching pattern and a carbonyl group at an unusual position. The vinylketone moiety present in six of these rather volatile compounds renders them highly unstable. Attempts to determine the absolute configurations of the chiral components are presently under way.

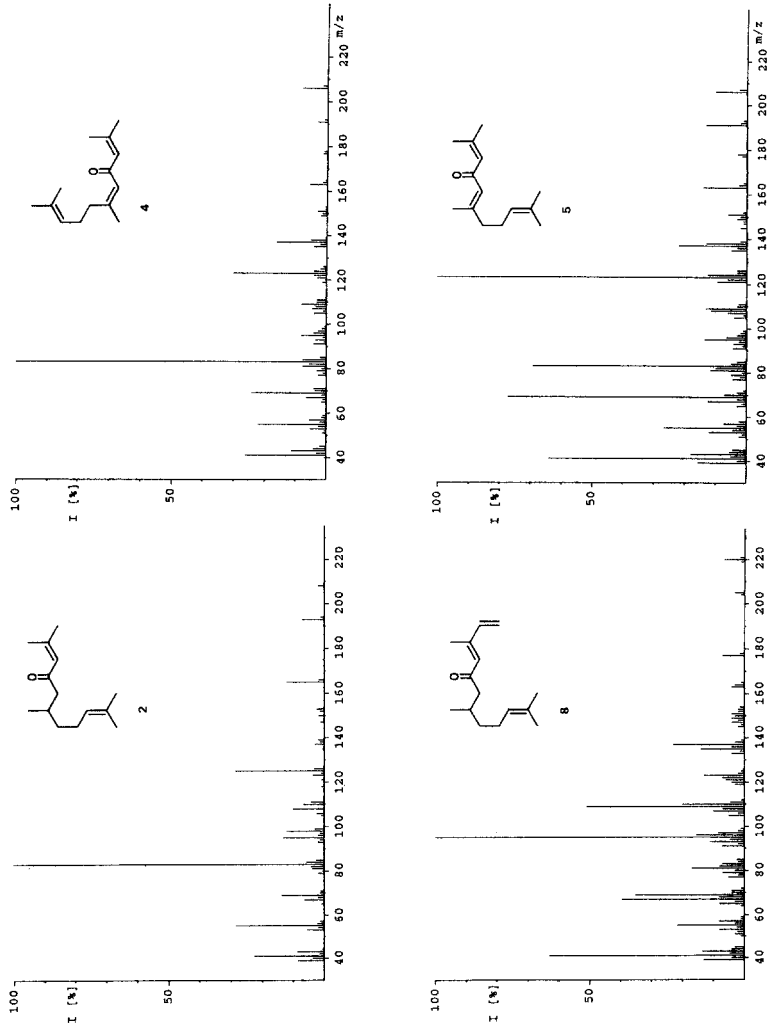

FIG. 3. Mass spectra (70 eV) of compounds **2**, **4**, **5**, and **8**.

Compounds **4** and **5** correspond to the known 2-methylpseudodamascone (Schulte-Elte et al., 1975), which may give an idea of the rose-like character of the intense smell produced by the *Nomada* females.

As for the biological function of the compounds, one may speculate that electrophilic vinylketones, which represent ideal Michael acceptors, are used as repellents or defense compounds. In some species of *Ips* bark beetles, 2-methyl-6-methylene-2,7-octadien-4-one (ipsdienone), which shows the same vinylketone substructure as some of the *Nomada* ketones reported here, acts as a strong repellent (J.P. Vité, U. Kohnle, W. Francke, unpublished). It is interesting to note that several unbranched vinylketones of acetogenetic origin are reported as defense compounds of termites (Spanton and Prestwich, 1982). Another vinylketone, 1-nonen-3-one, is the main compound in the cephalic secretion of females of the cleptoparasitic megachilid bee, *Coelioxys mandibularis* Nyl. (Tengö et al., 1982); however, its biological function remains unknown.

Acknowledgments—The authors wish to thank Yngve Sjögren for assisting in collecting the bees, and the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Swedish Natural Research Council for financial support.

(Received November 28, 1989; accepted November 16, 1990)

Abstract—Volatiles were captured on Porapak Q from foreign grain beetles, *Ahasverus advena* (Waltl), feeding on rolled oats at various population densities. At low population density, males, females, and mixed-sex beetles four to six weeks posteclosion and older produced 1-octen-3-ol. Mixed-sex beetles emitted almost pure (*R*)-(−) enantiomer. Weekly production rates of 1-octen-3-ol by males were at least four times greater than those of females. Production of 1-octen-3-ol was barely detectable in volatiles from mixed-sex adults maintained at the highest population density. Laboratory bioassays in a two-choice, pitfall olfactometer modified to retain responding beetles revealed that 1-octen-3-ol serves as an aggregation pheromone for *A. advena*. Both racemic and chiral 1-octen-3-ols were good attractants for mixed-sex adults in the pitfall olfactometer.

Key Words—*Ahasverus advena* (Waltl), foreign grain beetle, Coleoptera, Cucujidae, 1-octen-3-ol, volatile attractant, aggregation pheromone, population density.

INTRODUCTION

The foreign grain beetle, *Ahasverus advena* (Waltl), is a cosmopolitan pest of stored products. Primarily fungivorous, *A. advena* usually infests damp and

decaying, mold-damaged cereals, oilseeds, and other stored food (Sinha and Watters, 1985). The insect develops well on pure cultures of common storage fungi (David et al., 1974), and larvae and adults exhibit elevated levels of chitinolytic enzymes, indicating that fungal chitin can be utilized as a food source (Fukamizo et al., 1985). There are observations, however, confirming direct feeding on foods in the absence of visible mold (Woodroffe, 1962).

Identification of attractive semiochemicals for *A. advena* could lead to the development of integrated control programs (Levinson and Levinson, 1979; Burkholder, 1981). To date, we have found that males of six species of economically damaging, cucujid grain beetles produce aggregation pheromones (Oehlschlager et al., 1988). An additional aggregation pheromone, 1-octen-3-ol, was found to be produced by males and females of two of these species, *Oryzaephilus surinamensis* (L.) and *O. mercator* (Fauvel), when adults were maintained at low population densities in aeration cultures (A.M. Pierce et al., 1989).

The objective of the present study was to identify beetle-produced, attractive semiochemical(s) for adult *A. advena*.

METHODS AND MATERIALS

Insect Rearing. A. advena were reared at 28°C and 65–70% relative humidity in darkness. Stock cultures were set up in 3.8-liter glass jars containing 1 kg of large-flake, rolled oats and brewer's yeast (95:5, w/w) with an inoculum of 2500 adults. The medium initially had been sprayed with 80 ml of distilled water and mixed well. Numbers of adults were determined by mean weight (1 beetle = 0.42 mg, $N = 1600$).

Beetles for Aerations. Beetles were sexed as pupae by examination of the genital papillae (Halstead, 1963) using the following procedure. Late-stage larvae were removed from stock cultures and placed individually in 3.7-ml shell vials each containing a moistened oat flake. The open vials were kept at 28°C and 65–70% relative humidity in darkness until pupation occurred. Prior to sexing, pupae were placed on several layers of moistened filter paper in covered, 150-mm-diam. glass Petri dishes to loosen the posterior attachment of the last larval exuvia. After 30 min at approx. 24°C, the softened exuvia was gently removed from the tip of the abdomen with a fine brush and the sex determined. The segregated sexes were returned to jars of moistened rolled oats at approximately the same densities as used in aerations. Unless stated otherwise, for mixed-sex aerations, late-stage larvae were transferred directly to jars of moistened oats at the appropriate density. The beetles were kept at 28°C and 65–70% relative humidity until used in aerations as adults.

Collection of Volatiles. Volatiles from male, female, or mixed-sex beetles

were obtained by aeration of adults in vertically oriented, cylindrical glass chambers (18 cm × 10 cm OD) containing 50 g of large-flake, rolled oats (H.D. Pierce et al., 1984). Charcoal-filtered, humidified air was drawn by aspiration (1.65 liters/min) through a culture (held at 23–24°C in darkness) and then through a glass trap (150 mm × 14 mm OD) filled with conditioned Porapak Q (H.D. Pierce et al., 1984). At intervals of seven days, the culture was removed from the aeration chamber, the beetles separated from the oats and returned to a clean chamber with a fresh 50-g portion of oats, and the aeration continued using a fresh Porapak Q trap. Volatiles were recovered by extraction of the Porapak Q with purified pentane in a Soxhlet extractor for 24 hr and concentrated by distillation of the pentane through a Dufton column.

Two experiments were conducted using mixed-sex and single-sex beetles, respectively. For mixed-sex beetles, simultaneous aerations were set up one each at population densities of 2, 5, 50, and 200 beetles/g oats, along with a rolled oat control. The aeration with 2 beetles/g oats used virgin males and virgin females, which were combined in equal amounts immediately prior to commencement of aeration. For single-sex beetles, simultaneous aerations were set up with segregated virgin males and virgin females at a population density of 5 beetles/g oats, along with a rolled oat control.

The amounts of volatiles collected were expressed as beetle hours (bh) or gram hours (gh) where 1 bh = the volatiles from one adult aerated for 1 hr, and gh = the volatiles from 1 g of rolled oats aerated for 1 hr.

Moisture Content of Aeration Medium. At the time of medium change for aeration cultures, a 25- to 30-g sample of used medium was placed in an open, 100-mm-diam. glass Petri dish, immediately weighed, and dried to constant weight in a small convection oven at 50–52°C for one week. Moisture content of the unused, rolled oat medium was periodically checked in the same manner.

Test Beetles for Bioassay. Mixed-sex *A. advena* were harvested from stock cultures and placed in fresh medium at a density of approx. 10,000 beetles/kg at least one week before bioassays commenced. Test beetles were 5–12 weeks posteclosion at the time of bioassay. Approximately 48 hr prior to a bioassay, 0.8 g of beetles were removed from the culture and preconditioned without food at 23°C in darkness in a 6-liter Erlenmeyer flask through which charcoal-filtered, humidified air was drawn at 1.5 liters/min.

Bioassay Procedures. Several hours prior to a bioassay, 12 conditioned beetles were aspirated into each of up to 96, 60-ml glass vials. Unless stated otherwise, bioassays of pentane solutions were conducted using a two-choice, pitfall olfactometer (A.M. Pierce et al., 1981) in which oat flakes were placed individually in the experimental and control vials. The vials of test beetles and vials for the olfactometers then were placed in an environmental chamber maintained at 23°C and 60–65% relative humidity for approx. 2 hr before the bioassay commenced. Filter paper disks treated with a 10-μl aliquot of either an

experimental stimulus in purified pentane or purified pentane as a control were put singly into the bottoms (on top of the oat flake) of two glass vials suspended from holes in the bottom of a plastic Petri dish arena. Twelve beetles were released into the dish, and the lid was replaced. Bioassays for each test stimulus were replicated 10 or 12 times, using 12 fresh beetles in each replicate. After 2 hr in darkness, the numbers of beetles in experimental and control vials were recorded. All doses for a particular test stimulus were done in the same bioassay session, beginning with 12 replicates of the lowest dose and proceeding in sequence to the highest dose. The responsiveness of the test beetles was checked by bioassay of a standard low dose of Porapak Q-captured beetle volatiles at the start of a bioassay session.

In the initial bioassay session, response by *A. advena* in the two-choice, pitfall olfactometer was determined at selected time intervals by counting the number of beetles in the experimental and control vials. Counting the beetles in the vials necessitated picking up and slightly tilting the olfactometer dish. This process did not disturb the responding beetles if done gently. The experimental stimuli for this bioassay were a measure of frass from a mature stock culture and a pentane extract thereof. The latter was prepared by placing 2.5 g of frass in a sintered glass funnel. Approximately 10 ml of pentane was added, and the mixture was stirred with a spatula. The solvent then was drawn off by application of a slight vacuum. This process was repeated three times. The combined pentane washes were concentrated under a stream of nitrogen to 1 ml.

The untransformed data were analyzed by the paired-sample t test, $\alpha = 0.05$ (Zar, 1984), and results were expressed as the mean percent response of the total number of beetles per treatment.

Alcohols. Racemic 1-octen-3-ol and (*Z*)-3-nonenol were purchased from Bedoukian Research, Inc. (Danbury, Connecticut). (*R*)-(−)- and (*S*)-(+)-1-Octen-3-ol with optical purities of 98% and 99.5%, respectively, were obtained from Dr. A. Mosandl (Mosandl et al., 1986). 1-Nonanol was purchased from Aldrich Chemical Co., Inc. (Milwaukee, Wisconsin). (*Z*) -2-Octenol was available from a previous study (Oehlschlager et al., 1984). Chemical purities were >99% in all cases.

The enantiomeric excess (ee) and chirality of beetle-produced 1-octen-3-ol were determined by the method of Slessor et al. (1985).

Instrumental Methods. A Hewlett-Packard 5830A gas chromatograph equipped with a 18835B capillary inlet system and a flame-ionization detector was employed for analyses by gas chromatography (GC). Samples were analyzed on an open-tubular glass column (40 m × 0.5 mm ID) coated with SP-1000 (Supelco Canada Ltd., Oakville, Ontario). The temperature program for analytical GC was 70°C for 2 min, then 4°C/min to 180°C, holding for 30 min or less. Helium was the carrier gas, and the injection port and detector temper-

atures were 260°C and 270°C, respectively. Quantification of 1-octen-3-ol in purified pentane was conducted using methyl laurate as an internal standard.

Coupled gas chromatography–mass spectroscopy (GC-MS) was carried out on a Hewlett-Packard 5895B GC/MS-DS fitted with a fused silica column (30 m × 0.25 mm ID) coated with Carbowax 20M (J&W Scientific, Folsom, California) with helium as the carrier gas.

RESULTS

Aerations. When aerated in low-density aeration cultures, mixed-sex and single-sex *A. advena* produced 1-octen-3-ol (Figures 1 and 2). The highest rate of production of 1-octen-3-ol was found for mixed-sex beetles at the lowest population density of 2 beetles/g oats, followed next in this order by male, mixed-sex, and female beetles each at a density of 5 beetles/g oats (Figure 1). 1-Octen-3-ol was not produced in significant amounts by mixed- or single-sex

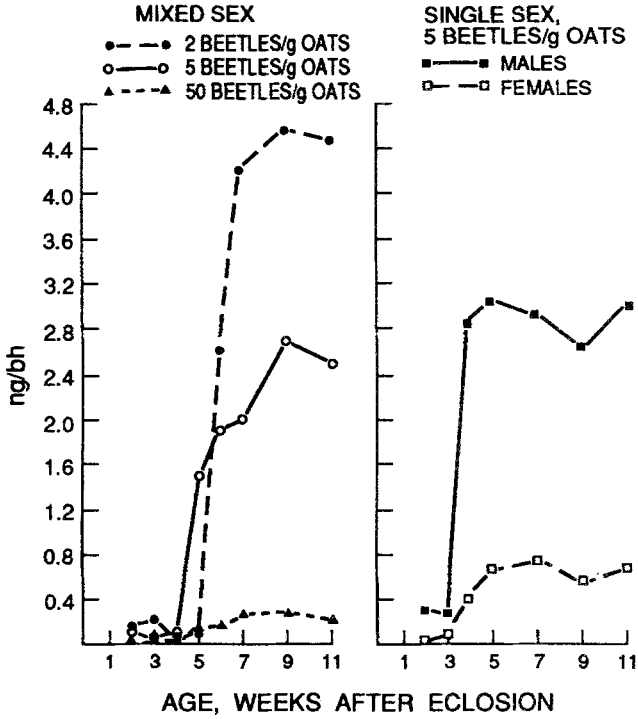

FIG. 1. Production of 1-octen-3-ol by *A. advena* in mixed- and single-sex aeration cultures as a function of adult age and population density.

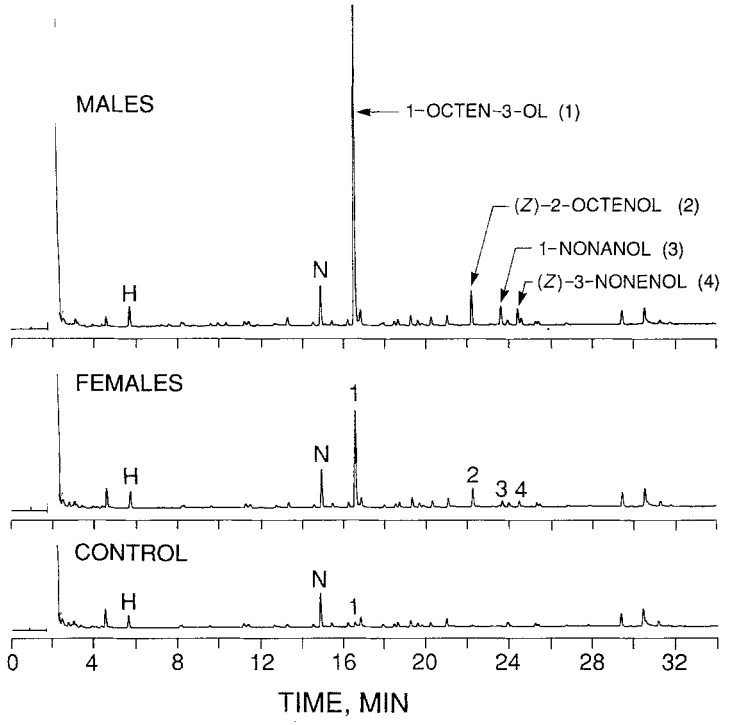

FIG. 2. Gas chromatograms of Porapak Q-captured volatiles from male and female *A. advena* (population density, 5 beetles/g oats) and the rolled oat control. Each chromatogram represents approximately the same amount of rolled oat volatiles. H = hexanal; N = nonanal.

beetles until four to six weeks posteclosion. Mixed-sex beetles at a density of 50 beetles/g oats produced low levels of 1-octen-3-ol at five weeks posteclosion and older. The elevated production rates of the alcohol at all of the above population densities were maintained throughout the 11 weeks of the experiments. Production of 1-octen-3-ol by mixed-sex adults at a density of 200 beetles/g oats was only slightly greater than the control values and ranged from 0.002 to 0.01 ng/bh. The amount of 1-octen-3-ol detected in the rolled oat control aerations was always <0.3 ng/gh.

Male and female *A. advena* produced small amounts of three additional alcohols, (Z)-2-octenol, 1-nonanol, and (Z)-3-nonenol, when production of 1-octen-3-ol was well established (Figure 2). These compounds were detected only when 1-octen-3-ol was present in significant amounts in beetle aeration volatiles. When expressed as a percent of the amount of 1-octen-3-ol present in these volatiles, the amounts of (Z)-2-octenol, 1-nonanol, and (Z)-3-nonenol

ranged from 4.1 to 11.4, 2.7 to 7.0, and 2.1 to 5.8% for males, and 9.7 to 18.7, 5.9 to 7.8, and 7.1 to 7.4% for females, respectively. The identities of the four alcohols were confirmed by GC-MS using authentic standards for comparison. Examination of the chromatograms from the beetle and rolled oat control aerations revealed no additional peaks in the beetle-aeration volatiles other than the four alcohols (Figure 2).

Mixed-sex *A. advena* aerated at a population density of 5 beetles/g rolled oats produced 1-octen-3-ol in the (*R*)-(−) configuration with an ee of 92%.

The mean moisture contents of the used aeration media were ≤10.7% for the single-sex aerations and controls, and ≤13.5% for the mixed-sex aerations and controls (Table 1). The moisture contents of the control media were similar to that of the respective single-sex or mixed-sex media. The moisture content of the unused medium was lower than that of any of the used aeration media.

Bioassays. The suitability of the two-choice, pitfall olfactometer for the identification of attractive, volatile semiochemicals for *A. advena* was determined by testing frass from mature stock cultures (Figures 3 and 4). Response to a measure of frass was quickly positive, and this response was maintained throughout the 2-hr test period (Figure 3). Response to an extract of frass was positive initially, but beetles immediately started climbing out of the test vials until no significant response was observed by 1–2 hr after the start of the bioassay (Figure 4). The addition of an oat flake in each pitfall vial retained the responding beetles in the vial of first choice until the end of the 2-hr test period (Figure 4), and this modification was used in all further bioassays.

To establish if the volatiles from low-density, older beetles contained

TABLE 1. MOISTURE CONTENT OF ROLLED OAT AERATION MEDIA (8 REPLICATES)

Culture type	Culture density (beetles/g medium)	Moisture content (%)	
		$\bar{X}$	Range
Unused medium		6.4	5.8–7.3
Male	5	10.0	9.0–10.9
Female	5	10.6	9.6–11.2
Single-sex control		10.7	9.9–12.2
Mixed-sex	2	13.1	12.5–13.6
Mixed-sex	5	13.4	12.8–13.9
Mixed-sex	50	13.5	12.6–13.9
Mixed-sex	200	12.9	12.1–13.4
Mixed-sex control		13.5	13.1–13.9

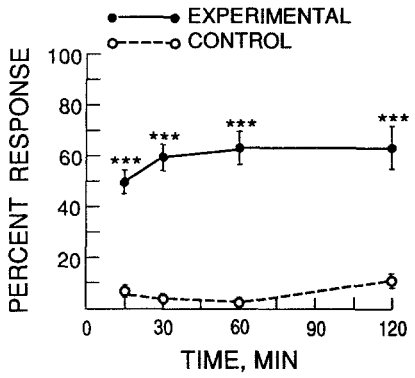

FIG. 3. Time-dependent response ($\bar{X} \pm$ SE) by mixed-sex *A. advena* in two-choice, pitfall bioassay to a 15-mg measure of frass (control = empty vial). Significant response (paired-sample *t* test) to experimental stimulus indicated by: ***$P < 0.001$ (10 replicates, 12 adults per replicate).

attractive semiochemicals, the Porapak Q-captured volatiles from mixed-sex and control aerations were bioassayed over a range of stimulus doses containing the same gh amounts of rolled oat volatiles (8.65–8650 gh) for both extracts (Figure 5). Mixed-sex *A. advena* responded well to beetle-aeration volatiles containing 1 ng or more of 1-octen-3-ol (Figure 5). Attraction to the rolled oat control, however, was obtained only at the highest test dose containing 2.6 ng of 1-octen-3-ol (Figure 5), suggesting that this alcohol was a major, beetle-produced attractant. Based on the shapes of the curves in Figure 5, the beetle-aeration volatiles were no better as an attractant than the rolled oat control at test doses containing similar, low amounts of 1-octen-3-ol.

Chiral and racemic 1-octen-3-ols were bioassayed at doses of 0.1 ng to 100 μg (Figure 6). The lower threshold for positive response for both (*R*)-(−)- and racemic 1-octen-3-ol was around 1 ng, while significant positive response was first demonstrated towards the (*S*)-(+) enantiomer at a 10 ng dose. Thus, all three 1-octen-3-ols were excellent attractants for mixed-sex *A. advena* over the experimental dose range of 10 ng to 10 μg, while the 100 μg doses elicited no significant response.

When (Z)-2-octenol, 1-nonanol, or (Z) -3-nonenol were bioassayed individually over an experimental dose range of 0.1 ng to 10 μg, no significant response was elicited from mixed-sex *A. advena* (data not shown). Preliminary bioassays of four-part mixtures of (Z)-2-octenol, 1-nonanol, (Z)-3-nonenol, and (*R*)-(−)-1-octen-3-ol showed no enhancement of the positive response to 1-octen-3-ol by the three minor alcohols (data not shown).

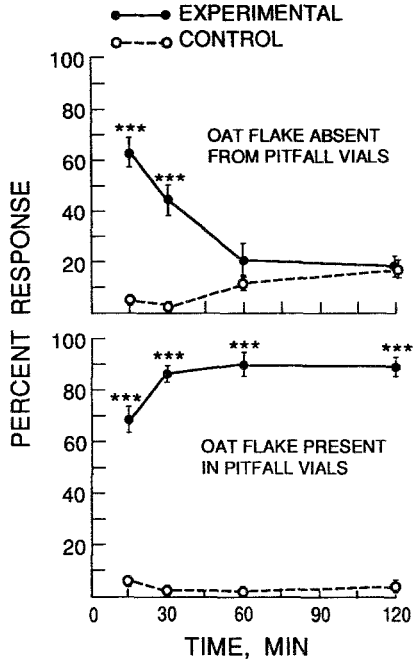

FIG. 4. Time-dependent response ($\bar{X} \pm$ SE) by mixed-sex *A. advena* in two-choice, pitfall bioassay to a pentane extract of 25 mg of frass, with oat flake absent from (top) or present in (bottom) experimental and control vials. Significant response (paired-sample *t* test) to experimental stimulus indicated by: ***$P < 0.001$ (10 replicates per treatment, 12 adults per replicate). Bioassays in this figure and in Figure 3 were performed in the same 2-hr session.

DISCUSSION

A. advena are excellent climbers of glass. In pitfall vials without oat flakes we determined that if, after initially responding to a volatile stimulus, the beetles found no host- and/or beetle-related stimuli, they climbed out of the vials, resulting in no significant response at the end of the 2-hr bioassay (Figure 4). The oat flake evidently provided host-related stimuli (possibly thigmotactic) that served to retain the responding beetles (Figure 4), as did frass from mature cultures containing visible mold (Figure 3). The same modification of the two-choice bioassay was necessary for *C. quadricollis* (H.D. Pierce et al., 1988). As suggested for *C. quadricollis*, volatile attractants might function not only to draw responding insects to an attractive source, but also to stimulate other behaviors such as searching for food and mates. If the secondary stimuli are not found, the responding insect may leave the site (H.D. Pierce et al., 1988).

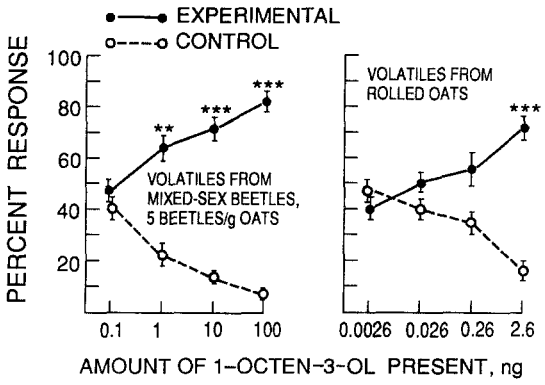

FIG. 5. Response ($\bar{X} \pm$ SE) by mixed-sex *A. advena* in two-choice, pitfall bioassay to Porapak Q-captured volatiles from (left) older, mixed-sex *A. advena* feeding on rolled oats at a population density of 5 beetles/g oats, and (right) response to the rolled oat control volatiles. The experimental stimuli in both series of treatments contained the same gh amounts of rolled oat volatiles. Significant response to experimental stimulus indicated by: $^{**}P < 0.01$, $^{***}P < 0.001$ (12 replicates per treatment, 12 adults per replicate). Bioassays in this figure were performed in the same 2-hr session.

(*Z*)-2-Octenol has been identified in the volatiles from mold (Kaminski et al., 1972) and mushrooms (Tressl et al., 1982). This alcohol also was found in low amounts in the volatiles from low-density *O. surinamensis* and *O. mercator* cultures of both sexes (A.M. Pierce et al., 1989). Although not attractive to *A. advena* or *O. mercator* (A.M. Pierce et al., 1989), (*Z*)-2-octenol was a weak attractant for *O. surinamensis* (A.M. Pierce et al., 1989).

As did *A. advena*, male and female *O. surinamensis* and *O. mercator* older than one month posteclosion produced large amounts of almost optically pure (*R*)-(−)-1-octen-3-ol when maintained in low-density aeration cultures (A.M. Pierce et al., 1989). As in the present study, both enantiomers of the alcohol were attractive to both *Oryzaephilus* spp. (A.M. Pierce et al., 1989). *O. surinamensis* is a primary pest of stored grain (Sinha and Watters, 1985). *A. advena*, as a secondary pest of stored grain, could be attracted to damaged grain stores lightly infested with *O. surinamensis* since both species produce and utilize 1-octen-3-ol.

1-Octen-3-ol is a well-known natural product produced in large amount by numerous species of molds (Kaminski et al., 1974) and mushrooms (Pyysalo, 1976). Mushroom-produced 1-octen-3-ol was found to be the (*R*)-(−) enantiomer (Dijkstra and Wikén, 1976). Since 1-octen-3-ol is known to be formed when grain is contaminated by molds (Kaminski et al., 1973), the alcohol may play a major role in the attraction of *A. advena* to deteriorating grain stores.

Our results suggest that 1-octen-3-ol is an aggregation pheromone, as well

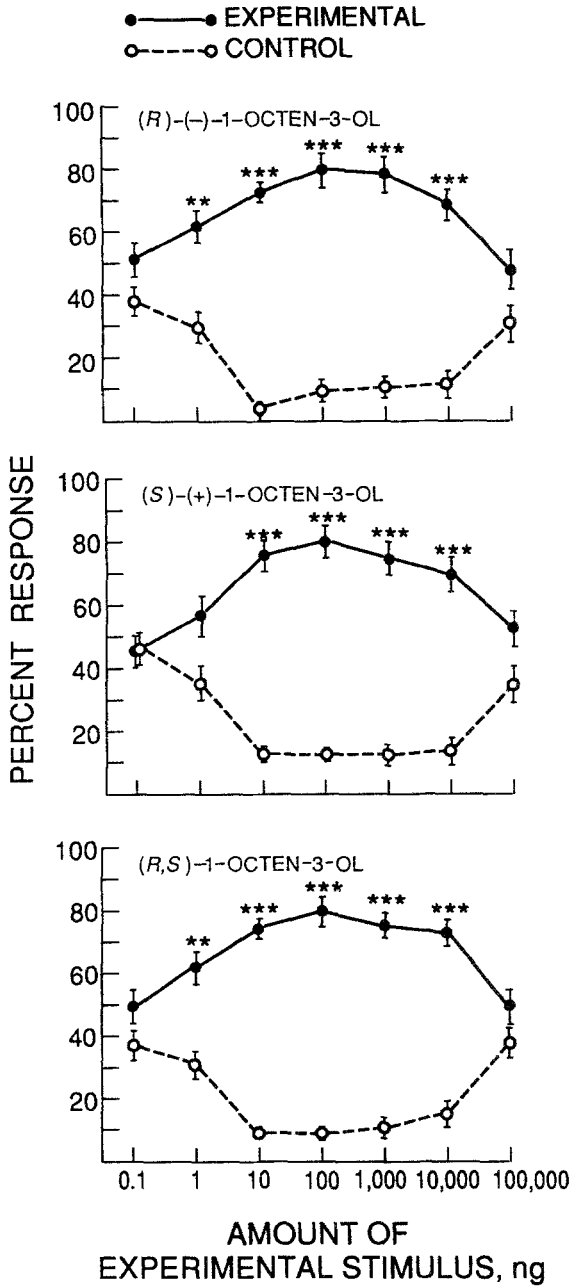

FIG. 6. Response ($\bar{X} \pm$ SE) by mixed-sex *A. advena* in two-choice, pitfall bioassay to (*R*)-(−)-, (*S*)-(+)-, and (*R*,*S*)-1-octen-3-ol. Significant response (paired-sample *t* test) to experimental stimulus indicated by: $^{**}P < 0.01$, $^{***}P < 0.001$ (12 replicates per treatment, 12 adults per replicate).

as a host kairomone, for *A. advena*, although the alcohol might be produced by associated symbiotic microorganisms. Symbiotic microorganisms have been implicated in pheromone biosynthesis for some bark beetles (Brand et al., 1976; Byers and Wood, 1981), and a fungal metabolite was identified as the wing gland pheromone of the moth, *Aphomia sociella* L. (Kunesch et al., 1987). A logical precursor of 1-octen-3-ol is linoleic acid (Wurzenberger and Grosch, 1982), which is found in abundance in the rolled oats fed to *A. advena*.

In contrast to the other cucujids studied to date (Oehlschlager et al., 1988), no other male-produced aggregation pheromones have been found for *A. advena*. 1-Octen-3-ol apparently was not derived in large amounts from the rolled oat medium since only trace amounts were detected in control aerations, and the moisture content of the medium both before and after aeration was too low for effective microbial growth (Milner et al., 1947). Had 1-octen-3-ol been produced primarily by fungal contamination of oats, there should have been equal or greater amounts produced as culture density increased. Rather, production of 1-octen-3-ol decreased as culture density increased (Figure 1). Moreover, production rates by males were at least four times greater than those by females. As found for *Oryzaephilus* spp. (A.M. Pierce et al., 1989), the onset of production of significant amounts of 1-octen-3-ol at the lower population densities occurred in older adults. The data indicate, therefore, that 1-octen-3-ol is an aggregation pheromone for *A. advena*, which functions to draw beetles into a lightly infested host. When population density is high, some unknown feedback mechanism evidently suppresses pheromone production (Figure 1), ensuring against overcrowding.

Acknowledgments—We thank Dr. A. Mosandl for gifts of the chiral 1-octen-3-ols and E. Merletti for technical assistance.

(Received November 28, 1989, accepted November 16, 1990)

Abstract—Responses by five species of cucujid grain beetles (mixed-sex adults) to various volatiles were assessed by means of a two-choice, pitfall olfactometer. The test volatiles were short-chain alcohols and ketones known to be produced by fungi. Both racemic and chiral 1-octen-3-ols were strong attractants for *Cryptolestes ferrugineus* (Stephens), as had been found previously for *Oryzaephilus surinamensis* (*L.*), *O. mercator* (Fauvel), and *Ahasverus advena* (Waltl). 3-Methylbutanol was another good attractant for these four cucujids, and it was the only test compound to which *Cathartus quadricollis* (Guér.) responded positively. 1-Octen-3-one, racemic 3-octanol, and 3-octanone showed various degrees of attractiveness for the former four species of cucujids. *O. surinamensis* was the only species of test beetle to show much positive response to 2-phenylethanol and ethanol. For *O. mercator* and *O. surinamensis*, 3-methylbutanol enhanced positive response to their respective cucujolide aggregation pheromones.

Key Words—Coleoptera, Cucujidae, grain beetles, *Oryzaephilus surinamensis* (L.), *Oryzaephilus mercator* (Fauvel), *Cryptolestes ferrugineus* (Stephens), *Ahasverus advena* (Waltl), *Cathartus quadricollis* (Guér.), fungal volatiles, attractant semiochemicals.

INTRODUCTION

Many species of stored-product arthropods are found in damp, deteriorating grain and stored food in close association with fungi and bacteria (Sinha and Wallace, 1966; Sinha and Watters, 1985). Various cucujid grain beetles and other storage arthropods are known to feed and reproduce on some species of fungi associated with grain (Sinha, 1968).

There is evidence that fungal-derived volatiles may serve as attractants for storage pests (Vanhaelen et al., 1979). In laboratory tests, adult *C. ferrugineus* were attracted to volatiles from grain-borne fungi (Dolinski and Loschiavo, 1973). *Oryzaephilus surinamensis* (L.) and *O. mercator* (Fauvel) responded positively to volatiles from fungal-infested frass in laboratory bioassays (A.M. Pierce et al., 1981). Unpublished analyses of these frass volatiles by coupled gas chromatography-mass spectroscopy revealed the presence of 1-octen-3-ol, 3-octanone, 3-octanol, 2-phenylethanol, and 3-methylbutanol.

We have identified male-produced aggregation pheromones (cucujolides) for six species of the economically important Cucujidae (Oehlschlager et al., 1988). Preliminary studies of trapping cucujids from stored grain, however, suggested that trap effectiveness might be improved with the addition of host-produced volatiles to the pheromone baits (Javer et al., 1990).

Our objective here was to test various short-chain alcohols and ketones, known to be produced by fungi, as potential attractants for five species of cucujids. The test beetles were the sawtoothed grain beetle, *O. surinamensis;* merchant grain beetle, *O. mercator;* rusty grain beetle, *C. ferrugineus;* foreign grain beetle, *Ahasverus advena* (Waltl); and squarenecked grain beetle, *Cathartus quadricollis* (Guér.).

METHODS AND MATERIALS

Insect Rearing. Beetles were reared on large-flake, rolled oats and brewer's yeast (95:5, w/w) in 3.8-liter glass jars at 28°C and 60–70% relative humidity in darkness. For *A. advena* and *C. ferrugineus*, the medium initially had been moistened with distilled water and mixed well.

Alcohols and Ketones for Bioassay. Racemic 3-octanol and 3-octanone were purchased from Chem Samples Co. (Columbus, Ohio). 3-Methylbutanol was obtained from Aldrich Chemical Co. (Milwaukee, Wisconsin) and 2-phenylethanol from Matheson Coleman & Bell (East Rutherford, New Jersey). Racemic 1-octen-3-ol was purchased from Bedoukian Research, Inc. (Danbury, Connecticut). (*R*)-(−)- and (*S*)-(+)-1-Octen-3-ol with optical purities of 98% and 99.5%, respectively, were obtained from Dr. A. Mosandl (Institut f. Pharmazie u. Lebensmittelchemie, 8700 Würzburg, Germany). 1-Octen-3-one was prepared by oxidation of 1-octen-3-ol with active MnO_2 in pentane and

was 99.4% pure after purification by gas chromatography (GC). Reagent grade ethanol was distilled through a Dufton column before use. All compounds were checked by GC before use and found to be ≥99% pure.

Cucujolides for Bioassay. Macrocyclic lactones used for bioassay were racemic 3(Z)-dodecen-11-olide (cucujolide II), racemic 3(Z),6(Z)-dodecadien-11-olide (IV), 3(Z),6(Z)-dodecadienolide (IX), and racemic 5(Z),8(Z)-tetradecadien-13-olide (V) (Oehlschlager et al., 1983, 1988; Millar and Oehlschlager, 1984).

Instrumental Methods. A Hewlett-packard 5830A gas chromatograph equipped with a 18835B capillary inlet system and a flame-ionization detector was employed for analyses by GC. Helium was the carrier gas, and the injection port and detector temperatures were 260°C and 270°C, respectively. Samples were analyzed on an open-tubular glass column (40 m × 0.5 mm ID) coated with SP-1000 (Supelco Canada Ltd., Oakville, Ontario). The temperature program for analytical GC was 70°C for 2 min, then 4°C/min to 180°C and holding. A Varian 1700 gas chromatograph fitted with a stainless-steel column (3.05 m × 6.4 mm OD) packed with 25% Carbowax 20 M on Chromosorb A (60–80 mesh) was used for preparative GC at 145°C.

Test Beetles for Bioassay. At least one week before bioassays commenced, mixed-sex adults were harvested from stock cultures and placed in fresh medium at a density of approx. 10,000 beetles/kg for *A. advena* and *C. quadricollis*, and 15,000–20,000 beetles/kg for *O. mercator* and *C. ferrugineus*. Since response by *O. surinamensis* to olfactory stimuli is extremely sensitive to population density (A.M. Pierce et al., 1983), test beetles were maintained at a low density of 1000 beetles/kg medium for at least one week before bioassays began.

Test beetles were used in bioassays 5–12 weeks after eclosion. Prior to a bioassay, up to 1500 *A. advena, C. ferrugineus, C. quadricollis*, or *O. surinamensis* were preconditioned without food at 23°C in darkness in a 6-liter Erlenmeyer flask through which charcoal-filtered, humidified air was drawn at 1.5 liters/min. This preconditioning, which reduced variability in olfactory responses, was carried out for 72 hr for *C. ferrugineus* and 48 hr for the other three species listed above. For *O. mercator*, sufficient preconditioning was achieved by holding each replicate of 12 beetles in a 60-ml glass vial without food for 20 hr at 23°C in darkness prior to a bioassay.

Bioassay Procedures. Bioassays were done at 23°C and 60–65% relative humidity. A two-choice, pitfall olfactometer (A.M. Pierce et al., 1981) was used to test attractiveness of experimental stimuli. Filter paper disks treated with a 10-μl aliquot of either an experimental stimulus in purified pentane or purified pentane as a control were put singly into the bottoms of two glass vials suspended from holes in the bottom of a plastic Petri dish arena. For *C. quadricollis* and *A. advena*, which are excellent climbers of glass, the bioassay was

modified by first placing an oat flake in the bottoms of the experimental and control vials to retain the responding beetles in the vial of first choice (H.D. Pierce et al., 1988; A.M. Pierce et al., 1991). Twelve beetles were released into the dish, and the lid was replaced. Bioassays for each test stimulus were replicated 12 times, using 12 fresh beetles in each replicate. After 2 hr, the numbers of beetles in experimental and control vials were recorded. Unless indicated otherwise, all doses for a particular test compound were done in the same bioassay session for a particular species of beetle, beginning with 12 replicates of the lowest dose and proceeding in sequence to the highest dose. The responsiveness of the test beetles was checked by bioassaying a standard, low dose of Porapak Q-captured beetle volatiles (H.D. Pierce et al., 1984) at the start of a bioassay session.

1-Octen-3-one, racemic 3-octanol, 3-octanone, 3-methylbutanol, 2-phenylethanol, and ethanol were tested over a range of doses from 0.1 or 1 ng to 100 μg or 1 mg for all five species. Chiral and racemic 1-octen-3-ols were bioassayed over a range of doses from 0.1 ng to 100 μg only for *C. ferrugineus*, since olfactory responses to the 1-octen-3-ols by the other four species are reported elsewhere (see Discussion). For *O. surinamensis* and *O. mercator*, experiments were conducted to test the response to 3-methylbutanol, the respective cucujolide aggregation pheromones, and mixtures thereof to determine if response to the pheromones could be enhanced by the addition of the alcohol. 3- Methylbutanol was used in these latter experiments since preliminary bioassays (Figure 5 below) indicated that this alcohol was a good attractant for *Oryzaephilus* spp.

The untransformed data were analyzed by the paired-sample t test (Zar, 1984), and the results expressed as the mean percent response of the total number of beetles per treatment. For some experiments, the differences between experimental and control values (untransformed) were analyzed by a t test for unpaired data. For these latter experiments, results were expressed as mean percent response = 100 (experimental − control)/N where experimental and control were the number of beetles in the vials containing the experimental and control stimuli, respectively, and N was the total number of beetles released into the dishes.

RESULTS

Individual Alcohols and Ketones. Both chiral and racemic forms of 1-octen-3-ol were similar, excellent attractants for *C. ferrugineus* at doses ranging from 1 ng to 10 μg, while the 100-μg doses were highly repulsive (Figure 1). Olfactory responses to chiral and racemic 1- octen-3-ols by *O. mercator, O. surinamensis, A. advena*, and *C. quadricollis* are reported elsewhere (A.M. Pierce et al., 1989, 1991; H.D. Pierce et al., 1988).

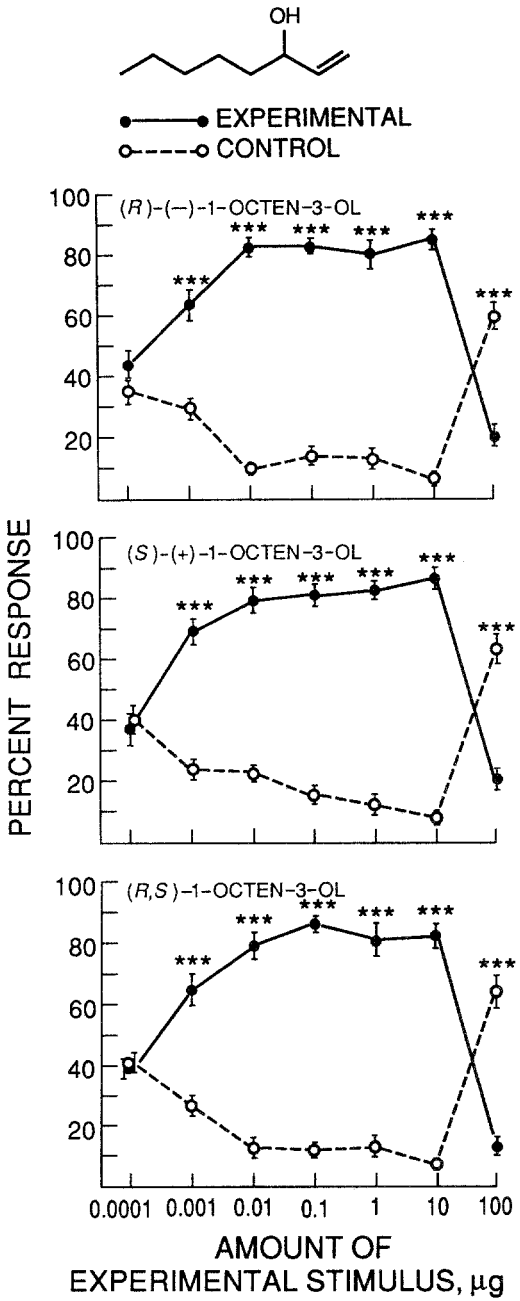

FIG. 1. Response ($\bar{X} \pm$ SE) by mixed-sex *C. ferrugineus* in two-choice, pitfall bioassay to (*R*)-(−)-, (*S*)-(+)-, and (*R*, *S*)-1-octen-3-ol. Significant response (paired-sample *t* test) to experimental stimulus indicated by: $***P < 0.001$ (12 replicates per treatment, 12 adults per replicate).

Positive responses were elicited from all species to 1-octen-3-one except from *C. quadricollis* (Figure 2). Of the four positively responding species, *O. mercator* had the lowest threshold for significant attraction at a 10-ng dose. For the four positive responders, the range of attractive doses was 100- or 1000-fold; at the 100 μg dose, positive response was either diminished or negative response was observed. The two highest doses of 1-octen-3-one, 10 μg and 100 μg, elicited negative response from *C. quadricollis*.

Racemic 3-octanol was an attractant for all species except *C. quadricollis* (Figure 3). Of the four positive responders, *A. advena* had the lowest threshold for positive response at the 10-ng dose and was positively attracted over the largest range of doses of 1000-fold. *C. quadricollis* was strongly repelled by doses of 1 μg and greater, while the other four species were repelled by a 100-μg dose.

The corresponding saturated ketone, 3-octanone (Figure 4), was a potent attractant for *C. ferrugineus* with high attraction at a 10-ng dose and a 10,000-fold range of attractive doses. *O. mercator* and *A. advena* also responded positively, but with a response threshold of 100 ng. Very slight positive response was elicited from *O. surinamensis*. *C. quadricollis* was strongly repelled by doses of 100 μg and 1 mg, and the other four species were repelled by the 1-mg dose.

3-Methylbutanol elicited significant positive responses from all five species at threshold doses of 1–10 ng (Figure 5). Positive attraction extended to the 10-μg dose for *O. surinamensis* and *A. advena*, and at least to 100 μg for *O. mercator* and *C. ferrugineus;* higher doses were not tested. Positive response by *C. quadricollis* declined at 10 μg of the alcohol.

O. surinamensis was the only species of the five tested to show much positive response to 2-phenylethanol (Figure 6). Except for *O. mercator*, all species were repelled by large amounts of this alcohol.

O. surinamensis was attracted to ethanol over an experimental range of 10 ng to 1 mg (Figure 7); higher doses were not tested. *O. mercator* and *A. advena* responded positively to 10 μg and 100 μg of ethanol, whereas no significant response was demonstrated by *C. ferrugineus* or *C. quadricollis* over a test range of 10 ng to 1 mg (data not shown).

3-Methylbutanol and Cucujolide Mixtures. Table 1 shows the response by *O. mercator* to 3-methylbutanol, cucujolides II + IV, and mixtures thereof. Cucujolides II + IV is the blend of macrolide aggregation pheromones produced by *O. mercator* (Oehlschlager et al., 1988). Positive response to 0.4 ng of II + IV was obtained with the addition of 1 ng of 3-methylbutanol. Positive response to 4 ng of II + IV was enhanced with the addition of 10 ng of the alcohol. No significant enhancement of response to the cucujolides was obtained by the addition of larger amounts of 3-methylbutanol in experiments 3, 4, 5, and 6 (Table 1). When 1 mg of 3-methylbutanol was added to 40 μg of II +

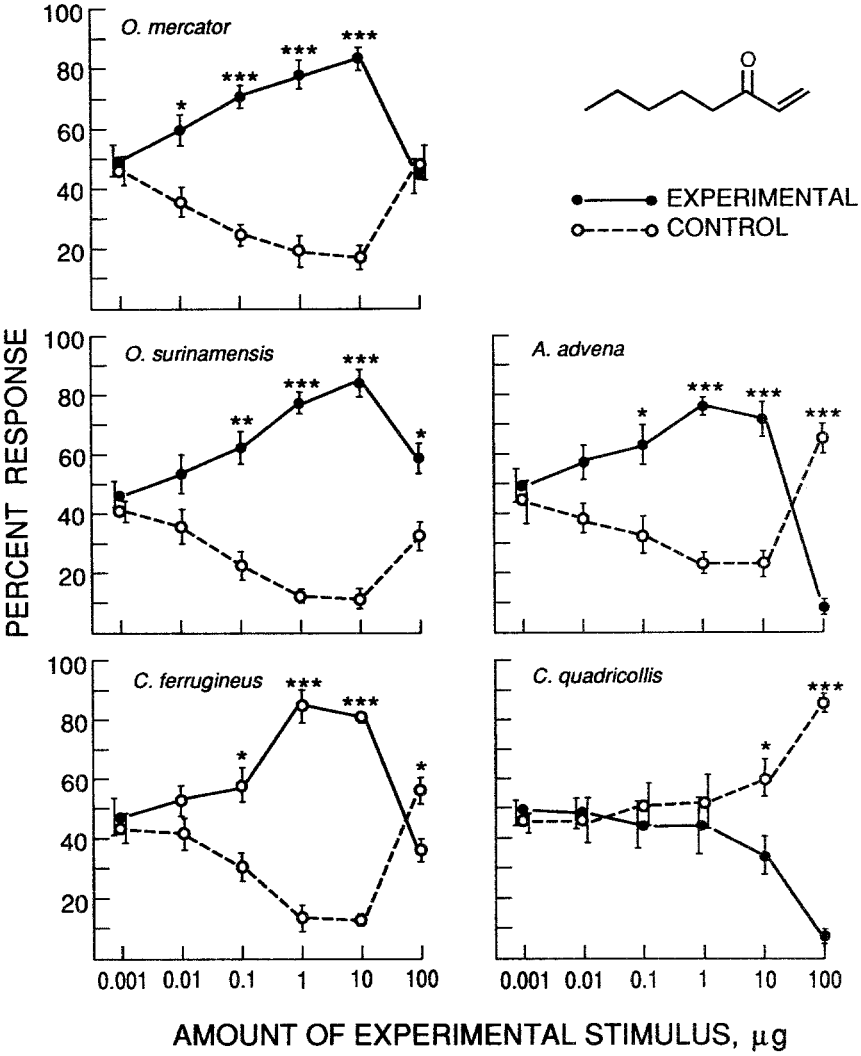

FIG. 2. Response ($\bar{X} \pm$ SE) by five species of cucujid grain beetles (mixed-sex) in two-choice, pitfall bioassay to 1-octen-3-one. Significant response (paired-sample t test) to experimental stimulus indicated by: $*P < 0.05$; $**P < 0.01$; $***P < 0.001$ (12 replicates per treatment, 12 adults per replicate).

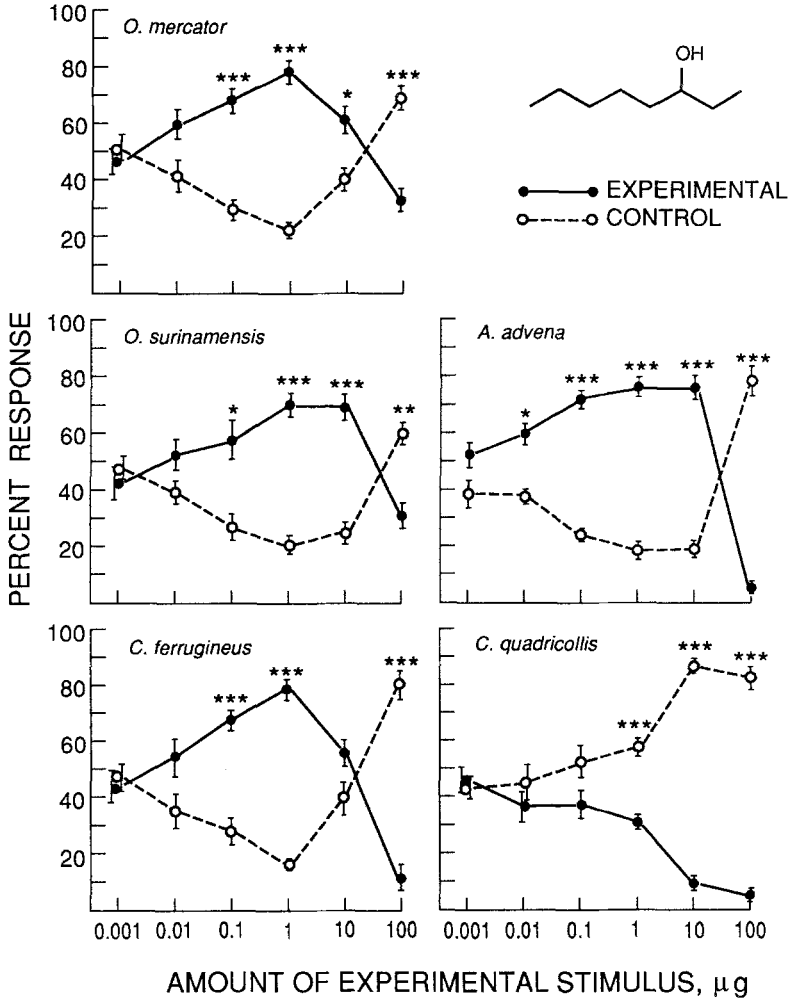

FIG. 3. Response ($\bar{X} \pm$ SE) by five species of cucujid grain beetles (mixed-sex) in two-choice, pitfall bioassay to (*R*,*S*)-3-octanol. Significant response (paired-sample *t* test) to experimental stimulus indicated by: $*P < 0.05$; $**P < 0.01$; $***P < 0.001$ (12 replicates per treatment, 12 adults per replicate).

IV, the repulsiveness of the high alcohol dose was counteracted by the attractive cucujolides.

Table 2 gives the response of *O. surinamensis* to 3-methylbutanol, cucujolides IV + IX + V, and mixtures thereof. A combination of cucujolides IV + IX + V is the blend of macrolide aggregation pheromones produced by *O.*

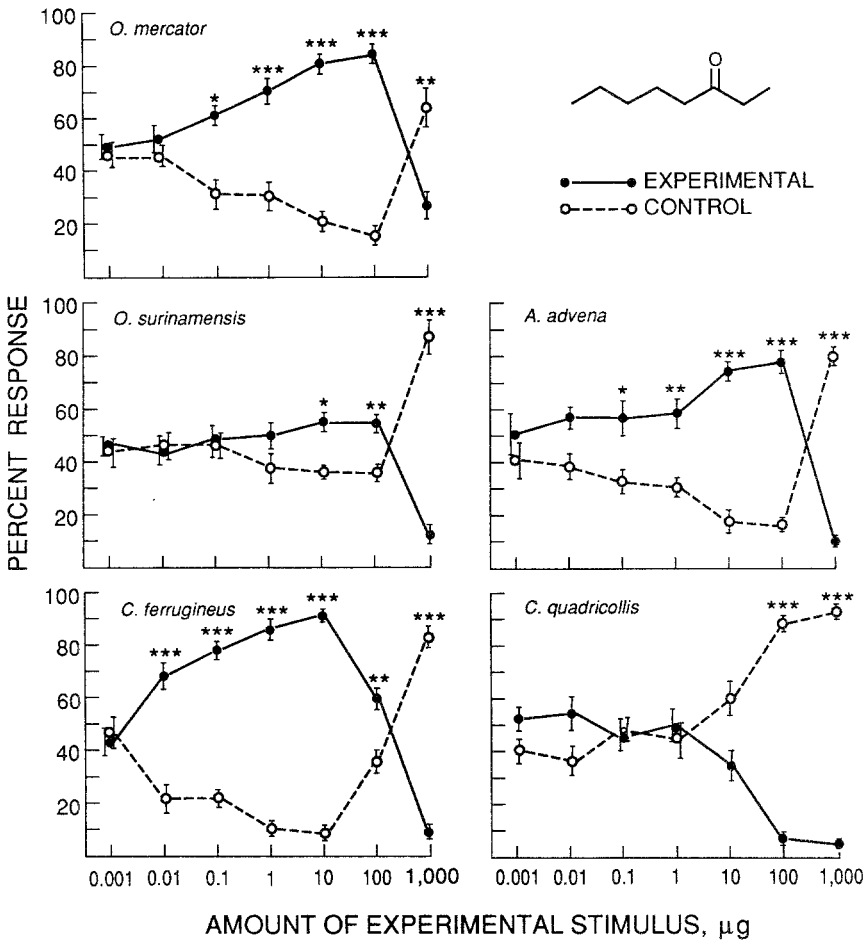

FIG. 4. Response ($\bar{X} \pm$ SE) by five species of cucujid grain beetles (mixed-sex) in two-choice, pitfall bioassay to 3-octanone. Significant response (paired-sample t test) to experimental stimulus indicated by: $*P < 0.05$; $**P < 0.01$; $***P < 0.001$ (12 replicates per treatment, 12 adults per replicate).

surinamensis (Oehlschlager et al., 1988). Positive response to IV + IX + V was enhanced by the addition of 10 and 100 ng of 3-methylbutanol to 9 and 90 ng of the cucujolides, respectively. No significant enhancement of response to the cucujolides was obtained by the combination of larger amounts of alcohol and cucujolides in experiments 4 and 5 (Table 2). A repellent 100 µg dose of 3-methylbutanol was counteracted by the presence of the attractive cucujolides.

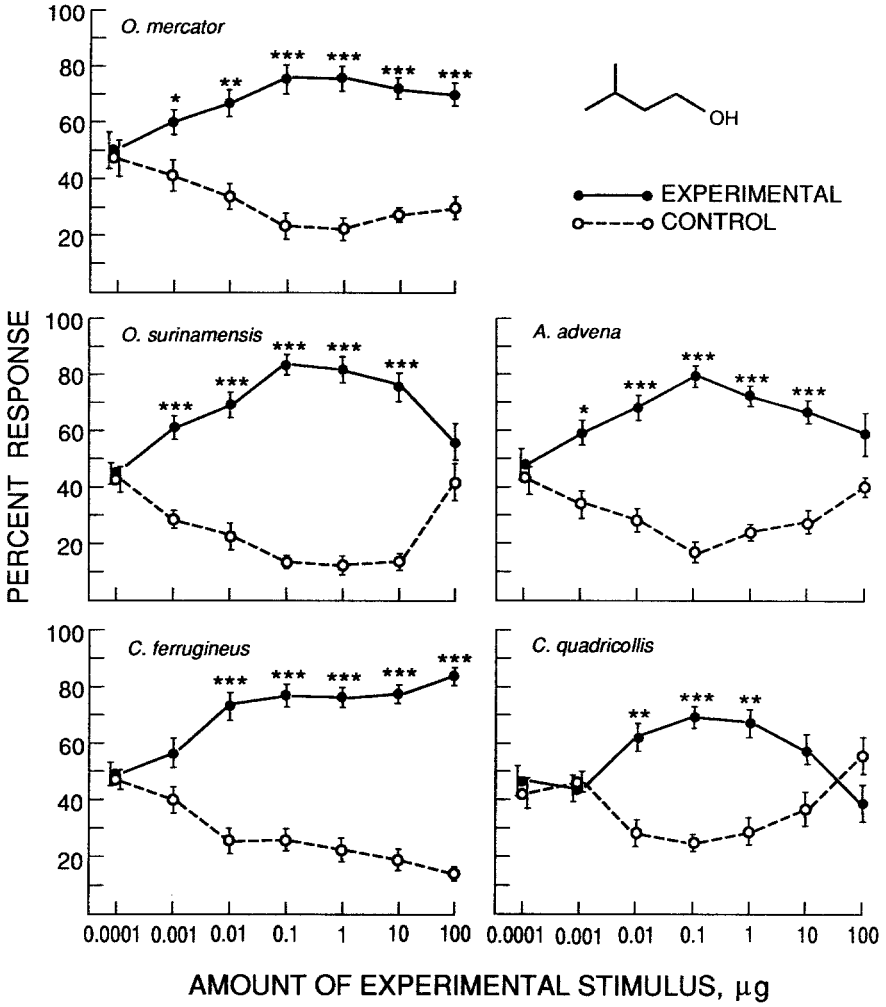

FIG. 5. Response ($\bar{X} \pm$ SE) by five species of cucujid grain beetles (mixed-sex) in two-choice, pitfall bioassay to 3-methylbutanol. Significant response (paired-sample t test) to experimental stimulus indicated by: $*P < 0.05$; $**P < 0.01$; $***P < 0.001$ (12 replicates per treatment, 12 adults per replicate).

DISCUSSION

Biological Implications. We have shown previously that chiral and racemic 1-octen-3-ols are strong attractants for *Oryzaephilus* spp. and *A. advena* (A.M. Pierce et al., 1989, 1991), as demonstrated in the present study for *C. ferru-*

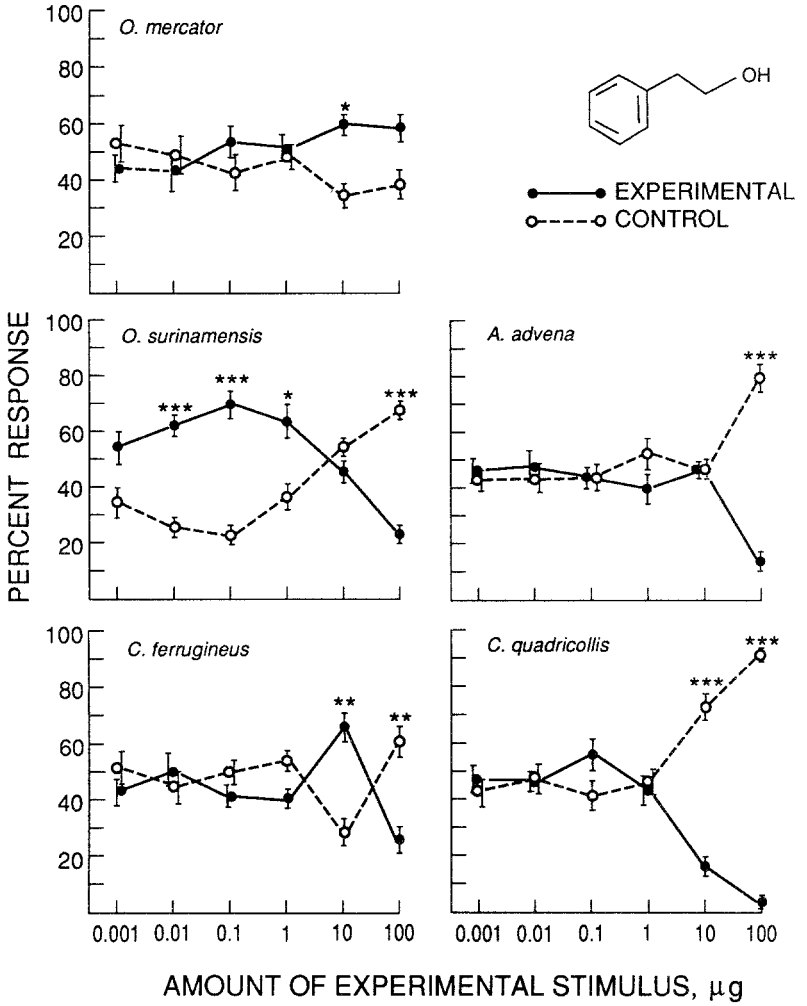

FIG. 6. Response ($\bar{X} \pm$ SE) by five species of cucujid grain beetles (mixed-sex) in two-choice, pitfall bioassay to 2-phenylethanol. Significant response (paired-sample t test) to experimental stimulus indicated by: $*P < 0.05$; $**P < 0.01$; $***P < 0.001$ (12 replicates per treatment, 12 adults per replicate).

gineus. When maintained at low population densities, male and female *Oryzaephilus* spp. and *A. advena* older than 1–1.5 months posteclosion produced large amounts of almost optically pure (*R*)-(−)-1-octen-3-ol as aggregation pheromone (A.M. Pierce et al., 1989, 1991). Production of 1-octen-3-ol by *C. ferrugineus* was never observed in similar experiments (A.M. Pierce, personal

is contaminated by bacteria as well as by molds (Kaminski et al., 1980). Although more commonly found as fungal metabolites, some of these compounds have been identified in the volatiles of stored cereals. For example, 1-octen-3-ol and 3-methylbutanol have been detected in the volatiles from oat groats (Heydanek and McGorrin, 1981), rice (Maga, 1984), and soybeans (del Rosario et al., 1984).

The positive responses to the alcohols and ketones in this study suggest that some of these volatiles might be used by the cucujids as host-finding kairomones in nature. The presence of aggregation pheromone-emitting cucujids on such an attractive host, in turn, further might enhance attraction of members

of the same species or, in the case of 1-octen-3-ol-emitting cucujids, of the same and different cucujid species. As an adaptive advantage for kairomone-producing microbes, the cucujids could serve as vectors for the microorganisms.

The repulsiveness of all the test compounds except 3-methylbutanol and ethanol to *C. quadricollis* in this study probably is not ecologically significant since negative responses occurred at high doses unlikely to be found in nature. While small amounts of 1-octen-3-ol were repellent to *C. quadricollis*, the presence of the male-produced aggregation pheromone overrode the repellent effect of 1-octen-3-ol and, hence, aggregation on a food source and mating would not be inhibited (H.D. Pierce et al., 1988). It was suggested that 1-octen-3-ol might function alone as a female-produced epideictic pheromone (Prokopy, 1981) to promote dispersion of female *C. quadricollis* (H.D. Pierce et al., 1988).

Some of the test alcohols and ketones have been implicated in the communication systems of other arthropods, which supports Blum's (1970) concept of pheromonal parsimony. For instance, 3-methylbutanol is a potent host-produced kairomone for cheese mite (Yoshizawa et al., 1972) and a pheromone for scolytid beetles (Borden, 1985). Ethanol and 2-phenylethanol have been identified as a kairomone and pheromone, respectively, for scolytid beetles (Borden, 1985). A number of myrmicine ants release 3-octanone and 3-octanol as major components of their alarm pheromone complex (Crewe et al., 1970). 1-Octen-3-ol is an oxen-produced kairomone that serves as a powerful attractant for tsetse flies (Hall et al., 1984).

Practical Implications. The data in Tables 1 and 2 suggest that, for *Oryzaephilus* spp., adding 3-methylbutanol to field traps containing cucujolide aggregation pheromones might be an economical way of extending the attractive range of the less volatile cucujolides. The addition of small amounts of attractive, rolled oat-produced aldehydes to small amounts of cucujolides lowered the response threshold by mixed-sex *O. mercator* to the pheromones in laboratory bioassays (A.M. Pierce et al., 1990). Adding (*R*, *S*)-1-octen-3-ol to cucujolide mixtures also enhanced response to the cucujolides in the two-choice, pitfall bioassay for *O. mercator* and *O. surinamensis* (A.M. Pierce et al., 1989). Field traps baited with a mixture of cucujolides and 1-octen-3-ol required 100-fold less of cucujolides than traps baited with only the cucujolides for equivalent performance in recapturing *O. surinamensis* (H.D. Pierce et al., 1990). As found with high amounts of 3-methylbutanol and cucujolides in the present study, the attractiveness of the cucujolides counteracted the repulsiveness of high doses of 1-octen-3-ol in laboratory bioassays (A.M. Pierce et al., 1989) and in field traps (H.D. Pierce et al., 1990).

Results to date for several cucujid species suggest that the most efficient and cost-effective approach for the use of semiochemicals in field traps might be to use a combination of pheromones plus appropriate host-produced coat-

tractants. Laboratory trapping studies utilizing mixtures of the most attractive volatiles identified for a particular species need to be conducted under controlled, but realistic, conditions to determine the efficacy of these mixtures as trap baits. Many pheromones or pheromone blends of stored-grain beetles, while species-specific, are not repellent to other species (Lindgren et al., 1985; Oehlschlager et al., 1988), and some host and fungal kairomones are attractive to more than one species. Studies need to be done, therefore, to design improved, complex baits that can be used in the smallest number of traps to attract the largest possible number of beetle species.

Acknowledgments—We thank Dr. A. Mosandl for gifts of the chiral 1-octen-3- ols and E. Merletti for technical assistance.

Abstract—Ovipositional host-finding in the navel orangeworm, *Amyelois transitella* (Walker), is brought about by an in-flight response to host odors. Wind-tunnel studies of the response of gravid females to almonds showed that this response is mediated primarily by long-chain fatty acids, particularly oleic acid and linoleic acid. Evidence for the behavioral activity of fatty acids is based on the fact that: (1) behavioral activity of almond oil was concentrated in a single liquid chromatographic fraction whose composition was predominantly long-chain fatty acids, (2) behavioral activity was lost when either almond oil or the active fraction of that oil was treated with diazomethane, (3) full activity was elicited by a selective extraction of free fatty acids from crude almond oil, and (4) upwind response by females was elicited by a blend of synthetic oleic and linoleic acids, albeit at a level less than that elicited by almond oil. Five fatty acids identified from the almond oil were: myristic acid (1%), palmitic acid (16%), stearic acid (3%), oleic acid (58%), and linoleic (22%). Attraction to various combinations of synthetic acids was observed only when oleic acid was present, and oleic acid elicited upwind flights to the source when presented alone; however, short-range responses were enhanced by the addition of linoleic acid, which elicited no long-range

orientation by itself. Despite significant levels of attraction to synthetic blends, the percentage of females flying to the source was lower than that flying to acidulated almond oil, the best natural attractant tested. Thus, although long-range response may be mediated primarily by a blend of oleic and linoleic acids, additional and as yet unidentified components must also play an important role. Long-range chemically modulated host finding in this and other generalist plant feeders is discussed with respect to current models of the evolution of host finding, and it is argued that suggestions that long-range host finding should be correlated with narrowness of host utilization are logically flawed and are not supported by our current understanding of specific examples of host finding.

Key Words—Host finding, *Amyelois transitella*, navel orangeworm, Lepidoptera, Pyralidae, flight behavior, chemoorientation, attraction, fatty acids, oleic, linoleic, palmitic

INTRODUCTION

Amyelois transitella (Walker), the navel orangeworm, was first detected in the United States in rotting fruit and its initial presence elicited little concern because of its apparent preference for fallen or diseased fruits (Wade, 1961); however, since that time, this insect has become the key pest of almonds, as well as a serious problem in pistachios and walnuts, causing nut growers in the western United States many millions of dollars in damage each year. Previous work based on field trapping suggested that host finding by the navel orangeworm was mediated by odors of almond nuts and/or volatiles from frass of navel orangeworm larvae (Curtis and Clark, 1979; Andrews and Barnes, 1982; Rice et al., 1984). A long-range response to almond odors was confirmed by Phelan and Baker (1987) in studies of flight by navel orangeworm females in a laboratory wind tunnel. This work demonstrated that mated females, but not males or virgin females could be induced to take off and fly more than 1.5 m up an odor plume of almond by-products. Unrefined oil from almonds was determined to be the most potent source of flight activity on a per-weight basis, with 100 mg of this oil eliciting a response several times greater than mummified almonds, the preferred sites of oviposition in the field. Recently, the zigzagging flight track of navel orangeworm females flying to host odors was analyzed in further detail by Haynes and Baker (1989), who describe track angles for females in contact with a host-odor plume and after loss of the odor plume. Comparison of various angular and velocity components of the flight pattern revealed a counterturning program very similar to that of navel orangeworm males flying to female sex pheromone.

In the present study, we examined the chemical basis of host finding in navel orangeworm females with the objective of characterizing the constituents of almond odor that are responsible for ovipositional attraction.

METHODS AND MATERIALS

Navel orangeworm larvae were reared on a honey–bran–glycerol diet according to the methods of Strong et al. (1968). Pupae were collected from rearing containers and were placed in cups with moist vermiculite held in mating cages. The behavioral characterization of almond-odor components responsible for ovipositional attraction of navel orangeworm females was carried out in wind tunnels at both institutions. The construction of the Riverside tunnel, which measured 0.6 × 0.6 × 1.8 m, has been described previously (Willis and Baker, 1984). The tunnel at the OARDC is similar in operation although somewhat larger. The working portion of this tunnel measured 2.5 m long × 1 m wide × 0.5 m high and was constructed of 6-mm Plexiglas. Airflow was generated by a 3/4-horsepower Dayton model 3C152 fan with a 64-cm-diam. six-wing blade and was made laminar as it was forced through three muslin screens spaced 10 cm apart. The wind speed was maintained at 0.4 m/sec by a 61 × 61-cm adjustable-louver box mounted on the upwind side of the fan box, which was equipped with standard fiberglass furnace filters to reduce the ambient dust reaching the muslin screens. The odor plume was exhausted from the downwind end of the wind tunnel and was directed outside the building by a 30-cm-diam. flexible exhaust duct and a 25-cm-diam. 1/15-horsepower exhaust fan. The tunnel was illuminated by three 60-W incandescent white bulbs mounted 1.2 m above the tunnel floor and operated at 30 V to provide 0.2 lx at floor level during bioassays. Females 3 to 6 days old were selected from the mating cages and were acclimated to experimental conditions by holding them in the wind without odors for 0.5 hr prior to testing, which was conducted 2.5–0 hr before lights-out. Odor sources were applied to a 5.5-cm-diam. filter-paper disk held 20 cm above the tunnel floor at the upwind end of the tunnel, and the female moths were released at the downwind end in groups of 10 individuals from 5.5-cm-diam. × 9.0-cm-long screen release cylinders placed on a 15-cm-tall platform. Four categories of female behaviors were recorded: takeoff, flight up the plume, flight to the odor source (those approaching to within 5 cm of the source), and landing on the source. Treatments were presented individually in a randomized complete-block design. Percent response results were analyzed by two-way ANOVA after $\sin^{-1}(x + .005)^{1/2}$ and means were separated using Duncan's new multiple-range test (SAS, 1985), except for response to different quantities of acidulated almond oil, which was subjected to regression analysis.

Crude almond oil and almond soapstock were obtained from Liberty Vegetable Oil Co. (Sante Fe Springs, California). Soapstock is composed of salts of free fatty acids removed during the refining of vegetable oils by treating the oils with potassium or sodium hydroxide. The free fatty acids were reconstituted by making the soapstock strongly acidic (pH 3) with H_2SO_4. The resulting oil, termed acidulated almond oil, was separated from the aqueous layer and an

unidentified intermediate layer in a separatory funnel. High-purity authentic samples (>99% by capillary GC) of constituents identified from almond oil were obtained from Aldrich Chemical Co. (Milwaukee, Wisconsin) and were stored at −20°C under nitrogen. Acidulated oils from various other commodities also were tested for their ability to evoke orientation by navel orangeworm females; these acidulated oils included peanut, corn, soybean, and palm kernel.

A preliminary fractionation of 0.5 ml crude almond oil was carried out using a silica-gel SepPak (Millipore Corp., Milford, Massachusetts), eluting with 2 ml hexane, 2 ml ether–hexane (5:95), 2 ml ether, and 2 ml methylene chloride. Fractions were bioassayed for behavioral activity by presenting them individually and in combination to females in the wind tunnel. Characterization of active constituents was carried out on a Hewlett-Packard 5890 capillary gas chromatograph interfaced with a Hewlett-Packard 5970 Mass Selective Detector (GC-MS); electron-impact mass spectra were generated at 70 eV. Splitless injections were made onto either DB-1 (30 m × 0.25 mm ID, 0.25-μm film thickness) or DB-23 (30 m × 0.25 mm ID, 0.25-μm film thickness) fused-silica capillary columns (J & W Scientific, Folsum, California). Fatty acids were extracted from 1 ml of crude almond oil by washing the oil three times with 4 ml of an aqueous 10% $NaHCO_3$ solution. The aqueous fractions were combined and brought to pH 3 with H_2SO_4. This solution then was extracted three times with 10 ml hexane, and the hexane fractions were combined and concentrated to 1 ml under N_2. Fatty acids were derivatized to their methyl esters with diazomethane generated from 1-methyl-3-nitro-1-nitrosoguanidine (MNNG) using a micro-diazomethane-generation apparatus (Aldrich Chemical Co.). Presence and position of double bonds were confirmed using the epoxidation method of Bierl-Leonhardt et al. (1980). After derivatization of fatty acids to methyl esters, double bonds were epoxidized and the epoxides were submitted to hydrogenation to reduce remaining double bonds in diunsaturated constituents. The resulting products were analyzed using GC-MS.

RESULTS

Wind-tunnel bioassay of the SepPak fractionation of crude almond oil demonstrated full activity to be contained in the ether fractions. Upwind flights to the source were 15/50 (30%) for crude almond oil, 17/50 (34%) for the ether fractions, and 14/50 (28%) for all fractions combined. No response was elicited by the hexane, hexane–ether, or methylene chloride fractions. GC analysis of the active fractions suggested the primary constituents to be fatty acids. Treatment of the fraction with diazomethane followed by GC-MS supported this initial supposition, as the original peaks, which tailed excessively, were now replaced with earlier-eluting peaks of much greater symmetrical shape (Figure

1). Mass spectrometry indicated methyl esters of myristic acid (1%), palmitic acid (16%), stearic acid (3%), oleic acid (58%), and linoleic (22%). The position of double bonds in each was confirmed by epoxidation, in which oleic acid produced the single compound 9,10-epoxyoctadecanoic acid, palmitoleic acid gave rise to 9,10-epoxyhexadecanoic acid, while linoleic acid produced two peaks, 9,10-epoxyoctadecanoic acid and 12,13-epoxyoctadecanoic acid. Diagnostic MS ions used for confirmation of double-bond position were *m/z* 155 and *m/z* 199 for 9,10-epoxyoctadecanoic acid, *m/z* 113 and *m/z* 241 for 12,13-epoxyoctadecanoic acid, and *m/z* 127 and *m/z* 199 for 9,10-epoxyhexadecanoic acid.

That almond-oil fatty acids played a role in navel orangeworm attraction was verified by treating crude almond oil with diazomethane. Only about a quarter as many females were attracted to the diazomethane-treated oil compared to the untreated oil (Figure 2). This level of response to diazomethane-treated oil was not significantly different from that to blank filter paper, which attracted no females. The reduction in the number of females landing on the treated oil was even greater, with a 24-fold higher response to the untreated oil. Navel orangeworm attraction to free fatty acids removed from crude almond oil was compared with that to crude oil using the amount of free fatty acids found in 100 mg of oil (3 mg for this batch of crude oil). Female navel orangeworm flew to the acidulated almond oil at levels significantly higher than to the crude oil (45 $\pm$ 3.4% vs. 30 $\pm$ 3.7%, respectively; $P < 0.05$, six groups of 10

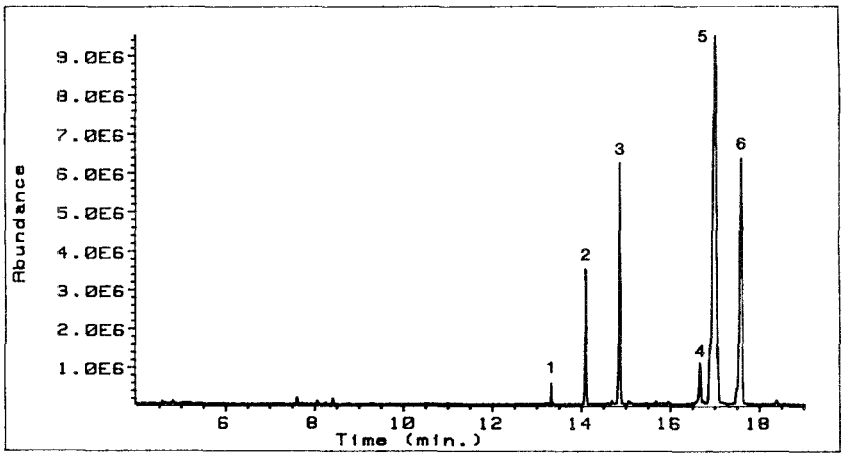

FIG. 1. Capillary gas chromatogram of the behaviorally active silica-gel fraction of crude almond oil after treatment with diazomethane. Column: DB-23 (30 m $\times$ 0.25 mm). 1 = methyl myristate, 2 = 20 ng methyl pentadecanoate (internal standard), 3 = methyl palmitate, 4 = methyl stearate, 5 = methyl oleate, and 6 = methyl linoleate. Temperature program: 30°C increased to 200°C at a rate of 12°C/min.

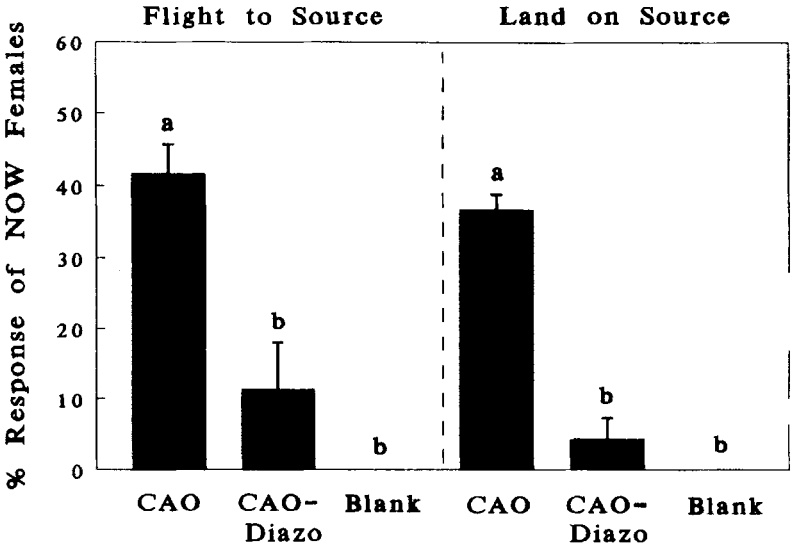

FIG. 2. Response ($\bar{X} \pm$ SEM) of navel orangeworm (NOW) females to 100 mg crude almond oil (CAO), 100 mg CAO treated with diazomethane, or blank filter paper. Bars marked by the same letter are not significantly different ($P < 0.05$, six replicates of 10 females).

females). Furthermore, of the females that approached the acidulated oil, 93% of those females landed, which was comparable to the 94% landing rate found with the crude oil.

Since the behavioral activity appeared to be concentrated in the fatty-acid components of the crude almond oil, subsequent work focused on acidulated almond oil. A dose–response curve was generated to determine the quantity of acidulated almond oil evoking maximal upwind orientation and landing by navel orangeworm females. Flights to the source were analyzed as a fourth-order polynomial. The highest-order significant polynomial we found was a quadratic relationship, with the resulting model: $y = 0.057x - 0.001x^2$, $r^2 = 0.81$. Thus, within the range of 0.5–50 mg, the probability of female flight to the source increased with increasing amount of oil, with the negative quadratic indicating a slight leveling off of response at the highest dose (Figure 3). A regression analysis of landing response and the quantity of almond oil yielded a similar model: $y = 0.054x - 0.001x^2$, $r^2 = 0.81$. Furthermore, there was no evidence of premature arrestment at the higher levels of oil, as landing rates were similar in all quantities for which comparisons could be made. At 5 mg, 10 mg, and 50 mg of acidulated almond oil, landing rates were 92%, 90%, and

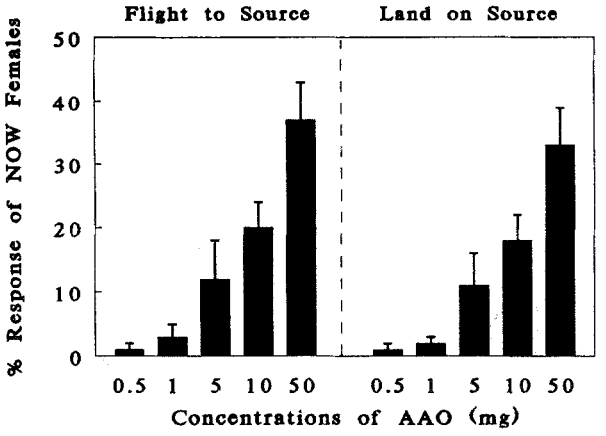

FIG. 3. Response ($\bar{X} \pm$ SEM) of NOW females to different quantities of acidulated almond oil (AAO) (nine replicates of 10 females).

91%, respectively, for those females approaching the source, while percent approaches to the source at the lower concentrations were too low for informative comparisons. Since 50 mg of acidulated oil evoked the greatest long-range response without premature arrestment, this became the positive control in subsequent bioassays to which other treatments were compared.

A wind-tunnel bioassay of acidulated oils from commodities other than almonds indicated that the behaviorally active constituents were not unique to almonds (Figure 4). Acidulated peanut oil evoked the second highest response, with the number of females flying up to and the percentage landing on the source slightly lower than that to acidulated almond oil. The number of flights to acidulated corn oil was lower still, with the number of landings much lower. Responses to acidulated soybean and palm kernel oils were significantly lower than other oils tested, with no females flying to palm kernel oil.

Binary combinations of synthetic samples of either myristic and palmitic acids or palmitic and linoleic acids elicited no flights to the source when presented at the amounts found in 50 mg acidulated oil (Figure 5). Although the combination of oleic and palmitic acids did evoke some flights to source, this activity was not significantly higher than zero. The highest activity elicited among binary combinations was that to oleic plus linoleic acids. This blend attracted 40% of females to the source, not significantly different from that to the five- acid blend. Acidulated almond oil evoked more flights to the source than any combination of synthetic fatty acids tested, 59% of females, although this was not significantly higher than the response to the oleic–linoleic acid blend. The difference in response to natural compared to synthetic odor sources

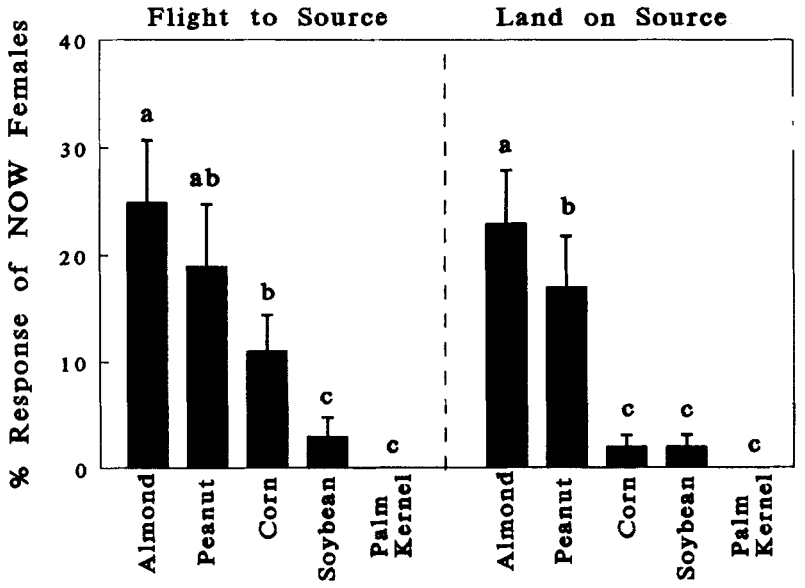

FIG. 4. Response ($\bar{X} \pm$ SEM) of NOW females to 50 mg of various acidulated oils. Bars marked by the same letter are not significantly different ($P < 0.05$, 12 replicates of 10 females).

was much more pronounced when the number of landings were measured. The most active synthetic blend, oleic acid plus linoleic acid, only evoked landing in 14% of females, which represented 35% of those approaching the source, whereas 86% of females approaching acidulated almond oil landed on the source. The proportion of females landing on the oleic–linoleic acid blend was not significantly different from the proportion landing on the total-fatty-acid blend (10% of all females, 32% of source-approaching females). Finally, oleic acid and linoleic acid were tested individually to determine the relative contribution of these two components to navel orangeworm female attraction. When comparing flights to the source, oleic acid elicited a response comparable to that of the synthetic total fatty-acid blend (Figure 6), while linoleic acid elicited no flights to the source. However, the number of females landing on oleic acid was significantly lower than the number landing on the four-acid blend. These overall female landing rates corresponded to 36% of females approaching oleic acid and 65% of females approaching the five-acid mixture. As in the previous experiment, more females approached the acidulated almond oil than approached the synthetic fatty acids, with the difference in response amplified when landing rates were compared; of females approaching the acidulated oil, 81% landed.

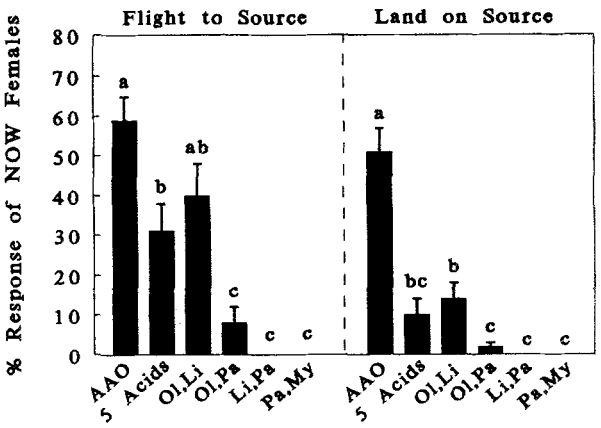

FIG. 5. Response ($\bar{X} \pm$ SEM) of NOW females to 50 mg acidulated almond oil (AAO), a blend of five synthetic fatty acids: 29 mg oleic (Ol), 11 mg linoleic (Li), 8 mg palmitic (Pa), 1.5 mg stearic, and 0.5 mg myristic (My), or various binary combinations of these acids. Bars marked by the same letter are not significantly different ($P < 0.05$, nine replicates of 10 females).

DISCUSSION

The role of volatiles in navel orangeworm ovipositional behavior was first implicated by Ortega (1950), who observed greater navel orangeworm egg-laying in walnuts previously damaged by navel orangeworm larval feeding; Caltagirone et al. (1968) made similar observations in almonds. Curtis and Clark (1979) confirmed this increased egg-laying to be chemically mediated by demonstrating that it also could be elicited by extracts of the larval frass. The results of our bioassay-guided identification of navel orangeworm ovipositional attractants strongly suggest a primary role played by long-chain fatty acids in eliciting this behavior. Our wind-tunnel observations demonstrated that despite the relatively low volatility of these compounds, gravid navel orangeworm females can detect and respond to them from a distance of at least 2 m. Evidence for the behavioral activity of fatty acids derives from our observations: (1) that the behavioral activity of almond oil was concentrated in a single liquid chromatographic fraction whose composition was predominantly long-chain fatty acids; (2) that behavioral activity was lost when either almond oil or the active fraction of that oil was treated with diazomethane, a reagent narrowly reactive with acidic compounds; (3) that full activity could be elicited by a selective extraction of free fatty acids from crude almond oil; and (4) that upwind response by females could be elicited by a blend of synthetic oleic and linoleic acids, albeit at a level less than that elicited by almond oils. Although treatment of the almond

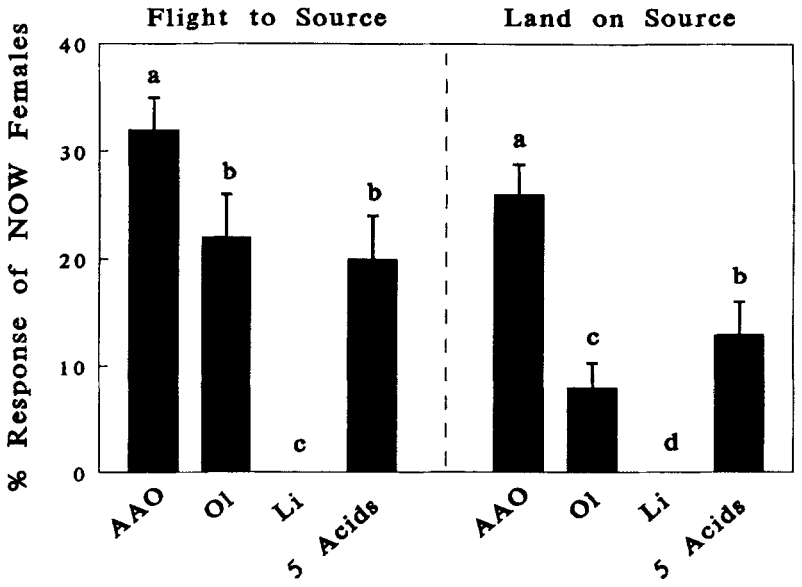

FIG. 6. Response ($\bar{X} \pm$ SEM) of NOW females to acidulated almond oil (AAO), 29 mg oleic acid (Ol), 11 mg linoleic acid (Li), or a blend of five synthetic fatty acids: 29 mg oleic, 11 mg linoleic, 8 mg palmitic, 1.5 mg stearic, and 0.5 mg myristic. Bars marked by the same letter are not significantly different ($P < 0.05$, 22 replicates of 10 females).

oil with diazomethane greatly diminished response, some upwind orientation persisted. This may have been due to the methyl esters acting as fatty-acid analogs, evoking a low level of response in females, or it may indicate that additional non-fatty-acid components of almond odor play a secondary role in navel orangeworm attraction. The fact that acidulated oils from other commodities can elicit a long-range response in navel orangeworm females also is suggestive that ubiquitous long-chain fatty acids are the key components modulating host finding, rather than volatile compounds unique to almonds. Moreover, the level of response to the acidulated oils was correlated with the relative proportion of oleic acid in those oils. Acidulated peanut oil, which we determined to be composed of 57% oleic acid, 18% linoleic acid, and 18% palmitic acid, had the fatty-acid composition most similar to acidulated almond oil and elicited the highest level of response. Acidulated corn oil, which is 26% oleic acid, 59% linoleic acid, and 12% palmitic acid, elicited a lower navel orangeworm response. Acidulated soybean oil is only 22% oleic acid, 55% linoleic acid, 11% palmitic acid, and in addition contains 8% linolenic acid. Acidulated palm kernel oil is predominantly lauric acid (51%) and contains only 15% oleic acid and only 1% linoleic acid. This oil evoked no upwind flights to the source.

In an early attempt to discover chemical attractants for the navel orangeworm, Price et al. (1967) screened over 200 compounds with a variety of chemical functionalities placed in water-bucket field traps. Those compounds consistently eliciting the highest trap catch were all phenyl-containing constituents, with phenyl propionate being the most active compound. The trap catch by all chemicals was strongly female-biased. It is not known what function if any these compounds serve in the chemical ecology of the navel orangeworm; however, they do not appear to be important in ovipositional behavior, as Curtis and Clark (1979) later reported that phenyl propionate actually inhibited navel orangeworm egg-laying. One possibility is that they elicit food-finding behavior in adults foraging for nectar sources. Later, Lieu et al. (1982a,b) identified 42 components from a steam distillation extraction of wheat bran, predominantly aldehydes, and almost 50 components from an ether extract of larval frass, including the same long-chain fatty acids found to be behaviorally active in the present study; however, although both of the original substrates were known to elicit oviposition and presumably attraction in the field (Rice et al., 1976; Curtis and Clark, 1979), none of the identified constituents evoked a significant navel orangeworm response in a laboratory ovipositional bioassay. This was true even when a blend of the four principal long-chain fatty acids was presented. The discrepancy in results between these earlier studies and our own probably are due to the difference in bioassay methods. While Lieu et al. (1982a,b) were measuring an ovipositional response, our use of the wind-tunnel bioassay allowed us to observe the long-range orientation of navel orangeworm females. Since we found a lower landing response to the synthetic fatty acids relative to the almond oils, this probably explains why Lieu et al. (1982a,b) did not measure a significant ovipositional response to these compounds.

Despite the importance of understanding how insects locate their host plants, surprisingly few systems have been characterized for the chemicals responsible in long-range host finding. In fact, this paucity of well-studied examples has led Jermy et al. (1988) to suggest that "distant olfactory attraction to host plants in nature may be much rarer than has been thought." We use the term "long-range response" to chemicals *sensu* Kennedy (1977), who defined it mechanistically as chemically modulated orientation far enough from an odor source to preclude chemotactic response to a longitudinal chemical gradient. In practice, this usually represents a distance greater than a few decimeters. Many studies have suggested a role played by volatiles in host finding and/or selection by phytophagous insects (reviewed by Ramaswamy, 1988). Unfortunately, the evidence typically is circumstantial or at best confounds short-range acceptance behaviors with long- distance orientation to host odors, since conclusions are usually based on "end-result" observations or nondiscriminating bioassays (Kennedy, 1977). Furthermore, tests of synthetic host-plant compounds rarely utilize release rates comparable to a natural odor source. Some of our best doc-

umented cases for the role of volatile chemicals in long-distance host-finding are found in phytophagous flies. In a series of wind-tunnel studies, Hawkes and Coaker (1979, *et ante*) documented host-odor-modulated anemotaxis in the cabbage fly, *Delia brassicae*. In response to volatiles from crucifers, these flies landed in the plume, faced upwind, and walked or made a series of hopping flights to the odor source. The same behaviors also were observed in the field, and it was concluded that response to host odors can occur from greater than 15 m (Hawkes, 1974). This orientation behavior has been characterized more recently in greater detail by measuring flight track-angles and insect airspeed in response to discrete plumes and dispersed clouds of allylisothiocyanate, a major volatile constituent of crucifer odors (Nottingham and Coaker, 1985). Similar behavioral responses have been documented for the onion fly (*Delia antiqua*) as reviewed by Miller and Strickler (1984), and the apple maggot fly (*Rhagoletis pomonella*). The latter, whose host-finding behavior also has been examined in the wind tunnel, shows the same chemically modulated response to a blend of synthetic 8- to 10-carbon esters as to an extract of apple volatiles (Fein et al., 1982).

In concurrent and complementary discussions by May and Ahmad (1983) and Lance (1983) on the proximal mechanisms of host finding in oligophages and polyphages, respectively, it is argued that breadth of host utilization by an insect herbivore (among other factors) will be a major determinant in the evolution of long-range response to host odors. The basic premise underlying this argument is that since the host of the specialist is more likely to be rarer and interspersed among nonhosts, there is a more intense selection pressure to be able to recognize and locate the host from a distance. Correspondingly, generalist feeders are less likely to "require accurate, specific, long-distance orientation mechanisms" (Lance, 1983). It is postulated that once the generalist is in contact with a plant, the variation in suitability of plant material is better assessed by gustatory stimuli and/or cues from other modalities. However, although the selection may be less intense for herbivores with broad dietary ranges than for the specialist feeders, nonetheless there is an adaptive advantage in the use of more efficient mechanisms for generalists as well. Thus, while the nature of the chemical cues utilized and the narrowness of the tuning of the herbivore's receptor system would be expected to differ between two species with different breadths of host range, there is no reason to believe that a broad host range would obviate host-plant finding by a long-range response. Furthermore, as pointed out by May and Ahmad (1983), evidence to support the specialist feeder–long-range host-finding model is not only lacking but actually runs counter. For example, the highly polyphagous *Schistocerca gregaria* can use odor-modulated anemotaxis to locate its host from a distance (Kennedy and Moorehouse, 1969), and the Japanese beetle appears to use a diverse group of compounds in finding its hosts, based on observations of beetles flying into

baited traps from a distance (Fleming, 1969; Ladd and McGovern, 1984 and references therein). Long-range chemoorientation to host odors also has been demonstrated recently in another polyphagous feeder, *Trichoplusia ni* (Landolt, 1989), as well as in the broadly feeding nitidulid beetles, *Carpophilus hemipterus* and *C. lugubris* (Blackmer and Phelan, in press; Phelan and Lin, in press), all of which display zigzagging flight up a laboratory wind tunnel to a variety of host odors and/or synthetic blends. The navel orangeworm is extremely broad in its host diet, feeding on the nuts, fruits, and seed pods from plants as diverse as *Acacia*, citrus, almonds, and *Yucca* (Wade, 1961). The detailed behavioral studies on the navel orangeworm (Phelan and Baker, 1987; Haynes and Baker, 1989; and this study) leave little doubt that host finding in this insect also is based primarily on a chemically modulated long-distance response.

In conclusion, we would submit that the proposed relationship between narrower host-plant utilization and increased powers of long-range host location is not supported by the evidence of well-studied examples, including the navel orangeworm. Here we have demonstrated that ovipositional host finding by the broadly feeding navel orangeworm is mediated at some distance from the host by means of a long-range response to a blend of long-chain fatty acids, primarily oleic and linoleic acids. However, although a synthetic blend of these chemicals can elicit upwind flights to the odor source, it does not reproduce the same level of navel orangeworm response as either crude or acidulated almond oils. This difference between response to natural compared to synthetic sources of odor was even greater when close-range behaviors such as landing were considered. Although the behaviorally active acidulated almond oil is composed almost solely of long-chain fatty acids, the relatively low vapor pressure of these components would make their relative abundance in the volatile profile greatly reduced. Thus, minor components of these oils, such as products of fatty-acid breakdown probably represent a significant contribution to almond odors. Work presently is being carried out to characterize the potential behavioral role played by these more volatile constituents in eliciting close-range response to host odors.

Acknowledgments—We thank R.S. Vetter and B.A. Nault for technical assistance, and Liberty Vegetable Oil Co., Sante Fe Springs, California, for supplying the crude almond oil and the almond soapstock. Thanks also to J.L. Blackmer and Drs. L.R. Nault and R.E. Treece for critical review of the manuscript. trans-2-NONENAL INSECT REPELLENT, INSECTICIDE, AND FLAVOR COMPOUND IN CARROT ROOTS, CELL SUSPENSIONS, AND "HAIRY" ROOT CULTURES

D.A. CHAMBERLAIN,[1,2] G. WILSON,[1] and M.F. RYAN[2,*]

(Received May 31, 1990; accepted November 19, 1990)

Abstract—As *trans*-2-nonenal (T2N) acts as an insect repellent, an insecticide, and a flavor compound, it would be desirable to manipulate its concentration in plants. Simple, rapid , and accurate trapping on cartridges of activated charcoal detected T2N in headspace over carrot roots and regenerants. Concentrations ranged from 0.07 to 0.43 ppm total volatiles over the homogenized roots of a range of European carrot cultivars with the following statistically significant differences: Long Chantenay > Sytan > Vertou > Touchon Prima. This suggests that the expression of T2N is determined genetically. Given the potential for genetic manipulation by *in vitro* techniques, the release of T2N and other terpenoids was monitored in carrot cell suspensions and in "hairy" root cultures of cv. Gelbe Rheinische. T2N concentrations were 6.23 ppm and 0.005 ppm, respectively, as compared with 0.15 ppm over the homogenized root of the same cultivar. Two terpenoids additional to T2N were detected from cell suspension cultures as compared with 14 from "hairy" root cultures. The ready detection in regenerants of this significant aldehyde indicates that its presence could be monitored in derivatives of other *in vitro* manipulations.

Key Words—*trans*-2-Nonenal, insecticide, carrot root, root regenerants, genetic differences, genetic manipulation.

INTRODUCTION

The side effects of synthetic pesticides are leading to a reappraisal of natural compounds for use in pest control. There is both a theoretical basis, related to coevolution, and practical evidence for the occurrence of insecticides in plants (e.g., Ryan et al., 1978; Ryan and Byrne, 1988). The application of plant tissue culture techniques facilitates two new approaches in the exploitation of natural plant products in crop protection. First, cultures of plant cells provide an industrial biosynthetic source of natural compounds having insecticidal properties (Zieg et al., 1983). Second, plant tissue culture methods enable the cloning, by somatic embryogenesis, of an elite individual plant having desirable chemical properties. Obvious preliminary steps are the screening of plant populations for cultivars and individual plants having elevated levels of a natural plant defense compound, followed by the screening of *in vitro* regenerants for satisfactory synthesis of the compound.

Unusually, perhaps, the naturally occurring aldehyde *trans*-2-nonenal (hereafter T2N) is an insect repellent, insecticide, and a flavor compound. Bioassays of 36 components of carrot root oil indicated that T2N repelled and killed the larva of the parasitic, and thus adapted, insect, *Psila rosae* (F.), the carrot fly: the lethal concentration (LD_{50}) of the vapor in a non-contact bioassay was 4000 ppm (Guerin and Ryan, 1980). T2N at 50 ppm elicited 98% repellency from the American cockroach, *Periplaneta americana* (Scriven and Meloan, 1984). More recently, T2N proved effective against a broad range of 11 insect and three acarine pests (Taha, 1987; Awde, 1988).

Results from a human test panel indicated that T2N, representing 0.3% of carrot root oil obtained by steam distillation, had the lowest odor threshold of all carrot root volatiles tested (Buttery et al., 1968). Subsequently, use of multidimensional scaling of odor compounds derived from cold solvent extraction led to the claim that T2N was the single compound closest to carrot odor (Alabran et al., 1975). However, this compound with *trans*-2,*cis*-6-nonadienal is generally recognized as producing the characteristic aroma of cucumber (Forss et al., 1962).

The foregoing spectrum of effects suggests that it would be appropriate to manipulate the concentration of T2N in carrot root. Accordingly, we examined intrinsic variability in the production of this compound by comparing its concentration in the headspaces of roots from eight carrot cultivars with a European provenance. Our use of small charcoal traps enabled rapid, simple, and sufficient absorption to provide, from a single root, a concentration detectable by GC-MS. Given the potential for the derivation of new cultivars by *in vitro* techniques, we also sought this compound in the headspaces of undifferentiated cell suspension cultures and of differentiated "hairy" root cultures. The latter are profuse, quick-growing, regenerated roots induced *in vitro* by plasmid-

transformed cells. Such cultures may represent an industrial source of secondary metabolites (Rhodes, 1988).

METHODS AND MATERIALS

Collection and Analysis of volatiles. Collection and analysis of volatiles employed microtraps containing 2 mg of washed and sieved activated charcoal in a glass capillary tube (ID 2 mm). Traps were precisely matched into groups of three, with the same resistance to airflow, by use of a bubble flowmeter attached to each individual trap outlet on the sampling apparatus. Thus, the headspace was sampled in triplicate (Figure 1). Control experiments showed that such traps absorbed more than 93% of total test volatiles from a headspace stream flowing at 60 ml/min over 2.5 hr. Volatiles from carrot material, thus aerated and maintained in a water bath at 40°C, were swept onto the charcoal traps (Figure 1) for subsequent identification by GC-MS.

Entrapped volatiles were desorbed at the head of the gas- chromatographic column using a modification of the method of Clarke and Cronin (1975) (Figure 2). Essentially, each charcoal trap was oriented in the injection apparatus such that depressing the plunger placed the trap in the heating block governing the temperature of the injection port (280°C). Thus, for 100 sec desorbed volatiles were swept directly by the carrier gas into the GC capillary column. Modifications to the original injection/desorbtion apparatus were as follows: (1) the trap was attached tightly to the central plunger by a detachable silicone rubber collar facilitating trap removal and replacement; (2) the injection apparatus was

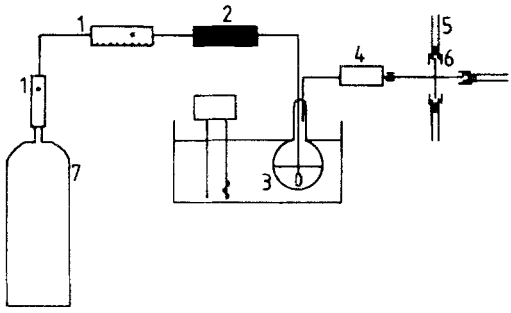

FIG. 1. Schematic diagram of the volatile collection apparatus. Air passed from cylinder (7) through flowmeters (1), was cleaned by passage over activated charcoal (2), and entered the sample flask (3) through a 10-cm × 0.6-cm-ID teflon tube and a sintered glass sparger. Volatile-enriched air then passed over anhydrous calcium chloride, packed in a 12-cm Pasteur pipet (4), and into a three-armed glass manifold (6), ID 0.2 cm, attached by Si-rubber collars to three charcoal capillary traps (5).

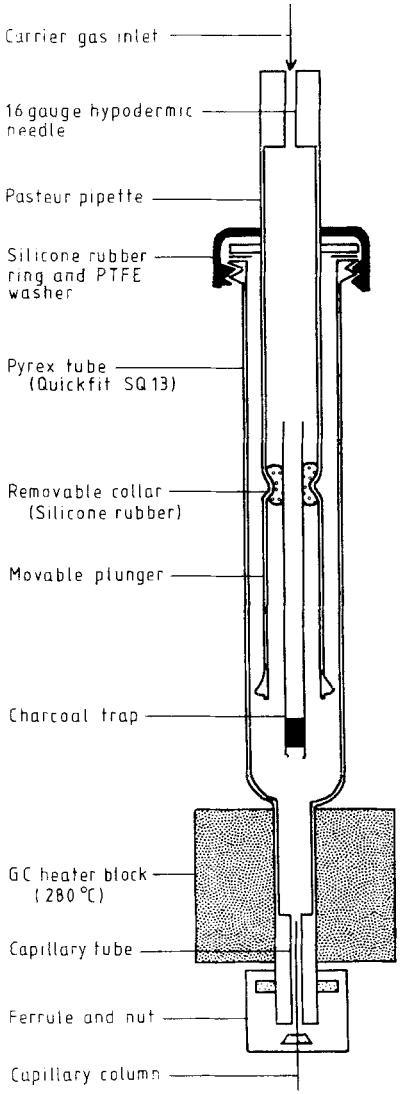

FIG. 2. Desorption device for transfer of adsorbed volatiles from the charcoal capillary trap to the head of the GC-column. Modified after Clarke and Cronin (1975), see text for other details.

attached to the column using a ferrule fitting to eliminate leakages; (3) the procedure was simplified by the use of a prerun purge (2 min), thus obviating the need to purge the outer jacket (e.g., no carrier gas bypass) (Figure 2). For GC conditions see the legend to Figure 3 (below).

Carrot Plants, Cell Suspensions, and "Hairy" Root Cultures. Carrot seeds of seven cultivars representing a spectrum of resistance to the carrot root fly, *Psila rosae* (F.) (Maki and Ryan, 1989) were obtained from The Institute of Horticultural Research, Wellesbourne, Warwick, U.K. These were sown in a cold glasshouse in April 1987 and the roots harvested in September of that year.

Undifferentiated cell suspension cultures derived from cv. Gelbe Rheinische were maintained on Murashige and Skoog (1962) medium (1 μM 2,4-dichlorophenoxy acetic acid; 1 μM naphthalene acetic acid) and subcultured at four-week intervals using a 1 : 10 inoculum ratio. Cells were harvested by filtration for headspace analysis 14 days after inoculation.

Transformed root cultures ("hairy" roots) of cv. Gelbe Rheinische were established according to the method of Leemans et al. (1982) using *Agrobacterium rhizogenes*, strain LBA 9402, containing the binary vector pBin 19. Roots grown in hormone-free Murashige and Skoog liquid medium were subcultured every two weeks. Both root cultures and cell suspension cultures were grown in an orbital shaker (100 rpm, 5 cm throw) in low fluorescent light at 23°C.

All plant material was washed free of either soil or culture medium, frozen in liquid nitrogen, and ground vigorously in a hand-held coffee grinder (Braun 120 W). The resultant powder, still frozen, was sieved through a 10-gauge mesh, and a 10-g batch was weighed into a 100-ml long-necked flask. To this was added 10-ml distilled water containing 12.5 ng hexanol, as internal standard, prior to aeration.

RESULTS AND DISCUSSION

Aeration of the same carrot root, intact and then homogenized,gave qualitatively similar GC profiles. *trans*-2-Nonenal (T2N) was identified in the headspace over the homogenized roots of all cultivars studied, in concentrations from 0.07 to 0.43 ppm of total volatiles entrapped. Significant differences in concentrations were: Long Chantenay > Sytan > Vertou > Danvers > Clauses Jeune Obtuse > Touchon Prima (Figure 3). These results suggest that the concentration of T2N in carrot root is determined genetically, a conclusion further indicated by the similar values obtained for the related cultivars Long Chantenay and Royal Chantenay. Therefore, the concentration of T2N in carrot and other plant species may be amenable to genetic manipulation through the application of plant tissue culture methods.

T2N headspace concentrations over the homogenates of cell suspension

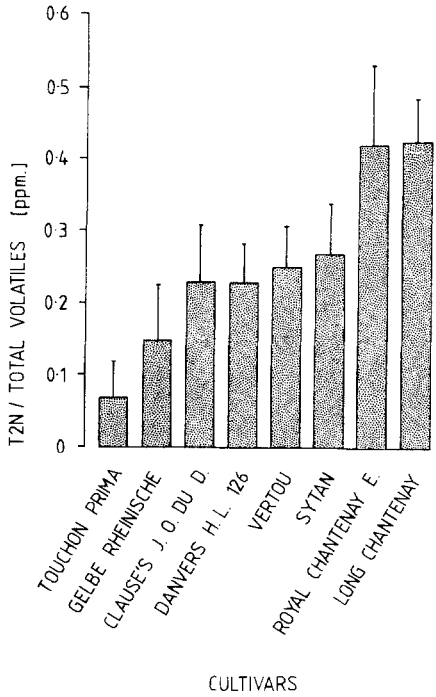

FIG. 3. Relative proportion of *trans*-2-nonenal in the total headspace volatile component of homogenized whole root from eight carrot cultivars (ppm) as judged from GC using the internal standard method (hexanol as internal standard). Vertical bars representing standard errors indicate the precision of the method. Values obtained from cell suspension and "hairy" root cultures (cv. Gelbe Rheinische) were 6.23 and 0.005 ppm, respectively. GC conditions: Hewlett Packard 5890A chromatograph linked to automatic computing integrator 3380A; glass capillary Supelcowax column, 530 μM ID, 30m long; carrier gas, helium 2 ml/min; injection port temperature 280°C; column temperature, 22°C for 100 sec, then 5°C/sec rise to 52°C maintained for 100 sec, then 2°C/min rise to 210°C.

cultures and "hairy" root were 6.23 ppm and 0.005 ppm total volatiles, respectively, a 125-fold difference. The former is equivalent to 14-fold more than over homogenized root, whereas the latter concentration is comparable to that over whole root (Figure 4). The enhanced concentration in cell suspension culture reflects the relatively low level of total volatiles present because T2N peak areas, per unit fresh weight of tissue, were roughly similar from cell suspensions and whole root. It is relevant that selection and screening of plant cell cultures for secondary metabolites has led to the isolation of some 20 cell lines, from other plant species, capable of accumulating secondary plant products at levels exceeding that in the plant (Wilson, 1988).

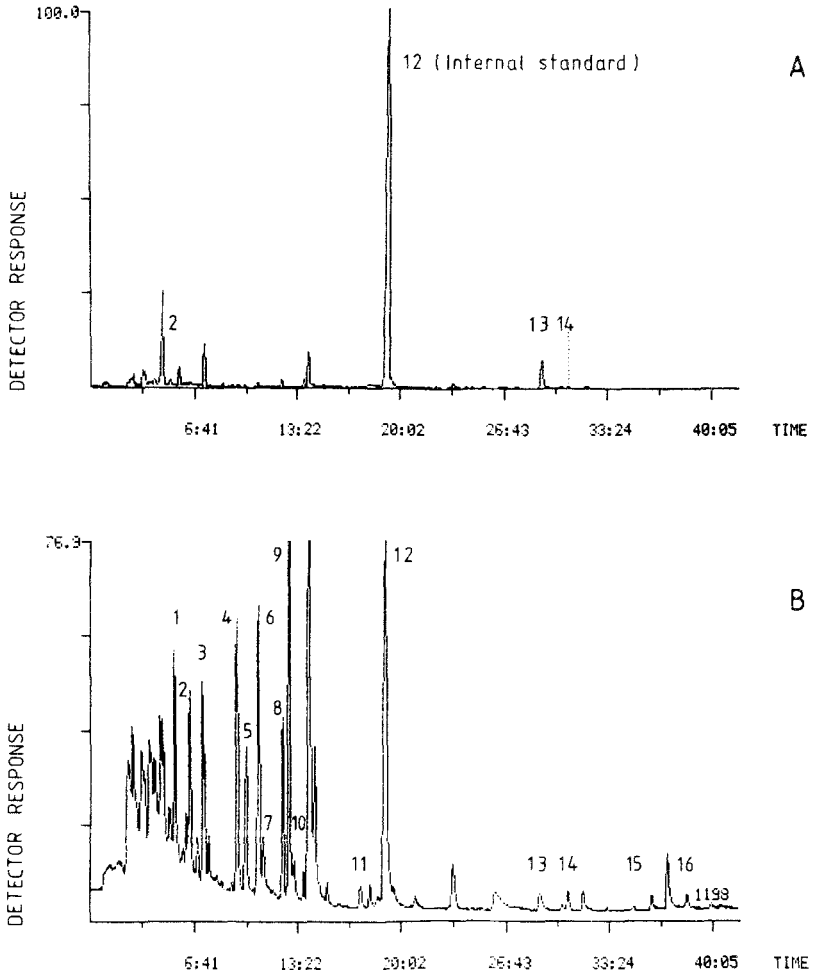

FIG. 4. GC traces from GC-MS analysis of headspace volatiles of homogenized cells from carrot cell suspension cultures (A) and from cultured "hairy" roots (B) (cv. Gelbe Rheinische): VG Analytical 7070E mass spectrometer, PYE 204 gas chromatograph, Finnigan-Mat INCOS 2400 data system. For peak identifications, see Table 1.

Only camphene and bornyl acetate, in addition to T2N, were confirmed from cell suspensions, whereas 14 additional compounds were from "hairy" root cultures (Figure 4, Table 1). All except *trans*-ocimene, *cis*-ocimene, β-himachalene, and β-selinene have been identified from carrot root in previous investigations.

These carrot cell suspension cultures, therefore, resemble cultures of several other plants in which the range of mono- and sesquiterpenes, synthesized

and accumulated by undifferentiated cells in culture, is markedly less than in the whole plant (Charlewood et al., 1988). As some free monoterpenes are toxic to plant cells, it was suggested that isoprenoid synthesis was severely limited by end-product inhibition. Accordingly, it is interesting that two of the three compounds identified from cell suspension cultures have entomological significance: T2N is an insecticide and insect repellent, and bornyl acetate is employed as a host-location cue by the larva of the carrot fly (Guerin and Ryan, 1980). In cucumber, T2N is synthesized through the oxidation of linoleic acid by lipoxygenase followed by hydroperoxide cleavage (Galliard et al., 1976). However, most terpenes are synthesized through the acetate–mevalonate pathway which, apart from the synthesis of low levels of camphene and bornyl acetate, appears to be suppressed in the present cell suspensions.

By contrast, once morphological differentiation has become established, either as a callus or in "hairy" root formation (Figure 4), additional secondary metabolic pathways become functional. The GC profile of carrot "hairy" root cultures contains many terpenes characteristic of the whole carrot root, which is consistent with the accumulation of secondary metabolites such as nicotine

and atropine in "hairy" roots of other plant species (Rhodes et al., 1986; Kamada et al., 1986).

The sensitivity and simplicity of the present method of charcoal trapping, combined with direct GC injection, facilitates the sampling of relatively small amounts of tissue and thus the screening of individual plants. Our present detection of significant differences in T2N concentrations between different cultivars should lead to the identification of an elite plant. Cloning by somatic embryogenesis from such a parent could provide a basis for accelerated crop improvement through the development of cultivars having enhanced levels of the insecticide. The present methodology will allow the monitoring of T2N from such regenerants.

Acknowledgments—We thank the National Board for Science and Technology (*EOLAS*), Dublin, for funding a proposal from Michael F. Ryan and Graham Wilson.

DEFENSIVE STRATEGY OF TWO *Hypselodoris* NUDIBRANCHS FROM ITALIAN AND SPANISH COASTS

(Received June 18, 1990; accepted November 19, 1990)

Abstract—*Hypselodoris* nudibranchs from different geographic areas (Spain and Italy) have been studied in order to investigate their general defensive strategy. Longifolin (**1**) and nakafuran-9 (**2**) are the main ichthyodeterrent allomones used by the mollusks to avoid predation. Evidence of their dietary origin is presented and the very effective strategy against predators, which includes secretion of allomones into the mucus and their storage into specific mantle dermal formations (MDFs), is also discussed.

Key Words—Opisthobranch, nudibranch, *Hypselodoris webbi, Hypselodoris villafranca*, sponge, *Dysidea fragilis*, chemical defense, longifolin, nakafuran-9, isotavacfuran .

INTRODUCTION

Nudibranchs are apparently unprotected shell-less mollusks. In spite of the absence of mechanical defense, only seldom they are victims of predators. In fact, nudibranchs have elaborated a series of very effective defensive strategies (Edmunds, 1966; Ros, 1977; Thompson, 1960), including the use of chemicals that generally derive from the diet and that sometimes are directly produced by the animal (Karuso, 1987).

The defensive allomones generally are localized in the mantle of the mol-

lusks, and they can display either ichthyotoxic or feeding-deterrent properties. A rigorous test to evaluate these activities should be directed against predators living in the same habitat as the nudibranch. However, as this experimental procedure is difficult, it is generally accepted tests are performed in aquaria with freshwater fishes to detect ichthyotoxicity (*Gambusia affinis*) (Coll et al., 1982; Gunthorpe and Cameron, 1987) and feeding deterrency (*Carassius auratus*) (Cimino et al., 1982; Thompson et al., 1982).

During our studies of the defensive strategies of Mediterranean opisthobranchs (Cimino et al., 1982, 1985, 1986; Cimino and Sodano, 1989), we have observed that longifolin (**1**), already known as a plant metabolite (Hayashi et al., 1972), is the defensive allomone of Tyrrhenian *Hypselodoris webbi* (Cimino et al., 1982), displaying both ichthyotoxic and ichthyodeterrent activities. A dietary origin was strongly suspected for longifolin on the basis of its presence among the metabolites of the sponge *Pleraplysilla spinifera* (Cimino et al., 1975). However, it is unlikely that *H. webbi* preys upon *P. spinifera*. In fact, **1** is present in *P. spinifera* only as a minor component along with two major sesquiterpenoids (Cimino et al., 1975, 1978) that are absent in *H. webbi*.

It is interesting to observe that , to our knowledge, there are no reports regarding the diet of *H. webbi*. Recently (García-Gómez et al., 1990), **1** has been found also in populations of *H. webbi* from the Straits of Gibraltar; in particular, it is located in mantle dermal formations (MDF's) strategically placed near gills and rhinophores.

In this paper, we aim to clarify: (1) the origin of longifolin in *H. webbi;* (2) the distribution of the defensive allomone, or related metabolites, in specific organs and in the mucous secretion of the nudibranch; and (3) by a comparative study, the defensive strategy exhibited by populations of *H. webbi* and *H. villafranca* from the Spanish and Italian coasts.

METHODS AND MATERIALS

General Experimental Procedures. [^{1}H]- and [^{13}C]NMR spectra were performed in $CDCl_3$ or C_6D_6 on a WM 500 Bruker spectrometer coupled to an Aspect 2000 computer system. Chemical shifts expressed in δ units are reported in ppm downfield from the internal standard TMS ($\delta = 0$). Mass spectra were recorded with AEI MS 30 and Kratos MS 50 mass spectrometers.

Commercial Merck silica gel 60 (70–230 mesh ASTM) was used for column chromatography. Analytical TLC was carried out using precoated silica gel Merck F254 plates. The chromatograms were sprayed with either Ehrlich's reagent or 0.1% $CeSO_4$–2 N H_2SO_4 and heated to detect the spots. The extract of *H. villafranca* from Asturias also was analyzed on silica gel TLC treated with a solution of $AgNO_3$ (8% in acetone–water 8:2) and fractionated on a silica gel–$AgNO_3$ (8%) column.

Anatomical dissections were made observing the animal through a Swift Microscope (20–40×).

Biological Material. The sponge *Dysidea fragilis* was collected in Taranto (Mediterranean Sea) during October 1988 and in Asturias (Atlantic Ocean) during December 1988.

Collections of *H. webbi* were made from: Blanes, March 1990; Castellammare di Stabia, December 1988; and Taranto, August 1989. Specimens of *H. villafranca* were collected from Taranto (June and October 1988 and March 1989) and Asturias (December 1988). The location of these stations is shown in Figure 1.

All the Mediterranean material was collected either snorkeling or scuba-diving between 0.2 m and 10 m depth, whereas the Atlantic material was collected in the tidal zone. Mucous secretions were obtained disturbing the animals with a glass stick.

Anatomical Dissection. Frozen animals were usually dissected in four parts: mantle dermal formations (MDFs), rest of mantle and foot, digestive gland, and the rest of the viscera (reproductive organs, digestive duct, etc.).

Isolation Procedure of Liposoluble Material. All the biological material (sponge, whole nudibranchs, dissected parts, mucous secretion) was treated with acetone. The acetone extract was evaporated at reduced pressure and the residue treated with diethyl ether. Generally, the ethereal extracts were analyzed by SiO_2 TLC (petroleum ether) and fractionated on SiO_2 column (petroleum ether). In particular, the MDFs of *H. webbi* collected in Castellammare were treated with C_6D_6, and the extract was dried on Na_2SO_4 and then submitted to NMR analysis without any purification. The diethyl ether soluble fraction from the

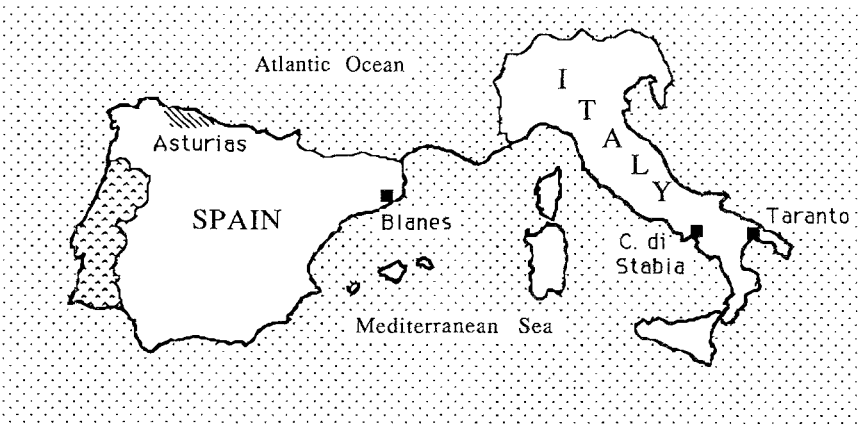

FIG. 1. Localities where *Hypselodoris* and sponges were collected.

acetone extract of Atlantic *H. villafranca* (24 specimens) was first eluted on silica gel column with *n*-heptane, obtaining longifolin (**1**) (6 mg) along with an unresolved mixture (15 mg) of less polar furanosesquiterpenoids. Further purification of the latter fraction on $AgNO_3$–SiO_2 (8%) column (*n*- heptane–benzene 9 : 1) gave nakafuran-9 (**2**) (4 mg). Furthermore, the highly unstable metabolite, isotavacfuran (**3**), of *H. webbi* (Blanes), was isolated, protecting the extracts from light during preparation for analysis.

RESULTS

Chemical Analysis. After extraction with acetone, dry weights of the dissected parts and amounts of the extracts from single specimens of *H. webbi* were determined (Table 1). Those of *H. villafranca* are summarized in Table 2.

All the specimens collected in a single area were extracted simultaneously. In the case of *H. webbi* from Castellammare, the mean value (obtained by halving the observed weights from two animals) was preferred for a better comparison with the other specimens. The observed differences are probably due to the different size of the mollusks. In particular, the amount of longifolin (**1**) in *H.*

webbi from Blanes seems to be too scanty. However, the size of the animal was small, as supported by the dry weights, and another sesquiterpenoid, isotavacfuran (**3**), cooccurs in the same organism. Analogously, the main differences observed for *H. villafranca* can be explained by: (1) the anatomical dissections were made by different operators (in particular, the MDFs from Asturias were completely devoid of other tissues); (2) the minor amounts of **1** in population from Asturias are counterbalanced by the presence of other furanosesquiterpenoids; and (3) the specimens were collected in different seasons.

The [^{1}H]NMR spectrum of longifolin (**1**) from the MDFs of a specimen of *H. webbi* collected in Castellammare is reported in Figure 2. Moreover, 25 mg of longifolin (**1**) were also isolated from the acetone extract of the mucous secretion of the same animal. The [^{1}H]- and [^{13}C]NMR data for **1, 2** and isotavacfuran (**3**) are reported below. The assignments have been supported by a series of two-dimensional NMR experiments and confirmed by ^{1}H–^{1}H selected decouplings.

Moreover, we have obtained from Atlantic *Dysidea fragilis* (dry weight 19 g) 10 mg of nakafuran-9 (**2**), whereas *Dysidea fragilis* from Taranto (dry weight 1 g) yielded 6 mg of pure longifolin (**1**).

Spectral Data of 1, 2, and 3. Longifolin (**1**): (3-methyl-2-[(2′*E*)-3′-methyl-4′-(4″-methyl-2″-furyl)-2′-butenyl] furan; $C_{15}H_{18}O_2$ EI-MS *m/z:* 230 (M^+); [^{1}H]NMR (C_6D_6): 1.60 (3H, s, CH_3- 3′); 1.78 (3H, s, CH_3-4″); 1.81 (3H, s, CH_3-3); 3.16 (2H, s, H-4′); 3.22 (2H, d, J= 7.0 Hz, H-1′); 5.46 (1H, t, J= 7.0 Hz, H-2′); 5.77 (1H, bs, H-3″); 6.00 (1H, d, J = 1.5 Hz, H-4); 6.92 (1H, bs, H-5″); 7.07 (1H, d, J = 1.5 Hz, H-5). The [^{1}H]NMR spectrum in C_6D_6 is reported in Figure 2, and numeration is according to Guella et al., (1985b). The assignments, already reported in the quoted paper, have been confirmed by two dimensional NMR experiments: ^{1}H-^{1}H COSY, ^{1}H-^{13}C HETCOR.

Nakafuran-9 (**2**): $[\alpha]_D = -107.5$ (c = 0,2 $CHCl_3$); C_{15} H_{18} O_2 EI-MS *m/z* (%): 216 (M^+, 100), 201 (55), 175 (35). [^{1}H]NMR ($CDCl_3$): 1.08 (3H, s, H-15's); 1.37 (1H, ddd, J = 4.1, 13.3 and 13.3 Hz, H-5a); 1.57 (3H, s, H-13's or H-14's); 1.59 (3H, s, H-14's or H-13's); 1.72 (1H, ddd, J = 2.7, 2.7 and 13.0 Hz, H-12a), 1.79 (1H, ddd, J = 1.8, 4.3 and 13.0 Hz, H-12b); 1.92 (1H, bddd, J = 4.1, 4.1 and 13.3 Hz, H-5b); 1.95 (1H, bd, J = 15.5 Hz H-9a); 2.25 (1H, ddd, J = 4,1, 13.3 and 16.0 Hz, H-4a); 2.33 (1H, ddd, J

= 4.1, 4.1 and 16.0 Hz, H-4b); 2.37 (1H, bdd, J = 5.2 and 15.5, H-9b); 3.17 (1H, m, H-10); 6.06 (1H, d, J = 1.7 Hz, H-2); 7.12 (1H, d, J = 1.7 Hz, H-1). [^{13}C]NMR ($CDCl_3$): 13.2 (C-14); 19.8 (C-13); 23.0 (C-4); 30.7 (C-15); 31.8 (C-10); 37.6 (C-6); 38.2 (C-9); 38.6 (C-5); 41.3 (C-12); 113.1 (C-2); 118.3 (C-3); 126.3 (C-7 or C-8); 129.5 (C-8 or C-7); 138.4 (C-1); 156.2 (C-11).

Numeration is according to Schulte et al. (1980). The assignments have been supported by ^{1}H-^{1}H decoupling experiments, ^{1}H-^{1}H COSY, and ^{1}H-^{13}C HETCOR. The comparison with the previous reported NMR data has revealed some minor differences, in particular for the [^{13}C]NMR resonances assigned to the methyls.

Isotavacfuran (**3**): (3-methyl-2-[(3′*E*) -3′-methyl-4′-(4″-methyl-2″-furyl)-3′-butenyl] furan C_{15} H_{18} O_2 EI-MS *m/z:* 230 (M^+); [^{1}H]NMR (C_6D_6): 1.77 (6H, s, CH_3-3 or CH_3-4″); 1.78 (3H, s, CH_3-4″ or CH_3-3); 1.88 (3H, s, CH_3-3′); 2.34 (2H, t, J = 7.5 Hz, H-2′); 2.60 (2H, t, J = 7.5 Hz, H-1′); 5.95 (1H, bs, H-3″); 5.98 (1H, d, J = 1.5 Hz, H-4); 6.11 (1H, bs, H-4′); 6.91 (1H, bs, H-5″); 7.08 (1H, d, J = 1.5 Hz, H-5).

Numeration and assignments are according to Guella et al. (1985b).

DISCUSSION

Hypselodoris webbi is a well-studied opisthobranch with a very broad distribution in Atlantic and Mediterranean waters. This animal has received the names of *Doris scacchi* Delle Chiaje, 1830; *Doris elegans* Cantraine, 1835; *Doris picta* Philippi, 1836; *Doris valenciennesi* Cantraine, 1840; *Doris nardi* Vérany, 1846; and *Doris calcarea* Vérany, 1846. However, this species should be named *Hypselodoris webbi* D'Orbigny, 1839, according to Bouchet and Ortea (1980). All the references to the specific names *elegans* or *valenciennesi* in the genus *Hypselodoris, Doris*, or *Glossodoris* found in Atlantic and Mediterranean literature should be attributed to *H. webbi*.

Surprisingly, in spite of being one of the better studied Chromodorididae, data regarding the diet of *H. webbi* are not reported in the literature. On the basis of the presence of large amounts of longifolin (**1**) in its digestive gland, predation of the nudibranch upon an unknown sponge was suspected (Cimino et al., 1982). However, the real origin of the ichthyotoxic and feeding deterrent **1** is uncertain. In fact, its finding in *H. webbi* specimens living in different geographical areas (García-Gómez et al., 1990) could support de novo biosynthesis (Faulkner, 1988b).

Aiming at clarification, we have extended our studies to possible prey living in both Italian and Spanish *H. webbi* habitats, with particular attention to *Dysidea* sponges, known to be the prey of Pacific *Hypselodoris* species (Faulkner, 1988a; Karuso, 1987).

Further studies also have been performed on the small *H. villafranca* (Risso, 1818) (=*Glossodoris gracilis*), which also contains longifolin (**1**) and which, on the basis of this evidence, was deemed to be a sponge predator (Cimino et al., 1980).

H. webbi was collected from three different stations (Castellammare di Stabia, Taranto, and Blanes). Large amounts of **1** were present in all the populations (Table 1). The anatomical dissections (according to García-Gómez et al., 1986, 1990) confirmed that the presence of **1** on the mantle is limited to the MDFs. In particular, the MDFs from a Tyrrhenian specimen were extracted with C_6D_6 and, without any purification, analyzed directly by NMR. The [^{1}H]NMR spectrum (Figure 2) revealed the presence of very abundant and pure **1**.

Large amounts of longifolin (**1**) also were found in the digestive gland (Table 1) and in the mucous secretion of the nudibranch (experimental).

The chemical analysis of the organic molecules from *H. webbi* populations (Taranto and Blanes) confirmed the presence of **1**, but also revealed the cooccurrence of other furanosesquiterpenoids (Table 1). More exactly, nakafuran-9 (**2**), the already known feeding deterrent allomone of the Hawaian nudibranchs *H. godeffroyana* and *Chromodoris maridadilus* (Schulte et al., 1980), was characterized as a minor component from the Italian nudibranchs, while, as already reported (García-Gómez et al., 1990), a second slightly less polar, Ehrlich-positive metabolite of **1**, was detected by TLC analysis of the ethereal extract of the Spanish mollusks. In spite of its high instability, it was characterized after a careful isolation procedure. The spectral data were identical to those of isotavacfuran (**3**) already described as the synthetic isomer of the sponge metabolite tavacfuran (**4**) (Guella et al., 1985b) (Figure 3).

Substantially coherent results have been obtained studying *H. villafranca* from two different stations (Taranto and Asturias). From the Italian specimens, **1** was isolated as the main metabolite, while the organic extracts from the Spanish animals were characterized by the presence of a complex mixture of furanosesquiterpenoids, which includes **1** and nakafuran-9 (**2**) as major components (Table 2).

Analogously, in the anatomical dissection (Table 2) of *H. villafranca*, the allomones were found in the MDFs, in the digestive gland, and in the mucous secretion of the mollusk. On the contrary, they were completely absent in both the mantle devoid of MDFs and the rest of the viscera devoid of digestive glands. The number of MDFs seems to be related to the animal size: we observed three to five of them in the anterior part and two to five in the posterior part of *H. villafranca*, and 15–30 in the anterior part (sometimes continuously) and 14–20 in posterior part of *H. webbi*.

It seems that both these nudibranchs (Figure 4) have elaborated an artful defensive strategy. When molested, these mollusks secrete a white mucus full

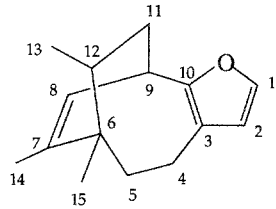
4. Tavacfuran



5. Nakafuran-8

FIG. 3. Furanosesquiterpenoid structures **2, 3, 4,** and **5.**

of ichthyodeterrent furanosesquiterpenoids. However, if the predator bites the prey, the MDFs explode, delivering further amounts of antifeedant compounds to defend gills and rhinophores, vital organs for the animals. However, the origin of the defensive allomones remains to be clarified.

During the collection of biological material in Taranto, *H. villafranca* was observed while it was feeding on a white sponge, identified as *Dysidea fragilis*. The chemical analysis revealed large amounts of **1** in the sponge, supporting a prey–predator relationship between *D. fragilis* and *H. villafranca*. Until now, in spite of the widespread presence of *H. webbi*, it was not possible to detect such relationships with any sponge. In fact, *H. webbi* usually was observed swimming or moving on bare rock. The lack of field observation could be due either to night diet or to other reasons. The above reported data on *H. villafranca* stimulated other direct observations on *H. webbi* (Mollo, unpublished results) in an aquarium. Specimens of *H. webbi* collected in Sorrento (20 km from Castellammare di Stabia) were observed grazing upon *D. fragilis*. Simultaneously, the levels of the allomone **1** sharply decreased in starved individuals maintained for some days in tanks without sponges.

Analogously, the probable sponge origin of nakafuran-9 (**2**) was supported by the chemical analysis of *D. fragilis* collected in Asturias. In fact, abundant **2** was detected in lipid extracts from the Atlantic sponge, which should be one of the prey of the Atlantic *H. villafranca*. It is worth noting that previous chem-

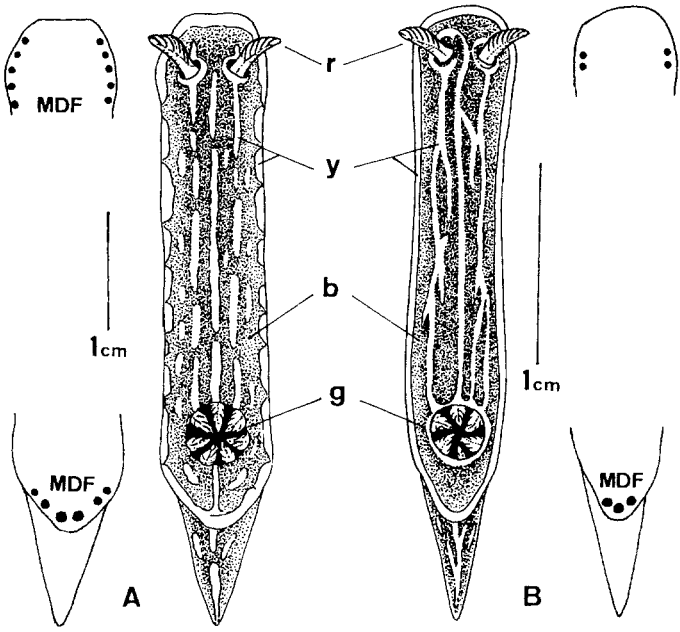


FIG. 4. Dorsal view of *H. webbi* (A) and *H. villafranca* (B) and schematic distribution: r = rhinophores, y = yellow, b = blue, g = gills.

ical studies on another specimen of Atlantic (North Brittany Sea) *D. fragilis* (Guella et al., 1983, 1985a) revealed a different pattern of furanosesquiterpenoids, while *D. fragilis* collected at Hawaii (Schulte et al., 1980) contains **2** along with its isomer nakafuran-8 (**5**).

According to these data, we can suggest both species of *Hypselodoris* nudibranchs from Italian and Spanish coasts live in communities where *Dysidea* (or related) sponges are not rare, and they sequester from the sponges some feeding deterrent metabolites that are helpful for their own defense against predators.

In particular, *H. webbi* is able to select in different geographical areas the variety of *Dysidea fragilis* very rich in longifolin (**1**). However, on the basis of chemical analysis, sometimes its diet may be extended to other *Dysidea* (or related) species. In fact, in both the Spanish and Italian populations of *H. webbi*, longifolin (**1**) cooccurs with other metabolites that are completely absent in the extracts of the Italian *D. fragilis*, but that are known to be characteristic (nakafuran-9) or closely related (isotavacfuran) to *Dysidea* metabolites. The extraordinary mechanism that brings the dietary defensive sesquiterpenoids into the MDFs remains to be clarified. Most likely, the allomones are stored in these protected formations to avoid the dangerous effects of its own weapon to the animal. Surprisingly, no openings were observed in the MDFs, as reported in

the paper of García-Gómez et al. (1986), the first to suggest a defensive role for the MDFs.

Both *Hypselodoris* species are conspicuous in appearance (Figure 4): they present a dark blue body or white–yellow body with some yellow longitudinal lines and points. MDFs are always camouflaged in the yellow border of the mantle. They are aposematic species, exhibiting Müllerian mimicry, together with other *Hypselodoris* species, as was predicted by Ros (1976) studying coloration. The presence of the same kind of defensive compounds in different species further supports this assumption. Actually, *H. cantabrica* and *H. tricolor* seem to be related in that they present the same kind of allomones.

Acknowledgments—We thank Miss D. Rosell (C.E.A.B.-C.S.I.C., Blanes, Spain) for identifying the sponges. We also thank Mr. A. Crispino, Mr. A. Trabucco, Mr. R. Turco, and Mr. G. Villani for their valuable technical assistance. Thanks are extended also to the staff of the ICMIB NMR Service. This work is part of a CSIC (Spain)-CNR (Italy) bilateral project, and it is partially supported by the "Progetto Finalizzato Chimica Fine II" CNR-Roma.

(Received September 18, 1990, accepted November 19, 1990)

Abstract—Four major volatile components emitted from flowers of *Abelia grandiflora* were identified based on retention time using two capillary columns of different polarities and electron impact mass spectrometry. These are phenylacetaldehyde, benzaldehyde, 2-phenylethanol, and benzyl alcohol. A blend of these compounds was as effective as a cluster of flowers in stimulating upwind flight by male *Trichoplusia ni* to the source in a wind-tunnel test. Phenylacetaldehyde or 2-phenylethanol were each as effective as the complete blend in stimulating source location by male moths. Attraction to a source of the synthetic blend was demonstrated in virgin males and females and mated males and females, but virgin moths of both sexes were more likely than mated moths to complete the sequence of behavioral responses necessary to locate the odor source.

Key Words—Lepidoptera, Noctuidae, *Trichoplusia ni*, floral attractants, anemotaxis, wind tunnel.

INTRODUCTION

Volatile chemicals emitted from plants facilitate host-finding in a wide range of insects. In moths, such volatile chemicals often enable females to locate suitable oviposition sites (Phelan and Baker, 1987; Liu et al., 1988; Ramaswamy, 1988; Haynes and Baker, 1989; Landolt, 1989; Tingle et al., 1989) but may also allow male and female adults to find their own food resources (Wiesenborn and Baker, 1990). Feeding by adult female moths may improve reproductive suc-

*To whom correspondence should be addressed.

0098-0331/91/0300-0637$06.50/0

cess by increasing egg production, extending the ovipositional period, improving ovipositional host-finding success, and/or increasing resources allocated to each egg. Feeding by adult males may improve mate-finding success, increase longevity and the associated chances for multiple mating, or increase "nutritive" spermatophore size, thereby indirectly improving reproductive success. Adult cabbage looper moths, *Trichoplusia ni* (Hübner) and other Plusiinae feed on nectar from the ornamental shrub *Abelia grandiflora* (André), (honeysuckle family, Caprifoliaceae); both male and female moths are attracted to these flowers from sunset to 1 AM (Grant, 1971a). Olfactory stimuli play an important role in mediating nectar-finding by *T. ni*, but the chemical composition of these cues has not been defined.

METHODS AND MATERIALS

Abelia grandiflora plants were maintained in a greenhouse (maximum daytime temperature 35°C, minimum nighttime temperature 21°C). Volatile collections were conducted for 24 hr from flower clusters of six *A. grandiflora* plants. Volatile floral compounds were collected on 70 mg of Tenax-TA (Alltech, Deerfield, Illinois), which had been loaded into a glass tube (0.5 cm diam. × 5.5 cm long) plugged at both ends with glass wool. The large open ends of two glass funnels (10 cm diam.) were butted against one another to enclose a flower cluster containing 6–10 open flowers. The funnels were sealed together with Teflon tape and supported in position with a ringstand to avoid stress to the plant stem. A Tenax trap was attached to the 3.0-cm stems of both funnels with a 2-cm section of Tygon tubing. Air was drawn through the system at 175–200 ml/min via a vacuum pump attached to one of the traps. Approximately 400 μl of HPLC- grade hexane was added to the Tenax and was allowed to drip into a graduated vial. Additional hexane was added to the Tenax until exactly 600 μl was recovered in the vial. One hundred microliters of this solution was combined with 100 μl of a 100 ng/μl solution of (*R*)-(+)-1-phenylethanol (internal standard). One microliter of this solution was injected into a Hewlett-Packard (Avondale, Pennsylvania) 5890A gas chromatograph linked to a Hewlett-Packard 5970B mass selective detector (MSD). The gas chromatograph was equipped with a 30-m DB-Wax capillary column (J&W Scientific, Folsom, California, 0.25 μm film thickness, 0.25 mm diam.). The oven temperature was held at 40°C for 2 min and then increased by 10°C/min to a final temperature of 210°C. The MSD scanned from 40 to 400 *m/z*. Analyses were also conducted using 30-m DB-5 capillary column (J&W Scientific, 0.25 μm film-thickness, 0.25 mm diam.) with the same temperature program. Identifications were based on comparisons of retention times and mass spectra of the floral volatiles to authentic phenylacetaldehyde (Aldrich Chem. Co., Milwaukee, Wisconsin),

2-phenylethanol (Sigma Chem. Co., St. Louis, Missouri), benzaldehyde (Sigma) and benzyl alcohol (Sigma).

Cabbage looper larvae were reared on an artificial diet following the procedures described by Shorey and Hale (1965). Pupae were separated according to sex. Pupae and adults were held in 3.8-liter paper cartons with nylon screen lids. Males and females were maintained in separate environmental chambers under a photoperiod of 16:8 (light–dark) with temperature cycling from 25°C during the photophase to 22°C during the scotophase. Adults had access to a cotton pad saturated with 10% sucrose–water. In most of the bioassays virgin males were used, but when mated adults were required, 2- to 3-day-old virgin male and female moths were placed together 4 hr into the scotophase in a 40 × 46 × 40-cm (l × w × h) observation box with a clear Plexiglas top that allowed observations to be made under dim red light. Pairs in copula were transferred from the box to 0.5-liter cartons. At the initiation of the photophase, mated males and females were sorted into separate containers by observing the dorsal long abdominal scales found only on males (Grant, 1971b).

To conduct wind-tunnel tests for behavioral responses of *T. ni* to floral volatiles, 3- to 4-day-old adult moths were placed into hardware cloth cylinders (8 × 4.5 cm diam.) with aluminum lids before the start of the scotophase. A wind tunnel similar to that described by Miller and Roelofs (1978) was used. These behavioral assays were conducted under dim red light 0–2 hr after the initiation of a scotophase. Moths were released individually 1.5 m downwind of the stimulus source. Behavioral responses to the test stimulus were noted in the following categories: wing fanning in the release cage (WF), upwind flight in the odor plume (UWF, consisting of repeated counterturns directly downwind of the stimulus source), the distance of the moth's closest approach to the test stimulus, and source contact (SC).

A randomized complete block design was used for four experiments. An arcsine-square root transformation was used on percentage data before analyses of variance were performed. The first experiment included the following test stimuli: a cluster of 10 *A. grandiflora* flowers whose stem was placed in a 4-dram vial with water, and 0.1, 1.0, and 10.0 mg of phenylacetaldehyde in 100 μl of hexane. In all experiments, this volume was delivered onto ca. 35 mg of cotton sealed in the hollow interior of a polyethylene vial cap that had a removable lid (vial closure, 1.9 cm diam. × 1.2 cm high). A 3-mm hole was cut in the cap to increase the rate of volatilization from this source. This experiment consisted of nine blocks with five moths per treatment per block. In the second experiment, a blend of synthetic chemicals was prepared to approximate the blend ratios of compounds identified in volatile emissions from *A. grandiflora* flowers (1.0 mg phenylacetaldehyde, 0.77 mg 2- phenylethanol, 0.80 mg benzaldehyde, 0.13 mg benzyl alcohol in 100 μl of hexane). This synthetic blend and 100 μl of hexane (blank) were delivered to the plastic caps as above.

Again, 10 *A. grandiflora* flowers served as a positive control. Twelve blocks with five moths per treatment per block were used. In the third experiment, an evaluation of male moths' responses to the blend of synthetic compounds was compared to each compound individually (1 mg) (eight blocks, five moths per treatment per block). In the last experiment, an evaluation of the responses of virgin males and females and mated males and females to the complete synthetic blend vs. hexane blank was conducted (eight blocks, five moths per treatment for each sex and mating status per block).

RESULTS

Compounds with retention times (RT) identical to authentic phenylacetaldehyde, 2-phenylethanol, benzaldehyde, and benzyl alcohol were found in volatile collections from flower clusters using relatively polar (DB-Wax, Figure 1) and relatively nonpolar (DB-5) capillary columns. These identifications were supported by mass spectra. Authentic benzaldehyde and the first unknown were characterized by ions at *m/z* 51, 77 (base peak), 105, and 106 (molecular ion). Synthetic phenylacetaldehyde and an unknown peak with RT identical to this

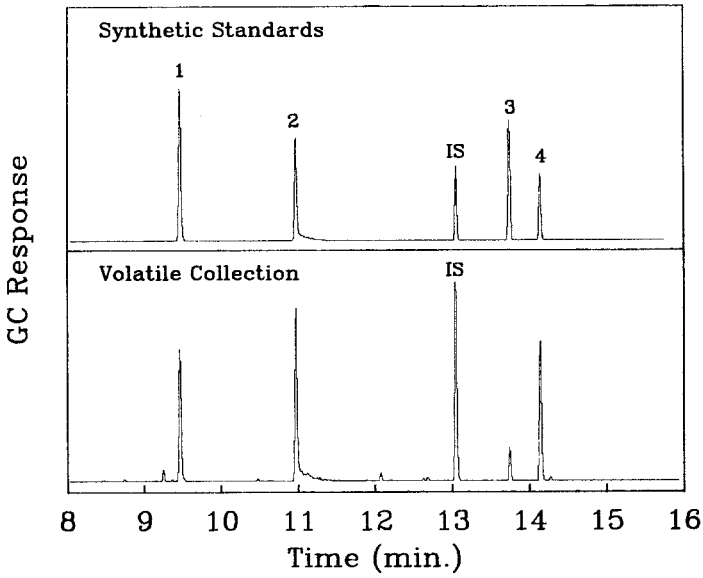

FIG. 1. Total ion chromatograms of synthetic standards and volatile collection from *Abelia grandiflora* flowers. The internal standard (IS) was (*R*)-(+)-1-phenylethanol.**1** = benzaldehyde, **2** = phenylacetaldehyde, **3** = benzyl alcohol, **4** = 2- phenylethanol.

compound were characterized by ions at *m/z* 65, 91 (base peak) and 120 (molecular ion). A third floral compound and authentic benzyl alcohol were characterized by ions at *m/z* 79 (base peak), 107, and 108 (molecular ion). Synthetic 2-phenylethanol and a fourth floral compound were characterized by ions at *m/z* 65, 91 (base peak), and 122 (molecular ion).

The quantity of phenylacetaldehyde, 2-phenylethanol, benzaldehyde, and benzyl alcohol emitted from *A. grandiflora* flowers in a 24-hr period was determined using two capillary columns (Table 1). Results using the DB-Wax column and MS detector indicated that phenylacetaldehyde was the most abundant compound recovered from these collections (37.4%), followed by benzaldehyde (33.3%), 2-phenylethanol (24.2%), and benzyl alcohol (5.1%). Results were similar using a DB-5 column and a flame ionization detector. The results from the DB-Wax column were used to formulate a blend of synthetic compounds that mimics the proportions of compounds found in volatile collections from flowers.

In the first behavioral experiment, 38% of male moths flew upwind and contacted a plastic cap containing 0.1 mg of phenylacetaldehyde, which was significantly lower than the response stimulated by a cluster of flowers (76%, overall $F = 7.7$, $P < 0.05$, analysis of variance, Scheffé's multiple comparison procedure). The percentage of males contacting sources containing 1.0 mg (60%) and 10.0 mg (67%) was not significantly different from the response to the flower cluster ($P > 0.05$). One milligram of phenylacetaldehyde was selected as the standard dose for additional experiments.

The synthetic blend of floral compounds stimulated wing fanning, upwind flight, flight to within 0.5 m, and source contact at levels not significantly different from levels stimulated by a cluster of *Abelia* flowers (Table 2). Of those

TABLE 2. BEHAVIORAL RESPONSES OF MALE *Trichoplusia ni* TO HEXANE CONTROL (BLANK), CLUSTER OF *Abelia grandiflora* FLOWERS, AND BLEND OF SYNTHETIC COMPOUNDS IDENTIFIED FROM THESE FLOWERS ($N = 12$)[a]

Treatment	Behavioral response ± SEM (%)[b]			
	WF	UPW	≤0.5 m	SC
Blank	73.3 ± 4.5b[c]	1.7 ± 1.7b	0 b	0 b
Flowers	86.7 ± 3.8ab	56.7 ± 7.3a	53.3 ± 7.5a	53.3 ± 7.5a
Synthetic Blend[d]	91.7 ± 3.0a	65.0 ± 6.1a	56.7 ± 6.0a	56.7 ± 6.0a

[a] Twelve experimental blocks, each block consisted of five moths released individually to a specific test stimulus.

[b] WF = wing fanning in the release cage; UPW = upwind flight in odor plume; ≤0.5 m = moth progressed to within 0.5 m of the test stimulus source; SC = source contact.

[c] Means in the same column are significantly different if they do not share a letter in common ($P < 0.05$, ANOVA and Scheffé multiple comparison procedure).

[d] The synthetic blend consisted of 1 mg phenylacetaldehyde, 0.77 mg 2-phenylethanol, 0.80 mg benzaldehyde, and 0.13 mg benzyl alcohol applied to plastic cap.

moths that initiated upwind flight to flowers or the synthetic blend, most completed this flight by contacting the source (94.0 and 87.2%, respectively). Wing fanning in the release cage was not a good assay for activity of test stimuli, because the percentage of moths exhibiting this behavior was high even for the hexane (blank) treatment.

The synthetic blend was not significantly better in stimulating source contact than two of its components, phenylacetaldehyde or 2-phenylethanol (Table 3). While moderate numbers of male moths initiated upwind flight to benzaldehyde or benzyl alcohol, very few of these were able to maintain their upwind progress and contact the source.

The synthetic blend stimulated upwind flight to the source in virgin males and females and in mated males and females (Figure 2). There was a significant difference between the blank and synthetic blend regardless of mating status or sex of the moths in terms of the percentage of moths that fanned their wings, initiated upwind flight, progressed to within 0.5 m of the source, and contacted the source ($P < 0.05$, $F = 25$, 103, 140, 196, respectively). Interestingly, the mating status of the moth also had a significant effect on upwind flight, flying to within 0.5 m, and contacting the source ($P < 0.05$, $F = 11$, 7, 7, respectively). Mated moths were less likely to complete this sequence of behaviors than were virgins. Males and females were equally likely to exhibit each of the behaviors recorded ($P > 0.05$, $F = 0$, 0.1, 0.1, 0.3, in sequence).

TABLE 3. BEHAVIORAL RESPONSES OF MALE *Trichoplusia ni* TO FOUR VOLATILE CHEMICALS IDENTIFIED FROM *Abelia grandiflora* FLOWERS AND TO A BLEND OF THESE COMPOUNDS ($N = 8$)[a]

Treatment	Behavioral Response ± SEM (%)[b]

[c] See Table 2 for chemical composition of this blend.
[d] Means in the same column are significantly different if they do not share a letter in common ($P < 0.05$, ANOVA and Scheffé multiple comparison procedure).

DISCUSSION

Phenylacetaldehyde is reported to be an attractant for Plusiinae moths (including *T. ni*) and other Noctuidae (Smith et al., 1943; Creighton et al., 1973). It has been identified as a volatile compound emitted by the bladder flower, *Araujia sericofera* Brothero, that attracts and traps many species of moths (Cantelo and Jacobson, 1979). From our study it appears to be a major constituent of the blend of volatile compounds emitted from flowers of *A. grandiflora*, an ornamental shrub that is frequently visited by *T. ni* moths foraging for nectar (Grant, 1971a).

Another component of the fragrant blend of compounds from these flowers is 2-phenylethanol. 2-Phenylethanol has been identified from male scent brushes of several species of moths (Aplin and Birch, 1970; Birch et al., 1990). Jacobson et al. (1976) isolated this compound from the genital scent brushes of male *T. ni*, but others have been unable to detect it (Hagan and Brady, 1981; Landolt and Heath, 1990). It is possible that the overt behavioral response of female *T. ni* to 2-phenylethanol documented by Jacobson et al. (1976) was due to its proposed role in stimulating nectar-finding behavior, rather than to their proposal that it mediated precopulatory behavior. Benzaldehyde and benzyl alco-

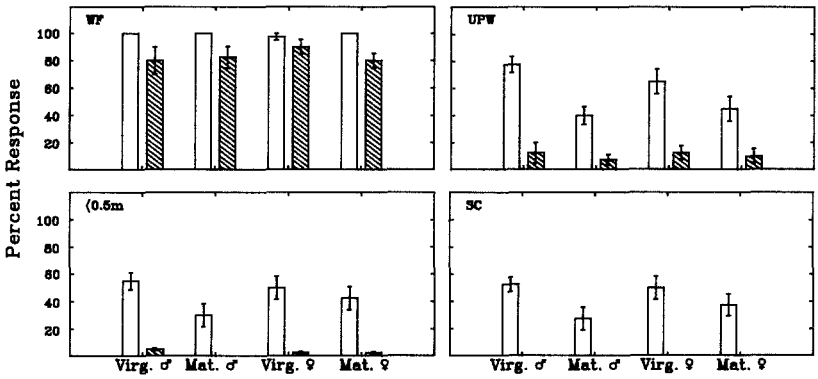

FIG. 2. Behavioral responses of virgin and mated, male and female *Trichoplusia ni* to hexane blank (cross-hatched bars) and a blend of phenylacetaldehyde, 2-phenylethanol, benzaldehyde, and benzyl alcohol (open bars). hol, two additional components of *Abelia's* volatile blend, have been identified from scent brushes of other noctuid moths (see Birch et al., 1990). While our wind tunnel assays have not identified an important role for these two compounds in mediating upwind flight to *Abelia* flowers, it is possible that their presence increases the specificity of the response. Grant (1971a) indicated that mainly plusiine moths were observed feeding on *A. grandiflora* flowers. The response to phenylacetaldehyde includes species from other subfamilies in Noctuidae (Cantelo and Jacobson, 1979). Benzaldehyde has been reported to have a repellent effect on several species of moths (Hirai, 1982). We did not observe any decrease in source location as a consequence of including benzaldehyde in the synthetic blend, and in fact benzaldehyde by itself did stimulate a few moths to fly upwind and contact the source.

The demonstration that a synthetic blend of floral chemicals stimulates upwind flight and source-finding in virgin and mated individuals of both sexes suggests the importance of nectar-finding for reproductive success in all adult *T. ni*. Our finding that mated adults were less successful than virgins in locating these odor sources may reflect a refractory period for foraging behavior after mating. In females, this change could indicate a shift towards ovipositional host-finding activity during the hours in which nectar-feeding usually occurs.

(Received August 9, 1990; accepted November 20, 1990).

Abstract—The response of the striped ambrosia beetle, *Trypodendron lineatum* (Olivier) (Coleoptera: Scolytidae), to a semiochemical-baited funnel trap was studied in a wind tunnel in the first of two experiments. Wind speeds were tested over a range of 0.0–0.9 m/sec. Percent beetle capture decreased linearly with increasing wind speed within the range tested. A second experiment showed that in the presence of wind, beetles flew upwind to a semiochemical-baited substrate. In still air, they tended to fly randomly and erratically; yet in close proximity to the baited substrate, a greater proportion of the beetles were arrested in response to the chemical stimuli and landed on the substrate than when an airflow was present. These results suggest that *T. lineatum* are capable of responding to semiochemicals under varied wind conditions typically present in a forest where they use wind to orient to olfactory stimuli. However, greater numbers are arrested in response to the stimuli under relatively still conditions.

Key Words—*Trypodendron lineatum*, Coleoptera, Scolytidae, flight behavior, wind speed, semiochemicals, wind tunnel.

INTRODUCTION

Several species of scolytid beetles have been found to exhibit upwind flight to attractive material in the field (Chapman, 1962; McMullen and Atkins, 1962; Gara, 1963; Botterweg, 1982; Byers, 1988). It has been difficult to demonstrate

this behavior in a wind tunnel, where only two scolytid species (Choudhury and Kennedy, 1980; Salom and McLean, 1990a), one anobiid species (Birch and White, 1988), and one clerid species (Mizell et al., 1984) have exhibited upwind flight to semiochemicals.

The striped ambrosia beetle, *Trypodendron lineatum* (Olivier) (Coleoptera: Scolytidae), a xylomycetophagous pest of most coniferous tree species in western North America and northern Europe (Borden, 1988), uses semiochemicals to find suitable hosts for colonization, mating, and reproduction. These compounds include the attractive host kairomone, ethanol (Moeck, 1970, 1971), and the aggregation pheromone, lineatin, 3,3,7-trimethyl-2,9-dioxatricyclo[3.3.1.$0^{4,7}$]nonane (MacConnell et al., 1977; Borden et al., 1979). During spring flight dispersal, *T. lineatum* must detect and respond to suitable host material; mainly dead or dying coniferous trees or logs that have aged for at least two months (Mathers, 1935). Temperature (Chapman and Kinghorn, 1958), time of day (Rudinsky and Daterman, 1964), and wind direction (Chapman, 1962; Salom and McLean, 1989) are known to affect general flight activity, but little is known about close-range flight behavior in response to host material (Borden et al., 1986; Byers, 1988).

The wind tunnel studies presented here examined the effect of wind speed on close-range response of *T. lineatum* to a lineatin- and ethanol-baited trap and loglike substrate. The first study was designed to determine the wind speed at which the highest proportion of test beetles would respond positively to a semiochemical-baited funnel trap (Lindgren, 1983). Based on field data from Chapman (1962) and Rudinsky and Daterman (1964), it was hypothesized that the highest proportion of beetles would be captured at the lower end of the wind speed range tested (0.0–0.9 m/sec). A second study was designed to evaluate the flight characteristics of *T. lineatum* in the presence and absence of semiochemicals at different wind speeds. It was hypothesized that different flight behavior characteristics could be identified for beetles responding to semiochemicals under moving and still air conditions.

METHODS AND MATERIALS

Insects. Beetles were collected daily during May and June of 1986 and 1988 in lineatin-baited, multiple-funnel traps placed near a large log boom storage area at the mouth of the north arm of the Fraser River, British Columbia. Captured beetles were stored at 4°C, under a 14:10 hr (light–dark) photoperiod, in 1-liter plastic jars containing slightly moistened cloth towels. The jars were checked twice weekly to maintain appropriate moisture levels. Most beetles survived for 50–100 days under these conditions. Since the beetles were

captured in pheromone traps, they were judged to have had sufficient flight exercise to ensure subsequent response to semiochemicals (Graham, 1959; Bennett and Borden, 1971).

Beetles were sexed and scrutinized for presence of all tarsi, both antennae, and for an overall generally healthy appearance in the morning prior to flight in the wind tunnel. Only beetles that met these standards were tested further. The beetles were allowed to acclimate to the warmer room temperatures (22–25°C) for 10 min before release, a period sufficient to ensure maximal response to the trap (Salom, 1989).

Wind Tunnel. The studies were conducted in a wind tunnel (Angerilli and McLean, 1984), 3.6 m long and 1.2 m high and wide. Cool white fluorescent lights (72 W), set 1.5 m above the wind tunnel, simulated diurnal conditions and facilitated direct observations of flying beetles. A sheet of cellulose acetate was placed over the top of the tunnel to diffuse the incoming light and reduce glare. Vertical light measurements, made 0.8 m from the ceiling in the exhaust, middle, and wind entrance sections of the tunnel, averaged 127 lx (SD = 20 lx). Wind speed measurements were made using a Lambrecht hotwire anemometer (sensitivity = ± 2 cm/sec). No air movement was found to occur along the tunnel, across the tunnel, or vertically within the tunnel at 0.0 m/sec.

A release platform consisting of a circular, flat glass plate 13 cm diam., was suspended horizontally 35 cm above the tunnel floor and 1 m from the downwind screen. Preliminary trials suggested that optimal response by *T. lineatum* occurred when the release platform was placed at this height. It was high enough for beetles to be continuously exposed to the semiochemical plume prior to takeoff (Choudhury and Kennedy, 1980), and we assumed it was close enough to the striped floor to use optomotor cues if needed. The plate was covered with a white industrial paper towel to enhance traction for the insects. A 16-cm^2 $\times$ 0.7-cm-deep plastic weighing boat, covered by the same material, was taped to the upper side of the glass plate. This allowed the beetles two perching opportunities for flight takeoff: the first around the edge of the weighing boat and, if they fell off of that, a second opportunity around the edge of the glass plate.

Effect of Different Wind Speeds on Percent Beetle Capture in Funnel Traps. A multiple-funnel trap, placed in the center of the upwind section of the tunnel, ca. 0.6 m from the screen at the airflow entrance of the tunnel, was baited with two lineatin Biolure dispensers (Consep Membranes of Bend, Oregon), one in the upper and one in the lower portion of the trap, and a plastic bottle dispenser (Phero Tech. Inc., Delta, British Columbia, Canada) containing 95% ethanol in the middle. Release rates, determined gravimetrically at 20°C in the laboratory, were 100–120 μg/day for each lineatin dispenser and 75 mg/day for the ethanol dispenser. The dispensers were identical to those used in mass-trapping programs of *T. lineatum* throughout southwestern British Columbia, and the

release rates were well within the range of rates that elicited positive responses observed for *T. lineatum* in the wind tunnel (Salom and McLean, 1988).

A nine-replicate, randomized complete block design was used, in which the treatments were wind speeds of 0.00, 0.15, 0.30, 0.45, 0.60, 0.75, and 0.90 m/sec (0–3.2 km/hr). For each treatment, males and females were tested separately. Groups of 50 males and 30–50 females were placed on the release tray. All treatments within one block (replication) were run for each sex on the same day, and the experiment was run for nine days over a 21-day period. Each replication of a given treatment lasted for 20 min. Beetles were used only once.

An additional three-replicate, control experiment assessed male and female catches in unbaited traps in still air. Prior to these replicates, the funnel trap, tunnel, and release tray were cleaned with a 0.5% sodium hypochlorite solution.

All data were subjected to analysis of variance with the GLM procedure (SAS, 1985) to test for differences between sex. Since treatment values were set at equal intervals throughout the wind-speed range tested, the data were subjected to orthogonal polynomial analysis (SAS Institute, 1985). This allowed for the prediction of the model needed to "fit" the data for regression analysis (Hicks, 1982).

Flight Behavior at Different Wind Speeds. A preliminary study was conducted in the wind tunnel at 0.3 m/sec wind speed to determine the number of beetles landing in or on various semiochemical-baited substrates. The substrates tested were a 28-cm-diam. × 71-cm-long log of western hemlock, *Tsuga heterophylla* (Raf.) Sarg., oriented either vertically or horizontally across the width of the tunnel; a simulated log (SL) of the same dimensions and orientations as the real log, made of cardboard, cotton fiber tag paper, and construction paper; and a vertically oriented funnel trap. All substrates were baited with two lineatin and one ethanol dispenser. The beetles showed no preference for any substrate or orientation ($F_{4,50} = 0.75$; $P > 0.05$) with mean percent captures ranging from 12.2 to 15.8 (SE = 1.3–2.1). Therefore, a horizontal SL was used to test the effect of wind speed on flight behavior, because it allowed for control of released volatiles not possible with a real log and assumed the position of most infested material in the field. The SL was placed on two concrete blocks with holes to reduce the disruption of air flow. Two lineatin lures and an ethanol dispenser, identical to those used in study 1, were attached to the SL along the upwind side, providing a large, relatively even downwind plume, as verified by releasing $TiCl_4$ smoke at the different wind speeds. The release platform and its placement in the tunnel were the same as in the trap catch study above.

To study *T. lineatum* flight behavior, the overall experiment was divided into two parts. Part 1 examined beetle response to a SL baited with lineatin and ethanol. Part 2 examined beetle response to an unbaited SL, serving as a control. In each part, beetles were studied at wind speeds of 0.0, 0.3, 0.6, and 0.9

m/sec. Parts 1 and 2 were conducted on separate experimental days. The tunnel and the release platform were carefully cleaned with a 0.5% sodium hypochlorite solution prior to running part 2.

Two beetles of the same sex were released per replicate and observed for up to 8 min in the experiment. Fifty replicates were run for each level of wind speed and baiting treatment (lineatin and ethanol or none) tested. Beetles were used only once. Observation parameters included occurrence of flight, body orientation prior to and during flight takeoff (relative to the SL and the direction from which the wind was blowing), overall flight direction, type of flight, and lock-on behavior.

Overall flight direction was scored as uptunnel, downtunnel, or nondirectional, depending upon the predominant direction flown by the insect throughout the observation period. If beetles did not exhibit predominant up-or downtunnel flight, they were considered nondirectional fliers. These categories were based on the general amount of time a beetle spent in each section of the tunnel.

Type of flight was scored as: (1) erratic—quick, sharp changes in movement, with no specific direction of flight; (2) steady—slow and stable, with a narrow flight line that may have included more than one directional heading throughout the flight period; and (3) direct—a fast, straight-line flight to some endpoint, with only one directional heading. Sometimes beetles exhibited and were recorded having more than one type of flight behavior.

Lock-on behavior in this study was considered steady flight in a predominantly uptunnel direction, with the insect orienting specifically toward the SL, and finally hovering around or landing on the SL. This differs from the traditional definition used for Lepidoptera, where the moths narrow their flight track in a zigzag pattern during upwind flight (Sweeney and McLean, 1987).

All observations were recorded on a cassette tape and later transcribed onto data sheets. The data were summarized as frequencies and analyzed separately, for each behavioral category, as multidimensional contingency tables using the CATMOD procedure in SAS Institute (1985). This procedure uses a linear models approach to the analysis of categorical data, applying general weighted least-squares regression techniques to cell proportions in complex categorical data layouts (Kleinbaum and Kupper, 1978). This approach allowed us to test for first-and second-order interactions, main effects, and contrast between levels of main effects, for a specific response, using the chi- square (χ^2) statistic.

RESULTS

Effect of Different Wind Speeds on Percent Beetle Capture in Funnel Traps. The relationship between the numbers of *T. lineatum* caught at different wind speeds did not differ between sexes ($F_{1,102} = 2.42$; $P > 0.05$); therefore, the

data were pooled. A linear model was determined to be the best fit of the data for regression analysis ($F_{1,107} = 65.7$; $P < 0.001$). The percent of beetles captured in the traps decreased as wind speed increased within the range tested (Figure 1). However, much of the variation in these data is not explained by the regression ($r^2 = 0.33$). The high variation in the results may be due in part to the varied physiological states (e.g., varying energy reserves) of the beetles (Atkins, 1966; Borden, 1982), or perhaps the conditions in the wind tunnel were not optimal for *T. lineatum* response, or both. Beetle responses to the unbaited control treatment in still air averaged only 2.7% (SE = 1.0), indicating lack of contamination in the tunnel and little attraction to the trap alone.

Flight Behavior at Different Wind Speeds. The number of beetles taking flight was not influenced by wind speed. However, frequency of flight was analyzed by sex and bait separately because of a significant interaction occurring between these factors ($\chi^2_1 = 17.1$; $P \leq 0.01$), with less males responding than females to a baited SL (Table 1).

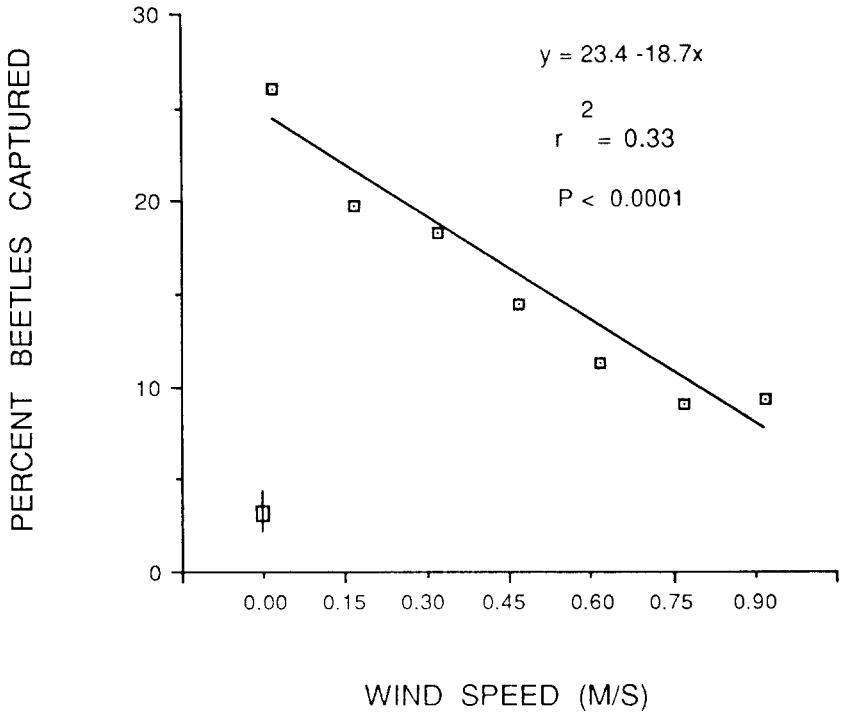

FIG. 1. The percent capture of *Trypodendron lineatum* in a semiochemical-baited funnel trap in a wind tunnel at different wind speeds. The box with a vertical line represents the mean percent ± SE response of the beetles at 0.0 m/sec to an unbaited funnel trap.

0.6	47	76
0.9	45	67

[a] One hundred beetles released for each wind speed of each bait treatment. No significant differences in number of beetles flying, where each sex within each bait treatment was analyzed separately.

Most beetles faced uptunnel prior to and during takeoff (Figure 2). Body orientation did not differ between males and females ($\chi^2_3 = 4.4$; $P > 0.05$); therefore, the data for both sexes were pooled. Uptunnel body orientation increased significantly in the presence of an airflow for both baited and unbaited treatments (Figure 2). The presence of semiochemicals did not result in increased uptunnel orientation, but it did result in a significant increase in the occurrence of nondirectional orientation at 0.3 m/sec ($\chi^2_4 = 9.6$; $P < 0.05$).

Overall flight direction did not differ between males and females ($\chi^2_2 = 4.7$; $P > 0.05$); therefore, the data were pooled. Upon exposure to wind, flight direction changed from uptunnel and nondirectional to downtunnel for both the baited and unbaited treatments (Figure 3). Increases in wind speed above 0.3 m/sec did not cause any further change in flight direction for the baited treatment, but it did cause an increase in downwind flight for the unbaited treatment. A higher frequency of beetles exhibited uptunnel flight in the presence of semiochemicals, with statistical differences occurring at wind speeds of 0.3 ($\chi^2_2 = 7.1$; $P < 0.05$), 0.6 ($\chi^2_2 = 10.9$; $P < 0.01$), and 0.9 m/sec ($\chi^2_2 = 8.8$; $P < 0.05$).

Data for type of flight showed significant speed by bait ($\chi^2_6 = 20.3$; $P < 0.005$) and by sex ($\chi^2_6 = 16.4$; $P < 0.05$) interactions, leading to a separate analysis for each factor and preventing statistical comparisons between the factors. However, in still air, steady flight of both sexes appeared to be more frequent in response to the baited treatment than to the unbaited treatment (Fig-

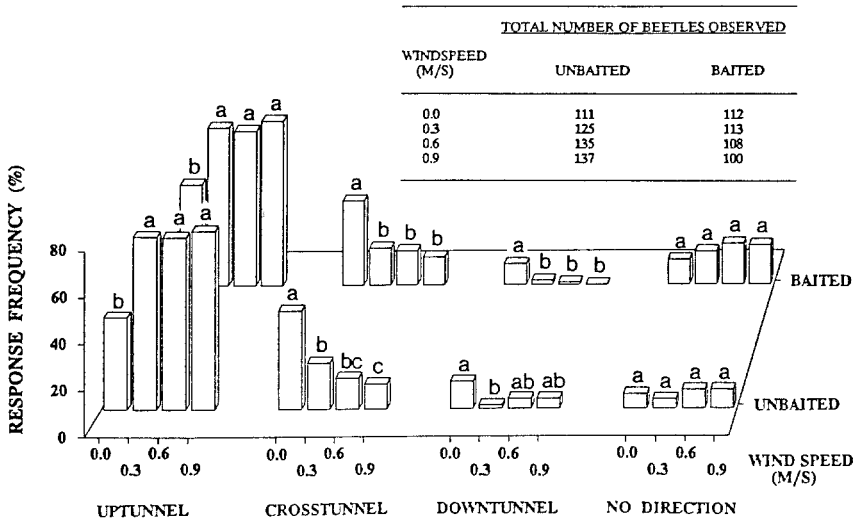

FIG. 2. Body orientation of *T. lineatum*, prior to and during flight takeoff, at different wind speeds and in the presence of an unbaited and semiochemical-baited simulated log. Male and female data were pooled. Bars with different letters for each orientation within a bait treatment category are significantly different (χ^2; $P \leq 0.05$), for individual comparisons. Orientation categories are relative to the simulated log and the direction from which the wind was blowing. Nondirectional orientation was tallied for beetles facing toward the floor from the edge or underneath the tray.

ure 4). Occurrence of steady flight decreased significantly in the presence of wind for the baited treatment, compared to no difference observed for beetles in the unbaited treatment. The frequency of erratic flight displayed by female beetles in response to both baited and unbaited SLs decreased significantly as wind speed increased from 0.6 to 0.9 m/sec (Figure 4). In response to the baited SL, the frequency of erratic flight of male beetles varied significantly, with no apparent pattern to changing wind speed, but was unchanged in response to the unbaited treatment (Figure 4). As wind speed increased from 0.6 to 0.9 m/sec, erratic and steady flight decreased for both males and females, while direct flight increased.

No differences in lock-on responses were observed between males and females ($\chi^2_2 = 1.94$; $P > 0.05$); therefore, the data were pooled. The frequency of *T. lineatum* exhibiting a lock-on response to a baited and unbaited SL interacted significantly with wind speed ($\chi^2_6 = 32.9$; $P < 0.001$), preventing statistical comparisons between the two treatments. However, the lock-on response was generally higher in the presence of semiochemicals at all wind speeds than when the semiochemicals were absent (Figure 5). The differences in response

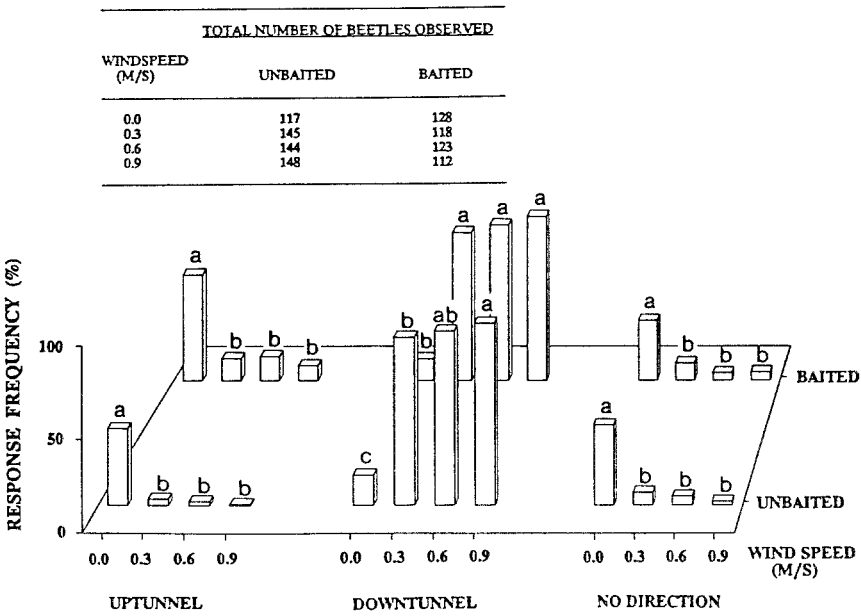

FIG. 3. Overall flight direction exhibited by *T. lineatum*, at different wind speeds, in the presence of an unbaited and semiochemical-baited, simulated log. Male and female data were pooled. Bars with different letters for each directional flight response within a bait treatment category are significantly different (χ^2; $P \leq 0.05$) for individual comparisons.

between these treatments were especially noticeable in the absence of wind, where 54% of the flying beetles showed lock-on behavior in the presence of a baited SL, with 29% landing on it, compared to only 8% locking on in the presence of an unbaited SL, of which less than 5% landed. The frequency of the responses decreased in the presence of an airflow, yet increasing wind speed from 0.3 to 0.9 m/sec did not result in further decreases.

DISCUSSION

In the first study, the decrease in the number of beetles caught in the funnel traps, with increased wind speed, was expected since *T. lineatum* prefer to fly under low wind speed conditions (Rudinsky and Daterman, 1964). The high frequency of beetle capture in still air was unanticipated. The data suggest that, depending on the presence or absence of wind, *T. lineatum* may use different mechanisms or flight patterns for orienting toward and landing on host material. This is not unlike the different mechanisms used by *Ips paraconfusus* Lanier

WINDSPEED (M/S)	TOTAL NUMBER OF BEETLES OBSERVED			
	MALES		FEMALES	
	UNBAITED	BAITED	UNBAITED	BAITED

0.3	64	40	72	74
0.6	75	44	64	73
0.9	65	41	74	67

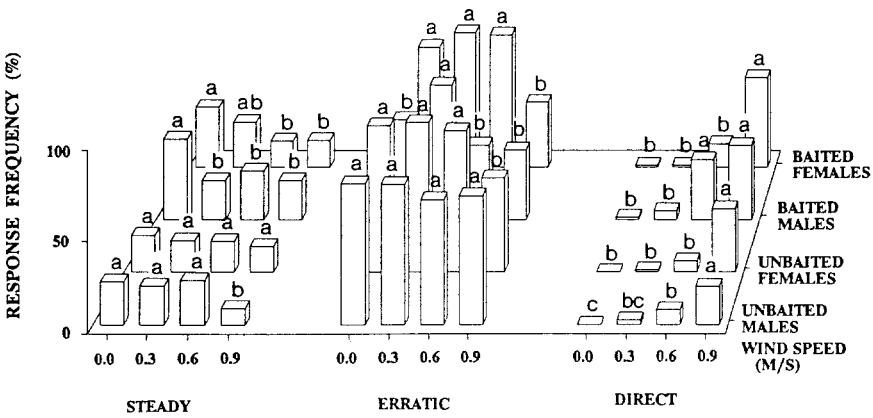

FIG. 4. Type of flight exhibited by *T. lineatum*, at different wind speeds, in the presence of an unbaited and semiochemical-baited simulated log. Bars with different letters for flight type response within each bait treatment and sex category are significantly different (χ^2; $P \leq 0.05$) for individual comparisons.

observed in pedestrian bioassays in the absence and presence of wind (Akers and Wood, 1989a,b).

In the second study, the occurrence of flight was unaffected by wind (Table 1), and may have been due to the range of wind speed we tested being below the threshold observed to inhibit beetle flight in the field (Chapman, 1962).

In still air, the higher frequencies of lock-on and landing response to a semiochemical-baited SL seem to have resulted from random flight bringing the beetles close to the SL by chance, followed by arrestment. This interpretation is based mostly on observation and could not be deduced from the categorical data collected, since we recorded up to three types of flight for each beetle, with none being mutually exclusive (Figure 4). Arrestment at the SL suggests chemotaxis as a possible mechanism. Akers and Wood (1989a) demonstrated that walking *I. paraconfusus* were capable of responding chemotactically from a distance of 16–18 cm away from a pheromone source in still air. Visual attraction to the silhouette also may have contributed to beetle arrestment. Further studies are needed to separate the effects of both olfactory and visual stimuli on *T. lineatum* arrestment.

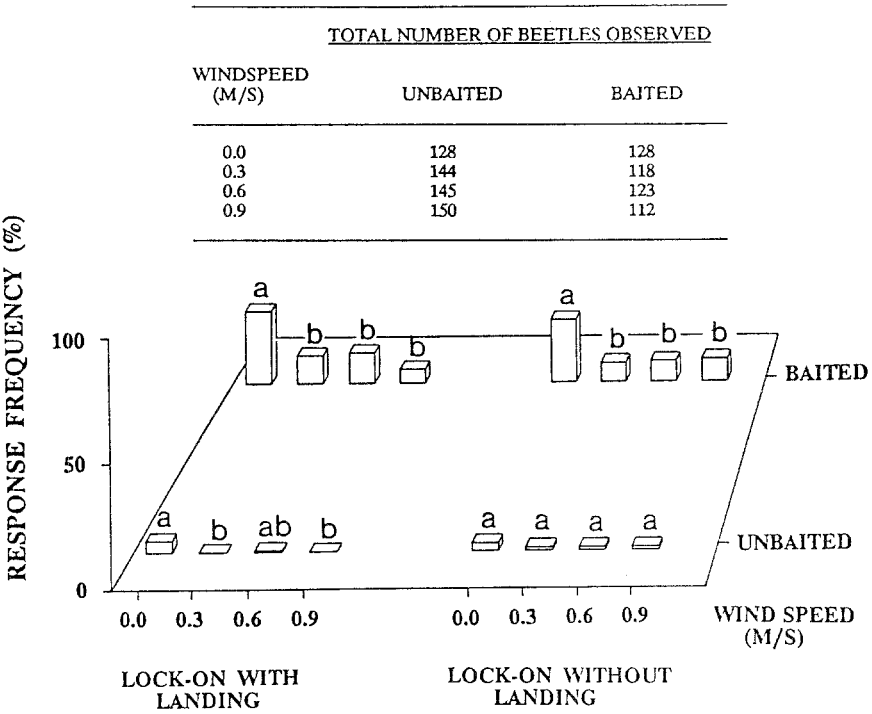

FIG. 5. Lock-on response exhibited by *T. lineatum*, at different wind speeds, in the presence of an unbaited and semiochemical-baited simulated log. Male and female data were pooled. Bars with different letters for each behavior within a bait treatment category are significantly different (χ^2; $P \leq 0.05$) for individual comparisons.

Compared to still air conditions, *T. lineatum* flight behavior changed in the presence of wind. Overall flight direction shifted substantially from uptunnel to downtunnel at a wind speed as low as 0.3 m/sec (Figure 3).

In the field, *T. lineatum* have been observed flying upwind to attractive sources (Chapman, 1962; Salom and McLean, 1989, 1990b), however close-range (i.e., < 1 m) orientation and landing on the host substrate does not appear to require air movement. The responses reported in wind-tunnel studies by Choudhury and Kennedy (1980) for *Scolytus multistriatus* (Marsh.), Birch and White (1988) for *Anobium punctatum* (Deg.), and Mizell et al. (1984) for *Thanasimus dubius* (F.) did not test insect response to a pheromone source in still air. In studies with Lepidoptera, Farkas and Shorey (1972) first demonstrated that the pink bollworm, *Pectinophora gossypiella* (Saund.), did not require moving air to fly toward a pheromone source. Baker and Kuenen (1982) confirmed these results with *Grapholita molesta* (Busk.) and showed that the zig-

zagging mechanism used by these moths to orient to the odor source would not change if wind was removed once the behavior had been initiated. Little evidence is currently available to indicate this behavior is also used by scolytids (Byers, 1989).

With wind present, beetles tended to fly downwind, away from the source of semiochemicals (Figure 3). Despite the constant exposure of the beetles to the semiochemical plume, only 20% of the beetles flew upwind. The high frequency of nonresponders may have been a result of the artificial conditions imposed on the beetles by the wind tunnel (i.e., lack of space for full flight behavior).

Another explanation for the low frequency of upwind flight to a baited substrate may be due to the variation in physiological state of individual beetles, considered an important factor in influencing orientation of bark beetles to olfactory stimuli. Borden (1982) and Wood (1982) hypothesized that some beetles respond immediately to semiochemicals and colonize suitable host trees nearby, while others fly for a period of time before responding and thus start new centers of attraction at greater distances. Atkins (1966, 1969) determined that there was a strong correlation between dispersal distance and fat content in *Dendroctonus pseudotsugae* Hopk. Physical state of the beetles, such as nematode or microorganism infection, also may play a role in this (Nickel, 1971). *Trypodendron lineatum* was not evaluated for the presence of such infections in this study. Although we are not sure of the physiological mechanism influencing *T. lineatum*, we believe the variability in response behavior within a population may account for the high variation in response for our study. Variation in scolytid response and difficulty in eliciting beetle response to semiochemicals in a wind tunnel have been reported for other scolytids (Byers, 1988; Akers and Wood; 1989b). Even in pedestrian bioassays, low frequency of ambrosia beetle response to semiochemicals is quite common, with 40–50% response being the highest observed (Borden et al., 1976; MacConnell et al., 1977).

The decreases in *T. lineatum* response to semiochemicals at increasing wind speeds correspond well with observations in field situations, where twice as many marked *T. lineatum* were recaptured in a forest when wind speed averaged less than half the normal speed (i.e., 0.18 m/sec compared to 0.39 m/sec) (Salom and McLean, 1990a). Other scolytids such as *D. frontalis* Zimm. (Vité et al., 1964) and *D. ponderosae* (Edson, 1978) have been captured in higher numbers during periods of calm air.

It may be argued that by increasing the wind speed in the tunnel, a decrease in the size of the semiochemical plume would result, reducing the chance that beetles will respond while in flight. Sanders (1985) showed that a plume of smoke released from a point source the size of a lure decreased in size with an increase in wind speed. However, in our studies, a test with $TiCl_4$ smoke showed

that the plume sizes did not decrease significantly between 0.25 and 0.75 m/sec from the simulated log.

In relating our wind-tunnel results to *T. lineatum* dispersal and subsequent attraction to host material, it is important to understand beetle response capabilities under varied environmental conditions as well as their own varied physiological states. In a mark–recapture study, Salom and McLean (1991) found that beetles were consistently recaptured in significantly higher numbers (ratio of 3:1) in the forest than in open settings, although the latter settings were closer to the beetle release sites. Wind speed was ca. 4× higher in the open than in the forest, supporting the hypothesis that low wind speed is critical in arresting beetle flight at sources of attraction. The field data, as well as the wind-tunnel study reported here, suggest that once *T. lineatum* reach within 1 or 2 m of the host, arrestment and subsequent landing on the host is best facilitated during periods of light or no wind. When wind is present, *T. lineatum* can orient to and land on a host, but will do so at lower frequencies. The differences in *T. lineatum* flight behavior in the absence and presence of wind, as they search for attractive host material, allow them to optimize their search by enabling them adapt to the varying environmental conditions encountered.

(Received September 10, 1990; accepted November 20, 1990)

Abstract—Originally isolated from *Dipterocarpus kerrii*, the two previously uncharacterized sesquiterpenes, **1** and **20**, were synthesized from α-gurjunene. A novel process involving *m*-chloroperoxybenzoic acid oxidation of α-gurjunene produced **20** in one step. Spectroscopic studies determined that the diene moiety in **20** is nonconjugated and also found the C-4 tertiary alcohol center to have the α-configuration, while the other stereocenters have configurations matching the corresponding centers in α-gurjunene. Bioassays with termites demonstrated that **20** was more toxic than **1**, resulting in a 50% mortality in seven days when offered to *Neotermes ?dalbergiae* on filter papers. The chemicals appear to result from biotransformation of α-gurjunene. In view of its similarity to the known sesquiterpene γ-gurjunene, we suggest that **20** be referred to as γ-gurjunenol.

Key Words—*Dipterocarpus kerrii*, sesquiterpenes, chemical synthesis, dienol, tropical biology, termiticide, *Neotermes*, α-gurjunene, γ-gurjunene, γ-gurjunenol, bioassay, stereochemistry.

INTRODUCTION

Many tropical trees produce resins that possess a number of biologically active natural products. These provide chemical defense against insects and fungi

*To whom correspondence should be addressed.

[1] Presented at the ICSE/PSNA Joint Meeting, August 11–15, 1990, Université Laval, Québec City, Québec, Canada.

0098-0331/91/0300-0663$06.50/0

(Langenheim, 1990). In forests of Southeast Asia, trees of the plant family Dipterocarpaceae are well known for their production of resins. Often containing sesquiterpenes, these resins circulate throughout the tree.

In addition to several known sesquiterpenes isolated from the biologically active fractions of dipterocarp tree resins (Messer et al., 1990), we have discovered two novel sesquiterpenes (Richardson et al., 1989). Because these novel compounds could have contributed to the biological activity of impure fractions of resins of the Southeast Asian tree *Dipterocarpus kerrii* King, additional investigation was needed to determine whether the chemicals could be of ecological significance. Although structures for these novel compounds were proposed, the limited amounts of these compounds available prevented a definitive assignment of stereochemistry and toxicity (Richardson et al., 1989).

Refinement of stereochemical detail in the assigned structures and additional bioassays required preparation of gram quantities of the previously unknown compounds. Additionally, since these compounds are labile and are found only in fresh resins gathered from trees growing in the Malay Archipelago, a synthetic source of the compounds was required to permit further study. In this paper, we describe the preparation of the novel sesquiterpenes from their probable biosynthetic precursor, α-gurjunene, which is itself the major component of *D. kerrii* resin. We report the final and complete structure and stereochemistry of **20**, as well as a novel route for its preparation. Bioassays demonstrated pronounced termiticidal activity for **20**, but the related structure, **1**, was much less toxic.

METHODS AND MATERIALS

Solvents and Chemicals

Unless otherwise noted, all reaction solvents and reagents used were anhydrous commercial grade. Reactions were conducted under an atmosphere of anhydrous nitrogen in glassware that had been oven dried overnight at 130–140°C and allowed to cool under a stream of nitrogen.

α-Gurjunene. For the majority of these studies, enriched samples of α-gurjunene were obtained via purification of crude *D. kerrii* resin. By GLC analysis, the composition of crude resin was found to be approximately 85% α-gurjunene. Using fractional vacuum distillation, material of 89–92% purity could be obtained, and this was used as starting material in most of the studies directed at preparation of **1** and **20**. Samples of starting material obtained in this fashion were contaminated with other resin components with GLC retention times and TLC mobilities very similar to those for α- gurjunene, but further purification was not attempted. These contaminants did not complicate any of the chemical reactions described and were not found to interfere in the purifi-

cation of the desired reaction products. Experiments requiring very pure starting material utilized >97% pure (−)-α-gurjunene purchased from Fluka Chemie, AG. Our previous work established that (−)-α-gurjunene is the major volatile component in crude *D. kerrii* resin (Richardson et al., 1989).

γ-Gurjunene. Studies involving γ-gurjunene utilized >98% pure material from Fluka Chemie, AG.

Instrumentation

Natural and synthetic chemicals of interest were identified using a combination of analytical thin-layer chromatography (TLC), gas–liquid chromatography (GLC), gas chromatography–mass spectrometry (GC-MS), Fourier transform-nuclear magnetic resonance spectroscopy (both [^{1}H]- and [^{13}C]NMR), ultraviolet spectroscopy (UV), and infrared spectroscopy (IR).

Analytical TLC was performed on precoated plates (0.25 mm, silica gel, Kodak, Rochester, New York). Spots were visualized by examination under ultraviolet light and/or treatment with anisaldehyde spray reagent (90% of a 5% solution of *p*-anisaldehyde in ethanol–5% glacial acetic acid–5% concentrated sulfuric acid) followed by brief heating with a heat gun.

Analytical GLC was performed with a Varian model 1800 gas chromatograph equipped with a flame ionization detector and a fused silica NON-PAKD capillary column (SPB-1, dimethylpolysiloxane, 0.5 mm × 15 m, Supelco, Inc.) with a carrier gas (helium) flow rate of 30 ml/min. Samples were analyzed with oven temperature held at 150°C for 5 min followed by programming at 20°C/min to 250°C. Injector and detector temperatures were 250°C.

GC-mass spectra were measured with electron impact (EI) ionization at 70 eV using a Hewlett-Packard GC-MS system consisting of the following components: a model 5890 gas chromatograph fitted with a fused silica capillary column (HP-1, cross-linked methylsilicone, 12 m × 0.2 mm × 0.33 μm film thickness, helium carrier gas, 12 psi) coupled to a model 5971A mass selective detector. Capillary split injection (50:1) was used with an injector temperature of 250°C. Samples were analyzed with oven temperature held at 150°C for 5 min followed by programming at 20°C/min to 250°C.

NMR spectra were measured on an IBM-Bruker model WP200SY (200 MHz) NMR spectrometer. Spectra were measured in $CDCl_3$ or deuteriobenzene solution containing 0.05% v/v tetramethylsilane (TMS) as internal standard. [^{1}H]NMR data are presented as follows: chemical shift in ppm on the δ scale relative to internal TMS [multiplicity, number of hydrogens, coupling constant(s) in Hertz]. [^{13}C]NMR data were measured at 50.3 MHz using broadband ^{1}H decoupling and are presented in ppm on the δ scale relative to internal TMS, chloroform solvent (77.0 ppm), or benzene (128.0 ppm).

Ultraviolet spectra were measured on a Perkin-Elmer model Lambda 3A

UV/visible spectrophotometer. Infrared spectra were obtained on a Perkin-Elmer model 283B spectrophotometer with samples as thin films or in $CHCl_3$ solution. Optical rotations were measured on a Perkin-Elmer model 241 polarimeter in a 1-dm cell.

Purification of synthetic materials was performed using flash chromatography (Still et al., 1978) on silica gel (average particle size 40 μm, J.T. Baker, Phillipsburg, New Jersey) using the indicated solvent for elution.

Purification and Syntheses

α-Gurjunene, 3 (Figure 1). Vacuum distillation (0.7 mm) of crude *D. kerrii* resin (7.7 g; 85% α-gurjunene, GLC analysis) gave two fractions, each as a light yellow oil: 77–78°C (4.44 g; 89% α-gurjunene by GLC; 56% recovery) and 79–80°C (0.99 g; 92% α-gurjunene by GLC; 13% recovery). Pot residues from each vacuum distillation of crude resin were retained and combined. Vacuum distillation (2.5 mm) of this material (23.47 g; 70% α-gurjunene by GLC) yielded additional material (5.95 g; 25% recovery) of somewhat lower purity (80% α-gurjunene by GLC).

Conjugated Dienol, 1 (Figure 1). To a solution of partially purified **3** (2.79 g, 89% α-gurjunene, equivalent to 2.48 g, 12.1 mmol of pure **3**) in glacial acetic acid (6.9 ml) and freshly distilled acetic anhydride (8.3 ml) was added selenium dioxide (0.55 g, 4.97 mmol). The resulting reddish-brown mixture was stirred magnetically at room temperature for 24 hr, a second portion of selenium dioxide (0.56 g, 5.08 mmol) was added, and the solution was stirred at room temperature for an additional period of three days.

The mixture was diluted with methylene chloride and suction filtered through a pad of Celite. Water (20 ml) was added to the filtrate, which was stirred at room temperature for 2 hr and then concentrated in vacuo to remove water and acetic acid. The resulting crude product was dissolved in chloroform (50 ml), washed with water (3 × 30 ml) and saturated $NaHCO_3$, and dried over anhydrous Na_2SO_4. Removal of the drying agent and evaporation of the solvent gave 4.86 g of crude acetate **5** as a brown oil. TLC analysis (90:10 hexanes–ether) showed the major product as a spot with $R_f = 0.5$. Purification by flash chromatography (90:10 hexanes–ether) gave 1.11 g (40% yield) of pure acetate **5** as light yellow oil. IR and [^{1}H]NMR data (reported below) were in agreement with those of other workers (Streith and Ourisson, 1963).

Lithium aluminum hydride (0.48 g, 12.6 mmol) was weighed into a 500 ml three-necked round-bottom flask fitted with a 50-ml pressure-equalizing addition funnel and a reflux condenser. Anhydrous ether (38 ml) was added via the addition funnel and the resulting slurry was stirred magnetically at room temperature. A solution of **5** (2.57 g, 9.87 mmol) in anhydrous ether (27 ml) was introduced dropwise via the addition funnel over the course of 0.5 hr and

the funnel was rinsed with a second volume of ether (20 ml), which was added to the reaction mixture. After stirring at room temperature for 40 min, ethyl acetate (6.3 ml, 64.2 mmol) was added via the addition funnel to quench excess hydride, and the mixture was stirred for 10 min. Next, a solution of methanol and water (50:50 v/v, 25 ml) was added and the mixture was stirred for an additional 90 min. The mixture was washed with water (3 × 20 ml), dried over Na_2SO_4, and concentrated in vacuo to give 1.02 g of crude **1** as a brown oil with a single major spot at R_f = 0.44 by TLC (50:50 hexanes–ether). Purification by flash chromatography (50:50 hexanes–ether) gave 0.43 g (20% yield) of pure conjugated dienol **1**. [^{1}H]NMR and IR data (reported below) were in agreement with those previously reported (Streith and Ourisson, 1963); IR, [^{1}H]NMR, [^{13}C]NMR (see Table 1) and GC-MS data (reported below) were in agreement with data for natural **1** (Richardson et al., 1989).

Conjugated Dienol ***1.*** IR (thin film): 3401, 1706, 1459, 1380 cm^{-1}; [^{1}H]NMR: δ 0.68 (d, 3H, J = 7), 1.21 (two overlapping s, 6H total), 1.27 (m, 2H), 1.71 (br. s, 3H), 1.78 (br. d, 1H, J = 11), 1.9–2.1 (m, 3H), 2.12 (br. d, 1H, J = 18), 2.29 (m, 1H), 2.45 (br. dd, 1H, J = 8, 18), 3.34 (m, 1H), 5.4 (m, 1H), 5.67 (br. s, 1H); [^{13}C]NMR: (Table 1); UV (cyclohexane): λ_{max} = 244 nm (ϵ = 12,900); $[\alpha]_D$ = +55.1° (c = 1.67 × 10^{-3} g/ml, CCl_4); GC-MS *m/z* (rel. intensity): 220 (M^+, 0.8), 205 (1.0), 202 (M-H_2O, 23.5), 187 (15.8), 162 (16.2), 161 (9.8), 159 (58.4), 147 (19.5), 145 (46.6), 133 (22.3), 131 (57.2), 120 (27.2), 119 (40.5), 107 (24.2), 105 (76.3), 94 (27.0), 91 (88.2), 81 (35.1), 79 (38.3), 77 (44.7), 59 (43.4), 41 (100).

Nonconjugated Dienol ***20*** *(γ-Gurjunenol, see Figure 8) Epoxidation at 0°C.* To a solution of *m*-chloroperbenzoic acid (80% pure, 0.465 g, 2.15 mmol) in methylene chloride (20 ml) at 0°C was added, via syringe, α-gurjunene, **3** (80% pure, 0.50 g, 1.96 mmol) in methylene chloride (10 ml). The reaction mixture was stirred magnetically at 0°C for 10 min, diluted with methylene chloride (10 ml), and washed with saturated aqueous Na_2CO_3 (3 × 15 ml). After drying (Na_2SO_4), concentration in vacuo afforded 0.73 g of crude product as a colorless oil with a major product spot at R_f = 0.51 by TLC analysis (70:30 hexanes–ether). Purification by flash chromatography (70:30 hexanes–ether) gave pure **20** (0.173 g, 43% yield) as a colorless oil. Two minor products were also observed by TLC (R_f = 0.40 and 0.26). These were isolated as a mixture from flash chromatography of the crude epoxidation reaction mixture. Analysis

by IR and [^{1}H]NMR showed these materials to be the *m*-chlorobenzoic acid esters, **21**, epimeric at C-4 (see Figure 9). Present in roughly equal amounts ([^{1}H]NMR analysis), these materials were isolated in 24% yield (0.175 g) based on starting **3**. The more polar epimer was determined to have an α C-4 tertiary hydroxyl group by correlation with structure **20** using the following chemical modifications: benzoate ester elimination (KOtBu, DMF, 150 C, 1.5 hr) from the more polar epimer produced **20**, while the same conditions with the less polar epimer produced isomeric material.

20. IR, [^{1}H]NMR, [^{13}C]NMR (see Table 2) and GC-MS data were in agreement with data for natural **20** (Richardson et al., 1989). IR (thin film): 3453, 2965, 1645, 1448, 1378, 1187 cm^{-1}; [^{1}H]NMR: δ 0.83 (d, 3H, J = 7), 1.27 (s, 3H), 1.28–1.5 (br. m, 4H), 1.72 (br. s, 3H), 1.40–1.89 (br. m, 6H), 2.85 (m, 1H), 3.03 (m, 1H), 4.68 (br. s, 1H), 4.76, (br. s, 1H), 5.71 (dd, 1H, J = 3.2, 6.5); [^{13}C]NMR: (Table 2); UV (cyclohexane): no absorption; $[\alpha]_D$ = +143° (c = 3.5 × 10^{-4} g/ml, CCl_4); GC-MS *m/z* (rel. intensity): 220 (M^+, 14.1), 205 (M-CH_3, 30.8), 202 (9.0), 187 (14.8), 173 (5.5), 162 (100), 159 (24.6), 149 (35.5), 147 (29.5), 145 (22.5), 131 (20.4), 120 (17.3), 119 (46.1), 117 (12.3), 107 (43.3), 105 (58.6), 95 (23.7), 93 (48.1), 91 (60.4), 81 (22.3), 79 (53.1), 77 (36.4), 67 (22.2), 55 (31.7).

21. The following data are for a 50:50 mixture of epimers at C-4. IR (thin film): 3450, 2955, 1717, 1550, 1295, 1263, 1125; [^{1}H]NMR: δ 0.85 (d, 3H, J = 7), 0.91 (d, 3H, J = 7), 1.28 (s, 3H), 1.34 (s, 3H), 1.55 (s, 3H), 1.57 (s, 3H), 1.59 (s, 3H), 1.605 (s, 3H), 1.65–2.10 (overlapping multiplets, 20H, total for both epimers), 2.95–3.30 (overlapping multiplets, 2H, total for both epimers), 5.75 (m, 2H, total for both epimers), 7.36 (dd, 2H, total for both epimers, J = 7, 7), 7.50 (m, 2H, total for both epimers), 7.85 (m, 2H, total for both epimers), 7.95 (m, 2H, total for both epimers).

Epoxidation at −50°C. To a slurry of *m*-chloroperbenzoic acid (80% pure, 0.116 g, 0.538 mmol) in methylene chloride (3 ml) at −50°C was added, via syringe, α-gurjunene, **3** (Fluka, 0.100 g, 0.489 mmol) in methylene chloride (1 ml); a second portion of methylene chloride (1 ml) was used to rinse the syringe and was added to the reaction mixture. The reaction was stirred magnetically at −50°C for 10 min, was diluted with methylene chloride (10 ml) and was washed with saturated aqueous Na_2CO_3 (3 × 5 ml). After drying (Na_2SO_4), concentration in vacuo afforded 0.142 g of crude product as a colorless oil. TLC analysis showed the same product mixture as reaction at 0°C, but analysis by [^{1}H]NMR showed the crude mixture to contain approximately 50% of a new product (tentatively identified as epoxide **6**), along with the same mixture of products observed in epoxidations conducted at 0°C. Purification by flash chromatography (70:30 hexanes–ether) gave pure **20** (0.082 g, 76% yield) as a colorless oil. Epoxide **6** was not isolated and apparently rearranged to **20** during chromatography.

Dihydro-13,14-γ-gurjunenol ***14*** *(see Figure 5).* To γ-gurjunenol, **20** (0.104 g, 0.469 mmol) dissolved in 95% ethanol–benzene (50:50 v/v, 7.5 ml) in a 20 ml test tube was added $(Ph_3P)_3RhCl$ (Wilkinsons's catalyst, 50 mg), which slowly dissolved with swirling to give a deep orange solution. The test tube was placed in a Parr hydrogenation apparatus, which was sealed, evacuated with a water aspirator, and then filled with hydrogen (45 psi). The evacuation–hydrogen pressurization operations were repeated three times, and the reaction mixture was agitated under 45 psi of hydrogen. After 6 hr, the system was brought to atmospheric pressure and a 0.25-ml aliquot was removed and concentrated in vacuo. Analysis by [^{1}H]NMR showed complete consumption of starting material and the presence of single new product, **14**. TLC analysis (70:30 hexanes–ether) showed a single spot with the same R_f (0.51) as starting material. Flash chromatography (50:50 hexanes–ether) afforded pure **14** as a colorless oil (0.468 g, 45% yield). IR ($CHCl_3$, 0.07 M): 3600, 2960, 1465, 1382 cm^{-1}; [^{1}H]NMR: δ 0.79 (d, 3H, J = 7), 0.845 (d, 3H, J = 6.4), 0.850 (d, 3H, J = 6.4), 1.29 (s, 3H), 1.31–1.47 (overlapping multiplets, 3H), 1.51–1.98 (overlapping multiplets, 9H), 3.09 (m, 1H), 5.77 (d, 1H, J = 3.4, 6.1).

5,6-Epoxydihydro-13,14-γ-gurjunenol ***19*** *(see Figure 8).* To a solution of *m*-chloroperbenzoic acid (80%, 0.168 g, 0.077 mmol) in methylene chloride (1 ml) at 0°C was added **14** (0.0157 g, 0.0706 mmol) in methylene chloride (0.3 ml) via syringe. The syringe was rinsed with fresh methylene chloride (2 × 0.3 ml), which was added to the reaction mixture. After 2.5 hr, TLC analysis (50:50 hexanes–ether) showed complete consumption of starting **14** (R_f = 0.40) and a single new product spot (R_f = 0.56). The reaction mixture was diluted with methylene chloride (10 ml), washed with saturated Na_2CO_3 (10 ml), and dried (Na_2SO_4). Concentration in vacuo afforded crude **19** (0.0138 g) as a colorless oil. Analysis of this material by [^{1}H]NMR showed no starting material and a single epoxide product. Purification by flash chromatography (90:10 hexanes–ether) gave pure **19** as a colorless oil (0.0102 g, 61% yield). IR ($CHCl_3$, 0.07 M): 3495, 2965, 1468, 1386, 1188 cm^{-1}; [^{1}H]NMR: δ 0.97 (d, 6H, J = 6.7), 1.02 (d, 3H, J = 7.7), 1.22 (s, 3H), 1.23–1.57 (overlapping multiplets, 4H), 1.6–1.8 (overlapping multiplets, 2H), 1.81–1.93 (overlapping multiplets, 5H), 2.52 (br. t, 1H, J = 9.1), 2.86 (s, 1H, -OH), 3.08 (s, 1H, epoxide-H).

Termite Bioassays

Bioassays were conducted in Bogor, Indonesia (Messer et al., 1990). Solutions of test chemicals were prepared in dichloromethane to dispense 1-, 5-, and 10-mg quantities of the compounds onto 4.5-cm-diameter Whatman No. 1 filter paper circles. Control filter papers were treated with dichloromethane. After the solvent had been allowed to evaporate off at ambient temperature (25–31°C), the filter papers were placed in 5-cm Petri dishes. To each of the eight replicate

dishes prepared for each condition, 25 *Neotermes ?dalbergiae* termites were added. Thus at the beginning of a bioassay, $N = 200$ for each condition. At daily intervals the number of termites surviving was recorded, dead termites were removed, and the filter papers were moistened with water. Except when being counted, termites were kept covered, in a darkened room, at ambient laboratory temperatures and humidity (25–31°C, ca. 85% relative humidity). Bioassays were terminated after 14 days.

Statistical Testing

All statistical tests were performed on untransformed data with Data Desk (Velleman, 1989). A normal distribution was confirmed for all data prior to statistical testing. Statistical significance of treatment effects was determined by performing pooled *t* tests on counts of termites surviving at day 14 in each dish of a condition and in control dishes at the same time point. A one-way analysis of variance of counts of termites surviving at day 14 was used to determine if application rates were significant for each test chemical.

RESULTS AND DISCUSSION

Structural Analysis

Our initial investigation of the chemical ecology of the dipterocarp *D. kerrii* had located two novel sesquiterpene dienols in the termiticidal and fungicidal fractions of this tree's resin (Richardson et al., 1989). Following extensive spectroscopic work, these materials were assigned the structures **1** and **2** (Figure 1). Neither of these compounds had been isolated previously from a natural source, although **1** had been reported (Streith and Ourisson, 1963) as a product of synthetic manipulations of α-gurjunene, **3**. The need to extend the toxicity studies begun in our initial investigation, and the need to confirm and complete

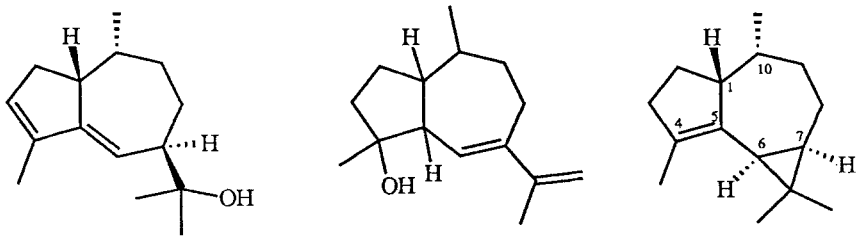

FIG. 1. Sesquiterpenes isolated from *D. kerrii* resin. Structure **2** has been revised to **20**; see text.

the structural assignments for **1** and **2** made in that work, required efficient, nonambiguous chemical syntheses of these sesquiterpenes.

Preparation of **1** was straightforward and followed the two-step process previously developed (Streith and Ourisson, 1963) in structural work with α-gurjunene (Palmade et al., 1963). In our hands, the first step, oxidation of **3** with selenium dioxide in acetic anhydride, produced the dienol acetate **5** in 40% yield. As shown in Figure 2, this process is believed (Streith and Ourisson, 1963) to proceed via initial allylic oxidation at C-3, followed by olefin isomerization with concomitant rupture of the cyclopropane, and is terminated by capture of the C-11 carbocation center in **4** by acetate. Subsequent reduction of **5** with lithium aluminum hydride produced the target dienol **1** in 20% yield (Newton, 1989).

Our spectroscopic data (IR and [^{1}H]NMR) for **5** and **1** matched those reported by Ourisson for these materials (Streith and Ourisson, 1963). More importantly, our data (GC-MS, [^{1}H]NMR, and [^{13}C]NMR) (Table 1) for synthetic **1** matched our previously measured data for naturally occurring **1** (Richardson et al., 1989). These data make it clear that our original structural assignment for the sesquiterpene dienol **1** was correct.

In contrast, we found our UV and optical rotation data for synthetic and natural **1** (Richardson et al., 1989) to differ somewhat: natural **1**: UV (cyclohexane) λ_{max} = 243 nm (ϵ = 2400); $[\alpha]_D$ = +50° (c ≈ 2 × 10^{-4} g/ml, CCl_4); synthetic **1:** UV (cyclohexane) λ_{max} = 244 nm (ϵ = 12,900); $[\alpha]_D$ = +55.1° (c = 1.67 × 10^{-3} g/ml, CCl_4). We feel this disagreement simply indicates that the very small sample of **1** (<0.2 mg) that we originally isolated was not pure. This is not surprising in view of the considerable lability of **1**, which we have reported previously (Richardson et al., 1989).

The lability of these materials posed a significant difficulty in our initial structural work, particularly in studies with the second sesquiterpene dienol. Due to the limited quantity of this dienol available for spectroscopic study and due to its slow but steady decomposition in NMR solvents, we were able to report only a preliminary structure (**2**) for this natural product in our previous publication (Richardson et al., 1989). As shown in Figure 1, we originally proposed that **2**, like **1**, was a member of the guiane sesquiterpene family and

[a]Spectra were measured in C_6D_6.

contained both tertiary alcohol and conjugated diene moieties. However, we were unable to assign the stereochemical configuration of C-1, C-4, C-5, and C-10, and the determination of these centers was one of the primary reasons for developing a synthetic route to **2**.

It can be seen that structure **2** is isomeric with dienol **1**. The ready availability of synthetic **1**, using the chemistry discussed above, initially made attractive a synthetic route to **2** via isomerization of **1**. Although conceptually straightforward, we decided that isomerization of **1** was impractical due to the marginal stability of the highly substituted dienols involved. Furthermore, this preparative approach would not be unambiguous with respect to construction of the C-4 and C-5 stereocenters. Instead, we pursued a more novel route for synthesis of this material, which would provide efficient access to synthetic **2** and which would also use α-gurjunene as starting material.

Our plan, as diagrammed in Figure 3, was to treat α-gurjunene with *m*-chloroperbenzoic acid (MCPBA) to prepare epoxide **6**. This material, either after isolation or *in situ* during the epoxidation process, would then undergo acid-promoted epoxide cleavage, via intermediate **7**, to produce carbocation **8** after rearrangement and cyclopropane cleavage. Ultimately, **8** would undergo deprotonation, under the action of exogenous base, to give either the conjugated dienol **9** or the nonconjugated dienol **10** as final product. (Of course, substitution, via direct capture of carbocation **8**, could compete with this process.) We anticipated that **10** would be the preferred product of this process since its for-

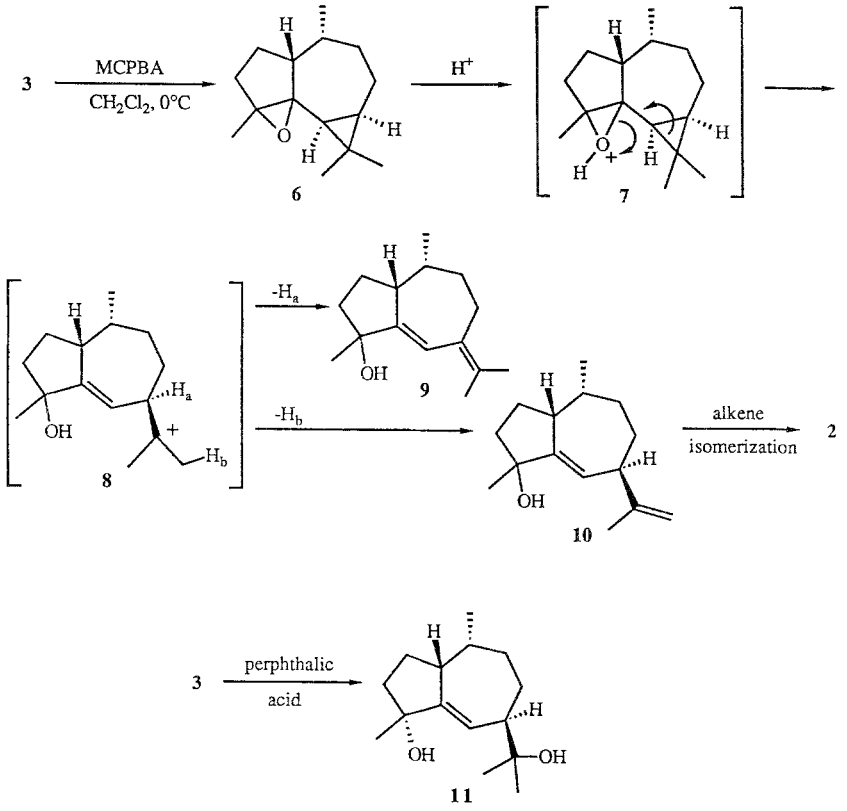

FIG. 3. Synthesis plan for preparation of dienol **2** from α-gurjunene, **3**.

mation via deprotonation is statistically more likely and because the stability of the conjugated diene **9** should be offset by steric factors since its C-7/C-11 double bond is both exocyclic and tetrasubstituted. Final conversion of **10** into the target dienol **2** would require isomerization of its C-5/C-6 double bond into conjugation with its isopropylidene unit. Although we anticipated that this process would require some experimentation, literature reports of this type of transformation using organometallic reagents (Curran et al., 1987; Whitesides and Neilan, 1976) gave us confidence that this overall approach was sound.

In addition, a general literature precedent existed for this epoxidative transformation of α-gurjunene. As depicted in Figure 3, a previous study reported preparation of diol **11** from treatment of α-gurjunene with the epoxidizing agent perphthalic acid (Palmade et al., 1963). This study did not establish the mechanism for formation of this material, but it is reasonable to suggest that it arises via trapping, by an oxygen-containing nucleophile, of an intermediate carbo-

cation like **8** in Figure 3. Ourisson established that the C-4 tertiary alcohol in this material had α-configuration, as shown in structure **11**, implying that the epoxidation process had proceeded on the α-face of the C-4/C-5 double bond in **3**. Similar stereochemical results have been observed in reactions of **3** with diborane (Pesnelle and Ourisson, 1965) and with osmium tetroxide (Palmade et al., 1963). Hence, it was anticipated that our approach to **2** would give material with the following stereochemical detail: (1) The C-1 and C-10 centers would have configurations identical to those in α-gurjunene. (Since dienol **1** was found to have this stereochemistry at C-1 and C-10, we anticipated that these centers would be the same in **2**.) (2) C-4 would carry an α-tertiary alcohol group. (Our prediction was that MCPBA, like other electrophiles studied, would attack α-gurjunene from the α-face of the alkene to provide a final product with an α-tertiary alcohol center.) (3) The C-5 configuration would require determination. (Prediction of the configuration at this center was difficult since it would depend upon the process used to isomerize **10** to **2**.) Thus, although it was uncertain if this route would provide material with stereochemical configuration exactly identical to natural **2**, we were confident that it would give rapid access to material which would have the correct connectivity and which would answer several of our configurational questions.

In the event, we were delighted to find that treatment of α-gurjunene with 1.1 equivalents of MCPBA (methylene chloride, 0°C) resulted in complete consumption of starting material in 10 min (GLC analysis) and gave a crude product whose [^{1}H]NMR spectrum was almost identical (Newton, 1989) to original spectra for natural **2**! Although this crude material contained several products, analysis by both TLC and GLC showed a single major product that could be isolated in pure form by flash chromatography. Both [^{1}H]NMR and [^{13}C]NMR (Table 2) data for this synthetic material matched those we originally measured for natural **2** (Richardson et al., 1989). We interpreted this result to mean that MCPBA-epoxidation of **3** had proceeded to intermediate diene **10** as depicted in Figure 3 and that this material had subsequently undergone acid-catalyzed isomerization to **2** *in situ*. The isolated yield for **2** under these conditions was 33–48%.

Although IR data for natural and synthetic **2** were also in good agreement (see above), two other measurements were not. First, the rotation for freshly purified synthetic **2** was higher than that measured for natural **2** (synthetic **2**: $[\alpha]_D = +143°$ c $= 3.5 \times 10^{-4}$ g/ml, CCl_4; natural **2**: $[\alpha]_D = +63°$ c $\approx 2 \times 10^{-3}$ g/ml CCl_4; Richardson et al., 1989). As with the comparison of synthetic and natural **1** above, we interpreted this result simply to mean that our original sample of natural **2** had not been pure. However, we also found that freshly purified samples of synthetic **2** showed no significant UV absorption, meaning that this substance did not contain a UV chromaphore, while natural material had shown a peak at $\lambda_{max} = 219$ nm ($\epsilon = 1400$). Since it was evident

[a]Structure **2** has been revised to **20**; see text. Spectra were measured in $CDCl_3$.

that the NMR data for the natural and synthetic materials matched, this result implied that our initial structure assignment for dienol **2** was in error. It was evident, however, that the nature of our error would have to be fairly minor and that the major details in our original structure had to be correct, since the structure of the starting material for our one-step synthetic process had so many parallels with the structure for **2** originally proposed.

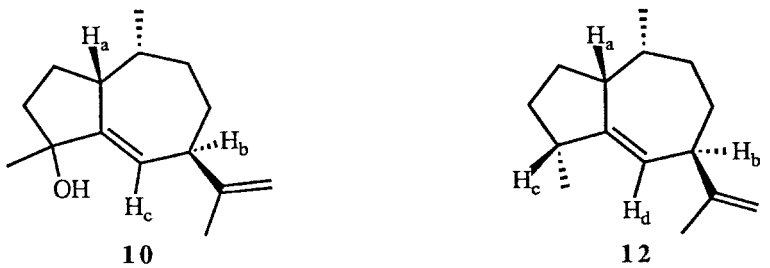
The simplest solution to this problem was to retain the guiane sesquiterpene framework for **2** and to hypothesize that the diene system in this material was nonconjugated. The alkene signals in NMR spectra (^{1}H and ^{13}C) of **2** clearly indicate the presence of an isopropylidene moiety and a second, trisubstituted double bond. Thus, the most straightforward modification of structure **2** meeting these requirements was to position the trisubstituted alkene at C-5/C-6 rather than C-6/C-7. This produced the nonconjugated dienol **10** (see Figure 9), the same structure which appeared as an intermediate in our original synthetic route to **2**, above (Figure 3).

Proving that **10** was in fact the correct structure for both our second *D. kerrii* dienol and the product of MCPBA epoxidation of α-gurjunene required: (1) establishing that the diene system was nonconjugated, with the trisubstituted double bond at C-5/C-6; and (2) determining the configuration of the C-4 tertiary alcohol center. The configurations of the centers at C-1, C-7 and C-10 in **10** were assigned to be identical with the configurations of the corresponding centers in α-gurjunene. This was logical since the epoxidation process produc-

ing **10** from α-gurjunene would not have affected the configurations of these centers.

Unfortunately, attempts to determine directly the stereochemical configuration of **10** using difference NOE and two-dimensional NOE (NOESY) techniques were inconclusive. As a result, it was necessary to employ an indirect approach, involving chemical modification, in order to prove and refine our new hypothetical structure for compound **10**. Fortunately, our structural work with **10** was aided by the availability of a naturally occurring sesquiterpene with marked structural similarities to **10**, namely γ-gurjunene, **12**. As shown in Figure 4, γ-gurjunene essentially duplicates hypothetical structure **10**, with the exception that C-4 in this material, which bears an α-methyl group, lacks a tertiary alcohol moiety. Hence, both literature data for γ-gurjunene (Ehret and Ourisson, 1969) and data acquired through our own measurements (Richardson and Lindeman, unpublished data) served as a useful reference for confirming and refining hypothetical structure **10**.

For example, [^{1}H]NMR spectra for γ-gurjunene and **10** show strong parallels. The allylic protons in **12** appear in two groups: H_a and H_b (C-1 and C-7, respectively, Figure 4) overlapping at δ 2.85, and H_c (C-4) at δ 2.50 (Richardson and Lindeman, unpublished data). As revealed in the spectroscopic data above, compound **10** shows two allylic signals at δ 3.03 and 2.85, which can be reasonably labeled, in analogy with the assignments in **12**, as H_a and H_b, respectively (Figure 4). Compound **12** shows an olefin proton signal at δ 5.40 (H_d) which appears as a double-double-doublet due to coupling with all three allylic protons H_a, H_b, and H_c. A similar double-doublet signal is present in the [^{1}H]NMR of **10** at δ 5.71. By analogy with **12**, it is reasonable to conclude that this signal in **10** corresponds to a trisubstituted olefin proton on C-6 (labeled H_c), which couples to the two allylic protons at C-1 (H_a) and C-7 (H_b). Finally, both compounds show the presence of isopropylidene olefin protons, but with slight differences: **12**: δ 4.72 and 4.73 (500 MHz, Messer et al., 1990; these signals are unresolved at 200 MHz, Richardson and Lindeman, unpublished data); **10**: δ 4.76 and 4.68 (200 MHz, Newton, 1989). These differences



10 **12**

FIG. 4. Structure of γ-gurjunene (**12**) and partial revised structure (**10**) for dienol **2**.

in chemical shift are probably due to subtle conformational effects that place the isopropylidene groups in **10** and **12** in slightly different magnetic environments.

Likewise, [^{13}C]NMR spectra for the two compounds have similar chemical shifts for the four olefinic carbons in each molecule: **10**: δ 152.09, 145.83, 123.85, 110.96 (Richardson et al., 1989); **12**: δ 150.48, 147.13, 122.28, 110.52 (Richardson and Lindeman, unpublished data). Furthermore, just as we established for compound **10**, γ-gurjunene is not UV-active (Ehret and Ourisson, 1969). Thus, all of the NMR data, and the lack of UV activity for these materials, suggest that the diene systems are similar in both sesquiterpenes (e.g., both contain an isopropylidene group and a trisubstituted double bond) and lend support to our hypothesis that **10** includes a nonconjugated diene. Since the olefinic proton H_c in **10** shows allylic coupling to both H_a and H_b, the only reasonable position for the trisubstituted double bond was at C-5/C-6.

Additional support for these conclusions was obtained by studying chemical modifications of **10** and **12**. Previous workers (Ehret and Ourisson, 1969) had shown that selective reduction of the isopropylidene double bond in **12** could be accomplished, using hydrogen in the presence of Wilkinson's catalyst (Figure 5), to give a 92% yield of dihydro-13,14-γ-gurjunene, **13**. Although somewhat slower (6 hr vs. 2.5), reduction of **10** under these conditions dis-

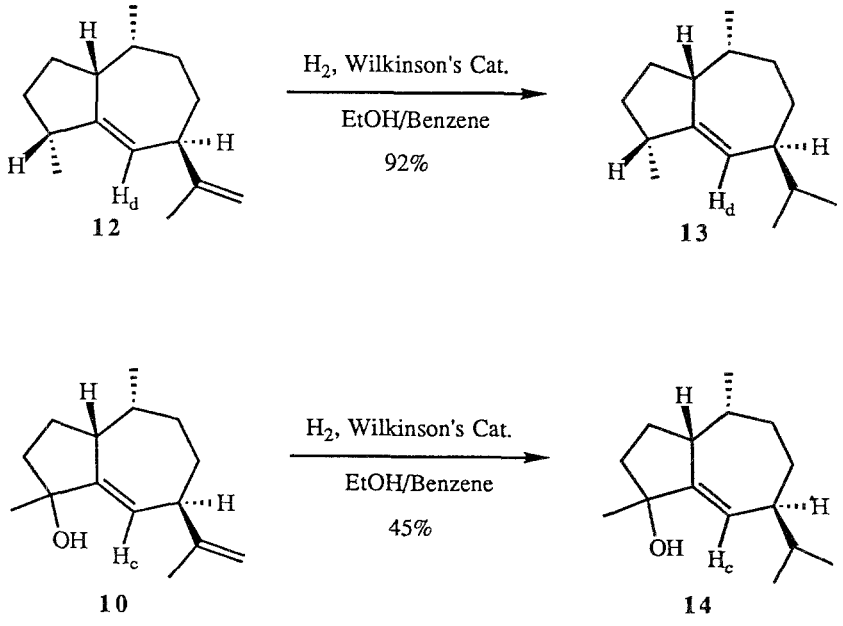


FIG. 5. Selective hydrogenations of **12** and **10**.

played the same selectivity for the disubstituted double bond, giving dihydro-13,14-**10** (**14**, Figure 5) in 45% yield.

The selectivity of these reductions could be verified by the following features in the corresponding [^{1}H]NMR spectra: (1) the disappearance of the signals for the isopropylidene olefin and methyl group protons; (2) the appearance of isopropyl methyl group doublets in **13** (δ 0.88 and 0.85, Richardson and Lindeman, unpublished data) and in **14** (δ 0.855 and 0.850); (3) the disappearance of one of the original allylic proton signals in both **10** and **12** [e.g., the signal for H_b (Figure 4) in both **10** and **12** is shifted upfield since this proton is no longer doubly allylic after reduction]; and (4) the multiplicity and chemical shift of trisubstituted olefin proton signals in both **10** and **12** (H_c and H_d, respectively, in Figures 5 and 6) were changed only slightly by the reduction [H_d: **12**, δ 5.40, (ddd); **13**, δ 5.42, (ddd); H_c: **10**, δ 5.71, (dd); **14**, δ 5.80, (dd)]. In both reactions, selective reduction of the disubstituted double bonds was good evidence that the diene systems were nonconjugated, since hydrogenation of conjugated dienes is usually complicated by poor selectivity and double-bond migration (e.g., 1,2- and 1,4-hydrogen addition; Cais, 1964). Hence, although the yield for reduction of **10** was somewhat lower than that for **12**, due to the inherent liability of the allylic alcohol system, this final piece of chemical evidence placed the nonconjugated diene structure we have assigned to compound **10** on a firm footing.

With the position of the trisubstituted double bond in **10** located at C-5/C-6, the final structural problem to solve was the configuration of the C-4 ter-

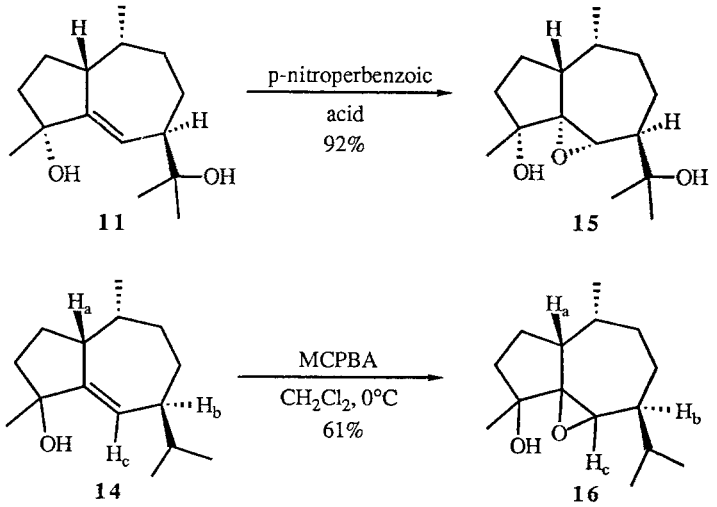

FIG. 6. Epoxidation of allylic alcohols **11** and **14**.

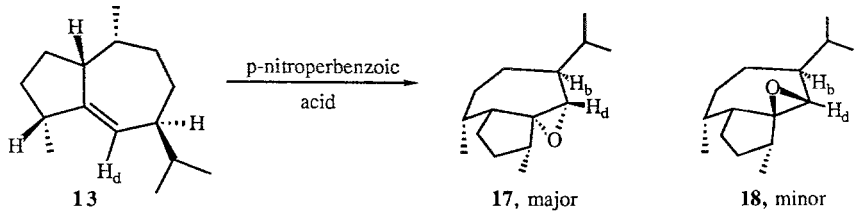
tiary alcohol center. We accomplished this assignment using a chemical modification approach that mirrored the original structural studies on both α- and γ-gurjunene (Streith and Ourisson, 1963). As shown in Figure 6, *p*-nitroperbenzoic acid epoxidation of the diol **11**, obtained from perphthalic acid oxidation of α-gurjunene (Figure 3), proceeded to give epoxide **15** (Palmade et al., 1963). Using IR spectroscopy, the stereochemical relationship between the C-4 hydroxyl center and the epoxide was deduced as follows: At high dilution, **15** showed two hydroxyl bands at 3615 cm^{-1} and 3510 cm^{-1} in its IR spectrum, which were assigned as free (C-13) and internally hydrogen-bonded hydroxyl groups (C-4), respectively. An intramolecular hydrogen bond at the C-4 hydroxyl group was interpreted to mean that this group was associated with the new epoxy group, which required that both groups be positioned on the same face of **15**. This interpretation was strengthened by the known tendency of allylic alcohol epoxidations to occur under the stereochemical direction of the hydroxyl group (Henbest and Wilson, 1957; Tanaka et al., 1974).

With this approach, treatment of our monohydroxy compound **14** with MCPBA produced a single epoxide product (TLC and [^{1}H]NMR analysis) in 61% yield. High-dilution (0.07 M) IR spectra for this epoxide product showed a single band in the hydroxyl region at 3495 cm^{-1}, while **14** had shown hydroxyl absorption at 3600 cm^{-1} at same concentration. This implied, as with compound **15**, that epoxidation of **14** had produced a product containing an intramolecular hydrogen bond between epoxide and hydroxyl groups. This result indicated that the epoxide and hydroxyl groups in this material were syn, but, as shown in structure **16** (Figure 6) for this product, this information alone did not enable us to assign the configuration of the C-4 hydroxyl group. As above, a syn relationship between these groups had been anticipated on the basis of the usual internal asymmetric induction observed in epoxidation of allylic alcohol systems.

A configurational assignment for C-4 could be made, however, using [^{1}H]NMR data for compound **16**. As with compound **10**, discussed above, the olefin proton (H_c, Figure 6) on the trisubstituted double bond in compound **14** appears as a double-doublet due to coupling with allylic protons H_a and H_b. Upon epoxidation, the signal for this proton is shifted to δ 3.08 and appears as a singlet, implying that in compound **16** this proton has adopted a new configuration that does not have the proper dihedral angles with respect to H_a and H_b to allow for coupling. This observation may be used to infer the stereochemical relationship between the known C-7 isopropyl group center and the C-5/C-6 epoxide centers, and, hence, can be used to deduce the configuration of the C-4 hydroxyl group.

Making these deductions relies upon reference to [^{1}H]NMR data measured in earlier γ-gurjunene structural studies (Ehret and Ourisson, 1969). As depicted in Figure 7, it was found that *p*-nitroperbenzoic acid epoxidation of dihydro-

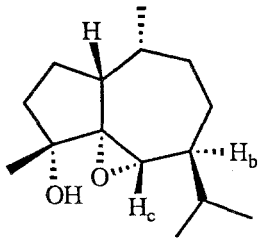


13 17, major 18, minor

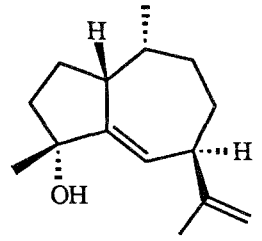
FIG. 7. Epoxidation of dihydro-13,14-γ-gurjunene (**13**) and stereochemistry of product epoxides.

13,14-γ-gurjunene, **13** (Figure 5), produced a pair of epoxide products, **17** and **18**, in yields of 52% and 5%, respectively. The signals for the epoxide protons (H_d) in the [^{1}H]NMR spectra of these materials appeared as follows: **17**, δ 3.12, (singlet); **18**, δ 3.00, (doublet, J = 4 Hz). Using conformational arguments, Ehret and Ourisson convincingly demonstrated that the only structures for **17** and **18** that were consistent with the measured NMR data were those shown in Figure 7. In these structures, both epoxides adopt a quasiboat conformation for the cycloheptane system, with **17** being the α-epoxide and **18** being the β-epoxide. In this conformation, the dihedral angles between H_d and H_b in **17** and **18** are 90° and 60°, respectively. Thus, as observed, and in agreement with the usual Karplus relationships, coupling between these protons would not be expected in **17**, while a small coupling would be expected in **18**.

Although we isolated only a single epoxide product, **16**, from epoxidation of our compound **14** (Figure 6), the structural similarity between our system and those in Ourisson's studies made the remaining configurational assignment in **16** straightforward. As previously discussed, the signal for epoxide proton H_c (on C-6) in **16** appears as a singlet (δ 3.08) in the [^{1}H]NMR spectrum of this material. Since it is reasonable to assume that the cycloheptane system in **16** would adopt a conformation similar to that in Ourisson's systems **17** and **18** (e.g., quasiboat), a singlet for H_c indicates that this proton does not couple with the C-7 proton (H_b). This result, in analogy to **17**, implies a *trans* relationship between these protons, with H_c being β (Figure 6). A β position for H_c requires the C-5/C-6 epoxide to be in the α position. Finally, since our previous IR measurements had determined a syn relationship between the epoxide and hydroxyl groups, an α-epoxide implied that the C-4 tertiary alcohol group must also be in the α position. Thus, structure **19** results (Figure 8) as a complete assignment for the epoxide, shown as partial structure **16**, above. This information for **19** implies that the C-4 hydroxyl group in the second sesquiterpene dienol that we originally isolated from *D. kerrii* resin (Richardson et al., 1989) is also α, and, thus, our final structure assignment for this material is **20**, depicted in Figure 8. Hence, the major direction of attack by MCPBA during



19



20

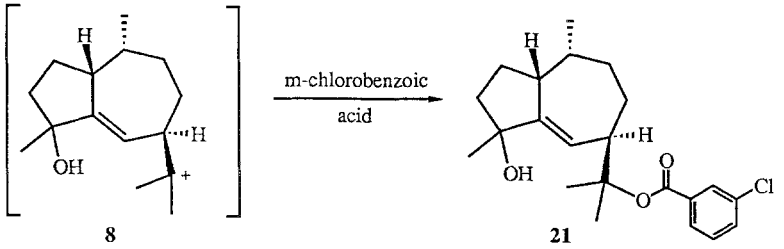
FIG. 8. Structure of epoxide from epoxidation of allylic alcohol **14** and final revised structure for dienol **20**, γ-gurjunenol (originally assigned structure **2**, see text).

epoxidation of α-gurjunene is on the α-face of the C-4/C-5 double bond, which agrees with observations recorded for various other electrophiles, as discussed above. In view of the marked structural similarities which exist between the second *D. kerrii* dienol and γ-gurjunene, we suggest that **20** be referred to as γ-gurjunenol. To the best of our knowledge, this is the first report of structure **20** in the literature.

In addition to **20**, crude epoxidation mixtures also showed the presence of two more polar products by TLC analysis (70:30 hexanes–ether; R_f = 0.40 and 0.26, respectively). These products could be isolated in pure form and were established, through chemical modification studies and analysis of IR, [^{1}H]NMR, and GC-MS spectra, to be the m-chlorobenzoic acid esters, **21**. Epimeric at the C-4 tertiary alcohol center, these side products were isolated in essentially equal amounts (10–14% yields) and presumably arise via trapping of the intermediate carbocation **8** (Figure 9) by m-chlorobenzoic acid present in epoxidation reaction mixtures.

Interestingly, when epoxidation of α-gurjunene was conducted at −50°C, this process was essentially just as rapid as at 0°C (complete in 10 min, GLC) but, after the same workup, it gave a crude product, which [^{1}H]NMR analysis showed to include approximately 50% of a previously unobserved material. This new product was quite labile and would disappear ([^{1}H]NMR analysis) if left standing in $CDCl_3$ solution at room temperature for 48 hr. Attempts to observe this new product using other analytical techniques (GC-MS, TLC) were unsuccessful. Finally, we were surprised to find that immediate column chromatography of the crude product from reaction at −50°C produced a 76% yield of **20**—a significantly higher yield than observed in epoxidations at 0°C.

We interpreted these results to mean that at both reaction temperatures epoxidation proceeds initially to give the intermediate epoxide **6**, as shown above in Figure 3. Apparently, at 0°C, this material undergoes fairly rapid protonation by the acid present to give the unstable intermediate **7**, which then solvolyzes to give **20**, along with the usual ester side products, **21**. At −50°C, however,



8 21

FIG. 9. Proposed mechanism for formation of m-chlorobenzoic acid ester side products, **21**, during epoxidation of α-gurjunene.

protonation and/or subsequent solvolysis appear to be much slower, and once the reagent-derived acids are removed in the workup, a sufficient amount of epoxide **6** then survives to be observed by [^{1}H]NMR. We conclude that due to its expected acid lability, epoxide **6** decomposes during chromatographic purification of the crude product on silica gel, producing a higher net yield of the desired product, **20**, since MCPBA and its reaction products are no longer present to complicate this process. The acid lability of this new product, our putative epoxide **6**, could be confirmed directly with simple [^{1}H]NMR experiments. For example, addition of 0.25 ml of 0.6 M $CHCl_3$ solution of trifluoroacetic acid to a freshly prepared [^{1}H]NMR sample of the crude material from epoxidation at −50°C resulted in the immediate disappearance of the new product and left only signals for **20** and the ester side products, **21**.

Bioassay Results

Bioassay results conducted at the 10-mg application rate are shown in Figure 10. At all dosages assayed, termites that were offered the test compounds showed greater mortality than those in control dishes (one-way ANOVA, $P < 0.05$, with 14 *df* in *t* tests of all conditions). The mortality caused by each of the test compounds was dose-dependent ($P < 0.0005$, 2 *df*). However, only compound **20** showed significant toxicity, at the 10-mg application rate, as judged by the criterion of achieving a 50% kill in seven days.

Identity of Toxic Components

In previous work we localized the toxicity of *D. kerrii* resin within two bioactive fractions, the first containing roughly equal amounts of spathulenol and **1**, and the second containing roughly equal amounts of epicyclocolorenone and **20** (originally assigned structure **2**). In conjunction with the results reported here, it is possible to infer the following: (1) **1** does not contribute substantially to the toxicity of the first fraction, implying that spathulenol is largely responsible for the bioactivity of this particular fraction. We conclude this because in

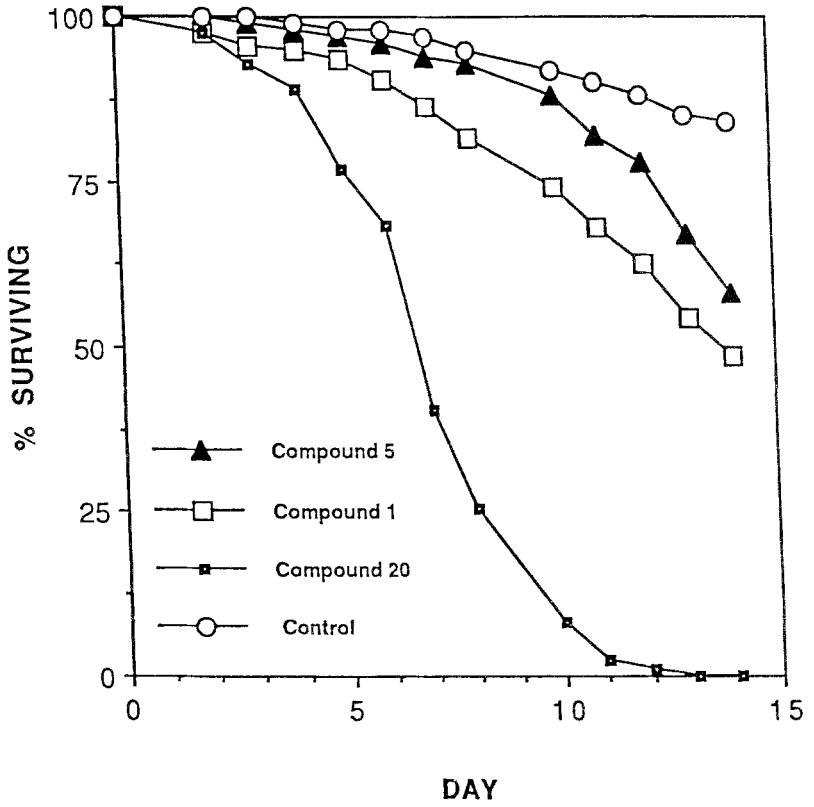


FIG. 10. Toxicity of synthetic compounds **1**, **5**, and **20** to *Neotermes ?dalbergiae* drywood termites; 10-mg application rate. Details in text.

pure form **1** causes very little mortality (<50% in two weeks), while in the mixture with spathulenol 50% mortality was observed after seven days. (2) In pure form, **20** causes 50% mortality within seven days. The same level of toxicity is observed in mixtures with epicyclocolorenone, suggesting that the toxic effects of this mixture are due primarily to **20** (Richardson, et al., 1989). It is unlikely that synergistic effects operate in these mixtures, since other studies did not find evidence for synergism, either between various resin sesquiterpenes or between purified components or crude resins and the insecticide synergist piperonyl butoxide (Messer, 1990; Messer et al., 1990).

We also examined toxicity of the synthetic precursor to **1**, the corresponding acetate **5**. This was of interest since the tertiary alcohol moiety in **1** was labile in dilute acid. Since it is known that acidic conditions are often present in insect alimentary tracts (Noirot and Noirot, 1969), we speculated that the

acetate group might enhance the toxicity of the compound **1** structure as it would render the oxygenated center at C-13 less susceptible to acid-catalyzed solvolysis. While **5** was found to be less sensitive than **1** to acidic conditions, it is only slightly more toxic, as shown in Figure 10.

In conclusion, along with completing and verifying their structures, we have found that sesquiterpenes **1** and **20** belong to a family of resin-derived components that play a role in defending dipterocarps from biological attack (Richardson et al., 1989; Messer, 1990). In comparison to other plant defensive compounds (Harborne, 1982), these sesquiterpenes are not very toxic. This may reflect that these compounds have evolved in response to chronic fungal and insectan insults, which are continuously present and which do not require an acute response. Fresh *D. kerrii* resin, which contains α-gurjunene as its principal component, contains roughly 4% of both **1** and **20** (Richardson et al., 1989). Because of their lability, the dienols are found only in fresh resins of *D. kerrii*, while α-gurjunene persists as resins age. In view of their structural similarities with α-gurjunene, this suggests that the dienols arise via biosynthetic modification of this parent structure as opposed to spontaneous degradation during the aging of resins.

ANNOUNCEMENT

The University of Pennsylvania will host the Chemical Signals in Vertebrates VI Symposium from June 16–22, 1991 at the Penn Tower Hotel in Philadelphia. Abstracts are solicited for a very wide variety of vertebrate chemical communications (odor perception mechanisms and systems) in aquatic and terrestrial environments. Presentations are 20 minutes plus 10 minute discussions before general sessions or may be submitted as a poster, the format to be ascertained by the abstract review committee. These were due by March 15, 1991.

For further information on program and housing, please write to:

PARENTALLY PROVIDED ALKALOID DOES NOT PROTECT EGGS OF *Utetheisa ornatrix* (LEPIDOPTERA: ARCTIIDAE) AGAINST ENTOMOPATHOGENIC FUNGI[1]

GREGGORY K. STOREY,[2] DANIEL J. ANESHANSLEY,[3] and THOMAS EISNER[4,*]

(Received June 11, 1990; accepted November 26, 1990)

Abstract—Eggs of *Utetheisa ornatrix* proved equally vulnerable to fungal infection (*Beauveria bassiana*, *Paecilomyces lilacinus*) whether they contained parentally provided pyrrolizidine alkaloid (monocrotaline) or were free of such alkaloid. In in vitro tests, monocrotaline, either as free base or N-oxide, had no inhibiting effect on fungal cultures.

Key Words—Entomopathogenic fungi, insect egg, *Utetheisa ornatrix*, Lepidoptera, Arctiidae, chemical defense, pyrrolizidine alkaloid, monocrotaline, parental investment.

INTRODUCTION

The arctiid moth *Utetheisa ornatrix* is chemically protected at all stages of development. As a larva, it feeds on plants of the genus *Crotalaria* (Leguminosae), containing pyrrolizidine alkaloids (Sharma et al., 1965; Johnson et al., 1985). It sequesters these alkaloids systemically, retains them through metamorphosis, and as an adult bestows them upon the eggs (Conner et al., 1981; Dussourd et al., 1988). The alkaloids are proven defensive agents. They render

*To whom correspondence should be addressed.

0098-0331/91/0400-0687$06.50/0

adults unpalatable to orb-weaving spiders (Eisner and Meinwald, 1987) and eggs to coccinellid beetles (Dussourd et al., 1988). Unanswered was the question of whether the alkaloids might also protect the eggs against entomopathogens. We present evidence here that one pyrrolizidine alkaloid, monocrotaline, the toxic principle of *Crotalaria spectabilis*, one of the primary food plants of *U. ornatrix* (Conner et al., 1981), fails to protect the eggs against entomopathogenic fungi.

Our experiments were of two kinds. First, we measured the infectivity of selected fungi to *U. ornatrix* eggs that were either parentally endowed with monocrotaline or free of the chemical. Second, we determined the inhibiting effect of monocrotaline, in either of its natural chemical forms (free base; N-oxide), upon fungal cultures.

METHODS AND MATERIALS

Utetheisa *Eggs.* The two types of eggs (with or without monocrotaline) were obtained from laboratory cultures of *U. ornatrix* raised, respectively, on monocrotaline-containing and monocrotaline-free diet. The two diets have been described (Conner et al., 1981; Dussourd et al., 1988). The monocrotaline-free diet is a semi-synthetic pinto bean-based mixture (PB diet); the monocrotaline-containing diet is made of the same mixture, with 10% of its pinto bean content replaced by *C. spectabilis* seeds (CS diet). Analyses had shown eggs from PB-raised parents to be totally devoid of alkaloid, while those from CS-raised parents contained in the order of 0.9 μg monocrotaline/egg, ca. 90% in N-oxide form (J. Kopecky, J. Meinwald, T. Eisner, unpublished).

Fungal Cultures. The entomopathogenic fungi used and the insects from which they were isolated, were as follows: *Beauveria bassiana*, from the little leaf-notcher beetle, *Artipus floridanus* (Curculionidae); *Paecilomyces lilacinus*, from Fuller's rose beetle eggs, *Pantomorus cervinus* (Curculionidae); *Metarhizium anisopliae*, from the mole cricket, *Scapteriscus vicinus* (Gryllidae); and *Paecilomyces fumosoroseus*, from the sweet potato whitefly, *Bemisia tabaci* (Aleyrodidae).

The fungi were obtained originally as monosporal isolates and kept at −70°C in the culture collection of the Citrus Research and Education Center, University of Florida.

Pure cultures of the fungi were grown on Sabouraud dextrose agar (SDA) in Petri dishes (15 × 100 mm) at 27°C. After 10 days, conidia were harvested by scraping the plates with a sterile microscope slide. Conidia then were placed in 10 ml sterile deionized water (SDW), vortexed 1 min, and washed twice in SDW using centrifugation (5000 *g*, 5 min) to remove agar residue. Conidial concentration in the suspension was determined by hemacytometer counts. Sus-

pensions were stored at −20°C. All experiments were conducted with conidial suspensions (and dilutions thereof) prepared by this method.

Prior to each experiment, viability of conidia was evaluated by inoculating 100 μl of Sabouraud dextrose broth (SDB) with 100 μl of the conidial suspension and incubating for 24 hr at 27°C. Conidia were checked (inverted phase microscopy, 400×) for incidence of germ tube formation, which was invariably at levels above 90%.

Monocrotaline. Monocrotaline free base was obtained commercially (Sigma Chemical Co., St. Louis, Missouri). Monocrotaline N-oxide was prepared from the free base by Robert K. Vander Meer (USDA-ARS, P.O. Box 14565, Gainesville, Florida 32604).

Effect of Fungi upon Eggs. U. ornatrix egg clusters [17.1 ± 9.1 (SD) eggs/cluster, 4–44 range, $N = 125$ clusters), either monocrotaline-laden (parents CS-diet raised) or monocrotaline-free (parents PB-diet raised), were dipped in conidial suspensions of *B. bassiana* or *P. lilacinus* and then placed on agar plates (15 g agar/liter) and incubated at 27°C for 96 hr. Each fungal suspension was tested at five concentrations [0 (= control), 4.5×10^4, 4.5×10^6, 4.5×10^7, 4.5×10^8 conidia/ml]. Viability per cluster was scored as percent eggs that hatched.

For each fungus, the experimental series was run three times, with one to three egg clusters of each type per concentration. Since replicate values did not differ statistically, they were lumped for calculation of mean viabilities. Total number of egg clusters per sample concentration ranged from five to nine.

Effect of Monocrotaline on Fungi. Due to differences in solubility, the N-oxide and free-base forms of monocrotaline were assessed by slightly different procedures.

1. Monocrotaline N-Oxide. Effect on the germination of four fungi was assessed: *B. bassiana*, *M. anisopliae*, *P. lilacinus*, and *P. fumosoroseus*. Eight aqueous dilutions [0 (= water), 0.08, 0.15, 0.31, 0.63, 1.25, 2.5, 5.0 μg/μl] of an aqueous monocrotaline N-oxide solution were filter-sterilized by passage through an HPLC solvent syringe filter (0.45 μm, MSI Cameo). Standard volumes of each dilution (100 μl), together with 100 μl of SDB conidial suspension (ca. 1×10^5 conidia/ml) of one of the fungi, were added to individual wells of a sterile multiwell microtiter plate. After 24 hr of incubation at 27°C, conidial germination was scored by checking (inverted phase microscopy, 400×) approximately 100 conidia per well for presence or absence of germ tube. Three replicates per conidial dilution were assayed, providing the basis for calculation of mean percent germination per sample.

2. Monocrotaline Free Base. The procedure was similar as under (1), except that only two fungi were used (*B. bassiana*, *M. anisopliae*) and the free base samples were added (5 μl) to the test wells in methanol solution and allowed to dry by solvent evaporation before addition (200 μl) of the SDB conidial

suspension. Since this essentially involved surface application of the test chemical, test dosages were expressed as quantity of chemical per unit of well surface area.

Four filter-sterilized dilutions of a methanol solution of the free base were tested [0 (= methanol), 0.15, 1.5, and 15 $\mu g/cm^2$]. Incubation was again at 27°C, with three replicates per dilution sample, and check for germ tube formation was at 24 hr. The three values again provided the basis for calculation of mean percent germination per sample.

RESULTS

Effect of Fungi upon Eggs. As is evident from Figure 1, the two fungi proved comparably infective to monocrotaline-containing (CS) and monocrotaline-free (PB) eggs. For both fungi, statistical comparison at the 4.5×10^6 conidia/ml concentration level, where viabilities were around 50%, indicates no statistical difference in the effect upon the two eggs ($t < 0.53$, $P > 0.5$, $df = 16$).

Effect of Monocrotaline upon Fungi. Neither the free base nor the N-oxide form of the compound had an inhibiting effect on the fungi tested. Conidial germination was consistently above 98%, even with the highest chemical concentrations assayed [for the $N = 28$ N-oxide samples and their controls ($N = 4$), mean germination was consistently 100.0%; for the $N = 6$ free-base samples, mean germination ranged from 98.6% to 99.0% and was 99.3% for the controls ($N = 2$)].

DISCUSSION

Our data indicate that *U. ornatrix* eggs are vulnerable to fungal infection and that one pyrrolizidine alkaloid, monocrotaline, provides no protection against such infection. Whether one can generalize from this single compound, and from the relatively few fungi against which it was tested, that pyrrolizidine alkaloids as a group are ineffective as antifungal agents remains uncertain. The only defensive function so far proven for pyrrolizidine alkaloids in *Utetheisa* concerns their deterrence to arthropodan predators (Eisner and Meinwald, 1987; Dussourd et al., 1988).

The concentration range at which we assessed monocrotaline for conidial inhibition (0–15 μg free base; 0–5 μg N-oxide) spans the level at which pyrrolizidine alkaloid occurs in *Utetheisa* eggs in nature. This level, while not determined for monocrotaline itself, but for the closely related pyrrolizidine alkaloid usaramine, sequestered by *Utetheisa* from another food plant (*Crota-*

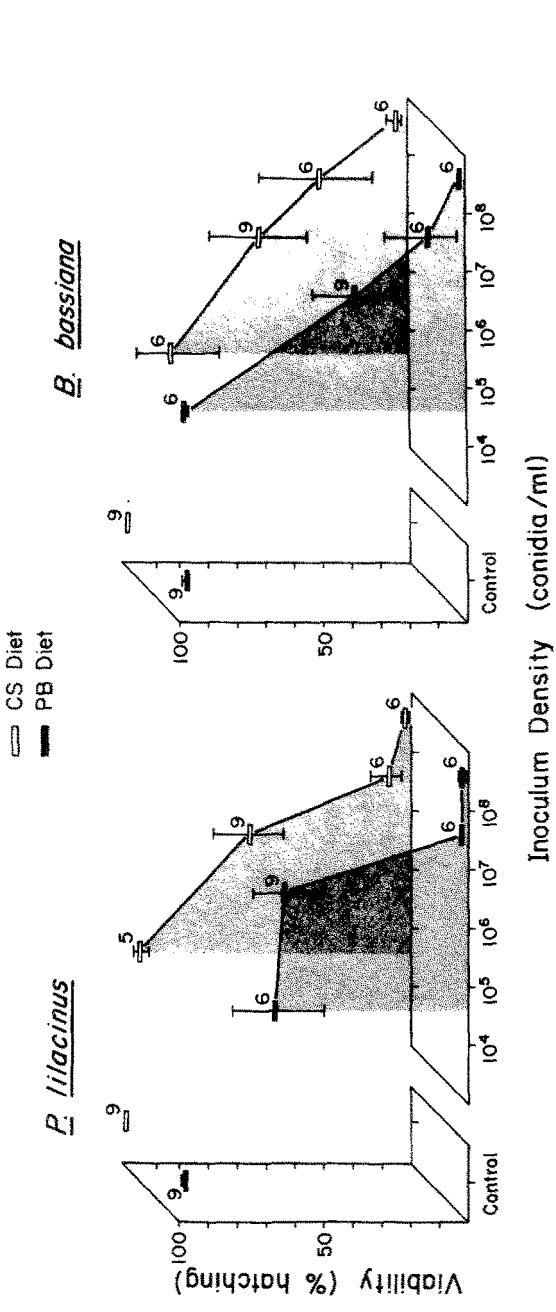

FIG. 1. Infectivity of *Paecilomyces lilacinus* and *Beauveria bassiana*, at various inoculum densities, to *Utetheisa ornatrix* eggs. Viability per egg cluster is expressed as percent (mean ± standard error) that hatched. Number of clusters per sample is given by numerals beside means. CS diet = monocrotaline-containing eggs from parents raised on CS diet; PB diet = monocrotaline-free eggs from parents raised on PB diet. For purposes of plotting, the square root of the viabilities (as probabilities) were transformed to arc sines to determine means and standard error of the means. Probabilities of 1 and 0 were changed (according to Snedecor and Cochran, 1980, pp. 327–328) to $0.25/N$, where N = number of eggs per cluster.

laria mucronata), was found to be on the order of 0.8 μg/egg, with upwards of 95% in N-oxide form (B.L. Roach, cited in Dussourd et al., 1988).

The fungi used in our study were conspecifics or congeners of species proven to be pathogenic to other insect eggs. Thus, *P. fumosoroseus* was shown to be infective to eggs of a noctuid moth and of two curculionid beetles (Rodriguez-Rueda and Fargues, 1980; Poprawski et al., 1985). The curculionid eggs were further shown to be vulnerable to infection by *B. bassiana* and *M. anisopliae*, as well as to a second species of *Paecilomyces* and *Metarhizium*.

Surprisingly little is known about the susceptibility of insect eggs to entomopathogenic infection (Steinhaus, 1963; Ferron, 1978), or about antibiotic mechanisms by which insect eggs might be protected against such infection. Our negative data notwithstanding, we are tempted to predict that such mechanisms exist and that interesting strategies will be uncovered by which antifungal or antibacterial agents are maternally, paternally, or biparentally transmitted to insect eggs.

Abstract—The biological activities of synthetic periplanone analogs, including four candidates of periplanone-A (P-A), were evaluated by behavioral and electroantennogram (EAG) assays. Among 16 periplanone analogs, six compounds evoked pheromonal activity from the male American cockroaches. The threshold dosages of these biological active analogs were 10–10^5 times lower than that of the known periplanone mimic, germacrene-D. The conformation required for eliciting the pheromonal activity is discussed in terms of the structure–activity relationship of these analogs. Hauptmann's P-A elicited the strongest pheromonal activity among four candidates of P-A in our bioassay, suggesting that Hauptmann's P-A is a natural P-A produced from female cockroaches.

Key Words—American cockroach, *Periplaneta americana*, Orthoptera, Blattidae, pheromone, mimics, analog, electroantennogram, EAG, bioassays, periplanone analogs.

INTRODUCTION

The study of pheromone mimics of the American cockroach, *Periplaneta americana*, were initiated after the discovery by Bowers and Bodenstein (1971) that the plant-derived terpenoids, (+)-bornyl acetate, α- and β-santalol caused sexual excitement in male American cockroaches.

Stimulated by this discovery, Nishino et al. (1977) examined many bicyclic monoterpenoids and found (+)-*trans*-verbenyl acetate elicited pheromonal activity. Structural factors for sex pheromonal activity of verbenyl acetate and

*To whom correspondence should be addressed.

related compounds have been investigated, and these demonstrated that (+)-verbanyl methyl carbonate expressed the strongest activity among the derivatives (Nishino and Takayanagi, 1981; Nishino et al., 1982; Manabe and Nishino, 1983, Manabe et al., 1985).

On the other hand, germacrene-D was found to be a sex pheromone mimic and its derivatives have been investigated (Tahara et al., 1975; Takahashi et al., 1978). So far, no decisive conclusion about the structure–activity relationship of the germacrene-type structure analogs has been drawn.

The first purpose of this paper is to determine the relative thresholds of periplanone analogs and offer valuable information for the elucidation of the structure–activity relationship among periplanone analogs.

The second purpose is to confirm the correct structure of periplanone-A (P-A) by behavioral and electroantennogram (EAG) assays. Persoons et al. (1974) first isolated P-A with P-B (**1**) (Figure 1), and proposed a tentative structure of P-A (**4**) (Figure 1) (Persoons et al., 1982). This proposed structure was examined during its synthesis. The spectroscopic data, however, did not coincide with those reported by Persoons and it was found to be biologically inactive (Shizuri et al., 1987a,b). The spectroscopic data of Persoons' P-A were reinvestigated and another structure (**5**) (Figure 1) was proposed (Shizuri et al., 1987c).

Hauptmann et al. (1986) isolated a new sex pheromone component having a germacrene skeleton (Hauptmann's P-A, **2**), contrary to the structure pro-

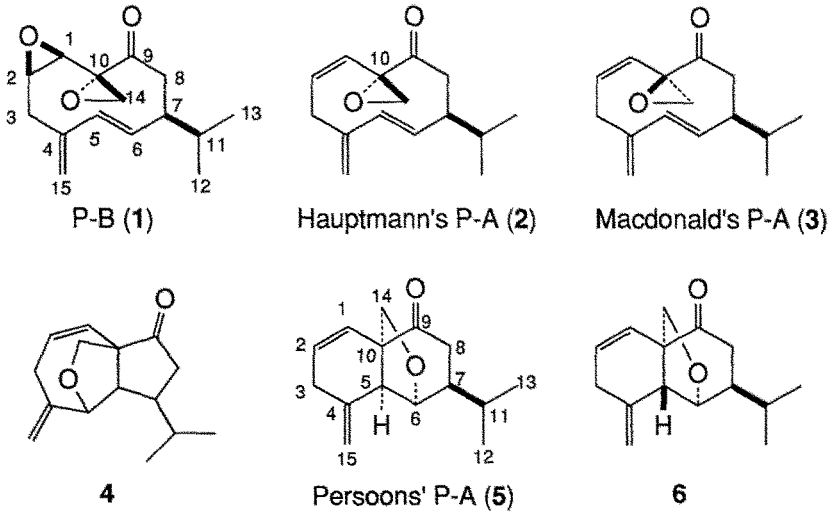

FIG. 1. Periplanone-B and four candidates of Periplanone-A. The numbering scheme for the carbon atoms of compounds **1**, **2**, and **5** are according to Persoons et al. (1982).

posed by Persoons. Meanwhile, Macdonald et al. (1987) synthesized the C-10 epimer of Hauptmann's P-A (**3**) and claimed that this was the correct structure of the P-A (Macdonald's P-A) (Figure 1).

Recently, Kuwahara and Mori (1991) synthesized both Hauptmann's and Macdonald's P-A. X-ray crystallographic analysis of the synthetic Hauptmann's P-A showed that Hauptmann's assumption about the structure of P-A was correct. It also was determined that thermal rearrangement of Hauptmann's P-A yielded a compound that had identical spectroscopic properties to those of Persoons P-A (Persoons et al., 1982). The structure of the rearrangement product from Hauptmann's P-A (**2**) was established to be **5** (Figure 1) by X-ray crystallographic analysis (Kuwahara and Mori, 1989). In this study, behavioral and EAG responses of four candidates of P-A are examined in order to provide biological evidence of the structural elucidation of P-A.

METHODS AND MATERIALS

Pheromones and Analogs. Synthetic pheromones and analogs, except for germacrene-D, were used for this assay. The chemical and optical purity of each test compound is summarized in Table 1. Eighteen compounds that we

TABLE 1. PURITY OF COMPOUNDS TESTED

Compound No.	Chemical purity	Optical purity
1	Crystal	100% ee
2	>99%	>98% ee
3	>99%	>98% ee
5	Crystal	>99% ee
6	Crystal	(±)
7	Crystal	>98% ee

18	>99%	(±)
19	>99%	Diastereomeric mixture

used in this assay were divided into four groups, based on their chemical structural features.

Group 1 includes P-B (Figure 1) and periplanone analogs that have a germacrene skeleton (Figure 2). (−)-P-B (**1**) (Persoons et al., 1976) was synthesized in optically active form (Kitahara et al., 1987). Analog **7** also was synthesized in optically active form (Mori et al., 1988). Analogs **8** and **9** were optically active intermediates in the synthesis of (−)-P-B (Mori et al., 1990a). Germacrene-D (**10**), isolated from ylang-ylang essential oil, was a gift from Dr. Y. Takagi of T. Hasegawa Inc.; the chemical purity was 98% as judged by GLC.

Group 2 includes analogs that have no *exo*-methylene and isopropyl groups on the 10-membered ring (Figure 3). Analog **11**, which has the same three oxygen-containing functionalities in the same positions as those of P-B, was prepared as a P-B analog, and **12** as a Hauptmann's P-A analog. Analogs **13**–**17** were the synthetic intermediates in the synthesis of analog **11** (Mori et al., 1990b).

Group 3 includes the chain analogs **18** and **19** (Figure 4), which have a partial structure of periplanones.

Group 4 includes the candidates of P-A, Hauptmann's P-A (**2**), Macdonald's P-A (**3**), Persoons' P-A (**5**) and the epimer of Persoons' P-A (**6**) (Figure 1). Persoons' P-A (**5**) was prepared from Hauptmann's P-A (**2**) by thermal rearrangement on gas chromatography (Kuwahara and Mori 1989). Hauptmann's

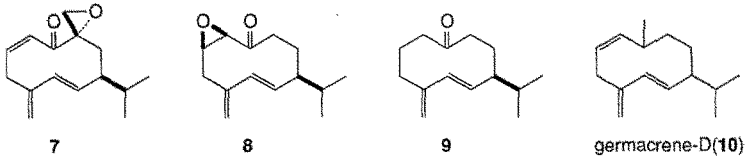

FIG. 2. Periplanone analogs, group 1.

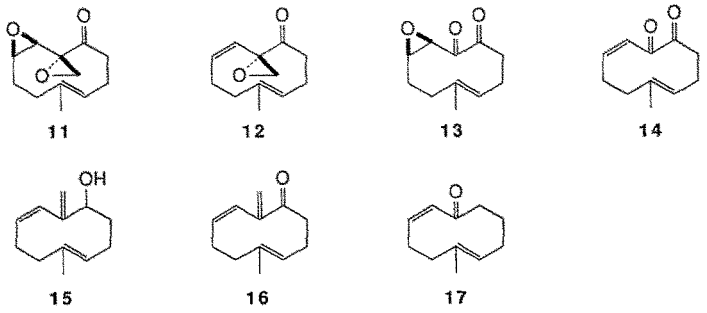

FIG. 3. Periplanone analogs, group 2.

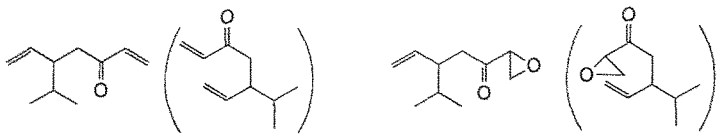

18 19

FIG. 4. Periplanone analogs, group 3.

P-A (**2**) and Macdonald's P-A (**3**) were synthesized in optically active form (Kuwahara and Mori,1990). The analog **6**, which is the C-5 epimer of Persoons' P-A, was synthesized in racemic form (Mori and Igarashi, 1989). The decadal dilution series of each test compound, of which the concentrations were $10-10^{-7}$ $\mu g/\mu l$, were prepared in distilled *n*-hexane.

Behavioral Assay for Pheromonal Activity. Behavioral assay was performed using essentially the same procedure as described by Okada et al. (1990b). Five male cockroaches in a glass assay box were exposed to a stimulant introduced in an airstream for 5 min. Responses of the insects were recorded by a video tape recorder. Locomotory activity was measured by counting the number of times the cockroaches crossed a line drawn across the center of the bottom of the assay box. The number of wing-raising individuals per total test insects during the test period was expressed as a wing-raising rate in percentage. A male cockroach that raised his wing for both extended and momentary periods was counted in the rate.

EAG Recording. An antenna of the male cockroach was cut away from the head at the scape and placed on the plastic stage. EAGs were recorded with Ag–AgCl electrodes. The recording electrode was a glass capillary (ID = 0.7 mm) filled with TES Ringer solution, it was inserted in the apical end of the antenna, and the indifferent electrode was positioned into the pool of Ringer solution (ϕ = 10 mm, depth = 15 mm) where the proximal end was dipped. One microliter of the test solution was directly applied to the inner side of a disposable pipet (BDL 4642, Dickinson Co. Ltd.) and the solvent (*n*-hexane) was allowed to evaporate. Then the disposable pipet was attached to the pheromone application system. Pheromone vapor (total volume 2 cc, duration 0.5 sec, controlled by a glass syringe whose plunger was regulated by a speed-control motor) was introduced into an airstream (flow rate 1 liter/min) purified with a charcoal filter and water, and applied to the middle part of the antenna. Each antenna was stimulated by a series of test compounds at an interval of 30 sec. The EAG responses were automatically analyzed with our original measurement program on a microcomputer (PC9801XL4, NEC Co. Ltd.) equipped with an A-D converter (ADZ-2000, Dia-medical Co. Ltd.) after having been amplified with a microelectrode and a high gain amplifier (MEZ-8201, AVH-11, Nihon Kohden Co. Ltd.) by a factor of 10^3.

RESULTS

Dose responses of behavioral and EAG activities for the test compounds that elicited any behavioral activity are shown in Figure 5. The mean locomotory activity and SD of the control (*n*-hexane) was 2.1 ± 2.3. The upper value of 99% confidence intervals of locomotory activity was 3.4. The mean wing-raising rate and SD of the control was 0.0 ± 0.0. The mean EAG amplitude and SD of the control was 0.22 ± 0.09 mV. The upper value of 99% confidence intervals of the EAG amplitude was 0.32 mV.

The significant responses of locomotory activity and EAG amplitude are defined to be the responses that are greater than the upper values of the 99% confidence intervals.

All compounds of the group 1 evoked the typical pheromonal activity. P-B (**1**) elicited the strongest activity among the tested compounds. The dose that evoked a significant locomotory activity was 10^{-8} μg (Okada et al., 1990b). The dose that evoked a significant EAG amplitude was 10^{-7} μg. Compound **7** is an analog of Hauptmann's P-A (**2**), differing only in the position of the carbonyl and spiro epoxy groups on the ring. This analog elicited the strongest activity among all of the analogs except for the natural periplanones. Significant locomotory activity was elicited at 10^{-4} μg, significant EAG amplitude was 10^{-3} μg. Analog **8**, having a carbonyl and an epoxy group on the germacrene skeleton, elicited significant locomotory activity at 10^{-2} μg and significant EAG at 10^{-1} μg. Analog **9**, which has a carbonyl group on the germacrene skeleton, evoked significant locomotory activity at 10^{-1} μg. The threshold dosage of the EAG response was 10^{-1} μg. The wing-raising behavior was rather weak and the behavior lasted for a very short period even at 10 μg. Germacrene-D (**10**), which has no oxygen-containing functionality, elicited significant locomotory activity at 10 μg. Significant EAG amplitude was elicited at 1 μg. The wing raising activity at 10 μg was weak, as with the analog **9**.

In the group 2, analog **11**, having the same oxygen-containing functionalities at the same positions as those of P-B but no *exo*-methylene and isopropyl groups on the ten 10-membered ring system, evoked significant locomotory activity at 10^{-3} μg. Analog **12**, which has the same oxygen-containing functionalities at the same positions as those of Hauptmann's P-A (**2**), elicited no behavioral and EAG response. Compound **13**, an analog of **11**, also failed to elicit pheromonal activity. Analogs **14–17** elicited no significant behavioral and EAG responses even at the dose of 10 μg.

In group 3, analogs **18** and **19** elicited no significant behavioral and EAG responses even at a dosage of 10 μg.

In group 4, Hauptmann's P-A (**2**) elicited significant locomotory activity at 10^{-6} μg. Significant EAG response was recorded at 10^{-4} μg. The locomotory threshold dosage of Macdonald's P-A (**3**) was 10^{-2} μg, 10^4 times higher than

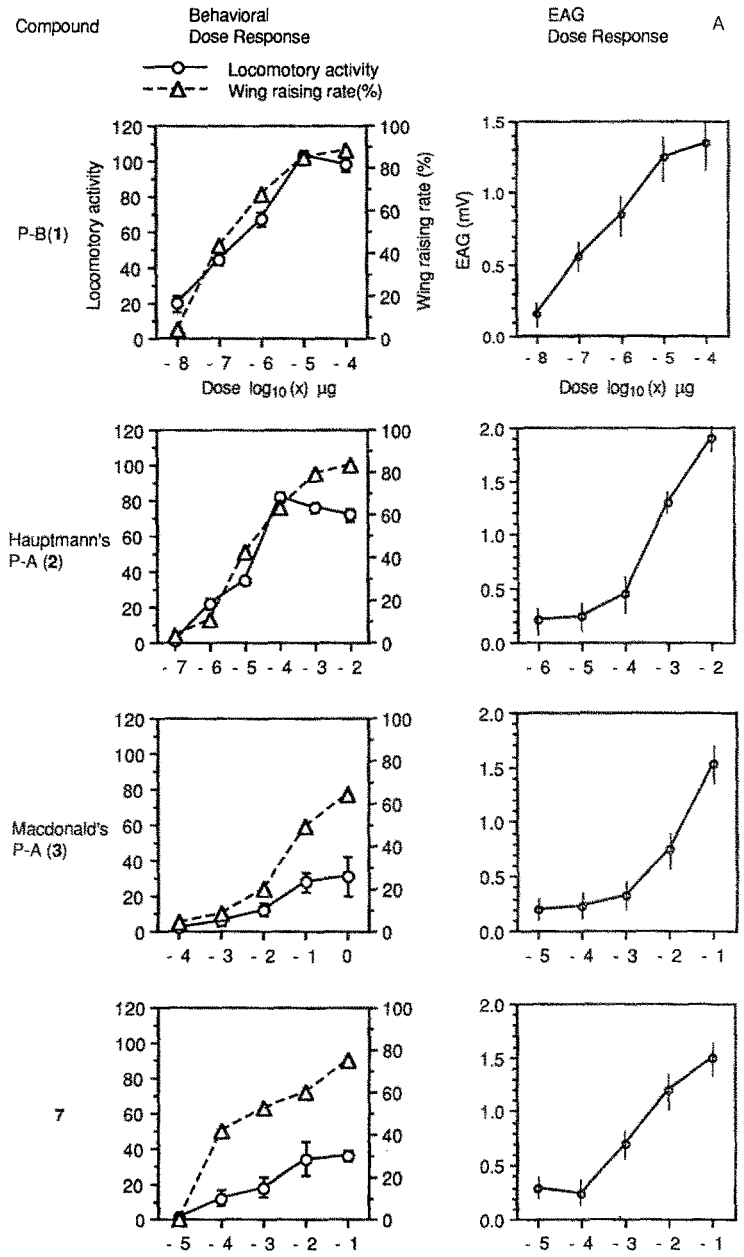

FIG. 5. Dose response of periplanone analogs. Measurements of behavioral and EAG response are repeated 10 times at each data point. (Replication in the case of P-B and P-A is 20 times). Vertical bars indicate standard errors.

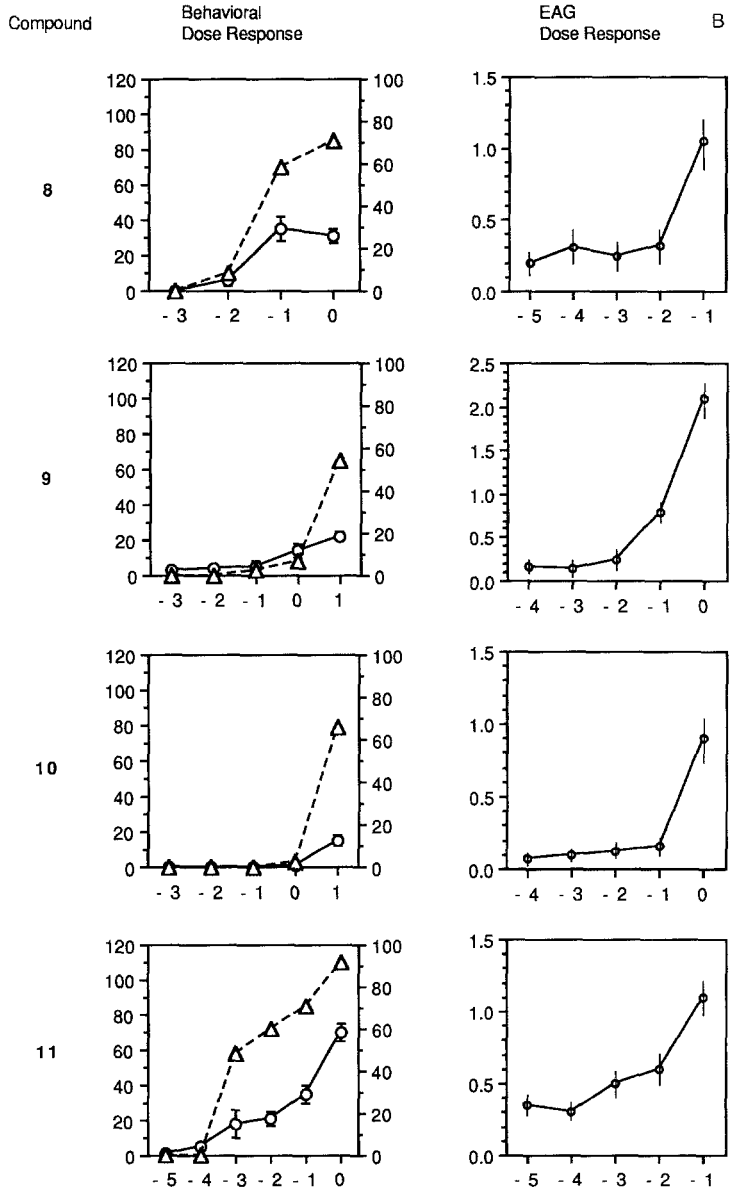

FIG. 5. Continued

that of Hauptmann's P-A (**2**). A significant EAG amplitude of analog **3** was recorded at 10^{-2} μg.

Behavioral and EAG assays indicate that Persoons' P-A (**5**) was inactive even at 10 μg. The epimer of Persoons' P-A (**6**) also was inactive even at 10 μg.

No inhibitory or synergistic effect of the biologically inactive analogs **5**, **6**, and **12–19**, to the pheromonal activity of P-B was observed even when 10 μg of these analogs were mixed with 10^{-6} μg of P-B. ($P > 0.05$)

DISCUSSION

Structure–Activity Relationship of Periplanone Analogs. Of the six analogs, **3**, **7**, **8**, **9**, **10**, and **11**, found to have pheromonal activity in our bioassay, five are germacrene derivatives, the exception being analog **11**. Other analogs, **5**, **6**, and **12–19**, have neither significant behavioral nor EAG activity. These inactive analogs show no significant inhibitory and/or synergistic effects to the pheromonal activity of P-B during their addition to P-B.

The structure–activity relationship of the germacrene analogs in the group 1 indicates that the number of the oxygen-containing functionalities on the ring system concerns the effectiveness of the pheromonal activity. The threshold dosages of locomotory activity and wing-raising became higher with the sequential removal of the oxygen-containing functionalities.

The chain analogs **18** and **19** had no pheromonal activity, suggesting that a specific conformation of the molecule resulting from the 10-membered ring system is important to elicit pheromonal activity.

The strong activity of analog **11** possessing the same oxygen-containing functionalities as those of P-B (**1**) indicates that the proper position of the functionalities is important to elicit the activity. But analog **12**, which has the same two oxygen containing functionalities at the same positions as those of P-A (**2**) had no activity. This suggests that the three-dimensional configuration of oxygen atoms and ring conformation of analog **12** are different from those of P-A.

The structure–activity relationship of Hauptmann's P-A (**2**) and Macdonald's P-A (**3**) also indicated that a specific conformation relating to the three-dimensional configuration of the oxygen atom in the spiro epoxy must be important for eliciting activity.

Stable conformations of natural periplanones (**1**, **2**), active analogs **7** and **11**, and Persoons' P-A (**5**) were examined by X-ray crystallographic analysis (Figure 6) (Okada et al., 1990a; Mori et al., 1990a,b; Kuwahara and Mori, 1989). The analysis indicates that all these active compounds (**1**, **2**, **7**, **11**) have a common conformational property on the 10-membered ring and the three-dimensional position of the oxygen atoms (Figure 6). It is noteworthy that the

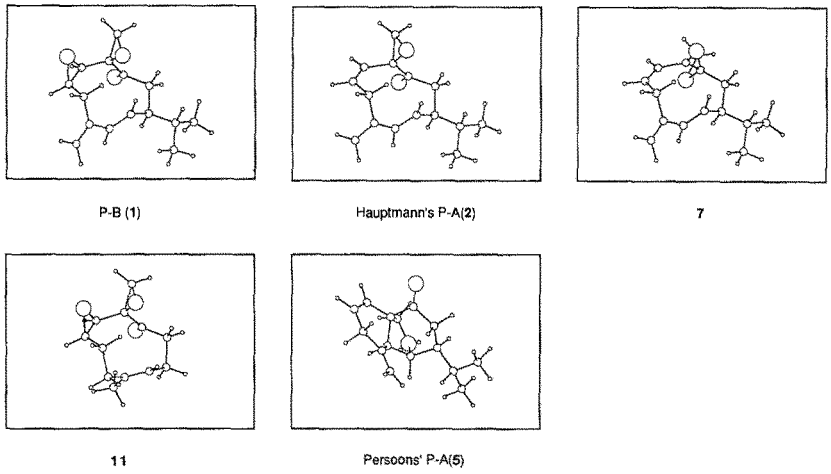

FIG. 6. Stereoscopic drawings of periplanones and their analogs. These conformations of P-B (**1**), Hauptmann's P-A (**2**), **7**, and **11** are drawn according to coordinates from X-ray crystallographic analyses (Okada et al., 1990a; M. Mori et al., 1990a,b). Persoons' P-A (**5**) is drawn according to the molecular mechanics calculation analysis (Program MM2). The conformation is superimposable on that of the corresponding alcohol of Persoons' P-A obtained from an X-ray crystallographic analysis (Kuwahara and Mori, 1989). Large, medium, and small circles indicate oxygen, carbon, and hydrogen atoms, respectively.

three-dimensional configuration of oxygen atoms in analog **7** is superimposable on those of natural periplanones (Mori et al., 1990a). The conformation of Persoons' P-A (**5**), which elicited no pheromonal activity, could not be superimposed on those of natural periplanones.

Both natural periplanones (**1**, **2**) and active analogs **3**, **7–11** could elicit typical male pheromonal behaviors such as antennal waving, rapid locomotion, wing-raising, and homosexual behavior. In the case of natural periplanones, the dose–response curve of the wing-raising rate increased in a manner parallel to that of the locomotory activities with ascent of sample dosages (Figure 5). On the contrary, analogs **3**, **7**, and **11** showed a slightly different response pattern from those of the natural periplanones. Dose–responses of the wing-raising and locomotory activities were not parallel. The wing-raising activity was greater than the locomotive activity.

Correct Structure of Natural P-A. There has been discussion as to which structure of P-A, Hauptmann's (**2**), Macdonald's (**3**) or Persoons' P-A (**5**), was correct. Nishino et al. isolated Hauptmann's P-A from the female's feces. However, they could not detect Persoons' P-A. Moreover synthetic Persoons' P-A elicited no behavioral and EAG responses in our assay. This strongly suggests

that Persoons' P-A is an artificial product derived from Hauptmann's P-A in the isolation procedure. (Sass, 1983; Nishino et al., 1988; Kuwahara and Mori, 1989). Takahashi et al. (1988) reported that the behavioral activity of Hauptmann's P-A (**2**) was 1000 times greater than Macdonald's P-A, and similar results could be obtained in our behavioral and EAG assay. The above results indicate that Hauptmann's P-A is a natural P-A produced from female American cockroaches.

Acknowledgments—The authors are indebted to Profs. K. Mori and T. Kitahara, and Dr. S. Kuwahara, The University of Tokyo, for generously supplying the samples of synthetic Macdonald's P-A, Persoons' P-A and its epimer, and to Dr. T. Takagi of T. Hasegawa Co. Ltd. for providing the germacrene-D.

ALLELOPATHIC POTENTIAL OF *Nuphar lutea* (L.) SIBTH. & SM. (NYMPHAEACEAE)

STELLA D. ELAKOVICH* and JEAN W. WOOTEN

Department of Chemistry and Biochemistry and Department of Biological Sciences
University of Southern Mississippi
Hattiesburg, Mississippi 39406

(Received October 9, 1990; accepted November 26, 1990)

Abstract—Aqueous extracts of *Nuphar lutea* (L.) Sibth. & Sm. leaves (blades plus petioles) and roots plus rhizomes were tested for allelopathic activity using lettuce seedling and *Lemna minor* L. assay systems. The 12.5, 25, 125, and 250 parts per thousand (ppt) treatments of both extracts killed the lettuce seedlings. At 2.5 ppt of extract, radicle growth of lettuce was 29% of the control for leaves and 31% of the control for roots plus rhizomes. *Lemna minor* frond number was reduced to 34% of the control by the 25 ppt leaf extract and to 43% of the control by the 25 ppt roots plus rhizomes extract. *L. minor* was killed by concentrations of 125 ppt and above of both plant part extracts. As expected, the frond number and total chlorophyll content measured by the *L. minor* assay were highly correlated. Osmotic potentials below 143 mOsmol/kg had no influence on *L. minor* growth. Neither the osmotic potential nor the pH of the undiluted extracts of *N. lutea* were in the range known to influence the growth of either lettuce seedlings or *L. minor*. *Nuphar lutea* extracts were many times more inhibitory than 16 other hydrophytes we previously examined.

Key Words—Allelopathy, bioassay, duckweed, *Lemna minor*, lettuce seedling, *Nuphar lutea*, osmotic potential, *Lactuca sativa*.

INTRODUCTION

Examinations of the allelopathic potential of hydrophytes have accelerated since Oborn et al. (1954) first suggested that these plants could influence the growth and distribution of neighboring plants. Among hydrophytes, *Eleocharis coloradoensis* (Britt.) Gilley has been examined most frequently for its allelopathic

*To whom correspondence should be addressed.

0098-0331/91/0400-0707$06.50/0

potential. Field observations of Yeo (1980) over a 12-year period showed *E. coloradoensis* capable of displacing species of *Potamogeton* and *Elodea*. Aquaria experiments of Frank and Dechoretz (1980) supported Yeo's findings involving *Potamogeton*. Nichols and Shaw (1983) made field observations that suggested three species of *Eleocharis* can displace other aquatics. Ashton et al. (1985) bioassayed organics leached from the culture media in which axenically cultured *E. coloradoensis* was grown. They found these leachates inhibited *Hydrilla verticillata* (L.f.) Royle and *Potamogeton pectinatus* L. as well as tomato cell cultures and lettuce seedling roots. Aqueous extracts of *E. interstincta* (Vahl.) R.&S. and *E. cellulosa* Torr. inhibited the growth of the duckweed *Lemna paucicostata* Hegelm (Sutton and Portier, 1989). We recently reported the allelopathic potential of 16 aquatic and wetland plants as determined by two bioassays (Elakovich and Wooten, 1989). Continuation of this work led to the examination of the allelopathic potential of *N. lutea* by way of lettuce seedling and *L. minor* bioassays.

Both pH and osmotic potential can influence the outcome of allelopathy bioassays. Bell (1974) explored the influence of osmotic potential in assays for allelopathy that used the terrestrial grass *Bromus rigidus* Roth. He concluded that results from test solutions having osmotic concentrations in excess of 50 mOsmol/kg should be interpreted with care. Buchanan et al. (1978) found that osmotic potentials of -1.8 atm (approximately 148 mOsmol/kg for mannitol solutions) had no influence on germination of the two terrestrial grasses and three cereals he examined. Cheng and Riemer (1988) found that neither osmotic potentials of less than 70 mOsmol/kg nor pH differences affect lettuce germination or growth. Between pH 4 and 6 there is little influence on growth of *L. minor* under control conditions (Einhellig et al., 1985). The influence of osmotic potential on *L. minor* growth has not been examined previously.

Nuphar lutea is comprised of nine subspecies. We examined the subspecies *N. lutea* ssp. *macrophyllum* (Small) Beal, which occurs in ponds, lakes, sluggish streams, or backwaters, pools in marshes and swamps, and ditches and canals. It ranges from southern Maine to southern Wisconsin, southward to southern Florida and Texas (Godfrey and Wooten, 1981). *N. lutea* produces alkaloids having a regular sesquiterpenic skeleton incorporated into 3-furyl-substituted piperidines or quinolizidines as well as C_{30} alkaloids, which contain a sulfur atom along with two 3-furyl substituents (Wrobel and Ruszkowska, 1979; LaLonde and Wong, 1977; Iwanow et al., 1986). Salin and Bridges (1982) have characterized an iron-containing superoxide dismutase that is present in the leaves. Cullen et al. (1973) examined the antifungal activity of the rhizomes whose medicinal utility had been reported 20 years earlier (Tatarov, 1945).

This paper explores the allelopathic potential of *N. lutea* according to the results of two bioassays commonly applied to plant extracts. The influence of osmotic potential on *L. minor* growth is also examined.

METHODS AND MATERIALS

Field-collected, fresh *N. lutea* (L.) Sibth. & Sm. plants, growing in a quiescent pond, were washed free of debris and drained of excess water. Plants were divided into two portions: (1) leaves, including blades and petioles; and (2) rhizomes and roots. These two portions were treated as separate samples in all assays. A 200-g fresh-weight aliquot of each sample and 200 ml of distilled, deionized water were blended in a commercial Waring blender, and the resulting pulpy mixture was refrigerated for 24–72 hr. The mixture was filtered through cheese cloth and the filtrate centrifuged at 22,095*g* at 4°C for 20 min to remove particulate matter. It then was sterilized by filtration through a 0.45-μm Millipore filter. This extract, considered 100%, was diluted to achieve test concentration solutions expressed as parts per thousand (ppt). Since extracts were prepared by blending equal amounts of plant material and water, the actual plant concentration was smaller than the extract concentrations reported here.

Lettuce seedling bioassays on each sample were conducted using 0 (control), 25, 125, and 250 ppt of extract per test plate. Each test plate contained 30 ml of 1.0% agar and the appropriate amount of distilled water. The osmotic potential of each undiluted plant extract was measured with a Wescor 5100 Series Micro Osmometer; pH of each extract also was determined. Each extract was assayed under axenic conditions in two duplicate 9-cm disposable sterile Petri dishes. Twenty lettuce seeds (*Lactuca sativa* L. Black Seeded Simpson), germinated to the point of radicle appearance, were transferred to the prepared Petri dishes. After three to four days or when the control plate showed good growth, the radicle lengths were measured to the nearest millimeter. After results of the initial lettuce seedling bioassays were examined, the experiments were repeated using extract concentrations of 2.5, 12.5, and 25 ppt.

Bioassays using *L. minor* were performed under axenic conditions according to the method of Einhellig et al. (1985), modified as previously described (Elakovich and Wooten, 1989). Initial extract concentrations were identical to the lower concentrations used in the lettuce seedling assay, 2.5, 12.5, and 25 ppt. A second set of assays included concentrations of 22, 111, and 222 for the roots and rhizomes extract, and 22, 25, and 125 ppt for the leaf extract. Each concentration was tested twice (two duplicates) using six wells per trial (N = 6/duplicate). The osmotic potential and pH of each test solution were measured. Four fronds were added initially to each well. The assays were terminated and the fronds were counted when there were approximately 20 fronds in each control well. Counted fronds were placed in a small test tube and 1.5 ml of 95% ethanol was added to extract chlorophyll. After 24 hr at room temperature or 48–72 hr in a refrigerator, 1.5 ml of water was added to each tube. The absorbance of the chlorophyll extracts was read at 649 nm and 665 nm. Total chlorophyll concentration was calculated from the formula: μg chlorophyll/ml

solution = (5.10) × (A665nm) + (20.02) × (A664nm) (G.R. Leather, personal communication).

The influence of osmotic potential on *L. minor* frond growth was determined by addition of mannitol to the growth medium to achieve osmotic potentials of 74, 143, and 266 mOsmol/kg. The *L. minor* assay was carried out as described above with a sample containing growth medium with no added mannitol (60 mOsmol/kg) serving as the control.

Results were subjected to analyses of variance and either the *t* test or Duncan's multiple-range test, as appropriate. Pearson product–moment correlations were calculated from frond and chlorophyll data.

RESULTS AND DISCUSSION

Assumptions of the analysis of variance were valid for all data; no transformations were necessary. Mean radicle growth of the control in the initial lettuce seedling bioassay for the leaf extract was 2.26 cm and for roots plus rhizomes 2.35 cm. Seedlings exposed to all extract concentrations (25, 125, and 250 ppt) died. The experiments using lower concentrations of leaf extract resulted in control mean radicle growth of 1.95 cm and growth at 2.5 ppt of 0.57 cm, 29% of the control; seedlings died at 12.5 and 25 ppt of extract (Table 1). The 2.5 ppt of roots plus rhizomes extract also caused a significant reduction ($P \leq 0.001$) in radicle length with values at 31% of the control. Seedlings died at the two higher concentrations (Table 1). There was no difference in activity between the leaf and the roots plus rhizomes extracts (*t* test, $P \leq 0.05$).

In one experiment, *L. minor* mean frond number at 25 ppt of leaf extract was 34% of the control, 5.6 fronds as compared to 16.5 for the control. At 12.5 and 2.5 ppt, mean frond number was 53% and 78% of the control, respectively. In the second experiment, which tested concentrations of 22, 25, and 125 ppt, the original fronds died before any growth occurred at 125 ppt. All means were different (Duncan's multiple-range test, $P \leq 0.05$) except for those between 22 and 25 ppt in the second experiment. In tests with 22, 111, and 222 ppt of extract from roots plus rhizomes, growth was observed only at the lowest concentration. This growth was 50% of the control (significantly different, *t* test, two-tailed $P \leq 0.001$). *Lemna minor* died in treatments of 111 and 222 ppt, so a second experiment examined the effects of lower extract concentrations. At 2.5 ppt of roots plus rhizomes extract, mean frond number was reduced to 78% of control, whereas growth in 12.5 ppt was 65%, and at 25 ppt it was 43%. The observed difference between 2.5 and 12.5 ppt of extract was not significant ($P \leq 0.05$). Results of the 22 and 25 ppt extract concentrations from the two experiments agree well.

[b] Significantly different, T-test, 2-tailed, $p < = 0.001$.
[c] This assay included extract concentrations of 25, 125, and 250 ppt. All seedlings died.

both plant parts were highly correlated ranging from $r = 0.82$–0.91 ($P \leq 0.001$) except at 25 ppt of experiment 2 for leaf extract where $r = 0.63$ ($P = 0.029$). Results of leaves compared with roots plus rhizomes from experiment 1, were not different except for the 12.5 ppt treatment (t test, $P \leq 0.05$).

The influence of osmotic potential on *L. minor* frond growth is illustrated in Figure 1. The test solutions decreased slightly in osmotic potential over the course of the experiment; osmotic potentials measured at the beginning of the assay are shown in Figure 1. Mean frond numbers for plants grown in solutions of 60, 74, and 143 mOsmol/kg were not different (Duncan's multiple-range test, $P \leq 0.05$). Only at 266 mOsmol/kg was there growth inhibition.

The osmotic potential of the undiluted extract of leaves of *N. lutea* was 115 mOsmol/kg; that of the roots plus rhizomes was 107 mOsmol/kg. The osmotic potential of the diluted leaf extract at the end of the assay was

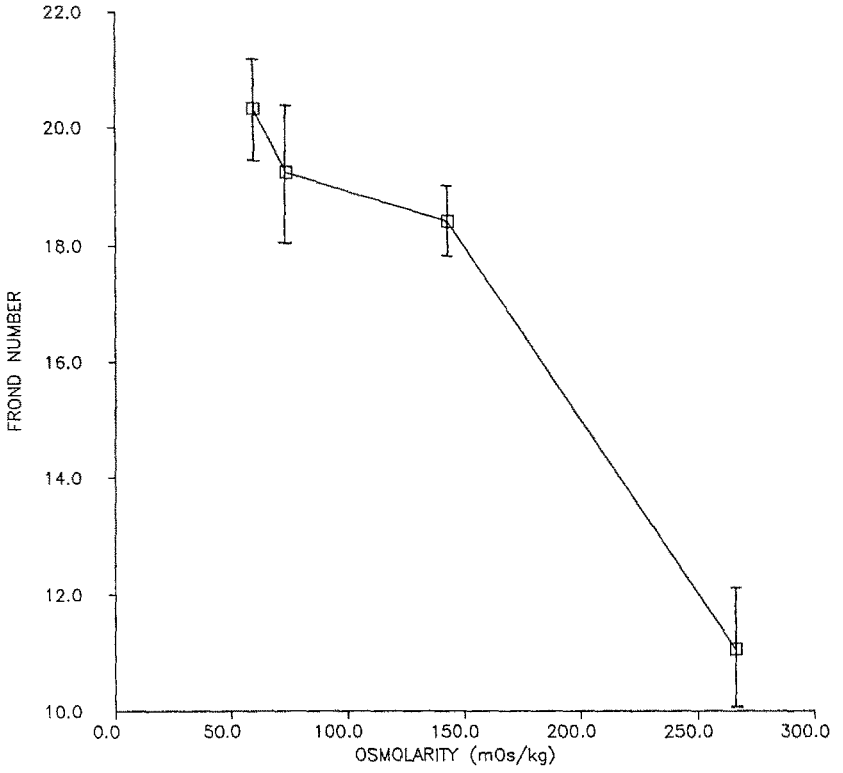

FIG. 1. Effect of osmotic potential (in milliosmoles per kilogram) on *L. minor* frond growth. Standard error is indicated with a vertical line.

33 mOsmol/kg at 25 ppt, and 52 mOsmol/kg at 125 ppt. The osmotic potential of the growth medium alone was 60 mOsmol/kg at the beginning of the assay. Extracts of both the leaves and roots plus rhizomes of *N. lutea* were strongly inhibitory to lettuce seedling growth, *L. minor* frond growth, and *L. minor* chlorophyll production. Our results (Figure 1) show that as long as the osmotic potential was below 143 mOsmol/kg, it did not contribute to growth inhibition of *L. minor*; Cheng and Riemer (1988) found that osmotic potentials of less than 70 mOsmol/kg do not affect lettuce seedling growth. Thus, neither the lettuce seedling nor the *L. minor* growth inhibition we observed can be attributed to osmotic potential.

Both extracts of *N. lutea* were acidic: the pH of the leaf extract was 4.05, that of the roots plus rhizomes was 4.00. Initial pH of the *L. minor* growth medium was 4.65. Not surprisingly, this unbuffered medium changed pH during the week or so of the assay. In one experiment the pH at the end of the

assay period was 6.8 in the control, 5.7 in the 25 ppt sample, and 4.55 in the 125 ppt sample. Although these are distinctly different pH values, they are still in the range (pH 4–6) where growth of *L. minor* is expected to be good (Einhellig et al., 1985). In fact, the final high pH of the control may slightly reduce *L. minor* growth, so that the observed growth inhibition of the extracts of lower pH may be a minimal expression of growth inhibition.

Elimination of pH and osmotic concentration as causative agents of growth inhibition does not prove that observed inhibition is due to allelopathy, but it certainly strengthens the case for allelopathy. There is no universal bioassay for the quantification of allelopathic potential. Seed germination tests appear to be less sensitive than seedling growth bioassays (Einhellig et al., 1985). The *L. minor* bioassay allows use of an aquatic plant as the target species and allows determination of both frond number and chlorophyll content. Frond number alone often adequately determines inhibitory activity, but would not be sufficient if the allelochemical reduced frond size but not number (Einhellig et al., 1985). The high correlation of frond number and chlorophyll content for *N. lutea* extracts indicates frond number alone is a sufficient measure of growth. Earlier work in our laboratories (Elakovich and Wooten, 1989) has shown that results of lettuce seedling assays are not completely correlated with results of *L. minor* assays, and the lettuce seedling assay is more sensitive. The results with *N. lutea* confirm these earlier results. Of the 16 selected hydrophytes we examined earlier, none showed inhibition (Dunnett's test) of *L. minor* at 20 ppt of extract, and only 12 of the 16 showed inhibition at 200 ppt of extract. All of these extracts inhibited growth of lettuce seedlings at 250 ppt of extract, but only six showed inhibition (Dunnett's test) at 25 ppt of extract. Thus *N. lutea* is many times more inhibitory than any of these 16 other hydrophytes!

As mentioned earlier, the alkaloid content of *N. lutea* has been extensively examined. Other alkaloids have been shown to be allelopathic (Rice, 1984), but the allelopathic activity of the *Nuphar* alkaloids has not been investigated. *Nuphar lutea* is thus a good candidate for further work to determine the nature of the compounds causing the growth inhibition reported here.

PHEROMONAL ACTIVITY OF SINGLE CASTOREUM CONSTITUENTS IN BEAVER, *Castor canadensis*

D. MÜLLER-SCHWARZE* and PETER W. HOULIHAN

College of Environmental Science and Forestry
State University of New York
Syracuse, New York 13210

(Received May 22, 1990; accepted November 27, 1990)

Abstract—Behavioral activity of single components of beaver castoreum was demonstrated for the first time. In four experiments samples were presented to free-ranging beaver in their family territories. First, responses to whole castoreum and anal gland secretion (AGS) from males and females were tested. Second, 24 compounds, known to be constituents of beaver castoreum, were individually screened for activity. Four of these consistently released immediate responses during the observation periods. These are the phenols 4-ethylphenol and 1,2-dihydroxybenzene and the ketones acetophenone and 3-hydroxyacetophenone. In the most complete responses, the beaver sniffed from the water, were attracted to the odor, swam toward its source, went on land, and then approached, sniffed, pawed, and scent-marked the artificial scent mound. 4-Ethoxyphenol, a compound not yet found in castoreum, also released these responses. Five additional compounds resulted in a few delayed visits to the samples during the night following the observations, as evidenced by destroyed scent mounds. These are 4-methyl-1,2-dihydroxybenzene, 4-methoxyacetophenone, 5-methoxysalicylic acid, salicylaldehyde, and 3-hydroxybenzoic acid. Third, mixtures of 24 and six compounds were tested. Responses to these mixtures could be as strong as those to whole castoreum. Fourth, the four regularly active compounds were tested in two additional beaver populations and proved to be active there, too. The response was strongest in the densest beaver population.

INTRODUCTION

Mammals use mixtures of compounds as well as single compounds as intraspecific olfactory signals, most of them arguably termed pheromones.

Mixtures. Examples of active mixtures are the scent marks of marmosets and tamarins (Callitrichidae) (reviewed by Epple et al., 1986); the "maleness" (or "aggression") signal in mice (Novotny et al., 1985); and the puberty-delaying pheromone in the urine of female mice, *Mus musculus* (Novotny et al., 1986). Biological activity of several compounds of a mixture may interact in synergistic, redundant, or additive fashion. We discuss the first two.

Synergism. Aggressive behavior in male laboratory mice is intensified by a mixture of two compounds from the urine, dehydrobrevicomin and 2-*sec*-butyl-4,5-dihydrothiazole. Either compound alone is inactive. It is important to note that they have to be dissolved in (otherwise inactive) urine. An aqueous solution of the two compounds is not active (Novotny et al., 1985).

The scent marks of the saddle-back tamarin, *Saguinus fuscicollis*, from the secretion of the circumgenital–suprapubic glands, contain at least 16 volatile butyrate esters, squalene, and several other unidentified volatile acids, alcohols, aldehydes, alkanes, and esters. Both the butyrate esters and and the volatiles are necessary for coding information on gender and subspecies (reviewed in Epple et al., 1986). This synergism of many compounds also has been involved in the term *odor image* (Albone, 1984).

Three compounds have been identified in the chest gland secretion of the primate *Galago crassicaudatus*. These are benzyl cyanide, 2-(hydroxyphenyl)ethanol, and *p*-hydroxybenzyl cyanide. Individually, none of the three compounds released any response from free-ranging galagos. But a mixture of compounds **1** and **2** applied to pipes was sniffed as frequently as pipes carrying galago scent marks after having been left for one week in a galago cage. A mixture of all three compounds also elicited a high rate of sniffing. No specific pattern of scent marking was reported (Katsir and Crew, 1980).

Redundancy. The puberty-delaying pheromone in the urine of female mice consists of three compounds. These are *n*-pentyl acetate, *cis*-2-penten-1-yl-acetate, and 2,5-dimethyl pyrazine. The biological effect, puberty delay in young females by 1.5–3.7 days, can be brought about by the pyrazine only, the two acetate esters, or all three compounds combined (Novotny et al., 1985), amounting to redundancy. An earlier example of redundancy is the sex pheromone of the domestic boar (*Sus scrofa*). Boar saliva contains α-androstenol and α-androstenone, either of which increases the probability of a sow in estrus assuming the mating stance. Activity is not increased by mixing both compounds (Melrose et al., 1971).

Single-Component Pheromones. Some pheromones consist of only one compound. The best investigated examples are the two sex pheromones of the

golden hamster, *Mesocricetus auratus*. The male is attracted by dimethyl disulfide in the mature female's vaginal secretion (Singer et al., 1976). Actual mounting is stimulated by aphrodisin, a protein ($alpha_{2u}$-globulin; mol wt = 17,000 daltons) (Singer et al., 1987).

The beaver, *Castor canadensis*, is one of the few mammals that permit rigorous experiments in the field. It resides year-round in family territories; is large enough to be observed from a distance; often occurs in partially open habitat; can be conditioned to the presence of people; can be observed during the last hours of daylight when its typically nocturnal activity begins; exhibits simple, predictable, and easily quantifiable behavior; and sizable populations are reasonably accessible to researchers. Therefore, we chose the beaver as a model for chemical stimulus–response experiments in a free-ranging mammal.

Beavers scent mark their territories by building mud piles on the banks of their ponds and applying two secretions, castoreum from their castor sacs and anal gland secretion, to these mounds. These scent mounds have been described many times, starting with 19th-century naturalists. Here we concentrate on chemical studies, the composition of beaver castoreum and anal gland secretion having been well investigated. Table 1 lists all compounds identified in castoreum by Lederer (1946), Valenta and Khaleque (1959), and Maurer and Ohloff (1976).

Fractions of castoreum release typical scent-marking responses. The more castoreum constituents are included in the mixture, the more intense are the responses (Müller-Schwarze et al., 1986). Beaver were attracted to neutrals and phenolics, but not to carboxylic acids and amines from castoreum (Svendsen and Huntsman, 1988). The biological significance of none of the single compounds is known. Therefore we embarked on testing single castoreum constituents for their pheromonal activity in a natural setting.

METHODS AND MATERIALS

Study Areas. The castoreum components were tested between 1986 and 1988 in three beaver populations in New York State: (1) first, in 1986 and 1987, 25 castoreum constituents were screened at the Reinemann Sanctuary near Dolgeville, Fulton County, at the southern fringe of the Adirondack Park; the four most active compounds were tested further (2) at Allegany State Park (ASP) in western New York in 1987 and (3) in 1988 at the Huntington Wildlife Forest (HWF), a campus of the College of Environmental Science and Forestry (ESF), located in the center of the Adirondack Park. The beaver colonies in all three areas were located on streams and had 1–12 dams. The ponds were small and open enough to observe beaver behavior on the opposite bank. The average family size was 5.7 animals (SD = 6.8, range 1–7) at ASP and 3.8 (SD = 1.53, range 1–7) at HWF.

[a] Adapted from Lederer (1946), Valenta and Khaleque (1959), and Maurer and Ohloff (1976).

Stimulus Preparation. Of the known constituents of beaver castoreum (Lederer, 1946, 1950), 24 compounds (Tables 2 and 3) plus cholesterol (a major castoreum constituent) were obtained commercially. Samples for bioassays were prepared at concentrations representing their relative proportions in castoreum as described by Lederer (1946). The amounts dissolved in 0.25 ml ethanol as

[a] Compounds in *italics* released at least some responses. Those also *underlined* were active immediately (during observation period) and consistently so.
[b] Used only in mixture, not as single compound.
[c] Not yet described for castoreum.

solvent and used for one trial are given in Table 2. A sample used in a particular trial represented 1/30 gland equivalent (GE), i.e., as much material as was found in 1/30 of the contents of one castor sac of average size (about 40 g, including contents and surrounding tissue). Castoreum was obtained from trappers in the western Adirondack region and kept frozen until needed.

SixMix contained the following six compounds with strong phenolic or beaverlike odors: benzoic acid, according to Lederer (1950) after cholesterol (8.0%) the second most abundant constituent of castoreum (2.6%); 4-ethylphenol, the third most abundant component (0.227%); 5-methoxysalicylic acid, 1,2-dihydroxybenzene, 3-hydroxyacetophenone, and 4-hydroxyacetophenone.

Controls (solvent only on the mudpile) and blanks (mud only) were used at ASP and HWF. Since in previous experiments (Müller-Schwarze et al., 1986) solvent controls never released any response, and the number of samples screened was already large, no controls were used at the Reinemann Sanctuary.

Stimulus Presentation. In the field, an artificial scent mound (ASM) was built by scooping mud from the pond with a trowel. The pile was about 30 cm in diameter and 10 cm high. In the center of the mud pile, a cork (4 cm diameter) was placed. The sample was applied to the cork with a disposable pipette. A tongue depressor was broken in half and one of the halves set vertically into

the scent mound next to the cork. This was to ascertain whether subtle responses had occurred during the night, such as a beaver inspecting the scent mound or moving over it without pawing and thus destroying the mound.

The ASM was placed about 50 cm from the water's edge and upwind from the main activity area, i.e., lodge and main dam, of the beaver colony. The observer sat on higher ground on the slope opposite the ASM, always downwind or crosswind from the main activity area of the beaver.

Behavior Observations. The ASM was built and scent applied at about 1700 hr, $\frac{1}{2}$ to 1 hr before the first beaver was expected to emerge from the lodge. Observation started about $\frac{1}{2}$ hr before the first beaver emerged and ended with fading daylight. Between May and August the changing times of emergence and nightfall determined the observation period. Depending on the month and the weather, the observation periods ranged from 1 to 4 hr, starting as early as 1700 hr and terminating as late as 2115 hr.

During the weeks before the experiment, as many beaver as possible of the observation colonies had been live-trapped, immobilized with Rompun and Ketaset (2 and 22 mg/kg body weight, respectively), sexed, measured, weighed, assigned to age classes (adult, 2-year-old, 1-year-old, kit), and individually marked with anodized aluminum ear tags in different color combinations for both ears. At ASP, 41 beaver were tagged (males: five adults, three 2-year-olds, and six yearlings; females: nine adults, 10 2-year-olds, six yearlings, and two kits). At HWF, 72 beaver were tagged (males: 16 adults, five 2-year-olds, and seven yearlings; females: 19 adults, five 2-year-olds, and six yearlings, one 2-year-old of unknown sex, and 13 kits).

Each individual was observed from the time it emerged until nightfall. This time period typically included several activity bouts, interspersed with visits to the lodge. The frequencies and durations of the following behaviors were recorded with a portable computer (Tandy 102) for the two seasons at ASP (1987) and HWF (1988), and with stopwatches and field notebooks for the earlier two seasons: emerging, swimming (fast, slow; near dam or in pond), feeding, tail-slapping, diving, sniffing from water, land visit, activity at ASM (sniffing, pawing, marking), and dam maintenance. If several beaver were in view simultaneously, observations focused on the animal nearest the sample. If more than one beaver went on land and responded to the sample, only the responses of the first animal were considered for analysis, because the first animal changes the stimulus situation for subsequent visitors to the ASM. The time of each behavior observation was automatically recorded by the computer, or noted in the field book, respectively. During the computer recording, a notebook and a stopwatch were held ready as backups.

If no responses to the ASM occurred during the observation period, the mound was examined the following morning for signs of beaver visits during

the night ("overnight activity"). The most unequivocal indicator of overnight beaver activity was a destroyed scent mound.

The sample sizes for 1986 and 1987 at Reinemann Sanctuary are given in the caption of Figure 1. Table 4 lists the sample sizes for the 1987 experiments at Allegany State Park, and Huntington Wildlife Forest in 1988.

Statistics. The means of the responses to the various treatments were compared with the *t* test and the Kruskal-Wallis test (Conover, 1980).

RESULTS

Responses of Beaver. The beaver responded to the ASMs with sniffing in the direction of the ASM from the water, approaching into the wind while swimming in zigzag fashion, going on land at the ASM (termed "land visit"), walking to the ASM, sniffing the ASM, pawing the ASM with the front feet, stepping forward to straddle the ASM, lowering the hindquarters and contacting

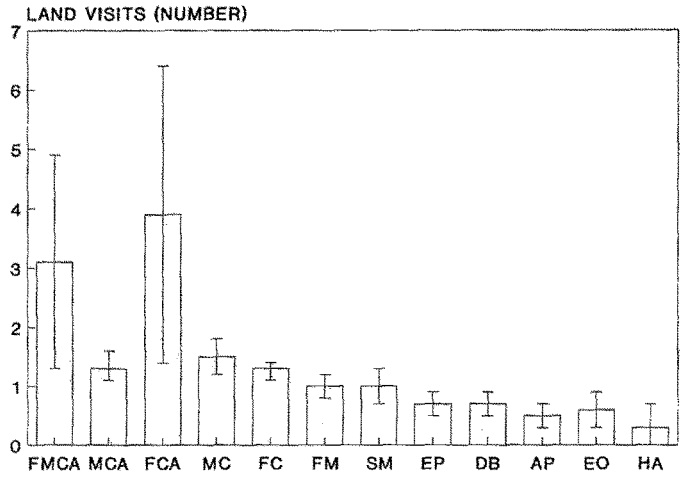

FIG. 1. The number of land visits in response to 12 treatments at Reinemann Sanctuary in 1986 and 1987. *Abscissa*: FMCA: mixture of female and male castoreum and anal gland secretion (AGS), n = 17; MCA: male castoreum and AGS, n = 21; FCA: female castoreum and AGS, n = 13; MC: male castoreum, n = 8; FC: female castoreum, n = 8; FM: full mixture of 24 compounds, n = 17; SM: six strong smelling phenolic and beaverlike compounds (SixMix), n = 8; EP: 4-ethylphenol, n = 10; DB: 1,2-dihydroxybenzene, n = 9; AP: acetophenone, n = 8; EO: 4-ethoxyphenol, n = 8; HA: 3-hydroxyacetophenone, n = 6. *Ordinate*: Mean number of land visits. Dispersion measure is standard error of mean. n refers to samples sizes.

the ASM with the cloaca, and marking the ASM with secretion from the castor sacs and/or the anal glands. The behavior at the mound itself varied from brief sniffing to elaborate obliteration of the artificial scent mound. The response was graded and did not always include the entire sequence. Beaver also hiss when encountering an ASM, but this vocalization can be heard only under optimal

conditions (short distance, no wind), so this sound was not included in the analysis. One animal may repeat the described sequence, and other colony members, except kits of the year, may have their turn at the scent mound. In the past, we have observed up to 19 visits to one experimental scent mound by various members of a colony during one evening's observations. In this study, one beaver responded by sniffing from the water in 75% of the observation nights, two individuals in 25%, and three animals on one occasion each.

Of the several behavioral measures examined, the most inclusive is the duration (in seconds) of a land visit to the ASM (Müller-Schwarze et al., 1986) (Figure 2). It includes the durations of the approach to the mound, sniffing, pawing, marking, and leaving for the water. The stronger the response at the mound, the longer the land visit lasts. On the other hand, a weak response consists in a brief sniffing at or toward the mound while the beaver is on land. Activity is operationally defined here as attracting one or more beaver of a family, inducing it to go on land, visit the scent mound and perform specific behaviors there.

Responses to Whole Castoreum Secretion. The responses to whole castoreum of males and females, with and without added anal gland secretion, were the strongest of all samples. The frequencies or durations of the various behaviors are presented in the left five bars of Figure 1–6. The number of land visits (Figure 1) did not vary significantly across the samples. The mean total durations of "time on land" (Figure 2) ranged from 27.1 sec for a mixture of male and female castoreum and AGS to 57.5 sec for male castoreum. The responses to castoreum samples from males and females, with and without AGS added,

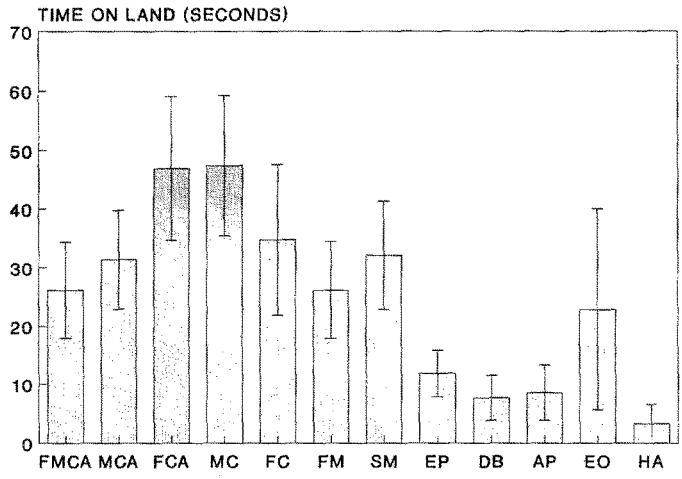

FIG. 2. Average time on land, in seconds (ordinate). Abbreviations as in Figure 1.

did not differ significantly. Sniffing the sample at close range (Figure 3) follows essentially the same pattern. The shorter durations of sniffing the most complex samples may indicate quicker recognition of a clearer signal. Pawing the scent mound was a more stereotyped behavior. With the exception of the female castoreum/AGS stimulus (FCA) the response levels (Figure 4) did not differ between the treatments as much as those for sniffing. The frequencies of straddling the scent mound, the motor pattern for scent marking (Figure 5), paralleled the sniffing durations of Figure 3. Nearly all experimental scent mounds with castoreum samples or mixtures were destroyed eventually, whether during the observation period or the subsequent night, (Figure 6).

Screening of Individual Compounds. There were five compounds among the 24 tested that were consistently active. These were the phenols 4-ethylphenol (EP), 1,2-dihydroxybenzene (DB), and 4-ethoxyphenol (EO), not yet described for castoreum, and the two ketones acetophenone (AP) and 3-hydroxyacetophenone (HA). These compounds are underlined in Table 2 and their structural formulae given in Figure 7. Five additional compounds resulted in occasional delayed destruction of the scent mound during the night, but never during the observations. These are the phenol 4-methyl-1,2-dihydroxybenzene (MD), salicylaldehyde (SA), 5-methoxysalicylic acid (MS), and 3-hydroxybenzoic acid (HB). This group of compounds is italicized in Table 2 and the structural formulae given in Figure 8. The activities of these compounds were not significantly different from zero. At this point, they should be considered merely pheromone candidates.

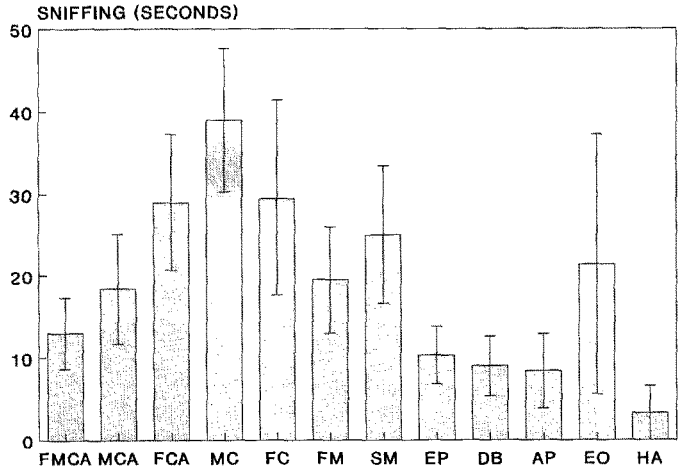

FIG. 3. Average duration of sniffing, in seconds (ordinate). Abbreviations as in Figure 1.

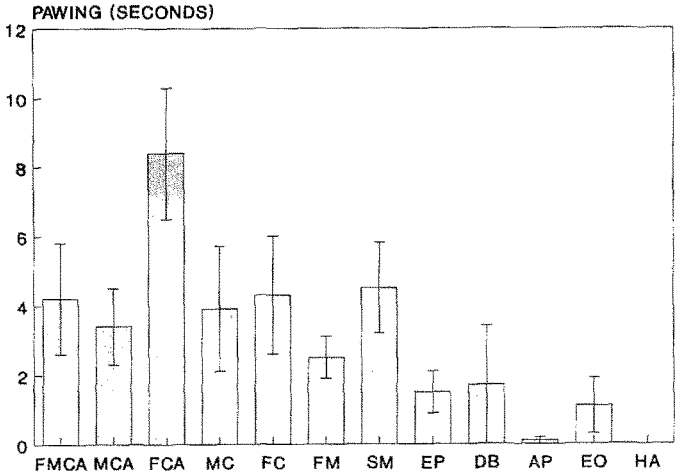

FIG. 4. Average duration of pawing the artificial scent mound, in seconds (ordinate). Abbreviations as in Figure 1.

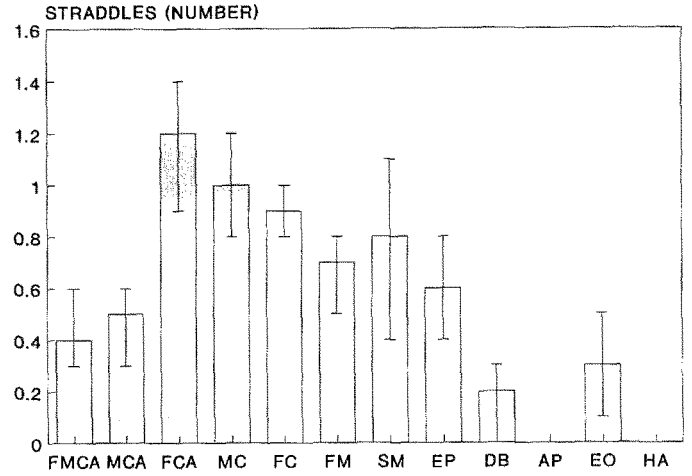

FIG. 5. Average frequencies of straddling (scent marking) the artificial scent mound. Abbreviations as in Figure 1.

The responses to the single compounds are shown in the bars on the right in Figures 1–6. Figure 2 summarizes the overall responses (time on land) for the active compounds, compared with castoreum as standard. Three single compounds were significantly less active than male castoreum (EP: $P = 0.004$; DB: $P = 0.006$; AP: $P = 0.02$). MP did not differ significantly. Only EP activity

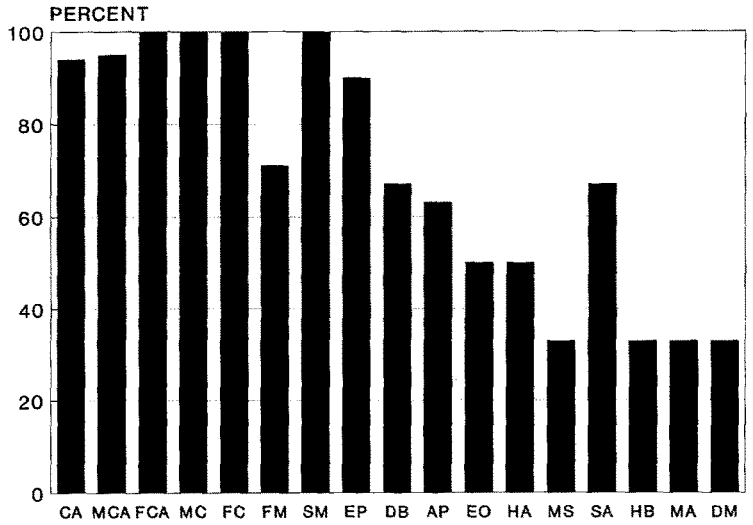

FIG. 6. Percent of artificial scent mounds obliterated. Includes incidents observed directly and scent mounds found destroyed the following morning. CA: castoreum and AGS from both sexes; MCA: same from male only; FCA: same, from female only. MC, FC: male or female castoreum, respectively. FM, SM: Mixture of 25 or six compounds, respectively. EP: 4-ethylphenol; DB: 1,2-dihydroxybenzene; AP: acetophenone. EO: 4-ethoxyphenol; HA: 3-hydroxyacetophenone; MS: 5-methoxysalicylic acid; SA: salicylaldehyde; HB: 3-hydroxybenzoic acid; MA: 4-methoxyacetophenone; DM: 4-methyl-1,2-dihydroxybenzene.

was significantly different ($P = 0.03$) from zero ($P = 0.06$ and 0.07 for DB and AP, respectively). MP did not differ significantly from zero. None of the differences between single compounds was significant.

Among the single compounds, 4-ethylphenol samples (EP) were obliterated in nine of 10 cases, 1,2-dihydroxybenzene (DB) in six of nine, and salicylaldehyde (SA) in four of six cases (Fig. 6).

Mixtures. The responses to mixtures of all 24 compounds (FullMix) or a selection of six phenol- or "beaverlike"-smelling castoreum constituents (SixMix) are shown as FM and SM in Figures 1–6. Both mixtures did not differ significantly from male or female castoreum, although FullMix was less active than SixMix and almost differed significantly ($P = 0.06$) from male castoreum. The difference between the two mixtures was not significant. FullMix ($P = 0.055$) and SixMix ($P = 0.01$) differed significantly from zero . SixMix was significantly more active than the single compounds EP ($P = 0.028$) and BD ($P = 0.03$), barely ($P = 0.068$) more active than AP, and not different from EO. There was no significant difference between FullMix and any of the single compounds.

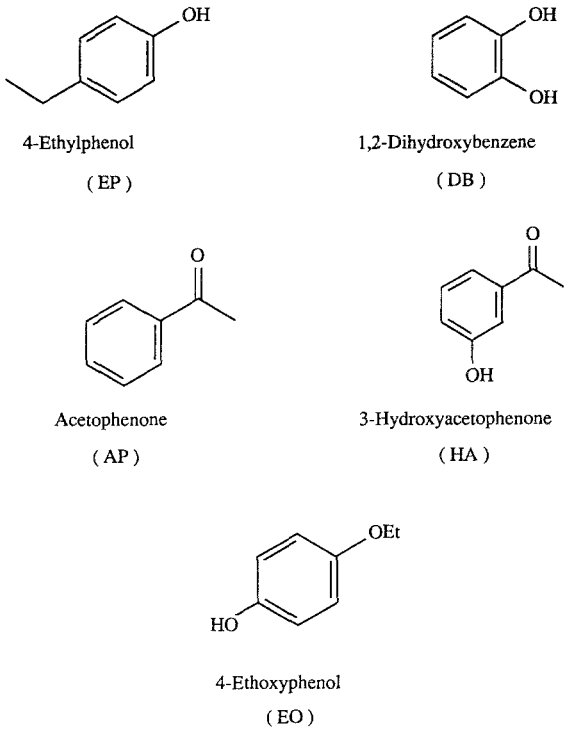

FIG. 7. Structural formulae, names, and abbreviations used in text, for the three phenols and two ketones that were most active.

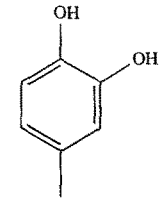
FullMix was tested with and without cholesterol, the most abundant castoreum constituent (Lederer, 1946). With cholesterol, the mixture was less active. Because cholesterol is not volatile and was difficult to keep in the ethanol samples, it was not used for further tests. Therefore, all FullMix data refer to a mixture of 24 compounds, not including cholesterol.

Responses by Different Populations. Further tests of the four most active compounds on two additional New York populations, in Allegany State Park (ASP) and the Huntington Wildlife Forest (HWF), confirmed the findings at the Reinemann Sanctuary.

At Allegany State Park, only one of the single compounds, 4-ethylphenol, was used. Figure 9 shows that from the water, the beaver sniffed castoreum samples the longest. Castoreum differed significantly ($P = 0.05$) from controls and blanks. Activity of EP was intermediate between blanks and controls (NS), and castoreum ($P = 0.05$). The frequencies of land visits to the samples showed a similar distribution (Figure 10).

At Huntington Wildlife Forest, 4-ethylphenol, 1,2-dihydroxybenzene,



1,2-dihydroxy-4-methylbenzene

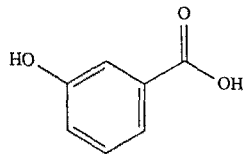
5-methoxysalicylic acid
(MS)



3-hydroxybenzoic acid
(HB)

FIG. 8. Structural formulae, names, and abbreviations for five compounds with minor activity.

4-methoxyphenol, and acetophenone were tested. All four compounds elicited some sniffing from the water, but for much shorter times than castoreum (Figure 11). Table 5 lists the significant differences between pairs of samples. Land visits to the scent mounds were most frequent for castoreum, followed by 4-ethylphenol and 4-methoxyphenol, rare for 1,2-dihydroxybenzene, and absent for acetophenone. (Figure 12). More detailed information can be found in Houlihan (1989).

Beaver at Allegany State Park consistently responded more strongly to the samples than their counterparts at Huntington Wildlife Forest. This confirms earlier experiments where ASP beaver showed more intense responses to castoreum samples than Adirondack beaver at Cranberry Lake Biological Station. The behavior of beaver in the dense population at Allegany State Park will be described in detail elsewhere.

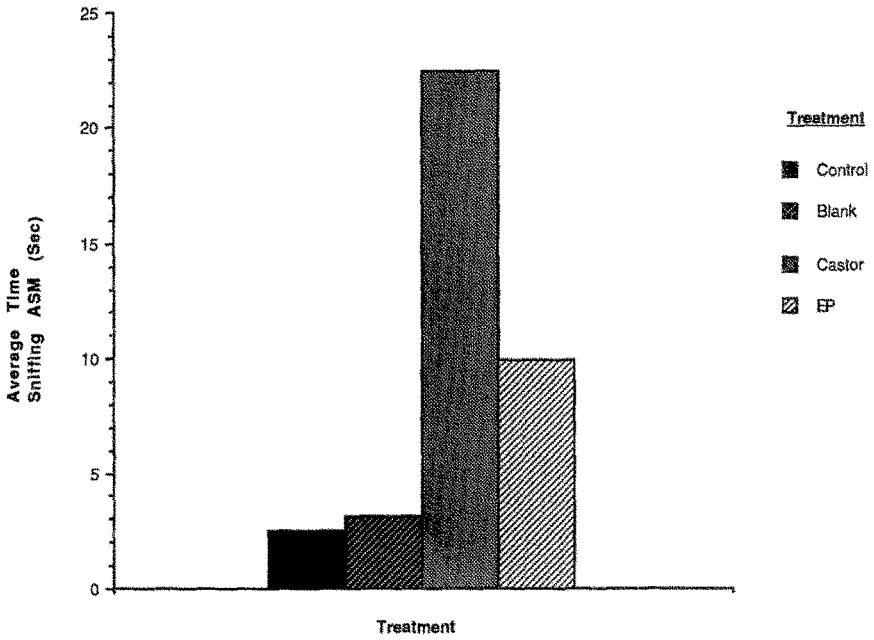


FIG. 9. Average time of sniffing from the water, in seconds (ordinate) for control (solvent = ethyl alcohol), blanks, castoreum, and 4-ethylphenol (EP). Fourteen sites received each treatment once. Allegany State Park, 1987. Differences between treatments are significant (Kruskal-Wallis, $t = 9.87$, $df = 3$, $P = 0.02$).

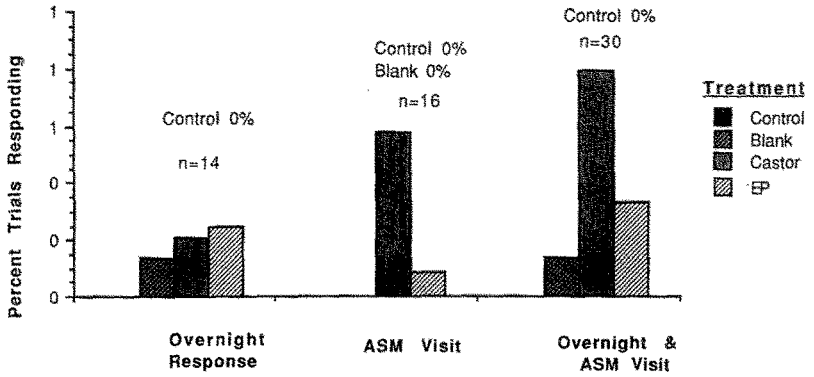

FIG. 10. Percentages of trials with overnight obliteration of the artificial scent mound (left), a visit to the mound during observations (center) and both combined (right). Allegany State Park, 1987. Treatments: control, blank, castoreum, and 4-ethylphenol (EP). Sample size n = trials with a given response.

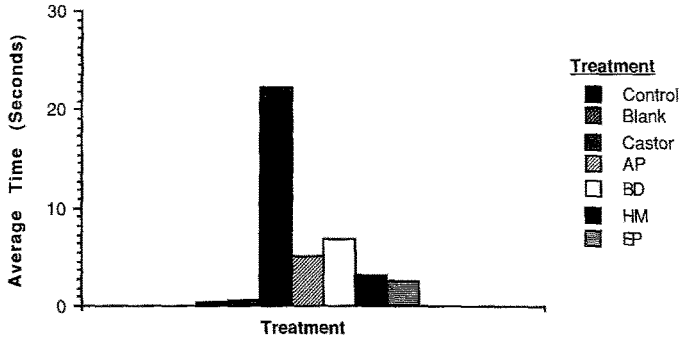

FIG. 11. Average time in seconds (ordinate) spent sniffing the artificial scent mound from the water. Samples: AP = acetophenone; DB = 1,2 dihydroxybenzene; EO = 4-ethoxyphenol; EP = 4-ethylphenol. Seven sites received each treatment once. Huntington Wildlife Forest, 1988). Differences between treatments are significant (Kruskal-Wallis, $t = 18.22$, $df = 6$, $P = 0.006$).

TABLE 4. SAMPLE SIZES FOR BIOASSAYS AT ALLEGANY STATE PARK (ASP) AND HUNTINGTON WILDLIFE FOREST (HWF)[a]

	No of Colonies	Control	Blank	Castor	EP	DB	EO	AP	Total
ASP 1987	14	27	25	27	26	0	0	0	105
HWF 1988	8	16	16	15	17	19	13	15	111

[a]EP = 4-ethylphenol; DB = 1,2-dihydroxybenzene; EO = 4-ethoxyphenol; AP = acetophenone.

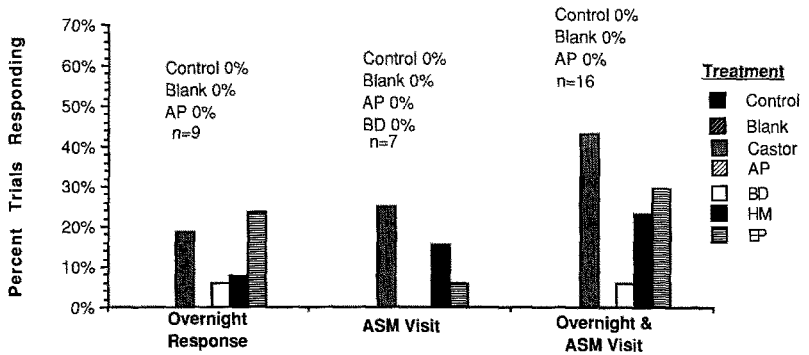

FIG. 12. Percentages of trials with overnight obliteration of the artificial scent mound (left), a visit to the mound during observations (center), and both combined (right). Samples as in Figure 11; n as in Figure 10. Huntington Wildlife Forest, 1988.

Sex Differences. At Huntington Wildlife Forest male beaver showed stronger responses than females to castoreum and 4-ethylphenol. Males sniffed the samples longer from the water (Figure 13) and also more often (44%) than other sex and age classes. In 46% of these observations, an adult of unknown sex responded, and the remaining 10% represented all other sex and age classes. Fifty percent of the land visits to the AMS were by adult males, 15% by 2-year-old males, and the remainder equally by adult females and yearling males and females. Only one animal responded in over 80% of the visits, and up to six animals responded.

DISCUSSION

This is the first time individual compounds of castoreum have been shown to be active by releasing specific behaviors in free-ranging beaver. The bioassay exploited the more tractable responses of resident beaver to strange beaver scent

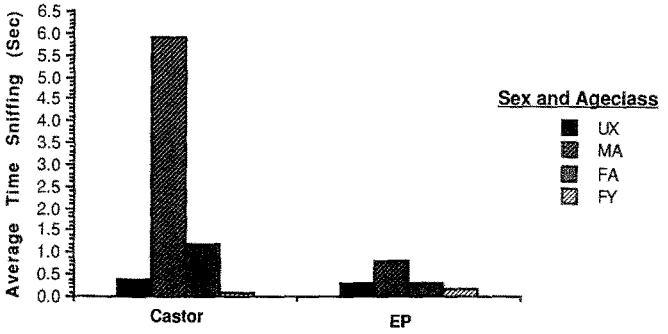

FIG. 13. Sex and age-class differences in the time (in seconds) spent sniffing the artificial scent mound from the water. UX: Unidentified sex or age; MA: adult male; FA: adult female; FY: female yearling.

TABLE 5. PAIRWISE COMPARISONS BETWEEN MEAN DURATIONS OF SNIFFING ASM FROM WATER FOR SEVEN DIFFERENT TREATMENTS, HUNTINGTON WILDLIFE FOREST[a]

	Control

marks near their lodge(s). We are well aware that castoreum most likely serves other functions, such as attracting the other sex, orientation in one's own territory, or assessing breeding condition or strength of neighboring territory owners.

Undoubtedly, different castoreum components may have different functions. The more volatile constituents may serve as long-distance signals to attract the attention of conspecifics, while other, less volatile compounds provide information at close range. Still other compounds may act as a slow-release matrix.

There was no evidence that repeated exposure of the same beaver families led to either habituation or sensitization, as response increases or decreases over time were not significant.

Sex differences of responses suggest that the adult male in the colony plays a greater role in scent marking and responding to intruders than the female. A recent study also found that male beaver show more alarm behavior and scent mark for a longer period during the summer than the female (Buech, 1989). However, in two of our three study areas, sex differences in behavior remain unknown because too few individuals were tagged.

The compounds tested so far appear to act together in additive as well as redundant fashion. The stronger effect of mixtures suggests that the activities of single compounds add up. The five most active phenols and ketones have the same effects and at the same intensities. They can be substituted for one another. This constitutes redundancy, even though their effects are far smaller than that of whole castoreum.

For some stimuli, there was a tendency for activity to decrease with increasing complexity. For example, the most complex mixture, castoreum and AGS from both sexes (left bar in Figures 1–6) was less active than the castoreum/AGS mixtures from either sex alone. Also, SixMix was more active than the mixture of 24 compounds (FullMix). At this point, it is unknown how the numerous compounds may interact to reduce activity.

The higher response level at Allegany State Park is probably related to population density. The ASP population is unexploited. All suitable and many marginal sites are occupied. The yearly turnover rate of sites is high, and the distances between colonies are short. This may result in high intercolony contact and competition, which in turn may increase the probability and intensity of a reaction to foreign scent marks in a family's home colony.

This work has demonstrated that it is possible to bioassay rigorously specified chemical stimuli of mammals in the field despite the numerous intervening variables. The disadvantages of such "noise" are more than compensated for by the natural context.

The precise functions of the various constituents remain to be elucidated. The more volatile compounds are suited to attract attention to the scent mound

over a longer distance, while mixtures of other compounds are expected to provide information on number, sex, age, and status at close range.

Acknowledgments—Most of the work was supported by the Adirondack Wildlife Program, New York State Legislature. Preparation of the manuscript was partially supported by grant GB 88-19982 from the U.S. National Science Foundation. We thank Lucinda Smarro for collecting data at the Reinemann Preserve during the 1986 and 1987 seasons. Thanks go to Dr. William Porter and Richard Sage for facilitating our work at the Huntington Wildlife Forest in Newcomb; Manager Larry Watkins for his support during our work at the Reinemann Sanctuary; and Hugh Dunne, Regional Director, and Dan Colvin for help at Allegany State Park. Undergraduate assistants and volunteers too numerous to mention helped over the years. Timothy Schwender helped to compile the data. We thank Drs. R.M. Silverstein and Francis X. Webster for advice in chemical matters and critical reading of the manuscript.

BARK CONSUMPTION BY VOLES IN RELATION TO MINERAL CONTENTS

LENNART HANSSON

Department of Wildlife Ecology
Swedish University of Agricultural Sciences
S-750 07 Uppsala, Sweden

(Received July 31, 1990; accepted November 29, 1990)

Abstract—Recent field experiments with impregnated wooden sticks have demonstrated a pronounced use by small rodents of mineral supplies, especially sodium, and such findings seemed related to vole damage to forestry seedlings. Consumption of the bark of experimentally introduced aspen twigs and of sodium-impregnated sticks by voles (mainly or only *Microtus agrestis*) correlated significantly on clear-cuts but not on unmanipulated abandoned fields. Such a correlation appeared when abandoned fields were cut continuously in summer. At vole peak densities, bark of pine seedlings experimentally fertilized with sodium was consumed but not bark of seedlings fertilized with calcium or control seedlings. Field pine seedlings attacked by voles had significantly higher levels of calcium, sodium, and phosphorus than the nearest untouched seedling. However, sodium and phosphorus contents correlated strongly. Sodium and calcium supply to voles in laboratory feeding trials did not diminish the moderate interest in pine bark. Such conditions are, however, assumed to mimic a situation of bark sampling in low-density populations. Sodium, and possibly also calcium, requirements are concluded to be partial determinants of the destructive bark consumption by voles at the peaks of their multiannual population cycles.

Key Words—Sodium, calcium, phosphorus, vole, *Microtus agrestis*, bark consumption, field experiments.

INTRODUCTION

Voles, such as *Clethrionomys glareolus* and *Microtus agrestis*, have a diversified diet in summer (Stenseth et al., 1977, Hansson, 1985). The winter diet consists of just a few plant species but is often supplemented with bark from tree seedlings (e.g., Hansson, 1988). North Scandinavian voles fluctuate

0098-0331/91/0400-0735$06.50/0

strongly in numbers, with density peaks every three or four years (Hansson and Henttonen, 1985). Bark is consumed especially by the cyclic peak populations, e.g., on clear-cut and regenerated forest land (Hansson, 1989). Considerable damage can occur in Scandinavian forests during peak years, especially by *M. agrestis* (Myllymäki, 1977).

Voles on Swedish clear-cuts eagerly seek sodium (and sometimes also calcium), especially in strongly cyclic populations and in peak winters (Hansson, 1990). Thus, bark and sodium and/or calcium interest may be related. Bark is especially high in sodium (Lichens and Borman, 1970), and voles may seek both energy and minerals in their bark attacks during winter food shortages. Other minerals, such as phosphorus, also may be involved as they have been shown to be in generally short supply in certain models of nutrient acquisition (Barkley et al., 1980). However, field experiments failed to demonstrate any important role for phosphorus (Hansson, 1990). Laboratory experiments demonstrated that extra sodium and calcium, but not phosphorus, improved microtine reproduction (Batzli, 1986).

The hypothesis that bark consumption is due partly to a deficit in sodium or other minerals was tested by: (1) supplying both bark and sodium in various types of vole habitat—correlations in utilization would indicate some common factor behind these types of consumption; (2) fertilization of tree seedlings with preferred minerals—bark attacks on seedlings treated with a specific mineral would indicate that this is preferred or in deficit; (3) analyses of mineral contents of field seedlings debarked and untouched by voles—differences in mineral contents would indicate deficiencies; and (4) laboratory feeding of bark together with access to mineral solutions—diminished bark consumption with the supply of a certain mineral would indicate that bark consumption was stimulated by specific mineral requirements.

METHODS AND MATERIALS

Bark vs. Na Consumption. Twigs, 1 m long, taken from the top of one aspen (*Populus tremula*) clone growing at Uppsala and hence genetically identical, were put out on clear-cuts and abandoned fields in south-central and northern Sweden in 1986 and 1987. As sampling units, two twigs (ca. 1.5 cm diam.) were located 1 m from a 10 × 3 × 1-cm spruce stick impregnated with 1 M NaCl for 24 hr (cf. Weeks and Kirkpatrick, 1978; Hansson, 1990). The stick was placed under a wooden shelter. Twigs and sticks were distributed in autumn in randomly selected patches of dense shrubby vegetation on clear-cuts, interspersed with nival space in winter. The placement on more generally sheltered abandoned fields was completely random. The Na sticks could have attracted

the voles to the aspen sticks, and therefore a pilot experiment was performed with aspen sticks in direct contact with the Na stick, at 1 m distance and at 100 m distance on one large abandoned field at Uppsala. The mass of the sticks and the areas of bark removed were measured after snowmelt in spring. Studies on clear-cuts were performed both in south-central and northern Sweden, with a higher level of vole population cycling in the northern area. Abandoned fields in south and south-central Sweden had, respectively, stable and weakly cyclic populations (Hansson and Henttonen, 1985).

To see if food quality affected a possible relationship between Na and bark consumption, both items were distributed together on an abandoned field, half of which had been repeatedly cut during two summers (1986–1987) to produce continuously growing and thus, probably, more nutritious food. Cut vegetation, dry and unpalatable, was left as shelter. Vole densities did not differ substantially between the two types of vegetation (Hansson, 1990).

Another experiment was run on 10 plots fertilized with a total of 1 M NaCl/4 m^2 (Inouye et al., 1987) in May and June, 1988. The plots were supplied with both Na sticks and aspen bark in the autumn of 1988. Fifteen untreated plots acted as controls.

Fertilization. Pine (*Pinus sylvestris*) seedlings, 5–8 years old, were randomly selected in groups of three in spring 1987 for fertilization on reforested clear-cuts in south-central and northern Sweden. In May 1987, 20 seedlings in each region were provided with, respectively, 1 M NaCl or 1 M $CaCl_2$ as salt around each stem base or were left untreated. The treatments were repeated in May 1988 but seedlings already attacked by voles were replaced with new undamaged ones. The seedlings were regularly inspected for any animal damage each summer and autumn and again in the following spring. The year 1987 was a vole peak and 1988 a vole decline year on these clear-cuts.

Bark Mineral Concentrations. Pine seedlings attacked by voles (probably only *M. agrestis*) on clear-cuts in south-central Sweden during the peak vole winter 1987–1988 were examined regarding contents of Ca, Na, and P in comparison with nearby undamaged seedlings. Bark was sampled directly after snow melt in April 1988, while the ground was still frozen, on partly consumed seedlings and at the same stem height on the closest totally undamaged seedling within 2 m and thus within reach of the foraging voles. The mineral contents were determined at the Swedish Laboratory for Agricultural Chemistry, Uppsala.

Laboratory Feeding. Immature *M. agrestis* were caught in autumn and kept over winter in laboratory mouse cages on laboratory mouse pellets and water. In winter, one third of them were also given access to a 0.5% NaCl solution and one third to a 1% $CaCl_2$ solution (cf. Batzli, 1986). Every second week, starting with week 2, each animal was given two 15-cm pine stem parts,

ca. 1.5 cm diam., taken from clear-cut seedlings. Bark consumption was examined daily but comparisons between treatments were made for total weekly consumption.

RESULTS

Bark vs. Na Consumption. Consumption of aspen bark did not depend on the distance to Na sticks (Table 1), so Na and bark were consumed independently. The country-wide experiments in the vole increase and peak winters of 1986–1987 and 1987–1988 (Table 2) showed that Na and bark consumption were significantly correlated on clear-cuts but not on abandoned fields. Even on clear-cuts only a small proportion of the total variation was explained by the other variable.

Na and bark consumption on experimentally managed areas disclosed a

Control	18	1.8	22.9	0.18	NS

highly significant correlation on repeatedly cut parts of the abandoned field but no correlation at all in areas of undisturbed vegetation (Table 2). Relatively more Na was consumed at the repeatedly cut areas. The experiment with Na-fertilized plots gave inconclusive results, as Na sticks (both on treatment and control plots) were attacked, but not the aspen bark, during the vole decline winter of 1988–1989.

Fertilization. Among the fertilized pine seedlings, only Na-treated seedlings were attacked by voles; the difference between treatments was highly significant in the vole peak year of 1987–1988 (Table 3, $G = 29.64$, $P < 0.001$). No attack was observed in a low year for vole populations, 1988–1989. However, in both summers voles and other larger animals, especially hares (*Lepus timidus*), had investigated the ground around seedlings fertilized with both Na and Ca. The soil was usually torn up and covered with vole (and hare) droppings. These effects were much more evident in the northern than in the southern study region. Likewise, significantly more Na seedlings were gnawed by voles in the northern than in the southern region ($G = 11.38$, $P < 0.001$). The voles gnawed both root and stem bark close to the root as well as pure wood both in roots and the stem. Most seedling attacks occurred in the summer of 1987. Thus, the vole attacks differed to some extent from normal bark gnawing by voles, which usually is restricted to stem bark in winter.

Bark Mineral Concentrations. Bark of pine seedlings gnawed by voles (probably only *M. agrestis*) in the peak winter of 1987–1988 (Table 4) contained significantly higher concentrations of Na (Wilcoxon matched-pairs signed-ranks test: $T = 1$, $P < 0.001$), Ca ($T = 13$, $P < 0.05$), and even P (T

= 0, $P < 0.001$). The variability (SD) in Na concentrations was especially high in vole-attacked seedlings (Table 5); the voles had obviously sought the very highest Na concentrations. The mineral concentrations were highly correlated: Na–Ca with $r = 0.77$, $P < 0.001$ and Na–P with $r = 0.95$, $P < 0.001$). While Na alone explained 91% of the variation in P, a multiple correlation analysis showed that the inclusion of Ca increased this proportion to 93%.

Laboratory Feeding. The bark consumption in the laboratory varied strongly between vole individuals, as evident from the standard deviation in Table 5, and most voles did not touch the pine bark at all. The consumption increased gradually during each week and from week 2 to week 6 with access to Na. As the bark consumption was not normally distributed, comparisons between treatments were made with the Kruskal-Wallis test. No significant differences occurred in either week 2 ($H = 2.46$), week 4 ($H = 1.77$), or week 6 ($H = 1.51$) but there was a tendency for bark consumption to be higher when there was access to Ca and Na. Contingency tests with animals divided into

attacking and nonattacking individuals did not reveal any significant differences, either. Individual voles showed consistent behavior towards bark. The correlation between consumption in weeks 2 and 4 was 0.63 ($P < 0.001$) and between weeks 2 and 6 was 0.60 ($P < 0.001$).

DISCUSSION

The main aspen experiments were performed both in southern and northern Sweden and at very contrasting densities to test for generality in the results. The differences between clear-cuts and abandoned fields may depend on a temporal difference in the craving for Na, being maximum on clear-cuts in winter and on abandoned fields in summer (Hansson, 1990). Aspen bark was only eaten in winter, when voles on abandoned fields may rely on Na-rich storage organs of grasses and forbs (Hansson, 1971, 1979, 1990) and therefore may show less interest in supplemented Na. The relatively greater use of sodium on fields with continuously growing vegetation may depend on changes in food habits, probably with higher consumption of green leaves, and possibly a higher need for Na in detoxification of plant defense substances (Pehrson, 1983). Vole diet on unmanipulated abandoned fields may include relatively more Na-rich storage organs. Na sticks were obviously preferred to bark, probably due to the much lower Na content in the bark.

The intense bark consumption in summer on Na-fertilized seedlings in northern Sweden during a population peak may relate to the very high interest in Na sticks during the peak year (Hansson, 1990). The excessive Na levels in both bark and wood of the fertilized seedlings may have induced a foraging behavior normally released only under winter food conditions at lower bark Na concentrations. However, bark is probably not attacked only as a result of its mineral content. The large amounts consumed, evident also from stomach analyses (Hansson and Larsson, 1978), imply that it is an important energy source in winter.

Sampling of bark for chemical analyses was performed while the ground was still frozen, so the mineral concentrations found should reflect true late autumn–winter conditions when the seedlings are attacked by voles. The very strong correlation between Na and P is remarkable and implies that one of the minerals should not be considered a primary target for the voles. This correlation thus will explain the significant relation between bark consumption and P content as voles otherwise seem generally to reject P (Inouye et al., 1986; Hansson, 1990). It is still unclear how important Ca is in this food selection but animals during peak populations also readily gnawed Ca-impregnated sticks (Hansson, 1990). Furthermore, bark consumption on reforested clear-cuts was more extensive in areas with high, compared to low, Ca soil levels (Larsson,

1973). Other analyses also have demonstrated higher Ca levels in attacked than rejected pine (*Pinus contorta*) seedlings (Hansson, unpublished observations). The importance of Ca in vole bark attacks needs further examination.

Laboratory experiments did not show less bark consumption when there was access to Na and Ca but rather the reverse. However, the animals examined were well-fed on a diet rich in minerals and probably behaved as animals from only slightly cyclic populations, which do not show any pronounced or density-dependent bark consumption (Hansson, 1989). Such animals seemed only to sample bark, without using it either as a main energy or nutrient source. They then may identify and remember trees with high nutrient content. Bark consumption becomes important in the diet of voles only at peak densities in highly cyclic populations (Hansson, 1988, 1989).

Certain *M. agrestis* individuals showed a much more pronounced bark consumption under laboratory conditions than others. These differences may well be related to interindividual variation of this species in the digestion of coarse food (Hansson and Jaarola, 1989). Bark-consuming individuals may be at an advantage in situations of nutrient stress.

In conclusion, Na seems to be one important factor in bark consumption of both conifer seedlings and deciduous trees and shrubs. However, substantial use may occur only under nutrient or energy stress and may be related to population density and level of resource utilization. Vole densities usually decline dramatically after widespread attacks on *P. sylvestris* bark (e.g., Hansson, 1986). The relative importance of minerals and energy in bark consumption of various tree species needs further study, as does the importance of mineral nutrients in the population dynamics of voles.

Abstract—Hydrocarbons of worker honeybees of known pedigree were extracted and analyzed using gas chromatography and mass spectrometry. Variability in hydrocarbon extracts of individual workers is determined at least in part genetically. Correlations in hydrocarbon composition of extracts were highest among more closely related individuals. Individuals maintained in groups exchange hydrocarbons but still maintain enough self-produced compounds to retain genetically determined individual characteristics. These results demonstrate that extractable hydrocarbons of bees provide sufficiently reliable genetic information to function as labels for use during kin recognition.

INTRODUCTION

The question "when should animals cooperate?" has troubled biologists since Charles Darwin (1859). W.D. Hamilton formulated the rules by which adaptive cooperation or competition should be determined when he developed his theory of the evolution of altruism by kin selection (Hamilton, 1964a,b). His theory states that cooperation and competition should be decided on the basis of the genetic relationships of individuals, with those more closely related being more likely to cooperate. Although his theory does not require that individuals recognize kin, demonstration of functional kin recognition coupled with discriminating behavior on the basis of genetic relatedness provides strong evidence for the importance of kin selection in shaping social interactions of individuals.

Kin recognition systems have been demonstrated throughout the animal group that shows the most extreme forms of cooperative behavior, the Hymenoptera. Recent reviews of recognition in ants (Breed and Bennett, 1987), social bees (Page and Breed, 1987; Getz, 1991), and social wasps (Gamboa et al., 1986) attest to its widespread occurrence. The honeybee society is particularly interesting to study because it consists of a single queen mother who mates with about 17 males (see Page, 1986). This results in the colony consisting of a large number of subfamilies where individuals having the same drone father belong to the same subfamily and are super sisters while those with different drone fathers are half sisters (Page and Laidlaw, 1988). Recent research on the honeybee, *Apis mellifera* L., has demonstrated recognition abilities operating at several levels including: nestmates versus nonnestmates, super sisters versus half sisters for immature and adult workers and queens (see Getz, 1991, for a recent review of kin recognition in honeybees).

Several studies have demonstrated that the labels used by workers in recognition, under specific laboratory conditions, are endogenous in origin and genetically variable (Breed, 1981, 1983; Getz and Smith, 1983, 1986; Breed et al., 1985, 1988a). One common feature of these experiments is the confinement of teneral adults in groups of 10 for approximately five days prior to conducting behavioral assays. Breed et al. (1988a) demonstrated that cues used in recognition in laboratory studies are acquired within about the first 12 hr after emerging as adults. Unrelated individuals that are younger than about 12 hr old are indistinguishable from close relatives and are accepted or rejected without regard for genetic relatedness. Those 12 hr or older are accepted into the social group of 10 workers on the basis of genetic relatedness (cf. Getz et al., 1989).

The identities of recognition cues are unknown; however, it is likely that chemical signals used to discriminate among nestmates of different genetic relationships would function as contact pheromones within the crowded confines of the hive. Recent work on ants implicates the role of cuticular hydrocarbons in nestmate recognition. Recognition labels of individuals of *Camponotus flori-*

danus (Morel and Van der Meer, 1987), *Camponotus vagus* (Clement et al., 1987), and *Pseudomyrmex spp.* (Mintzer, 1988) are altered by rinsing their cuticle with a nonpolar solvent that removes their hydrocarbons or by applying the extracted hydrocarbons of another individual to their cuticular surface. Errard and Jallon (1987) demonstrated the relationship between the ontogeny of recognition labels, demonstrated by rejection of an unfamiliar, heterospecific individual, and the acquisition of hydrocarbons. Vander Meer et al. (1989) demonstrated that sufficient variability exists in cuticular hydrocarbon patterns between colonies to serve as nestmate recognition labels in *Solenopsis invicta.*

The olfactory system of honeybees is very sensitive to hydrocarbon compounds. Getz and Smith (1987) and Getz et al. (1988, 1989) demonstrated that worker honeybees can be conditioned to discriminate among different mixes of 10–25 carbon compounds. They also demonstrated that adult honeybee workers can discriminate between glass rods that have been rubbed on different adult workers (glass rods are assumed to be contaminated with cuticular hydrocarbons of these individuals). Breed and coworkers (unpublished data) demonstrated that contamination of the cuticle of bees with some hydrocarbon compounds, but not others, profoundly affected recognition in small social groups.

Before hydrocarbons can function as kin recognition labels for use in intracolonial interactions of individuals, they must show reliable variability that correlates with genetic relatedness (i.e., be heritable) and have the ability to be preserved on individuals without excessive blending and sharing among nestmates. In this paper, we present evidence that the hexane-extractable hydrocarbons of honeybees have these necessary properties.

METHODS AND MATERIALS

Source of Bees. Worker honeybees used in this experiment were the progeny of two different queens, designated A and B. A series of crosses was performed, using instrumental insemination (Laidlaw, 1977), that resulted in an array of genetic relationships among the progeny (Figure 1, Table 1). Both queens were homozygous for the single-gene recessive mutant, cordovan (see Tucker, 1986), and each was inseminated with the semen of two different drones: one drone carried the cordovan gene and one carried the wild type. The paternity of progeny of each queen could be distinguished by integument color. Workers belonging to the subfamily of the cordovan drone had a brown-striped integument while those of the wild-type drone had black stripes.

Handling of Bees. Combs containing pupae and emerging workers were removed from the colony of each queen and taken into the laboratory. Combs were maintained in an incubator at 33 °C. Newly emerged, teneral workers were collected from the combs and placed into 0.14-liter, paraffin-lined, cardboard

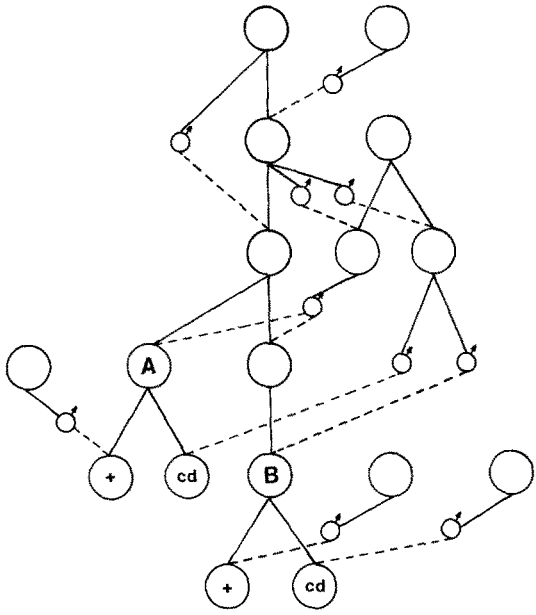

FIG. 1. Pedigree for worker progeny of queens A and B that belong to the wild-type (+) and cordovan (cd) subfamilies. Solid lines represent eggs, dashed lines sperm. The original queen and her drone mate were unrelated and selected from among commercial colonies maintained in the experimental apiary. See also the genetic relationships shown in Table 1.

TABLE 1. GENETIC RELATIONSHIPS (G; PAMILO AND CROZIER, 1982) AMONG AND BETWEEN MEMBERS OF CORDOVAN (cd) AND WILD-TYPE (+) SUBFAMILIES OF COLONIES A AND B (SEE FIGURE 1).

Colony		A		B	
		+	cd	+	cd
A	+	0.80	0.41	0.18	0.18
	cd	0.41	0.91	0.36	0.36
B	+	0.18	0.36	0.80	0.30
	cd	0.18	0.36	0.30	0.80

cups. Each cup received 10 workers. Three cups were set up for the progeny of each of the two colonies. One cup contained 10 workers of the wild-type subfamily (super sisters); one contained 10 workers of the cordovan subfamily (super sisters); and one contained five workers from the wild-type and five from the cordovan subfamilies (half sisters and super sisters). Each cup was provided with a vial of 50% sucrose solution and a vial of water. All sucrose and water came from the same homogeneous source. After five days, all surviving workers were collected and individually frozen in glass vials at −20°C until their hydrocarbons were extracted.

Hydrocarbon Analyses. Hydrocarbons were analyzed for a total of 32 individuals, four cordovan and four wild-type progeny of each queen from each of the homogeneous, super sister groups. An additional four individuals of each of the two subfamilies were analyzed from the mixed group of queen A while three cordovan and five wild type were analyzed from the mixed group of B.

For analyses, hydrocarbons were extracted from each bee for 10 min in 2 ml of hexane. Hexane extracts then were analyzed with a Hewlett Packard 5995C gas chromatograph–mass spectrometer (GC-MS) equipped with a 10-m methylsilicone capillary column. Each *n*-alkane in the series from C_{23} to C_{33} was present in the hexane extract and was individually identified. They are, in ascending order (see Figure 2) peaks 1, 2, 4, 5, 7, 9, 11, 13, 15, 17, and 19. An additional nine peaks were selected as "characters" for statistical analyses of relationships among individual samples, representing individual worker bees, for a total of 20 characters. The additional peaks probably represent unsaturated and methylated derivative compounds of the *n*-alkane series (see Blomquist et al., 1980b; Carlson and Bolton, 1984; Francis et al., 1985, 1989; Carlson, 1988; Smith, 1988).

Statistical Analyses. The total area under each peak (a quantitative measure) was considered to be an independent character for each individual. The similarity among pairs of individuals was determined for these 20 characters using a product-mean correlation coefficient (Sneath and Sokal, 1973, pp. 137–140, 190–192). The correlation coefficient yielded a measure of similarity that was independent of total quantities of each compound, it was dependent only on relative quantities within each individual sample. A correlation matrix of all pairwise comparisons of individuals was generated.

The mean correlation coefficient for all independent comparisons was calculated for each individual from the homogeneous (all super sister) group to individuals belonging to the following categories: super sisters from homogenous groups, half sisters from homogenous groups, super sisters from mixed groups, and half sisters from mixed groups (Table 2). In addition, mean correlations were calculated for each individual from a homogeneous group to all

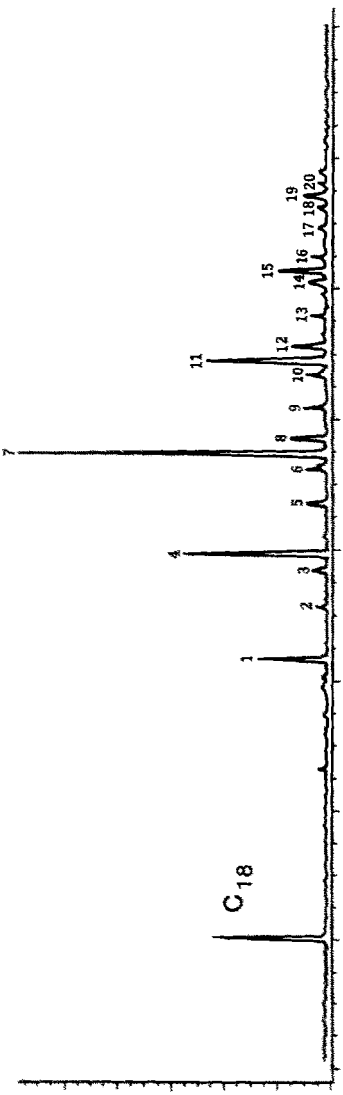

FIG. 2. Gas chromatograph of hexane-extractable compounds from a single worker. Numbered peaks were used in correlation analyses discussed in text.

[a] Each individual worker shown (1–16) was maintained in a homogeneous subfamily group, either cordovan (cd) or wild type (+), from either queen A or B, and was compared with groups of super sisters (SS) and half sisters (HS) maintained in homogeneous and mixed-subfamily (heterogenous) groups, and with non-sibling progeny that were maintained in homogeneous groups.

nonsiblings (progeny of the other queen) of each subfamily, separately. Comparisons of the mean similarities of individuals to super sisters, half sisters in homogeneous and mixed groups, and nonsiblings in homogenous groups then were made using Wilcoxon's signed-ranks and two-sample tests (Sokal and Rohlf, 1981, pp. 449–450).

RESULTS

Individuals from homogeneous groups of both colonies were significantly more similar to their own nestmates in eight of the 12 comparisons shown (Table 3, intercolony comparisons). All four of the nonsignificant comparisons were between half sisters in homogenous groups and members of the unrelated colony. The bias was still toward a closer similarity among nestmates for three of the four nonsignificant comparisons.

The closer similarities shown between nestmates compared to nonnestmates could be either genetic or environmental in origin. Workers could obtain hydrocarbons directly from wax comb prior to emerging. However, comparisons among siblings of different subfamilies (representing different genotypic distributions) that emerged from the same combs demonstrate that the composition of hydrocarbons on individuals is genotypically determined (Table 3, intracolony comparisons). Individuals were more similar to groups of their super sisters, in both homogeneous and mixed groups, than they were to their half sisters. Similarity to their own super sisters in homogeneous groups could be explained on the basis that they shared a common "cup" environment resulting in the transfer and sharing of nongenetically variable labels through social interactions or contact with a common food source or paraffin substrate. However, comparisons of individuals from homogeneous groups with half and super sisters from "mixed" groups only can be explained on the basis of genetically acquired hydrocarbons because they did not share the same cup environment.

Hydrocarbons are transferred and shared among social groups of individuals. Workers from homogeneous groups were more similar to their half sisters maintained in the mixed groups than to their half sisters in homogeneous groups. Half sisters in heterogeneous groups were more similar to each other than were half sisters between homogeneous groups in all comparisons of Table 2. Hydrocarbons were transferred among individuals sharing a cup by either direct contact or perhaps indirectly by adsorption to the paraffin lining and then resorption onto the cuticle.

The mutant marker itself had no measurable effect on the degree of similarity among individuals. The gene for cordovan affects the deposition of melanin in the cuticle (Tucker, 1986) and could have other unknown pleiotropic effects on the hydrocarbon composition of individuals. If so, then individuals

[a] The mean correlations are compared for each of the eight super-sister individuals maintained in homogenous groups from each queen source (see Table 2) to the two designated groups. Wilcoxon's signed-ranks tests were conducted for statistical comparisons. SS = super sisters; HS = half sisters; Hm = from phenotypically homogeneous group (all super sisters); Ht = from phenotypically heterogeneous group (mixture of super and half sisters); cd = cordovan subfamily; + = wild-type subfamily; A = progeny of queen A; B = progeny of queen B.

[b] The mean correlation coefficient for group 1 is higher than the mean correlation for group 2 in all 20 comparisons.

[c] Using the designations in this row to refer back to Table 2, the reader will see that we are testing whether the mean correlations, X, for workers 1–8 as listed in the SS/Hm column are significantly greater than the values X in the Hs/Hm column.

that share the cordovan trait should tend to be more similar to each other than are wild-type individuals. However, an analysis of the similarity of individuals in Table 2 to their own homogeneous group of super sisters shows that this is not the case ($P > 0.05$, Wilcoxon's two-sample test). Another expectation of a "cordovan" effect would be for the same phenotypic groups of progeny of different queens to be more similar to each other. Again, an examination of Table 2 demonstrates that this did not occur ($P > 0.05$, Wilcoxon's signed-ranks test).

Differences in hydrocarbons were greater between subfamilies of colony B than colony A. This is demonstrated by larger differences in correlations between wild-type and cordovan nonnestmates for A workers compared with B workers (Table 2).

DISCUSSION

The extractable hydrocarbons of honeybee workers provide a sufficiently variable and heritable system of potential chemical signals to serve as labels in kin recognition. Honeybees contain an abundance of high-molecular-weight compounds of relatively low volatility. In laboratory studies, each individual maintains subfamily identification even though some label exchange does occur. This is essential to subgroup recognition because complete sharing and blending of compounds would eliminate any distinctive cues. Label exchange may be greater within nests of honeybees because workers are more crowded and probably have more intimate contact with each other and with the wax comb substrate.

Breed et al. (1988b) demonstrated that the wax combs of a honeybee colony provide the primary components of nestmate recognition at colony entrances. They propose that the comb may serve as a medium for adsorption and transfer of lipid-soluble compounds, such as cuticular hydrocarbons, produced by workers and queens. Cuticular hydrocarbons may be used in the absence of comb-acquired cues for nestmate recognition, such as occurs in laboratory studies. Breed et al. (1987) proposed that multiple sources of labels may be involved in recognition learning and that different learned sets of recognition cues, "templates," may be used in different behavioral contexts.

Waxes produced by bees may serve as cues for nestmate and intracolonial subgroup recognition. Nest-specific cues could reside in the wax comb while subgroup cues remain distinct on the cuticle of individuals. The wax secreted by bees for comb construction is composed of many of the same compounds found on the cuticle of bees (Blomquist et al., 1980a). Being itself a glandular secretion, it may also vary in composition among individuals as a consequence of varying genotype and introduce a genotypic component to nest recognition labels.

Unequivocal behavioral evidence is lacking for the role of hydrocarbons in nestmate and intracolonial group recognition; however, extractable hydrocarbons do fulfill the necessary requirements to function in that role. For now, at least, we have identified a candidate set of compounds, out of a vast number of possible compounds produced by bees (see Free, 1988, for a review), that we can evaluate on in our search for recognition labels.

(Received September 13, 1990, accepted December 3, 1990)

Abstract—A monoterpene alcohol was isolated from paraquat-induced lightwood in pines and identified as (+)-*cis*-3-pinen-2-ol [(+)-**3**]. More than a certain amount of (+)-**3** induced a laboratory flight response by the male cerambycid beetle, *Monochamus alternatus* Hope, but (+)-**3** stimulated no response by the female at any dose level tested. Compound (+)-**3** was not detected in trunks of sound pines.

Key Words—*Monochamus alternatus* Hope, Coleoptera, Cerambycidae, male, attractant, (+)-*cis*-3-pinen-2-ol, lightwood, pine.

INTRODUCTION

The herbicide paraquat drastically induces oleoresin-soaked wood (lightwood) in pines (Roberts et al., 1973). Lightwood formation, which is usually accompanied with heavy oleoresin exudation, does trigger a significant mass attack by a variety of beetles (Coleoptera: Scolytidae, Cerambycidae, Curculionidae, Rhynchophoridae, Platypodidae, and Buprestidae) (Hertel et al., 1977; Yamasaki and Suzuki, 1982). The attractive principle of lightwood has not hitherto been identified.

Recently, however, the sesquiterpene alcohol (+)-juniperol and the diterpene aldehyde (+)-pimaral were isolated from trunks of sound pines as well as lightwood and confirmed to be highly attractive to the female cerambycid beetle, *Monochamus alternatus* Hope (Sakai and Yamasaki, 1990).

The present paper describes the identification of (+)-*cis*-3-pinen-2-ol from lightwood as a male-specific attractant.

METHODS AND MATERIALS

Instrumental Analysis. A mass spectrum was measured with a JEOL JMS D-300 mass spectrometer with electron impact ion at an ionizing voltage of 70 eV. A high-resolution (HR) mass spectrum also was measured with the instrument. Proton nuclear magnetic resonance ([^{1}H]NMR) and carbon-13 ([^{13}C] NMR) spectra were run at 500 MHz and 125 MHz, respectively, on a JEOL JNM-GSX 500 spectrometer. ^{13}C−^{1}H shift correlation spectroscopy (COSY), [^{1}H−^{1}H]COSY, and nuclear Overhauser effect (NOE) difference spectra were taken with the spectrometer. All NMR spectra were recorded at 27.0°C using 5% deuterochloroform solutions with tetramethylsilane as an internal standard. Optical rotation was measured with a Horiba SEPA-200 polarimeter, and specific rotation ($[\alpha]_D$) was calculated.

*Isolation of (+)-*cis*-3-Pinen-2-ol[(+)-***3***].* Eighteen-year-old *Pinus densiflora* Sieb. et Zucc. and *P. thunbergii* Parl. were treated with paraquat early in May 1988 (Roberts et al., 1973). Lightwood samples were collected in mid-July 1988. Other sound 17-year-old trees of these species also were harvested.

Essential oils were obtained by steam distillation from freshly crushed wood materials. Minor constituent fractions were separated from the essential oils, respectively, by a combination (Sakai and Yamasaki, 1990) of reduced-pressure distillation and low-temperature liquid chromatography (Yamasaki et al., 1986). Yields: less than 2% of the essential oils.

The minor constituent fractions from the lightwood samples were submitted to silica gel thin-layer chromatography (TLC) using *n*-pentane–ether (5 : 1). Fractions with R_f values of 0.61–0.85 were combined and gas chromatographed (Sakai and Yamasaki, 1990). Compound (+)-**3**, giving a relative t_R of 1.43 (longifolene = 1) was isolated from lightwood formed in *P. densiflora* and *P. thunbergii* and purified by TLC.

The compound was completely missing in the minor constituent fractions from the sound pines (Ia and IIa in Figure 1).

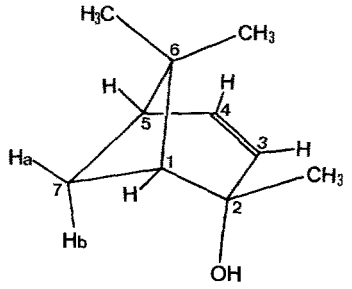

SCHEME 1. (1*R*, 2*R*, 5*R*)-(+)-2,6,6-trimethyl-bicyclo[3.1.1]hept-3-en-2-ol [(+)-*cis*-3-pinen-2-ol].

42.76(>CH—, C-5), 46.92(>C<, C-6), 53.95(>CH—, C-1), 74.24(>C<, C-2), 129.98(>CH—, C-3), 138.57(>CH—, C-4). The kinds of carbons were determined by distortionless enhancement by polarization transfer (DEPT).

The Insect. Approximately 100 individuals of each sex of *M. alternatus* (being attracted to paraquat-treated pines) were collected during mid-July 1989 and kept in individual containers (Yamasaki and Suzuki, 1982). They were marked with white spot(s) to distinguish individuals and randomized before use.

Laboratory Bioassay. Hourly duplicate tests were run by a concurrent employment of two 6.8 × 2.6 × 3.8-m chamber-type olfactometers at 30-min intervals from 8:00 PM to either 1:30 or 3:00 AM according to the previous method (Sakai and Yamasaki, 1990). Twenty-five individual insects were placed in each chamber. In one case, both chambers contained either all males or all females. In the second case, one chamber contained all males, and the other chamber contained all females. Pieces of filter paper impregnated with a *n*-pentane solution (40 μl) were placed into one inlet at 15-min intervals. The other was a blank (air only) inlet. The flow rate was about 5.1 m^3/min. The rate at the 30-min intervals was about 12.3 m^3/min.

RESULTS

(+)-3 as Male-Specific Attractant. Table 1 shows flight responses of both sexes of *M. alternatus* to this compound. No male responded to doses of 1.25 × 10^{-1}μg/15 min and less. On treatment with a dose of 12.5μg, four to five males were observed arriving at this odor source. At higher dose levels, the numbers were reduced to some extent, but the control, i.e., the number of individuals arriving at the blank inlet, increased somewhat; these phenomena may be due to a decrease in the odor concentration gradient in the chambers. It therefore seems likely that the dose of 12.5 μg/15 min is close to an adequate one under the test conditions.

[b] Number represents the mean of two replications; range in parenthesis; controls are shown in brackets.
[c] *n*-Pentane only (40 μl/15 min).

In contrast to the results obtained with males, (+)-**3** induced no flight response by females at any dose level tested. Most were at rest or walking, especially downwind. A few were flying in no specific direction.

(+)-Juniperol [(+)-**1**] and (+)-pimaral [(+)-**2**], and especially the combination of these compounds, are attractive to the female (Sakai and Yamasaki, 1990). As shown in Table 2, the attraction of (+)-**1** or (+)-**2** alone for the female and that of a blend of these two compounds in constituent composition (Figure 1) of essential oil (LW oil) from lightwood formed in *P. densiflora*, were found to be independent of adding (+)-**3**.

Attraction of (+)-3 with Other Compounds for Male M. alternatus. Table 3 shows flight responses of the male to this compound in combination with (+)-**1** and/or (+)-**2**. Compound (+)-**3** delivered in a ratio of 12.5 μg/15 min attracted four to five males, while (+)-**1** and (+)-**2** presented individually in the same ratio attracted only two and one males, respectively (August 10). Neither addition of (+)-**3** to (+)-**1** nor to (+)-**2** was effective in enhancing male attraction (August 8). Instead, a blend of these three compounds attracted seven

to nine males (August 8 and 9). The activity of the ternary blend reached almost that of 34.8 mg of LW oil (August 9).

On the other hand, two blends of (+)-**1** and (+)-**2** prepared in different ratios attracted three to five males (August 9 and 10). The other essential oil (CW oil), devoid of (+)-**3** (Figure 1), from sound *P. densiflora*, also attracted nearly the same number of males, i.e., four (August 9).

DISCUSSION

The two synthetic optical isomers of **3** are well known (Whitham, 1961; Bessière-Chrétien and Grison, 1970; Abraham et al., 1972; Jefford et al., 1973; Witkiewicz and Chabudziński, 1977; Brocki et al., 1980; Traynor et al., 1980). From data taken by means of gas chromatography–mass spectrometry, **3** has been presumed to occur in flowers of *Ophrys fusca* Link (Borg-Karlson et al., 1985), in leaves of *Eucalyptus sparsa* Boomsma (Brophy and Lassak, 1986), and in hindguts of the female *Dendroctonus frontalis* Zimm. (Renwick and Hughes, 1975). No evidence for optical isomerism has been presented in these reports. Recently, a racemate—$[\alpha]_D = 0.0°$ (c = 0.32, $CHCl_3$)—of the enantiomers of **3** was isolated from green stems, leaves, and flowers of the resinous half-shrub, *Gutierrezia sarothrae* (Epstein and Seidel, 1989). In this paper, the occurrence of the enantiomer, (+)-**3**, in paraquat-induced lightwood was clearly verified.

Neither enantiomer of **3** or racemic **3**, to our knowledge, has been known as an attractant for any insect species. Tables 1 and 2 demonstrate that (+)-**3** is an attractant specific for the male *M. alternatus*; in other words, the female is indifferent to this compound. Addition of (+)-**3** to the combination of (+)-**1** and (+)-**2** was more effective in enhancing male attraction (Table 3).

Compound (+)-**3** was not detected in the trunks of sound hosts (Figure 1). Nevertheless, we are not sure that this compound is absent in the body of *M. alternatus* or its habitats without paraquat-treated pines. Thus, we now do not know whether in this insect species (+)-**3** is related to sexual communication or has some physiological significance for the male sex.

AVERSIVE RESPONSES OF WHITE-TAILED DEER, *Odocoileus virginianus*, TO PREDATOR URINES

(Received September 10, 1990; accepted December 10, 1990)

Abstract—We tested whether predator odors could reduce winter browsing of woody plants by white-tailed deer (*Odocoileus virginianus*). Urine from bobcats (*Lynx rufus*) and coyotes (*Canis latrans*) significantly reduced browsing of Japanese yews (*Taxus cuspidata*), and repellency was enhanced when urine was reapplied weekly as a topical spray. Urine of cottontail rabbits (*Sylvilagus floridanus*) and humans did not reduce damage, suggesting that deer do not respond aversively to odors of nonpredatory mammals or occasional predators with which they lack a long evolutionary association. Bobcat and coyote urine were more effective in tests conducted with eastern hemlock (*Tsuga canadensis*), which is less palatable to white-tailed deer than Japanese yew. A dichloromethane extract of bobcat urine was as effective as unextracted urine in reducing damage to hemlocks. Testing of the organic components of bobcat urine, particularly the volatile components, may enable identification of the compounds responsible for the repellency we observed.

Key Words—bobcat, browsing, *Canis latrans*, coyote, *Lynx rufus*, *Odocoileus virginianus*, predator urine, repellent, semiochemicals, white-tailed deer, wildlife damage, *Taxus cuspidata*, *Tsuga canadensis*.

INTRODUCTION

Browsing of twigs of woody plants by white-tailed deer (*Odocoileus virginianus*) in winter often damages apple trees (Katsma and Rusch, 1979) and nurs-

*To whom correspondence should be addressed.

0098-0331/91/0400-0767$06.50/0

ery stock (Anderson, 1984), leading to significant economic losses (Anderson, 1984; Phillips et al., 1987). In addition, browsing by white-tailed deer can have a negative impact on natural regeneration of important timber species (e.g., Graham, 1954; Frelich and Lorimer, 1985). In areas where other forms of control are impractical, chemical repellents often are used (Scott and Townsend, 1985; Purdy et al., 1987). However, the majority of chemical repellents are either ineffective or reduce damage only slightly (Palmer et al., 1983; Conover, 1984, Swihart and Conover, 1990), perhaps because of anthropogenic notions regarding repellency (Shumake, 1977). Thus, the identification of effective repellents with a biological basis is needed for use against white-tailed deer.

Recognition and avoidance of odors of sympatric predators by mammalian prey has been documented (Fulk, 1972; Stoddart, 1980) and may have a genetic component (Müller-Schwarze, 1972; Gorman, 1984). In an applied context, the use of predator odors has reduced damage caused by several species of herbivorous mammals, including snowshoe hares (*Lepus americanus*) (Sullivan and Crump, 1984, 1986; Sullivan et al., 1985a; Sullivan, 1986), voles (*Microtus* spp.) (Sullivan et al., 1988a), pocket gophers (*Thomomys talpoides*) (Sullivan et al., 1988b), woodchucks (*Marmota monax*) (Swihart, 1991), and mule deer (*Odocoileus hemionus*) (Sullivan et al., 1985b; Melchiors and Leslie, 1985). However, the effect of predator odors on the behavior of white-tailed deer is largely unknown. Here, we report on the ability of odors of predators to repel white-tailed deer from woody plants placed in woodlots in Connecticut, U.S.A.

The degree to which a prey species responds aversively to odors of predators probably depends on several factors, including whether or not the predator and prey occur sympatrically (Müller-Schwarze, 1972), the duration of the association between predator and prey (e.g., Gorman, 1984), and the extent to which responses to odors can be culturally transmitted among prey (Swihart, 1991). In addition, the frequency of life-threatening versus innocuous encounters with a predator species may influence selection for an aversive response to the predator or its odor. Learned aversions also are undoubtedly influenced by the frequency of these events, although on a much shorter time scale.

Bobcats (*Lynx rufus*), coyotes (*Canis latrans*), and humans occur sympatrically with white-tailed deer throughout much of the herbivore's range (Hall, 1981). Bobcats and coyotes share a long ($\approx$ 1–2 million years) association with white-tailed deer (Kurtèn and Anderson, 1980), although coyotes have expanded their range into the southern and extreme eastern portions of the United States only in recent years (Hall, 1981). Although the relative importance of bobcats and coyotes as predators of deer is uncertain, coyotes are more likely to prey upon fawns (Mech, 1984), whereas bobcats also prey upon older deer (Marston, 1942). In Connecticut, humans currently are the most significant predators of deer, whereas bobcats and coyotes occur in low numbers. However, interactions between white-tailed deer and humans have occurred in the eastern United

States only for about 10,000 years (Nash, 1974). Moreover, learned aversions to odors of humans presumably are ameliorated in Connecticut because of the high frequency of encounters with human scent in suburban areas that prove to be innocuous or beneficial (e.g., availability of food around houses). Based on these factors, we hypothesized that the order of repellency of odors of these three predators to white-tailed deer would be: bobcat > coyote > human.

METHODS AND MATERIALS

Experiments were conducted during winter, 1989–1990, near Danbury in western Connecticut. Density of deer, as estimated by pellet-group counts in 1989 and 1990, averaged 8.3/km^2, and browsing damage to nursery stock and ornamental shrubs near houses often was severe. To ensure that deer were not inhibited from visiting experimental sites for reasons other than the presence of predator odors (e.g., dogs, lights, vehicles), experiments were conducted in wooded areas. Wooded areas were separated by >1.6 km to increase the likelihood that different sites were visited by different deer (see Severinghaus and Cheatum, 1956; Larson et al., 1978). Damage was expressed as the percentage of shoots that were browsed by deer, and differences among treatment means at the end of each experiment were examined using a nonparametric Kruskal-Wallis test with one-tailed multiple pairwise comparisons (Conover, 1980, p. 230).

Trials with Japanese Yews. Trial 1 was designed to test whether the odor of small amounts of urine could reduce feeding by deer. In addition to bobcat, coyote, and human urine, we tested whether deer responded to some common component(s) of mammalian urine by examining browsing in the presence of urine from cottontail rabbits (*Sylvilagus floridanus*). Distilled water served as a control.

On November 27, 1989, 5-year-old Japanese yews (*Taxus cuspidata*) were transplanted at six woodlots. Japanese yews are popular ornamental evergreen shrubs in Connecticut, and they also are highly palatable to deer (Conover and Kania, 1988; Swihart and Conover, 1990). All yews had been grown together under partial sunlight in a lath house and subjected to the same watering and fertilization schedule before transplanting. They had not been subjected to browsing before the experiment. In each woodlot, six plots were established at the vertices of a 3×2 rectangular grid, with a 20-m spacing between adjacent vertices. Five of the plots were randomly selected, and eight yews were planted at each of the five plots using a 4×2 configuration with 1-m spacing. For each yew, counts then were made of all shoots >1.25 cm in length (≈ 600 shoots per plot). After randomly assigning a treatment to each plot, a microcentrifuge tube (1.5-ml capacity) was attached to each yew with a twist-tie. Syringes then

were used to dispense 1.2 ml of the appropriate urine into each tube. Finally, a small wooden dowel was inserted through a hole drilled in the top of each tube. The dowels protruded 1.0–1.5 cm above each tube, thereby serving as a wick to enhance dissemination of scent. Microcentrifuge tubes and dowels also were attached to control yews. Damage was monitored periodically over the next 35 days by counting the number of browsed shoots.

In trial 2 we tested whether topical application of urine at weekly intervals could enhance its repellency. The following modifications were made to the design used in trial 1. One 7-year-old Japanese yew ($\approx$350 shoots per plant) was used at each plot. At weekly intervals beginning on December 1, 1989, each yew was sprayed with a mist of 6 ml of the appropriate treatment. To enhance retention of the urine, each treatment solution (and the water control) was mixed 100:1 with Vapor Guard (Miller Chemical and Fertilizer Corporation, Hanover, Pennsylvania). Browsing damage was monitored until January 24, 1990. One of the six study sites was eliminated from subsequent analyses because of repeated visits of either a large domestic cat or a small bobcat during the trial. Upon visiting the site, the felid would bite the wooden potting stakes used to label plots and urinate on or near treated yews.

Trial with Eastern Hemlock. Trial 3 was conducted to test whether increasing the frequency of topical application increased the repellency of bobcat and coyote urine. Trials were conducted using eastern hemlock (*Tsuga canadensis*), a native species whose regeneration has been hindered in recent years by browsing of white-tailed deer (see Frelich and Lorimer, 1985). To ensure that no prior browsing of plants had occurred, we used hemlock branches collected from the sun crowns of mature trees. Mature-stage branches are more palatable to deer than juvenile-stage growth (R.K. Swihart, unpublished data); hence, the use of mature-stage growth provided a powerful test of the repellency of the predator urines. At each plot, branches were attached with wire to the bases of saplings that had been cut to a height of <15 cm, and the number of shoots was counted ($\approx$ 175 shoots per plot). Seven experimental plots were established at each of 10 wooded sites on February 20 and 21, 1990, and a separate treatment was randomly assigned to each plot. Four plots were sprayed with 6 ml of either bobcat or coyote urine, two plots at weekly intervals, and two plots twice weekly. A fifth plot sprayed with distilled water served as a control.

To determine whether aversive responses of deer were elicited by organic components of predator urine, we tested a dichloromethane extract of the bobcat urine. One liter of urine was extracted with two 50-ml portions of dichloromethane in a separatory funnel. The combined extracts were concentrated in a Kuderna-Danish apparatus to 2.4 ml and then diluted to 1 liter with methanol. The methanol solution (6 ml) then was applied at weekly intervals to a sixth plot at each site. A seventh plot sprayed with a 2.4:1000 mixture of dichloro-

methane and methanol served as a control. Final estimates of browsing damage were made on March 20, 1990.

RESULTS

Trials with Japanese Yews. Onset of browsing to Japanese yews was rapid in trial 1; after 14 days 80% of shoots of control plants had been removed (Figure 1). Moreover, the presence of urine did not prevent browsing, and browsing of treated plants increased over time. Nonetheless, plants to which tubes containing bobcat and coyote urine had been attached exhibited significantly ($P < 0.05$) lower levels of browsing than did plants treated with water, rabbit urine, or human urine at the conclusion of trial 1. Damage to yews treated with human urine, rabbit urine, or water was statistically indistinguishable. Yews treated with bobcat urine were browsed significantly ($P < 0.05$) less than those treated with coyote urine.

The repellency of bobcat and coyote urine was enhanced by repeated topical application in trial 2. Although the progression of damage to control yews was reasonably similar in trial 1 and trial 2, damage to plants treated with bobcat or coyote urine was substantially lower (Figures 1 and 2). In fact, complete suppression of browsing was achieved with bobcat urine at three sites and with coyote urine at four sites. Moreover, no progressive increase in damage

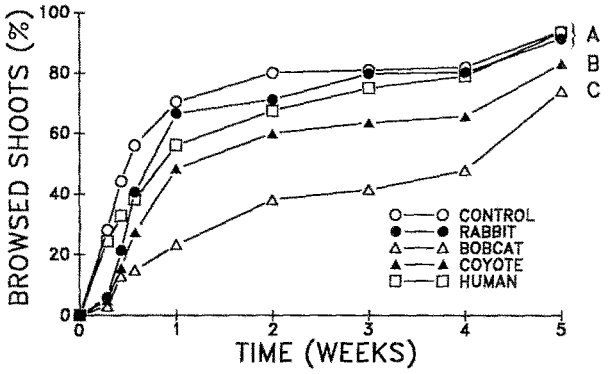

FIG. 1. Percentage of shoots of Japanese yews browsed by white-tailed deer in western Connecticut during a five-week period, winter 1989–1990. Treatments were 1.2 ml of urine placed in microcentrifuge tubes; distilled water served as a control. Significant differences occurred among treatments in the level of deer browsing at the end of the trial (Kruskal-Wallis $T = 16.3$, $P = 0.003$), although treatments sharing the same letter did not differ significantly ($\alpha = 0.05$).

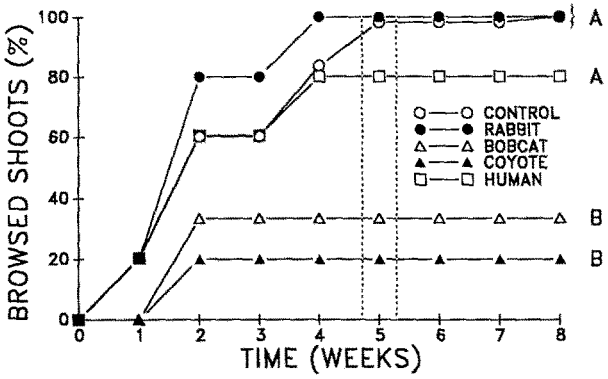

FIG. 2. Percentage of shoots of Japanese yews browsed by white-tailed deer in western Connecticut during an eight-week period, winter 1989–1990. Urine or a distilled water control (6 ml) was sprayed on each plant at weekly intervals. Significant differences occurred among treatments in the level of deer browsing at the end of the trial (Kruskal-Wallis $T = 14.8$, $P = 0.006$), although treatments sharing the same letter did not differ significantly ($\alpha = 0.05$). Dashed vertical lines enclose the levels of browsing that were present when trial 1 was terminated (Figure 1).

occurred. After eight weeks, yews treated with bobcat or coyote urine had received significantly ($P < 0.05$) less browsing by deer than had yews treated with water, rabbit urine, or human urine (Figure 2). Yews treated with human or rabbit urine did not differ from control plants. Checks of three of the study sites four weeks after the trial was terminated revealed that no yews treated with coyote urine had been browsed, whereas one yew treated with bobcat urine and the only human-treated yew that had vegetation remaining had been browsed.

Trials with Eastern Hemlock. Eastern hemlock was browsed less by deer than were the Japanese yews in the earlier trials. Indeed, no browsing occurred at three sites, necessitating their removal before analyses. For control plants, the percentage ($\bar{X} \pm$ SE) of hemlock shoots browsed after four weeks at the remaining seven sites was 30.8 ± 11.3, whereas the percentage of yew shoots browsed was 81.9 ± 10.4 in trial 1 and 83.7 ± 16.3 in trial 2.

No differences were evident in the percentage of hemlock shoots browsed that were treated with water (25.7 ± 13.4) or methanol–dichloromethane (35.9 ± 12.0). Thus, mean values of these controls were calculated at each site and used in analyses. Bobcat and coyote urine depressed levels of browsing significantly, but no additional reductions in browsing were obtained by increasing the rate at which they were applied (Figure 3). In addition, the dichloromethane extract of bobcat urine reduced browsing as effectively as the unextracted urine (Figure 3).

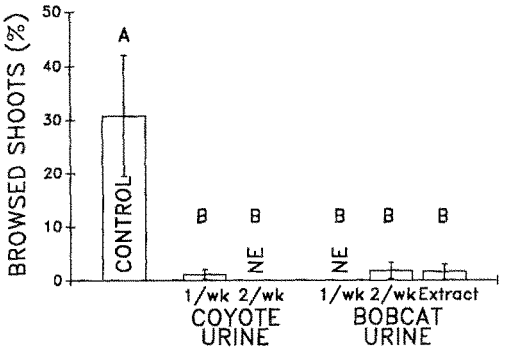

FIG. 3. Percentage of shoots of eastern hemlock browsed by white-tailed deer in western Connecticut during a four-week period, winter 1989–1990. Urine, a dichloromethane extract of bobcat urine, or a control (water or dichloromethane–methanol) was sprayed on each plant at weekly (1/wk) or twice weekly (2/wk) intervals. Significant differences occurred among treatments in the level of deer browsing at the end of the trial (Kruskal-Wallis $T = 29.9$, $P < 0.001$), although treatments sharing the same letter did not differ significantly ($\alpha = 0.05$). NE = not eaten.

DISCUSSION

In general, our prediction regarding the relative effectiveness of the three predator odors (bobcat > coyote > human) was upheld. In trial 1, bobcat urine was significantly more repellent than coyote and human urine, and coyote urine was more repellent than human urine (Figure 1). When reapplied at weekly intervals as a topical spray, both coyote and bobcat urine were more effective than human urine (Figure 2). Although yews repeatedly treated with coyote urine suffered slightly less damage than those treated with bobcat urine, the differences were not significant. In contrast, mule deer in British Columbia were repelled more by coyote than by bobcat urine (Sullivan et al., 1985b).

White-tailed deer appear more alarmed by the presence of bobcats than of coyotes, and this may be related to the contrasting styles of hunting of the two predators (Marchinton and Hirth, 1984). Coyotes, like other canids, chase deer (Marchinton and Hirth, 1984), whereas bobcats employ an ambush hunting style that enables them to kill deer that are bedded (Marston, 1942). It is possible that differences in the uncertainty of a predator's whereabouts, arising from contrasting hunting styles, could lead to differences in the aversive responses of prey exposed to fear-provoking stimuli (i.e., predator scents). In prey such as deer, which are capable of culturally transmitting aversive behaviors, conditions such as prevailing predator densities may be more influential in determining the relative magnitude of aversive responses.

At least two factors could contribute to the ineffectiveness of human urine

as a repellent. As mentioned previously, white-tailed deer and humans have existed sympatrically in the northeastern United States for a relatively brief period in evolutionary terms, thereby mitigating against the development of innate responses to human odors. In addition, the relatively high number of people inhabiting areas in the midst of deer habitat in Connecticut ensures that deer commonly encounter sensory stimuli associated with humans or their activities that do not reinforce an aversive response.

Sullivan et al. (1985b) reported that for periods of four to seven days, mule deer in British Columbia browsed untreated salal (*Gaultheria shallon*) leaves significantly more than leaves associated with bobcat or coyote urine. Based upon tests of a wide variety of predator odors, they concluded that mule deer responded aversively to odors that indicated "predator" but not to novel odors. Similarly, Gorman (1984) found that voles (*Microtus arvalis*, *M. agrestis*) responded aversively to anal gland secretions of a predator (stoat, *Mustela erminea*) but not to those of a nonpredator (guinea pig, *Cavia porcellus*). White-tailed deer reacted aversively to predator but not to nonpredator urines in our study, thus providing additional evidence that herbivorous mammals can distinguish predator odors from nonpredator odors and adjust their behavior accordingly.

The effectiveness of bobcat and coyote urine placed in microcentrifuge tubes declined over time (Figure 1), suggesting that deer either habituated to the scents or that the repellent components of the odors were lost via evaporation or degradation. Similar reductions in efficiency of predator urine placed in tubes or vials were reported by Sullivan et al. (1985a,b), Sullivan (1986), and Swihart (1991). Innate responses to fear-provoking olfactory stimuli should not habituate (Bolles, 1970, Müller-Schwarze, 1974), although habituation in response to learned avoidance responses seems possible in the absence of occasional reinforcement. Experiments with naive mule deer suggested that aversive responses to predator odors may have a genetic component (Müller-Schwarze, 1972).

The prolonged effectiveness of bobcat and coyote urine when reapplied periodically (Figures 2 and 3) supports the idea that evaporative loss of volatile components of the urine was likely the cause of the gradual decline in effectiveness observed in trial 1. Volatility appears to be an important property of semiochemicals (Wheeler, 1976), and volatile constituents of red fox (*Vulpes vulpes*) urine and mustelid anal gland secretions repel snowshoe hares (Sullivan and Crump, 1986), voles (Sullivan et al., 1988a, 1990b), and pocket gophers (Sullivan et al., 1988b, 1990a). Moreover, fermented eggs, which are repellent to deer (Bullard et al., 1978b), contain amines and volatile fatty acids that are also found in anal gland secretions of canids (Preti et al., 1976, Bullard et al., 1978a).

An alternative explanation for the increased effectiveness of the predator

urines applied as a spray in our study is that components of the urine may function as taste repellents. Baines et al. (1988) recently patented a synthetic deer repellent containing felinine, a nonvolatile amino acid found in the urine of domestic cats and bobcats (Westall, 1953; Mattina et al., 1991), as well as the acidic component of lion (presumably *Panthera leo*) feces. However, we were unable to find published documentation of the repellency of these compounds. Our results with the dichloromethane extract of bobcat urine indicate that organic constituents of the urine were responsible for the repellency we observed. It is doubtful that felinine was present above trace quantities in the extract because it is a charged compound and should not partition into the nonaqueous phase. We have identified >25 volatile constituents of bobcat urine (Mattina et al., 1991), and further trials are planned to determine the repellency and mode of action of specific components of the urine.

From a practical perspective, reduction of damage by herbivorous mammals to agricultural crops could benefit from identification and synthesis of the actively repellent compounds in excreta or glandular secretions and from development of effective slow-release devices to enhance the compounds' long-term effectiveness. Significant progress in these areas has been made for semiochemicals from red fox (Jorgenson et al., 1978, Wilson et al., 1978, Sullivan and Crump, 1986) and mustelids (Crump, 1980a,b, Brinck et al., 1983, Sullivan and Crump, 1984, Sullivan et al., 1990a,b). Because of the importance of white-tailed deer as an agricultural pest in much of the eastern United States, further clarification of the role and utility of predator urines as repellents of deer is warranted.

Acknowledgments—We thank P.M. Picone and M. Day for their diligent assistance in the field and laboratory portions of this study. M.R. Conover graciously permitted us to use his unpublished data on deer density near Danbury, Connecticut. The manuscript was improved by the comments of M.R. Conover, P.M. Picone, T.P. Sullivan, and an anonymous reviewer.

Abstract—Conformational parameters of pheromonally active analogs (**1** and **2**) of periplanones, the sex pheromones of the American cockroach, were investigated by molecular mechanics calculations. They existed in several conformers with small energy differences. These results were supported by NMR analysis. The structural features of the conformers of the analogs were compared with X-ray structures of periplanones.

Key Words—Conformational analysis, molecular mechanics, structure–activity relationships, periplanone, periplanone analogs, sex pheromone, *Periplaneta americana* L., American cockroach, Orthoptera, Blattidae.

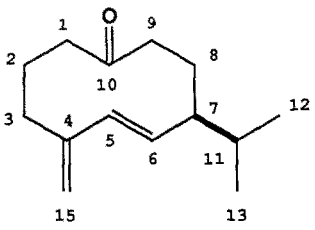
INTRODUCTION

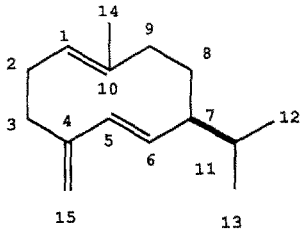
The utilization of molecular mechanics (MM) calculations on the conformational analysis of organic molecules has become an active area of research. We have already reported the application of MM analysis on the conformational property of insect pheromone serricornin (Chuman et al., 1990).

Periplanones-A (P-A) (**3**) (Hauptmann et al., 1986a) and -B (P-B) (**4**) (Figure 1) (Persoons et al., 1974) are the major sex pheromone components produced by female american cockroach (*Periplaneta americana* L.). Their activity is extremely high: threshold 10^{-5} μg for **3** and 10^{-7} μg for **4**. The X-ray crystallographic analyses of them (P-A: Kuwahara and Mori, 1989; Mori et al., 1990; P-B: Hauptmann et al., 1986b) have established that their 10-membered rings adopt similar twist-chair (TC) conformations.

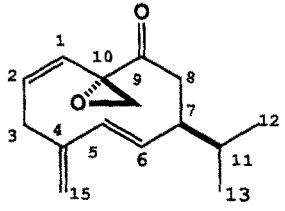
Recently, we reported the conformational analyses of periplanones and their analogs by the use of NMR and X-ray crystallographic analyses, and pointed out the conformational resemblances among the bioactive analogs (Mori et al., 1990). However, the structurally simplified analog (**1**) [(4*S*, 5*E*)-7-methylene-4-(1-methylethyl)-5-cyclodecen-1-one] and germacrene-D (**2**) (Tahara et al.,



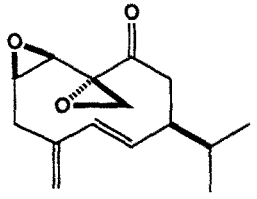
Analog (1)



Germacrene-D (2)



Periplanone-A (3)



Periplanone-B (4)

FIG. 1. Structures of analog (**1**), germacrene-D (**2**), periplanones-A (**3**) and -B (**4**). The same numbering scheme for the C atoms is employed in this paper as has been used for P-B by Persoons et al. (1974).

1975) (activity thresholds: 1 μg for **1** and 10 μg for **2**) did not yield crystalline samples suitable for X-ray analysis, and their complicated NMR spectra did not provide sufficient information (NOEs and $^3J_{HH}$'s) for conformational analyses. Thus, we attempted to investigate the conformational properties of these compounds by MM calculations to overcome the difficulty of the structural assignments by conventional methods.

METHODS AND MATERIALS

The details of the preparations and purity determinations of compounds **1–4** have been described in our previous paper. (Mori et al., 1990) Their bioassay data also have been reported. (Okada et al., 1990) The synthesis of racemic compound (**1**) was first reported by Schreiber and Santini (1984). [^{1}H]NMR (500 MHz) spectra were recorded at 27°C in C_6D_6 solution with Me_4Si as internal standard.

Molecular Mechanics Calculations. MM2 molecular mechanics program (Burkert and Allinger, 1982; version '87: Molecular Design Ltd., Farallon Drive, San Leandro, California, U.S.A.) was employed to the structural optimizations. The three-dimentional structures were visualized and superimposed using QUANTA program (Polygen Co., Waltham, Massachusetts, U.S.A.) run on an IRIS-4D/80GT computer system (Silicon Graphics Inc., Mountain View, California, U.S.A.).

The initial geometries of the ring conformations, including the rotamers, regarding isopropyl group were exhaustively generated by CONFLEX2 program (Gotō and Ōsawa, 1989; QCPE #592). They were all geometry optimized by MM2 to identify the most stable conformations. The Boltzmann population of each energy minimum at 25°C was calculated on the basis of their steric energies.

The conformers of 10-membered ring conformation on the aspect of dihedral angles were defined using a new nomenclature (in CONFLEX2, unpublished).[6]

Calculations of Vicinal Coupling Constants ($^3J_{HH}$). Averaged vicinal H/H coupling constants ($^3J_{HH}$) were calculated on MM2-geometry-optimized struc-

[6]A note on the ring nomenclature: In view of inconveniences inherent to the current ring nomenclatures, we devised the following new definition in CONFLEX2. Details will be described elsewhere. 1. Classify all the endocyclic bonds in a ring structure as g^+, g^- and anti. 2. When two contiguous gauches of the same sign exist, the midpoint is a corner. 3. When two contiguous gauches of the opposite sign exist, the midpoint is a pseudocorner, if at least one side is connected to anti. 4. Number of bonds between corners and/or pseudocorners is entered in sequence between brackets, in such a way that the smallest possible integer results. 5. When a pseudocorner appears, the number of bonds is primed. When more than two possibilities exist, corner is preferred to pseudocorner.

tures of **1** and **2** using Altona's empirical modification of Karplus equation (Haasnoot et al., 1980). These calculations were based on 93 energy minima of **1** and 47 of **2**, which were found by MM2 calculation.

RESULTS and DISCUSSION

Conformational Analysis by Molecular Mechanics Calculation

Analog 1. CONFLEX2 generated 577 initial geometries for **1**, which were structurally optimized by MM2, to identify 93 energy minima. The number of major conformers over 5% Boltzmann population at 25°C ($\Delta SE < 1.1$ kcal/mol) was five, and the number over 1% population ($\Delta SE < 2.1$ kcal/mol) was 12. The conformational parameters of the major five conformers are summarized in Table 1. The perspective drawings of these structures are reproduced in Figure 2. Regarding the ring conformation, the major five conformers can be classified into three types. For example, both **1A** and **1D** (the rotamer of **1A** with respect to the isopropyl group) possess [1′324′] type ring conformations. Similarly, both **1B** and **1E** (the rotamer of **1B**) possess [1′4′1′4′] type ring conformations. The relative ratio of ring conformations of the stable conformers of **1** at 25°C is [1′324′]:[1′4′1′4′]:[132′4′] = 56:30:14. As shown in Table 1, the dihedral angles along C6-C7-C8-C9-C10-C1 and C7–C11 atoms are practically coincident in **1A–1E** structures. Therefore, the ring conformation involving C7 isopropyl and C10 carbonyl groups are well conserved in the major conformers, in contrast to the flexible C2–C5 region of the ring.

The most stable conformer **1A** has similar conformational features as the X-ray structure of periplanones. The superimposition (Figure 3) clearly showed the overlapping of **1A** and the X-ray structure of P-B (**4**). A significant match on the location of C10 carbonyl oxygen of **1A** with that of the spiro-epoxy group in **4** was also noteworthy.

Germacrene-D (2). CONFLEX2 generated 626 initial geometries for **2**, and their structural minimization by MM2 identified 47 energy minima. There is no predominant conformer, and five conformers are found within ΔSE 0.5 kcal/mol; 11 over 1% population ($\Delta SE < 1.6$ kcal/mol). The conformational parameters of the major five conformers are summarized in Table 2. The perspective drawings of these structures are shown in Figure 4. As regards the ring conformation, the stable conformers can be classified into three types as well as those of **1**. The relative ratio of ring conformations of the major five conformers of **2** at 25°C is [1′324′]:[1′3′2′4′]:[232′3′] = 34:35:31. As can be seen from Figures 2 and 4, conformer **2A** has features analogous to **1C**. This analogy is found in the cases of **2B/1B**, **2C/1A**, **2D/1D**, and **2E/1E**, respectively. All five stable conformers have similar dihedral angles along the C6-C7-C8-C9-C10-C1-C2 regions of the rings (Table 2). Among the conformers, the

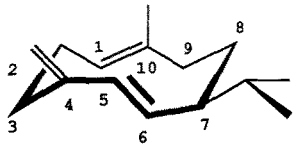
calculations and reported that **2** adopted two main conformations **2E** (CC) and **2C** (TC) in the relative ratio at 25°C of CC : TC : others = 82 : 17 : 1. The most stable conformation, **2A**, identified in our work was not found by them. Our result was more reliable in terms of the exhaustive generation of initial geometries by CONFLEX2 and the use of an improved version of MM2 program for the calculations.

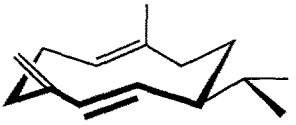
Comparisons of Calculated and Observed NMR Data

To verify the conformational properties of **1** and **2** predicted by MM calculation, their calculated NMR parameters ($^3J_{HH}$'s) were compared with those observed experimentally.

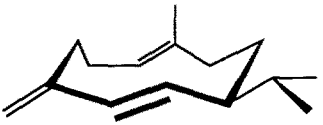
Coupling Constants ($^3J_{HH}$'s). Because of the high multiplicity and overlappings of the [^{1}H]NMR spectra of **1** and **2**, their coupling constants, except those of well-separated olefinic and methyl signals, have not been determined in our previous work. In the present study, further examination of the 1.0–2.7 ppm region of the spectrum of **1** enabled us to assign the splitting patterns of the signals of C3 and C8 geminal proton pairs. For the four vicinal couplings between the protons of H2 and H3, as well as for H8 and H9, the population-weighted coupling constants were calculated on the basis of the MM2 structures and their Boltzmann populations. As shown in Table 3, the calculated values



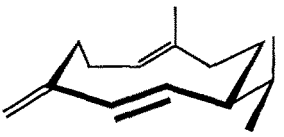
2A (23.8%)



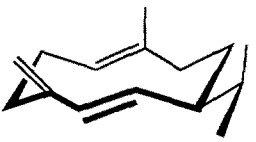
2B (16.6%)



2C (15.8%)



2D (10.8%)



2E (10.8%)

FIG. 4. Major conformers of germacrene-D (2).

essentially agreed with those observed, while the values were not accurately coincident (Masamune, et al., 1986).

CONCLUSIONS

The MM calculations on the periplanone analogs **1** and **2** revealed that they exist in several conformers with small energy differences. These results were coincident with those of NMR analysis. Regarding the ring conformation, the conformational parameters of **1** and **2** resemble each other. In the case of **2**, the substitution of the C10 carbonyl group of **1** into the methyl group and the presence of the C1–C10 *trans* double bond do not cause any drastic change on the conformation, although they must contribute to the difference of the relative ratio and the order of the conformers between **1** and **2**.

The conformers **1A** and **2C** adopt ring conformations very similar to those of natural pheromones established by X-ray analyses, and the other stable conformers can be regarded as partially altered ("flapped") ones. The similarity

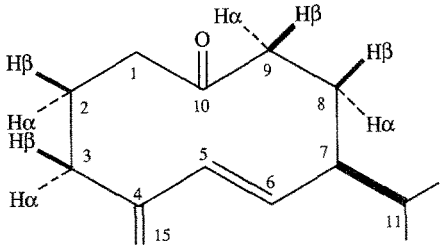
[a]



of structure is not a sufficient condition for activity. For instance, there are many examples from enzyme-substrate binding studies in which the X-ray structures of enzymes do not necessarily represent the active conformers. However, we have already mentioned that the X-ray structures of the periplanones were well explained by their NMR analyses, and the close conformational resemblance between natural pheromones and the bioactive analogs was shown by X-ray and NMR analyses (Mori et al., 1990). Thus, examination of the structural resemblances of the most stable conformers of the analogs **1** and **2** with that of **4** is useful in correlating structure with activity.

The activity thresholds for the natural periplanones are 10^{-7}–10^{-5} μg, while they are 1 and 10 μg for **1** and **2**, respectively. Since the removal and

substitution of the oxygen-containing functionalities on **3** and **4** greatly reduce the activity (Mori et al., 1990), these significant decrease in activity are attributed to the lack of electrostatic effects of the functionalities, which can strongly interact with the pheromone receptor. As each of the analogs exits in a mixture of conformers, it may also contribute to the low activity.

The present work showed that the results obtained by MM analysis should be of great value for understanding structure–activity relationships for the type of compounds studied.

Abstract—Male beetles of the larger grain borer, *Prostephanus truncatus* Horn (Coleoptera: Bostrichidae) were shown to produce material causing an electroantennographic (EAG) response from both male and female beetles. Volatiles from mixed sex cultures were collected on Porapak Q and fractionated by liquid chromatography (LC) with gradient elution. The total volatiles and the fractions were analyzed by gas chromatography (GC) linked to EAG, and two compounds eluting in the same LC fraction elicited EAG responses from male and female beetles. These were assumed to be components of the male-produced aggregation pheromone. Amounts of these compounds obtained were very low and less than 10^{-3} times the amounts of the aggregation pheromone components produced by the related species, *Rhyzopertha dominica*, under similar conditions. The most abundant of these EAG-active compounds was identified as 1-methylethyl (2*E*)-2-methyl-2-pentenoate by comparison of its GC retention times and mass spectrum with those of synthetic analogs. The synthetic compound elicited electrophysiological and behavioral responses in both male and female beetles significantly greater than those to structural analogs. This compound is attractive to *P. truncatus* beetles in the field, and has been given the trivial name of "trunc-call 1".

Key Words—Storage pests, aggregation pheromone, *Prostephanus truncatus*, larger grain borer, Coleoptera, Bostrichidae; 1-methylethyl (2*E*)-2-methyl-2-pentenoate.

*To whom correspondence should be addressed.

INTRODUCTION

The larger grain borer, *Prostephanus truncatus*, is a pest of maize and cassava and was previously considered to be a sporadic, minor pest essentially restricted to Central America, Mexico, and the southern states of the United States (Fisher, 1950; McGuire and Crandall, 1967). In 1981, its presence was confirmed in Tanzania (Dunstan and Magazini, 1981; Hodges et al., 1983a), and subsequently it has been reported in other countries in East and West Africa (Kega and Warui, 1983; Harnisch and Krall, 1984; Krall, 1984; Muhihu and Kibata, 1985). It has become established rapidly, and in Tanzania, it is now frequently the major pest in farm-stored maize, capable of causing weight losses in excess of 30% during six months (Hodges et al., 1983a; Hodges, 1986; McFarlane, 1988).

In order to survey the distribution of this pest and to determine the effectiveness of control measures against it, a simple and reliable method of detection is required. In the past, this has been undertaken by extensive sampling and visual observation. More recently, Hodges et al. (1983b) reported the use of traps for monitoring *P. truncatus* in farm stores. These were baited with dominicalures 1 and/or 2, components of the aggregation pheromone of the related lesser grain borer, *Rhyzopertha dominica*, identified by Williams et al. (1981). This paper describes the identification of one of the components of the male-produced aggregation pheromone of *P. truncatus*, undertaken with the aim of improving the specificity and effectiveness of traps for monitoring this pest. A preliminary report of this work was given by Hodges et al. (1984).

METHODS AND MATERIALS

Pheromone Collection and Purification

Prostephanus truncatus beetles from a culture of Tanzanian origin were maintained on maize kernels in 3-liter round-bottomed flasks that had been silanized with a mixture of trimethylsilyl chloride and hexamethyl-disilazane in dichloromethane. Air was drawn into the flask through a charcoal inlet filter (12 × 2 cm; 24 g; 10–18 mesh), and entrained volatiles were collected in two glass tubes packed with Porapak Q (50–80 mesh; 2.5 g; 4 × 1.5 cm). The Porapak was purified by washing with dichloromethane before use.

The cultures were maintained at 25 °C under subdued lighting, and aeration was carried out continuously at 1 liter/min. The collection tubes were extracted twice weekly by percolating through dichloromethane (25 ml). Typically, collections were made from two cultures, each containing approximately 1000 beetles of both sexes, over a three-week period. The Porapak extracts were

combined and evaporated to approximately 0.5 ml on a rotary evaporator at room temperature.

The residue was subjected to liquid chromatography (LC) on a Florisil column (100–200 mesh; 10 g; 30 × 1 cm) using gradient elution with 50-ml portions of pentane–ether mixtures containing 0, 2, 5, 10, 20, 30, 50, 75, and 100% diethyl ether. Fractions of 10 ml were collected and 2-μl aliquots checked for biological activity by electroantennography (EAG).

The effectiveness of the above procedures for collection, work-up, and chromatography of the pheromone was checked by treating a culture of *Rhyzopertha dominica* in the same manner.

Breakthrough times of model compounds on Porapak Q were studied using an empty 3-liter, round-bottomed flask with charcoal inlet filter as above. Microgram quantities of synthetic compounds were placed on a small square of aluminum foil (2 × 2 cm) in the flask, and air was drawn through the flask at 4 liters/min. Volatiles were collected on two tubes packed with purified Porapak Q (50–80 mesh; 0.1 g; 1 cm × 4 mm) connected in series. The second tube was changed at intervals to check for compounds breaking through the first tube. The Porapak was extracted with dichloromethane (1 ml), a known amount of hexyl or octyl acetate added as internal standard, and the solution analyzed directly by capillary gas chromatography (GC).

In order to determine the origin of the pheromone, five freshly emerged *P. truncatus* beetles of each sex were placed in separate screw-topped vials (8 × 2 cm) with a filter paper (7 cm diam.; Whatman No. 52) for three days. The filter paper was cut into three and the pieces inserted into separate Pasteur pipets for assay of biological activity by EAG (see below). Beetles were sexed according to the procedure of Shires and McCarthy (1976).

Gas Chromatography (GC)

Numerous GC columns and running conditions were used during the course of this work, but the definitive data presented here was obtained with the following columns: 1.8 × 2 mm ID glass columns in a Varian 2100 packed with (A) 2.5% SE 30 + 0.25% Carbowax 20 M and (B) 5% Carbowax 20 M on 100–120 mesh Chromosorb G AW DMCS, temperature programmed from 60°C at 4°C/min with nitrogen carrier gas flow of 25 ml/min; 25 m × 0.32 mm ID fused silica capillary columns in a Carlo Erba Fractovap 4160, coated with (C) nonpolar CP Sil 5 CB (chemically bonded methylsilicone; Chrompack) and (D) polar CP Wax 57 CB (chemically bonded Carbowax 20 M; Chrompack), with helium carrier gas linear velocity of 25 cm/sec, splitless injection at 220°C and the oven held at 40°C for 2 min, then raised to 50°C or 60°C at 20°C/min and temperature programmed at 1°C/min.

Electroantennography (EAG)

EAG responses from *P. truncatus* were recorded using modifications of basic techniques described previously for Lepidoptera (Moorhouse et al., 1969; Nesbitt et al., 1977) and Diptera (Hall et al., 1984). Adult *P. truncatus* were restrained by means of a metal strip in a hole drilled to fit the beetle in a Perspex disk, as described by Angst and Lanier (1979). The antennae were laid and held dorsal surface uppermost on a thin bed of plasticine. The glass recording electrode was inserted through a small hole cut in the distal segment of one antenna by means of a micro-knife (Beavor Micro-sharp, Waltham, Massachusetts, USA), and the reference electrode was inserted into a similar hole in the basal segment of the other antenna.

Crude mixtures of volatiles or fractions from LC were tested as samples (1 μl) syringed onto the inner wall of a new Pasteur pipet. The solvent was allowed to evaporate for 30 sec before positioning the pipet in such a way that the tip was 1 cm above the EAG preparation, and a 3-sec pulse of nitrogen (100 ml/min) was blown through the pipet. An interval of 3 min was allowed between tests. At least three replicates were recorded for each sample, and the results are reported as the mean $\pm$ SD. Filter papers exposed to beetles were placed in a Pasteur pipet and tested under similar conditions. Synthetic compounds were tested as samples (100 ng) in hexane (1 μl) deposited on filter paper (Whatman No. 1; 1-cm disks) in Pasteur pipets. Solvent was removed with a 3-sec pulse of nitrogen (500 ml/min), and the sample delivered to the antennal preparation in a 1-sec pulse of nitrogen (500 ml/min). Stimuli were given in random sequence at 1-min intervals, and each compound was tested three times on each of 10 insects (four males and six females). Mean responses were normalized to the mean response to 1-methylethyl (2*Z*)-2-methyl-2-pentenoate [Figure 1 (II)] for each insect. There were no obvious differences in absolute or relative magnitudes of the responses of male and female beetles, and results for each sex

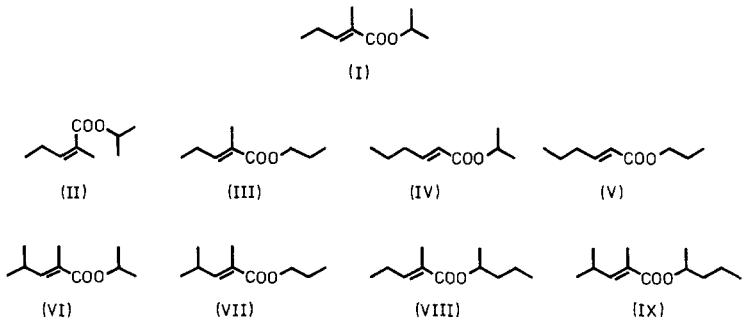

FIG. 1. Structures of synthetic compounds I–IX.

were combined. Mean responses for each compound were subjected to analysis of variance and differences between means tested for significance by Duncan's new multiple-range Test (DNMRT) (Duncan, 1955).

Linked GC-EAG analyses were carried out essentially as described by Moorhouse et al. (1969) by splitting the GC column effluent and pulsing one part at intervals over the antennal preparation. For analyses with the fused silica capillary columns, the column effluent was split 50:50 using a low-dead-volume connector (SGE) without makeup gas. One half went to the flame ionization detector, the other half to a small, three-necked reservoir (volume approx. 5 ml) through which nitrogen (100 ml/min) was pulsed for 3 sec at 17-sec intervals into a constant stream of nitrogen (100 ml/min) passing over the antennal preparation.

Mass Spectrometry

For gas chromatography coupled to mass spectrometry (GC-MS) a Pye 204 instrument was used with the column effluent led directly to the source of the mass spectrometer (VG Micromass 70-70F with Data System 2025) with electron impact ionization at 70 eV, 200°C. The GC injection system consisted of a short length of silanized glass-lined steel tube fitted into the injection port and connected directly to the column (25 m × 0.22 mm ID fused silica capillary column coated with OV-101; oven temperature held at 50°C for 10 min and then programmed at 2°/min to 100°C; helium carrier gas at 0.7 kg/cm^2).

Synthesis

For this work, (2*E*)-2-methyl-2-pentenoic acid and (2*E*)-2,4-dimethyl-2-pentenoic acid were synthesized as outlined previously by Hodges et al. (1983b) (Figure 2), although the former compound is now obtainable from Aldrich Chemical Co. (2*E*)-2-Hexenoic acid was obtained from Aldrich Chemical Co. The corresponding acid chlorides were produced by treating the acids with a slight excess of freshly distilled oxalyl chloride at room temperature, and these

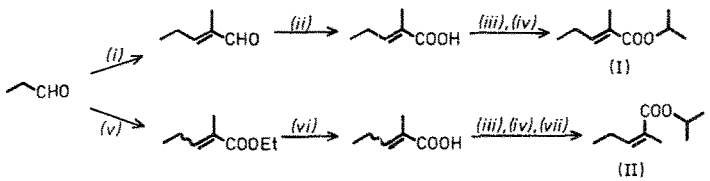

FIG. 2. Synthesis of the *E* (I) and *Z* (II) isomers of 1-methylethyl 2-methyl-2-pentenoate. Reagents: (i) aqueous NaOH; (ii) aqueous silver oxide; (iii) oxalyl chloride; (iv) 2-propanol; (v) triethylphosphonopropionate/KOBu^t/THF; (vi) aqueous KOH/EtOH; (vii) Florisil chromatography.

were converted to esters by reaction with a slight excess of 1-propanol, 2-propanol or (±)-2-pentanol in the absence of solvent. After aqueous work-up, the esters were purified by short-path distillation to give products that were greater than 95% pure by capillary GC analysis with the expected infrared (IR), [^{1}H]nuclear magnetic resonance (NMR), and mass spectra (MS). Structures of the compounds synthesized are shown in Figure 1.

1-Methylethyl (2E)-2-methyl-2-pentenoate (I) (Figure 2). (2*E*)-2-Methyl-2-pentenal was prepared on 2 M scale in 69% yield by addition of propionaldehyde to sodium hydroxide (cf. Nielsen and Houlihan, 1968). This was oxidized to (2*E*)-2-methyl-2-pentenoic acid on 0.4 M scale in 83% yield with aqueous silver oxide (cf. Pearl, 1963). Freshly distilled oxalyl chloride (32 g, 0.25 M) was added dropwise to (2*E*)-2-methyl-2-pentenoic acid (20 g, 0.2 M) in a dry, round-bottomed flask with stirring. Effervescence occurred, and, after 1 hr at room temperature, the mixture was heated gently for a few minutes. Excess oxalyl chloride then was removed on a rotary evaporator to give the crude acid chloride, IR (film) 1750 (s), 1640 (m) cm^{-1}. This was treated with 2-propanol (15 g, 0.25 M), and, after standing overnight, the IR spectrum indicated reaction was complete. The mixture was added to saturated brine, the layers separated, and the aqueous layer extracted twice with petroleum spirit (bp 40–60°C, 100 ml). The combined organic extracts were washed once with dilute sodium hydroxide solution and twice with saturated brine, dried over magnesium sulfate, and the solvent removed on a rotary evaporator. The residue was distilled to give a main fraction bp 79°C/20 mm of 1-methylethyl (2*E*)-2-methyl-2-pentenoate (23 g, 74%). Capillary GC analysis showed a major peak accounting for >97% of the volatile material. Both GC and NMR analyses showed the presence of approx. 1.5% of the *Z* isomer. IR (film): 1710 (s), 1650 (m) cm^{-1}; NMR (270 MHz, $CDCl_3$): δ 1.02 (3H, t, J = 7.7 Hz, $\underline{CH}_3-CH_2$), 1.27 (6H, d, J = 6.3 Hz, $\underline{CH}_3-CH$), 1.81 (3H, broad singlet, $\underline{CH}_3-C=C$), 2.18 (2H, broad quint, J = 7.5 Hz, $CH_3-\underline{CH}_2-C=C$), 5.05 (1H, sept, J = 6.3 Hz, $\underline{CH}-O$), 6.72 (1H, broad triplet, J = 7.7 Hz, $\underline{CH}_2-CH=C$).

1-Methylethyl (2Z)-2-methyl-2-pentenoate (II) (Figure 2). Reaction of triethylphosphonopropionate with potassium *tert*-butoxide in tetrahydrofuran at room temperature followed by addition of propionaldehyde at −78°C gave ethyl 2-methyl-2-pentenoate in 67% yield after flash chromatography on silica gel. GC analysis showed the product was a 27:73 mixture of the *Z* and *E* isomers, and this ratio was only improved to 31:69 by using trimethylphosphonopropionate as recommended by Nagaoka and Kishi (1981). The mixture of ethyl esters was hydrolyzed with 1 N potassium hydroxide in 1:1 water–ethanol at room temperature to give the corresponding acids in 86% yield with no change in isomeric ratio. The acids were converted to the 1-methylethyl esters as above in 68% yield, again with no change in isomeric ratio. Interestingly, esterification with 2-propanol using *N*, *N*′-dicyclohexylcarbodiimide and catalytic 4-pyr-

rolidinopyridine in dichloromethane (Hassner and Alexanian, 1978) caused essentially complete isomerization to the *E* isomer. The mixture of 1-methylethyl esters was separated by chromatography on Florisil eluted with 1% diethyl ether in petroleum spirit (bp 40–60°C). The *Z* isomer was eluted first and was purified by short-path distillation (bp 75°C/20 mm). GC and NMR analyses showed less than 0.1% of the *E* isomer. IR (film): 1712 (s), 1648 (m) cm^{-1}; NMR (250 MHz, $CDCl_3$): δ 1.01 (3H, t, J = 7.5 Hz, $C\underline{H}_3-CH_2$), 1.28 (6H, d, J = 6.3 Hz, $C\underline{H}_3-CH$), 1.87 (3H, overlapping double triplet, J = 1.5, 1.5 Hz, $C\underline{H}_3-C=C\underline{H}-CH_2$), 2.43 (2H, pentet of quartets, J = 7.5, 1.5 Hz, $CH_3-C\underline{H}_2-CH=C-CH_3$), 5.07 (1H, heptet, J = 6.3 Hz, $C\underline{H}-O$), 5.87 (1H, triplet of quartets, J = 7.5, 1.5 Hz, $CH_2-C\underline{H}=C-CH_3$). Spectral data for the *E* and *Z* isomers agree with those of Chan et al. (1968) for the methyl esters.

Behavioral Bioassay

Synthetic compounds were bioassayed in chambers made from plaster of Paris disks (8.5 cm diam. × 1.3 cm deep). A cartwheel pattern of channels (4 × 3 mm deep) was molded into the upper surface of each disk, consisting of a circular channel (7.5 cm outer diameter) with six equally spaced radial channels to the center. Holes (0.8 cm diam. × 1.3 cm deep) were drilled at the center and where each radial joined the outer circle. The chambers were covered with plastic lids fitted with a deep red filter (Kodak No. 70) to prevent external lighting disturbing beetles placed in them. Bioassays were performed in a darkened room at 27°C and 70% relative humidity. Male and female beetles, 7–14 days old, were removed from cultures at least four days prior to testing and conditioned on wheat flour at a density of not more than one beetle per 5 g.

Synthetic compounds (50 μg) were impregnated into the walls of polyethylene vials (1 × 0.8 cm; 1.5-mm-thick walls) by placing a solution of the compound in pentane (100 μl) in the vial, allowing the solvent to evaporate, and sealing the vial. The test vial was placed in one of the outer holes of the bioassay chamber, and untreated vials were placed in the other five outer holes and the central hole, the tops of the sources being flush with the bottom of the channels. A single beetle was placed at the center of the chamber, and observations were made by shining a light through the lid. The position of the test beetle relative to the treated vial was recorded every minute for the first 10 min of the bioassay and then every 5 min for the next 20 min. The extent to which the beetle was attracted or arrested by the test material was scored by giving one point if the beetle was observed resting within 1 cm of the treated dispenser or 2 points if it was stationary on it. After a test, the treated dispenser was discarded and the bioassay chamber baked in a ventilated oven at 60°C to remove any residual volatile materials.

Bioassays on synthetic compounds were replicated 20 times. The score for each test was expressed as a percentage of the maximum possible score (28), and these were subjected to an arcsine transformation followed by one-way analysis of variance and the Newman-Keuls multiple range test. As no significant difference could be found between the responses of male and female beetles, the results for the two tests were pooled.

RESULTS

Isolation of Biologically Active Material

Attempts to use the laboratory bioassay described above to demonstrate production of a pheromone by either sex of *P. truncatus* did not give statistically meaningful results. However, modification of the techniques used with Lepidoptera made it possible to record EAG responses from *P. truncatus*, and significant EAG responses were obtained from either sex to air blown over filter papers that had been exposed to male beetles, but not to air blown over filter papers exposed to female beetles (e.g., EAG responses from female 1.38 $\pm$ 0.15 mV and 0.15 $\pm$ 0.04 mV respectively; response to air blown over clean filter paper 0.0 mV). These results suggested that the male beetles produced an aggregation pheromone detected by both sexes.

As it is extremely time-consuming to sex large numbers of *P. truncatus* reliably and without damage to the beetles (Shires and McCarthy, 1976), volatiles were collected from large mixed-sex cultures on maize kernels. The crude mixtures of volatiles from these cultures also elicited significant EAG responses from male and female *P. truncatus*. Analyses of the crude mixtures by linked GC-EAG using packed and capillary columns defined two areas of EAG activity that occurred consistently in different collections. With both nonpolar and polar GC columns, the first of these coincided with a characteristic triplet of GC peaks. These were subsequently shown by GC-MS to be the isomeric diethylbenzenes, impurities leached from the Porapak.

On LC separation of the crude mixture of volatiles, these diethylbenzenes eluted with pentane, while EAG activity was confined to fractions eluting with 5% ether in pentane: e.g., EAG response to crude mixture of volatiles 1.18 mV; responses to five fractions eluted with 5% ether in pentane 0.09, 0.35, 1.76, 0.32, 0.18 mV; responses to solvents and other LC fractions <0.10 mV. Linked GC-EAG analyses of the active LC fractions showed the same two areas of EAG activity as were found on analysis of the crude mixture: e.g., EAG responses to active GC fractions were 1.66 mV and 1.55 mV, with all other fractions giving zero response or slight positive polarizations. The GC retention data for these EAG-active fractions 1 and 2 are shown in Table 1, and they were assumed to contain components of the male-produced aggregation pheromone of *P. truncatus*.

TABLE 1. GC RETENTION DATA FOR COMPOUNDS ON FUSED SILICA CAPILLARY COLUMNS

Compound	ECL[a]	
	CP Sil 5CB (C)	CP Wax 57CB (D)
EAG-active component 1	6.40	6.24
EAG-active component 2	9.54	9.91
I	6.40	6.24
II	5.95	5.49
III	7.03	7.15
Z isomer of III	6.54	6.30
IV	6.62	6.73
Z isomer of IV	6.18	5.88
V	7.18	7.55
Z isomer of V	6.72	6.72
VI	6.76	6.29
Z isomer of VI	6.23	5.46
VII	7.41	7.19
Z isomer of VII	6.87	6.24
VIII (dominicalure 1)	8.20	7.88
Z isomer of VIII	7.69	7.03
IX (dominicalure 2)	8.52	7.87
Z isomer of IX	7.95	6.93
Peak width at half height	0.012	0.023

[a]Equivalent chain lengths relative to the retention times of acetates of straight-chain, saturated alcohols (Harris and Habgood, 1966); retention times of hexyl, heptyl and octyl acetates: column C, 7.18, 10.35, and 13.83 min; column D, 7.57, 10.25, and 13.27 min.

The first area of activity coincided with a small GC peak, which would have represented 1–2 μg obtained from two cultures, each containing approximately 1000 beetles and entrained for three weeks. In these collections, only nanogram quantities of a component in the fraction causing the second EAG response were obtained, and it was not possible to obtain sufficient material of the requisite purity for further identification work.

It was thought possible that active material was being lost at some stage during the collection, work-up, and fractionation of the volatiles. As a check on this, a culture of *R. dominica* was treated in an identical manner. A single culture containing approximately 1000 beetles of mixed sex entrained for three weeks gave 2.81 mg of dominicalure 1, 1-methylbutyl (2*E*)-2-methyl-2-pentenoate (VIII), and 2.66 mg of dominicalure 2, 1-methylbutyl (2*E*)-2,4-dimethyl-2-pentenoate (IX) (ratio 1.06:1). LC purification gave greater than 90% recovery, the components eluting with 5% ether in pentane.

Following identification of the major pheromone component of *P. trun-*

catus, it was apparent that this is more volatile than the two dominicalures, and the effectiveness of the collection procedure was checked with synthetic pheromone. There was no breakthrough using 0.1 g Porapak and a flow rate of 4 liters/min for 24 hr, equivalent to 2.5 g Porapak at a flow rate of 0.5 liters/min for 200 days.

It was thus concluded that, under the conditions used, the major component of the aggregation pheromone of *P. truncatus* was not being lost and that it is produced at 10^{-3} the rate of each component of the pheromone of *R. dominica*.

Identification of Major EAG-Active Component

GC-MS analysis was carried out on the EAG-active LC column fractions. The mass spectrum of the first EAG-active GC peak (Figure 3a) showed similarities with that reported by Williams et al. (1981) for dominicalure 1, 1-methylbutyl (2*E*)-2-methyl-2-pentenoate (VIII), particularly dominant peaks at *m/e*

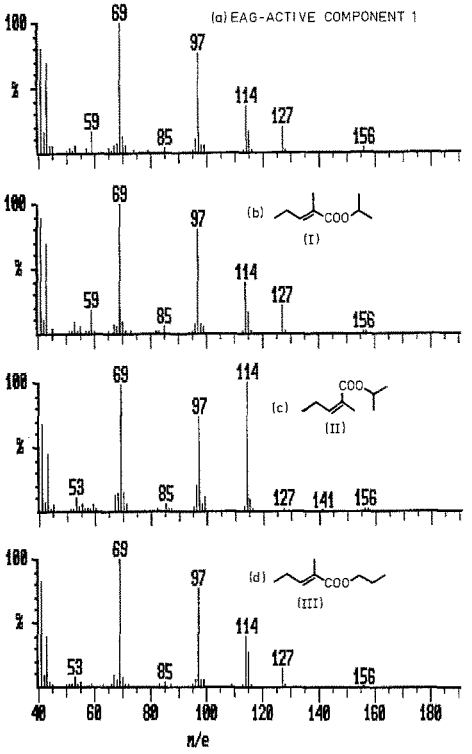

FIG. 3. Mass spectra of (a) natural and (b–h) synthetic compounds.

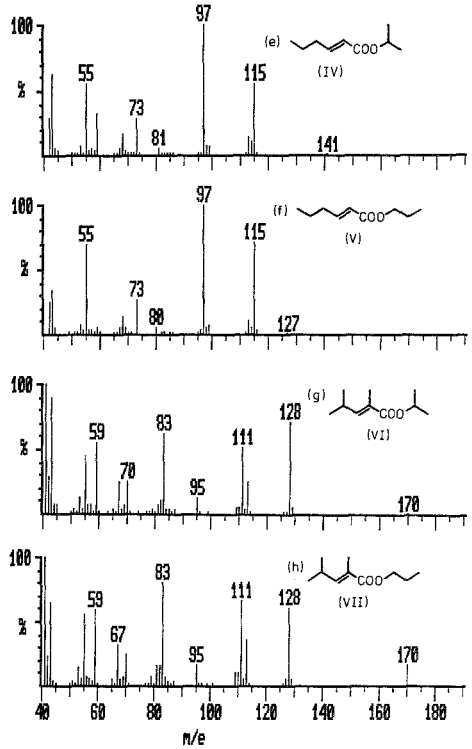

FIG. 3. Continued.

97 [$CH_3CH_2CH{=}C(CH_3)CO^+$ ·] and *m/e* 69 [$CH_3CH_2CH{=}C(CH_3)^+$ ·]. There was a possible molecular ion at *m/e* 156 corresponding to dominicalure 1 with two less carbon atoms ($C_9H_{16}O_2$). Other significant peaks occurred at *m/e* 114 [$CH_3CH_2CH{=}C(CH_3)COOH^+$ ·] (cf. *m/e* 115 in the spectrum of dominicalure 1) and *m/e* 127 ($M^+ - 29$). The mass spectrum suggested the propyl esters of 2-methyl-2-pentenoic acid as candidate structures, and these were synthesized as the *E* isomers (I) and (III). The mass spectrum of the 1-methylethyl (isopropyl) ester (I) (Figure 3b) was superimposable on that of the naturally occurring active component (Figure 3a) and that of the propyl ester (III) (Figure 3d) was similar. However, only compound I cochromatographed with the natural EAG-active compound on both nonpolar and polar capillary GC columns (Table 1). 1-Methylethyl (2*Z*)-2-methyl-2-pentenoate (II), the *Z* isomer of (I), also was prepared and shown to have different GC retention times (Table 1) and a significantly different mass spectrum (Figure 3c) from that of the natural EAG-active compound.

Other candidate structures of formula $C_9H_{16}O_2$ were the propyl esters of

2-hexenoic acid. The *E* isomers (IV and V) were synthesized, but these differed in their GC retention times (Table 1) and their mass spectra (Figure 3e and 3f) from those of the natural pheromone component. Also synthesized were the two propyl esters (VI) and (VII) of (2*E*)-2,4-dimethyl-2-pentenoic acid, the acid moiety of dominicalure 2, 1-methylbutyl (2*E*)-2,4-dimethyl-2-pentenoate (IX) (Williams et al., 1981). The GC retention times for these two compounds are shown in Table 1 and their mass spectra in Figure 3g and 3h.

Small (approx 0.5–1.5%) amounts of the corresponding *Z* isomers were detected in the synthesized *E* isomers of all the above compounds by GC-MS analysis with selective ion monitoring using the two most abundant ions in the mass spectrum of the *E* isomer. The GC retention times of these *Z* isomers are shown in Table 1.

GC analyses of biologically active fractions from LC of volatiles collected from cultures of *P. truncatus* showed that none of the compounds listed in Table 1, except compound I, was present (less than 2% of I).

Biological Activities of Synthetic Compounds

The EAG response from *P. truncatus* to compound I was compared with the responses to the other compounds synthesized. In order to demonstrate that the EAG activity used as a criterion in the isolation and identification is correlated with some behavioral activity, the synthetic compounds were also tested in a laboratory bioassay designed to show attractant and/or arrestant activity. Results are shown in Figure 4. By both EAG and bioassay, 1-methylethyl (2*E*)-2-methyl-2-pentenoate (I) was the most active compound, followed by 1-methylethyl (2*E*)-2,4-dimethyl-2-pentenoate (VI). Replacing the branched acid and/or alcohol moieties by straight-chain analogs reduced activity. The dominicalures 1 and 2 (VIII and IX) were also significantly less active than I in both assay systems, although this may have been due, at least in part, to the higher molecular weights and lower volatilities of the latter compounds. The stimulus in the EAG tests would thus be expected to contain a lower concentration of the dominicalures than of the other test compounds, and the release rate of dominicalure 2 (IX) from the polythene vial dispensers used in the bioassay is known to be lower than that of compound I (Hodges et al., 1984). The *Z* isomer of I, compound II, was not available for bioassay, but in the EAG tests it showed only low activity.

DISCUSSION

Two compounds have been detected in volatiles collected from mixed-sex cultures of *P. truncatus* that elicit EAG responses from male and female beetles. The amounts of material produced were exceptionally small, less than 10^{-3} the

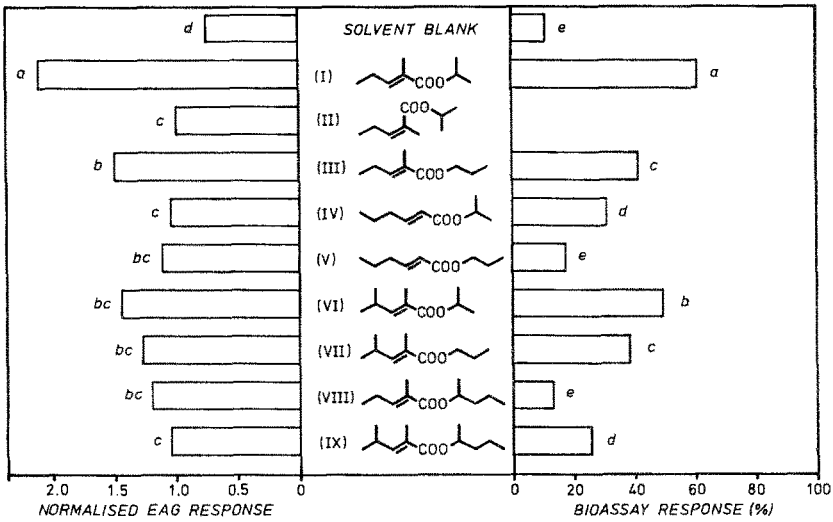

FIG. 4. EAG and bioassay responses of male and female *P. truncatus* beetles to synthetic compounds I–IX. EAG responses are means of three replicates on each of 10 insects normalized to response to compound II for each insect; responses with the same letter are not significantly different at the 5% level by DNMRT. Bioassay responses are mean percentages of maximum possible score for 20 replicates, and responses with the same letter are not significantly different at the 5% level by Newman-Keuls multiple range test after arcsine transformation of the data; compound II was not available for bioassay.

amounts of the aggregation pheromone components produced by the related species, *R. dominica*, under identical conditions. It was not possible to obtain sufficient material for identification of the minor component in this work, but the major EAG-active component was identified as 1-methylethyl (2*E*)-2-methyl-2-pentenoate (I) by comparison of its GC retention times on polar and nonpolar capillary columns and its mass spectrum with those of a range of synthetic compounds. Compound I is the isopropyl ester of the acid moiety of dominicalure 1 (VIII), one of the components of the male-produced aggregation pheromone of the related bostrichid species, *R. dominica*, identified by Williams et al. (1981).

Synthetic I was more active to *P. truncatus* than structurally related compounds in EAG tests, and this EAG activity was correlated with behavioral activity in a laboratory bioassay demonstrating attractant and/or arrestant activity. In field tests carried out in maize stores in Togo, traps made of corrugated cardboard sprayed with permethrin and baited with a polyethylene vial impregnated with 2 mg of compound I caught over twice as many *P. truncatus* beetles as similar traps baited with 2 mg of dominicalure 2 (IX) (Hodges et al., 1984).

EAG studies showed that active material is produced by the male beetles only, and 1-methylethyl (2*E*)-2-methyl-2-pentenoate (I) is proposed as the major component of the male-produced aggregation pheromone of *P. truncatus*. The trivial name "trunc-call 1" has been suggested for this compound (P. Dobie, NRI, personal communication).

During the course of writing up this work, modification of the techniques used for collection of pheromone gave sufficient of the minor EAG-active compound for it to be identified as 1-methylethyl (2*E*,4*E*)-2,4-dimethyl-2,4-heptadienoate. Lures containing mixtures of this compound with I have been shown to be significantly more attractive to *P. truncatus* beetles than lures containing I alone in both stores (Dendy et al., 1991) and the open field (Dendy et al., 1989a,b). Details of the identification of the structure of this minor pheromone component will be published separately.

Acknowledgments—Thanks are due to Mrs. Jane Smith and Mrs. Julie Dendy of NRI for assistance with the entrainment and bioassay work respectively, and to Dr. Rosemary White of NRI for synthesis of compound II.

(Received December 27, 1990; accepted January 2, 1991)

Abstract—The defensive secretion of *Tenebrio molitor* contains a mixture of 2-methyl-1,4-benzoquinone and *m*-cresol. The phenol had not previously been detected in the secretion, although some investigators reported presence of 2-ethyl-1,4-benzoquinone as a second component. We failed to detect the latter quinone in secretion samples from three laboratory populations of *T. molitor*.

Key Words—2-Methyl-1,4-benzoquinone, *m*-cresol, *Tenebrio molitor*, Coleoptera, Tenebrionidae, defensive glands.

INTRODUCTION

As part of a study of how parasitization encumbers an insect's ability to use its defensive glands, we recently had occasion to look into the chemistry of the defensive secretion of *Tenebrio molitor*, a beetle commonly maintained in laboratory culture and used worldwide in biological research. Unexpectedly, our findings about the composition of the beetle's secretion differed from those previously reported (Schildknecht, 1959; Tschinkel, 1975a; Kanehisa, 1978). We here present our results.

METHODS AND MATERIALS

Tenebrio molitor. The defensive glands of *T. molitor*, and the mechanism by which the glands are everted for defensive use, have been described (Tschinkel, 1975b,c). We used beetles from three sources: (1) our Cornell culture (replenished periodically with individuals purchased from Rainbow Mealworms, Compton, California); (2) S.C. Johnson & Sons, Inc., Racine, Wisconsin; and (3) Department of Entomology, Kansas State University, Manhattan, Kansas.

We "milked" the beetles of secretion by squeezing them gently with forceps so as to cause them to evert the glands, then wiping the glands with small pieces of filter paper, and transferring the papers to vials with hexane for extraction. Beetles were milked without regard to sex. Milkings of beetles from any one source were lumped, providing three samples [beetles milked per sample = 10 (Cornell); 4 (Wisconsin); 6 (Kansas)].

Instrumentation. Gas chromatography [Hewlett-Packard (= HP) 5890 equipped with flame ionization detector] was performed on a 25-m × 0.22-mm fused-silica capillary column coated with DB-5 (J. & W. Scientific). Temperature program: 40°C for 4 min, then to 260°C at 8°C/min.

Infrared and mass spectra were obtained with a HP 5890 gas chromatograph linked in series to a HP 5965A FTIR detector and a HP 5970 mass selective detector (MSD). Mass spectra were also obtained on a HP 5890 gas chromatograph linked to a Finnigan ion trap detector (ITD 800).

RESULTS

Capillary gas chromatography of the Cornell secretion sample (Figure 1) revealed two primary peaks, accounting for about 99.5% of the volatile components. Mass spectra (ITD and MSD) of the first component were closely similar to those given for 2-methyl-1,4-benzoquinone (McLafferty and Stauffer, 1989) and matched those of an authentic sample of this compound. The natural compound and the authentic sample also had identical gas-phase FTIR spectra.

The mass spectrum of the second component showed that it was a cresol [*m/z*(%), 108(M^+, 82), 107(100), 90(7), 79(42), 77(40), 63(6), 53(11), 51(11)], but could not unambiguously resolve the isomeric structure of the compound (McLafferty and Stauffer, 1989). However, differences that we determined between the *o*, *m*, and *p* isomers of cresol by FTIR spectrometry (Figure 2) allowed unambiguous identification of the unknown as *m*-cresol.

As further evidence for the nature of the components, peaks 1 and 2 (Figure 1) had chromatographic retention times identical to those of authentic 2-methyl-1,4-benzoquinone and *m*-cresol, respectively. Of the three cresols,

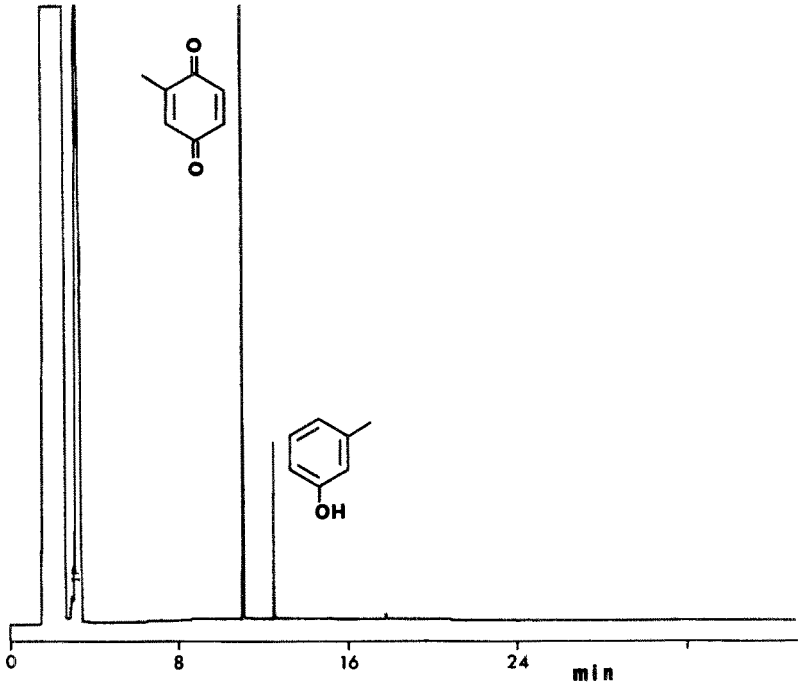

FIG. 1. Gas chromatogram (hexane) of *Tenebrio molitor* defensive secretion (Cornell sample). See text for column and temperature program.

o-cresol had the shortest retention time; *m*- and *p*-cresol eluted closely together, in that order.

The secretion samples from the Wisconsin and Kansas beetles proved to contain the same two primary components. There were some differences in the ratio of the components in the three samples (Table 1).

DISCUSSION

The finding that our three samples contained the same two primary compounds leads us to believe that 2-methyl-1,4-benzoquinone and *m*-cresol are characteristic components of the *T. molitor* secretion. Schildknecht (1959) previously had reported the presence of 2-methyl-1,4-benzoquinone in the secretion of this beetle. Tschinkel (1975a) and Kanehisa (1978) also reported presence of this quinone, but claimed the additional presence of 2-ethyl-1,4-benzoquinone. Kanehisa (1978) based his identification of the latter compound on TLC and packed column retention data only. We found no evidence for the presence of this quinone, which we would have detected at the 2-ng level.

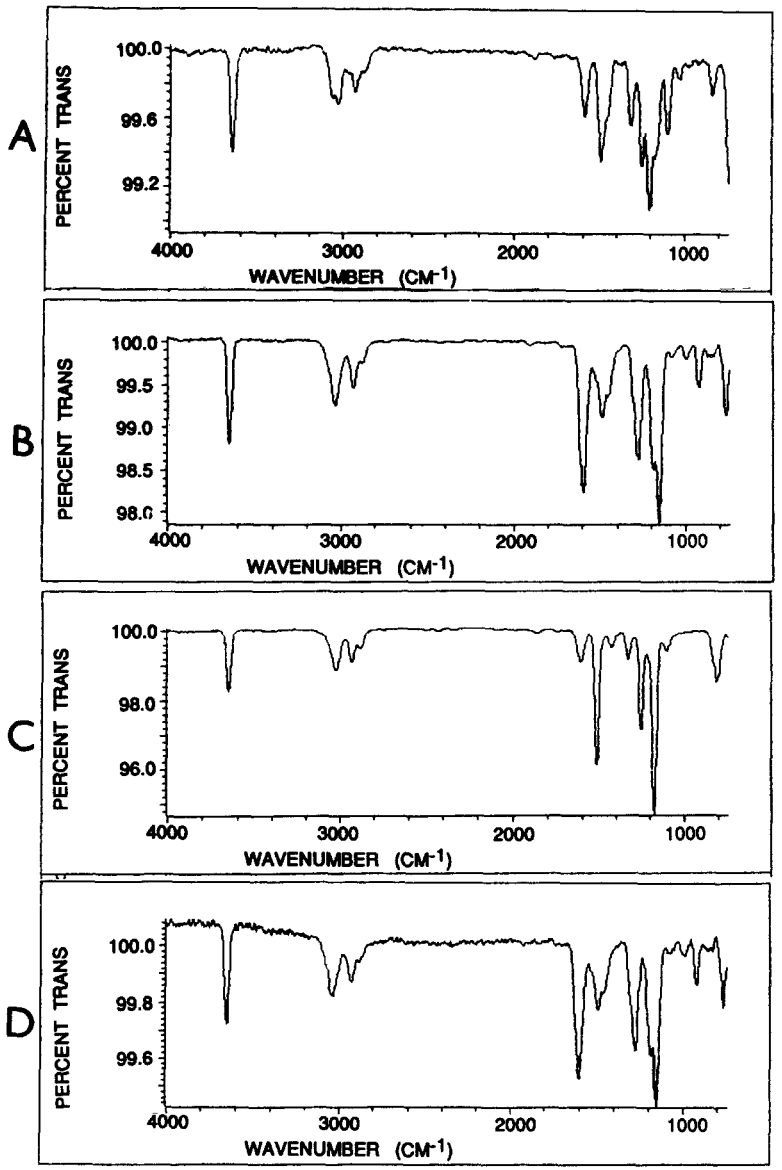

FIG. 2. Gas-phase FTIR spectra of authentic *o*-cresol (A), *m*-cresol (B), and *p*-cresol (C), and of the second-eluting component (Figure 1) of the *Tenebrio molitor* defensive secretion (D). Resolution = 8 cm^{-1}.

TABLE 1. RELATIVE PERCENT OF MAJOR COMPONENTS IN DEFENSIVE SECRETION OF *Tenebrio molitor* FROM THREE SOURCES

Source	2-Methyl-1,4-benzoquinone	*m*-Cresol
Cornell	87.5	12.5
Wisconsin	97.0	3.0
Kansas	68.0	32.0

(Received April 11, 1989; accepted January 7, 1991)

Abstract—The secretion of the tergal glands of *Cryptocercus punctulatus* consists of a complex mixture of 27 compounds. Of this mixture, only one compound (compound B) is specific for females. By dissecting 200 tergal glands, 50 μg of pure compound B was collected by preparative GC; it was identified as (*Z*, E-4,6,8-trimethyl-7,9-undecadien-5-ol. Its functions as well as its absolute configuration still have to be determined.

Key Words—Dictyoptera, Cryptocercidae, *Cryptocercus punctulatus*, cockroach, woodroach, 4,6,8-trimethyl-7,9-undecadien-5-ol.

INTRODUCTION

Chemical analysis of the secretions of male and female tergal glands of the woodroach, *Cryptocercus punctulatus*, shows the presence of a compound (called compound B), which is specific to females and is abundant in those

*To whom correspondence should be addressed.

0098-0331/91/0500-0811$06.50/0

females entering their oviposition period (Brossut et al., 1991). The comparative analysis of the tergal secretions from more than 200 females at different stages of their life suggests that compound B acts during sexual or parental behavior.

C. punctulatus is a primitive species of cockroach that lives in galleries in rotten wood, and its biology is still relatively unknown. Due to the lack of observations and of bioassays, currently no functional role in the behavior and/or life history of this insect can be attributed to compound B.

The composition of the tergal secretions in males and females has been reported in an earlier paper (Brossut et al., 1991). This paper is devoted to the identification of compound B isolated from female *C. punctulatus*. The structure is discussed with regard to those of other insects pheromones.

METHODS AND MATERIALS

Insects were collected from rotten hardwood logs at Mountain Lake Biological Station, Giles County, Virginia, during the spring and summer of 1984, 1985, and 1986. The tergites bearing the glands were dissected and placed individually in pure distilled pentane.

Tergal glands were dissected from 210 females (Brossut et al., 1991). After GC analysis of all the extracts from individual insects, all the samples were pooled, giving about 500 μg of secretion from which 50 μg of pure compound B was collected by preparative GC.

Gas chromatographic (GC) analyses were carried out with a Packard 429 gas chromatograph fitted with a split–splitless injector and a flame-ionization detector. The capillary column used was a DB5 fused silica column (30 m $\times$ 0.32 mm ID, J and W Scientific) with temperature programming from 60°C to 220°C at 2°C/min. Injector and detector temperatures were, respectively, 230°C and 250°C. Helium was used as the carrier gas at a flow rate of 5 ml/min. The GC traces were recorded and integrated by a CR3A Shimadzu integrator.

For preparative GC, a Varian 1440 chromatograph, fitted with a Pyrex column (3 m $\times$ 3.2 mm) packed with 10% SE 52 on 80–100 mesh Chromosorb WAW-DMCS and a flame ionization detector, was used with nitrogen as the carrier gas (flow rate 15 ml/min). Injector and detector temperatures were 230°C and 250°C, respectively, and oven temperatures were programmed from 100°C to 200°C at 2°C/min. An effluent splitter was used that allowed 10% of the effluent to flow to the detector. Fractions were collected in U-shaped glass tubes (1 mm ID) cooled to 0°C.

The sample, diluted to 100 μl with hexane, was injected in ca. 5-μl quantities into the column and the trapped component was rinsed from the tube into a Teflon-lined capped vial with distilled hexane, evaporated to dryness, and

redissolved in benzene-d_6 (99.99% D, Spectrométrie Spin et Techniques, Paris). The purity of collected fractions was monitored by capillary GC.

Gas chromatographic–mass spectrometric (GC-MS) analyses were carried out with a Nermag R 10-10-C quadrupole mass spectrometer coupled to a Girdel 31 gas chromatograph fitted with a split–splitless injector and a DB5 fused silica capillary column (60 m × 0.32 mm ID). The GC conditions described above were used. The column was directly connected to the ion source of the spectrometer through a heated transfer line maintained at 260°C.

Electron impact (EI) mass spectra were obtained at 70 eV on a 0.8-sec. cycle, the instrument scanning from 25 to 300 amu with the ion source maintained at 150°C. Chemical ionization (CI) mass spectra were generated at 90 eV using methane or ammonia at a source pressure of 0.2 and 0.3 torr, respectively, with a source temperature of 90°C, and the instrument scanning from 60 to 300 amu in 0.7 sec.

Microhydrogenation was performed on-line in the GC-MS system by means of a fused silica capillary reactor (Schomburg et al, 1982). The reactor, consisting of a 60-cm piece of a deactivated fused silica capillary column (6 m × 0.32 mm ID) statically coated with a 0.5% CH_2Cl_2 solution of palladium acetylacetonate (Fluka), was connected to the inlet of the analytical column with a zero-dead volume capillary butt-connector (Supelco). Palladium metal was precipitated at 220°C under hydrogen flow. Hydrogen then was used as the carrier gas at a flow rate of 1.5 ml/min, and the GC conditions were those previously described.

Fourier transform infrared (FT-IR) spectra were taken in the gas phase on a Bruker IFS 85 FT-IR spectrometer coupled, via a Bruker gold-coated lightpipe (36 cm × 1.5 mm ID) maintained at 240°C, to a Carlo-Erba 5160 gas chromatograph equipped with a DB5 fused silica wide-bore capillary column (30 m × 0.54 mm ID), an on-column injector, and a flame-ionization detector. The carrier gas was helium at a flow rate of 7 ml/min and temperature programming from 50 to 230°C at 5°C/min.

[^{1}H]NMR spectra were recorded on a Bruker WM400 instrument in 5 mm-ID NMR tubes using the benzene-d_6 mentioned above as solvent. The signal due to the residual protons of the deuterated solvent was used as internal reference ($S = 7.15$).

RESULTS

A typical gas–liquid chromatogram of pentane extract of female tergal glands (Figure 1) showed two main components. Compounds A was unambiguously identified as linalyl acetate by comparison of its mass spectrum, FT-IR spectrum, and retention index with those of the pure compound (Sarsynthèse).

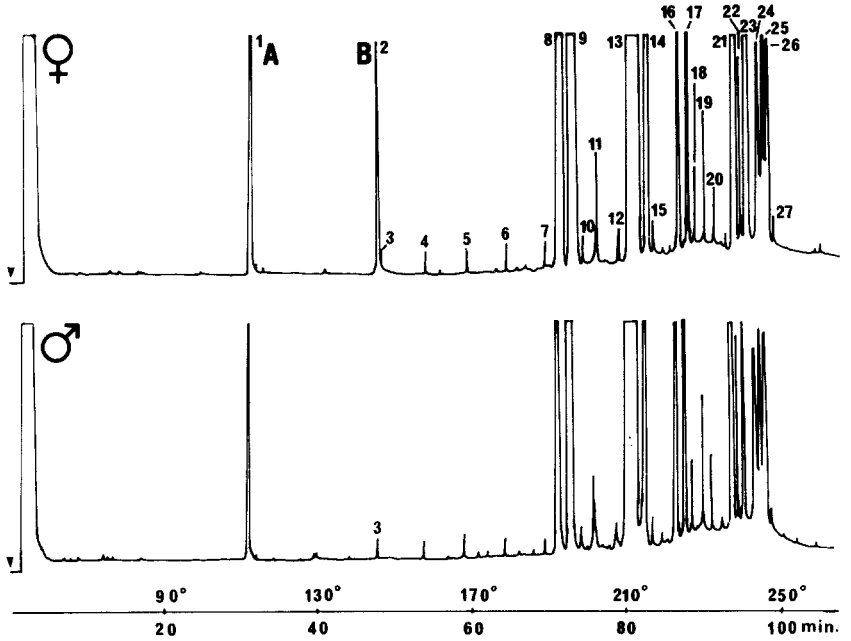

FIG. 1. Capillary gas chromatogram of the tergal gland secretion from females and males of *Cryptocercus punctulatus*. Conditions: DB5 fused silica column (30 m × 0.32 mm ID); temperature 60–220°C (2°C/min); carrier gas, helium at a flow rate of 5 ml/min. 1 (A), linalyl acetate; 2 (B), 4,6,8-trimethyl-7,9-undecadien-5-ol; 3, C-15; 4, C-16; 5, C-17; 6, C-18; 7, C-19; 8, unsaturated fatty acid; 9, hexadecanoic acid; 10, C-20; 11, unidentified; 12, C-21; 13, linoleic acid, 14, oleic acid; 15, C-22; 16, tricosene; 17, C-23; 18, unidentified; 19, tetracosene; 20, C-24; 21, pentacosene; 22, unidentified; 23, C-25; 24, 25, 26, methyl esters of diunsaturated fatty acids; 27, C-26. Compounds 8, 9, 11, 13, 14, and 18 are found everywhere on the body surface of males and females.

The mass spectrum of compound B (Figure 2) showed no molecular ion, and a possible candidate, borneol, based on a similarity of mass spectra, was promptly eliminated as pure borneol was eluted long before compound B under the GC conditions used. Peaks *m/z* 31 and *m/z* 45 are characteristic of an aliphatic alcohol (Budzikiewicz et al., 1964).

The molecular weight of B was determined by chemical ionization GC-MS with methane and ammonia as reagent gases. The highest observed peak in the methane-CI mass spectrum was *m/z* 211 accompanied with a more intense ion at *m/z* 209 and a low abundance ion at *m/z* 210. Another important ion was observed at *m/z* 193. These pseudomolecular ions characterized an alcohol of molecular weight 210, with ions at *m/z* 193, 209, 210, and 211 being respectively $[M - 17]^+$, $[M - 1]^+$, $[M]^+$, and $[M + 1]^+$ (Sarris et al., 1984).

The molecular weight and functionality of B were confirmed by the ammonia CI mass spectrum showing very intense pseudomolecular ions at *m/z* 193, $[M - 17]^+$, 211, $[M + 1]^+$, and 228 $[M + 18]^+ = [M + NH_4^+]$, again characteristic of an aliphatic alcohol of mol wt 210 (Sarris et al., 1984).

These pseudomolecular ions and their isotopic contributions suggested a possible molecular formula $C_{14}H_{26}O$ and two sites of unsaturation.

On-line microhydrogenation gave a mass spectrum (Figure 3) with the spectral pattern of a branched aliphatic saturated alcohol (spectral search in the EPA/NIH mass spectral data base) but with no molecular ion; however, an ion at *m/z* 196 attributed to $[M - 18]^+ = [M - H_2O]$ suggested a molecular weight of 214. This was confirmed by NH_3 CI-MS (*m/z* 232, M + 18) and CH_4 CI-

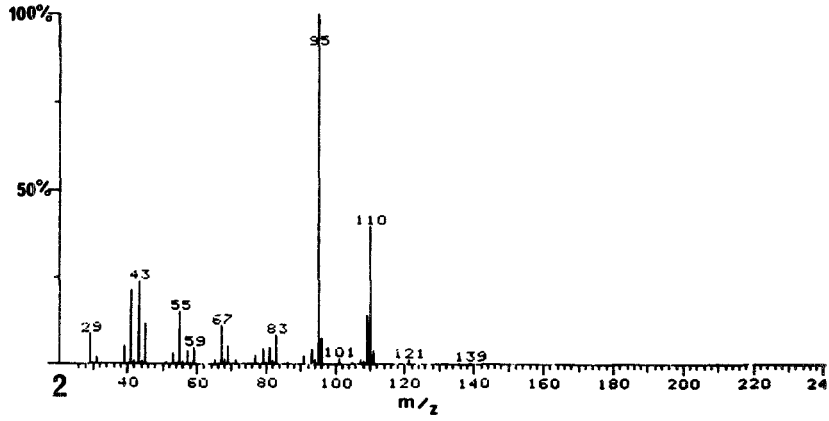

FIG. 2. Mass spectrum of compound B.

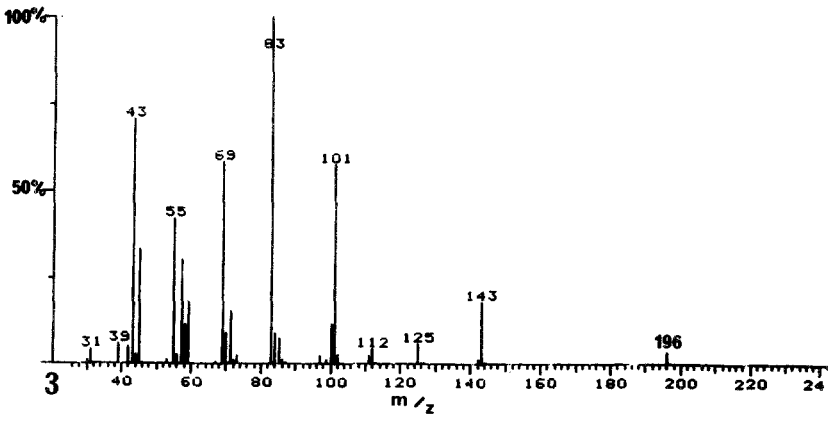

FIG. 3. Mass spectrum of compound B after hydrogenation.

MS (m/z 197, $[M - 17]^+$; 213, $[M - 1]^+$), revealing two carbon–carbon double bonds, accounting for the two sites of unsaturation.

The GC-FT-IR spectrum of B (Figure 4) confirmed the hydroxyl group, the OH stretching frequency (ν_{OH} = 3668 cm^{-1}) falling in the range of the secondary alcohols (Nyquist, 1984). Another stretching frequency (ν_{OH} = 3605 cm^{-1}) revealed an intramolecular hydrogen bonding, probably with one of the carbon–carbon double bonds, via a (5 + π) or (6 + π) system (Nyquist, 1984). An absorption at 960 cm^{-1} was tentatively attributed to a CH out-of-plane deformation (δCH) of an (*E*-disubstituted ethylenic bond —CH=CH— (Le Quere et al., 1987).

The 400-MHz [^{1}H]NMR spectrum (C_6D_6) of B isolated by preparative GC (Figure 5B) revealed signals due to three olefinic hydrogens at δ6.12, 5.47, and 5.38. Mutual couplings were solved by two dimensional NMR (chemical shifts correlation COSY, Figure 5A) and confirmed by selective irradiations. The proton at δ6.12 (dd) was coupled (J = 16 Hz) to one of the other vinyl hydrogen (δ5.47) confirming one *E* double bond, and coupled to a three-hydrogen doublet of doublet (J = 1.5 Hz) at 1.66 (methyl group). The vinyl hydrogen at δ5.47 (dg) also was coupled to the same methyl group (J = 7 Hz). Therefore, these signals were attributed to an (*E*)-propenyl group CH_3—CH=CH— bonded to a non-hydrogen-bearing carbon, since no other couplings were observed for these signals. The other olefin multiplet at δ5.38 (dq) was coupled to a one-

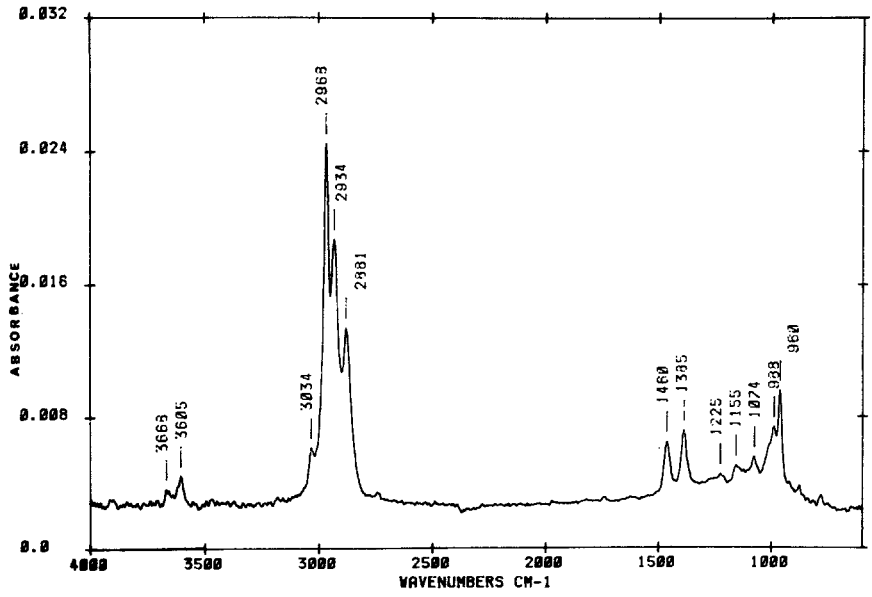

FIG. 4. Vapor-phase infrared spectrum of compound B.

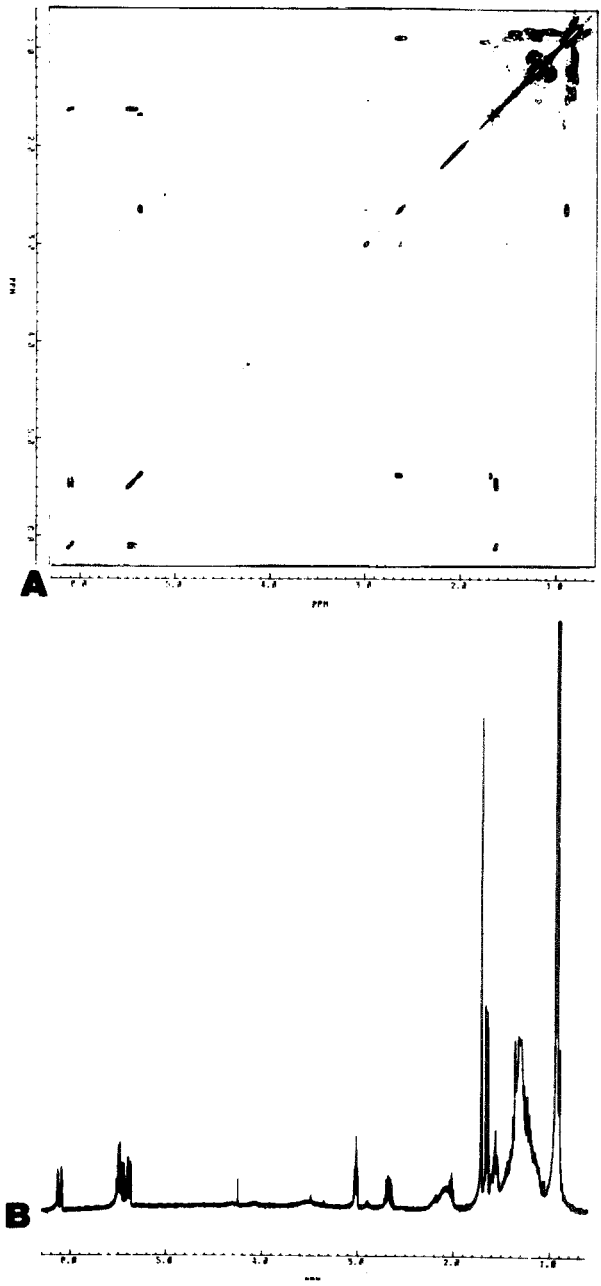

FIG. 5. [^{1}H]NMR (400.13 MHz) of B in benzene-d_6. (A) Two dimensional spectrum (COSY with a flip angle of 45° for the mixing pulse). (B) One-dimensional spectrum.

hydrogen multiplet at $\delta 2.67$ (J = 10 Hz) and to a three-hydrogen doublet at $\delta 1.71$ (J = 1.5 Hz), revealing a butenyl group $CH_3-C=CH-CH$. The geometry of this double bound could not be determined either by IR or NMR since the allylic coupling (J = 1.5 HZ) could not be considered as typically *cis* or *trans*.

The single-hydrogen multiplet at $\delta 2.67$ (ddq) also was coupled to a methyl group at $\delta 0.93$ (J = 7 Hz) and to a one-hydrogen doublet of doublet at $\delta 3.02$ (J = 6 Hz), confirming a methine hydrogen. The signal at $\delta 3.02$ which was identified by the downfield shift as a methine hydrogen geminal to the hydroxyl group, also was coupled (J = 6 Hz) to an unresolved multiplet at $\delta 1.57$. Therefore, the partial structure $CH_3-C=CH-CH(CH_3)-CHOH-CH$ could be deduced for compound B by addition of the (*E*)-propenyl group. The very upfield part of the spectrum was not completely understood, and integrals of the different overlapped multiplets at $\delta 0.85$–1.6 represented far more than the remaining 11 hydrogens necessary to complete the $C_{14}H_{26}O$ formula. These extra hydrogens possibly corresponded to water, giving rise to the broad signal at $\delta 1.1$–1.5. Traces of hexane also may contribute to the signals at $\delta 0.85$–1.0 and $\delta 1.2$–1.3.

However, as already outlined, irradiation of the methine signal at $\delta 3.02$ resulted in partial collapse of the unresolved multiplet at $\delta 1.57$; owing to the splitting pattern and coupling constants of the signal at $\delta 3.02$, the multiplet at $\delta 1.57$ was attributed to a methine hydrogen. Careful observation of the two-dimensional NMR spectrum revealed that this methine hydrogen is probably coupled to a doublet at $\delta \simeq 0.93$ overlapping the methyl group already identified, and also coupled to a multiplet at $\delta \simeq 1.22$, hidden in the broad signal at $\delta 1.1$–1.5.

More detailed assessments regarding the unknown part of the molecule could not be deduced from the NMR spectra. However, a triplet (J = 7.5 Hz) centered at $\delta 0.91$, partially overlapped and was attributed to a terminal methyl group coupled to a methylene group.

Thus, the structure of compound B was postulated to be a branched undecadienol with three methyl groups, i.e., (*E*7, *E*9)- or (*Z*7, *E*9)-4,6,8-trimethyl-7,9-undecadien-5-ol (Figure 6).

Structures B_1 and B_2 (Figure 6) are consistent with the main fragmentations displayed in the mass spectrum and also with the mass spectrum of the hydrogenated compound.

In the GC-FT-IR spectrum, the difference between the unassociated ν_{OH} and the intramolecular hydrogen bonded $\nu_{OH}:\pi$ frequencies is relatively large ($\Delta\nu_{OH}$ = 63 cm^{-1}); moreover, the $\nu_{OH}:\pi$ is located at a frequency (3605 cm^{-1}) lower than common frequencies for $\nu_{OH}:\pi$ of a (5 + π) intramolecular hydrogen bonded structure in secondary unsaturated alcohols (Nyquist, 1984).

These observations suggest an intramolecular ring structure larger than a

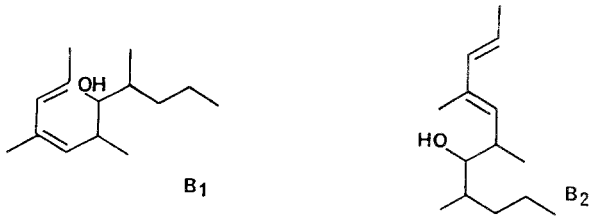

FIG. 6. The two possible structures of compound B. The GC-FT-IR spectrum favor the configuration B_1: (*Z*, *E*)4,6,8-trimethyl-7,9-undecadien-5-ol.

$(5 + \pi)$ system, therefore favoring configuration B_1, where a large $(7 + \pi)$ or $(5 + 2\pi)$ intramolecularly hydrogen-bonded ring structure is more likely to occur.

DISCUSSION

Primitive woodroaches of the genus *Cryptocercus* are the best living representatives of the ancestral blattarian–isopteran stock (Cleveland et al., 1934; McKittrick, 1964, 1965). Several aspects of their life history (Seelinger and Seelinger, 1983; Nalepa, 1984, 1988a,b) and morphology (Farine et al., 1989) strongly resemble the termites.

In the cockroaches, sex pheromones have been identified in two species: *Nauphoeta cinerea* and *Periplaneta americana*. In *N. cinerea*, the males produce a mixture of three compounds: 3-hydroxy-2-butanone, methyl 2-thiazolidine, and a derivative of the thiazoline (Brossut and Sreng, 1985). In *P. americana*, the periplanone B emitted by the females has a structure close to that of germacrene (Ritter and Persoons, 1979). Only one sex pheromone has been identified in termites: the *n*-tetradecyl propanoate produced by the females of *Reticulitermes flavipes* (Clement et al., 1989). These pheromones, including compound B from *C. punctulatus*, are very different in their structure. This chemical diversity can be explained easily by the phylogeny of these groups, where the three species of cockroaches and the termite *R. flavipes* are phylogenetically not closely related.

Compound B is basically a diunsaturated alcohol with conjugated double bonds. Such a structure is not unusual in insect pheromones, especially in beetles. For example, the enantiomers of ipsenol and of ipsdienol, although different from compound B by the length of their chain and by their configuration, are alcohols with conjugated double bonds (Silverstein, 1979).

Compound B very likely is formed from four propionate units and an acetate stopper, a general principle giving rise to numerous natural products, among which several pheromones occur (Francke, 1984). 4,6-Dimethyl-7-hydroxy-

nonan-3-one (serricornin) from the beetle *Lasioderma serricorne* (Chuman et al., 1979; Levinson et al., 1981) shows some analogies with compound B. Its reduced form would present roughly the same sequence as compound B. Another component of the sex pheromone of the cigarette beetle is closely related to compound B (Chuman et al., 1983) as it presents the same 4,6,8-methyl branching and as its cyclization would lead to the same basic heterocyclic structure. Other insect pheromones, such as invictolide from *Solenopsis invicta* and stegobinon from *Stegobium paniceum*, also possess the same trimethyl branching (Francke, 1984).

Of the 27 compounds identified from the tergal secretions of *C. punctulatus*, 20 compounds are found in both male and female; compound B is found only in the female; and six compounds are found everywhere on the body surface of both sexes (tergites, sternites, head, thorax) (Brossut et al., 1991).

Although the biological data are scarce, the morphological studies clearly indicate the existence of a secretory cycle in female tergal glands, which could be explained only by the production of a product involved in sexual or parental behavior; obviously, it must be compound B (Farine et al., 1989).

Work is in progress to determine the absolute configuration of natural 4,6,8-trimethyl-7,9-undecadien-5-ol as well as its biological function on the basis of synthetic reference samples.

Acknowledgments—We thank Dr. Wittko Francke for valuable discussions and comments on the manuscript. At the present time, the possible enantiomers are being synthesized by Dr. Kenji Mori.

(Received April 11, 1989; accepted January 7, 1991)

Abstract—Males and females of *Cryptocercus punctulatus* possess tergal glands, but they differ in position, size, morphology, and secretion chemistry. Compound A (linalyl acetate) is the most abundant of the 21 compounds found only in the secretion of these glands. Compound B, 4,6,8-trimethyl-7,9-undecadien-5-ol, is specific to the tergal secretion of females. *C. punctulatus* lives only in the United States; its distribution is disjunct. Compound A is found in samples from the eastern population but is absent in samples from the western population. The amount of compound B per gland in samples from the western population is at least twice as high as in the samples from the eastern populations.

Key Words—Glandular secretions, *Cryptocercus punctulatus*, Dictyoptera, Cryptocercidae, linalyl acetate, 4,6,8-trimethyl-7,9-undecadien-5-ol.

INTRODUCTION

Like many other species of cockroaches, adults of *Cryptocercus punctulatus* Scudder possess tergal glands (Lehrer, 1979; Seelinger and Seelinger, 1983).

*To whom correspondence should be addressed.

0098-0331/91/0500-0823$06.50/0

These glands usually produce chemical signals in adult males only and during precopulatory behavior (Roth, 1969; Brossut and Roth, 1977; Brossut et al., 1975). In most species, they are hidden by the wings but are exposed when males adopt the "wing-raised" posture in response to antennal contact with a female. The female subsequently climbs on the back of the male to feed on the secretion of these glands and is then correctly positioned for mating.

Both sexes of *C. punctulatus* possess tergal glands, but they differ in position, size, and morphology (Farine et al., 1989). In females, the tergal gland is located transversely on the intersegmental membrane at the anterior edge of the 7th tergum. The bilobed gland is narrow, 1 mm, but has a total width of 4 mm; the glandular epithelium is about 1 mm thick. The gland is normally covered by the edge of the 6th tergum but can be exposed when the female stretches her abdomen. In the male, the tergal gland is smaller and is located at the anterior edge of the 8th tergum. It is crescent shaped, with a total width of 1 mm, and is completely concealed within the anal chamber formed by the expanded 7th tergum. The glandular epithelium of these glands lacks reservoirs sensu stricto; however, several morphological modifications in the form of intracuticular reservoirs and large subcuticular spaces (Farine et al., 1989) allow extracellular, intraglandular storage of the secretion. The function of these glands is unknown, but there is some evidence to indicate that the activity of the female gland can be correlated with her reproductive status (Farine et al., 1989; Nalepa and Brossut, unpublished).

The distribution of *C. punctulatus* in the United States is disjunct. An eastern population is found in the Appalachian Mountains from Pennsylvania to Georgia, and a western population occurs in northern California, Oregon, and Washington (Cleveland et al., 1934). Here we reported the results of a chemical analysis of male and female tergal secretions of the eastern population and, additionally, an attempt to compare tergal secretions of the two populations.

METHODS AND MATERIALS

Insects were collected from rotten logs (primarily hardwood) at Mountain Lake Biological Station, Giles County, Virginia, during the spring and summer of 1984, 1985, and 1986, and from rotted coniferous logs in Douglas, Josephine, and Jackson counties, Oregon, during the summer of 1987.

Females found alone, pairs without nymphs, and pairs with nymphs of class I, II, III (Nalepa, 1984), were collected in Virginia. The physiological states of females found alone or with a male were determined by dissection. Glands from females of the same category were pooled (137 females, 10 pools, 7–35 glands per pool). Additionally, the glands of 37 females were analyzed individually. The tergal gland secretions of females from Oregon were analyzed

using two pools of five glands each. The social status of these females was unknown.

The analysis of male tergal secretions was done on a pool of 20 tergal glands and on 15 individually dissected glands from Virginia; two pools of five glands each were analyzed from Oregon.

The terga bearing the glands were dissected from the insect, immersed in pure distilled pentane, and stored at −20°C. The head, thorax, internal organs, sterna, and remaining terga also were extracted in pentane. Results of comparative extractions with pentane and methylene chloride showed that the secretion is soluble in both solvents. Only pentane was used, because methylene chloride also extracts hydrocarbons and fatty acids of high molecular weight present on the entire body surface and of no interest in this study. The extracts were filtered using glass wool and chromatographed without further purification.

A Packard 429 gas chromatograph fitted with a split–splitless injector and a flame ionization detector was used for gas chromatographic (GC) analysis. The capillary column used was a DB5 fused silica column (30 m × 0.32 mm ID, J and W Scientific), with temperature programming from 60°C to 220°C at 2°C/min. Injector and detector temperatures were, respectively, 230°C and 250°C. Helium was used as the carrier gas at a flow rate of 5 ml/min. The GC traces were recorded and integrated by a CR3A Shimatzu integrator for the quantitative analysis.

Using GC conditions just described, gas chromatographic–mass spectrometric (GC-MS) analyses were carried out with a Nermag R 10-10-C quadrupole mass spectrometer coupled to a Girdel 31 gas chromatograph fitted with a split–splitless injector and a DB5 fused silica capillary column (60 m × 0.32 mm ID). The GC conditions described above were used. The column was directly connected to the ion source of the spectrometer through a heated transfer line maintained at 260°C.

Electron impact (EI) mass spectra were obtained at 70 eV on a 0.8-sec cycle, the instrument scanning from 25 to 300 amu with the ion source maintained at 150°C.

Most of the compounds were identified by comparison of their mass spectra and retention indexes with those of pure compounds (Sigma, Sarsynthèse). The pure compounds were coinjected with the samples. The identification of compound B was carried out by pooling all samples studied here and by using additional techniques (Le Quéré et al., 1991).

RESULTS

Twenty-seven peaks observable on chromatograms were studied, and 24 were identified as indicated in the captions of Figure 1. A detailed account of the identification of compound B, 4,6,8-trimethyl-7,9-undecadien-5-ol, is given in Le Quéré et al. (1991).

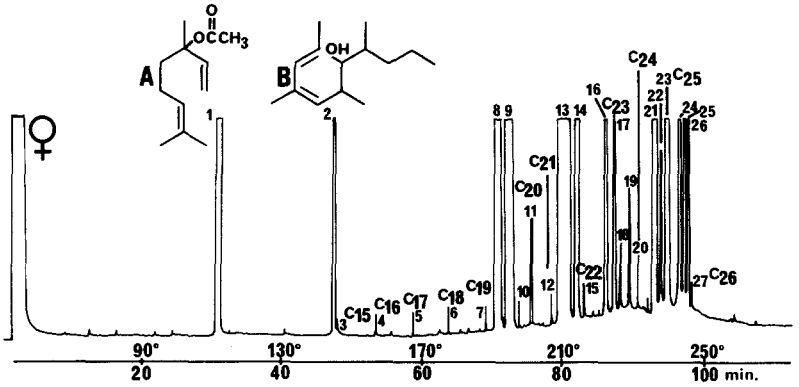

FIG. 1. Capillary gas chromatogram of the tergal gland secretion from a female *Cryptocercus punctulatus* collected in Virginia. Conditions: DB5 fused silica column (30 m × 0.32 mm ID); temperature 60–220°C (2°C/min); carrier gas, helium at a flow rate of 5 ml/min. 1 (A), linalyl acetate; 2 (B), 4,6,8-trimethyl-7,9-undecadien-5-ol; 3, C-15; 4, C-16; 5, C-17; 6, C-18; 7, C-19; 8, unsaturated fatty acid; 9, hexadecanoic acid; 10, C-20; 11, unidentified; 12, C-21; 13, linoleic acid; 14, oleic acid; 15, C-22; 16, tricosene; 17, C-23; 18, unidentified; 19, tetracosene; 20, C-24; 21, pentacosene; 22, unidentified; 23, C-25; 24, 25, 26, methyl esters of diunsaturated fatty acids; 27, C-26. Compounds 8, 9, 11, 13, 14, and 18 are found everywhere on the body surface.

Among these 27 compounds, six also were found everywhere on the body surface (8, 9, 11, 13, 14, 18). Twenty compounds (compound A, unsaturated and saturated hydrocarbons, methyl esters of diunsaturated fatty acids) were found only in the tergal secretions, and one (compound B) was specific for females.

Compound A (1), linalyl acetate, was found only in samples from Virginia (Figure 2). The amount present in male tergal glands was quite uniform, about 6 μg/gland. In the female tergal glands, however, the amount ranged from 4.6 to 29 μg/gland in the pooled samples and from 2.4 to 50.72 μg in individual samples.

Compound B, 4,6,8-trimethyl-7,9-undecadien-5-ol, occurred in female tergal secretions of both populations (Figure 2). It was absent in extracts of other parts of females and in extracts from body parts of males. The amount of compound B per gland in two pooled samples from Oregon females (235 and 265 ng) was at least twice as high as in the samples collected in Virginia (22–147 ng/gland in pooled samples; 20–199 ng in individual samples).

Except for compounds A and B, all other compounds were found in the tergal secretions from both sexes in both locations. Compounds 6, 9, 11, 13, 14, 18, four of which are fatty acids, were found adsorbed in the cuticular waxes of the several body parts analyzed (terga, sterna, head, thorax). In gland

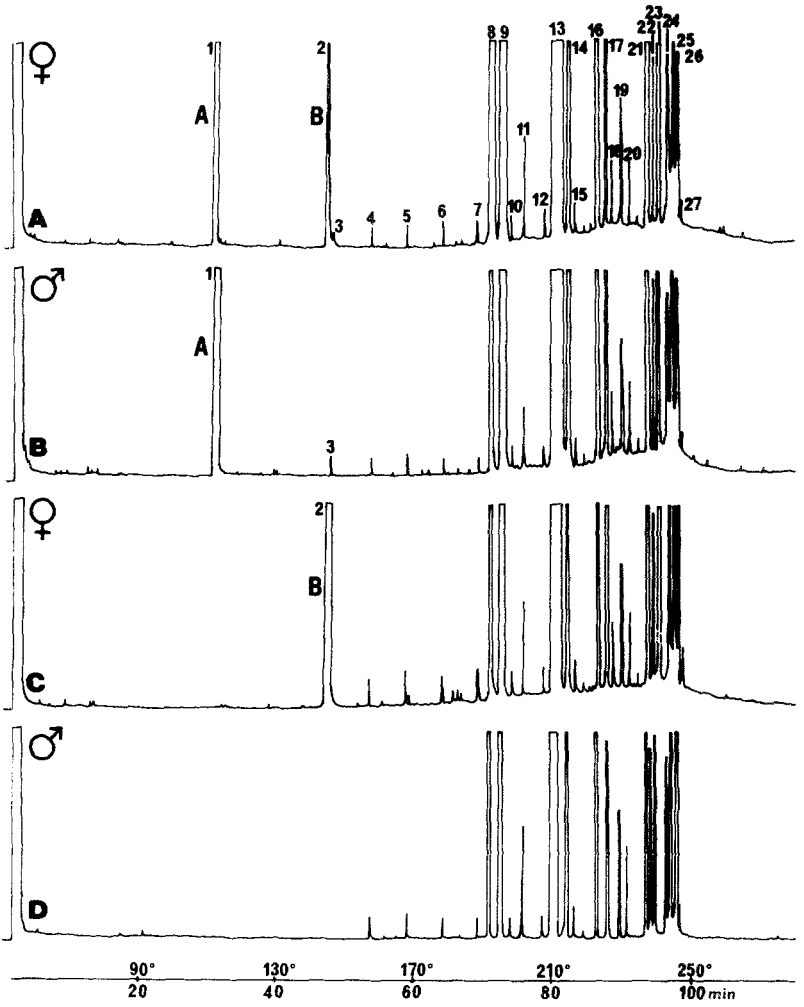

FIG. 2. Capillary gas chromatograms of tergal gland secretions from: (A) female collected in Virginia; (B) male from pair collected in Virginia; (C) pool of five females collected in Oregon; (D) pool of five males collected in Oregon. The GC conditions were the same as for Figure 1.

extracts, these six compounds must come from the part of the tergum dissected with the gland. However, the amount of linoleic acid (13) is much higher in gland extracts (about 20% in samples from Virginia, about 30% in samples from Oregon) than in other body parts (from 6% to 10%). The percentage of the other compounds varied from 0.2% (8) to 8% (9).

The three methyl esters of diunsaturated fatty acids (24–26) are found in gland extracts of both sexes and in the same percentages (about 2% for compounds 24 and 25). Compound 26 is about twice as abundant in samples from Oregon (about 8%) as in samples from Virginia (about 4%). For the most part, hydrocarbons are present in small amounts. Three exceed 1% (docosane about 1.4%, tricosene about 2%, pentacosane about 3%). Pentacosene is the only abundant hydrocarbon (12–15%).

In females, the average amount of secretion extracted from one gland was 20 μg, but varied from 6 to 30 μg. The percentages of the products reported above were usually not correlated with age or reproductive status. Preliminary evidence, however, indicates there may be a relationship between the reproductive status of females and the total amount of compound B and, to a lesser extent, of compound A present in the glands of Virginia populations. Studies designed to monitor the amount of these two compounds over the course of female life history are in progress.

DISCUSSION

Linear hydrocarbons are common in insect exocrine secretions (Blum, 1981). However, series of 10 or more hydrocarbons are found mainly in ants and bees. Often, linear hydrocarbons are found with other compounds that are responsible for the biological activity of the secretion. In the Dufour's glands of halictine bees, C-19 to C-28 hydrocarbons are found with C-16 to C-24 macrocyclic lactones (Hefetz et al., 1986). In *Andrena* bees, C-13 to C-24 hydrocarbons are found with farnesyl and geranyl esters (Tengö and Bergström, 1975). The cephalic secretions of the fire bee contain two major components with vesicatory proprieties (diketones), which occur with 13 hydrocarbons (from C-11 to C-23) and with a similar series of carboxylic acids, esters, and monoketones (Brian et al., 1984). Dufour's glands of cleptoparasitic bees contain an complex oily mixture of alkanes, alkenes, and methyl alkanes from C-23 to C-33, which, deposited on the brood cell walls and pollen balls, provides a waterproof lining for both (Hefetz et al., 1982).

The Dufour's gland secretion in *Formica* ants is a complex mixture of saturated, monounsaturated, diunsaturated, and methyl-branched alkanes from C-9 to C-19 (Lofquist and Bergström, 1980). The undecane, which is a releaser of swarming and pairing activity, always represents 50% or more of the secretion. Several species of stable flies and sciarid flies use unsaturated and saturated hydrocarbons as sex pheromones (Uebel et al., 1975; Kostlec et al., 1980). In the horn fly *Hematobia irritans*, (Z)-5-tricosene, (Z)-9-pentacosene, and (Z)-9-heptacosene elicit male courtship behavior (Bolton et al., 1980).

In cockroaches, the aggregation pheromone produced by mandibular glands

is a mixture of undecane and tetradecane in *Blaberus craniifer* (Brossut et al., 1974). In *Eublaberus distanti*, it is a mixture of undecane, 4-heptanone, 2,6-dimethyl-4-heptanone, and octanol (Brossut, 1979). In both species, these pheromones attract conspecifics from a distance.

In *C. punctulatus*, the saturated hydrocarbons and the tetracosene are present in small amounts, from 0.1% to 0.5% of the secretion. Tricosene represents about 2%, and pentacosene, which is the only abundant hydrocarbon, from 12% to 15% of the secretion. Although we do not know the structure of the three methyl esters of diunsaturated fatty acids found in *C. punctulatus*, they are probably similar to those commonly found in the pheromonal blends of many species of Lepidoptera (see Inscoe, 1984, and references therein).

C. punctulatus from Oregon is presumed to have a biology similar to that of the eastern population, yet linalyl acetate is absent in the tergal secretions of both sexes. *C. punctulatus* lives primarily in hardwood logs in Virginia and in coniferous logs in Oregon, but it is doubtful that the presence or absence of linalyl acetate could be due to their food source; no trace of this compound was found in the internal organs.

The high amounts of compound B found in females from Oregon may be specific to the population from this area or may be related to the time of collection; the eastern population was collected later in the summer (August) than any of the western samples (June). In addition, the lack of linalyl acetate (compound A) in the tergal secretions of the individuals from Oregon suggests that tergal secretions may vary between populations. Intraspecific variations in the chemistry of exocrine secretions of insects are, for the most part, correlated with geographic separation of populations; many examples are found in defensive secretions, especially termites (Parton et al., 1981; Everaerts et al., 1988). In *C. punctulatus* variation in the secretion is not surprising since the two populations of this insect probably have been isolated geographically since the Tertiary.

In many species of termites, female tergal glands are used together with the sternal glands during the calling posture, functioning to attract males from a distance. Later, the glands initiate and control tandem behavior: the male follows the female, trying to keep his mouthparts in contact with her tergal glands (Grassé, 1982, 1984; Ampion and Quennedey, 1980). In many species of cockroaches, tergal glands are found in adult males only, where they produce aphrodisiacs. During the wing-raising posture of the male, these glands are exposed and the female feeds on them prior to copulation (Brossut and Roth, 1977). The role of tergal glands in the behavior and/or life history of *C. punctulatus* remains a matter of supposition. Because of the position of the male glands in this woodroach, it is unlikely that they produce a sexual attractant; moreover, all compounds found in the secretion of the male glands also are found in those of the female. The position of the female glands and the presence

of a female-specific compound suggests a possible role in sexual behavior, but the glands also may be involved in aggregative or parental behavior (see Farine et al., 1989).

Synthesis of reference samples of compound B is in progress. Bioassays will clarify its biological function. Tergal secretions from more than 1000 females (collected each month during one year) are being analyzed individually to monitor the amount of the different compounds over the course of their life history.

Acknowledgments—The kindness of Dr. Paul Catts and the field assistance of Dr. Richard Zack and J. Patrick Rand made the collection of the western population of *C. punctulatus* possible.

BIOSYNTHESIS, PRODUCTION SITE, AND EMISSION RATES OF AGGREGATION-ATTACHMENT PHEROMONE IN MALES OF TWO *Amblyomma* TICKS

PETER A. DIEHL,* PATRICK GUERIN, MICHELE VLIMANT, and PASCAL STEULLET

Institute of Zoology, University
Chantemerle 22, CH-2007 Neuchâtel, Switzerland

(Received August 9, 1990; accepted January 7, 1991)

Abstract—The aggregation-attachment pheromone components *o*-nitrophenol (ONP) and methyl salicylate (MS) in male *Amblyomma variegatum* ticks appeared after three days of feeding on the host and reached high values after about six days. Variable quantities of 1.3–7.3 μg ONP and about 0.6 μg MS were present within ticks. ONP and MS were released at the high rates of 300–1800 ng/hr and 20–600 ng/hr per male tick, respectively. After a temporary decrease, males continued to emit at high rates after nearby attachment of females. In *A. hebraeum*, ONP showed a similar pattern, but with a delay of about a day. A male, which had fed during 14 days, contained about 2 μg and released 225–280 ng/hr. Emission in forcibly detached males of both species dropped rapidly to low levels of less than 10 ng/hr per tick. Host skin and tick feces in the vicinity of feeding males were pheromone-impregnated. The very high emission rates are consistent with the observations that the pheromone is an important component of the host-location mechanism of conspecifics. ONP and MS are produced in the dermal glands type 2 associated with the ventrolateral cuticle.

Key Words—*Amblyomma variegatum*, *Amblyomma hebraeum*, Acari, aggregation-attachment pheromone, host location, *o*-nitrophenol, methyl salicylate, pheromone glands.

INTRODUCTION

The partially fed females of at least 14 tick species from five genera of metastriate ticks attract fed males by using the volatile 2,6-dichlorophenol as sex

*To whom correspondence should be addressed.

0098-0331/91/0500-0833$06.50/0

attractant pheromone; this substance is produced by the foveal glands (Sonenshine, 1984, 1985, 1986, Sonenshine et al., 1982). After establishment of close contact, the following scenario occurs in *Dermacentor andersoni* and *D. variabilis*. A mounting sex pheromone induces the mounting and exploratory behavior that guides the male to the gonopore on the female venter (Hamilton et al., 1989). The male then probes the gonopore and inserts its chelicerae. After recognition of a genital sex pheromone, copulation is induced and a spermatophore placed into the vagina (Allan et al., 1988, 1989).

Unlike the situation in most metastriate species, the males of *Amblyomma gemma, A. hebraeum, A. maculatum, A. lepidum*, and *A. variegatum* begin to emit an aggregation–attachment pheromone after several days of feeding on the host. This pheromone attracts conspecific females and males to the feeding males, and in *A. hebraeum* even nymphs (Gladney, 1971; Gladney et al., 1974a,b; Norval and Rechav, 1979; Rechav, 1977; Rechav et al., 1976, 1977; Schöni, 1987; Schöni et al., 1984). The males clasp the attracted ticks very efficiently; this results in the formation of dense clusters at suitable feeding sites like the genitals or belly.

The pheromone is active over a considerable distance; steers infested with male *A. hebraeum* (Norval et al., 1989a), or artificial sources of pheromone for *A. hebraeum* and *A. variegatum* proved to be attractive over several meters downwind (Hess and De Castro, 1986; Norval et al., 1989b). In an extreme case, a few *A. hebraeum* males reached the steer within 13 min of first being sighted 9 m away (Norval et al., 1989a). The pheromone is thus an important component of the host-location bouquet of products, most probably together with other host volatiles such as CO_2.

The aggregation–attachment pheromone of six-day-fed male *A. variegatum* is composed of *o*-nitrophenol (ONP), methyl salicylate (MS), and nonanoic acid in a ratio of 2:1:8 μg per tick (Schöni, 1987; Schöni et al., 1984). The long-range attractant ONP induced an incomplete aggregation; MS and nonanoic acid contribute to the complete activity, but do not induce aggregation when offered separately (Schöni, 1987; Schöni et al., 1984). The closely related *A. hebraeum* emitted ONP, benzaldehyde, and 2-methylpropanoic acid, along with some nonanoic and other medium chain fatty acids (Apps et al., 1988).

The sex attractant pheromone 2,6-dichlorophenol (2,6-DCP) has been reported in females of *A. variegatum* and in both sexes of *A. maculatum* (Kellum and Berger, 1977; Wood et al., 1975). In the latter species, this pheromone has been shown to attract fed males; but no behavioral response was observed in females to explain the presence of 2,6-DCP in males.

Males of both *A. variegatum* and *A. hebraeum* become attractive only after about three or five days of feeding, respectively (Norval and Rechav, 1979; Rechav, 1977; Schöni, 1987; Schöni et al., 1984). In this paper we report on the time course of biosynthesis and emission of the aggregation–attachment

pheromone components ONP and MS in *A. variegatum* males and, to a lesser extent, of ONP in *A. hebraeum* males, from the initiation of feeding on rabbits. We also looked for the possible site of pheromone production among the different exocrine glands of *A. variegatum*.

METHODS AND MATERIALS

Ticks. Adults of *Amblyomma variegatum* Fabricius and *A. hebraeum* Koch (Acari, Ixodidae) were supplied by Ciba-Geigy Ltd. (St. Aubin, Switzerland), where they are bred on Simmenthaler calves. During molting, ticks were held at 29°C and 90% relative humidity and thereafter in constant darkness at 28°C and 80–90% relative humidity for several months. Ticks were never older than about 9 months.

For on-host experiments, the ticks were placed inside a nylon bag glued to the shaved back of mature New Zealand female rabbits (weight ca. 2 kg). Before adding the unfed *A. variegatum* males, a synthetic pheromone mixture of 100 ng of ONP, 30 ng of MS, and 250 ng of nonanoic acid dissolved in a few microliters of methanol was placed at several locations on the host skin to induce rapid attachment. Benzaldehyde and 2-methylpropanoic acid replaced MS for *A. hebraeum* (cf. Apps et al., 1988). Ticks attached generally within the first 30–45 min. Unattached ticks were removed after 1 hr to ensure good synchronization.

Chemicals. All chemicals for pheromone extractions and analysis were of analytical or HPLC (high-performance liquid chromatography) grade.

Pheromone Extractions. Five to 10 ticks were removed from the host with forceps at selected times during feeding, placed in methanol, cut into small pieces with fine scissors, and the volume made up to 1 ml/5 ticks. The extract was sonicated for about 2 min in an ultrasonic bath and then stored at −18°C. Recovery rates were estimated to be about 95% as judged from an experiment where known amounts of ONP and MS were injected into unfed males before extraction.

Hydrolysis. A 0.1-ml aliquot of the methanolic extracts from unfed males or mature males, which had fed for 14 days, corresponding to about one-half tick equivalent, was mixed with 0.4 ml H_2O and 0.5 ml KOH (5 M) and then boiled under reflux for 20 min. After cooling, an aliquot of 0.1 ml was acidified to about pH 2 with 6 M hydrochloric acid. Methanol was added to 30% before separation by HPLC.

Dissection. Dissection of ticks was performed in cell-culture medium TC199 (Seromed) under a binocular microscope with very fine scissors and forceps. The various organs were rinsed several times in fresh dissecting medium before extraction and sonication in methanol.

Histology. Pieces of dorsal and ventrolateral cuticle were fixed in 2.5% glutaraldehyde in a phosphate buffer (Sörensen, 0.1 M at pH 7.2, with 1.5% saccharose for 2 hr at 4°C) followed by postfixation in a mixture containing 1% OsO_4, 1.25% $K_2Cr_2O_7$, and 11% saccharose for 24 hr at 4°C. After three rinses in distilled water containing 11% saccharose for 30 min, the pieces were dehydrated in acetone and embedded in Spurr's medium. Semithin sections were cut with a diamond knife and stained with toluidine blue.

Some of the dehydrated cuticle pieces were critical-point-dried in CO_2 in a Balzers CPD device for scanning electron microscopy. The mounted specimens were coated with carbon and then gold sputtered in a Balzers sputtering apparatus. The dermal glands were observed in a Philips 500 PSEM scanning electron microscope.

Sampling of Volatiles. Sampling of volatile pheromones was performed by absorption to reverse-phase Sep-Pak Light cartridges (C_{18}, Millipore) coated with NaOH (Kuwata and Tanaka, 1988). To collect volatiles from ticks on the host, a simple apparatus was constructed from a polypropylene funnel, diam. 3.2 cm. A small polypropylene Y piece as an air inlet was glued into the funnel wall; the stem of this Y piece, acting as inlet, was connected by a short piece of plastic tubing (PVC) to an air-purifying system consisting of (1) an activated charcoal filter (20 cm × 2 cm), (2) a Sep-Pak cartridge, and (3) a small pipet containing Porapak (50–80 mesh, Millipore), in series. A short tubing led from the funnel outlet to another Sep-Pak cartridge followed by a Porapak-filled pipet connected to a water pump. The modified funnel was lightly pressed against the skin of the rabbit with the attached ticks, and the air sucked through the device at a rate of about 30 ml/min for 15 min.

In the case of sampling from ticks removed from the host, the funnel was replaced by a 500-ml gas-wash bottle containing the ticks.

The absorbed volatiles were eluted by gently pushing about 100 μl of methanol through the Sep-Pak cartridge with a small syringe. Generally, the first two drops were yellow, indicating the presence of ONP. We observed no breakthrough into the back-up Porapak cartridge.

HPLC. HPLC separations were performed with a Kontron liquid chromatograph consisting of two 420 pumps, a Rheodyne 7125 injector with a 1-ml sample loop, and a 250 mm × 4 mm or a 125 mm × 4 mm reverse-phase column RP-18 (Nucleosil 120-5 C_{18}, Macherey-Nagel). For separation, a gradient of methanol–aqueous buffer (KH_2PO_4, 0.02 M at pH 4) was employed at a flow rate of 1.2 ml/min at room temperature: 30 sec at 30% methanol, then step to 50% followed by a gradient to 100% methanol in 5 min and a final purge at 100% for 10 min. Before injection, sample aliquots of up to 400 μl were prepared by adjusting with buffer to contain 30% methanol and then centrifuged, if particles were present. In general, we injected aliquots of between 0.1 and 0.5 tick equivalents for whole tick extracts, and half or the entire extract in the case of the sampled volatiles.

UV-VIS detection of the eluting compounds was achieved with Hewlett-Packard HP 1040 photodiode array detector controlled by a HP ChemStation with chromatograms registered simultaneously at 210, 254, and 280 nm. For identification, the retention times and spectra of unknown compounds were compared with spectra from various reference compounds injected at the same conditions. Quantification of ONP and MS was done with the external standard method at 210 nm. The minimum quantities of ONP or MS for unambiguous identification were about 30–50 ng.

The reproducibility of retention times and area measurements was tested by repetitive injections of standards. For ONP, the retention time and the area showed coefficients of variation of 0.3 and 2.2%, respectively. In view of the good reproducibility, we injected only one aliquot of the different extracts. Between injections, both syringe and injector were carefully rinsed with methanol. Blank runs revealed no cross contamination.

GC Electrophysiology. The presence of ONP, MS, and nonanoic acid in a few extracts was tested by injection of 1-μl extract aliquots onto a capillary GC (Carlo-Erba HRGC 5160 Mega) fitted with an on-column injector and a FID and ECD detector in tandem. Separation was achieved on a G&W DB-wax fused silica capillary column (30 m, 0.32 mm ID) with H_2 (linear flow at 0.5 m/sec) using a temperature program of 80–230°C at 8°C/min. The column was simultaneously interfaced with the ONP-sensitive dII wp/sw/A sensilla of the Haller's organ on the tarsus of the first pair of legs (Schöni, 1987) via a glass Y-piece outlet splitter. The branch of the splitter leading to the biological detector passes through a heated (250°C) transfer line in the wall of the chromatograph. Upon exit to the exterior, the effluent is swept over the tick sensillum by a temperature- (22°C) and humidity- (100% relative humidity) controlled airstream in a water-jacketed glass tube, at a flow rate of 35 cm/sec. Responses of the olfactory cells were recorded with a glass electrode in contact with the severed tip of the sensillum. The reference electrode, also of glass, was placed at the base of the leg. Action and receptor potentials were recorded using an amplifier (Syntech, Hilversum, Netherlands) linked to a pulse-code modulator and video-cassette recorder (Gödde, 1985). Identification was based on the selective response of the biological detector to ONP and matching of retention times of unknowns with authentic standards.

RESULTS

Biosynthesis of Attachment–Aggregation Pheromone during Feeding. In whole extracts of *Amblyomma variegatum* males that fed on rabbits, traces of ONP were detectable by HPLC for the first time on day 4 after onset of feeding (150 ng/tick). The concentration increased during the following two days to 1.3–2 μg/tick at day 6. After this and up to day 19, variable amounts of about

1.3—7.3 μg/tick were measured (mean 3.4 ± 0.7 μg SEM er tick; $N = 9$). Methyl salicylate was detected only at day 8 (40 ng/tick), and thereafter reached about 0.6 μg/tick after day 10. Males removed at day 1, 2, or 3 after onset of feeding and kept alive at 30°C and 90% relative humidity did not contain detectable amounts of ONP or MS if assayed later at day 8. After hydrolysis of extracts of unfed males, no ONP or salicylic acid (from MS) was present. Hydrolysis of extracts from mature males also did not increase the pheromone content cited above.

Extracts of *A. hebraeum* males by day 14 of feeding contained about 1.9 μg ONP per tick; benzaldehyde was not detectable under our conditions.

Emission Rates of Attached Ticks. On one rabbit, traces of ONP emitted by *A. variegatum* males and the surrounding host skin covered by the sampling device were first detected at day 3 after onset of the blood meal (7 ng/hr per tick, see Figure 1A). Thereafter emission rose rapidly and reached a plateau at day 6 (620 ng/hr per male tick).

When four female ticks were added to these males at day 12, the ONP emission rate of 975 ng/hr per male tick just before contact, dropped after the encounter between the sexes over the next 4 hr to a level of 110 ng/hr per tick, but thereafter increased again to variable levels of 310–1650 ng/hr per male tick (Figure 1A). At day 12 we began to observe another control group of four males in parallel on the same rabbit (Figure 1A). The emission was comparable to that of the paired females–males, with variable rates between 350 and 1780 ng/hr per male tick.

Traces of volatile MS was detectable for the first time in *A. variegatum* males at day 4 of feeding (5 ng/hr per tick; Figure 1B). Increase in emission over the next days followed the pattern described for ONP. A drop occurred after pairing of the males with the females. The variable rates were lower than for ONP (20–600 ng/hour per tick). The ratio between emitted ONP and MS after 12 days of feeding varied between 2:1 and 7:1 with a mean value of about 4:1.

Host skin adjacent to 12-day feeding ticks also emitted pheromone products: ONP at 40 ng/cm^2/hr and MS at 10 ng/cm^2/hr. An area beginning about 5 cm away from the nearest tick gave off ONP at about 10 ng/cm^2/hr. No emission was detected from areas further away. In addition, feces collected near a tick contained about 140 ng ONP and 35 ng MS per milligram dry weight.

A. hebraeum males began to emit ONP one day later than *A. variegatum* males at a rate of 8 ng/hr per tick (Figure 2). The release appeared to reach a plateau after seven days of feeding with rates of 225–280 ng/hr per tick.

Emission Rates of Forcibly Removed Ticks. Mature ticks of both *Amblyomma* species, forcibly removed after 14 days of feeding, released ONP during the first few minutes at rates comparable to attached ticks (Figure 3; 950 and 250 ng/hr per male tick for *A. variegatum* and *A. hebraeum*, respectively).

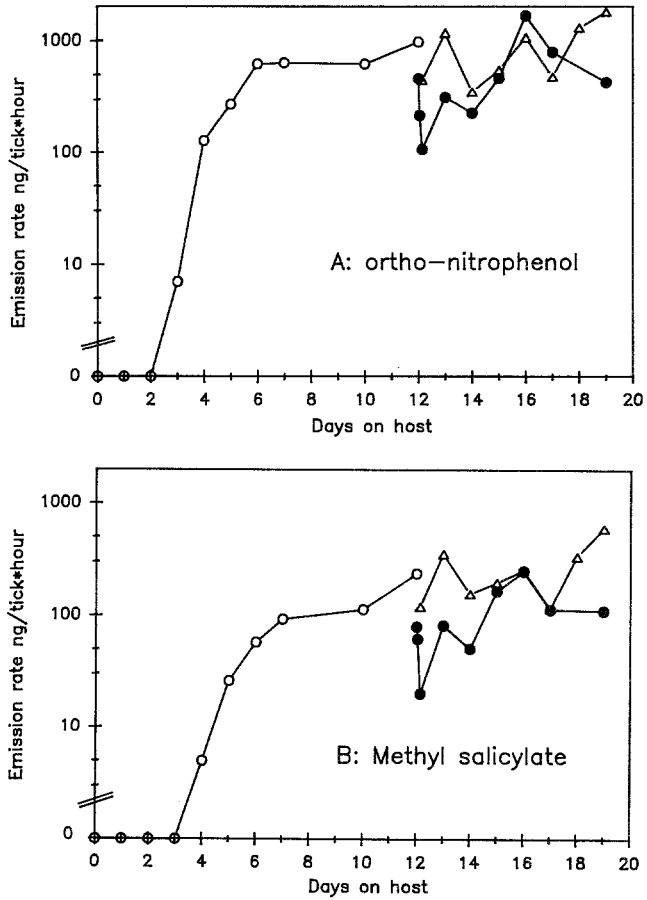

FIG. 1. Emission rate of *o*-nitrophenol (A) and methyl salicylate (B) and four males of *Amblyomma variegatum* after attachment on the rabbit (open circles). At day 12, four females were added; after an initial drop, the males continued to emit at high rates (filled circles). Open triangles: another group of four males without females on the same rabbit.

However, the emission dropped within a few hours to very low levels of less than 10 ng/hr per male tick in both species. Emission of MS in *A. variegatum* (not shown) diminished in a similar way. After one day, ticks still contained ONP in amounts comparable to attached males (one to several micrograms of ONP).

Localization of Pheromone Production. Analysis of a small piece of dorsal cuticle bearing the two foveal glands of mature *A. variegatum* or *A. hebraeum* males revealed only traces of ONP; by contrast, nearly all of the total extract-

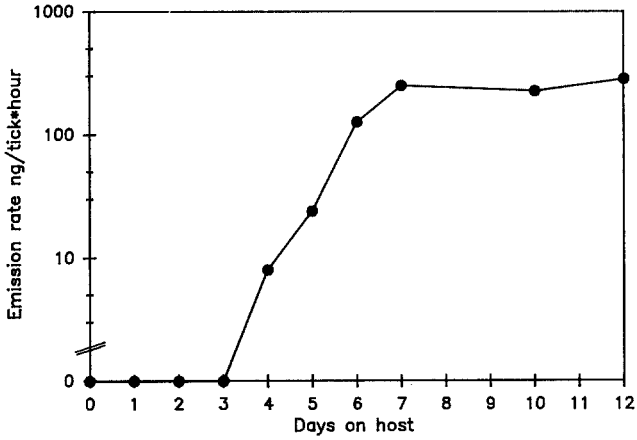

FIG. 2. Emission rate of *o*-nitrophenol from 25 males of *Amblyomma hebraeum* during the first 12 days following attachment on the rabbit.

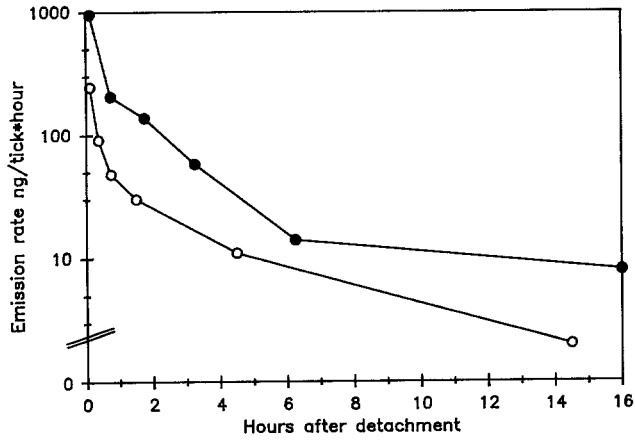

FIG. 3. Emission rates of *o*-nitrophenol in forcibly detached males of *Amblyomma variegatum* (filled circles, $N = 20$) and *Amblyomma hebraeum* (open circles, $N = 25$). Each point represents the relase rate, calculated as the mean pheromone amount collected during the sampling period per hour and per tick, at the midpoint of the sampling period.

able ONP and MS (in *A. variegatum*) were found in the rest of the tick. Systematic analysis of different organs from *A. variegatum* males showed that the pheromone was nearly absent from (1) dorsal cuticle without the lateral border, (2) legs, and (3) internal organs such as gut, salivary glands, and excretory,

nervous, and genital systems. Nearly all of the ONP and MS was associated with the ventral cuticle behind the genital opening and with the lateral border.

Dissection and histology of the cuticle revealed the presence of very large dermal glands type 2 (variable, from 200 up to 500 μm diam.) on the ventro lateral side, but not on the dorsal cuticle (Figure 4). In unfed males, these dermal glands were much smaller (60–80 μm diam.).

HPLC analysis of several extracts from carefully dissected and rinsed dermal glands type 2 allowed unambiguous detection of ONP and MS by comparison of retention times and UV spectra of the natural products with that of authentic standards (Figure 5). Presence of ONP was confirmed by combined capillary GC linked electrophysiology, using the ONP-sensitive dII wp/sw/A sensillum on the first pair of legs as a selective biological detector (Figure 6). We conclude that ONP and MS accumulate in these type 2 dermal glands and not in the dorsally located foveal glands.

DISCUSSION

Biosynthesis and Emission in A. variegatum. Our studies on the time course of biosynthesis and emission of ONP and MS in *A. variegatum* males demonstrated that unfed and feeding male ticks up to day 2 did not contain measurable amounts of ONP or MS or hydrolyzable conjugates. This contrasts with the case of the sex attractant pheromone 2,6-DCP, which is already present in unfed females of other metastriate species (Sonenshine, 1984a, 1986; Sonenshine et al., 1982). Trace of ONP emission was detected for the first time by HPLC from ticks at day 3, and within the male at the fourth day. Thus, release of ONP begins apparently as soon as synthesis starts. The mean ONP content of whole mature male ticks was 3.4 μg (range 1.3–7.3 μg). A similar amount of ONP (2 μg/tick) in males fed for six days was described (Schöni, 1987; Schöni et al., 1984). These substantial pheromone quantities represent up to about 0.25% of the weight of a fed male (average weight of 32 mg) or,in comparison, about 20 g for an average adult human. This contrasts sharply again with the sex pheromone 2,6-DCP, which occurs only in nanogram quantities, e.g., only 16 ng/tick were detected in hexane extracts of sexually active female *A. variegatum* that had been feeding for six days (Wood et al., 1975).

The timing of MS emission followed a similar pattern to that of ONP, but was only detectable one day later. Unlike ONP however, we detected MS in whole-body extracts not before day 8. This very low initial body content is very different from the reported value of about 1 μg/tick found previously in males feeding for six days on cows (Schöni, 1987; Schöni et al., 1984).

The emission from males and their surroundings on the host as measured with the Sep-Pak cartridge proved to be variable. Clearly, an impregnation of

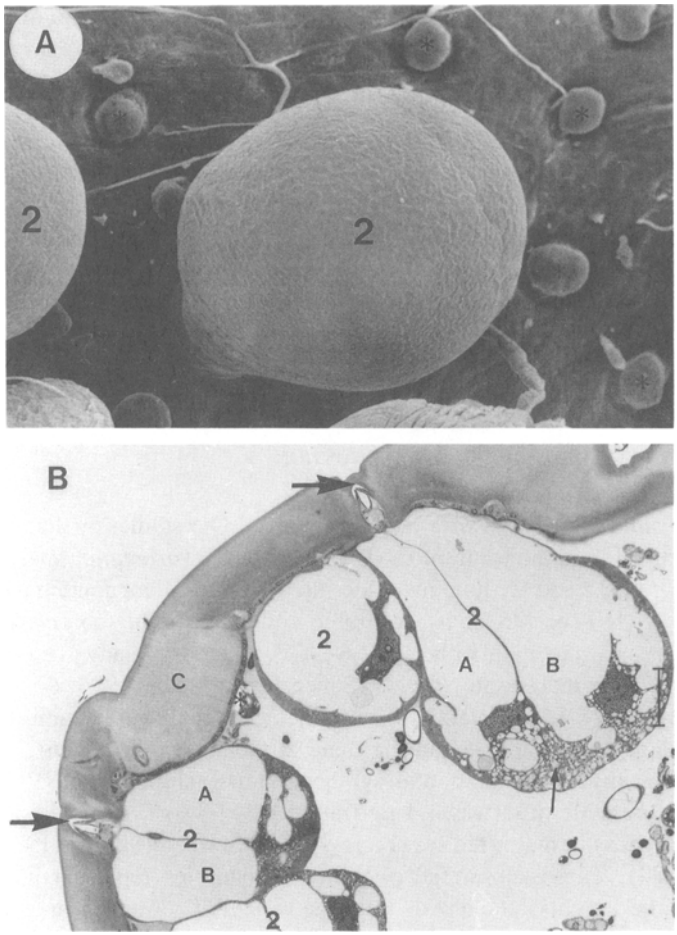

FIG. 4. Mature male of *Amblyomma variegatum* after 12 days of feeding. (A) Scanning electron micrograph of an exposed piece of ventral cuticle. Numerous small dermal glands type 1 (*) are visible; they are found all over the dorsal and ventral cuticle. Two very large dermal glands type 2 (2) are present; they are only associated with the ventrolateral cuticle. Magnification: 340× (B) Semithin section from the ventral cuticle. One small dermal gland type 1 (*) and four very large dermal glands type 2 (2) are present. The huge gland lumens (A,B) and the cytoplasm with many small secretory vesicles (⟶) are visible. (C) cuticle. ⟶: two canals with valvelike regions. Magnification: 190×.

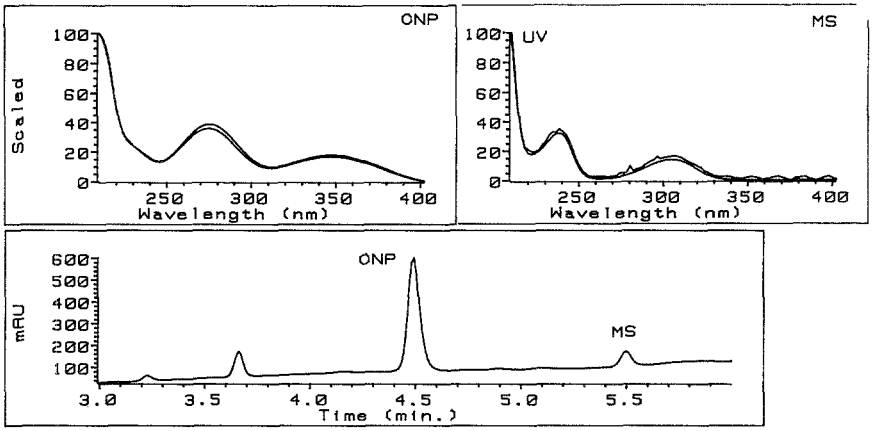

FIG. 5. Presence of *o*-nitrophenol (ONP; 890 ng) and methyl salicylate (MS; 60 ng) in a methanolic extract corresponding to about 75 dissected dermal glands type 2 of *Amblyomma variegatum* males at day 12 of feeding. Lower trace: HPLC separation on a reverse-phase column RP_{18} (125 × 4 mm) at 210 nm. The retention times and the UV-VIS spectra (upper traces) of the unknowns and of authentic standards are nearly identical.

the skin and feces occurred in the immediate vicinity, presumably through direct contact with the male, and up to a few centimeters away through adsorption from the vapor phase. We therefore collected not only from males per se, but also from the surroundings covered by the funnel. The true emission rates from attached males remains unknown; nevertheless, most of the collected pheromones should stem from the ticks because forcibly detached animals showed comparable release rates over the first few minutes in the absence of a contaminated substrate. Interestingly, release seemed to be temporarily lower during the first few hours after pairing with females. Females are apparently not disturbed by subsequent exposure to large quantities of pheromone in the immediate vicinity of the males.

Biosynthesis and Emission in A. hebraeum. Whole-body content of ONP in *A. hebraeum* was similar to *A. variegatum*, but emission rates appeared to be somewhat lower at about 250 ng/tick/hr. This value agreed with the maximum release of 400 ng/tick/hr as estimated by capillary GC-MS after tapping with the dynamic solvent effect (Apps, personal communication).

Apps et al. (1988) found that no MS, but benzaldehyde instead, was detectable in volatiles from *A. hebraeum*. Thus, the attachment–aggregation pheromone of both species contains ONP as a nonspecific main component, but differs with respect to the secondary components. *A. variegatum* probably uses MS and nonanoic acid in addition, whereas *A. hebraeum* uses benzaldehyde and 2-

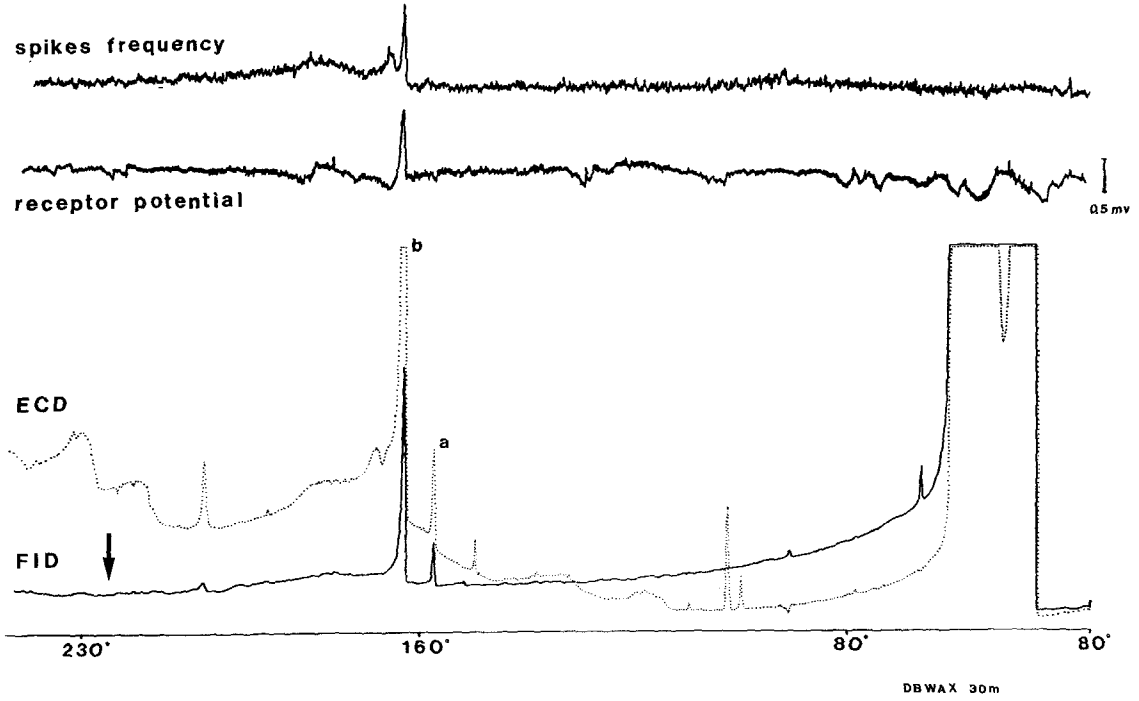

FIG. 6. Capillary gas chromatography-linked single sensillum analysis of a dermal gland type 2 methanolic extract of *Amblyomma variegatum* males at day 12 of feeding. FID, flame ionization detector; ECD, electron capture detector of the chromatograph. Recordings were made of receptor and action potentials of the *o*-nitrophenol-sensitive cell of the DII wp/sw/A sensillum on the Haller's organ of an *Amblyomma variegatum* male, placed opposite the effluent conduit of the gas chromatograph. Frequency/voltage conversion was applied to the AC trace to provide an on-line readout of the spike frequency. Note the selectivity of the olfactory unit for *o*-nitrophenol (b), with no response to methyl salicylate (a), the second major aromatic component of the extract. The elution temperature of nonanoic acid is indicated by the arrow. Detection limit for this product was about 1 ng.

methylpropanoic acid with maximum release rates of about 17 and 950 ng/tick/hr, respectively; in addition, variable amounts of medium-chain fatty acids such as nonanoic acid might be present (Apps et al., 1988).

A. hebraeum males matured at a slightly slower pace than *A. variegatum* on rabbits. This is in good agreement with earlier observations (Norval and Rechav, 1979; Rechav, 1977; Schöni, 1987; Schöni et al., 1984). In both species, the development of the clasping behavior was concomitant with the increase in pheromone release. In *A. variegatum* fed on cows, approximately 40% of the males showed clasping for the first time at day 3 (Schöni, 1987). This correlates with the time when we detected the first traces of emitted ONP in our rabbit-fed ticks. We observed that the remaining immature males developed the clasping behavior during the following two days, at a time when we noted a clear increase in ONP content and emission rates from the feeding ticks. It is tempting to speculate that the two phenomena may be controlled by the same hormones. Males prematurely detached during the first three days of feeding did not synthesize the pheromone; permanent contact with the host is a prerequisite for normal development.

Localization of Pheromone Glands. We found that ONP and MS are not associated with the foveal glands, as we initially suspected, but rather with the enormous dermal glands type 2 from the ventrolateral cuticle. Other tissues such as hypodermal cells or dermal glands type 1 from the same localization could also be implicated. However, this appears unlikely, because the dorsal cuticle, which contains these same cell types, is pheromone-free.

Dermal glands type 2 have not been reported previously to produce pheromones. Like the dermal glands type 1, in metastriate ticks, they are suspected to participate in the production of such secretions as molting fluid, the waterproofing wax layer or lipidic material on the cuticle of repleted ticks (Balashov, 1972; Lees, 1947). Our preliminary studies showed a secretory structure quite comparable to the foveal glands. Each dermal gland type 2 consists of two very large secretory cells, which contain many secretory vesicles. The glandular products are discharged into a huge lumen and gain the exterior through a cuticular duct. An innervated valvelike region in the duct might control the passage of secretion. This could represent the basis for a controlled release mechanism and explain the rapid decline in pheromone emission after forced detachment of males, and the temporary decrease in release rate after first contact with a female.

Nonanoic Acid. Schöni et al. (1984) found approximately 8 μg of nonanoic acid per tick in an ether extract of males at day 6 of feeding. Our HPLC technique was not sensitive enough to explore its biosynthesis and possible release, but neither did capillary GC did not this substrate in dermal gland extracts or in collected volatiles. Offered separately, nonanoic acid showed no influence on attraction, but together with MS in the blend it contributed to complete pheromone activity (Schöni et al., 1984; Schöni, 1987). It may function rather as a

contact chemostimulant. Male *A. hebraeum* intermittently released small amounts of nonanoic acid, among other medium-chain acids, but its behavioral role has not been elucidated (Apps et al., 1988).

Attachment–Aggregation Pheromones as Part of Host Location In both *Amblyomma* species, very high pheromone emission rates were observed. We estimate a maximum emission from a cow, infested with 152 male *A. variegatum* as reported by Hoogstraal (1956), to be in the order of about 7 mg/day! This complements various observations that indicate male infested steers or pheromone sources prove to be very attractive over a distance of several meters in the field; CO_2 further increased efficiency by rendering ticks active (Hess and De Castro, 1986; Norval et al., 1989a,b). These aggregation–attachment pheromones are thus efficient in signaling suitable hosts and must play an important part in the host-location strategy of the two *Amblyomma* species studied.

Acknowledgments—We are grateful for the generous financial support of the Swiss Office for Education and Science, the Swiss National Science Foundation (grant 3.609-0.87) and the Sandoz and Roche Foundations. We wish to thank Dr. Immler, and Misters Bouvard, Rohrer, and Cesari from Ciba-Geigy Ltd. (CRA St. Aubin) for generously supplying us with ticks. Dr. Apps (Pretoria) kindly communicated the pheromone emission rates of *A. hebraeum*.

(Received October 24, 1990; accepted January 14, 1991)

Abstract—The ability to discriminate prey chemicals from control substances and the presence of a poststrike elevation in tongue-flicking (PETF) rate are experimentally demonstrated in the lacertid lizard, *Podarcis muralis*. The tongue-flick attack score, a composite index of response strength, was significantly higher in response to integumental chemicals from cricket than to cologne or distilled water. The cricket chemicals additionally elicited a significantly greater rate of tongue-flicking and higher proportion of attacks by the lizards than did control stimuli. PETF combined with apparent searching movements strongly suggest the presence of strike-induced chemosensory searching (SICS). Experimental evidence indicates that both PETF and SICS occur in insectivorous representatives of three families of actively foraging autarchoglossan lizards, suggesting their widespread occurrence in such lizards. The adaptive roles of chemosensory behavior in the foraging behavior of *P. muralis* are discussed. It is proposed that these lizards may form chemical search images and that PETF and SICS may have been present in the lacertilian ancestors of snakes.

Key Words—Prey chemicals, tongue-flicking, feeding behavior, Reptilia, Lacertidae, *Podarcis muralis*.

INTRODUCTION

Knowledge about the importance of the chemical senses to lizards for locating and identifying prey is growing rapidly, but our understanding of chemosensory roles in foraging and other behaviors by lacertid lizards is fragmentary. *Lacerta vivipara* may be able to identify the vomodors (Cooper and Burghardt, 1990b)

0098-0331/91/0500-0849$06.50/0

of one of its predators, the snake *Vipera berus* (Van Damme et al., 1990); tongue-flicking rates in this lizard increase in cages previously occupied by the predator. Tentative experimental findings were presented by Kahmann (1939) on the use of the vomeronasal organ in feeding. Recently, an ability to discriminate integumentary chemicals of crickets from control substances was confirmed for *Podarcis hispanica* (Cooper, 1990a), but the sample size was very small ($N = 5$).

Lizards in several families of actively foraging insectivores can locate and identify prey by tongue-flicking (partially reviewed by Burghardt, 1970; Halpern, 1991; Simon, 1983; and Cooper, 1990b). Discrimination of prey chemicals has been demonstrated experimentally in representatives of several families of lizards that are insectivorous active foragers or cruising foragers (Regal, 1978), including Anguidae (Cooper, 1990c), Helodermatidae (Cooper, 1989b), Lacertidae (Cooper, 1990a), Scincidae (Loop and Scoville, 1972; Burghardt, 1973; Von Achen and Rakestraw, 1984; Nicoletto, 1985; Cooper and Vitt, 1989), Teiidae (Cooper, in press), Varanidae (Cooper, 1989b), and possibly Cordylidae (gerrhosaurines; Cooper, in press), as well as in a nocturnal gecko (Dial, 1978; Dial et al., 1989) and an herbivorous iguanid (Pedersen, 1988; Krekorian, 1989; Cooper and Alberts, 1990). Accordingly, it may be predicted that typical lacertids, the vast majority of which appear to be actively foraging insectivores, are capable of prey chemical discrimination.

Some lizards that can discriminate prey chemicals also use chemical cues in a manner analogous to strike-induced chemosensory searching (SICS) in rattlesnakes (Chiszar and Scudder, 1980). After striking and envenomating potentially dangerous prey, such as large rodents, rattlesnakes and many other venomous snakes relocate the prey after it has been incapacitated by following the prey's scent trail. Shortly after releasing the envenomated prey, a rattlesnake greatly increases its tongue-flick rate and follows the prey's trail by tongue-flicking (Chiszar and Scudder, 1980).

The elevated tongue-flicking rate and searching behavior constitute SICS; the larger behavior pattern is called the strike–release–trail strategy. Some nonvenomous snakes (Cooper et al., 1989), a varanid lizard (Cooper, 1989c), and a cordylid lizard (Cooper, in press) exhibit behavior similar to SICS despite failure to voluntarily release prey. This was discovered after removal of prey items from their mouths. Because the lizards not only increase their tongue-flicking rates, but also their locomotion, apparently searching for the removed prey (Cooper, 1989c), they show SICS.

In this paper I present experimental findings on responses to prey chemicals by a lacertid lizard, *Podarcis muralis*. The topics investigated are (1) the ability to detect and respond differentially to prey chemicals, (2) the presence of one component of SICS, the poststrike elevation in tongue-flicking (PETF),

and (3) the duration of PETF. Roles of chemical cues in lacertid foraging are discussed.

Prey odor discrimination in squamate reptiles appears to be mediated by vomerolfaction (Cooper and Burghardt, 1990c), with the tongue serving as a sampling device that delivers chemicals from the external environment to the mouth, where the chemicals are transferred via the vomeronasal ducts to the vomeronasal organs above the roof of the mouth for sensory analysis. Normal responses to food chemicals require vomeronasal participation (Halpern and Frumin, 1979; Halpern and Kubie, 1980; Graves and Halpern, 1990; Cooper and Alberts, 1991). Thus, tongue-flicking behavior has been used extensively as an observable index of chemosensory investigation (e.g., Burghardt, 1970; Cooper and Burghardt, 1990a; Halpern, 1991) and is so used here.

METHODS AND MATERIALS

Subjects and Maintenance. Sixteen adult *P. muralis* purchased from a commercial dealer were maintained in the laboratory from their arrival on December 27, 1989, for several months before the experiments. This allowed habituation to experimental conditions, especially the close proximity of an experimenter's hand. Each lizard was housed individually in a 30 × 30 × 26-cm glass terrarium containing a water bowl, a wooden shelter board, a sand substrate, and a wire screen top.

Fluorescent lighting was provided during the daylight hours. Air temperatures fluctuated from 22 to 29°C. Because these temperatures were lower than those expected to produce the highest tongue-flicking rates (Cooper and Vitt, 1986; Van Damme et al., 1990), undercage heaters were used to allow the lizards to thermoregulate and to remain fully active even when air temperatures were low. Cloacal temperatures were typically in the low thirties.

The lizards were fed crickets to satiation three times per week. Water was available ad libitum. To prepare the lizards for the experiments, the experimenter would move slowly while feeding and watering them. *Podarcis muralis* is warier than many lizard species, but a sufficient number of individuals became habituated to the experimenter's presence to allow completion of the experiments.

Prey Odor Discrimination. The ability of the lizards to discriminate prey chemicals from control substances was assessed by an experiment with a randomized blocks design in which each individual responded to three stimuli presented on cotton swabs: integumentary chemicals of domestic crickets, cologne (Mennen Skin Bracer, Spice Scent), and distilled water. Stimuli were prepared by initially dipping the cotton tip of a 15-cm wooden applicator in distilled

water; other substances were added when needed by either dipping a moistened swab in cologne or by rolling a moistened cotton over the integument of a cricket. The distilled water condition served as an odorless control to gauge responsiveness to the experimental milieu. Cologne was a pungency control to indicate degree of response to a highly odorous substance lacking trophic or social relevance. Each swab was used only once.

To begin a trial, the experimenter slowly approached a lizard's cage and carefully removed its wire cover to avoid disturbing the lizard. He then placed the cotton tip of the applicator 1–1.5 cm anterior to the lizard's snout. Tongue-flicks directed to the applicator were counted for 60 sec or until the lizard bit the applicator, whichever came first. Timing began when the first tongue-flick occurred. In addition, the presence or absence of biting and latency to biting were recorded; a latency of 60 sec was assigned if a lizard did not bite.

The experiment was conducted between 1200 and 1430 hr Central Standard Time on March 30, 1990. Nine lizards were tested with stimuli presented in random sequence, with approximately equal numbers of individuals tested with each stimulus in each of the three trials. The intertrial interval was ca. 60 min. The air temperature was only 25°C, but the sand and lizards were warmer. Although body temperature strongly affects tongue-flicking rates (Cooper and Vitt, 1986), the relative responsiveness to various chemical stimuli does not appear to be affected over a wide range (20–35°C) of temperatures (Van Damme et al., 1990).

Overall responsiveness in the three conditions was measured by the tongue-flick attack score for repeated measures experiments, TFAS(R) (Cooper and Burghardt, 1990a). If the lizard does not bite, TFAS(R) is the number of tongue-flicks it emits during the trial. If it bites, TFAS(R) is the maximum number of tongue-flicks emitted by that individual lizard in any of the three trials plus (60 − latency to bite in seconds). The stronger weight of biting than any amount of tongue-flicking in TFAS(R) reflects a conviction that a predatory attack is a stronger indication of feeding motivation than is chemosensory investigation by tongue-flicking. Numbers of tongue-flicks, latency to bite, and numbers of individuals biting in the three conditions were also compared.

Differences among stimulus conditions in TFAS(R) and number of tongue-flicks were tested for significance by analysis of variance for a single-factor experiment with a repeated measures design (Winer, 1962). Individual comparisons between pairs of means were made using Student-Newman-Keuls tests. Homogeneity of variance was tested by Hartley's tests for heterogeneity followed by logarithmic transformation where needed. Latency differences were examined by nonparametric Friedman two-way analysis of variance because the distribution of latency was nonnormal. The difference in number of lizards biting in response to cricket stimuli and the other two stimuli was assessed by a

binomial test (Siegel, 1956). Tests were two-tailed unless otherwise stated, with $\alpha = 0.05$.

PETF. In previous related studies of lizards and nonvenomous snakes (Cooper, 1989c, 1991b; Cooper et al., 1989), apparent searching movements have been noted qualitatively; only the increase in tongue-flicking rate has been treated quantitatively. Because tongue-flick rates might increase in the absence of search involving locomotion, it is important to distinguish the tongue-flicking behavior from SICS. The increase in tongue-flicking rate after the prey has been removed from the mouth of an animal is the poststrike elevation in tongue-flicking (PETF; Cooper, 1992).

The effect of biting on tongue-flicking rate was determined by counting tongue-flicks emitted in 10 consecutive minutes in four experimental conditions. In the strike condition, a cricket was tied to a white thread (ca. 25 cm) and was lowered to a position just above the sand 10 cm anterior to a lizard's snout. Immediately after the lizard bit the cricket, the experimenter removed the cricket from the lizard's mouth as gently as possible and immediately began counting tongue-flicks. The cricket was presented in the same way in the pull condition, but after the lizard approached and was poised to bite the cricket, the experimenter removed the cricket with one hand and simultaneously moved the lizard a short distance (as if separating it from bitten prey) with the other hand, then began counting tongue-flicks. In the sight condition, a cricket was held at the far side of the cage in clear view of the lizard. The cricket was removed after 10 sec or sooner if the lizard approached it. The lizard was not allowed to tongue-flick it. The string condition was similar to the sight condition except that no cricket was tied to the string. Counting of tongue-flicks was initiated upon removal of the experimental stimuli in the last two conditions.

Forced removal of prey from a lizard's mouth is a somewhat drastic experimental procedure that requires contact with the lizard. It seems likely to have behavioral effects beyond those on tongue-flicking. However, this procedure is necessary for demonstration of PETF in species that do not voluntarily release prey. The pull condition serves as a control for handling effects. In this condition, the lizard is allowed to tongue-flick the cricket. It is hoped that the only important difference from the strike condition is the absence of chemical and possibly other cues associated with biting. In a study of garter snakes, an additional control for the effects of tactile stimuli during biting was used to show that the chemical cues received during biting produced PETF (Cooper et al., 1989). The sight condition is a control for the effect of seeing the prey on tongue-flicking rates. Tongue-flicking rates expected in the experimental setting are revealed in the string condition. For further discussion of the experimental procedures and interpretation of results, see Cooper et al. (1989) and Cooper (1989c).

A repeated measures (randomized blocks) design in which each lizard responded in four conditions was used, with a partially counterbalanced sequence of presentation. Lizards were tested only once a day, two days after having been fed to satiation. Eight lizards were tested, all of which had been subjects in the study of prey odor discrimination. The experiment was conducted at 1200–1500 hr CST between April 6 and 18, 1990. Although the experiment was conducted at air temperatures of 25–27°C, the lizards were active and their bodies were warmer than the air temperature.

For each minute, the significances of differences among conditions were assessed by nonparametric Friedman two-way analysis of variance (Siegel, 1956), which was necessary because the tongue-flicking distributions were nonnormal due to frequent zero values. When the main condition effect was significant, individual comparisons were made between pairs of conditions (Hollander and Wolfe, 1973). Binomial tests were conducted to determine the significance of differences in numbers of days of greater relative magnitude for selected comparisons between conditions. Alpha was 0.05 and tests of significance were two-tailed except as noted.

RESULTS

Prey Odor Discrimination. The lizards tongue-flicked in all conditions, but emitted the most tongue-flicks in cricket trials and bit only in response to cricket stimuli, resulting in high TFAS(R) values for the cricket condition (Table 1). Variances of TFAS(R) were heterogeneous for the raw data (Hartley's $F_{max} = 15.76$; $df = 3, 8$; $P < 0.01$), but logarithmic transformation yielded homogeneity ($F_{max} = 2.49$; $df = 3, 8$; $P > 0.10$). The main condition effect for the transformed TFAS(R) data was highly significant ($F = 18.83$; $df = 2, 16$; $P < 0.002$). TFAS(R) was significantly greater in the cricket condition than in either the cologne or distilled water condition ($P < 0.01$ each), but did not differ between the two control conditions ($P > 0.10$).

The lizards tongue-flicked at a much higher mean rate in response to cricket stimuli than to the control stimuli; for the two control groups the means were similar but variance was somewhat larger in response to distilled water because two individuals emitted 85% of all tongue-flicks in that condition. Variances of tongue-flicks were heterogeneous for the raw data ($F_{max} = 11.65$; $df = 3, 8$; $P < 0.01$), but the heterogeneity was removed by logarithmic transformation ($F_{max} = 1.92$; $df = 3, 8$; $P > 0.10$). The stimulus effect was significant ($F = 9.39$; $df = 2, 16$; $P < 0.01$); with significantly more tongue-flicks emitted in response to cricket stimuli than to cologne ($P < 0.05$) or distilled water ($P < 0.01$).

Three lizards bit swabs bearing cricket stimuli; no bites occurred in trials with control stimuli. Thus, no significant difference in number of lizards biting occurred between the cricket condition and either of the control conditions taken individually. However, biting is predicted to be more frequent in response to prey stimuli. If it is assumed that there is an equal chance of a lizard biting in each condition, the probability that a given lizard that bites will do so in the cricket condition is 0.333 and the combined probability of it biting in one of the other conditions is 0.667. The likelihood of all three biting in the cricket condition is thus only 0.037 (one-tailed), indicating a significantly higher frequency of biting in response to cricket stimuli than to the combined controls. Latency to bite did not differ significantly among conditions ($\chi_r^2 = 1.50$, $df = 2$, $P > 0.10$).

PETF. The highest mean tongue-flicking rates occurred in the strike condition throughout the experiment except in minutes 2 and 6, when the means were higher in the pull condition (Table 2). There was also a tie for the highest mean between the strike and pull conditions in the fourth minute. During each of the first six minutes the pull condition elicited higher total tongue-flicks rates than did the sight and string conditions and had the individual emitting the greatest number of tongue-flicks among these conditions (binomial $P = 0.016$ for each comparison, one-tailed). In addition, the sight condition elicited higher tongue-flicking rates than did the string condition and had the individual emitting the greatest number of tongue-flicks for the two conditions in each of the

first six minutes (binomial $P = 0.016$ for each comparison, one-tailed). Overall, there were more tongue-flicks in the sight condition than in the string condition in eight of ten minutes, with one tie and one reversal [P (8 of 9) = 0.035, one-tailed].

Despite these consistent differences, numbers of tongue-flicks varied significantly among conditions only during the first three minutes. In the first minute, the main effect was significant ($\chi_r^2 = 18.56$, $df = 3$, $P < 0.001$). Significantly more tongue-flicks were emitted in the strike condition than in the pull ($P < 0.05$, one-tailed), sight ($P < 0.01$), and string ($P < 0.01$), and string ($P < 0.01$) conditions. There were no significant differences among the three control conditions. The main effect was only marginally significant during the second minute ($\chi_r^2 = 6.45$, $df = 3$, $P < 0.05$, one-tailed) and the numbers of tongue-flicks were not significantly greater in the strike condition than in the control conditions. The only significant difference was a greater response in the pull than in the string condition ($P < 0.05$, one-tailed). During the third minute, the tongue-flicking rate differed significantly among conditions ($\chi_r^2 = 7.91$, $df = 3$, $P < 0.05$), but PETF was absent because the number of tongue-flicks in the strike condition was significantly greater than that in only the string condition ($P < 0.05$). The sole other significant difference was that more tongue-flicks occurred in the pull condition than in the string condition ($P < 0.05$, one-tailed). The nonsignificant main effects for the remaining minutes all had probability values greater than 0.10 and χ_r^2 values with three degrees of freedom of 4.35, 1.88, 1.39, 1.48, 2.29, 0.56, and 2.59, consecutively).

Although movements were not quantified, individuals that tongue-flicked at high rates crawled while doing so. The locomotion, which presumably in part indicated searching movements, decreased greatly after the first few minutes, as did tongue-flicking. Most individuals that did not tongue-flick during a given minute were also still at that time. Differences among conditions, therefore, were closely related to the proportions of lizards that tongue-flicked (Figure 1). During the first few minutes, high proportions of lizards tongue-flicked in all conditions. Thereafter, the proportions fell rapidly in the three control conditions. They also decreased in the strike condition and became increasingly variable in the later minutes, but remained higher than in the control conditions throughout the experimental interval. Some individual lizards tongue-flicked in the early minutes, remained quiescent for several minutes, then tongue-flicked again later.

The proportion of individuals tongue-flicking was consistently higher in the strike condition than in the control conditions. It was higher than in the pull condition in nine of ten minutes (binomial $P = 0.02$, one-tailed), including the last seven minutes (binomial $P = 0.008$). The proportion tongue-flicking in the strike condition was higher than in the sight and string conditions in all ten minutes (binomial $P = 0.001$ for each comparison, one-tailed). Higher pro-

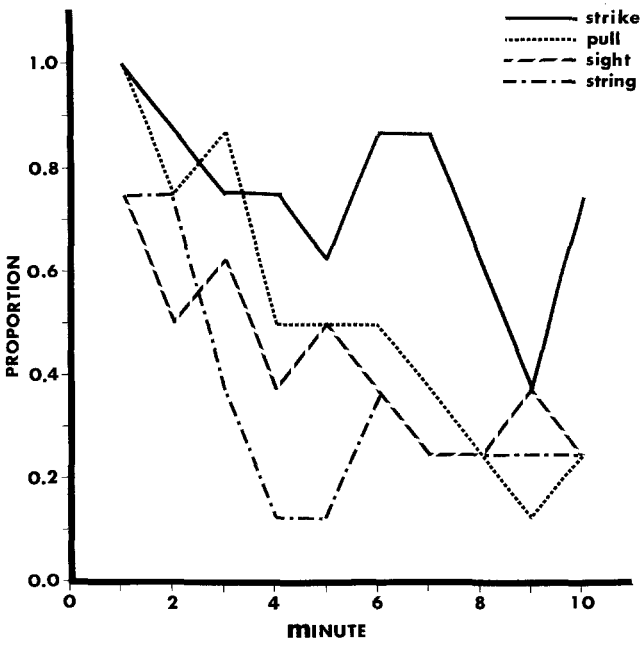

FIG. 1. Proportions of individuals of *Podarcis muralis* tongue-flicking at least once in the four experimental conditions.

portions tongue-flicked in the pull condition than in the other control conditions during the first seven days. For each comparison, the proportion was higher on six days for the pull condition, with a tie occurring on the remaining day. These differences are significant by a binomial (sign) test ($P = 0.016$, one-tailed). The proportions tongue-flicking were similar in the sight and string conditions, with ties on five days. Although greater proportions tongue-flicked in the sight condition than in the string condition in four of the remaining five days, the two conditions did not differ significantly (binomial $P = 0.19$, one-tailed).

DISCUSSION

Prey Odor Discrimination. Podarcis muralis readily detects prey chemicals and discriminates them from trophically irrelevant chemical stimuli. These results extend the previous findings for *P. hispanica* (Cooper, 1990a) to another lacertid species. In both species TFAS and numbers of tongue-flicks were significantly higher in response to prey chemicals than to control stimuli. However, *P. muralis* had TFAS and numbers of tongue-flicks over twice as great as those of *P. hispanica*. Reasons for these differences may include differences in

temperature (Cooper and Vitt, 1986), lighting, and random effects in small samples, as well as true interspecific differences.

Both biting and tongue-flicking contributed substantially to the difference between responses to prey chemicals and control chemicals. In this respect the responses of *P. muralis* are most similar to those of the varanid *Varanus exanthematicus* (Cooper, 1989b) and the anguid *Elgaria coerulea* (Cooper, 1990c), but it is now obvious that interspecific differences in the relative importance of biting and tongue-flicking exist among congeners. This is known in *Podarcis* (Cooper, 1990a, this paper) and *Elgaria* (Cooper, 1990c). Although the experimental conditions and procedures are similar in these cases, some of the apparent differences may reflect differential (defensive) responses to experimenters and uncontrolled experimental variables extraneous to chemosensory analysis and response.

Whatever the cause of the interspecific differences, it now seems likely that detection and recognition of prey chemicals are widespread in Lacertidae. The results agree with previous findings for lizard families consisting largely of active foragers (Cooper, 1989a, 1990a; Cooper and Vitt, 1989). Because information is available for only one or at most a few species per family, it will be important to determine the extent to which these responses to prey chemicals are phylogeneticaly constrained or are responsive to changes in foraging mode. Within families, most species have a similar foraging mode (Huey and Pianka, 1981; Vitt and Price, 1982); the crucial tests will require study of species that have evolved foraging modes atypical for their families.

PETF. The high level of tongue-flicking in the strike condition indicates that PETF occurs in *P. muralis*. PETF is now known to occur in all three species of actively foraging insectivorous lizards that have been studied (Cooper, 1989c, in press, this paper). Its demonstrated duration is brief in *P. muralis*, only 1 min, even shorter than the 2-min interval of PETF in a cordylid species (Cooper, in press). PETF was significant in a varanid (Cooper, 1989c) during the first 2 min but was not examined thereafter.

Although significant levels of PETF might be detected over a somewhat longer interval by using a larger sample size, it is clear that the major increase in tongue-flicking rate attributable to biting begins almost immediately and wanes rapidly. The criterion I have adopted for the existence of SICS in a particular minute is a combined significance of the condition effect and significantly higher number of tongue-flicks in the strike condition than in each of the three control conditions. This is a conservative criterion that could obscure some important findings.

The data on numbers of minutes in which more tongue-flicks were emitted and the greater proportion of lizards tongue-flicking in the strike condition than in the control conditions show that effects of biting last considerably longer than 2 min, some slight residual effects being manifest throughout the 10-min trials.

The sequelae of biting are thus a rapid increase in tongue-flicking and searching movements, followed by a rapid decrease in these behaviors, with a final, more prolonged interval of intermittent chemical monitoring at a reduced rate of tongue-flicking.

Roles of Prey Chemicals in Lacertid Foraging Behavior. As actively foraging insectivores, most lacertid species presumably search for prey that may be cryptic or hidden from view. The ability to respond selectively to prey chemicals must enhance the ability of these lizards to locate and confirm the identity of such prey. Some species of lacertids have been characterized as ambush foragers (Huey and Pianka, 1981) and would thus be expected not to use chemical cues to locate prey. These species would seemingly be good candidates for testing the intrafamilial responsiveness of reliance on prey chemical discrimination to changes in foraging. However, the movement frequencies of the putative lacertid ambush foragers are higher than those of typical phrynosomatid and polychrid (both formerly iguanid; Frost and Etheridge, 1989) ambush foragers, suggesting that prey chemical discrimination could retain importance for these lizards. Use of chemical cues intermediate to that of typical ambush and active foragers is currently unknown, but seems a distinct possibility in such cases.

The temporal pattern of responses to chemical cues in the PETF experiment is readily interpretable in terms of their probable adaptive significance in foraging. Having bitten prey that has escaped, a lizard has also sampled prey chemicals that may be used in an attempt to relocate the prey that is known to be in the vicinity. Insect prey, even if injured, are not nearly as likely to be captured by following a scent trail as are the envenomated prey of rattlesnakes. Furthermore, actively foraging lizards search for prey briefly in one area and then move to another for further search. Therefore, rapid tongue-flicking and searching movements should be beneficial only briefly, presumably explaining the brevity of these responses in *P. muralis*. This contrasts markedly with the prolonged chemosensory searching in rattlesnakes, which may last for hours (Chiszar et al., 1982, 1985) while the snake attempts to relocate envenomated prey that is unlikely to escape.

The longer-lasting intermittent tongue-flicking in *P. muralis* could be explained by periodic fluctuation of neural response to the prey chemicals to levels above threshold for tongue-flicking. Regardless of the physiological mechanism, such chemosensory investigation could be, but is not necessarily, adaptive. In a lizard that is likely to have moved to a new area to forage within a few minutes, any remaining responses to a specific prey chemical pattern might aid in the location of other individuals of the prey type likely to be in the area. This suggests the possibility that the lizards may form a chemical search image, as reported for a viperid snake by Chiszar et al. (1985).

Because PETF was accompanied by apparent searching movements, *P.*

muralis very likely shows SICS, as suggested previously in *V. exanthematicus* (Cooper et al., 1989) and *G. nigrolineatus* (Cooper, in press). The presence of PETF and very probably of SICS in three families representing the lacertoid, scincoid, and varanoid branches of Autarchoglossa (Estes et al., 1988) suggests that these behaviors are quite widespread in autarchoglossan lizards. Thus, SICS, which has been hypothesized to be a preadaptation for evolution of the strike–release–trail strategy in highly venomous viperid snakes (Cooper et al., 1989), may have been present in the lacertilian ancestors of snakes. The prediction that PETF and SICS are present in families of actively foraging lizards has now been supported for all three families studied.

Acknowledgments—This study was partially supported by a grant-in-aid from Auburn University at Montgomery.

(Received October 31, 1990; accepted January 14, 1991)

Abstract—To determine the relative sensitivities of tomato, cucumber, and bean to exogenously applied concentrations of ferulic acid (FA) and to determine whether FA-induced stress responses increase endogenous levels of abscisic acid (ABA), wild-type and *flacca* (ABA-deficient mutant) tomato (*Lycopersicon esculentum* Mill. cv. Ailsa Craig), cucumber, (*Cucumis sativus* L. cv. Early Green Cluster), and bean (*Phaseolus vulgaris* L. cv. Oregon 91) were treated with FA (0.0, 0.2, 0.4, 0.8 mM) in nutrient solution every other day for a total of two or three treatments. FA inhibited leaf growth and water utilization of wild-type tomato, *flacca* tomato, and cucumber, but not of bean. Acclimation to FA was observed following the first FA treatment and increased endogenous ABA levels were found in wild-type tomato, *flacca* tomato, and cucumber following multiple FA treatments. Induction of ABA biosynthesis occurred in wild-type tomato within 8 hr of FA treatment and maximum ABA levels were observed 24 hr after treatment. At that time, ABA levels of tomato treated with 0.4 and 0.8 mM FA were 13.7 times and 2.6 times higher than control levels, respectively. A second FA (0.4 or 0.8 mM) treatment, 48 hr after the first, did not appear to affect ABA levels. Ninety-six hours after the first treatment, ABA levels of tomato treated with 0.4 mM FA approached control levels; ABA levels of plants treated with 0.8 mM FA were 1.9 times higher than control levels. Control ABA levels increased gradually with time. The data showed that plant sensitivity and

ability of subsequent acclimation to phenolic acids, such as FA, were taxa dependent.

Key Words—Tomato, *Lycopersicon esculentum*, wild type and *flacca* mutant, cucumber, *Cucumis sativus*, bean, *Phaseolus vulgaris*, ferulic acid, leaf expansion, water utilization, abscisic acid, allelopathy.

INTRODUCTION

During episodes of water deficit, it has been well established that abscisic acid (ABA) levels increase dramatically in leaf and root tissue of mesophytic plants (Walton, 1980; Neill et al., 1984). Since endogenous ABA levels also can be increased by a variety of stresses, it has been suggested that the increase in ABA may be a general stress response that is associated with the process of acclimation (Zeevaart and Creelman, 1988). ABA accelerated the acclimation of cultured tobacco cells to high salt concentrations (LaRosa et al., 1987) and increased freezing and cold tolerance in potato and wheat (Chen et al., 1983; Lalk and Dorffling, 1985). Tomato plants exposed to stressful day/night temperatures ranging from 10/5 to 45/35°C accumulated ABA without alteration of plant water potential (Daie and Campbell, 1981), and ABA levels of tomato increased as a result of salt stress (Walker and Dumbroff, 1981). Waterlogged pea plants also exhibited increased ABA levels in an apparent absence of foliar water deficit (Jackson and Hall, 1987). In many of these cases, however, plant water status is believed to be modified, thereby enhancing ABA biosynthesis (Davies et al., 1986).

Recently, the effects of ferulic acid (FA) on the growth and metabolism of cucumber seedlings grown in nutrient solution and in soil systems have been extensively investigated. FA was taken up by the roots, translocated throughout the plant, and used as a precursor in lignin biosynthesis (Shann and Blum, 1987a,b). Physiologically, FA reduced leaf area expansion and shoot dry weight, suppressed germination, inhibited radicle growth, and inhibited seedling root growth in cucumber (Blum et al., 1984; 1985a,b; Blum and Rebbeck, 1989). FA also influenced photosynthetic rates, uptake of various minerals and ions, and certain enzyme (soluble cell wall peroxidase) activities (Balke, 1985; Shann and Blum, 1987b; Blum and Rebbeck, 1989).

Although all of these responses were clearly FA-induced, the initial impact of FA on plants appeared to occur at the root plasmalemma (Glass and Dunlop, 1974; Balke, 1985). The actual mechanism of perturbance at the plasmalemma has not been determined definitively. Circumstantial evidence, including ion uptake studies (Balke, 1985), has suggested that hydraulic conductivity of the roots decreases and that unabated water loss, via transpiration, in conjunction

with the FA-induced decrease in hydraulic conductivity results in visible wilting. Wilting occurred within a few hours upon addition of FA (above 0.5 mM) to nutrient solutions in which cucumber seedlings were grown (Blum and Dalton, 1985). There was no change in water potential (as detected by freezing-point depression) of nutrient solution to which FA had been added (Blum and Dalton, 1985). Stomatal closure occurred sometime during the latter stages of wilting. Leaf turgor returned 12–24 hr later. Stomata remained closed for several days even when roots were removed from the FA treatment (Blum et al., 1985a,b). Stomatal closure following FA treatment also was reported in soybean and grain sorghum (Patterson, 1981; Einhellig et al., 1985). Treatments of soybean and grain sorghum with FA also resulted in lowered leaf water potential (i.e., water potential became more negative) and in lowered stomatal diffusive conductance (Patterson, 1981; Einhellig et al., 1985). Since exogenously applied FA noticeably alters the water balance of various plant species, it appears that one of the subsequent physiological responses to FA treatment should be an increase in endogenous ABA levels.

ABA has been implicated in the regulation of water balance within plants (Walton, 1980; Davies et al., 1986; Zeevaart and Creelman, 1988). Endogenous ABA levels increased dramatically in water-stressed leaves (Harrison and Walton, 1975; Neill et al., 1984; Cornish and Zeevaart, 1988). Increased ABA levels were associated with reduced leaf water potential and with stomatal closure (Beardsell and Cohen, 1975; Raschke and Zeevaart, 1976). Mild water stress also increased endogenous root ABA levels in bean and sunflower (Walton, et al., 1976; Robertson et al., 1985).

The tomato mutant, *flacca*, has been reported to contain 17–26% of the endogenous ABA level of the wild type of the isogenic parent line, *Lycopersicon esculentum* Mill. cv. Ailsa Craig (Tal and Nevo, 1973; Neill and Horgan, 1985). These mutants have a "droopy, wilty" phenotype compared to wild type. They were identified as ABA-deficient primarily because complete reversion to the wild-type phenotype occurred when *flacca* plants were sprayed with ABA (Karssen et al., 1987). *Flacca* tomato plants wilt even under conditions of mild water stress (Darby et al., 1978). Both the failure to synthesize ABA in response to water stress and the low ABA levels in nonstressed leaves have corresponded very well with stomatal behavior (Karssen et al., 1987). Stomatal resistance to closure and higher root resistances are reported phenotypic characteristics (Tal and Nevo, 1973; Tal and Imber, 1971).

The present investigation was conducted to determine whether such FA-induced stress modified endogenous ABA levels. Three species were utilized. Two tomato taxa, the wild type and ABA-deficient mutant, *flacca*, of the isogenic parent line *Lycopersicon esculentum* cv. Ailsa Craig were chosen for their known differences in endogenous ABA levels. Tomato was chosen also for its reported sensitivity to phenolic compounds (gallotannic, gallic, and chlorogenic

acids) and its ability to accumulate ABA in stressed leaves (Floyd and Rice, 1967; Walker and Dumbroff, 1981; Neill and Horgan, 1985). Cucumber and bean species were chosen for their rapid growth rates and their predictable sensitivities and behaviors to FA (Blum et al., 1985a,b; Waters and Blum, 1987). ABA levels in bean leaves increased in response to water stress (Pierce and Raschke, 1981). The objectives of this research were: (1) to determine the relative sensitivities of four plant taxa (wild-type tomato, *flacca* tomato, cucumber and bean) to exogenously applied FA by monitoring leaf growth and water utilization and (2) to determine the effects of exogenously applied FA on the endogenous levels of ABA within these taxa.

METHODS AND MATERIALS

General Aspects. In the first experiment, seed coats of wild-type and *flacca* tomato of the isogenic parent line, *Lycopersicon esculentum* Mill. cv. Ailsa Craig (Institute of Horticultural Research, Worthing Road, Littlehampton, West Sussex, England) were scarified for 30 min with 10 N sulfuric acid. After a deionized-water rinse, seeds were placed in autoclaved glass Petri dishes (9 cm diameter) containing Whatman No. 1 filter paper and 10 ml deionized water. Twenty seeds were placed on the filter paper of each dish. The dishes were placed in the dark at 30°C until radicle-hypocotyls were approximately 1–2 cm in length. These 4-day-old seedlings then were transferred to styrofoam cups (with drainage holes) containing vermiculite moistened with modified Hoagland's nutrient solution, pH 5.5 (Hoagland and Arnon, 1950). KNO_3 and KH_2PO_4 were increased by 25% and 50%, respectively, and 0.01 mg Sequestrene 330 Fe per liter was substituted for EDTA-Fe solution. The seedlings were grown for six days in a lighted chamber with a photosynthetic photon flux density (PPFD) of 140 μEinsteins/m^2/sec (Blum and Dalton, 1985).

Tomato seedlings then were moved to a standard B-chamber of the Southeastern Plant Environmental Laboratory (NCSU Phytotron; Downs and Thomas, 1983) with a 26/22°C day/night temperature, 60–80% relative humidity, a 9-hr photoperiod, PPFD of 240–250 μEinsteins/m^2/sec provided by cool white fluorescent bulbs. Preliminary experiments revealed that these conditions were optimal for *flacca* tomato. On day 14, each seedling was transferred to a foil-covered jar containing 350 ml nutrient solution. Each seedling was suspended at the hypocotyl with a foam collar. Beginning on day 22, wild-type ($N = 24$) and *flacca* ($N = 24$) seedlings were treated with 0.0, 0.2, 0.4, or 0.8 mM ferulic acid (FA; Sigma Chemical Co., St. Louis, Missouri) in fresh nutrient solution every other day for the total of three treatments.

In a second experiment, cucumber seeds, *Cucumis sativus* L. cv. Early Green Cluster (Wyatt Quarles Seed Company, Raleigh, North Carolina), and

bean seeds, *Phaseolus vulgaris* L. cv. Oregon 91 (Rogers Brothers Seed Company, Boise, Idaho), were germinated in vermiculite moistened with nutrient solution. Cucumber and bean seedlings were transferred to 350 ml foil-covered jars when 3 or 5 days old, respectively, and moved to a standard B-chamber of the NCSU Phytotron with the same environmental conditions as experiment one. Twelve-day-old cucumber seedlings ($N = 24$) and 7-day-old bean seedlings ($N = 24$) were treated with 0.0, 0.2, 0.4, or 0.8 mM FA in fresh nutrient solution every other day for a total of three treatments.

In a third experiment, 22-day-old wild-type tomato seedlings ($N = 75$) were treated with 0.0, 0.4, or 0.8 mM FA in fresh nutrient solution every other day for a total of two treatments. Sets of 15 plants were harvested at 8, 24, and 48 hr after the first treatment and 24 and 48 hr after the second treatment. Each treatment had five replicates.

In each experiment, beginning with the phytotron-transfer day and prior to the first treatment, nutrient solutions were replaced every other day. Water was added daily to compensate for transpirational water loss. All solutions were continually aerated. All seedlings were arranged in a completely randomized block design in the B chamber.

Leaf Measurements. The length (L), width (W), and area of bean and cucumber leaves were used to develop leaf area models. The cucumber and bean leaf area models were: Area $= -0.58548 + [0.87881 \times (L \times W)]$; $r^2 = 0.99$; $N = 395$, where length and width are in centimeters; Area $= -1.457 + [0.00769 \times (L \times W)]$; $r^2 = 0.98$; $N = 121$, where length and width are in millimeters (Blum and Dalton, 1985), respectively. Leaf length and width measurements for the bean model included only primary leaves. Length and width were recorded just prior to treatments every other day starting on days 12 and 7 for cucumber and bean plants, respectively.

Due to the low r^2 values (wild type, $r^2 = 0.85$; *flacca*, $r^2 = 0.84$) models for tomato leaf areas could not be used. Leaf lengths (mm) were recorded just prior to treatments every other day, starting on day 22.

Water Utilization. Transpirational water loss from the foil-covered jars was measured between 12 and 1 PM daily starting on days 22, 12, and 7 for tomato, cucumber, and bean plants, respectively.

Leaf Measurement and Water Utilization Data Analysis. Mean absolute rate of leaf elongation (ARLE) and mean absolute rate of leaf area expansion (ARLAE) were determined as follows: ARL(A)E = Σ[seedling leaf (lengths or areas) on day_{x+2}] $-$ Σ [seedling leaf (lengths or areas) on day_x], where ARLE is mm/2 days and ARLAE is cm^2/2 days. Mean relative rates of leaf elongation (RRLE) and mean relative rates of leaf area expansion (RRLAE) were determined as follows: RRL(A)E = ln [Σ seedling leaf (lengths or areas) on day_{x+2}] $-$ ln [Σ seedling leaf (lengths or areas) on day_x], where RRLE is mm/mm/2 days and RRLAE is cm^2/cm^2/2 days. See Radford (1967) for details

that describe the derivation of these equations. Water utilization was calculated per unit leaf length for each tomato taxon and per unit leaf area for cucumber and bean. Analysis of variance and regression analysis (Steele and Torrie, 1980) were used to determine significant responses. Data were analyzed using Statistical Analysis System programs (SAS Institute Inc., 1988).

Tissue Processing for ABA Analysis. In the first experiment, when tomato seedlings were 28 days old, leaflets of the oldest fully expanded leaves (i.e., leaves 1 and 2) and leaflets of the remaining shoot were separated into samples designated "old" or "young" leaves, respectively. In the second experiment, when cucumber seedlings were 18 days old, four leaf disks (2 cm diameter/disk) were excised from the oldest fully expanded true leaf and from the third oldest leaf, and designated "old" and "young," respectively. Four leaf disks also were excised from each primary leaf of 15-day-old bean seedlings. In the third experiment, all wild-type tomato leaflets per seedling were harvested 8, 24, 48, 72, and 96 hr after the first treatment on day 22. Major veins were avoided when excising leaf disks. Each sample was immediately frozen in liquid nitrogen, lyophilized, and stored at −20°C until ABA analysis.

Lyophilized and powdered samples were suspended in extracting methanol (methanol, containing 0.1 g/liter butylated hydroxytoluene and 0.5 g/liter citric acid monohydrate at a ratio of 0.01 g dry tissue to 1.0 ml extracting methanol) and stirred overnight at 4°C in the dark. A C-18 Sep-Pak (Waters Co., Milford, Massachusetts) was utilized to clean up each leaf sample. Five milligrams of plant tissue in 70% extracting methanol was applied to each Sep-Pak. Each sample was eluted from the column with 70% extracting methanol. For tomato samples, 500 μl of each 70% methanol eluant was dried in a Speed Vac Concentrator (Savant, Farmingdale, New York). Dried tomato samples were resuspended in 1 ml Tris buffered saline (TBS; 6.05 g Tris/liter, 0.20 g $MgCl_2 \cdot 6H_2O$/liter, 8.8 g NaCl/liter, pH 8.8) solution. For cucumber and bean samples, 1500 μl of each 70% methanol eluant was dried in a Speed Vac Concentrator and then resuspended in 500 μl TBS solution.

Five samples of each taxon were spiked with 5.5 nCi/sample (±)-cis, trans-[^{3}H]-ABA, specific activity = 115 Ci/mmol (Amersham, Arlington Heights, Illinois) at the beginning of the extraction procedure to estimate recovery, which averaged >90% ± 0.09 SE. Similar recovery estimates were reported by Walker-Simmons (1987), Morris et al. (1988), and Norman et al. (1988). When unlabeled (+)-*cis, trans*-ABA, in the absence of plant sample, was carried through this extraction protocol, recovery ranged from 65% to 70%. ABA values were not corrected for percent recovery.

ABA Quantification. ABA was measured utilizing an immunoassay. Monoclonal antibody (Mab) to free *cis, trans*-(+)-ABA was purchased from Idetek Inc. (1057 Sneath Lane, San Bruno, California). The assay was an indirect ELISA (enzyme-linked immunosorbant assay) as described by Walker-Sim-

mons (1987). For this assay, abscisic acid-4′-bovine serum albumin (ABA-4′-BSA) conjugate was prepared according to Weiler (1979) and stored at −20°C.

The standard curve for the ELISA was linear ($r^2 = 0.99$) when plotted as a log by logit function. A linear regression was established for ABA levels from 5 to 150 pg/200 μl. When C-18 Sep-Pak-purified plant samples were added to standard amounts of ABA, no interference in the linearity of the immunoassay was detected. When 70% extracting methanol, in the absence of plant tissue, was carried through the C-18 Sep-Pak and ELISA protocols, no false positives were detected.

ABA quantification using this Mab has been evaluated and validated by numerous laboratories using GC-MS, GC-FID, and HPLC-UV (Raikhel et al., 1987; Walker-Simmons, 1987; Norman et al., 1988). The Mab used in this study has been demonstrated to possess little (< 1000-fold) or no cross-reactivity with ABA-related compounds (Weiler, 1980; Mertens et al., 1983).

ABA Data Analysis. Analysis of variance and regression analysis were conducted on the four taxa separately. In the third experiment, regression analyses were run for ferulic acid concentrations within each time interval.

RESULTS

Growth: Experiment 1. Regression analyses using data summarized in Table 1 showed that FA inhibited leaf elongation rates of both wild-type and *flacca* tomato. As FA concentrations were increased, concurrent decreases were observed in both ARLE and RRLE (Figure 1). ARLE of wild-type tomato exhibited linear trends for all three growth periods, while RRLEs were linear for the first two growth periods and convex curvilinear for the third. ARLE of *flacca* exhibited a concave curvilinear trend after initial FA treatment (growth period 22–24), a linear trend after the second treatment (growth period 24–26), and a convex curvilinear trend after the third treatment (growth period 26–28). RRLE of *flacca* exhibited a concave curvilinear trend during the first growth period and convex curvilinear trends for subsequent growth periods.

The effect of the initial treatment (day 22) of FA at 0.2, 0.4, and 0.8 mM on wild type was not as severe as it was on *flacca*. ARLE of treated plants, when compared to control plants, decreased 29%, 49%, and 90% for the wild type compared to 32%, 85%, and 100% for *flacca*, respectively (Table 1). Similarly, RRLEs decreased 15%, 44%, and 89% for wild type and 26%, 82%, and 100% for *flacca*, respectively. Thus, percent reductions were lower for wild-type than for mutant tomato. *Flacca* at 0.8 mM became necrotic after the initial treatment; visually, wild-type tomato appeared normal.

When comparing treated to control plants, it appeared from the shift in percent change over time that the wild type was less affected by subsequent

TABLE 1. MEAN ABSOLUTE AND RELATIVE RATES OF LEAF ELONGATION FOR WILD-TYPE AND *Flacca* SEEDLINGS GIVEN MULTIPLE FERULIC ACID TREATMENTS[a]

		Ferulic acid (mM)	Growth period (days)		
			22–24	24–26	26–28

[a] On treatment days, leaves were measured between 9 and 11 AM. Seedlings were treated at 2 PM. $N = 6$. Values in parentheses are standard errors.
[b] ARLE = mean absolute rates of leaf elongation.
[c] RRLE = mean relative rates of leaf elongation.

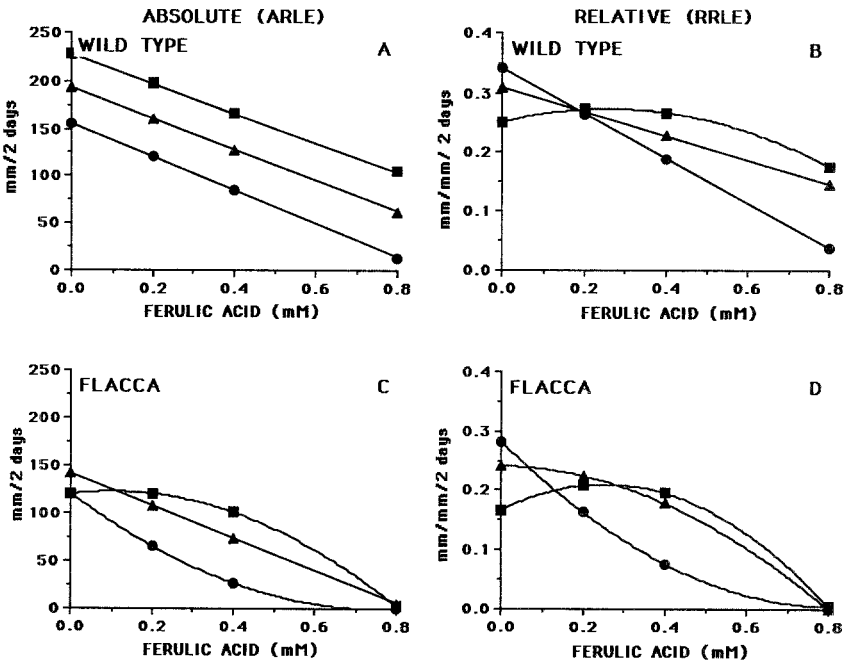

FIG. 1. Effects of ferulic acid concentrations (0.0, 0.2, 0.4, 0.8 mM) supplied in nutrient solution (pH 5.5) on mean absolute rates of leaf elongation (ARLE: A, C) and on mean relative rates of leaf elongation (RRLE: B, D) for wild-type tomato plants (A, B) and *flacca* plants (C, D). Each line was generated from a model for a specific two-day growth period: (●) 22–24, (▲) 24–26, and (■) 26–28 days from seed. The three points above each ferulic acid concentration represent either the predicted mean of the absolute rate of leaf elongation (mm/2 days) or the predicted mean of the relative rate of leaf elongation (mm/mm/2 days) of same six plants treated at the three different growth periods. Seedlings were treated on days 22, 24, and 26. For wild-type tomato seedlings, r^2 values ranged from 77% to 92% and from 60% to 90% for ARLE and RRLE, respectively. For *flacca* tomato seedlings, r^2 values ranged from 71% to 87% and from 73% to 85% for ARLE and RRLE, respectively. For all regression equations, $P \leq 0.0001$.

treatments. Reduction of ARLE for wild type in the third growth period (days 26–28) were six, three, and two times lower than ARLE of the first growth period (days 22–24) for 0.2, 0.4, and 0.8 mM, respectively (Table 1). These changes in response are even more apparent in RRLE, since in several instances, stimulation or no growth inhibition occurred for the second and third growth periods at 0.2 and 0.4 mM concentrations of FA. For *flacca*, 100% inhibition of ARLE and RRLE occurred at 0.8 mM for all growth periods. The magnitude of inhibition of ARLE and RRLE for *flacca* plants treated with 0.2 and 0.4 mM

FA was less for growth periods 2 and 3 than for the first growth period. In fact, either stimulation or no growth inhibition was observed in two instances.

Shifts in regression equations (Figure 1) for growth also suggested a reduction in the effect of FA after the first treatment. For example, RRLE equations of wild-type tomato shifted from linear to concave curvilinear from the first to third growth period, while *flacca* RRLE equations shifted from convex curvilinear for growth period 1 to concave curvilinear for growth periods 2 and 3.

Growth: Experiment 2. Regression analyses using data summarized in Table 2 showed that FA inhibited leaf area expansion rates of cucumber. FA had no apparent effect on bean growth or water utilization throughout the entire experiment (data not presented). During the first growth period (days 12–14), as FA concentrations were increased, concurrent decreases in ARLAE and RRLAE were observed in cucumber (Figure 2). In the initial growth period, ARLAE decreased in a concave curvilinear manner; RRLAE decreased linearly. ARLAE for subsequent growth periods decreased linearly. There were no effects of FA on RRLAE during the second and third growth periods.

The impact of FA on cucumber ARLAE for the first treatment (day 12) was more severe than subsequent treatments (Table 2). Reductions of ARLAE in the third growth period (days 16–18) were three, two, and 1.5 times lower than the reductions of the first growth period (days 12–14), for 0.2, 0.4, and 0.8 mM respectively. RRLAE of the first period was reduced 16%, 30%, and 56% from that of the controls. RRLAE of cucumber was not affected by subsequent treatments. The decline in response of FA was also evident in the shifts in regression equations. Cucumber ARLAE shifted from a convex curvilinear to linear trend for growth periods 2 and 3, respectively. Cucumber RRLAE was significant only for the first growth period.
